

ESSENTIALS OF Anatomy & Physiology

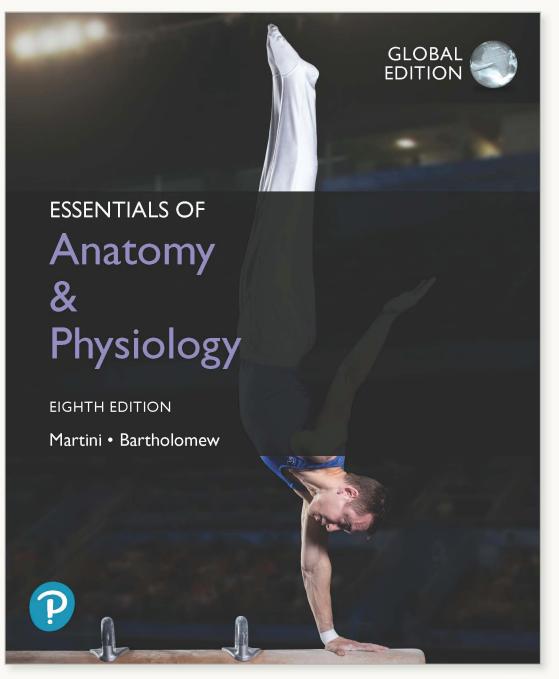

EIGHTH EDITION

Martini • Bartholomew

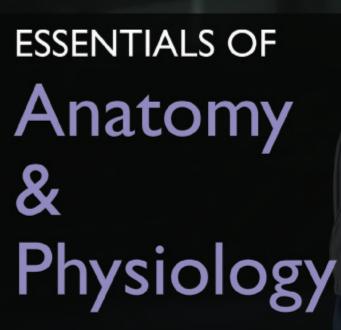

Martini's *Essentials of Anatomy and Physiology 8e* brings a legacy of superb illustration and text–art integration with a suite of new digital tools

The New Eighth edition takes the most popular features from the book and builds them out into effective interactives within Mastering A&P™

Spotlight Figures Visually Summarize Difficult Physiological Processes, Making Them Easier to Understand

These highly visual one- and two-page presentations of tough topics provide a bridge between readings and related figures and photos to communicate information in a student-friendly, visually effective format.

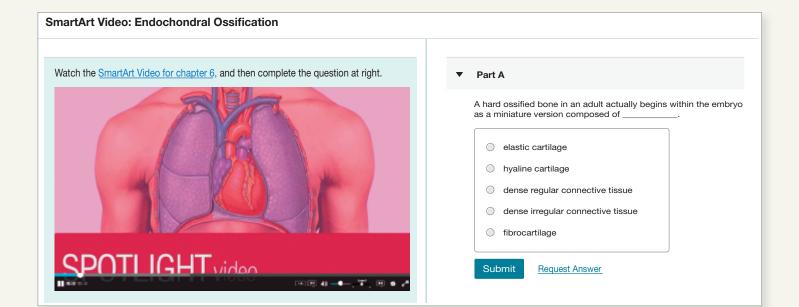

SPOTLIGHT Figure 8-9 PROPAGATION OF AN ACTION POTENTIAL Continuous Propagation Saltatory Propagation Axon hillock along an Unmyelinated Axon n 2 3 along a Myelinated Axon Initial segmen 023 In an unmyelinated axon, an action potential moves Because myelin limits the movement of ions along by continuous propagation. The action potential spreads by depolarizing the adjacent region of the axon membrane. This process continues to spread as a chain reaction down the axon. across the axon membrane, the action potential must "jump" from node to node during propagation. This results in much faster propagation along the axon. As an action potential develops at the initial segment (), the membrane potential at this site depolarizes to +30 mV. An action potential develops at the initial segment ①. 130 mV ۲ • • • `⊕ ⊕ • • æ ⊕ Na+ Graded ۲ • • Na ۲ 0,000 0,000 Cellu As the sodium ions entering at Ospread away from the open voltage-gated channels, a graded depolarization quickly brings the membrane in segment ©to threshold. 2 • A local current . . ۲ A local current produces a graded depolarization that brings the axon membrane at the next node to threshold. ۲ ⊕∕⊕ 6 Ð . • • Ð ⊕ An action potential now occurs in segment (2) while segment (3) begins repolarization. ⊕ • +30 mV An action potenti • • ● ● **●** ⊕ . • develops node ②. lops at ۲ ۲ æ . ۳ æ ⊕ 4 As the sodium ions entering at segment (2) spread laterally, a graded depolarization quickly brings the membrane in segment (3) to threshold, and the cycle is repeated. NEW Spotlight Figure Videos Bring This Effective Text Feature to Life

NEW! 10 Spotlight

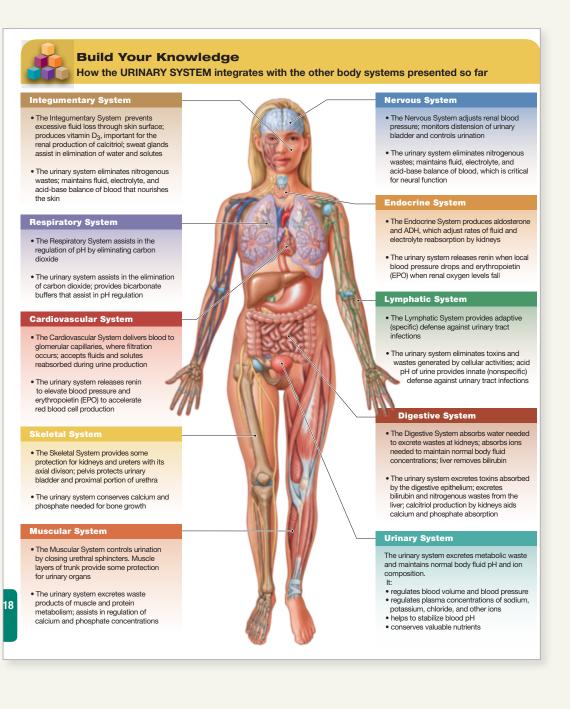

Videos bring the popular in-text feature to life, with narrated, annotated guidance that walks students through some of toughest topics in A&P. Spotlight Video topics include: Inflammation and **Regeneration**, Synovial Joints, The Contraction Cycle, Refractive Problems, The Composition of Whole Blood, The Heart: Internal Anatomy and Blood Flow, Pulmonary Ventilation, Chemical Events in Digestion, A Summary of Kidney Function, and **Regulation of Female** Reproduction.

Coaching Activities in Mastering A&P[™] allow instructors to assign the videos to ensure students view them.

Build Your Knowledge Integration Figures Emphasize That the Body Systems Work Together, Not in Isolation

Build Your Knowledge Integration features show students how body systems affect each other and work together to maintain homeostasis.

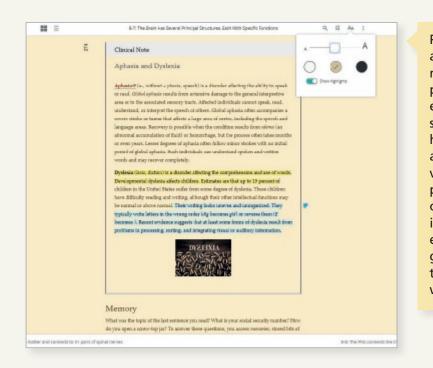

NEW Interactive Versions of These Figures Allow Students to Explore at Their Own Pace

Build Your Knowledge Coaching Activities are

assignable in Mastering A&P and provide hints and wrong answerspecific feedback to ensure mastery of the concepts.

The Most Affordable and Efficient Way to Learn—Pearson eText

Pearson eText is a simple-to-use, mobile-optimized, personalized reading experience. It allows students to easily highlight, take notes, and review key vocabulary all in one place—even when offline. Seamlessly integrated videos engage students and give them access to the help they need, when they need it.

central nervous system (ms) The brain and spinel cord	\$

Students can stop randomly searching online for study tools and flashcards that may not be credible or applicable to their course. Pearson eText contains study tools that align directly to the textbook adopted. Students can personalize a study notebook with the highlights and notes they take during reading, as well as the ones instructors share with the class, effectively creating a study guide.

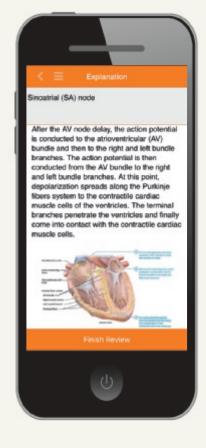

Mastering A&P[™] Is So Much More than Online Homework

NEW! PAL 3.1 Mobile, Customizable Flashcards allow students to create a personalized, mobile-friendly deck of flashcards and quizzes using images from the virtual Practice Anatomy Lab 3.1.

virtual Practice Anatomy Lab 3.1. Students can use the checklist to filter down to the images referenced in the course. For optimal viewing, access the flashcards on a mobile device using Mastering login credentials.

Dynamic Study Modules (DSMs) continue to be the most favored study tool of surveyed students in the Mastering learning tools suite. Using a flashcard, gaming style, students figure out what they know and don't know, building confidence before a test. DSMs are available to students with a Mastering subscription and allow students to study the structures instructors want them to learn.

Continue Learning the Toughest Topics in Mastering A&P and the eText

Interactive Physiology 2.0 are based on the award-winning tutorial program that helps students understand the most difficult physiological concepts. Updated and delivered in two formats for use with today's wide range of mobile devices and browsers.

A&P Flix are high-quality animations that remain trusted and among the most favored learning tools by instructors within the Mastering suite.

Pearson eText is available within Mastering when packaged with a new book, as an upgrade students can purchase online, or, with this title, can be adopted as a stand-alone item. Students can use the built-in **Notebook** to organize their notes, highlights and notes from their instructor.

Text and Illustration Team

FREDERIC (RIC) MARTINI, PH.D. (author) received his Ph.D. from Cornell University. In addition to his technical and journal publications, he has been the lead author of ten undergraduate texts on anatomy and physiology or anatomy. Dr. Martini is currently affiliated with the University of Hawaii at Manoa and

has a long-standing bond with the Shoals Marine Laboratory, a joint venture between Cornell University and the University of New Hampshire. He has been active in the Human Anatomy and Physiology Society (HAPS) for 26 years and is a President Emeritus of HAPS. He is also a member of the American Physiological Society, the American Association of Anatomists, the Society for Integrative and Comparative Biology, the Australia/New Zealand Association of Clinical Anatomists, and the International Society of Vertebrate Morphologists.

EDWIN F. BARTHOLOMEW, M.S. (author) received his undergraduate degree from Bowling Green State University in Ohio and his M.S. from the University of Hawaii. His interests range widely, from human anatomy and physiology to the marine environment, "backyard" aqua-

culture, and oil and watercolor painting. Mr. Bartholomew has taught human anatomy and physiology at both the secondary and undergraduate levels. In addition, he has taught a range of other science courses (from botany to zoology) at Maui Community College (now the University of Hawaii Maui College). For many years, he taught at historic Lahainaluna High School, the oldest high school west of the Rockies, where he assisted in establishing an LHS Health Occupations Students of America (HOSA) chapter. He has written journal articles, a weekly newspaper column, and many magazine articles. Working with Dr. Martini, he coauthored Structure & Function of the Human Body and The Human Body in Health and Disease (Pearson). Along with Dr. Martini and Dr. Judi Nath, he coauthored Fundamentals of Anatomy & Physiology, 11th edition. He also coauthored Visual Anatomy & Physiology, 3rd edition, with Dr. Martini, Dr. William Ober, Dr. Judi Nath, and Dr. Kevin Petti. Mr. Bartholomew is a member of the Human Anatomy and Physiology Society, National Science Teachers Association, and the American Association for the Advancement of Science.

WILLIAM C. OBER, M.D. (art coordinator and illustrator) received his undergraduate degree from Washington and Lee University and his M.D. from the University of Virginia. While in medical school, he also studied in the Department of Art as Applied to Medicine at Johns Hopkins Univer-

sity. After graduation, Dr. Ober completed a residency in Family Practice and later was on the faculty at the University of Virginia **10**

in the Department of Family Medicine. He was Chief of Medicine at Martha Jefferson Hospital and was an Instructor in the Division of Sports Medicine at UVA. He also was part of the Core Faculty at Shoals Marine Laboratory for 22 years, where he taught Biological Illustration every summer. He is currently a visiting professor of Biology at Washington and Lee University. The textbooks illustrated by his company Medical & Scientific Illustration have won numerous design and illustration awards.

CLAIRE E. OBER, R.N. (illustrator) practiced pediatric and ob-

stetric nursing before turning to medical illustration as a full-time career. She received her degree at Mary Baldwin College with distinction in studio art. Following a five-year apprenticeship, she has worked as Dr. Ober's partner in Medical & Scientific Illustration since 1986. She was on

the Core Faculty at Shoals Marine Laboratory and co-taught the Biological Illustration course.

KATHLEEN WELCH, M.D. (clinical consultant) received her

M.D. from the University of Washington in Seattle and did her residency at the University of North Carolina in Chapel Hill. For two years, she served as Director of Maternal and Child Health at the LBJ Tropical Medical Center in American Samoa and subsequently was a member of the

Department of Family Practice at the Kaiser Permanente Clinic in Lahaina, Hawaii. She was in private practice from 1987 until her retirement in 2012. Dr. Welch has been the Clinical Consultant for nine textbooks and the coauthor of one textbook and several clinical supplements. Dr. Welch is a Fellow of the American Academy of Family Practice and a member of the Hawaii Medical Association, the Maui County Medical Association, the American Medical Association, and the Human Anatomy and Physiology Society.

KEVIN PETTI, Ph.D. (contributor) Dr. Petti is a professor at San Diego State Miramar College, where he teaches courses in human anatomy and physiology, human dissection, and health education. He is President Emeritus of the Human Anatomy and Physiology Society (HAPS)

and holds a doctorate from the University of San Diego. As a dual U.S./Italian citizen, he also teaches courses in Italy that focus on the genesis of anatomy as a science and its influence on the Renaissance masters, a story unique to the Italian Peninsula. His students range from anatomy professors pursuing continuing education to undergraduates in study-abroad programs. Dr. Petti is often invited to speak about the connection between art and anatomy in medieval and Renaissance Italy at museums, conferences, and universities.

Preface

Welcome to the Eighth Edition of *Essentials of Anatomy & Physiology*! This textbook introduces the essential concepts needed for an understanding of the human body and helps students place information in a meaningful context, develop their problem-solving skills, and prepare for a career in a medical or allied health field. In this edition, we continue to build on this text's hallmark quality: a clear, effective visual and narrative presentation of anatomy and physiology. During the revision process, the author and illustrator team drew upon their combined content knowledge, research skills, artistic talents, and 50-plus years of classroom experience to make this the best edition yet.

The broad changes to this edition are presented in the **New to the Eighth Edition** section below. Also below are the sections **Learning Outcomes** and **Chapter-by-Chapter Changes in the Eighth Edition**.

New to the Eighth Edition

In addition to the technical changes in this edition, such as updated statistics and anatomy and physiology descriptions, we have simplified the presentations to make the narrative easier to read. We have also focused on improving the integration of illustrations with the narrative. These are the key changes in this new edition:

- Improved readability uses simpler, shorter, more active sentences to make reading and studying easier for students. In all chapters, the Flesch/Kincaid reading levels have been decreased.
- Improved text-art integration throughout the illustration program enhances the readability of figures. Tabular information is now integrated into the figures so that the relevant text is located immediately next to each part of a figure. Increased color saturation was also applied to the art throughout the text.
- Terminology has been updated based on *Terminologia Anatomica* and *Terminologia Histologica*, our references for anatomical and tissue terms. We continue to use possessive forms of diseases when the proposed alternative has not been widely accepted, e.g., Parkinson's disease and Huntington's disease.
- Mastering A&P[®], Pearson's online learning and assessment system, contains new assignable activities tied to features in the book, including 10 narrated, annotated Spotlight

Videos that walk students through these popular features to explain core concepts, and a Build Your Knowledge interactive widget that allows them to see how body systems work together to maintain homeostasis. In addition, many Spotlight figures have Coaching Activities in Mastering, and the Body System figures correspond to Concept Map Coaching Activities that will bring home the concept of body system integration. Instructors can assign homework from proven media programs such as Practice Anatomy Lab[™] (PAL[™]) 3.1 and Interactive Physiology[®]—all organized by chapter—and have assignments automatically graded. Mobile friendly Dynamic Study Module questions help students study effectively and efficiently by allowing them to quiz themselves anytime, anywhere. In the Mastering A&P Study Area, students can access a full suite of self-study tools, including Bone and Dissection videos and A&P Flix.

Learning Outcomes

The chapters of the Eighth Edition are organized around specific Learning Outcomes that indicate what students should be able to do after studying the chapter.

- Learning Outcomes appear in chapter-opening numbered lists, as well as directly below each relevant chapter section heading.
- Full-sentence chapter headings do more than introduce new topics; they state the core fact or concept that will be presented in the section. There is a one-to-one correspondence between the Learning Outcomes and the fullsentence section headings in every chapter.
- Checkpoints are located at the close of each section and ask students to pause and check their understanding of facts and concepts. The Checkpoints reinforce the Learning Outcomes presented on the chapter-opening page and below chapter section headings, resulting in a systematic integration of the Learning Outcomes over the course of the chapter. Answers are located in the blue Answers tab at the back of the book. All the Checkpoints have been reviewed, and questions were added or revised to reflect our improved readability.

All assessments in Mastering A&P are organized by the Learning Outcomes, making it easy for instructors to organize their courses and demonstrate results against goals for student achievement.

Chapter-by-Chapter Changes in the Eighth Edition

This annotated Table of Contents provides select examples of revision highlights in each chapter of the Eighth Edition.

Chapter 1 An Introduction to Anatomy and Physiology

- Section 1-1 revised (*cellular differentiation* replaces *differentiation*; *the same kind of organisms* replaces *similar, but not identical, organisms*; *Organisms exhibit movement.* replaces *Organisms can move.*)
- Figure 1-4 Negative Feedback: Control of Body Temperature revised (new title)
- Figure 1-10 Relationships among the Subdivisions of the Body Cavities of the Trunk revised (*visceral layer of serous pericardium* replaces *visceral pericardium*, *parietal layer of serous pericardium* replaces *parietal pericardium*)
- Related Clinical Terms revised (*acute* and *chronic* terms added; *injury* added to definition of *radiology*)

Chapter 2 The Chemical Level of Organization

- Section 2-1 revised (clarified definition of *radiation*)
- Spotlight Figure 2-7 Chemical Notation revised (simplified introduction and replaced spelled out numbers with numerals to better integrate the Visual Representation and Chemical Notation columns)
- Section 2-8 revised (clarified that, in physiology, the term *electrolyte* applies to both the ionizable substance and its ions)
- New Clinical Note (*Too Sweet on Sugar* replaces *Fatty Acids and Health*)

Chapter 3 Cell Structure and Function

- Section 3-7 Learning Outcome revised (sequence of interphase and mitosis now correlates with section discussion)
- Table 3-1 revised (*propagation of nerve impulses* replaces *conduction of nerve impulses*)
- Figure 3-5 Diffusion Across the Plasma Membrane revised (color of water molecules now matches those in Chapter 2 figures)
- Figure 3-9 The Sodium-Potassium Exchange Pump revised (corrected relative sizes of sodium and potassium ions)
- Spotlight Figure 3-7 Protein Synthesis, Processing, and Packaging revised (added magnification of TEM illustrating exocytosis)
- Section 3-10 revised (*cellular differentiation* replaces *differentiation*)

Chapter 4 The Tissue Level of Organization

- Figure 4-1 An Orientation to the Body's Tissues revised (*nervous tissue* replaces *neural tissue*)
- Figure 4-2 Cell Junctions revised (*basal lamina* replaces *clear layer* and *reticular lamina* replaces *dense layer*)
- Figure 4-3 The Surfaces of Epithelial Cells (added *Lateral surfaces* and *Basal surface* labels)
- Figure 4-4 Simple Epithelia revised (moved part letters to highlight tissue types and enhance text-art integration)
- Figure 4-5 Stratified Epithelia revised (moved part letters to highlight tissue types and enhance text-art integration)
- Figure 4-6 Methods of Glandular Secretion revised (*Modes* changed to *Methods* in figure title and letters added to different parts of the figure to enhance text-art integration)
- Table 4-2 revised (*Method of Secretion* replaces *Mode of Secretion*)
- Clinical Note Marfan's Syndrome revised (*Marfan* replaces *Marfan's*)
- Figure 4-9 Loose Connective Tissue revised (moved part letters to highlight tissue types and enhance text-art integration)
- Figure 4-10 Dense Connective Tissue revised (moved part letters to highlight tissue types and enhance text-art integration)
- Figure 4-11 Types of Cartilage revised (moved part letters to highlight tissue types and enhance text-art integration)
- Figure 4-14 Muscle Tissue revised (moved part letters to highlight tissue types and enhance text-art integration)
- Figure 4-15 Nervous Tissue revised (new title *Nervous Tissue* replaces *Neural Tissue*)

Chapter 5 The Integumentary System

- The text now uses *subcutaneous layer* as the primary term and *hypodermis* as the secondary term.
- Figure 5-1 The General Structure of the Integumentary System revised (*Subcutaneous layer* replaces *Hypodermis*)
- Spotlight Figure 5-2 revised (part labels added to better align text and art)
- Section 5-2 heading revised (shortened to *Epidermal pigmentation and dermal circulation influence skin color*)
- Figure 5-5 Hair Follicles and Hairs revised (*Subcutaneous layer* replaces *Hypodermis* in part b)
- Figure 5-6 Sebaceous Glands and Their Relationship to Hair Follicles revised (*Subcutaneous layer* replaces *Hypodermis*)
- Figure 5-7 Sweat Glands revised (*Eccrine sweat gland* replaces *Merocrine sweat gland* as primary term, *Subcutaneous layer* replaces *Hypodermis*)

• Build Your Knowledge revised (added *in females, specialized integumentary glands secrete milk* to Integumentary System functions)

Chapter 6 The Skeletal System

- Figure 6-1 A Classification of Bones by Shape revised (bone art enlarged, added *Sectional view* label to part c)
- Clinical Note: Types of Fractures and Steps in Repair revised (replaced x-rays of *Displaced fracture* and *Spiral fracture*)
- Figure 6-8 The Skeleton revised (enlarged figure and increased color and contrast; added *Sternum* label)
- Figure 6-9 The Axial and Appendicular Divisions of the Skeleton revised (*Rib cage* replaced *Thoracic cage* to correlate with the *Axial Skeleton* bone count; *coxal bone* deleted from *Hip bone* box)
- Figure 6-10 The Adult Skull, Part I revised (added leader dots to leader lines of *Coronal suture, Squamous suture,* and *Lambdoid suture*)
- Figure 6-12 Sectional Anatomy of the Skull revised (added forked leader to *Frontal sinuses* label)
- Figure 6-13 The Paranasal Sinuses revised (*Ethmoidal cells* replaces *Ethmoidal sinuses*)
- Figure 6-16 The Vertebral Column revised (color coded Vertebral regions to match art in later chapters)
- Figure 6-17 Typical Vertebrae of the Cervical, Thoracic, and Lumbar Regions revised (changed color in icon art to match Figure 6-18 icon art)
- Figure 6-19 The Sacrum and Coccyx revised (adjusted position of *Lateral sacral crest* leader line in part b)
- Figure 6-20 The Thoracic Cage revised (added thoracic cage definition)
- Figure 6-24 The Right Radius and Ulna revised (*RADIUS* and *ULNA* labels changed to *Radius* and *Ulna* to match use in other figures in chapter)
- Figure 6-25 The Bones of the Wrist and Hand revised (rearranged terms in *Proximal Carpals* box to match sequence as discussed in the text)
- Section 6-10 revised (*Plane* movement replaces *Gliding* movement)
- Figure 6-26 The Hip Bones and the Pelvis revised (*Sacro-iliac joint* replaces *Sacroiliac joint*)
- Figure 6-33 Rotational Movements revised (added a red dot to mark the location of the joint involved in rotational movements of the head)
- Section 6-11 heading and Learning Outcome revised (*joints* replaces *articulations*)
- Spotlight Figure 6-35 Synovial Joints revised (*Plane joint* replaces *Gliding joint; gliding* inserted into *Plane joint Movement* text)

• Figure 6-40 The Knee Joint revised (added *PCL* abbreviation after *Posterior cruciate ligament* and *ACL* abbreviation after *Anterior cruciate ligament* labels)

Chapter 7 The Muscular System

- Figure 7-1 The Organization of Skeletal Muscles revised (added part letters to enhance text-art integration)
- Figure 7-2 The Organization of a Skeletal Muscle Fiber revised (enhanced art)
- Figure 7-3 Changes in the Appearance of a Sarcomere during Contraction of a Skeletal Muscle Fiber (added *Relaxed myofibril* label in part a and *Relaxed myofibril* label in part b)
- Spotlight Figure 7-4 Events at the Neuromuscular Junction revised (updated ACh receptor membrane channel art and added text to step 5)
- Figure 7-6 Steps Involved in Skeletal Muscle Contraction and Relaxation revised (updated ACh receptor membrane channel and T tubule/Sarcoplasmic reticulum art)
- Figure 7-10 Muscle Metabolism revised (in part c, *the hy-drolysis of ATP* replaces *pyruvate* as the source of hydrogen ions at peak activity)
- Table 7-12 Muscle Terminology revised (*Terms Indicating Specific Regions of the Body* moved to left column to better correlate with anatomical terminology introduced in Chapter 1)
- Figure 7-17 Muscles of the Pelvic Floor revised (in part b, *transverse perineal* replaces *transverse perineus*)

Chapter 8 The Nervous System

- Section 8-1 revised (recognized the *enteric nervous system* (*ENS*) as a third division of the *peripheral nervous system*)
- Figure 8-5 Schwann Cells and Peripheral Axons revised (added *neurolemmocytes* as a secondary term for Schwann cells; *neurolemma* replaces *neurilemma*)
- Figure 8-14 Gross Anatomy of the Spinal Cord revised (*lumbosacral enlargement* replaces *lumbar enlargement; ventral roots* replaces *anterior roots; dorsal roots* replaces *posterior roots; spinal ganglion* replaces *dorsal root ganglion*)
- Figure 8-15 Sectional Anatomy of the Spinal Cord revised (*spinal ganglion* replaces *dorsal root ganglion*)
- Figure 8-16c The Brain revised (*Medial view* replaces *Sagittal section, Brainstem* replaces *Brain stem*)
- Section 8-8 The PNS connects the CNS with the body's external and internal environments, Cranial Nerves revision (added sentence: *If the full name of the cranial nerve is*

given, then only the Roman numeral is needed, such as optic nerve (II)). This addition affects cranial nerves figure labels and text narrative.

- Figure 8-22 The Basal Nuclei revised (removed *amygdaloid body* from *Basal Nuclei* box since it is considered a component of the limbic system)
- Figure 8-25 The Cranial Nerves, parts a and b revised (*N* preceding Roman numeral of named optic nerves is deleted)
- Figure 8-26 Peripheral Nerves and Nerve Plexuses revised (leader line from *Femoral nerve* corrected)
- Figure 8-27 Dermatomes revised (CN V replaces N V)
- Figure 8-29 A Stretch Reflex revised (*quadriceps muscles* replaces *muscles* in second line of caption)
- Figure 8-31 The Posterior Column Pathway revised (*Primary Sensory Cortex* changed to *Primary Somatosensory Cortex; Dorsal root ganglion* changed to *Spinal ganglion*)
- Figure 8-32 The Corticospinal Pathway revised (*brainstem* replaces *brain stem*)
- Figure 8-35 The Parasympathetic Division revised (*N* changed to *CN*; added postganglionic neuron on rectum art)
- Table 8-2 The Effects of the Sympathetic and Parasympathetic Divisions of the ANS on Various Body Structures revised (EYE: Sympathetic Effects - *Focusing for distance vision* replaces *Focusing for near vision*; Parasympathetic Effects -*Focusing for close vision* replaces *Focusing for distance vision*)

Chapter 9 The General and Special Senses

- Figure 9-3 Tactile Receptors in the Skin revised (added myelin sheath to afferent nerve fiber in Tactile Discs box; *bulbous corpuscle* replaces *Ruffini corpuscle; lamellar [pacinian] corpuscle* replaces *lamellated [pacinian] corpuscle*)
- Figure 9-4 Baroreceptors and the Regulation of Autonomic Functions revised (changed *carotid sinus* to *carotid sinuses* and added a second leader; *aortic arch* replaces *aortic sinus* and corrected position of leader line)
- Figure 9-6 The Olfactory Organs revised (in part a, changed Olfactory nerve fibers (*N I*) to Olfactory nerve fibers (*I*); in part b, *dendritic bulb* replaces *knob*)
- Figure 9-7 Taste Buds and Gustatory Epithelial Cells revised (new title; in part a, eliminated line spacing between the four primary taste sensations to indicate that all portions of the tongue provide sweet, salty, sour, and bitter sensations; in part b, *gustatory epithelial cell* replaces *gustatory cell*)
- Figure 9-8 The Accessory Structures of the Eye revised (*lateral angle* replaces *lateral canthus* and *medial angle* replaces *medial canthus*)

- Figure 9-10 The Sectional Anatomy of the Eye revised (in parts a and c, *fovea centralis* replaces *fovea*; in part b, *neural layer* replaces *neural part* and *pigmented layer* replaces *pigmented part*; part c caption revised [*Superior view of dissection of the right eye* replaces *Horizontal dissection of the right eye*])
- Figure 9-11 Retinal Organization revised (*pigmented layer* of retina replaces pigmented part of retina and neural layer of retina replaces neural part of retina; fovea centralis replaces fovea)
- Figure 9-14 Focal Point, Focal Distance, and Visual Accommodation revised (in part a, text in art changed to *"Light rays from a distant source (object) are parallel"*, and caption revised by adding *"the greater the angle of arriving light rays and"*; art in parts d and e exchanged to better match art in parts a, b, and c)
- Spotlight Figure 9-16 Refractive Problems revised (added *"a process called accommodation"* to the end of introductory paragraph)
- Figure 9-18 The Structure of Rods and Cones revised (*pig-mented epithelium* replaces *pigment epithelium*)
- Figure 9-20 The Visual Pathways revised (*Optic nerves* [II] replaces *Optic nerves* [N II])
- Figure 9-21 The Anatomy of the Ear revised (*Facial nerve* [*VII*] replaces *Facial nerve* [*N VII*] and *Vestibulocochlear nerve* [*N VIII*] replaces *Vestibulocochlear nerve* [*N VIII*])
- Figure 9-23 The Internal Ear revised (*ampullary crests* replaces *cristae*)
- Figure 9-24 The Semicircular Ducts revised (*ampullary crest* replaces *crista ampullaris; ampullary cupula* replaces *cupula; Vestibular nerve* replaces *Vestibular branch*)
- Figure 9-25 The Utricla and Saccule revised (*macula of utricle* replaces *macula*)
- Figure 9-27 Sound and Hearing revised (*Cochlear nerve* replaces *Cochlear branch of cranial nerve VIII*)
- Figure 9-28 Pathways for Auditory Sensations revised (*Vestibular nerve* replaces *Vestibular branch*; *Vestibuloco-chlear nerve* [*VIII*] replaces *Vestibulocochlear nerve* [*N VIII*]; in step 5, *auditory* replaces *acoustic*)

Chapter 10 The Endocrine System

- Figure 10-1 Organs and Tissues of the Endocrine System revised (deleted *Secretes* from the examples of Organs with Secondary Endocrine Functions)
- Figure 10-2 The Role of Target Cell Receptors in Hormone Action revised (*neurons* replaces *neural tissue*; *skeletal muscle fiber* replaces *skeletal muscle tissue*)
- Figure 10-4 Hypothalamic Control over Endocrine Function revised (added color coding to boxed text to enhance links between hypothalamic structures and functions)

- Figure 10-8 Pituitary Hormones and Their Targets revised (changed color of adrenal gland secretion oval to enhance link with revised boxed text color in Figure 10-4)
- Section 10-4 Title revised (*The thyroid gland synthesizes thyroid hormones that affect the rate of metabolism* replaces *The thyroid gland lies inferior to the larynx and requires io- dine for hormone synthesis*)
- Table 10-1 The Pituitary Hormones revised (under Target column, *Interstitial endocrine cells of testes* replaces *Interstitial cells of testes*)
- Figure 10-10 The Homeostatic Regulation of the Blood Calcium Ion Concentration revised (clarified that figure discusses calcium ion concentration in *blood* and calcitonin's limited role in bone deposition)
- Table 10-2 Hormones of the Thyroid Gland and Parathyroid Glands revised (*principal cells* replaces *chief cells*)
- Figure 10-13 The Endocrine Pancreas revised (*bile duct* replaces *common bile duct*)
- Figure 10-14 The Homeostatic Regulation of the Blood Glucose Concentration revised (added Homeostatic to figure title and clarified normal blood glucose levels is a range)
- Clinical Note Diabetes Mellitus revised (updated estimated number of people in the U.S. with some form of diabetes)
- Clinical Note Endocrine Disorders revised (*congenital hypo-thyroidism* replaces *cretinism* and *infantile hypothyroidism*)
- Build Your Knowledge revised (clarified that vitamin D₃ is a *precursor to calcitriol production* in the Integumentary System box)

Chapter 11 The Cardiovascular System: Blood

- Spotlight Figure 11-1 The Composition of Whole Blood revised (clarified definition of hematocrit; updated *normal hematocrit range for adult males and adult females*)
- Section 11-3 Abundance of Red Blood Cells section revised (described the composition of the three layers observed after centrifugation of whole blood)
- Section 11-3 Structure of RBCs section revised (clarified that a *flexible cell membrane* accounts for ability of RBCs bend and squeeze through capillaries)
- Section 11-3 Sex and Iron Reserves revised (*Sex and Iron Reserves* replaces *Gender and Iron Reserves*)
- Figure 11-3 Recycling of Hemoglobin revised (clarified that *Fe*²⁺ is an *iron ion;* added label to large intestine)
- Clinical Note Abnormal Hemoglobin revised (*sickle cell disease [SCD]* replaces *sickle cell anemia [SCA]*)
- Figure 11-6 Blood Types and Cross-Reactions revised (corrected shapes of anti-A and anti-B antibodies)
- Figure 11-7 Blood Typing Testing revised (added "clumping" or "no clumping" under test results for clarification)

• Figure 11-9 The Vascular, Platelet, and Coagulation Phases of Hemostasis revised (added *Endothelium* label for clarification)

Chapter 12 The Cardiovascular System: The Heart

- Section 12-1 revised (clarified that *pericardium* includes an outer *fibrous pericardium* and an inner *serous pericardium*)
- Figure 12-1 The Location of the Heart in Thoracic Cavity revised (*parietal layer of serous pericardium* replaces *parietal pericardium*, *visceral layer of serous pericardium* replaces *visceral pericardium*)
- Figure 12-3 The Position and Anatomy of the Heart revised (parts are rearranged; part a art now shows the position of the heart)
- Figure 12-4 The Heart Wall and Cardiac Muscle Tissue revised (*parietal layer of serous pericardium* replaces *parietal pericardium*, *visceral layer of serous pericardium* replaces *visceral pericardium*)
- Spotlight Figure 12-5 The Heart: Internal Anatomy and Blood Flow revised (*tricuspid valve* replaces *right atrioven-tricular valve*, *mitral valve* replaces *left atrioventricular valve*)
- Figure 12-6 The Valves of the Heart revised (*tricuspid* replaces *right AV* [*tricuspid*] *valve*, *mitral valve* replaces *left AV* [*bicuspid*] *valve*)
- Figure 12-8 Action Potentials in Cardiac Contractile Cells and Skeletal Muscle Fibers revised (new figure title; *cardiac contractile cell* replaces *cardiac muscle cell*, *skeletal muscle fiber* replaces *skeletal muscle*)
- Figure 12-11 The Cardiac Cycle revised (Changed color of central *Cardiac cycle* to enhance text and art)
- Figure 12-12 Heart Sounds revised (new part a art avoids crossing of leader lines)
- Figure 12-13 Autonomic Innervation of the Heart revised (*Vagus nerve* [X] replaces *Vagus* [N X])

Chapter 13 The Cardiovascular System: Blood Vessels and Circulation

- Figure 13-2 The Structure of the Various Types of Blood Vessels revised (clarified internal, or *lumen*, diameters of blood vessels)
- Figure 13-8 The Baroreceptor Reflexes of the Carotid Sinuses and Aortic Arch revised (new Figure title; *Baroreceptors in carotid sinuses and aortic arch* replaces *Baroreceptors in aortic and carotid sinuses*)
- Figure 13-18 The Venous Drainage of the Abdomen and Chest revised (*hemi-azygos* replaces *hemiazygos*)
- Figure 13-19 A Flowchart of the Tributaries of the Superior and Inferior Venae Cavae revised (*Hemi-azygos* replaces *Hemiazygos*)

- Figure 13-20 The Hepatic Portal System revised (clarified drainage of *left and right gastroepiploic veins*)
- BYK Integrator (*lactate* replaces *lactic acid*)

Chapter 14 The Lymphatic System and Immunity

- Definition of the term "immune response" revised from "a defense against specific antigens" to "the body's reaction to infectious agents and abnormal substances")
- Figure 14-1 The Components of the Lymphatic System revised (added CNS lymphatic vessels to the art; Other Lymphoid Tissues and Organs heading replaces Lymphoid Tissues and Organs heading because lymph nodes are organs)
- Spotlight Figure 14-4 Origin and Distribution of Lymphocytes revised (*hemocytoblasts* replaces *hematopoietic stem cells*)
- Figure 14-6 The Structure of a Lymph Node revised (*cortex* replaces *outer cortex; paracortex* replaces *deep cortex*)
- Figure 14-9 The Body's Innate Defenses revised (clarifies the roles of *complement*)
- Figure 14-11 Forms of Immunity revised (*artificially ac-quired* replaces *artificially induced*)
- Figure 14-12 An Overview of Adaptive Immunity revised (former title "An Overview of the Immune Response"; new title emphasizes that adaptive immunity is part of the "immune response")
- Figure 14-17 An Integrated Summary of the Immune Response (new title corresponds with broadened definition of the term "immune response"; *regulatory T cells* replaces *suppressor T cells*)

Chapter 15 The Respiratory System

- Figure 15-1 The Structures of the Respiratory System revised (*Respiratory bronchioles* replaces *Smallest bronchioles*)
- Figure 15-2 The Respiratory Mucosa revised (*mucus* replaces *mucus layer*)
- Figure 15-3 The Nose, Nasal Cavity, and Pharynx revised (*posterior internal apertures* replaces *internal nares*, and *nostrils* replaces *external nares*)
- Clinical Note Cystic Fibrosis revised (added text to clarify that cystic fibrosis affects not only the respiratory system, but also the digestive and reproductive systems)
- Figure 15-4 The Anatomy of the Larynx and Vocal Cords revised (*glottis in the open position* art and photomicrograph now positioned next to each other)
- Figure 15-5 The Anatomy of the Trachea revised (*main bronchi* replaces *primary bronchi* and *lobar bronchi* replaces *secondary bronchi*)
- Figure 15-6 Bronchial Branching and a Lobule of the Lung revised (new figure title; *segmental bronchi* replaces *tertiary bronchi*)

- Figure 15-7 Alveolar Organization revised (*pneumocyte type I* replaces *type I pneumocyte*, and *pneumocyte type II* replaces *type II pneumocyte*; *blood air barrier* replaces *respiratory membrane*)
- Figure 15-8 The Gross Anatomy of the Lungs revised (added caption "*The lobes are shown as though transparent to make the main branching of the bronchial tree visible*")
- Spotlight Figure 15-10 Pulmonary Ventilation revised (clarified *rib cage* structures and that *accessory respiratory muscles* are only active in *forced breathing*)
- Figure 15-11 Pulmonary Volumes and Capacities revised (TV replaces *V*_T as abbreviation for tidal volume; clarified table describing sex differences)
- Spotlight Figure 15-16 The Control of Respiration revised (*CN* replaces *N*)
- BYK Integrator revised (deleted *nourish* from Integumentary System description)

Chapter 16 The Digestive System

- Section 16-1 revised under *Secretion*, added *salts* to the substances released into the digestive tract
- Section 16-1 revised (clarified that the *enteric nervous system* [*ENS*] consists of the *myenteric plexus* and *submucosal plexus*)
- Figure 16-1 The Components of the Digestive System revised (*mechanical digestion* replaces *mechanical processing*, *chemical digestion* replaces *chemical breakdown*)
- Figure 16-2 The Structure of the Digestive Tract revised (included *muscularis mucosae* within the Mucosa box, *muscular layer* replaces *muscularis externa*)
- Figure 16-4 The Oral Cavity revised (*frenulum of tongue* replaces *lingual frenulum*)
- Figure 16-6 Teeth: Structural Components and Dental Succession revised (*cement* replaces *cementum*, *alveolar process* replaces *bone of alveolus*, *deciduous teeth* replaces *primary teeth*, *permanent teeth* replaces *adult teeth*)
- Figure 16-8 The Anatomy of the Stomach revised (*muscular layer* replaces *muscularis externa*; added *gastrin-producing G cells* to part d caption)
- Spotlight Figure 16-9 Regulation of Gastric Activity revised (*muscular layer* replaces *muscularis externa; neural inhibition* and *hormonal inhibition* added to *Intestinal Phase* KEY)
- Figure 16-11 The Intestinal Wall revised (*muscular layer* replaces *muscularis externa; Goblet cells* [*intestinal mucous cells*] replaces *Mucous cells*)
- Figure 16-13 The Pancreas revised (*bile duct* replaces *common bile duct*)
- Figure 16-14 The Surface Anatomy of the Liver revised (*bile duct* replaces *common bile duct*)
- Figure 16-15 Liver Histology revised (*portal triad* replaces *portal area; interlobular bile duct* replaces *bile duct, interlobular artery* replaces *branch of the hepatic artery proper,*

interlobular vein replaces *branch of hepatic portal vein; stellate macrophages* replaces *Kupffer cells*)

- Figure 16-16 The Gallbladder revised *(bile duct* replaces *common bile duct)*
- Figure 16-17 The Large Intestine revised (*teniae coli* replaces *tenia coli* because there is no singular form to refer to one of the longitudinal smooth muscle bands)
- Spotlight Figure 16-18 Chemical Events in Digestion (clarified large organic molecules are *chemically* broken down before absorption)
- BYK Integrator revised (clarified mechanical and chemical digestion functions in Digestive System box)

Chapter 17 Metabolism and Energetics

- Figure 17-2 Nutrient Use in Cellular Metabolism revised (*electron transport chain* replaces *electron transport system*)
- Figure 17-4 The Citric Acid Cycle revised (*electron transport chain* replaces *electron transport system*)
- Spotlight Figure 17-5 Electron Transport Chain and ATP Formation revised (new figure title and clarified the role of *chemiosmosis* in ATP formation)
- Figure 17-6 A Summary of the Energy Yield of Aerobic Metabolism revised (*electron transport chain* replaces *electron transport system*)
- Figure 17-7 Carbohydrate Metabolism revised (clarified that gluconeogenesis only involves noncarbohydrates; deleted *Other carbohydrates* box from art)

Chapter 18 The Urinary System

- Section 18-1 revised (metabolic wastes replaces organic wastes)
- Figure 18-2 The Position of the Kidneys revised (clarified locations of *last thoracic* and *third lumbar vertebrae* to better correlate with text)
- Figure 18-4 The Blood Supply to the Kidneys revised (part a, added *segmental artery* label; part b, *renal pyramid* replaces *medulla*, and added *interlobar artery* and *interlobar vein* labels to better correlate with part a)
- Figure 18-5 A Representative Nephron and the Collecting System revised (highlighted general functions of *descending limb* and *ascending limb* in the Nephron Loop box with bullet points; *descending thin limb* replaces *thin descending limb*)
- Figure 18-6 The Renal Corpuscle revised (in part a, *capsular outer layer* replaces *parietal epithelium*, *visceral layer* replaces *visceral epithelium*; in part b, *fenestrated capillary endothelium* replaces *capillary epithelium*, *foot processes of podocytes* replaces *filtration slits*; in part c, *foot processes* replaces *pedicels*)
- Figure 18-10 The Renin-Angiotensin-Aldosterone System and Regulation of GFR revised (new figure title; *systemic veins* replaces *venous reservoirs*)

- Figure 18-11 Organs for Conducting and Storing Urine revised (new figure title; *ureteral orifices* replaces *ureteral openings*)
- NEW Figure 18-12 The Control of Urination
- Figure 18-14 Ions in Body Fluids revised (caption revised to emphasize electrical neutrality within each fluid compartment)
- BYK Integrator Urinary System revised (*excretes* replaces *removes*)

Chapter 19 The Reproductive System

- Section 19-1 revised (*sperm* replaces *spermatozoa/spermatozoon* as the primary term)
- Figure 19-2 The Scrotum, Testes, and Seminiferous Tubules revised (*sperm* replaces *spermatozoa*)
- Section 19-2 revised (*dartos muscle* replaces *dartos*; *sustenocytes* replaces *sustentacular cells*; *prostate* replaces *prostate* gland)
- Figure 19-3 Spermatogenesis revised (*sperm* replaces *spermatozoa/spermatozoon*)
- Figure 19-6 The Penis revised (*foreskin* replaces *prepuce*)
- Spotlight Figure 19-7 Regulation of Male Reproduction revised (*interstitial endocrine cells* replaces *interstitial cells*; *sperm* replaces *spermatozoa*)
- Figure 19-10 Ovarian Follicle Development and the Ovarian Cycle revised (*ovarian follicle* replaces *follicle*; in caption, clarified that ovarian follicles enter *the 28-day* ovarian cycle as tertiary ovarian follicles)
- Section 19-3 revised (*functional layer* of endometrium replaces *functional zone* of endometrium, and *basal layer* of endometrium replaces *basilar layer* of endometrium)
- Figure 19-12 The Female External Genitalia revised (*bulb* of vestibule replaces vestibular bulb)
- Spotlight Figure 19-14 Regulation of Female Reproduction revised (*ovarian follicle* replaces *follicle*; temperature ranges added for both Celsius and Fahrenheit scales; and Menses label changed to Menstrual Phase)
- BYK Integrator Reproductive System revised (kidneys *excrete* replaces kidneys *remove* in Urinary System box)

Chapter 20 Development and Inheritance

- Figure 20-1 Fertilization revised (in part b, changed step 2 title and text in steps 3 and 4; clarified when DNA synthesis occurs, *sperm* replaces *spermatozoon*)
- Figure 20-3 Events in Implantation revised (*cytotrophoblast* replaces *cellular trophoblast*, *syncytiotrophoblast* replaces *syncytial trophoblast*)
- Figure 20-4 The Inner Cell Mass revised (*extra-embryonic* replaces *extraembryonic*, changed *Gastrulation* from *day* 12 to *day* 15)
- Spotlight Figure 20-5 Extra-Embryonic Membranes and Placenta Formation revised (added *mucus plug* to week 10/ step 5 art)

- Figure 20-6 The Placenta and Placental Circulation revised (*Mucus plug* replaces *Cervical (mucous) plug*)
- Figure 20-7 Development during the First Trimester revised (new part a Week 3 art and new Week 4, 8, and fiberoptic photographs)
- Figure 20-8 Fetal Development in the Second and Third Trimesters revised (new photograph of 6-month-old fetus)
- Figure 20-16 The Milk Ejection Reflex (new title replaces *The Milk Let-Down Reflex*)
- Figure 20-16 A Map of Human Chromosomes revised (*Down Syndrome* replaces *Down's Syndrome; Marfan's Syndrome* replaces *Marfan Syndrome; Sickle Cell Disease* replaces *Sickle Cell Anemia*)
- Section 20-8 The Human Genome revised (new title; added description of gene-editing technique *CRISPR/ Cas9*)

Acknowledgments

Every textbook represents a group effort. Foremost on the list are the faculty and reviewers whose advice, comments, and collective wisdom helped shape this edition. Their interest in the subject, their concern for the accuracy and method of presentation, and their experience with students of widely varying abilities and backgrounds made the review process an educational experience. To these individuals, who carefully recorded their comments, opinions, and sources, we express our sincere appreciation and best wishes.

We thank them for their participation and list their names and affiliations below.

Reviewers for the Eighth Edition

Meghan Andrikanich, Lorain County Community College Jaysen Arno, Pitt Community College Nick Butkevich, Schoolcraft College Kristin Jacobson Flex, Illinois Central College Deborah Furbish, Wake Technical Community College Layla Khatib, Moraine Valley Community College Brian Kipp, Grand Valley State University Tara Leszczewicz, College of DuPage Geralyne Lopez-de-Victoria, Midlands Technical College Sudeep Majumdar, Temple College Gary McIlvain, Marshall University Angela Porta, Kean University John Senter, Austin Community College George Spiegel, College of Southern Maryland Ashley Spring, Eastern Florida State College

Our gratitude is also extended to the many faculty and students at campuses across the United States (and out of the country) who made suggestions and comments that helped us improve this edition of *Essentials of Anatomy & Physiology*.

A textbook has two components: narrative and visual.

Virtually without exception, reviewers stressed the importance of accurate, integrated, and visually attractive illustrations in helping students understand essential material. The creative talents brought to this project by our artist team, William Ober, M.D. and Claire Ober, R.N., are inspiring and very much appreciated. Bill and Claire worked closely and tirelessly with us, imparting a unity of vision to the book as a whole while making it both clear and beautiful. The superb art program is also greatly enhanced by the incomparable bone and cadaver photographs of Ralph T. Hutchings, formerly of The Royal College of Surgeons in England.

We are deeply indebted to the Pearson staff and SPi Global, whose efforts were so vital to the creation of this edition. Special thanks are due to Norine Strang for her skillful management of the project through the entire production process. We appreciate the excellent design contributions of Jerilyn Bockorick, Design Manager, Mark Ong, cover designer, and Alisha Webber, interior text designer.

We must also express our appreciation to Lauren Chen and Kimberly Twardochleb for their work on the media supplements that accompany this title, and to our colleague Kevin Petti, for his outstanding efforts to script and record the new Spotlight Videos.

Thanks also to Wendy Mears, Product Marketing Manager, Derek Perrigo, Field Marketing Manager, and the entire Pearson Science sales team for keeping their fingers on the pulse of the market and helping us meet the needs of our users.

Above all, thanks to Jessica Picone for her patience in nurturing this project, and to Cheryl Cechvala, Senior Acquisitions Editor, for her dedication to the success of this book.

Finally, we would like to thank our families for their love and support during the revision process.

No two people could expect to produce a flawless textbook of this scope and complexity. Any errors or oversights are strictly our own rather than those of the reviewers, artists, or editors. In an effort to improve future editions, we ask that readers with pertinent information, suggestions, or comments concerning the organization or content of this textbook e-mail us directly at the e-mail address below. Any and all comments and suggestions will be deeply appreciated and carefully considered in the preparation of the next edition. martini@pearson.com

Acknowledgments for the Global Edition

Pearson would like to thank and acknowledge the following people for their work on this Global Edition.

Contents

An Introduction to Anatomy and Physiology 31

An Introduction to Studying the Human Body 32

- 1-1 All living things display responsiveness, growth, reproduction, movement, and metabolism 32
- 1-2 Anatomy is structure, and physiology is function 33 Anatomy • Physiology
- 1-3 Levels of organization progress from atoms and molecules to a complete organism 34
- 1-4 The human body consists of 11 organ systems 36
- **1-5** Homeostasis is the state of internal balance 36
- **1-6** Negative feedback opposes variations from normal, whereas positive feedback exaggerates them 40 Negative Feedback • Positive Feedback
- 1-7 Anatomical terms describe body regions, anatomical positions and directions, and body sections 43 Surface Anatomy • Sectional Anatomy
- **1-8** Body cavities of the trunk protect internal organs and allow them to change shape 45 The Thoracic Cavity • The Abdominopelvic Cavity

Chapter Review 52

The Chemical Level 💪 of Organization 55

An Introduction to the Chemical Level of Organization 56

- 2-1 Atoms are the basic particles of matter 56 Atomic Structure • Isotopes • Atomic Weight • **Electron Shells**
- 2-2 Chemical bonds are forces formed by interactions between atoms 58 Ionic Bonds • Covalent Bonds • Hydrogen Bonds
- 2-3 Decomposition, synthesis, and exchange reactions are important chemical reactions in physiology 61 Basic Energy Concepts • Types of Reactions • **Reversible Reactions**

- **2-4** Enzymes catalyze specific biochemical reactions by lowering a reaction's activation energy 64
- 2-5 Inorganic compounds usually lack carbon, and organic compounds always contain carbon 64
- 2-6 Physiological systems depend on water 65
- 2-7 Body fluid pH is vital for homeostasis 66
- 2-8 Acids, bases, and salts have important physiological roles 67 Salts • Buffers and pH
- 2-9 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio 68
 - Monosaccharides Disaccharides and Polysaccharides
- 2-10 Lipids contain a carbon-to-hydrogen ratio of 1:2 70 Fatty Acids • Fats • Steroids • Phospholipids
- 2-11 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids 73 Protein Function • Protein Structure • Enzyme Function
- 2-12 DNA and RNA are nucleic acids 76 Structure of Nucleic Acids
- 2-13 ATP is a high-energy compound used by cells 78
- 2-14 Chemicals form functional units called cells 80

SPOTLIGHT Chemical Notation 62 **CLINICAL NOTE** Too Sweet on Sugar? 71

Chapter Review 81

and Function 85

An Introduction to Cell Structure and Function 86

- **3-1** The study of cells provides the foundation for understanding human physiology 86 The Study of Cells • An Overview of Cell Anatomy
- 3-2 The plasma membrane separates the cell from its surrounding environment and performs various functions 87 Membrane Lipids • Membrane Proteins • Membrane Carbohydrates
- 3-3 Diffusion is a passive transport process that assists membrane passage 91 Diffusion

- 3-4 Carrier-mediated and vesicular transport processes assist membrane passage 95
 Carrier-Mediated Transport • Vesicular Transport
- 3-5 Organelles within the cytoplasm perform specific functions 99The Cytosol The Organelles
- 3-6 The nucleus contains DNA and enzymes essential for controlling cellular activities 106
 Nuclear Structure and Contents • Information Storage in the Nucleus
- 3-7 DNA controls protein synthesis, cell structure, and cell function 108
 Transcription Translation
- 3-8 Stages of a cell's life cycle include interphase, mitosis, and cytokinesis 111
 Interphase • Mitosis • Cytokinesis
- **3-9** Tumors and cancers are characterized by abnormal cell growth and division 114
- **3-10** Cellular differentiation is cellular specialization as a result of gene activation or repression 115

The Tissue Level of Organization 120

An Introduction to the Tissue Level of Organization 121

- **4-1** The four tissue types are epithelial, connective, muscle, and nervous 121
- **4-2** Epithelial tissue covers body surfaces, lines cavities and tubular structures, and serves essential functions 121

Functions of Epithelia • Intercellular Connections • The Epithelial Surface • The Basement Membrane • Epithelial Renewal and Repair

- 4-3 Cell shape and number of layers determine the classification of epithelia 125
 Cell Layers Cell Shapes Classification of Epithelia Glandular Epithelia
- 4-4 Connective tissue provides a protective structural framework for other tissue types 131
 Connective Tissue Proper • Types of Connective Tissue Proper • Fluid Connective Tissues • Supporting Connective Tissues

- 4-5 Tissue membranes are physical barriers of four types: mucous, serous, cutaneous, and synovial 140 Mucous Membranes • Serous Membranes • The Cutaneous Membrane • Synovial Membranes
- 4-6 The three types of muscle tissue are skeletal, cardiac, and smooth 141
 Skeletal Muscle Tissue Cardiac Muscle Tissue Smooth Muscle Tissue
- **4-7** Nervous tissue responds to stimuli and propagates electrical impulses throughout the body 143
- **4-8** The response to tissue injury involves inflammation and regeneration 144
- 4-9 With advancing age, tissue repair declines and cancer rates increase 145
 Aging and Tissue Structure • Aging and Cancer Rates

The Integumentary System 151

An Introduction to the Integumentary System 152

- 5-1 The epidermis is composed of strata (layers) with various functions 153
 Stratum Basale Intermediate Strata Stratum Corneum
- 5-2 Epidermal pigmentation and dermal circulation influence skin color 156 The Role of Pigmentation • The Role of Dermal Circulation
- 5-3 Sunlight has beneficial and detrimental effects on the skin 157

The Epidermis and Vitamin $\mathrm{D}_3\, \bullet\,$ Skin Cancers

- 5-4 The dermis is the tissue layer that supports the epidermis 158
- 5-5 The subcutaneous layer connects the dermis to underlying tissues 159
- 5-6 Hair is composed of dead, keratinized cells that have been pushed to the skin surface 159 The Structure of Hair and Hair Follicles • Functions of Hair • Hair Color
- 5-7 Sebaceous glands and sweat glands are exocrine glands found in the skin 162
 Sebaceous (Oil) Glands Sweat Glands

- **5-8** Nails are keratinized epidermal cells that protect the tips of fingers and toes 163
- 5-9 After an injury, the integument is repaired in several phases 164
 Repair of Skin Injuries Effects of Burns
- 5-10 Effects of aging include dermal thinning, wrinkling, and reduced melanocyte activity 167

Chapter Review 169

The Skeletal System 172

An Introduction to the Skeletal System 173

- 6-1 The skeletal system has five major functions 173
- 6-2 Bones are classified according to shape and structure 173
 Macroscopic Features of Bone • Microscopic Features of Bone
- 6-3 Ossification and appositional growth are processes of bone formation and enlargement 176
 Intramembranous Ossification • Endochondral Ossification • Bone Growth and Body Proportions • Requirements for Normal Bone Growth
- 6-4 Bone growth and development depend on a balance between bone formation and resorption, and on calcium availability 179
 The Role of Remodeling in Support • The Skeleton as a Calcium Reserve • Repair of Fractures
- 6-5 Osteopenia has a widespread effect on aging skeletal tissue 182
- 6-6 The bones of the skeleton are distinguished by bone markings and grouped into two skeletal divisions 182
 Bone Markings (Surface Features) Skeletal Divisions
- 6-7 The bones of the skull, vertebral column, and thoracic cage make up the axial skeleton 186 The Skull
 The Vertebral Column and Thoracic Cage
- 6-8 The pectoral girdles and upper limb bones, and the pelvic girdle and lower limb bones, make up the appendicular skeleton 196
 The Pectoral Girdles The Upper Limb The Pelvic Girdle The Lower Limb

- 6-9 Joints are categorized according to their range of motion or anatomical organization 204
 Immovable Joints (Synarthroses) • Slightly Movable Joints (Amphiarthroses) • Freely Movable Joints (Diarthroses)
- 6-10 The structure and functions of synovial joints enable various skeletal movements 206 Types of Movements at Synovial Joints
 Types of Synovial Joints
- 6-11 Intervertebral joints and appendicular joints demonstrate functional differences in support and mobility 209
 Intervertebral Joints Joints of the Upper Limb Joints of the Lower Limb
- 6-12 The skeletal system supports and stores energy and minerals for other body systems 214

SPOTLIGHT

Synovial Joints 210

CLINICAL NOTES

Chapter Review 216

An Introduction to Muscle Tissue 222

- 7-1 Skeletal muscle performs five primary functions 222
- 7-2 A skeletal muscle contains muscle tissue, connective tissues, blood vessels, and nerves 222
 Connective Tissue Organization Blood Vessels and Nerves
- **7-3** Skeletal muscle fibers have distinctive features 224 The Sarcolemma and Transverse Tubules • Myofibrils • The Sarcoplasmic Reticulum • Sarcomeres
- 7-4 The nervous system and skeletal muscles communicate at neuromuscular junctions 227 The Neuromuscular Junction • The Contraction Cycle
- 7-5 Sarcomere shortening and muscle fiber stimulation produce tension 230
 Frequency of Muscle Fiber Stimulation • Number of Muscle Fibers Activated • Isotonic and Isometric
- Contractions Muscle Elongation Following Contraction **7-6** ATP is the energy source for muscle
- contraction 237

ATP and CP Reserves • ATP Generation • Energy Use and the Level of Muscle Activity • Muscle Fatigue • The Recovery Period

- 7-7 Muscle performance depends on muscle fiber type and physical conditioning 240
 Types of Skeletal Muscle Fibers • Physical Conditioning
- **7-8** Cardiac and smooth muscle tissues differ in structure and function from skeletal muscle tissue 241 Cardiac Muscle Tissue • Smooth Muscle Tissue
- 7-9 Descriptive terms are used to name skeletal muscles 243
 Origins, Insertions, and Actions • Names of Skeletal Muscles
- 7-10 Axial muscles are muscles of the head and neck, vertebral column, trunk, and pelvic floor 247 Muscles of the Head and Neck • Muscles of the Spine • The Axial Muscles of the Trunk • Muscles of the Pelvic Floor
- 7-11 Appendicular muscles are muscles of the shoulders, upper limbs, pelvic girdle, and lower limbs 255
 Muscles of the Shoulders and Upper Limbs Muscles of the Pelvis and Lower Limbs
- **7-12** The size and power of muscle tissue decrease with advancing age 266
- 7-13 Exercise produces responses in multiple body systems 267

Chapter Review 269

The Nervous System 273

An Introduction to the Nervous System 274

- 8-1 The nervous system has anatomical and functional divisions 274
- 8-2 Neurons are specialized for intercellular communication and are supported by cells called neuroglia 275 Neurons • Neuroglia • Organization of Neurons in

the Nervous System

8-3 In neurons, a change in the plasma membrane's electrical potential may result in an action potential (nerve impulse) 281

The Membrane Potential • Propagation of an Action Potential

- 8-4 At synapses, communication takes place among neurons or between neurons and other cells 288 Structure of a Synapse • Synaptic Function and Neurotransmitters • Neuronal Pools
- 8-5 The brain and spinal cord are surrounded by three layers of membranes called the meninges 291
 The Dura Mater The Arachnoid The Pia Mater
- 8-6 The spinal cord contains gray matter surrounded by white matter and connects to 31 pairs of spinal nerves 292
 Gross Anatomy • Sectional Anatomy
- 8-7 The brain has several principal structures, each with specific functions 296
 The Major Regions of the Brain The Ventricles of the Brain The Cerebrum The Diencephalon The Midbrain The Pons The Cerebellum The Medulla Oblongata
- 8-8 The PNS connects the CNS with the body's external and internal environments 308 The Cranial Nerves • The Spinal Nerves • Nerve Plexuses
- 8-9 Reflexes are rapid, automatic responses to stimuli 313
 Simple Reflexes • Complex Reflexes • Integration and Control of Spinal Reflexes
- 8-10 Separate pathways carry sensory information and motor commands 316
 Sensory Pathways • Motor Pathways
- 8-11 The autonomic nervous system, composed of the sympathetic and parasympathetic divisions, is involved in the unconscious regulation of body functions 319

The Sympathetic Division • The Parasympathetic Division • Relationships between the Sympathetic and Parasympathetic Divisions

- 8-12 Aging produces various structural and functional changes in the nervous system 324
- 8-13 The nervous system is closely integrated with other body systems 326

SPOTLIGHTS

The General and Special Senses 335

An Introduction to General and Special Senses 336

- **9-1** Sensory receptors connect our internal and external environments with the nervous system 336
- 9-2 General sensory receptors are classified by the type of stimulus that excites them 337
 Pain Temperature Touch, Pressure, and Position Chemical Detection
- **9-3** Olfaction, the sense of smell, involves olfactory receptors responding to chemical stimuli 341 The Olfactory Pathways
- 9-4 Gustation, the sense of taste, involves taste receptors responding to chemical stimuli 343 The Taste Pathways
- **9-5** Internal eye structures contribute to vision, while accessory eye structures provide protection 344 The Accessory Structures of the Eye The Eye
- 9-6 Photoreceptors respond to light and change it into electrical signals essential to visual physiology 353
 Rods and Cones • Photoreceptor Structure • Photoreception • The Visual Pathways
- 9-7 Equilibrium sensations originate within the internal ear, while hearing involves the detection and interpretation of sound waves 358
 Anatomy of the Ear Equilibrium Hearing
- 9-8 Aging is accompanied by a noticeable decline in the special senses 368
 Smell and Aging Taste and Aging Vision and

Aging • Equilibrium and Aging • Hearing and Aging

SPOTLIGHT

Refractive Problems 354

Chapter Review 369

An Introduction to the Endocrine System 375

10-1 Homeostasis is preserved through intercellular communication 375

10-2 The endocrine system regulates physiological processes through the binding of hormones to receptors 376
 The Structure of Hormones • Hormone Action • The Secretion and Distribution of Hormones •

The Control of Endocrine Activity

- 10-3 The bilobed pituitary gland is an endocrine organ that releases nine peptide hormones 381
 The Anterior Lobe of the Pituitary Gland • The Posterior Lobe of the Pituitary Gland
- 10-4 The thyroid gland synthesizes thyroid hormones that affect the rate of metabolism 386 Thyroid Follicles and Thyroid Hormones • The C Cells of the Thyroid Gland and Calcitonin
- 10-5 The four parathyroid glands, embedded in the posterior surfaces of the thyroid gland, secrete parathyroid hormone to elevate blood calcium levels 390
- 10-6 The adrenal glands, consisting of a cortex and a medulla, cap each kidney and secrete several hormones 390 The Adrenal Cortex • The Adrenal Medulla
- **10-7** The pineal gland, attached to the third ventricle, secretes melatonin 393
- 10-8 The endocrine pancreas produces insulin and glucagon, hormones that regulate blood glucose levels 393
 Diabetes Mellitus
- 10-9 Many organs have secondary endocrine functions 395
 The Intestines • The Kidneys • The Heart • The Thymus • The Gonads • Adipose Tissue
- 10-10 Hormones interact to produce coordinated physiological responses 398 Hormones and Growth • Hormones and Stress • Hormones and Behavior • Hormones and Aging
- **10-11** Extensive integration occurs between the endocrine system and other body systems 403

SPOTLIGHT

The General Adaptation Syndrome 401

Chapter Review 405

The Cardiovascular System: Blood 409

An Introduction to the Cardiovascular System 410

- 11-1 Blood has several important functions and unique physical characteristics 410
 Composition of Blood Blood Collection and Analysis
- **11-2** Plasma, the fluid portion of blood, contains significant quantities of plasma proteins 411 Plasma Proteins
- 11-3 Red blood cells, formed by erythropoiesis, contain hemoglobin that can be recycled 414
 Abundance of Red Blood Cells • Structure of RBCs • Hemoglobin Structure and Function • RBC Life Span and Circulation • RBC Formation
- 11-4 The ABO blood types and Rh system are based on antigen-antibody responses 420
 Cross-Reactions in Transfusions • Testing for Blood Compatibility
- 11-5 The various types of white blood cells contribute to the body's defenses 423
 WBC Circulation and Movement • Types of WBCs • The Differential Count and Changes in WBC Abundance • WBC Formation
- **11-6** Platelets, disc-shaped structures formed from megakaryocytes, function in the clotting process 427
- 11-7 Hemostasis involves vascular spasm, platelet plug formation, and blood coagulation 427
 Phases of Hemostasis • The Clotting Process • Clot Retraction and Removal

SPOTLIGHT

The Composition of Whole Blood 412

CLINICAL NOTES

Abnormal Hemoglobin 416 Hemolytic Disease of the Newborn 422 Abnormal Hemostasis 429

Chapter Review 431

2 The Cardiovascular System: The Heart 434

The Heart's Role in the Cardiovascular System 435

12-1 The heart is a four-chambered organ, supplied by coronary circulation, that pumps oxygen-poor blood to the lungs and oxygen-rich blood to the rest of the body 435

The Surface Anatomy of the Heart • The Heart Wall • Internal Anatomy and Organization

- 12-2 Contractile cells and the conducting system produce each heartbeat, and an electrocardiogram records the associated electrical events 445 Contractile Cells • The Conducting System • The Electrocardiogram
- 12-3 Events during a complete heartbeat make up a cardiac cycle 450Phases of the Cardiac Cycle Heart Sounds
- 12-4 Heart dynamics examines the factors that affect cardiac output 452
 Blood Volume Reflexes • Autonomic Innervation • Hormones

SPOTLIGHT

The Heart: Internal Anatomy and Blood Flow 441

3 The Cardiovascular System: Blood Vessels and Circulation 459

An Introduction to Blood Vessels and Circulation 460

- 13-1 Arteries, arterioles, capillaries, venules, and veins differ in size, structure, and function 460
 The Structure of Vessel Walls Arteries •
 Capillaries Veins
- 13-2 Pressure and resistance determine blood flow and affect rates of capillary exchange 465
 Factors Affecting Blood Flow • Cardiovascular Pressures within the Systemic Circuit
- 13-3 Cardiovascular regulation involves autoregulation, neural processes, and endocrine responses 471
 Autoregulation of Blood Flow within Tissues • Neural Control of Blood Pressure and Blood Flow • Hormones and Cardiovascular Regulation
- 13-4 The cardiovascular system adapts to physiological stress 477
 Exercise and the Cardiovascular System The Cardiovascular Response to Hemorrhage
- 13-5 The pulmonary and systemic circuits of the cardiovascular system exhibit three general functional patterns 479
- **13-6** In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs in veins 480

- 13-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues other than the lungs' exchange surfaces, and returns deoxygenated blood to the right atrium 481
 Systemic Arteries • Systemic Veins
- 13-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials until birth 492
 Placental Blood Supply Fetal Circulation in the Heart and Great Vessels Circulatory Changes at Birth
- **13-9** Aging affects the blood, heart, and blood vessels 493
- **13-10** The cardiovascular system is both structurally and functionally linked to all other systems 494

SPOTLIGHT

Major Vessels of the Systemic Circuit 482

CLINICAL NOTES

Arteriosclerosis 463 Capillary Dynamics and Blood Volume and Pressure 469 Checking the Pulse and Blood Pressure 470 Exercise, Cardiovascular Fitness, and Health 477 Shock 478

Chapter Review 496

An Introduction to the Lymphatic System and Immunity 502

- 14-1 Anatomical barriers and defense processes make up nonspecific defense, and lymphocytes provide specific defense 502
- 14-2 Lymphatic vessels, lymphocytes, lymphoid tissues, and lymphoid organs function in body defenses 503

Functions of the Lymphatic System • Lymphatic Vessels • Lymphocytes • Lymphoid Tissues • Lymphoid Organs

- 14-3 Innate (nonspecific) defenses respond in a characteristic way regardless of the potential threat 511
 Physical Barriers Phagocytes Immune Surveillance Interferons The Complement System Inflammation Fever
- 14-4 Adaptive (specific) defenses respond to specific threats and are either cell mediated or antibody mediated 515

Forms of Immunity • An Overview of Adaptive Immunity

- 14-5 T cells play a role in starting and controlling adaptive immunity 517
 Antigen Presentation • T Cell Activation
- 14-6 B cells respond to antigens by producing specific antibodies 519

B Cell Sensitization and Activation • Antibody Structure • Antibody Function • Primary and Secondary Responses to Antigen Exposure • Summary of the Immune Response • Hormones of the Immune System

- 14-7 Abnormal immune responses result in immune disorders 526
 Autoimmune Disorders • Immunodeficiency Diseases • Allergies
- 14-8 The immune response diminishes as we age 527
- 14-9 For all body systems, the lymphatic system provides defenses against infection and returns tissue fluid to the circulation 528

SPOTLIGHT

Origin and Distribution of Lymphocytes 507

CLINICAL NOTES

"Swollen Glands" 509 Injury to the Spleen 511 AIDS 523 Stress and the Immune Response 527 Manipulating the Immune Response 528

Chapter Review 530

An Introduction to the Respiratory System 536

- 15-1 The respiratory system, composed of air-conducting and respiratory portions, has several basic functions 536
 Functions of the Respiratory System • Structures of the Respiratory System
- 15-2 The nose, pharynx, larynx, trachea, bronchi, and larger bronchioles conduct air into the lungs 538
 The Nose • The Pharynx • The Larynx • The Trachea • The Bronchi
- 15-3 The smallest bronchioles and the alveoli within the lungs make up the respiratory portion of the respiratory tract 544 The Bronchioles • The Blood Air Barrier • The Lungs • The Pleural Cavities
- **15-4** External respiration and internal respiration allow gas exchange within the body 548

- 15-5 Pulmonary ventilation—the exchange of air between the atmosphere and the lungs-involves pressure changes and muscle movement 549 Pressure and Airflow to the Lungs • Compliance • Modes of Breathing • Lung Volumes and Capacities
- 15-6 Gas exchange depends on the partial pressures of gases and the diffusion of molecules 552 Mixed Gases and Partial Pressures • Partial Pressures in the Pulmonary and Systemic Circuits
- 15-7 In gas transport, most oxygen is transported bound to hemoglobin, whereas carbon dioxide is transported in three ways 554 Oxygen Transport • Carbon Dioxide Transport
- **15-8** Neurons in the medulla oblongata and pons, along with respiratory reflexes, control respiration 557 The Local Control of Respiration • Control by the Respiratory Centers of the Brain • The Reflex Control of Respiration • Control by Higher Centers • Respiratory Changes at Birth
- **15-9** Respiratory performance declines with age 562
- **15-10** The respiratory system provides oxygen to, and removes carbon dioxide from, other organ systems 562

SPOTLIGHTS

Pulmonary Ventilation 550 The Control of Respiration 560

Gastritis and Peptic Ulcers 581 Stomach Cancer 581 Vomiting 585 Pancreatitis 588 Liver Disease 591 Colorectal Cancer 594 Diverticulosis 595 Diarrhea and Constipation 595 Lactose Intolerance 598

Chapter Review 602

An Introduction to Nutrition and Metabolism 608

17-1 Metabolism refers to all the chemical reactions in the body, and energetics refers to the flow and transformation of energy 608

- 17-2 Carbohydrate metabolism involves glycolysis, ATP production, and gluconeogenesis 610
 Glycolysis Energy Production Within Mitochondria Energy Yield of Glycolysis and Cellular Respiration Gluconeogenesis (Glucose Synthesis) Alternate Catabolic Pathways
- 17-3 Lipid metabolism involves lipolysis, beta-oxidation, and the transport and distribution of lipids as lipoproteins and free fatty acids 617
 Lipid Catabolism Lipids and Energy Production Lipid Synthesis Lipid Transport and Distribution
- 17-4 Protein catabolism involves transamination and deamination, and protein synthesis involves amination and transamination 619
 Amino Acid Catabolism Amino Acids and Protein Synthesis
- 17-5 Nucleic acid catabolism involves RNA, but not DNA 621
 RNA Catabolism • Nucleic Acid Synthesis
- 17-6 Adequate nutrition is necessary to prevent deficiency disorders and maintain homeostasis 622
 Food Groups and a Balanced Diet • Minerals, Vitamins, and Water • Diet and Disease
- 17-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heatproducing and heat-losing processes 626 The Energy Content of Food • Energy Expenditure: Metabolic Rate • Thermoregulation
- 17-8 Caloric needs decline with advancing age 629

SPOTLIGHT

Electron Transport Chain and ATP Formation 613

CLINICAL NOTES

Carbohydrate Loading 615 Dietary Fats and Cholesterol 617 Ketoacidosis 620

Chapter Review 630

An Introduction to the Urinary System 635

- 18-1 The urinary system—made up of the kidneys, ureters, urinary bladder, and urethra—has three major functions 635
- 18-2 The kidneys are highly vascular organs containing functional units called nephrons, which perform filtration, reabsorption, and secretion 636
 Superficial and Sectional Anatomy of the Kidneys The Blood Supply to the Kidneys The Nephron

- 18-3 Different portions of the nephron form urine by filtration, reabsorption, and secretion 643
 Nephron Processes Filtration at the Glomerulus Reabsorption and Secretion along the Renal Tubule Normal Urine
- 18-4 Normal kidney function depends on a stable GFR 650 The Local Regulation of Kidney Function • The Hormonal Control of Kidney Function
- 18-5 Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra, aided by urinary reflexes 653
 The Ureters The Urinary Bladder The Urethra The Control of Urination
- 18-6 Fluid balance, electrolyte balance, and acid-base balance are interrelated and essential to homeostasis 656
 The ECF and the ICF
- 18-7 Blood pressure and osmosis are involved in maintaining fluid and electrolyte balance 658
 Fluid Balance • Electrolyte Balance
- 18-8 In acid-base balance, regulation of hydrogen ions in body fluids involves buffer systems and compensation by respiratory and renal processes 660
 Acids in the Body • Buffers and Buffer Systems • Maintaining Acid-Base Balance • Acid-Base Disorders
- **18-9** Age-related changes affect kidney function and the control of urination 664
- **18-10** The urinary system is one of several body systems involved in waste excretion 665

SPOTLIGHT

A Summary of Kidney Function 648

CLINICAL NOTES

Kidney Failure 652 Urinary Tract Infections 654 Incontinence 655 Disturbances of Acid-Base Balance 663

Chapter Review 667

An Introduction to the Reproductive System 673

- 19-1 Basic reproductive system structures are gonads, ducts, accessory glands and organs, and external genitalia 673
- **19-2** Sperm formation (spermatogenesis) occurs in the testes, and hormones from the hypothalamus, pituitary gland, and testes control male reproductive functions 674

The Testes • Spermatogenesis • The Male Reproductive Tract • The Accessory Glands • The External Genitalia • Hormones and Male Reproductive Function

- 19-3 Ovum production (oogenesis) occurs in the ovaries, and hormones from the pituitary gland and ovaries control female reproductive functions 683 The Ovaries • The Uterine Tubes • The Uterus • The Vagina • The External Genitalia • The Mammary Glands • Hormones and the Female Reproductive Cycle
- 19-4 The autonomic nervous system influences male and female sexual function 695Male Sexual Function Female Sexual Function
- 19-5 With age, decreasing levels of reproductive hormones cause functional changes 696
 Menopause The Male Climacteric
- **19-6** The reproductive system secretes hormones affecting growth and metabolism of all body systems 697

An Introduction to Anatomy and Physiology

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **1-1** Describe the basic functions of living organisms.
- **1-2** Explain the relationship between anatomy and physiology, and describe various specialties of each discipline.
- **1-3** Identify the major levels of organization in organisms, from the simplest to the most complex.
- **1-4** Identify the 11 organ systems of the human body and contrast their major functions.
- **1-5** Explain the concept of homeostasis.
- **1-6** Describe how negative feedback and positive feedback are involved in homeostatic regulation.
- **1-7** Use anatomical terms to describe body regions, body sections, and relative positions.
- **1-8** Identify the major body cavities of the trunk and the subdivisions of each.

Clinical Notes

Homeostasis and Disease, p. 36 Imaging Techniques, pp. 50–51 **Spotlight** Levels of Organization, p. 35

An Introduction to Studying the Human Body

In this textbook we will introduce you to the essential, inner workings of your body—giving information about its structure (anatomy) and function (physiology). As a human, you are most likely very curious, and few subjects arouse so much curiosity as our own bodies. You will discover how your body works under normal and abnormal conditions and how it maintains an internal state of balance. As we proceed, you will see how your body deals with injury, disease, or anything that threatens that crucial balance in a changing environment.

Build Your Knowledge

Throughout each chapter, you will find Build Your Knowledge boxes that will coach you through anatomy and physiology concepts. This feature will help you connect new material with what you already know. At the end of each chapter that closes a body system, you will see a "capstone"

Build Your Knowledge page that will illustrate the integration of the body system with the other body systems presented up to that point in the book. Be sure to read every Build Your Knowledge box or page so that you can build your knowledge—and confidence!

1-1 All living things display responsiveness, growth, reproduction, movement, and metabolism

Learning Outcome Describe the basic functions of living organisms.

We live in a world containing an amazing diversity of living organisms that vary widely in appearance and lifestyle. One aim of **biology**—the study of life—is to discover the common patterns that underlie this diversity. Such discoveries show that all living things share these common functions:

- **Responsiveness.** Organisms respond to changes in their immediate environment. This property is also called *irritability*. You move your hand away from a hot stove, your dog barks at approaching strangers, fish are alarmed by loud noises, and tiny amoebas glide toward potential prey. Organisms also make longer-term changes as they adjust to their environments. For example, an animal may grow a heavier coat of fur as winter approaches, or it may migrate to a warmer climate. The capacity to make such adjustments is termed *adaptability*.
- *Growth.* Organisms increase in size through the growth or addition of **cells**, the simplest units of life. Single-celled creatures grow by getting larger. More complex organisms grow primarily by increasing the number of cells. Familiar organisms, such as dogs, cats, and humans, are made up of trillions of cells. As such multicellular

organisms develop, individual cells become specialized to perform particular functions. This specialization is called *cellular differentiation*.

- **Reproduction.** Organisms reproduce, creating new generations of the same kind of organisms.
- *Movement*. Organisms exhibit movement. The movement may be internal (transporting food, blood, or other materials within the body) or external (moving through the environment).
- *Metabolism.* Organisms rely on complex chemical reactions to provide the energy required for responsiveness, growth, reproduction, and movement. They also build complex chemicals, such as proteins. *Metabolism* refers to all the chemical operations in the body.

For normal metabolic operations, organisms must absorb materials from the environment. To generate energy efficiently, most cells require various nutrients they obtain in food, as well as oxygen, a gas. *Respiration* refers to the absorption, transport, and use of oxygen by cells. Metabolic operations often generate unneeded or potentially harmful waste products that must be eliminated through the process of *excretion*.

For very small organisms, absorption, respiration, and excretion involve the movement of materials across exposed surfaces. But creatures larger than a few millimeters across seldom absorb nutrients directly from their environment. For example, humans cannot absorb steaks, apples, or ice cream without processing them first. That processing, called *digestion*, takes place in specialized structures in which complex foods are broken down into simpler components that can be transported and absorbed easily.

Respiration and excretion are also more complicated for large organisms. Humans have specialized structures for gas exchange (lungs) and excretion (kidneys). Digestion, respiration, and excretion occur in different parts of the body, but the cells of the body cannot travel to one place for nutrients, another for oxygen, and a third to get rid of waste products. Instead, individual cells remain where they are but communicate with other areas of the body through an internal transport system—the circulation. For example, the blood absorbs the waste products released by each of your cells and carries those wastes to the kidneys for excretion.

Biology includes many subspecialties. In this text we consider two biological subjects: anatomy (ah-NAT-o-mē) and physiology (fiz-ē-OL-o-jē). Over the course of this book, you will become familiar with the basic anatomy and physiology of the human body.

CHECKPOINT

1. How do vital functions such as responsiveness, growth, reproduction, and movement depend on metabolism?

See the blue Answers tab at the back of the book.

1-2 Anatomy is structure, and physiology is function

Learning Outcome Explain the relationship between anatomy and physiology, and describe various specialties of each discipline.

The word *anatomy* has Greek origins, as do many other anatomical terms and phrases. **Anatomy**, which means "a cutting open," is the study of internal and external structure and the physical relationships between body parts. **Physiology**, also derived from Greek, is the study of how living organisms carry out their vital functions. The two subjects are interrelated. Anatomical details provide clues about probable functions. Physiological processes can be explained only in terms of their underlying anatomy.

The link between structure and function is always present but not always understood. For example, the anatomy of the heart was clearly described in the fifteenth century, but almost 200 years passed before anyone realized that it pumped blood. This text will familiarize you with basic anatomy and give you an appreciation of the physiological processes that make human life possible. The information will help you to understand many diseases to make informed decisions about your own health.

Anatomy

We can divide anatomy into gross (macroscopic) anatomy or microscopic anatomy. We do so on the basis of the degree of structural detail under consideration. Other anatomical specialties focus on specific processes, such as respiration, or on medical applications, such as developing artificial limbs.

Gross Anatomy

Gross anatomy, or *macroscopic anatomy*, considers features visible with the unaided eye. We can approach gross anatomy in many ways. **Surface anatomy** is the study of general form and superficial markings. **Regional anatomy** considers all the superficial and internal features in a specific region of the body, such as the head, neck, or trunk. **Systemic anatomy** considers the structure of major *organ systems*, which are groups of organs that work together in a coordinated manner. For example, the heart, blood, and blood vessels form the *cardiovascular system*, which circulates oxygen and nutrients throughout the body.

Microscopic Anatomy

Microscopic anatomy concerns structures that we cannot see without magnification. The boundaries of microscopic anatomy are set by the limits of the equipment used. A light microscope reveals basic details about cell structure, but an electron microscope can visualize individual molecules only a few nanometers (nm, 1 millionth of a millimeter) across. In this text, we will consider details at all levels, from macroscopic to microscopic.

We can subdivide microscopic anatomy into specialties that consider features within a characteristic range of sizes. **Cytology** (sī-TOL-o-jē) analyzes the internal structure of individual *cells*. The trillions of living cells in our bodies are made up of chemical substances in various combinations. Our lives depend on the chemical processes taking place in those cells. For this reason we consider basic chemistry (Chapter 2: The Chemical Level of Organization) before looking at cell structure (Chapter 3: Cell Structure and Function).

Histology (his-TOL-o-jē) takes a broader perspective. It examines **tissues**, groups of specialized cells and cell products that work together to carry out specific functions (Chapter 4). Tissues combine to form **organs**, such as the heart, kidney, liver, and brain. We can examine many organs without a microscope, so at the organ level we cross the boundary into gross anatomy.

Physiology

Physiology is the study of function in living organisms. **Human physiology** is the study of the functions of the human body. These functions are complex and much more difficult to examine than most anatomical structures. As a result, the science of physiology includes even more specialties than does the science of anatomy.

The cornerstone of human physiology is **cell physiology**, the study of the functions of living cells. Cell physiology includes events at the chemical or molecular levels—chemical processes both within cells and between cells. **Special physiology** is the study of the physiology of specific organs. Examples include renal physiology (kidney function) and cardiac physiology (heart function). **Systemic physiology** considers all aspects of the function of specific organ systems. Respiratory physiology and reproductive physiology are examples. **Pathological physiology**, or **pathology** (pah-THOLo-jē), is the study of the effects of diseases on organ or system functions. (The Greek word *pathos* means "disease.") Modern medicine depends on an understanding of both normal and pathological physiology, to know not only what has gone wrong but also how to correct it.

Special topics in physiology address specific functions of the human body as a whole. These specialties focus on functional relationships among multiple organ systems. Exercise physiology, for example, studies the physiological adjustments to exercise.

CHECKPOINT

- **2.** Describe how anatomy and physiology are closely related.
- **3.** Would a histologist more likely be considered a specialist in microscopic anatomy or in gross anatomy? Why?

See the blue Answers tab at the back of the book.

1-3 Levels of organization progress from atoms and molecules to a complete organism

Learning Outcome Identify the major levels of organization in organisms, from the simplest to the most complex.

To understand the human body, we must examine how it is organized at several different levels, from the submicroscopic to the macroscopic. **Spotlight Figure 1-1** presents the relationships among the various levels of organization, using the cardiovascular system as an example.

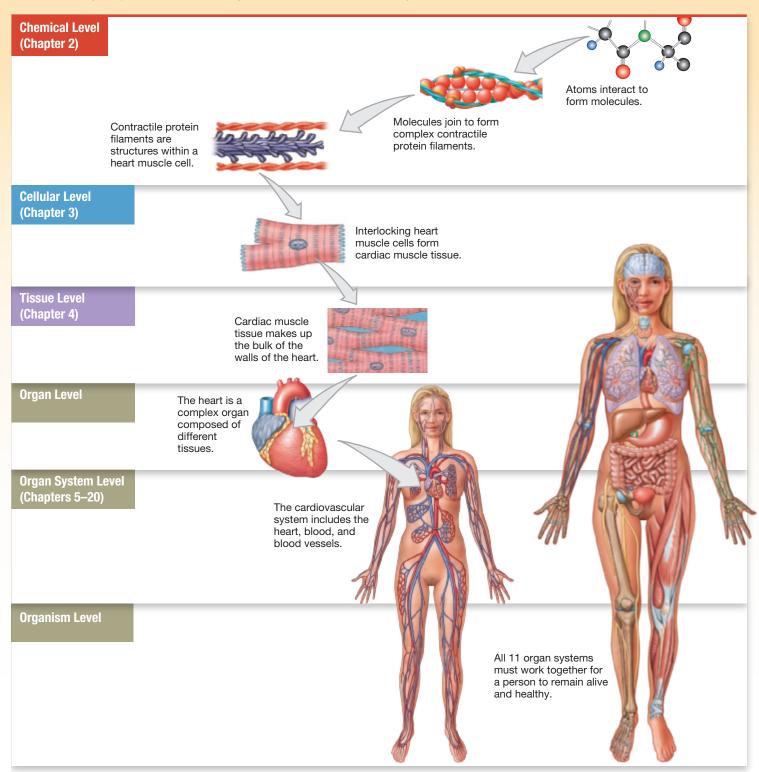

- **Chemical level.** Atoms, the smallest stable units of matter, combine to form *molecules* with complex shapes. Even at this simplest level, a molecule's specialized shape determines its function. This is the chemical level of organization.
- **Cellular level.** Different molecules can interact to form larger structures. Each type of structure has a specific function in a cell. For example, different types of protein filaments interact to produce the contractions of muscle cells in the heart. *Cells*, the smallest living units in the body, make up the cellular level of organization.
- **Tissue level.** A *tissue* is composed of similar cells working together to perform a specific function. Heart muscle cells form *cardiac muscle tissue*, an example of the tissue level of organization.
- **Organ level.** An *organ* consists of two or more different tissues working together to perform specific functions. An example of the organ level of organization is the *heart*, a hollow, three-dimensional organ with walls composed of layers of cardiac muscle and other tissues.
- **Organ system level.** Organs interact in *organ systems*. Each time it contracts, the heart pushes blood into a network of blood vessels. Together, the heart, blood, and blood vessels form the *cardiovascular system*, an example of the organ system level of organization.
- **Organism level.** All the organ systems of the body work together to maintain life and health. The highest level of organization is the *organism*—in this case, a human.

The organization at each level determines both the structural characteristics and the functions of higher levels. As Spotlight Figure 1-1 shows, the arrangement of atoms and molecules at the chemical level creates the protein filaments that, at the cellular level, give cardiac muscle cells the ability to contract. At the tissue level, these cells are linked, forming cardiac muscle tissue. The structure of the tissue ensures that the contractions are coordinated, producing a heartbeat. When that beat occurs, the internal anatomy of the heart, an organ, enables it to function as a pump. The heart is filled with blood and connected to the blood vessels, and the pumping action circulates blood through the vessels of the cardiovascular system. Through interactions with the respiratory, digestive, urinary, and other systems, the cardiovascular system performs a variety of functions essential to the survival of the organism.

Something that affects a system will ultimately affect each of the system's components. For example, the heart cannot pump blood effectively after massive blood loss. If the heart

SPOTLIGHT Figure 1-1 LEVELS OF ORGANIZATION

Our understanding of how the human body works is based on investigations of its different levels of organization. Interacting atoms form molecules that combine to form the protein filaments of a heart muscle cell. Such cells interlock, creating heart muscle tissue, which makes up most of the walls of the heart, a three-dimensional organ. The heart is only one component of the cardiovascular system, which also includes the blood and blood vessels. The various organ systems must work together to maintain life at the organism level.

36 FOUNDATIONS

cannot pump and blood cannot flow, oxygen and nutrients cannot be distributed. Very soon, the cardiac muscle tissue begins to break down as its individual muscle cells die from oxygen and nutrient starvation. These changes will also take place beyond the cardiovascular system: cells, tissues, and organs throughout the body will be damaged.

CHECKPOINT

4. Identify the major levels of organization of the human body from the simplest to the most complex.

See the blue Answers tab at the back of the book.

1-4 The human body consists of 11 organ systems

Learning Outcome Identify the 11 organ systems of the human body and contrast their major functions.

Figure 1-2 introduces the 11 organ systems in the human body and their major functions and components. The body's organ systems are (1) the integumentary system, (2) the skeletal system, (3) the muscular system, (4) the nervous system, (5) the endocrine system, (6) the cardiovascular system, (7) the lymphatic system, (8) the respiratory system, (9) the digestive system, (10) the urinary system, and (11) the reproductive system.

CHECKPOINT

- **5.** Identify the organ systems of the body and list their major functions.
- **6.** Which organ system includes the pituitary gland and directs long-term changes in the activities of the body's other systems?
- See the blue Answers tab at the back of the book.

1-5 Homeostasis is the state of internal balance

Learning Outcome Explain the concept of homeostasis.

Organ systems are interdependent, interconnected, and take up a relatively small space. The cells, tissues, organs, and organ systems of the body function together in a shared environment. Just as the people in a large city breather the same air and drink water from the local water company, the cells in the human body absorb oxygen and nutrients from the body fluids that surround them. All living cells are in contact with blood or some other body fluid. Any change in the composition of these fluids will affect the cells in some way. For example, changes in the temperature or salt content of the blood could cause anything from a minor adjustment (heart muscle tissue contracts more often, and the heart rate goes up) to a total disaster (the heart stops beating altogether).

Various physiological responses act to prevent potentially dangerous changes in the environment inside the body. **Homeostasis** (hō-mē-ō-STĀ-sis; *homeo*, unchanging + *stasis*, standing) refers to a stable internal environment. To survive, every living organism must maintain homeostasis. The term **homeostatic regulation** refers to the adjustments in physiological systems that preserve homeostasis.

Homeostatic regulation usually involves

- **1.** a **receptor** that is sensitive to a particular environmental change or *stimulus*;
- **2.** a **control center**, or *integration center*, which receives and processes information from the receptor; and
- **3.** an **effector**, a cell or organ that responds to the commands of the control center and whose activity opposes or enhances the stimulus.

You are probably already familiar with several examples of homeostatic regulation, although not in those terms. As an example, think about the operation of the thermostat in a house or apartment (Figure 1-3).

CLINICAL NOTE

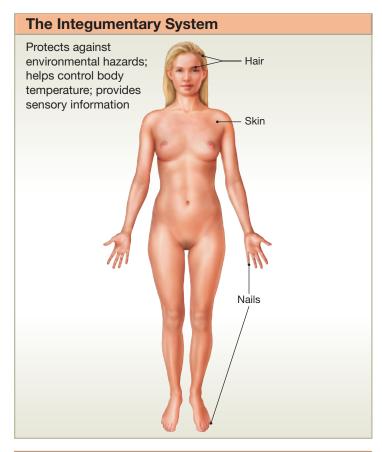

Homeostasis and Disease

The human body is amazingly effective in maintaining homeostasis. Nevertheless, an infection, an injury, or a genetic abnormality can sometimes have effects so severe that homeostatic responses can't fully compensate for them. One or more characteristics of the internal environment may then be pushed outside normal limits. When this happens, organ systems begin to malfunction, producing a state we know as illness or **disease**.

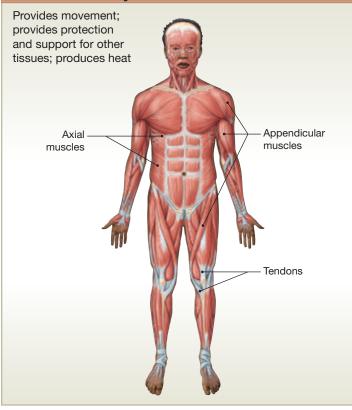

An understanding of normal homeostatic responses usually aids in thinking about what might be responsible for the signs and symptoms that are characteristic of many diseases. **Symptoms** are subjective—things that a person experiences and describes but that aren't otherwise detectable or measurable. Pain, nausea, and anxiety are examples. A **sign**, by contrast, is an objectively observable or measurable physical indication of a disease. Examples are a rash, a swelling, a fever, or sounds of abnormal breathing. Technology can reveal many additional signs that would not be evident to a physician's unaided senses: an unusual shape on an x-ray or MRI scan or an elevated concentration of a particular chemical in a blood test. We describe many aspects of human health, disease, and treatment in this textbook.

40 FOUNDATIONS

Figure 1-3 The Control of Room Temperature. In response to input from a receptor (a thermometer), a thermostat (the control center) triggers a response from an effector (in this case, an air conditioner) that restores normal temperature. When room temperature rises above the set point, the thermostat turns on the air conditioner, and the temperature returns to normal.

The thermostat is a control center that monitors room temperature. The thermostat shows the set point, the "ideal" room temperature—in this example, 22°C (about 72°F). The function of the thermostat is to keep room temperature within acceptable limits, usually within a degree or so of the set point. The thermostat receives information from a receptor, a thermometer exposed to air in the room, and it controls one of two effectors: a heater or an air conditioner. In the summer, for example, a rise in temperature above the set point causes the thermostat to turn on the air conditioner, which then cools the room (**Figure 1-3**). When the temperature at the thermometer returns to the set point, the thermostat turns off the air conditioner.

We can summarize the essential feature of temperature control by a thermostat very simply: A variation outside the desired range triggers an automatic response that corrects the situation. This method of homeostatic regulation is called *negative feedback*, because an effector activated by the control center opposes, or *negates*, the original stimulus.

CHECKPOINT

- 7. Define homeostasis.
- 8. Why is homeostatic regulation important to an organism?
- **9.** What happens to the body when homeostasis breaks down?
- See the blue Answers tab at the back of the book.

1-6 Negative feedback opposes variations from normal, whereas positive feedback exaggerates them

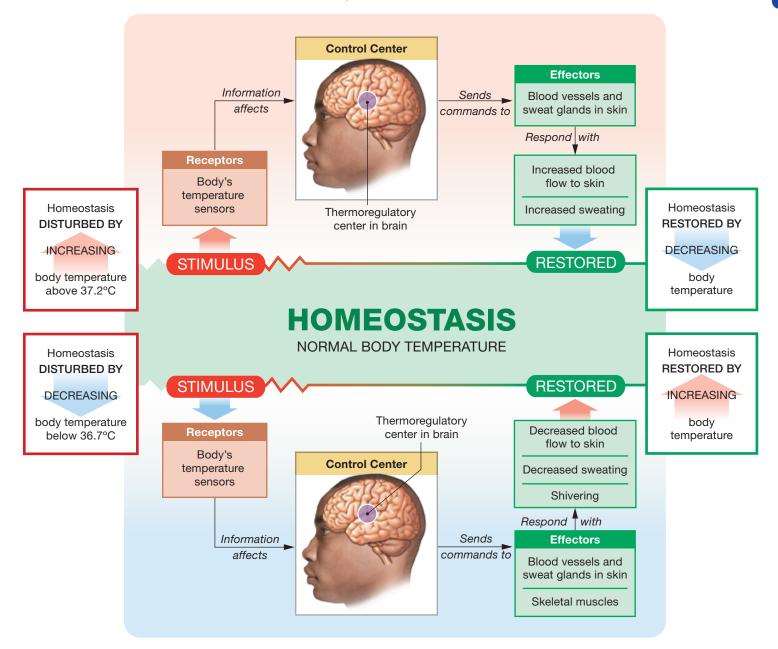

Learning Outcome Describe how negative feedback and positive feedback are involved in homeostatic regulation.

Homeostatic regulation controls aspects of the internal environment that affect every cell in the body. Most commonly, such regulation uses negative feedback. Positive feedback is less frequent because it tends to produce extreme responses.

Negative Feedback

The essential feature of **negative feedback** is this: Regardless of whether the stimulus (such as temperature) rises or falls at the receptor, *a variation outside normal limits triggers an automatic response that corrects the situation*.

Most homeostatic responses in the body involve negative feedback. For example, consider the control of body temperature, a process called *thermoregulation* (Figure 1-4). Thermoregulation involves altering the relationship between heat loss, which takes place primarily at the body surface, and heat production, which occurs in all active tissues. In the human body, skeletal muscles are the most important generators of body heat. **Figure 1-4** Negative Feedback: Control of Body Temperature. In negative feedback, a stimulus produces a response that opposes the original stimulus. Body temperature is regulated by a control center in the brain that functions as a thermostat with a set point of 37°C.

The thermoregulatory control center is located in the brain. This control center receives information from temperature receptors located in the skin and in cells in the control center. At the normal set point, body temperature is approximately 37°C (98.6°F).

If body temperature rises above 37.2°C (99°F), activity in the control center targets two effectors: (1) smooth muscles in the walls of blood vessels supplying the skin and (2) sweat glands. The muscle tissue relaxes and the blood vessels widen, or dilate, increasing blood flow at the body surface. The sweat glands accelerate, or speed up, their secretion. The skin then acts like a radiator, losing heat to the environment, and the evaporation of sweat speeds the process. When body temperature returns to normal, the control center becomes inactive. Superficial blood flow and sweat gland activity then decrease to normal resting levels.

If temperature at the control center falls below 36.7°C (98°F), the control center targets the same two effectors and skeletal muscles. This time, blood flow to the skin declines, and sweat gland activity decreases. This combination

۰.

reduces the rate of heat loss to the environment. However, body temperature gradually rises because skeletal muscles continue to produce heat. (Additional heat may be generated by *shivering*, which is caused by random contractions of skeletal muscles.) Once the body has warmed to the set point, the thermoregulatory center turns itself "off." Both blood flow and sweat gland activity in the skin then increase to normal resting levels.

Homeostatic responses using negative feedback maintain a normal range, not a fixed value. In the previous example, body temperature oscillates around the ideal set-point temperature. Thus, for any single individual, any measured value (such as body temperature) can vary from moment to moment or day to day. The variability among individuals is even greater, for each person has a slightly different homeostatic set point. It is, therefore, impractical to define "normal" homeostatic conditions very precisely.

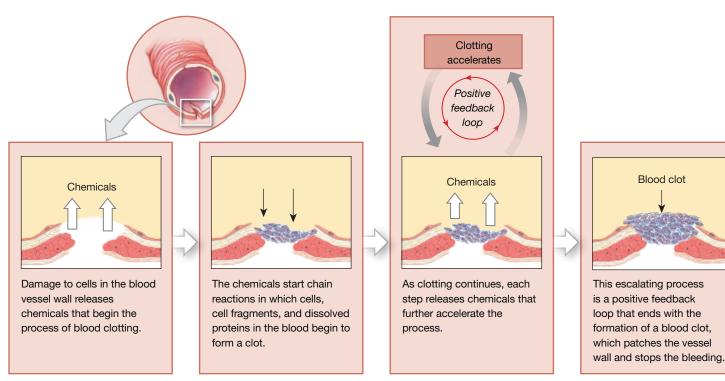

By convention, physiological values are reported either as average values obtained by sampling a large number of individuals or as a range that includes 95 percent or more of the sample population. For example, for 95 percent of healthy adults, body temperature ranges between 36.7°C and 37.2°C (98°F and 99°F). The other 5 percent of healthy adults have resting body temperatures outside the "normal" range (below 36.7°C or above 37.2°C). Still, these temperatures are perfectly normal for them, and the variations have no clinical significance.

Positive Feedback

In **positive feedback**, an initial stimulus produces a response that reinforces that stimulus. For example, suppose a thermostat were wired so that when the temperature rose, the thermostat would turn on the heater rather than the air conditioner. In that case, the initial stimulus (rising room temperature) would cause a response (heater turns on) that strengthens the stimulus. Room temperature would continue to rise until someone switched off the thermostat, unplugged the heater, or intervened in some other way before the house caught fire and burned down. This kind of escalating cycle is called a *positive feedback loop*.

In the body, positive feedback loops are involved in the regulation of a potentially dangerous or stressful process that must be completed quickly. For example, the immediate danger from a severe cut is blood loss, which can lower blood pressure and reduce the pumping efficiency of the heart. The positive feedback loop involved in the body's clotting response to blood loss is diagrammed in **Figure 1-5**. (We will examine blood clotting more closely in Chapter 11.) Labor and delivery (discussed in Chapter 20) is another example of positive feedback in action.

Figure 1-5 Positive Feedback. In positive feedback, a stimulus produces a response that reinforces the original stimulus. Positive feedback is important in accelerating processes that must proceed to completion rapidly. In this example, positive feedback accelerates blood clotting until bleeding stops.

CHECKPOINT

- **10.** Explain the function of negative feedback systems.
- **11.** Why is positive feedback helpful in blood clotting but unsuitable for the regulation of body temperature, as with a fever?

See the blue Answers tab at the back of the book.

1-7 Anatomical terms describe body regions, anatomical positions and directions, and body sections

Learning Outcome Use anatomical terms to describe body regions, body sections, and relative positions.

Early anatomists faced serious communication problems. For example, stating that a bump is "on the back" does not give very precise information about its location. So anatomists created maps of the human body. Prominent anatomical structures serve as landmarks, distances are measured (in centimeters or inches), and specialized directional terms are used. In effect, anatomy uses a language of its own, called *medical terminology*, that you must learn almost at the start of your study.

Anatomical terms are easier to understand if you are familiar with Latin and Greek word roots and their combinations. As new terms are introduced in the text, we will provide notes on their pronunciation and the relevant word roots. Look inside the back cover for additional information on foreign word roots, prefixes, suffixes, and combining forms.

Latin and Greek terms are not the only foreign words imported into the anatomical vocabulary over the centuries, and the vocabulary continues to expand. Many anatomical structures and clinical conditions were first named after either the discoverer or, in the case of diseases, the most famous victim. Most such commemorative names, or *eponyms*, have been replaced by more precise terms, but many are still in use.

Surface Anatomy

With the exception of the skin, none of the organ systems can be seen from the body surface. For this reason, you must create your own mental maps, basing your information on the terms given in **Figures 1-6** and **1-7**. Learning these terms now will make material in subsequent chapters easier to understand.

Anatomical Landmarks

Standard anatomical illustrations show the human form in the **anatomical position**. When the body is in this position, the hands are at the sides with the palms facing forward, and the feet are together (**Figure 1-6**). A person lying down in the

anatomical position is said to be **supine** (soo-PĪN) when face up and **prone** when face down.

Important anatomical landmarks are also presented in **Figure 1-6**. The anatomical terms are in boldface, the common names in plain type, and the anatomical adjectives in parentheses. Understanding these terms and their origins will help you remember both the location of a particular structure and its name. For example, the term *brachium* refers to the arm. Later chapters will discuss the *brachialis muscle* and the *brachial artery*, which are in the arm, as their names suggest.

Anatomical Regions

Major regions of the body, such as the *brachial region*, are referred to by their anatomical adjectives, as shown in **Figure 1-6**. To describe a general area of interest or injury, anatomists and clinicians often need to use broader terms in addition to specific landmarks. Two methods are used to map the surface of the abdomen and pelvis.

Clinicians refer to four **abdominopelvic quadrants** formed by a pair of imaginary perpendicular lines that intersect at the *umbilicus* (navel). This simple method, shown in **Figure 1-7a**, is useful for describing the location of aches, pains, and injuries, which can help a doctor determine the possible cause. For example, tenderness in the right lower quadrant (RLQ) is a symptom of appendicitis. Tenderness in the right upper quadrant (RUQ) may indicate gallbladder or liver problems.

Anatomists like to use more precise regional terms to describe the location and orientation of internal organs. They recognize nine **abdominopelvic regions** (Figure 1-7b). Figure 1-7c shows the relationships among quadrants, regions, and internal organs.

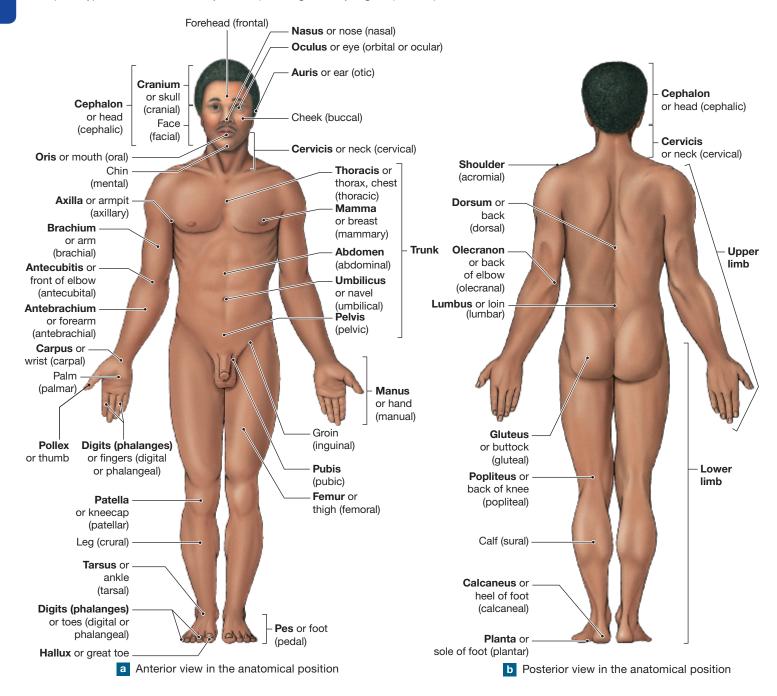

Anatomical Directions

Figure 1-8 presents the principal directional terms and some examples of their use. There are many different terms, and some can be used interchangeably. For example, *anterior* refers to the front of the body, when viewed in the anatomical position. In humans, this term is equivalent to *ventral*, which refers to the belly. Likewise, the terms *posterior* and *dorsal* refer to the back of the human body. Remember that *left* and *right* always refer to the left and right sides of the *subject*, not of the observer.

Sectional Anatomy

Sometimes the only way to understand the relationships among the parts of a three-dimensional object is to slice through it and look at the internal organization. An understanding of sectional views is particularly important now that imaging techniques enable us to see inside the living body

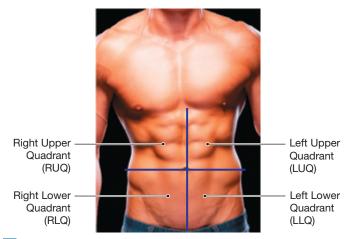

Figure 1-6 Anatomical Landmarks. Anatomical terms are shown in boldface type, common names are in plain type, and anatomical adjectives (referring to body regions) are in parentheses.

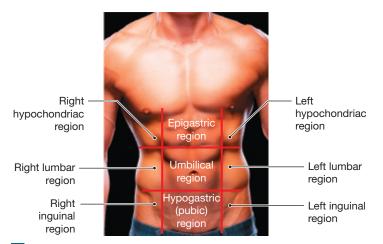

without resorting to surgery. Any slice (or section) through a three-dimensional object can be described with reference to three primary **sectional planes**, indicated in **Figure 1-9**:

- **1.** *Frontal plane.* The **frontal plane**, or *coronal plane*, runs along the long axis of the body. The frontal plane extends laterally (side to side), dividing the body into **anterior** and **posterior** portions.
- 2. *Sagittal plane*. The **sagittal plane** also runs along the long axis of the body, but it extends anteriorly and posteriorly (front to back). A sagittal plane divides the body into *left* and *right* portions. A cut that passes along the body's midline and divides the body into left and right halves is a **midsagittal section**. (Note that a midsagittal section does not cut through the legs.)

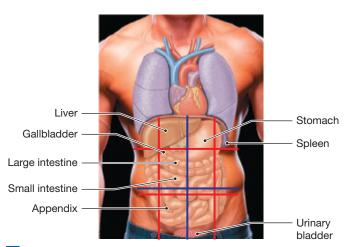

Figure 1-7 Abdominopelvic Quadrants and Regions.

a Abdominopelvic quadrants. The four abdominopelvic quadrants are formed by two perpendicular lines that intersect at the navel (umbilicus). The terms for these quadrants, or their abbreviations, are most often used in clinical discussions.

b Abdominopelvic regions. The nine abdominopelvic regions provide more precise regional descriptions.

c Anatomical relationships. The relationship between the abdominopelvic quadrants and regions and the locations of the internal organs are shown here.

3. *Transverse plane.* The **transverse plane** lies at right angles to the long (head-to-foot) axis of the body, dividing the body into **superior** and **inferior** portions. A cut in this plane is called a **transverse section**, or *cross section*. (Unless otherwise noted, in this book all anatomical diagrams that present cross-sectional views of the body are oriented as though the subject were supine, with the observer standing at the subject's feet and looking toward the head.)

CHECKPOINT

- 12. What is the purpose of anatomical terms?
- **13.** Describe an anterior view and a posterior view in the anatomical position.
- **14.** What type of section would separate the two eyes? See the blue Answers tab at the back of the book.

1-8 Body cavities of the trunk protect internal organs and allow them to change shape

Learning Outcome Identify the major body cavities of the trunk and the subdivisions of each.

The body's trunk is subdivided into three major regions established by the body wall: the thoracic, abdominal, and pelvic regions (**Figure 1-6**). Most of the vital organs of the body are located within these regions. The true **body cavities** are closed, fluid-filled spaces lined by a thin tissue layer called a *serous membrane*. The vital organs of the trunk are *suspended* within these body cavities. They do not simply lie there.

Early anatomists began using the term "cavity" when referring to internal regions. For example, they considered everything deep to the chest wall of the thoracic region to be within the thoracic cavity. They also considered all of the structures deep to the abdominal and pelvic walls to be within the abdominopelvic cavity. Internally, these two anatomical regions are separated by the **diaphragm** (DĪ-uh-fram), a flat muscular sheet.

The boundaries of the regional "cavities" and the true body cavities of the trunk are not identical, however. For example, the thoracic cavity contains two pleural cavities (each surrounding a lung), a pericardial cavity (surrounding the heart), and a large tissue mass, the mediastinum. Also, the peritoneal cavity extends only partway into the pelvic cavity. The boundaries between the subdivisions of the thoracic cavity and abdominopelvic cavity are shown in **Figure 1-10** (p. 48).

Figure 1-8 Directional References.

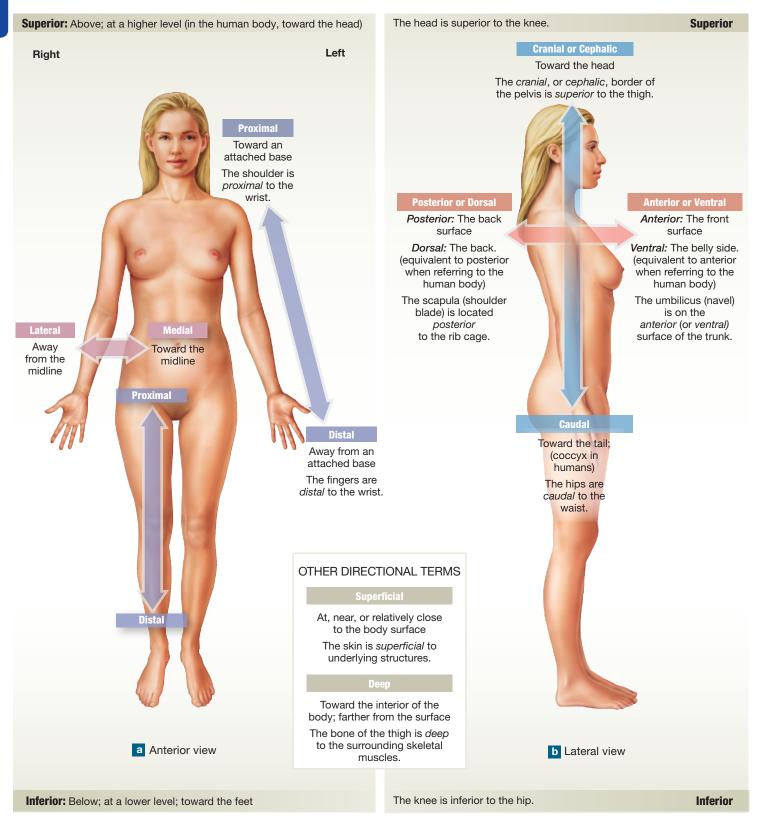

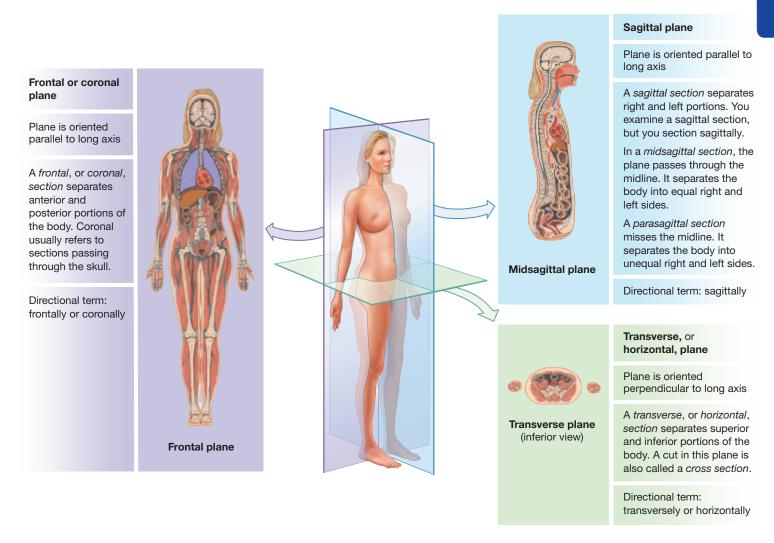

Figure 1-9 Sectional Planes.

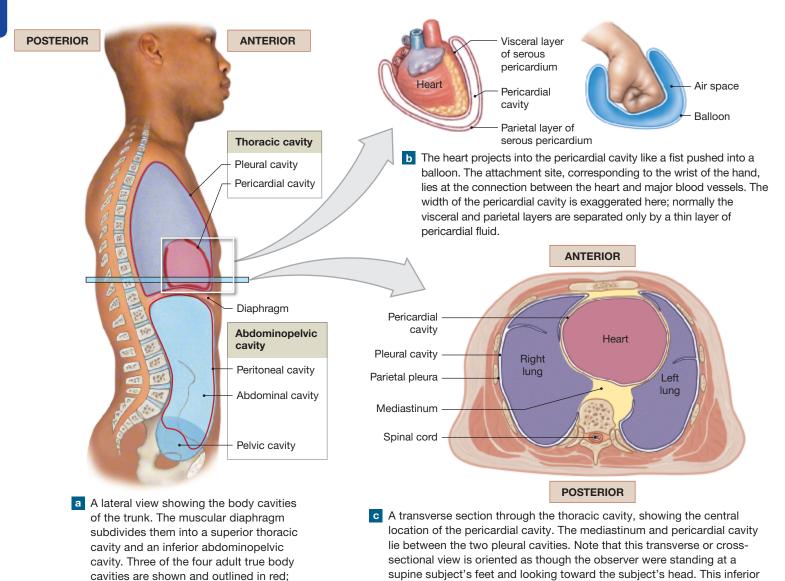

The body cavities of the trunk have two essential functions: (1) They protect delicate organs from accidental shocks and cushion them from the jolting that occurs when we walk, jump, or run; and (2) they permit significant changes in the size and shape of internal organs they surround. For example, the lungs, heart, stomach, intestines, urinary bladder, and many other organs can expand and contract without distorting surrounding tissues or disrupting the activities of nearby organs.

The internal organs that are enclosed by these cavities are called **viscera** (VIS-e-ruh). A delicate serous membrane lines the walls of these internal cavities and covers the surfaces of the enclosed viscera. Serous membranes produce a watery fluid that moistens the opposing surfaces and reduces friction. The portion of a serous membrane that covers a visceral organ is called the *visceral* layer. The opposing portion that lines the inner surface of the body wall or chamber is called the *parietal* layer. Because these opposing portions are usually in direct contact, the body cavities are called *potential spaces*.

The Thoracic Cavity

The thoracic cavity contains three internal chambers: a single *pericardial cavity* and a pair of *pleural cavities*—one for each lung (**Figure 1-10a,c**). Each of these three cavities is lined by shiny, slippery serous membranes. The heart projects into a space known as the **pericardial cavity**. The relationship between

Figure 1-10 Relationships among the Subdivisions of the Body Cavities of the Trunk.

the heart and the pericardial cavity resembles that of a fist pushing into a balloon (**Figure 1-10b**). The wrist corresponds to the *base* (attached portion) of the heart. The balloon corresponds to the serous membrane, or *serous pericardium* (*peri-*, around + *cardium*, heart), lining the pericardial cavity. The *visceral layer of serous pericardium* covers the heart, and the opposing surface is the *parietal layer of serous pericardium*.

only one of the two pleural cavities can

be shown in a sagittal section.

The pericardial cavity lies within the **mediastinum** (mē-dēa-STĪ-num) (**Figure 1-10c**). The connective tissue of the mediastinum surrounds and stabilizes the pericardial cavity and heart, the large arteries and veins attached to the heart, and the thymus, trachea, and esophagus. Each **pleural cavity** surrounds a lung. The serous membrane lining a pleural cavity is called a **pleura** (PLOOR-ah). The *visceral pleura* covers the outer surfaces of a lung. The *parietal pleura* covers the opposing surface of the mediastinum and the inner body wall.

view of a transverse section is the standard presentation for clinical

images. Unless otherwise noted, transverse or cross-sectional views in

this text use this same orientation (see Clinical Note: Imaging Techniques).

The Abdominopelvic Cavity

The abdominopelvic cavity extends from the diaphragm to the pelvis. It is subdivided into a superior **abdominal cavity** and an inferior **pelvic cavity** (Figure 1-10a). The abdominopelvic cavity contains the **peritoneal** (per-i-tō-NĒ-al) **cavity**, a chamber lined by a serous membrane known as the **peritoneum** (per-i-tō-NĒ-um). The *parietal peritoneum* lines the inner surface of the body wall. A narrow space containing a small amount of fluid separates the parietal peritoneum from the *visceral peritoneum*, which covers the enclosed organs.

The abdominal cavity extends from the inferior (toward the feet) surface of the diaphragm to the level of the superior (toward the head) margins of the pelvis. This cavity contains the liver, stomach, spleen, small intestine, and most of the large intestine. The organs are partially or completely enclosed by the peritoneal cavity. A few organs, such as the kidneys and pancreas, lie between the peritoneal lining and the muscular wall of the abdominal cavity. Those organs are said to be *retroperitoneal (retro*, behind).

The pelvic cavity is inferior to the abdominal cavity. The pelvic cavity contains the distal portion of the large intestine, the urinary bladder, and various reproductive organs. It also contains the inferior portion of the peritoneal cavity.

The true body cavities of the trunk in the adult share a common embryonic origin. The term "dorsal body cavity" is sometimes used to refer to the internal chamber of the skull (cranial cavity) and the total space enclosed by the vertebrae (vertebral cavity). These chambers, which are defined by bony structures, are structurally and developmentally distinct from true body cavities.

Many chambers, or spaces, within the body are not true body cavities. A partial list would include the cranial cavity, vertebral cavity, oral cavity, digestive cavity, orbits (eye

Build Your Knowledge

Recall that two methods are used to refer to the locations of aches, pains, injuries, and internal organs of the abdomen and pelvis. Clinicians refer to four abdominopelvic quadrants. Anatomists refer to nine abdominopelvic regions. \bigcirc **p. 43**

sockets), tympanic cavity of each middle ear, nasal cavities, and paranasal sinuses (air-filled chambers within some cranial bones that are connected to the nasal cavities). We discuss these structures in later chapters.

The Clinical Note: Imaging Techniques highlights some noninvasive clinical tests commonly used for viewing the interior of the body.

CHECKPOINT

- 15. Describe two essential functions of body cavities.
- **16.** Describe the various body cavities of the trunk.
- **17.** If a surgeon makes an incision just inferior to the diaphragm, what body cavity will be opened?
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

acute: A disease of short duration but typically severe.

auscultation (aws-kul-TĀ-shun): Listening to a patient's body sounds using a stethoscope.

chronic: Illness persisting for a long time or constantly recurring. Often contrasted with *acute*.

pathologist (pa-THOL-o-jist): A physician who specializes in the study of disease processes.

radiologist: A physician who specializes in performing and analyzing radiological procedures.

radiology (rā-dē-OL-o-jē): The study of radioactive energy and radioactive substances and their use in the diagnosis and treatment of disease and injury.

Over the past several decades, rapid progress has been made in discovering more accurate and more detailed ways to image the human body, both in health and disease.

X-rays

X-rays are the oldest and still the most common method of imaging. X-rays are a form of high-energy radiation that can penetrate living tissues. An x-ray beam travels through the body before striking a photographic plate. Not all of the projected x-rays arrive at the film. The body absorbs or deflects some of those

An x-ray of the skull, taken from the left side

x-rays. The ability to stop the passage of x-rays is referred to as radiopacity. When taking an x-ray, these areas that are impenetrable by x-rays appear light or white on the exposed film and are said to be radiopaque. In the body, air has the lowest radiopacity. Fat, liver, blood, muscle, and bone are increasingly radiopaque. As a result, radiopaque tissues look white, and less

radiopaque tissues are in shades of gray to black.

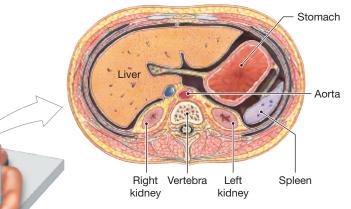

To use x-rays to visualize soft tissues, a very radiopaque substance must be introduced. To study the upper digestive tract, a radiopaque barium solution is ingested by the patient. The resulting x-ray shows the contours of the stomach and intestines.

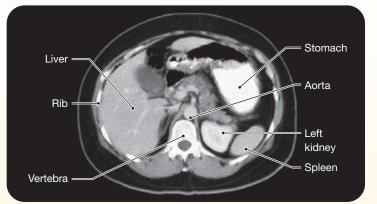

A barium-contrast x-ray of the upper digestive tract

Standard Scanning Techniques

More recently, a variety of scanning techniques dependent on computers have been developed to show the less radiopaque, soft tissues of the body in much greater detail.

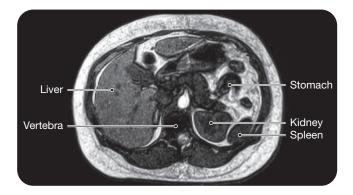

Diagrammatic views showing the relative position and orientation of the CT scan below and the MRI to the right.

CT scan of the abdomen

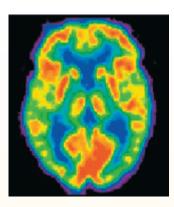

CT (computed tomography) scans use computers to reconstruct sectional views. A single x-ray source rotates around the body, and the x-ray beam strikes a sensor monitored by the computer. The x-ray source completes one revolution around the body every few seconds. It then moves a short distance and repeats the process. The result is usually displayed as a sectional view in black and white, but it can be colorized for visual effect. CT scans show three-dimensional relationships and soft tissue structures more clearly than do standard x-rays.

· Note that when anatomical diagrams or scans present cross-sectional views, the sections are presented from an inferior perspective, as though the observer were standing at the feet of a person in the supine position and looking toward the head of the subject.

MRI scan of the abdomen

An **MRI** of the same region (in this case, the abdomen) can show soft tissue structure in even greater detail than a CT scan. Magnetic resonance imaging surrounds part or all of the body with a magnetic field 3000 times as strong as that of Earth. This field causes particles within atoms throughout the body to line up in a uniform direction. Energy from pulses of radio waves are absorbed and released by the different atoms. The released energy is used to create a detailed image of the soft tissue structure.

PET scan of the brain

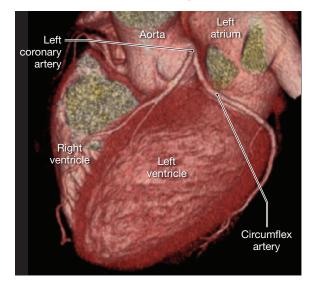

Positron emission tomography (**PET**) is an imaging technique that assesses metabolic and physiological activity of a structure. A PET scan is an important tool in evaluating healthy and diseased brain function.

Ultrasound of the uterus

In ultrasound procedures, a small transmitter contacting the skin broadcasts a brief, narrow burst of high-frequency sound and then detects the echoes. The sound waves are reflected by internal structures, and a picture, or echogram, is assembled from the pattern of echoes. These images lack the clarity of other procedures, but no adverse effects have been reported, and fetal development can be monitored without a significant risk of birth defects. Special methods of transmission and processing permit analysis of the beating heart without the complications that can accompany dve injections.

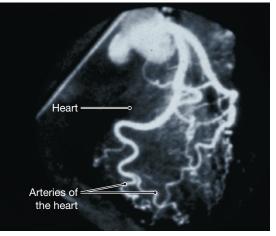

Special Scanning Methods

Spiral scan of the heart

A **spiral CT scan** is a form of three-dimensional imaging technology that is becoming increasingly important in clinical settings. During a spiral CT scan, the patient is on a platform that advances at a steady pace through the scanner while the imaging source, usually x-rays, rotates continuously around the patient. Because the x-ray detector gathers data quickly and continuously, a higher quality image is generated, and the patient is exposed to less radiation as compared to a standard CT scanner, which collects data more slowly and only one slice of the body at a time.

Digital subtraction angiography of coronary arteries

Digital subtraction angiography (DSA) is used to monitor blood flow through specific organs, such as the brain, heart, lungs, and kidneys. X-rays are taken before and after radiopaque dye is administered, and a computer "subtracts" details common to both images. The result is a high-contrast image showing the distribution of the dye.

Chapter Review

Summary Outline

- 1-1 All living things display responsiveness, growth, reproduction, movement, and metabolism *p. 32*
- **1. Biology** is the study of life; one of its goals is to discover the patterns that underlie the diversity of living organisms.
- 2. All living things, from single **cells** to large multicellular organisms, perform the same basic functions: They respond to changes in their environment; they grow and reproduce to create new generations; they are capable of producing movement; and they carry out the complex chemical reactions of metabolism. They absorb materials from the environment. Organisms absorb and consume oxygen during respiration, and they discharge waste products during excretion. Digestion occurs in specialized body structures that break down complex foods. The circulation forms an internal transportation system between areas of the body.

1-2 Anatomy is structure, and physiology is function *p. 33*

- **3. Anatomy** is the study of internal and external structure and the physical relationships among body parts. **Physiology** is the study of how living organisms function. All specific functions are performed by specific structures.
- **4. Gross (macroscopic) anatomy** considers features visible without a microscope. It includes *surface anatomy* (general form and superficial markings), *regional anatomy* (superficial and internal features in a specific area of the body), and *systemic anatomy* (structure of major organ systems).
- **5.** The boundaries of **microscopic anatomy** are established by the equipment used. **Cytology** analyzes the internal structure of individual *cells*. **Histology** examines **tissues** (groups of similar cells that have specific functional roles). Tissues combine to form organs, anatomical units with specific functions.
- 6. Human physiology is the study of the functions of the human body. It is based on **cell physiology**, the study of the functions of living cells. *Special physiology* studies the physiology of specific organs. *System physiology* considers all aspects of the function of specific organ systems. *Pathological physiology* (**pathology**) studies the effects of diseases on organ or system functions.

1-3 Levels of organization progress from atoms and molecules to a complete organism *p. 34*

7. Anatomical structures and physiological mechanisms are arranged in a series of interacting levels of organization. *(Figure 1-1)*

1-4 The human body consists of 11 organ systems p. 36

8. The major organs of the human body are arranged into 11 organ systems. The organ systems of the human body are the *integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, respiratory, digestive, urinary,* and *reproductive systems.* (*Figure 1-2*)

1-5 Homeostasis is the state of internal balance p. 36

- **9. Homeostasis** is the existence of a stable internal environment within the body. Physiological systems preserve homeostasis through **homeostatic regulation**.
- **10.** Homeostatic regulation usually involves a **receptor** sensitive to a particular stimulus; a **control center**, which receives and processes the information from the receptor, and then sends out commands; and an **effector** whose activity either opposes or enhances the stimulus. (*Figures 1-3, 1-4*)

1-6 Negative feedback opposes variations from normal, whereas positive feedback exaggerates them *p. 40*

- **11. Negative feedback** is a corrective response involving an action that directly opposes a variation from normal limits. (*Figures 1-3, 1-4*)
- **12.** In **positive feedback** the initial stimulus produces a response that reinforces the stimulus. (*Figure 1-5*)
- **13.** Symptoms of **disease** appear when failure of homeostatic regulation causes organ systems to malfunction.

1-7 Anatomical terms describe body regions, anatomical positions and directions, and body sections *p. 43*

14. Standard anatomical illustrations show the body in the **ana-tomical position**. If the figure is shown lying down, it can be either **supine** (face up) or **prone** (face down). (*Figure 1-6*)

- **15.** Abdominopelvic quadrants and abdominopelvic regions represent two different approaches to describing anatomical regions of the body. (*Figure 1-7*)
- **16.** The use of special directional terms provides clarity when describing anatomical structures. (*Figure 1-8*)
- **17.** The three **sectional planes** (**frontal** or **coronal plane**, **sagittal plane**, and **transverse plane**) describe relationships between the parts of the three-dimensional human body. (*Figure 1-9*)

1-8 Body cavities of the trunk protect internal organs and allow them to change shape *p. 45*

- **18. Body cavities** protect delicate organs and permit significant changes in the size and shape of internal organs. The body cavities of the trunk surround organs of the respiratory, cardiovascular, digestive, urinary, and reproductive systems. *(Figure 1-10)*
- 19. The diaphragm divides the (superior) thoracic and (inferior) abdominopelvic cavities. The thoracic cavity includes two pleural cavities (each surrounding a lung) with a central mass of tissue known as the mediastinum. Within the mediastinum is the pericardial cavity, which surrounds the heart. The abdominopelvic cavity consists of the abdominal cavity and the pelvic cavity. It contains the peritoneal cavity, a chamber lined by peritoneum, a serous membrane. (Figure 1-10)
- 20. Important radiological procedures (which can provide detailed information about internal systems) include x-rays, CT and spiral CT scans, MRI, PET scans, and ultrasound. Each of these noninvasive techniques has advantages and disadvantages. (Clinical Note: Imaging Techniques)

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A

_____ 1. cytology

_____ **3.** histology

_____ **7.** heart

_____ **11.** supine

_____**12.** prone

_____ **2.** physiology

_____ **4.** metabolism

_____ 5. homeostasis

_____ **6.** cardiac muscle

_____ **8.** integumentary

_____ 9. temperature regulation

_____13. serous membranes

_____ **14.** mediastinum

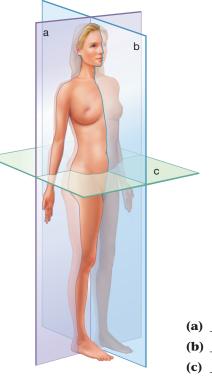

_____ **15.** pericardium

10. blood clot formation

- **COLUMN B**
- **a.** face down
 - **b.** study of tissues
 - c. stable internal environment
 - **d.** face up
 - e. study of vital body functions
 - **f.** positive feedback
 - g. organ system that has the skin
 - **h.** study of cells
 - i. negative feedback
 - j. between pleural cavities
 - k. all chemical activity in body
 - **1.** line true body cavities
 - **m.** tissue
 - n. serous membrane
 - o. organ

16. Label the three sectional planes in the figure below.

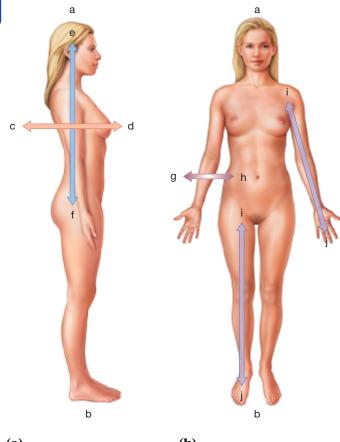

See the blue Answers tab at the back of the book.

(a) _____ (b) _____ (c) _____

17. Label the directional terms in the figures below.

(a)	(D)
(c)	(d)
(e)	(f)
(g)	(h)
(i)	(i)

- **18.** In terms of the different levels of organization in the human body, the lung is an example of a/an
 - **(a)** cell. **(b)** tissue.
- (c) organ. (d) organ system.
- 19. The trachea and bronchi are components of the(a) integumentary system.(b) respiratory system.
 - (c) skeletal system. (d) urinary system.
- **20.** In the anatomical position, the index finger is best described as being ______ to the middle finger.
 - (a) distal. (b) lateral.
 - (c) medial. (d) proximal.
- **21.** Which serous membrane lines the surface of the lung?

(d) a, b, and c are correct

- (a) pericardium (b) peritoneum
- (c) pleura

- Level 2 Reviewing Concepts
- **22.** What basic functions are common to all living things?
- **23.** What is the function of the pericardial fluid produced by the serous pericardium?
- **24.** Define homeostatic regulation in a way that states its physiological importance.
- **25.** How does negative feedback differ from positive feedback?
- **26.** Describe the anatomical location of the forearm relative to the arm and the digits.
- **27.** As a surgeon, you perform an invasive procedure that involves cutting through the peritoneum. Are you more likely to be operating on the heart or on the stomach?
- **28.** Which primary sectional plane separates the following organs?
 - (a) left lung, right lung
 - (b) left lung, stomach
 - (c) heart, spinal cord

Level 3 Critical Thinking and Clinical Applications

- **29.** A hormone called *insulin* is released from the pancreas in response to an increased level of glucose (sugar) in the blood. If this hormone acts through negative feedback, what effect will its release have on the blood glucose level?
- **30.** The humerus is the long bone found in the arm. When a fracture occurs in the distal end of the humerus, is the fracture site located closer to the shoulder or the elbow?

Homeostasis

The Chemical Level of Organization

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **2-1** Describe an atom and how atomic structure affects interactions between atoms.
- **2-2** Compare the ways in which atoms combine to form molecules and compounds.
- **2-3** Distinguish among the three major types of chemical reactions that are important for studying physiology.
- **2-4** Describe the crucial role of enzymes in metabolism.
- **2-5** Distinguish between organic and inorganic compounds.
- **2-6** Explain how the chemical properties of water make life possible.
- **2-7** Describe the pH scale and the role of buffers in body fluids.
- **2-8** Describe the functional roles of acids, bases, and salts.
- **2-9** Discuss the structures and functions of carbohydrates.
- **2-10** Discuss the structures and functions of lipids.
- **2-11** Discuss the structures and functions of proteins.
- **2-12** Discuss the structures and functions of nucleic acids.
- **2-13** Discuss the structures and functions of high-energy compounds.
- **2-14** Explain the relationship between chemicals and cells.

Clinical Note Too Sweet on Sugar?, p. 71 **Spotlight** Chemical Notation, p. 62

An Introduction to the Chemical Level of Organization

We begin our study of the human body with individual atoms and molecules. As you have seen, they are the body's most basic level of organization. All living and nonliving things people, elephants, oranges, oceans, rocks, and air—get their characteristics from the types of atoms involved and the ways those atoms combine and interact. **Chemistry** is the science that investigates *matter* and its interactions. A familiarity with basic chemistry will help you understand how atoms can affect the anatomy and physiology of the cells, tissues, organs, and organ systems that make up the human body.

Build Your Knowledge

The Build Your Knowledge feature reminds you of what you already know and prepares you to learn new material. Be sure to read every Build Your Knowledge box or page so that you can build your knowledge—and confidence!

Recall that atoms are the smallest stable units of matter (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology.**) Atoms combine to form larger structures, such as molecules or groups of molecules, with complex shapes.

Similar to how anatomy and physiology are interrelated, a molecule's specialized shape ("anatomy") determines its function ("physiology"). In turn, its functional role in body processes is affected by its molecular structure. **Dpp. 34, 35**

2-1 Atoms are the basic particles of matter

Learning Outcome Describe an atom and how atomic structure affects interactions between atoms.

Matter is anything that takes up space and has mass. *Mass* is the amount of matter that an object contains. Mass is a physical property that determines the weight of an object in Earth's gravitational field. On our planet, the weight of an object is essentially the same as its mass. However, the two are not always the same: In orbit you would be weightless, but your mass would remain unchanged. Matter occurs in one of three familiar states: solid (such as a rock), liquid (such as water), or gas (such as the atmosphere).

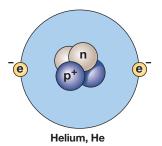

All matter is composed of substances called **elements**. Elements cannot be changed or broken down into simpler substances, whether by chemical processes, heating, or other ordinary physical means. The smallest stable unit of matter is an **atom**. Atoms are so small that atomic measurements are typically reported in billionths of a meter or *nanometers* (NAN-ō-mē-terz) (nm). The very largest atoms are almost half of one-billionth of a meter (0.5 nm) in diameter. One million atoms placed side by side would span a period on this page, but the line would be far too thin for you to see with anything but the most powerful of microscopes.

Atomic Structure

Atoms contain three major types of subatomic particles: protons, neutrons, and electrons. Protons and neutrons are similar in size and mass, but **protons** (p^+) have a positive electrical charge, and **neutrons** (n or n^0) are neutral—that is, uncharged. **Electrons** (e^-) are much lighter than protons—only 1/1836 as massive—and have a negative electrical charge. **Figure 2-1** is a diagram of a simple atom: the element *helium*. This atom contains two protons, two neutrons, and two electrons.

All atoms contain protons and electrons, normally in equal numbers. The number of protons in an atom is known as its **atomic number**. Each element includes all the atoms

Figure 2-1 A Diagram of Atomic Structure. The atom shown here—helium—contains two of each type of subatomic particle: two protons, two neutrons, and two electrons.

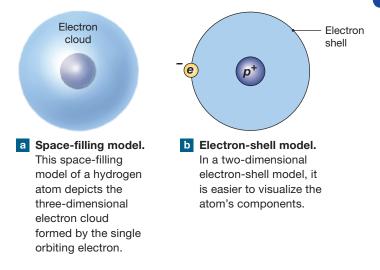

that have the same number of protons and thus the same atomic number. For example, all atoms of the element helium contain two protons.

Table 2-1 lists the 13 most abundant elements in the human body. Each element is universally known by its own abbreviation, or chemical symbol. Most of the symbols are easily connected with the English names of the elements. A few, such as Na for sodium, are abbreviations of their original Latin names—in this case, *natrium*.

Hydrogen is the simplest element. It has an atomic number of 1 because its atom contains one proton (Figure 2-2). The proton is located in the center of the atom and forms the **nucleus**. Hydrogen atoms seldom contain neutrons, but whenever neutrons are present in any type of atom, they are also located in the nucleus. In a hydrogen atom, a single electron orbits the space around the nucleus at high speed, forming an **electron cloud** (Figure 2-2a). Why does the negatively charged electron stay in the electron cloud? One reason is because it is attracted to the positively charged proton. The cloud is usually represented as a spherical **electron shell** (Figure 2-2b).

Table 2-1 Principal Elements in the Human Body		
Element (% of Bod	y Weight) Significance	
Oxygen, O (65)	A component of water and other compounds; oxygen gas is essential for respiration	
Carbon, C (18.6)	Found in all organic molecules	
Hydrogen, H (9.7)	A component of water and most other compounds in the body	
Nitrogen, N (3.2)	Found in proteins, nucleic acids, and other organic compounds	
Calcium, Ca (1.8)	Found in bones and teeth; important for membrane function, nerve impulses, muscle contraction, and blood clotting	
Phosphorus, P (1.0)	Found in bones and teeth, nucleic acids, and high-energy compounds	
Potassium, K (0.4)	Important for membrane function, nerve impulses, and muscle contraction	
Sodium, Na (0.2)	Important for membrane function, nerve impulses, and muscle contraction	
Chlorine, Cl (0.2)	Important for membrane function and water absorption	
Magnesium, Mg (0.0	6) Required for activation of several enzymes	
Sulfur, S (0.04)	Found in many proteins	
Iron, Fe (0.007)	Essential for oxygen transport and energy capture	
lodine, I (0.0002)	A component of hormones of the thyroid gland	

Figure 2-2 Hydrogen Atom Models. A typical hydrogen atom consists of a nucleus containing one proton and no neutrons, and a single electron orbiting around the nucleus.

Isotopes

The atoms of an element can differ in the number of neutrons in the nucleus. Such atoms of an element are called **isotopes**. The presence or absence of neutrons generally has no effect on the chemical properties of an atom of a particular element. As a result, isotopes can be distinguished from one another only by their **mass number**—the total number of protons and neutrons in the nucleus.

The nuclei of some isotopes are unstable, or *radioactive*. They spontaneously break down and emit *radiation* (energy as moving subatomic particles or waves, such as x-rays). Weak *radioisotopes* are used in some diagnostic procedures.

Atomic Weight

Atomic mass numbers are useful because they tell us the number of protons and neutrons in the nuclei of different atoms. However, they do not tell us the *actual* mass of an atom, because they do not account for the masses of electrons and the slight difference between the masses of a proton and neutron. They also don't tell us the mass of a "typical" atom, since any element consists of a mixture of isotopes. Yet we can determine the *average mass* of an element's atoms, a value known as **atomic weight**. Atomic weight takes into account the mass of the subatomic particles and the relative proportions of any isotopes.

For example, even though the mass number of hydrogen is 1, the atomic weight of hydrogen is 1.0079. In this case, the mass number and atomic weight differ primarily because a few hydrogen atoms have a mass number of 2 (one proton plus one neutron), and an even smaller number have a mass number of 3 (one proton plus two neutrons).

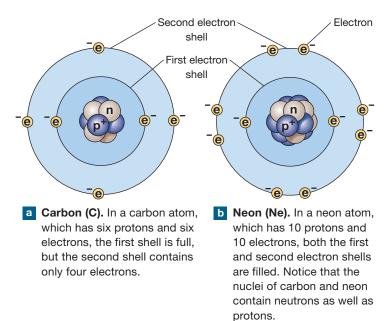

Electron Shells

Atoms are electrically neutral. Every positively charged proton is balanced by a negatively charged electron. For this reason, each increase in the atomic number has a comparable increase in the number of electrons. These electrons occupy an orderly series of electron shells around the nucleus, and only the electrons in the outer shell can interact with other atoms. *The number of electrons in an atom's outer electron shell determines the chemical properties of that element*.

Atoms with an unfilled outer electron shell are unstable that is, they will react with other atoms, usually in ways that give them full outer electron shells. An atom with a filled outer shell is stable and will not interact with other atoms. The first electron shell (the one closest to the nucleus) is filled when it contains two electrons. A hydrogen atom has one electron in this electron shell (Figure 2-2b), and thus hydrogen atoms can react with many other atoms. A helium atom has two electrons in this electron shell (Figure 2-1). Because its outer electron shell is full, a helium atom is stable. Elements that do not readily take part in chemical processes are said to be *inert*. The gaseous element, helium, is called an *inert gas* because its atoms will neither react with one another nor combine with atoms of other elements.

The second electron shell can contain up to eight electrons. Carbon, with an atomic number of 6, has six electrons. In a carbon atom, the first shell is filled (two electrons), and the second shell contains four electrons (**Figure 2-3a**). In a neon atom (atomic number 10), the second shell is filled (**Figure 2-3b**). Neon is another inert gas.

Figure 2-3 The Electron Shells of Two Atoms. The first electron shell of any atom can hold only two electrons. The second shell can hold up to eight electrons.

CHECKPOINT

- **1.** Define atom.
- **2.** How is it possible for two samples of hydrogen to contain the same number of atoms but have different weights?
- See the blue Answers tab at the back of the book.

2-2 Chemical bonds are forces formed by interactions between atoms

Learning Outcome Compare the ways in which atoms combine to form molecules and compounds.

An atom with a full outer electron shell is very stable and not reactive. The atoms that are most important to biological systems are *un*stable. For this reason, these atoms can interact to form larger structures (see **Table 2-1**). Atoms with unfilled outer electron shells can become stable by sharing, gaining, or losing electrons through chemical reactions with other atoms. They often form **chemical bonds**, which are forces that hold the participating atoms together once the reaction has ended.

Chemical bonding produces *molecules* and *compounds*. **Molecules** are chemical structures that contain more than one atom bonded together by shared electrons. A **compound** is any chemical substance made up of atoms of two or more different elements in a fixed proportion, regardless of the type of bond joining them. A compound is a new chemical substance. Its properties can be quite different from those of its component elements. For example, a mixture of hydrogen and oxygen gases is highly flammable, but chemically combining hydrogen and oxygen atoms produces a compound water—that can put out a fire's flames.

Ionic Bonds

Atoms are electrically neutral because the number of protons (each with a +1 charge) equals the number of electrons (each with a -1 charge). If an atom loses an electron, it then has a charge of +1 because there is one proton without a corresponding electron. Losing a second electron would leave the atom with a charge of +2. Similarly, adding one or two extra electrons to the atom gives it a charge of -1 or -2, respectively. Atoms or molecules that have an electric charge are called **ions**. Ions with a positive charge (+) are **cations** (KAT-ī-onz). Ions with a negative charge (-) are **anions** (AN-ī-onz). **Table 2-2** lists several common ions in body fluids.

Ionic (ī-ON-ik) **bonds** are chemical bonds created by the electrical attraction between anions and cations. Ionic bonds are formed in a process called *ionic bonding*, as shown

2

Table 2-2	The Most Common lons in Body Fluids	
Cations	Anions	
Na ⁺ (sodium)	Cl [−] (chloride)	
K ⁺ (potassium)	HCO ₃ ⁻ (bicarbonate)	
Ca ²⁺ (calcium)	HPO_4^{2-} (biphosphate)	
Mg ²⁺ (magnesium)	SO ₄ ²⁻ (sulfate)	

in **Figure 2-4a**. In the example shown, a sodium atom donates an electron to a chlorine atom. This loss of an electron creates a *sodium ion* with a +1 charge and a *chloride ion* with a -1 charge. The two ions do not move apart after the electron transfer because the positively charged sodium ion is attracted to the negatively charged chloride ion. In this case, the combination of oppositely charged ions forms the *ionic compound* **sodium chloride**, the chemical name for the crystals we know as table salt (**Figure 2-4b,c**).

Covalent Bonds

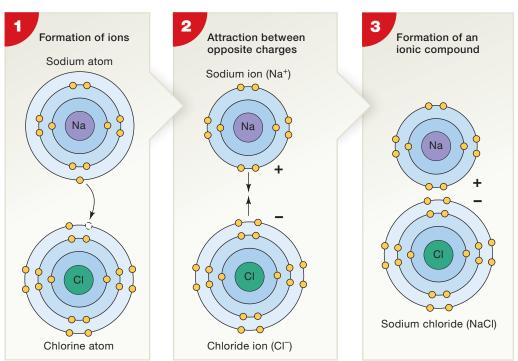

Another way atoms can fill their outer electron shells is by sharing electrons with other atoms. The result is a molecule held together by **covalent** ($k\bar{o}$ -VĀ-lent) **bonds** (Figure 2-5).

Figure 2-4	Ionic Bonding.
------------	----------------

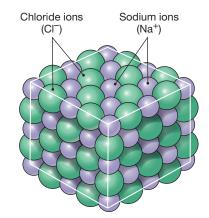

As an example, consider hydrogen. Individual hydrogen atoms, as diagrammed in Figure 2-2, are not found in nature. Instead, we find hydrogen molecules (Figure 2-5). In chemical shorthand, molecular hydrogen is indicated by H_2 . The H is the chemical symbol for hydrogen, and the subscript 2 indicates the number of atoms. Molecular hydrogen is a gas present in the atmosphere in very small quantities. The two hydrogen atoms share their electrons, with each electron whirling around both nuclei. The sharing of one pair of electrons (one electron from each atom) creates a **single covalent bond**.

Oxygen, with an atomic number of 8, has two electrons in its first electron shell and six in the second. Oxygen atoms (**Figure 2-5**) become stable by sharing two pairs of electrons (two electrons from each atom), forming a **double covalent bond**. Molecular oxygen (O_2) is an atmospheric gas that is very important to living organisms. Our cells would die without a constant supply of oxygen.

In our bodies, the chemical processes that consume oxygen also produce carbon dioxide (CO_2) as a waste product. In a carbon dioxide molecule, two oxygen atoms form double covalent bonds with the carbon atom, as shown in **Figure 2-5**.

a Formation of an ionic bond. 1 A sodium (Na) atom loses an electron, which is gained by a chlorine (Cl) atom. 2 Because the sodium ion (Na⁺) and chloride ion (Cl⁻) have opposite charges, they are attracted to one another. 3 The association of sodium and chloride ions forms the ionic compound sodium chloride.

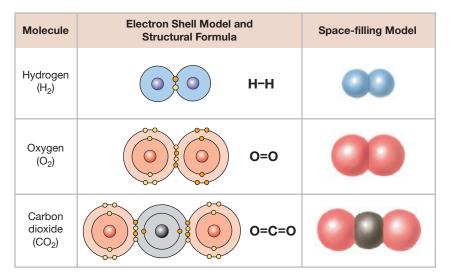

b Sodium chloride crystal. Large numbers of sodium and chloride ions form a crystal of sodium chloride (table salt).

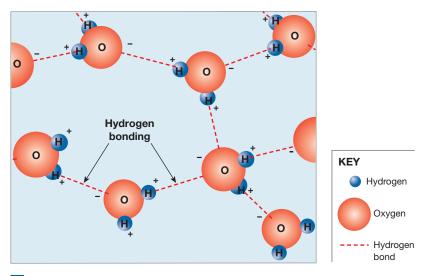

Photo of sodium chloride crystals. (magnified 0.5X)

Figure 2-5 Covalent Bonds in Three Common Molecules. In a molecule of hydrogen, two hydrogen atoms share their electrons such that each has a filled outer electron shell. This sharing of a pair of electrons creates a single covalent bond (—). A molecule of oxygen consists of two oxygen atoms that share two pairs of electrons. The result is a double covalent bond (—). In a molecule of carbon dioxide, a central carbon atom forms double covalent bonds with a pair of oxygen atoms.

Covalent bonds are very strong because the shared electrons tie the atoms together. When the electrons are shared equally, the bound atoms remain electrically neutral. Such covalent bonds are called **nonpolar covalent bonds**. Nonpolar covalent bonds between carbon atoms create the

Figure 2-6 Hydrogen Bonds between Water Molecules.

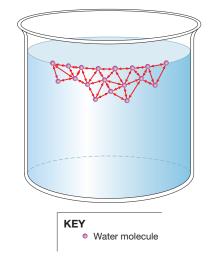

The unequal sharing of electrons in a water molecule causes each of its two hydrogen atoms to have a slight positive charge and its oxygen atom to have a slight negative charge. Attraction between a hydrogen atom of one water molecule and the oxygen atom of another is a hydrogen bond (indicated by dashed lines).

Elements differ in how strongly they hold or attract shared electrons. An unequal sharing between atoms of different elements creates a polar covalent bond. Such bonding often forms a polar molecule because one end, or pole, has a slight negative charge and the other a slight positive charge. For example, in a molecule of water, an oxygen atom forms covalent bonds with two hydrogen atoms. However, the oxygen atom has a much stronger attraction for the shared electrons than do the hydrogen atoms, so those electrons spend most of their time with the oxygen atom. Because of the two extra electrons, the oxygen atom develops a slight negative charge (Figure 2-6a). At the same time, the hydrogen atoms each develop a slight positive charge because their electrons are away part of the time.

Hydrogen Bonds

In addition to ionic and covalent bonds, weaker attractive forces act between adjacent molecules and between atoms within a large molecule. The most important of these weak

b Hydrogen bonding between water molecules at a free surface creates surface tension and slows evaporation.

attractive forces is the hydrogen bond. A **hydrogen bond** is the attraction between a slight positive charge on the hydrogen atom of one polar covalent bond and a slight negative charge on an oxygen or nitrogen atom of another polar covalent bond. The polar covalent bond containing the oxygen or nitrogen atom can be in a different molecule from the hydrogen atom, or in the same molecule. For example, water molecules are attracted to each other through hydrogen bonding (**Figure 2-6a**).

Hydrogen bonds are too weak to create molecules, but they can alter the shapes of molecules or pull molecules closer together. For example, the attraction between water molecules at a free surface slows evaporation and creates what is known as **surface tension** (**Figure 2-6b**). Surface tension acts as a barrier that keeps small objects from entering the water. It is the reason that insects can walk across the surface of a pond or puddle. Similarly, a layer of watery tears keeps small dust particles from touching the surface of our eyes.

CHECKPOINT

- **3.** Define chemical bond, and identify several types of chemical bonds.
- **4.** Oxygen and neon are both gases at room temperature. Why does oxygen combine readily with other elements, but neon does not?
- **5.** Which kind of bond holds atoms in a water molecule together? What attracts water molecules to each other?

See the blue Answers tab at the back of the book.

2-3 Decomposition, synthesis, and exchange reactions are important chemical reactions in physiology

Learning Outcome Distinguish among the three major types of chemical reactions that are important for studying physiology.

Cells stay alive by controlling chemical reactions. In a **chemical reaction**, existing bonds between atoms are broken or new chemical bonds form between atoms. These changes occur as atoms in the reacting substances, or **reactants**, are rearranged to form different substances, or **products** (Spotlight Figure 2-7).

In effect, each cell is a chemical factory. For example, growth, maintenance and repair, secretion, and muscle contraction all involve complex chemical reactions. Cells use chemical reactions to provide the energy required to maintain homeostasis and to perform essential functions. **Metabolism** (me-TAB-ō-lizm; *metabole*, change) refers to all the chemical reactions in the body.

Basic Energy Concepts

Knowing some basic relationships between matter and energy is essential for discussing chemical reactions. **Work** is the movement of an object or a change in the physical structure of matter. In your body, work includes movements like walking or running and also the building of complex molecules and the conversion of liquid water to water vapor (evaporation). **Energy** is the capacity to perform work. There are two major types of energy: *kinetic energy* and *potential energy*.

Kinetic energy is the energy of motion—energy that can be transferred to another object and do work. When you fall off a ladder, it is kinetic energy that does the damage. **Potential energy** is stored energy. It may result from an object's position (you standing on a ladder) or from its physical or chemical structure (a stretched spring or a charged battery). Kinetic energy must be used in climbing the ladder, in stretching the spring, or in charging the battery. The potential energy is converted back into kinetic energy when you fall, the spring recoils, or the battery discharges. The kinetic energy can then be used to perform work.

Energy cannot be destroyed; it can only be converted from one form to another. A conversion between potential energy and kinetic energy is never 100 percent efficient. Each time an energy conversion takes place, some of the energy is released as heat. *Heat* is an increase in random molecular motion, and the temperature of an object is directly related to the average kinetic energy of its molecules. Heat can never be completely converted to work or to any other form of energy. Cells cannot capture it or use it to perform work.

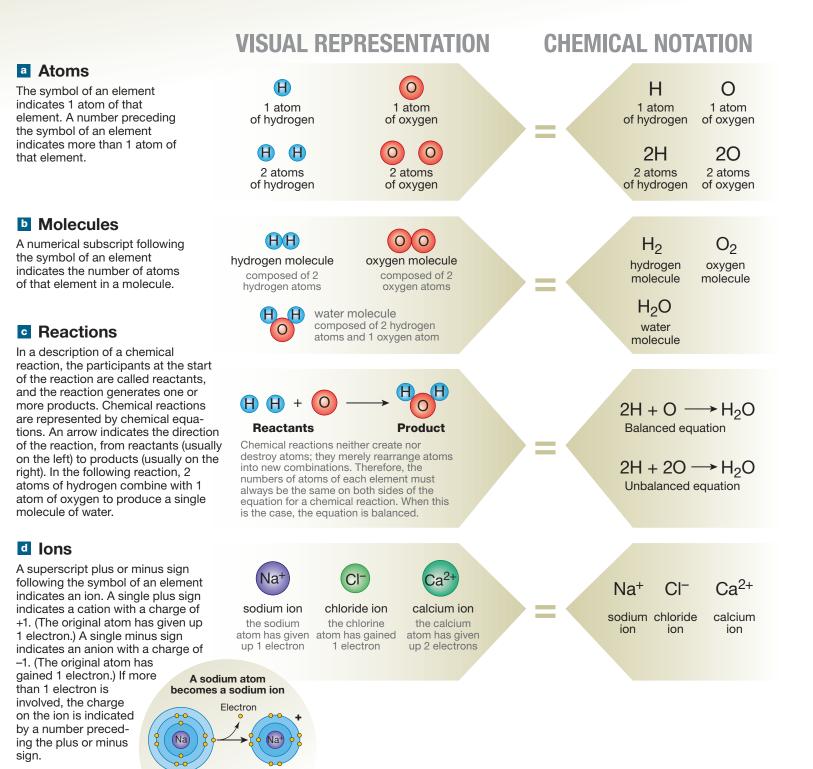

Cells do work as they build complex molecules and move materials into, out of, or within the cell. As they perform such work and convert energy from one form to another, heat is produced. For example, when skeletal muscle cells contract, they perform work. Potential energy (the positions of protein filaments and the covalent bonds between molecules inside the cells) is converted into kinetic energy, and heat is released. The amount of heat is related to the amount of work done. As a result, when you exercise, your body temperature rises.

Types of Reactions

Three types of chemical reactions are important to the study of physiology: *decomposition reactions, synthesis reactions*, and *exchange reactions*.

SPOTLIGHT Figure 2-7 CHEMICAL NOTATION

In order to discuss the specific compounds that occur in the human body, we must be able to describe chemical compounds and reactions clearly. To do this, we use a simple form of "chemical shorthand" known as **chemical notation**. Chemical notation enables us to describe complex events briefly and precisely; its rules are summarized below.

Sodium

atom (Na)

Sodium

ion (Na+)

Decomposition Reactions

A **decomposition reaction** breaks a molecule into smaller fragments. Such reactions take place during digestion, when food molecules are broken into smaller pieces. You could diagram a typical decomposition reaction as:

$$AB \longrightarrow A + B$$

Decomposition reactions involving water are important in the breakdown of complex molecules in the body. In **hydrolysis** (hī-DROL-i-sis; *hydro*-, water + *lysis*, a loosening), one of the bonds in a complex molecule is broken, and the parts of a water molecule (H and OH) are added to the resulting fragments:

$$A - B + H_2O \longrightarrow A - H + HO - B$$

Catabolism (kah-TAB-ō-lizm; *katabole*, a throwing down) refers to the decomposition reactions of complex molecules within cells. A covalent bond is a form of potential energy. When the bond is broken, it releases kinetic energy that can perform work. Cells can harness some of that energy to power essential functions such as growth, movement, and reproduction.

Synthesis Reactions

Synthesis (SIN-the-sis) is the opposite of decomposition. A synthesis reaction assembles larger molecules from smaller parts. These relatively simple reactions could be diagrammed as:

$$A + B \longrightarrow AB$$

A and B could be individual atoms that combine to form a molecule, or they could be individual molecules combining to form even larger products. Synthesis always involves the formation of new chemical bonds, whether the reactants are atoms or molecules.

Dehydration synthesis, or *condensation reaction*, is the formation of a complex molecule by the removal of water:

 $A - H + HO - B \longrightarrow A - B + H_2O$

Dehydration synthesis is the opposite of hydrolysis. We will encounter examples of both reactions in later sections.

Anabolism (a-NAB-ō-lizm; *anabole*, a building up) is the synthesis of new compounds in the body. Because it takes energy to create a chemical bond, anabolism is usually an "uphill" process. Living cells are constantly balancing their chemical activities, with catabolism providing the energy needed to support anabolism as well as other vital functions.

Exchange Reactions

In an **exchange reaction**, parts of the reacting molecules are shuffled, as follows:

$$AB + CD \longrightarrow AD + CB$$

The reactants and products contain the same components (A, B, C, and D), but the components are present in different combinations. In an exchange reaction, the reactant molecules AB and CD break apart (a decomposition), and then the resulting components interact to form AD and CB (a synthesis).

Reversible Reactions

Many important biological reactions are freely reversible. Such reactions can be diagrammed as:

$$A + B \Longrightarrow AB$$

This equation indicates that two reactions are occurring at the same time. One is a synthesis (A + B \longrightarrow AB), and the other is a decomposition (AB \longrightarrow A + B). At **equilibrium** (ē-kwi-LIB-rē-um), the rates of the two reactions are balanced. As fast as a molecule of AB forms, another degrades into A + B. As a result, the numbers of A, B, and AB molecules present at any given moment do not change. Altering the concentrations of one or more of these molecules will temporarily upset the equilibrium, shifting the reaction either towards product synthesis or decomposition. For example, adding additional molecules of A and B will increase the rate of the synthesis reaction (A + B \longrightarrow AB). As the concentration of AB rises, however, so does the rate of the decomposition reaction (AB \longrightarrow A + B), until a new equilibrium is established.

CHECKPOINT

- **6.** Using the rules for chemical notation, write the molecular formula for glucose, a compound composed of 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms.
- **7.** Identify and describe three types of chemical reactions important to human physiology.
- **8.** In living cells, glucose, a six-carbon molecule, is converted into two three-carbon molecules. What type of chemical reaction is this?
- **9.** If the product of a reversible reaction is continuously removed, what will be the effect on the equilibrium of the reaction?

See the blue Answers tab at the back of the book.

2-4 Enzymes catalyze specific biochemical reactions by lowering a reaction's activation energy

Learning Outcome Describe the crucial role of enzymes in metabolism.

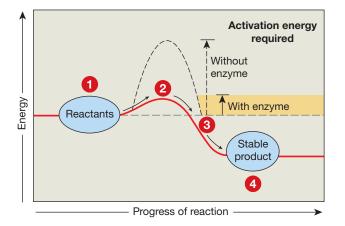

Most chemical reactions do not occur spontaneously, or they occur so slowly that they would be of little value to cells. Before a reaction can begin, enough energy must be provided to activate the reactants. The amount of energy required to start a reaction is called the **activation energy**.

Many reactions can be activated by changes in temperature or pH, but such changes are deadly to cells. For example, to break down a complex sugar in the laboratory, you must boil it in an acid solution. Cells would not survive such extreme measures. Instead, cells use special molecules called **enzymes** to speed up the reactions that support life. Enzymes belong to a class of substances called **catalysts** (KAT-uh-lists; *katalysis*, dissolution), which accelerate (speed up) chemical reactions without themselves being permanently changed. Cells make an enzyme molecule to promote each specific reaction. Most enzyme reactions are reversible reactions.

Enzymes promote chemical reactions by lowering the activation energy needed (**Figure 2-8**). Lowering the activation energy affects only the rate of a reaction, not the direction of the reaction or the products that are formed. An enzyme cannot bring about a reaction that would otherwise be impossible.

It takes activation energy to start a chemical reaction, but once it has begun, the reaction as a whole may absorb or release energy, generally in the form of heat. If the amount of energy released is greater than the activation energy needed to start the reaction, there will be a net release of energy.

Figure 2-8 The Effect of Enzymes on Activation Energy. Enzymes lower the activation energy required for a reaction to proceed readily (in order, from 1 to 4) under conditions in the body.

Reactions that release energy are said to be **exergonic** (*exo*-, outside). If more energy is needed to begin the reaction than is released as it proceeds, the reaction as a whole will absorb energy. Such reactions are called **endergonic** (*endo*-, inside). Exergonic reactions are relatively common in the body. They generate the heat that maintains our body temperature.

CHECKPOINT

10. What is an enzyme?

11. Why are enzymes needed in our cells?

See the blue Answers tab at the back of the book.

2-5 Inorganic compounds usually lack carbon, and organic compounds always contain carbon

Learning Outcome Distinguish between organic and inorganic compounds.

In the rest of this chapter we focus on nutrients and metabolites. **Nutrients** are the substances from food that are necessary for normal physiological functions. They include carbohydrates, proteins, fats, vitamins, minerals, and water. **Metabolites** (me-TAB-ō-līts) are substances that are involved in, or a by-product of, metabolism.

Like all chemical substances, nutrients and metabolites can be broadly categorized as inorganic or organic. **Inorganic compounds** are substances that generally do not contain carbon and hydrogen. (If present, they do not form C—Hbonds.) They include small molecules and ionic compounds. **Organic compounds** are substances that contain carbon covalently bonded with one or more other elements. Their molecules can be much larger and more complex than inorganic compounds.

The most important inorganic substances in the human body are water, carbon dioxide, oxygen, and ionic compounds, such as acids, bases, and salts. Water is the primary component of our body fluids and an essential compound for many chemical reactions. Most of the inorganic molecules and compounds in the human body exist in association with water. Carbon dioxide and oxygen are important gases dissolved in body fluids.

Cells produce carbon dioxide (CO₂) through normal metabolic activity. It is transported in the blood and released as a gas into the air in the lungs. Oxygen (O₂), an atmospheric gas, is absorbed at the lungs, transported in the blood, and consumed by cells throughout the body. The chemical structures of these key substances were introduced earlier in the chapter. \supset p. 60

2

Build Your Knowledge

Recall that carbon is the second most common element in our body and is found in all organic molecules. Recall too that carbon atoms contain four electrons in their outer electron shell. With this number of electrons, carbon atoms may form up to four single covalent bonds. Because these bonds may also include other C atoms, a very large number of different carbon frameworks can exist. These frameworks, in turn, provide many bonding sites for hydrogen, as well as oxygen, two other elements found in abundance in the human body and other living things. **⊃ pp. 57, 59**

CHECKPOINT

12. Distinguish between inorganic compounds and organic compounds.

See the blue Answers tab at the back of the book.

2-6 Physiological systems depend on water

Learning Outcome Explain how the chemical properties of water make life possible.

Water (H_2O) is the most important substance in the body, making up to two-thirds of total body weight. A change in the body's water content can have fatal consequences because virtually all physiological systems will be affected.

Three general properties of water are particularly important to the human body:

- Water is an essential reactant in the chemical reactions of living systems. Chemical reactions in our bodies take place in water, and water molecules also participate in some reactions. During the dehydration synthesis of large molecules, water molecules are released. During hydrolysis, complex molecules are broken down by the addition of water molecules. ⊃ p. 63
- Water has a very high heat capacity. Heat capacity is the ability of a substance to absorb and retain heat. It takes a lot of heat energy to change the temperature of a quantity of water. Why? The reason is that water molecules in the liquid state are linked to one another by hydrogen bonding. This bonding interferes with the

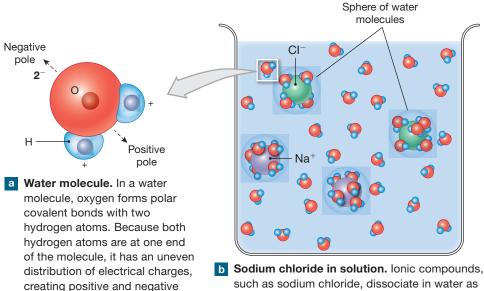

random motion, or kinetic energy, of the water molecules. (Recall that an object's temperature depends directly on the kinetic energy of its molecules. \bigcirc p. 61) So, an increase in water temperature depends on breaking up hydrogen bonds between water molecules. Water retains heat and will change temperature only slowly. As a result, body temperature is stabilized, and the water in our cells remains a liquid over a wide range of environmental temperatures. Hydrogen bonding also explains why a large amount of heat energy is required to change liquid water to a gas, or ice to liquid. When water finally changes from a liquid to a gas, all the hydrogen bonds are broken and the escaping water molecules carry away a great deal of heat. This feature accounts for the cooling effect of perspiration on the skin.

• *Water is an excellent solvent.* A remarkable number of inorganic and organic substances are water *soluble*, meaning they will dissolve in water. As the substances dissolve, their released ions or smaller molecules become uniformly dispersed throughout the water, creating a *solution*. The chemical reactions within living cells take place in solution. The watery component of blood, called plasma, carries dissolved nutrients and waste products throughout the body.

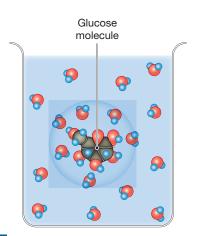

Most chemical reactions in the body take place in **solutions**, which consist of a uniform mixture of a fluid **solvent** and dissolved **solutes**. The solvent in organisms is usually water, forming an *aqueous solution*. The solutes may be inorganic or organic. Inorganic compounds held together by ionic bonds undergo **dissociation** (di-sō-sē-Ā-shun), or **ionization** (ī-on-i-ZĀ-shun) in water. In this process, ionic bonds are broken as individual ions interact with the positive or negative ends of polar water molecules (**Figure 2-9a**). As shown in **Figure 2-9b**, the result is a mixture of cations and anions, each surrounded by so many water molecules that they are unable to re-form their original bonds. Some organic molecules contain polar covalent bonds, which also attract water molecules. An example is glucose, an important soluble sugar in the body (**Figure 2-9c**).

An aqueous solution containing anions and cations can also conduct an electrical current. Substances that release ions when dissolved in water are called *electrolytes*. Electrical forces across cell membranes affect the functioning of all cells. As we will see, small electrical currents carried by ions are essential to muscle contraction and nerve function. (Chapters 7 and 8 discuss these processes in more detail.)

Figure 2-9 The Role of Water Molecules in Aqueous Solutions.

Sodium chloride in solution. Ionic compounds, such as sodium chloride, dissociate in water as the polar water molecules break the ionic bonds. Each ion remains in solution because it is surrounded by a sphere of water molecules.

c Glucose in solution. Water molecules are also attracted to an organic molecule containing polar covalent bonds. If the molecule binds water strongly, as does glucose, it will be carried into solution—in other words, it will dissolve. Note that the molecule does not dissociate, as occurs for ionic compounds.

CHECKPOINT

poles.

- **13.** List the chemical properties of water that make life possible.
- 14. Why does water resist changes in temperature?
- See the blue Answers tab at the back of the book.

2-7 Body fluid pH is vital for homeostasis

Learning Outcome Describe the pH scale and the role of buffers in body fluids.

A hydrogen atom involved in a chemical bond or participating in a chemical reaction can easily lose its electron, to become a hydrogen ion (H⁺). The concentration of hydrogen ions in blood or other body fluids is important because hydrogen ions are extremely reactive. In excessive numbers, they will break chemical bonds, change the shapes of complex molecules, and disrupt cell and tissue functions. For this reason, the concentration of hydrogen ions must be precisely regulated.

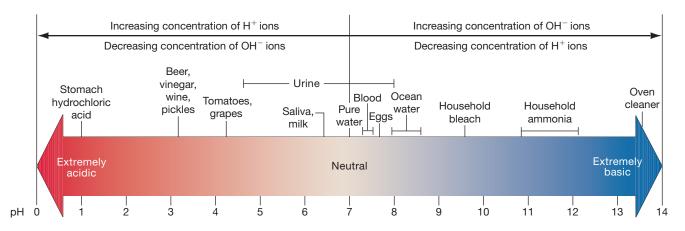

Hydrogen ions are normally present even in pure water because some water molecules dissociate spontaneously, releasing a hydrogen ion and a hydroxide (hī-DROK-sīd) ion (OH⁻). The concentration of hydrogen ions is usually reported as the **pH** of the solution. The pH value is a number between 0 and 14. Pure water has a pH of 7. A solution with a pH of 7 is called *neutral* because it contains equal numbers of hydrogen ions and hydroxide ions. A difference of one pH unit equals a tenfold change in H⁺ concentration. A solution with a pH below 7 is *acidic* (a-SI-dik) because there are more hydrogen ions than hydroxide ions. A pH above 7 is called *basic*, or *alkaline* (AL-kuh-lin), because hydroxide ions outnumber hydrogen ions.

The pH values of some common liquids are given in **Figure 2-10**. The pH of blood and most body fluids normally ranges from 7.35 to 7.45. Variations in pH outside this range can damage cells and disrupt normal cellular functions. For example, a blood pH below 7 can produce coma. A blood pH higher than 7.8 usually causes uncontrollable, sustained muscular contractions.

CHECKPOINT

- **15.** Define pH, and explain how the pH scale relates to acidity and alkalinity.
- **16.** Why is an extreme change in pH of body fluids undesirable?
- See the blue Answers tab at the back of the book.

Figure 2-10 pH and Hydrogen Ion Concentration. An increase or decrease of one pH unit corresponds to a tenfold change in H⁺ concentration.

2-8 Acids, bases, and salts have important physiological roles

Learning Outcome Describe the functional roles of acids, bases, and salts.

An **acid** (*acere*; sour) is any substance that breaks apart (dissociates) in solution to *release* hydrogen ions. (Because a hydrogen ion consists solely of a proton, hydrogen ions are often referred to simply as protons, and acids as "proton donors.") Acids and bases are often identified in terms of *strength*. Strength is a measure of the degree of dissociation of either an acid or a base when it is in solution. A *strong acid* dissociates completely in solution. Hydrochloric acid (HCl) is an excellent example:

$$HCl \longrightarrow H^+ + Cl^-$$

The stomach produces this powerful acid to help break down food.

A **base** is a substance that removes hydrogen ions from a solution. Many common bases are compounds that dissociate in solution to release a hydroxide ion (OH⁻). Hydroxide ions have a strong affinity, or attraction, for hydrogen ions and quickly react with them to form water molecules. A *strong base* dissociates completely in solution. For example, sodium hydroxide (NaOH) dissociates in solution as follows:

$$NaOH \longrightarrow Na^{+} + OH^{-}$$

Strong bases have a variety of industrial and household uses. Drain openers and lye are two familiar examples.

Weak acids and *weak bases* do not dissociate completely in solution. At equilibrium, a significant number of molecules

remain intact in the solution. So, for the same number of molecules in solution, weak acids and weak bases have less impact on pH than do strong acids and strong bases. The human body contains both weak acids and bases. Weak bases are important in counteracting acids produced during cellular metabolism.

Salts

A **salt** is an ionic compound consisting of any cation except a hydrogen ion and any anion except a hydroxide ion. Salts are held together by ionic bonds. In water they dissociate, releasing cations and anions. For example, table salt (NaCl) in solution dissociates into Na⁺ and Cl⁻ ions. These two ions are also the most abundant ones in body fluids.

The dissociation of table salt does not affect the concentrations of hydrogen ions or hydroxide ions, so NaCl, like many salts, is a "neutral" solute. Through their interactions with water molecules, however, other salts may indirectly affect the concentrations of hydrogen ions and hydroxide ions. The dissociation of such salts makes a solution slightly acidic or slightly basic.

Electrolytes (e-LEK-trō-līts) are substances whose ions can conduct an electrical current in solution. They include acids, bases, and salts. (In physiology, both the ionizable substance and its ions are referred to as electrolytes.) Examples of important ions in blood and other body fluids released by dissociation include sodium ions (Na⁺), potassium ions (K⁺), calcium ions (Ca²⁺), chloride ions (CI⁻), and bicarbonate ions (HCO₃⁻). Changes in the concentrations of these ions in body fluids will disturb almost every vital function. For example, decreasing potassium ion concentrations will lead to general muscular paralysis. Increasing potassium ion concentrations will cause weak and irregular heartbeats.

Buffers and pH

Buffers are compounds that stabilize pH by either removing or replacing hydrogen ions. Antacids such as Alka-Seltzer, Rolaids, and Tums are buffers that tie up excess hydrogen ions in the stomach. A variety of buffers, including sodium bicarbonate (also known as baking soda), are responsible for stabilizing the pH of most body fluids between 7.35 and 7.45. (We will consider the role of buffers and pH control in Chapter 18.)

CHECKPOINT

- 17. Define the following terms: acid, base, and salt.
- **18.** How does an antacid help decrease stomach discomfort?
- See the blue Answers tab at the back of the book.

2-9 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio

Learning Outcome Discuss the structures and functions of carbohydrates.

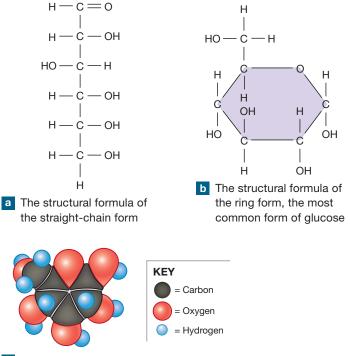

Carbohydrates are one of the four major classes of organic compounds. Organic compounds always contain the elements carbon and hydrogen. D p. 64 Many organic molecules are made up of long chains of carbon atoms linked by covalent bonds. These carbon atoms often form additional covalent bonds with hydrogen or oxygen atoms, and less often with nitrogen, phosphorus, sulfur, iron, or other elements.

A **carbohydrate** (kar-bō-HĪ-drāt) is an organic molecule that contains carbon, hydrogen, and oxygen in a ratio near 1:2:1. Familiar carbohydrates include the sugars and starches that make up roughly half of the typical U.S. diet. Our tissues can break down most carbohydrates.

Carbohydrates are most important as sources of energy, although they sometimes have other functions. Despite their importance as an energy source, carbohydrates account for only about 1 percent of total body weight. The three major types of carbohydrates are *monosaccharides, disaccharides,* and *polysaccharides*.

Monosaccharides

A **simple sugar**, or **monosaccharide** (mon- \bar{o} -SAK-uh-r \bar{n} d; *mono*-, single + *sakcharon*, sugar), is a carbohydrate containing from three to seven carbon atoms. This group includes **glucose** (GLOO- $k\bar{o}$ s), (C₆H₁₂O₆), the most important "fuel" in the body (**Figure 2-11**). Glucose and other monosaccharides dissolve readily in water. Blood and other body fluids rapidly distribute them throughout the body. Figure 2-11 The Structures of Glucose.

c A three-dimensional model that shows the organization of atoms in the ring form

Disaccharides and Polysaccharides

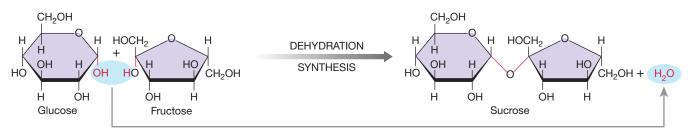

Carbohydrates other than simple sugars are complex molecules made of monosaccharide building blocks. Two monosaccharides joined together form a **disaccharide** (dī-SAK-uh-rīd; *di*-, two). Disaccharides such as *sucrose* (table sugar) have a sweet taste. Like monosaccharides, they are quite soluble in water.

The formation of sucrose (Figure 2-12a) involves dehydration synthesis, a process introduced earlier in the chapter. \bigcirc p. 63 Dehydration synthesis, or condensation, links molecules together by the removal of a water molecule. The breakdown of sucrose into simple sugars is an example of hydrolysis, the functional opposite of dehydration synthesis (Figure 2-12b).

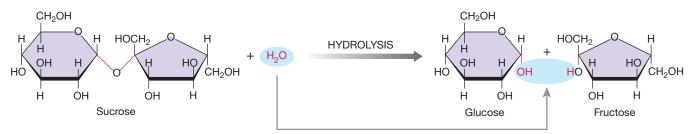

All carbohydrates except monosaccharides must be disassembled through hydrolysis before they can provide useful energy. Many foods contain disaccharides. Most sweet junk foods, such as candy and soft drinks, abound in simple sugars (commonly fructose) and disaccharides (generally sucrose). Some people cannot tolerate table sugar (sucrose) for medical reasons. Others avoid it because they do not want to gain weight (excess sugars are stored as fat). Many of these people use artificial sweeteners in their foods and beverages. These compounds have a very sweet taste but either cannot be broken down in the

2

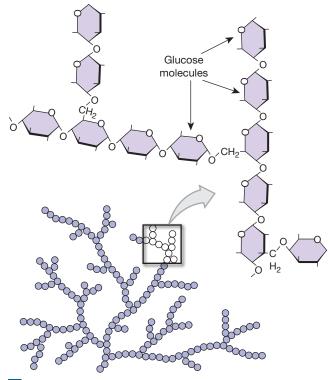

Figure 2-12 The Structure, Formation, and Breakdown of Complex Sugars.

a Formation of the disaccharide sucrose through dehydration synthesis. During dehydration synthesis, two molecules are joined by the removal of a water molecule.

b Breakdown of sucrose into simple sugars by hydrolysis. Hydrolysis reverses the steps of dehydration synthesis; a complex molecule is broken down by the addition of a water molecule.

c The structure of glycogen. Liver and muscle cells store glucose as the polysaccharide glycogen, a long, branching chain of glucose molecules.

body or are used in such small amounts that their breakdown does not affect the overall energy balance of the body.

Larger carbohydrate molecules are called **polysaccharides** (pol-ē-SAK-uh-rīdz; *poly-*, many). They form when repeated

dehydration synthesis reactions add additional monosaccharides or disaccharides. *Starches* are glucose-based polysaccharides important in our diets. Most starches are manufactured by plants. Your digestive tract can break these molecules into simple sugars. Starches found in potatoes and grains are important energy sources. In contrast, *cellulose*, a component of the cell walls of plants, is a polysaccharide that our bodies cannot digest. The cellulose of foods such as celery contributes to the bulk of digestive wastes but is useless as an energy source.

Glycogen (GLĪ-kō-jen), or *animal starch*, is a polysaccharide composed of interconnected glucose molecules (**Figure 2-12c**). Like most other large polysaccharides, glycogen will not dissolve in water or other body fluids. Liver and muscle tissues make and store glycogen. When these tissues have a high demand for energy, they break down glycogen molecules into glucose. When demands are low, the tissues absorb glucose from the bloodstream and rebuild glycogen reserves. **Table 2-3** summarizes information about the carbohydrates in the body.

CHECKPOINT

- **19.** A food contains organic molecules with the elements C, H, and O in a ratio of 1:2:1. What class of compounds do these molecules represent, and what are their major functions in the body?
- 20. When two monosaccharides undergo a dehydration synthesis reaction, which type of molecule is formed?See the blue Answers tab at the back of the book.

Table 2-3	Carbohydrates in the Body		
Structure	Examples	Primary Functions	Remarks
Monosaccharides (Simple Sugars)	Glucose, fructose	Energy source	Manufactured in the body and obtained from food; found in body fluids
Disaccharides	Sucrose, lactose, maltose	Energy source	Sucrose is table sugar, lactose is present in milk; all must be broken down to monosaccharides before absorption
Polysaccharides	Glycogen	Storage of glucose molecules	Glycogen is in animal cells; other polysaccharides (starches and cellulose) are plant products

2-10 Lipids contain a carbon-tohydrogen ratio of 1:2

Learning Outcome Discuss the structures and functions of lipids.

Lipids (*lipos*, fat) also contain carbon, hydrogen, and oxygen, but the ratios do not approximate 1:2:1. The reason is because they have relatively less oxygen than do carbohydrates. In addition, lipids may contain small quantities of other elements, including phosphorus, nitrogen, or sulfur. Familiar lipids include *fats*, *oils*, and *waxes*. Most lipids are insoluble in water. For this reason, special transport molecules carry them in the circulating blood.

Lipids form essential parts of the structure of all cells. In addition, lipid deposits are important as energy reserves. Based on equal weights, lipids provide roughly twice as much energy as carbohydrates when broken down in the body. When the supply of lipids exceeds the demand for energy, the excess is stored in fat deposits. For this reason there has been great interest in developing *fat substitutes* that provide less energy but have the same taste and texture as lipids.

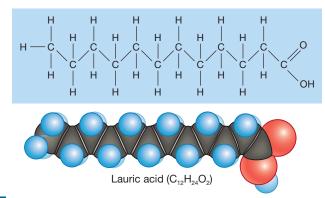

Lipids normally account for 12–18 percent of total body weight of adult men, and 18–24 percent of that of adult women. There are many kinds of lipids in the body. The major types are *fatty acids, fats, steroids,* and *phospholipids* (Table 2-4).

Fatty Acids

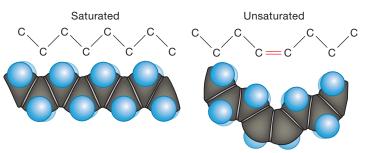

Fatty acids are long chains of carbon atoms with attached hydrogen atoms and end in a *carboxyl* (kar-BOK-sil) *group* (-COOH). The name *carboxyl* should help you remember that a carbon and a hydroxyl (-OH) group are the important

structural features of fatty acids. When a fatty acid is in solution, only the carboxyl end dissolves in water. The carbon chain, known as the hydrocarbon *tail* of the fatty acid, is relatively insoluble. **Figure 2-13a** shows a representative fatty acid, *lauric acid*.

Figure 2-13 Fatty Acids.

a Lauric acid shows the basic structure of a fatty acid: a long chain of carbon atoms and a carboxyl group (-COOH) at one end.

b A fatty acid is either saturated (has single covalent bonds only) or unsaturated (has one or more double covalent bonds). The presence of a double bond causes a sharp bend in the molecule.

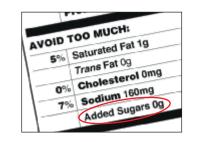

Table 2-4 Representative Lipids and Their Functions in the Body			
Lipid Type	Examples	Primary Functions	Remarks
Fatty Acids	Lauric acid	Energy sources	Absorbed from food or synthesized in cells; transported in the blood for use in many tissues
Fats	Monoglycerides, diglycerides, triglycerides	Energy source, energy storage, insulation, and physical protection	Stored in fat deposits; must be broken down to fatty acids and glycerol before they can be used as an energy source
Steroids	Cholesterol	Structural component of cell membranes, hormones, digestive secretions in bile	All have the same carbon-ring framework
Phospholipids	Lecithin	Structural components of cell membranes	Composed of fatty acids and nonlipid molecules

CLINICAL NOTE

Too Sweet on Sugar?

A baby's first and favorite taste is sweet: mother's milk is rich in *lactose* (milk sugar), a disaccharide of glucose and galactose. This preference for sweet persists throughout life. It is easier to tempt the poor appetite of a frail, elderly person with a bowl of pudding than with a bowl of steamed kale. Manufacturers of processed foods know this.

When heart disease became endemic in the United States, holding first place as the killer of Americans, the medical community advocated a low-fat diet for heart health. Artery-clogging fats were removed from manufactured foods—such as cookies, soups,

In a **saturated** fatty acid, such as lauric acid, the four single covalent bonds of each carbon atom permit each carbon to link to neighboring carbons on either side and to two hydrogen atoms. If any of the carbon-to-carbon bonds are double covalent bonds, then fewer hydrogen atoms are present and the fatty acid is **unsaturated**. The structures of saturated and unsaturated fatty acids are shown in **Figure 2-13b**. A *monounsaturated* fatty acid has a lone double bond in the hydrocarbon tail. A *polyunsaturated* fatty acid contains multiple double bonds.

Both saturated and unsaturated fatty acids can be broken down for energy, but a diet with large amounts of saturated fatty acids increases the risk of heart disease and other circulatory problems. Butter, fatty meat, and ice cream are popular dietary sources of saturated fatty acids. Vegetable oils such as olive oil or corn oil contain a mixture of unsaturated fatty acids.

Fats

Unlike simple sugars, individual fatty acids cannot be strung together in a chain by dehydration synthesis. But they can be attached to the compound **glycerol** (GLIS-er-ol) to make a **fat** through a similar reaction. In a **triglyceride** (trī-GLIS-er-īd), a glycerol molecule is attached to three fatty acids (**Figure 2-14**). Triglycerides are the most common fats in the body.

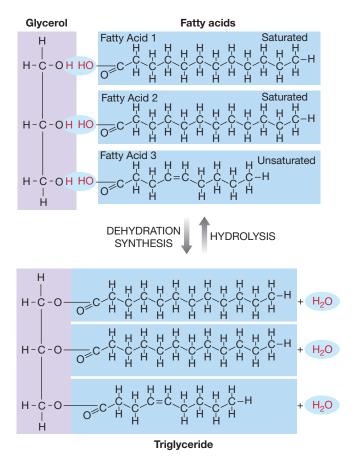

In addition to serving as an energy reserve, fat deposits under the skin serve as insulation. A mass of fat around a delicate organ, such as a kidney, provides a protective cushion. and other boxed, bagged, and frozen products—and replaced with sugar for flavor and mouth appeal.

The sweetening of the American diet has wreaked a new kind of havoc on American health. Dental hygienists see more *dental caries* (cavities). Obesity is climbing at an alarming rate. Grade-school children are developing more *type 2 diabetes*, formerly called "adult-onset diabetes." These serious and potentially fatal diseases generally did not appear until a person had lived several decades with a poor lifestyle.

Glucose is a necessary nutrient. Our body's cells depend on it for fuel; our neurons (brain cells) require it. However, we should meet our glucose needs through complex carbohydrates, or polysaccharides (such as glycogen). In contrast to simple sugars, complex carbohydrates are digested slowly by decomposition reactions in the digestive tract. The component monosaccharides of glucose are released and absorbed gradually, maintaining a steady blood glucose level. In turn, the pancreas is signaled only as needed to make the protein hormone *insulin*, which stimulates the transport of glucose into the body's cells. Complex carbohydrates promote satiety (fullness) and support healthy sugar metabolism.

Figure 2-14 Triglyceride Formation. The formation of a triglyceride involves the attachment of three fatty acids to a glycerol molecule through dehydration synthesis. In this example, a triglyceride is formed by the attachment of one unsaturated and two saturated fatty acids to a glycerol molecule.

Steroids

2

Steroids are large lipid molecules composed of four connected rings of carbon atoms. They differ in the carbon chains that are attached to this basic structure. **Cholesterol** (koh-LES-ter-ol; *chole-*, bile + *stereos*, solid) is probably the best-known steroid (**Figure 2-15**). All our cells are surrounded by *cell membranes*, or *plasma membranes*, that contain cholesterol. Also, some chemical messengers, or *hormones*, are derived from cholesterol. Examples include the sex hormones testosterone and estrogen.

The cholesterol needed to maintain cell membranes and manufacture steroid hormones comes from two sources. One source is the diet. Animal products such as meat, cream, and egg yolks are especially rich in cholesterol. The second source is the body itself. The liver can synthesize large amounts of cholesterol. The body's ability to synthesize this steroid can make it difficult to control blood cholesterol levels by dietary restriction alone. This difficulty can be a problem because a strong link exists between high blood cholesterol

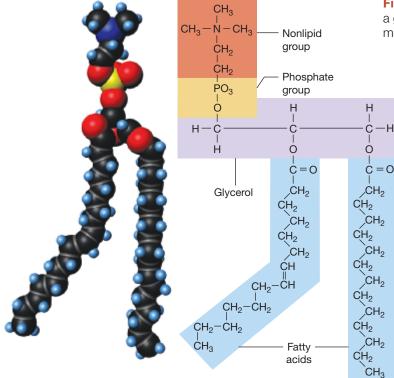

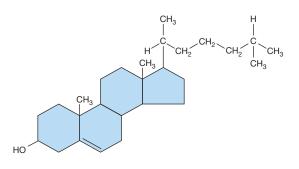

Figure 2-15 A Cholesterol Molecule. Like all steroids, cholesterol contains a complex four-ring structure.

levels and heart disease. Current nutritional advice suggests limiting cholesterol intake to under 300 mg per day. This amount represents a 40 percent reduction for the average adult in the United States. (We will examine the connection between blood cholesterol levels and heart disease in Chapters 11 and 12.)

Phospholipids

Phospholipids (FOS-fō-lip-idz) consist of a glycerol and two fatty acids (a diglyceride) linked to a nonlipid group by a phosphate group (PO_4^{3-}) (**Figure 2-16**). The nonlipid portion of a

Figure 2-16 A Phospholipid Molecule. In a phospholipid, a glycerol with two fatty acids (a diglyceride) is linked to a nonlipid molecule by a phosphate group. This phospholipid is lecithin.

phospholipid is soluble in water, but the fatty acid portion is relatively insoluble. Phospholipids are the most abundant lipid components of cell membranes.

CHECKPOINT

- **21.** Describe lipids.
- **22.** Which kind of lipid would be found in a sample of fatty tissue taken from beneath the skin?
- **23.** Which lipids would you find in human cell membranes?

See the blue Answers tab at the back of the book.

2-11 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids

Learning Outcome Discuss the structures and functions of proteins.

Proteins are the most abundant organic molecules in the human body and in many ways the most important. The human body contains many different proteins, and they account for about 20 percent of total body weight. All proteins contain carbon, hydrogen, oxygen, and nitrogen. Smaller quantities of sulfur and phosphorus may also be present.

Protein Function

Proteins perform a variety of functions, which can be grouped into seven major categories:

- **1.** *Support.* **Structural proteins** create a three-dimensional framework for the body, providing strength, organization, and support for cells, tissues, and organs.
- **2.** *Movement.* **Contractile proteins** are responsible for muscular contraction. Related proteins are responsible for the movement of individual cells.
- **3.** *Transport.* Insoluble lipids, respiratory gases, minerals such as iron, and several hormones are carried in the blood attached to **transport proteins**. Other specialized proteins transport materials between different parts of a cell.
- **4.** *Buffering.* Proteins provide a buffering action, helping to prevent potentially dangerous changes in pH in body fluids.

- **5.** *Metabolic regulation.* Many proteins are enzymes. Enzymes speed up chemical reactions in living cells. The sensitivity of enzymes to environmental factors is extremely important in controlling the pace and direction of metabolic operations.
- **6.** *Coordination and control.* Protein **hormones** can influence the metabolic activities of every cell in the body or affect the function of specific organs or organ systems.
- **7.** *Defense.* The tough, waterproof proteins of the skin, hair, and nails protect the body from environmental hazards. In addition, proteins known as **antibodies** protect us from disease. Special **clotting proteins** restrict bleeding after an injury to the cardiovascular system.

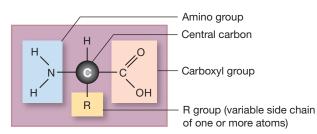

Protein Structure

Proteins are long chains of organic molecules called **amino acids**. The human body contains significant quantities of the 20 different amino acids used in building proteins. Each amino acid consists of five parts: a central carbon atom, a hydrogen atom, an amino group ($-NH_2$), a carboxyl group (-COOH), and an R group (a variable *side chain* of one or more atoms) (**Figure 2-17a**). The name *amino acid* refers to the presence of the *amino* group and the acidic carboxyl group, which all amino acids have in common. (The carboxyl group is acidic because it can release a hydrogen ion.) The different R groups distinguish one amino acid from another, giving each its own chemical properties. For example, an R group may be polar, nonpolar, or electrically charged.

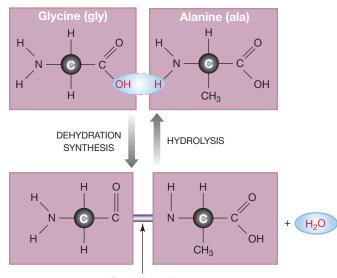

A typical protein contains 1000 amino acids. The largest protein complexes may have 100,000 or more. The individual amino acids are strung together like beads on a string, with the carboxyl group of one amino acid attached to the amino group of another. This connection is called a **peptide bond** (**Figure 2-17b**). **Peptides** are molecules made up of amino acids held together by peptide bonds. A molecule that consists of two amino acids is called a *dipeptide*. Tripeptides and larger chains of amino acids are called *polypeptides*. Polypeptides containing more than 100 amino acids are usually called proteins.

At its most basic level, the *structure* of a protein is established by the sequence of its amino acids (**Figure 2-18a**). The *characteristics* of a particular protein are determined in part by the R groups on its amino acids. But the properties of a protein are more than just the sum of the properties of its

Figure 2-17 Amino Acids and the Formation of Peptide Bonds.

a Structure of an Amino Acid. Each amino acid consists of a central carbon atom to which four different groups are attached: a hydrogen atom, an amino group (–NH₂), a carboxyl group (–COOH), and a variable group generally designated R.

Peptide bond

b Peptide Bond Formation. Peptides form when a dehydration synthesis reaction creates a peptide bond between the carboxyl group of one amino acid and the amino group of another. In this example, glycine (for which R = H) and alanine (for which R = CH₃) are linked to form a dipeptide.

parts, for polypeptides can have highly complex shapes that are important to their function. Proteins can have four levels of structural complexity (**Figure 2-18**):

- **1. Primary structure** is the sequence of amino acids linked by peptide bonds along the length of a single polypeptide chain (**Figure 2-18a**).
- 2. Secondary structure is the shape that results from hydrogen bonding between atoms at different parts of the polypeptide chain. Hydrogen bonding may create either an *alpha helix* (simple spiral) or *beta sheet* (a flat pleated sheet) (Figure 2-18b). A polypeptide chain may have both helical and pleated sections.

- **3. Tertiary structure** is the complex coiling and folding that gives a protein its final three-dimensional shape (**Figure 2-18c**). Tertiary structure results mainly from interactions between the R groups of the polypeptide chain and the surrounding water molecules, and from interactions between the R groups of amino acids in different parts of the molecule.
- 4. Quaternary structure develops when individual polypeptide chains interact to form a protein complex (Figure 2-18d). Each of the polypeptide subunits has its own secondary and tertiary structures. For example, the protein *hemoglobin* contains four subunits. Hemoglobin is found within red blood cells, where it binds and transports oxygen. In *keratin* and *collagen*, two (keratin) or three (collagen) alpha-helical polypeptides are wound together like the strands of a rope. Keratin is the tough, water-resistant protein at the surface of the skin and in hair and nails. Collagen is the most abundant structural protein in the body. It is found in skin, bones, cartilages, and tendons. It forms the framework that supports cells in most tissues.

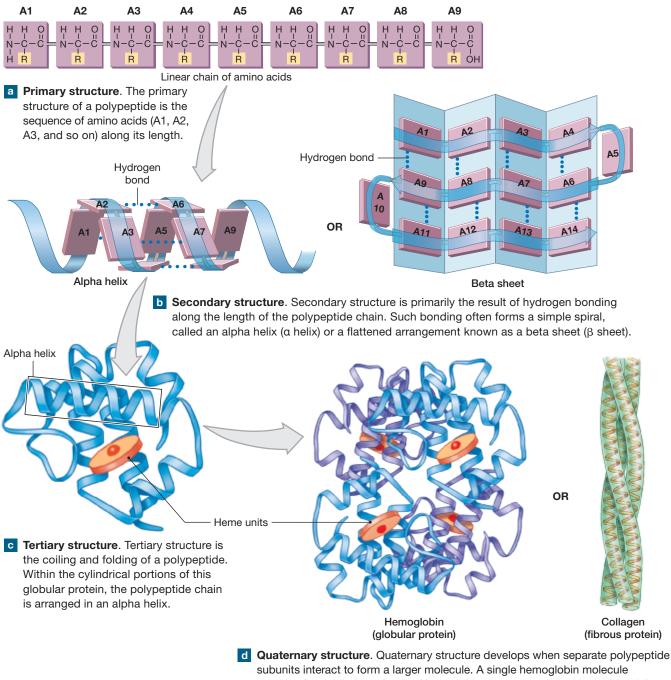

Proteins fall into two general structural classes based on their overall shape and properties:

- **Fibrous proteins** form extended sheets or strands. Fibrous proteins are tough, durable, and generally insoluble in water. They usually play structural roles in the body.
- **Globular proteins** are compact, generally rounded, and soluble in water. The unique shape of each globular protein comes from its tertiary structure. Many enzymes, hormones, and other molecules that circulate in the bloodstream are globular proteins. These proteins usually have active, functional roles in the body.

The shape of a protein determines its functional properties. The 20 common amino acids can be linked in an astonishing number of combinations, creating proteins of enormously varied shape and function. Small differences can have large effects. Changing one amino acid in a protein of 10,000 amino acids or more may make the protein incapable of performing its normal function. For example, several cancers and *sickle cell anemia*, a blood disorder, result from single changes in the amino acid sequences of complex proteins.

The shape of a protein—and thus its function—can be altered by small changes in the ionic composition, temperature, or pH of its surroundings. For example, very high body temperatures (over 43°C, or 110°F) cause death because at these temperatures proteins undergo **denaturation**, a change in their three-dimensional shape. Denatured proteins are

Figure 2-18 Protein Structure.

subunits interact to form a larger molecule. A single hemoglobin molecule contains four globular subunits. Hemoglobin transports oxygen in the blood. In collagen, three helical polypeptide subunits intertwine. Collagen is the principal extracellular protein in most organs.

nonfunctional, and the loss of structural proteins and enzymes causes irreparable damage to organs and organ systems. You see denaturation in progress each time you fry an egg. As the temperature rises, the structure of the abundant proteins dissolved in the clear egg white changes. Eventually the egg proteins form an insoluble white mass.

Enzyme Function

Enzymes are among the most important of all the body's proteins. \bigcirc p. 64 These molecules catalyze the reactions that sustain life: Almost everything that happens inside the human body does so because a specific enzyme makes it possible.

Figure 2-19 shows a simple model of enzyme function. Recall that an enzyme functions as a catalyst—to speed up a chemical reaction without itself being permanently changed or consumed. The reactants in an enzymatic reaction are called **substrates**. They interact to form a specific **product**. For an enzyme to catalyze a reaction, the substrates must bind to a special region of the enzyme called the active site. This binding depends on the complementary shapes of the two molecules, much as a key fits into a lock. The shape of the active site is determined by the three-dimensional shape of the enzyme molecule. Substrate binding temporarily changes the shape of the enzyme. Once the reaction is completed and the products are released, the enzyme is free to catalyze another reaction. Enzymes work quickly. For example, an enzyme providing energy during a muscular contraction performs its reaction 100 times per second.

Each enzyme works best at an optimal temperature and pH. As temperatures rise or pH shifts outside normal limits, bonds are broken and proteins change shape. Enzyme function deteriorates as a result.

Each enzyme catalyzes only one type of reaction. This *specificity* is due to the ability of its active sites to bind only to substrates with particular shapes and charges. The complex reactions that support life proceed in a series of interlocking steps, each step controlled by a different enzyme. Such a reaction sequence is called a *metabolic pathway*. (We will consider important metabolic pathways in later chapters.)

CHECKPOINT

- 24. Describe a protein.
- **25.** How does boiling a protein affect its structural and functional properties?
- See the blue Answers tab at the back of the book.

2-12 DNA and RNA are nucleic acids

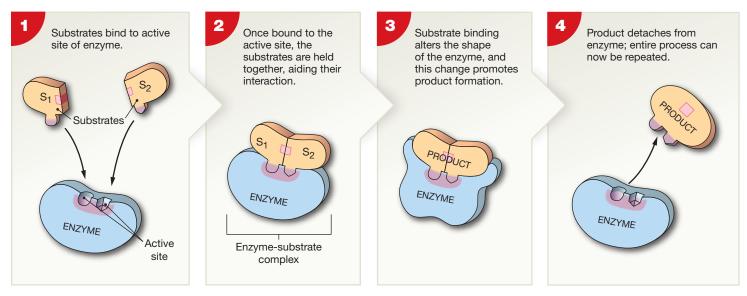

Learning Outcome Discuss the structures and functions of nucleic acids.

Nucleic (noo-KLĀ-ik) **acids** are large organic molecules made of carbon, hydrogen, oxygen, nitrogen, and phosphorus. Nucleic acids store and process information at the molecular level inside cells. The two classes of nucleic acid molecules are **deoxyribonucleic** (dē-oks-ē-rī-bō-noo-KLĀ-ik) **acid**, or **DNA**, and **ribonucleic** (rī-bō-noo-KLĀ-ik) **acid**, or **RNA**.

The DNA in our cells determines our inherited characteristics, including eye color, hair color, and blood type. DNA affects all aspects of body structure and function because DNA molecules encode the information needed to build proteins. By directing the synthesis of structural proteins, DNA controls the shape and physical characteristics of our bodies. By controlling the manufacture of enzymes, DNA regulates not only protein synthesis, but all aspects of cellular metabolism, including the creation and destruction of lipids, carbohydrates, and other vital molecules.

Several forms of RNA cooperate to manufacture specific proteins using the information provided by DNA. In Chapter 3 we will detail the ways DNA and RNA work together.

Figure 2-19 A Simple Model of Enzyme Function. Each enzyme contains a specific active site somewhere on its exposed surface. Because the structure of the enzyme is not permanently affected, the entire process can be repeated.

2

Structure of Nucleic Acids

A nucleic acid (**Figure 2-20**) is made up of subunits called **nucleotides**. Each nucleotide has three parts: a *sugar*, a *phosphate group* (PO_4^{3-}), and a *nitrogenous* (*nitrogen-containing*) *base* (**Figure 2-20a**). The sugar is always a five-carbon sugar, either **ribose** (in RNA) or **deoxyribose** (in DNA). There are five nitrogenous bases: **adenine** (A), **guanine** (G), **cytosine** (C), **thymine** (T), and **uracil** (U). Both RNA and DNA contain adenine, guanine, and cytosine. Uracil is found only in RNA, and thymine only in DNA (Figure 2-20b).

Important structural differences between RNA and DNA are listed in Table 2-5. A molecule of RNA is a single chain of nucleotides (Figure 2-20c). A DNA molecule consists of two nucleotide chains. They are held together by weak hydrogen bonds between the opposing nitrogenous bases (Figure 2-20d). Because of their shapes, adenine can bond only with thymine, and cytosine only with guanine. For this reason, adenine-thymine and cytosine-guanine are known as **complementary base pairs**.

The two strands of DNA twist around one another in a **double helix**. This shape resembles a spiral staircase, with the stair steps corresponding to the nitrogenous base pairs.

Figure 2-20 The Structure of Nucleic Acids. Nucleic acids are long chains of nucleotides.

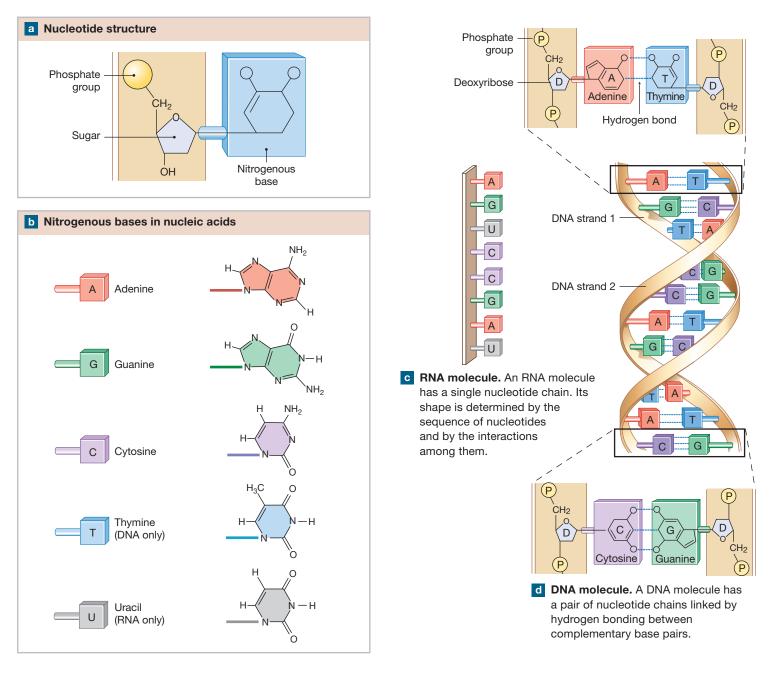

Table 2-5 A Comparison of RNA and DNA

Table 2-3 A companison of thick and Dick				
Characteristic	RNA	DNA		
Sugar	Ribose	Deoxyribose		
Nitrogenous Bases	Adenine Adenine			
	Guanine	Guanine		
	Cytosine	Cytosine		
	Uracil	Thymine		
Number of Nucleotides in a Typical Molecule	Varies from fewer than 100 nucleotides to about 50,000	Always more than 45 million nucleotides		
Shape of Molecule	Single strand	Paired strands coiled in a double helix		
Function Performs protein synthesis as directed Stores genetic information that cont by DNA Stores genetic information that cont Stores genetic information that cont		Stores genetic information that controls protein synthesis		

CHECKPOINT

- **26.** Describe a nucleic acid.
- **27.** A large organic molecule composed of ribose sugars, nitrogenous bases, and phosphate groups is which kind of nucleic acid?
- See the blue Answers tab at the back of the book.

2-13 ATP is a high-energy compound used by cells

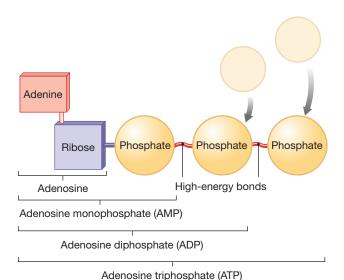

Learning Outcome Discuss the structures and functions of high-energy compounds.

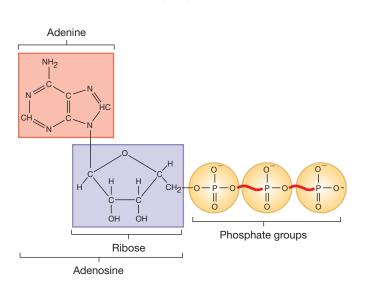

The energy that powers a cell comes from the breakdown (catabolism) of organic molecules such as glucose. To get to where it is needed, that energy must be transferred from molecule to molecule or from one part of the cell to another.

The usual method of energy transfer involves the creation of high-energy bonds by enzymes within cells. A **high-energy bond** is a covalent bond that stores an unusually large amount of energy (as does a tightly twisted rubber band attached to the propeller of a model airplane). When that bond is later broken, the energy is released under controlled conditions (as when the propeller is turned by the untwisting rubber band).

In our cells, a high-energy bond usually connects a phosphate group (PO_4^{3-}) to an organic molecule, resulting in a **high-energy compound**. Most high-energy compounds are derived from nucleotides, the building blocks of nucleic acids. The most important high-energy compound in the body is **adenosine triphosphate**, or **ATP**. ATP is composed of the nucleotide *adenosine monophosphate (AMP)* and two phosphate groups (**Figure 2-21**). The addition of the two phosphate groups requires a significant amount of energy. When the first of these groups is added, AMP becomes *adenosine diphosphate (ADP)*.

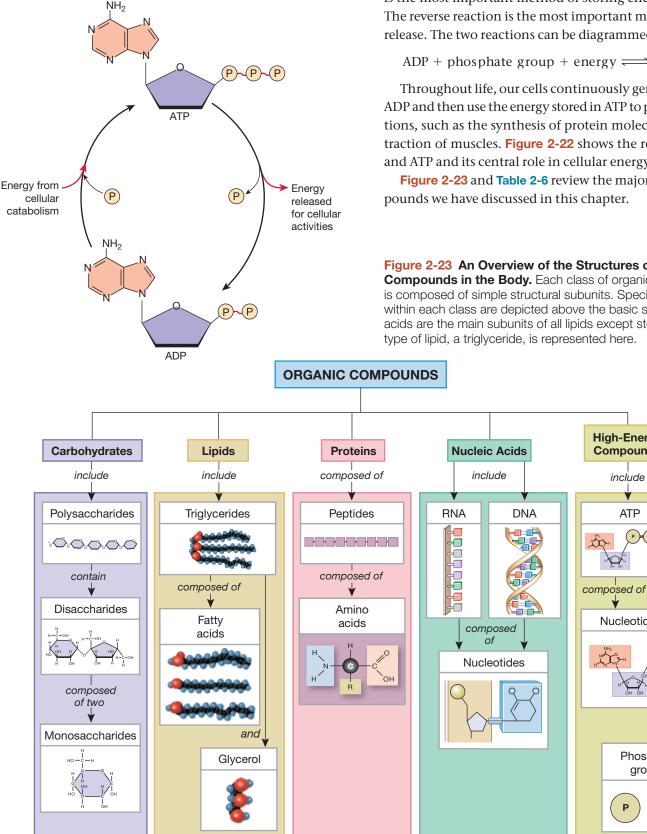

Figure 2-21 The Structure of ATP. A molecule of ATP is formed by attaching two phosphate groups to the nucleotide adenosine monophosphate (AMP). These two phosphate groups are connected by high-energy bonds.

2

Figure 2-22 The Recycling of ADP and ATP and the Energy Flow within Cells.

In ATP, a high-energy bond connects a phosphate group to adenosine diphosphate (ADP). The conversion of ADP to ATP is the most important method of storing energy in our cells. The reverse reaction is the most important method of energy release. The two reactions can be diagrammed together as:

 $ADP + phosphate group + energy \implies ATP + H_2O$

Throughout life, our cells continuously generate ATP from ADP and then use the energy stored in ATP to power vital functions, such as the synthesis of protein molecules or the contraction of muscles. Figure 2-22 shows the recycling of ADP and ATP and its central role in cellular energy flow.

Figure 2-23 and Table 2-6 review the major chemical compounds we have discussed in this chapter.

Figure 2-23 An Overview of the Structures of Organic

Compounds in the Body. Each class of organic compounds is composed of simple structural subunits. Specific compounds within each class are depicted above the basic subunits. Fatty acids are the main subunits of all lipids except steroids. Only one type of lipid, a triglyceride, is represented here.

Table 2-6	The Structure and Function of Biologically Important Inorganic and Organic Compounds				
Class	Building Blocks	Sources	Functions		
INORGANIC					
Water	Hydrogen and oxygen atoms	Absorbed as liquid water or generated by metabolism	Solvent; transport medium for dissolved materials and heat; cooling through evaporation; medium for chemical reactions; reactant in hydrolysis		
Acids, bases, salts	$H^+,OH^-,various$ anions and cations	Obtained from the diet or generated by metabolism	Structural components; buffers; sources of ions		
Dissolved gases	Oxygen, carbon, nitrogen, and atoms of other elements	Atmosphere, metabolism	O2: required for normal cellular metabolism		
			CO ₂ : generated by cells as a waste product		
ORGANIC					
Carbohydrates	C, H, and O; CHO in a 1:2:1 ratio	Obtained from the diet or manufactured in the body	Energy source; some structural role when attached to lipids or proteins; energy storage		
Lipids	C, H, O, sometimes N or P; CHO not in 1:2:1 ratio	Obtained from the diet or manufactured in the body	Energy source; energy storage; insulation; structural components; chemical messengers; protection		
Proteins	C, H, O, N, often S	20 common amino acids; roughly half can be manufactured in the body, others must be obtained from the diet	Catalysts for metabolic reactions; structural components; movement; transport; buffers; defense; control and coordination of activities		
Nucleic acids	C, H, O, N, and P; nucleotides composed of phosphates, sugars, and nitrogenous bases	Obtained from the diet or manufactured in the body	Storage and processing of genetic information		
High-energy compounds	Nucleotides joined to phos- phates by high-energy bonds	Synthesized by all cells	Storage or transfer of energy		

CHECKPOINT

- **28.** Describe ATP.
- **29.** What are the products of the hydrolysis of ATP?

See the blue Answers tab at the back of the book.

2-14 Chemicals form functional units called cells

Learning Outcome Explain the relationship between chemicals and cells.

The human body is more than a random collection of chemicals. The biochemical building blocks discussed in this chapter are the components of *cells*. D p. 34 Each cell behaves like a miniature organism, responding to internal and external stimuli. A lipid membrane separates the cell from its environment, and internal membranes create compartments with specific functions. Proteins form an internal supporting framework and act as enzymes to accelerate and control the chemical reactions that maintain homeostasis. Nucleic acids direct the synthesis of all cellular proteins, including the enzymes that enable the cell to synthesize a wide variety of other substances. Carbohydrates provide energy for vital activities. They also form specialized compounds in combination with proteins or lipids. (In the next chapter we consider the roles of such compounds within a living, functional cell.)

CHECKPOINT

- **30.** Identify six elements common to organic compounds.
- **31.** Identify the biochemical building blocks discussed in this chapter that are the components of cells.
- See the blue Answers tab at the back of the book.

2

RELATED CLINICAL TERMS

familial hypercholesterolemia: A genetic disorder resulting in high cholesterol levels in blood and cholesterol buildup in body tissues, especially the walls of blood vessels.

galactosemia: A metabolic disorder resulting from the lack of an enzyme that converts galactose, a monosaccharide in milk, to glucose within cells. Affected individuals have elevated galactose levels in the blood and urine. High levels of galactose during childhood can cause abnormalities in nervous system development and liver function, and cataracts.

nuclear imaging: A procedure in which an image is created on a photographic plate or video screen by the radiation emitted by injected radioisotopes.

phenylketonuria (PKU): A metabolic disorder resulting from a defect in the enzyme that normally converts the amino acid phenylalanine to tyrosine, another amino acid. If the resulting elevated phenylalanine levels are not detected in infancy, mental delay can result from damage to the developing nervous system. Treatment consists of controlling the amount of phenylalanine in the diet, especially during infancy and early childhood.

radiopharmaceuticals: Drugs that incorporate radioactive atoms; administered to expose specific target tissues to radiation. **tracer:** A radioisotope-labeled compound that can be tracked in

the body by the radiation it releases.

Chapter Review

Summary Outline

An Introduction to the Chemical Level of Organization p. 56

1. Chemistry is the study of *matter* and its interactions.

2-1 Atoms are the basic particles of matter *p. 56*

- **2.** Atoms are the smallest units of matter. They consist of **protons**, **neutrons**, and **electrons**. (*Figure 2-1*)
- **3.** An **element** consists entirely of atoms with the same number of protons (**atomic number**). Within an atom, an **electron cloud** surrounds the nucleus. (*Figure 2-2; Table 2-1*)
- **4.** The **mass number** of an atom is equal to the total number of protons and neutrons in its nucleus. **Isotopes** are atoms of the same element whose nuclei contain different numbers of neutrons. The **atomic weight** of an element is its average mass because it takes into account the abundance of its various isotopes.
- **5.** Electrons occupy a series of **electron shells** around the nucleus. The number of electrons in the outermost electron shell determines an element's chemical properties. *(Figure 2-3)*

2-2 Chemical bonds are forces formed by interactions between atoms *p. 58*

- 6. Atoms can combine through chemical reactions that create chemical bonds. A molecule is any chemical structure consisting of atoms held together by shared electrons. A compound is any chemical substance made up of atoms of two or more different elements in specific proportions.
- **7.** An **ionic bond** results from the attraction between **ions**, which are atoms that have gained or lost electrons. **Cations**

are positively charged ions, and **anions** are negatively charged ions. (*Figure 2-4; Table 2-2*)

- 8. Sharing one pair of electrons creates a single covalent bond; sharing two pairs forms a double covalent bond. An unequal sharing of electrons creates a polar covalent bond. (*Figure 2-5*)
- **9.** A **hydrogen bond** is the attraction between a hydrogen atom with a slight positive charge and a negatively charged atom in another molecule or within the same molecule. Hydrogen bonds can affect the shapes and properties of molecules. (*Figure 2-6*)

2-3 Decomposition, synthesis, and exchange reactions are important chemical reactions in physiology p. 61

- **10. Metabolism** refers to all the **chemical reactions** in the body. Our cells capture, store, and use energy to maintain homeostasis and support essential functions.
- **11.** The rules of **chemical notation** are used to describe chemical compounds and reactions. *(Spotlight Figure 2-7)*
- **12.** Work involves movement of an object or a change in its physical structure, and **energy** is the capacity to perform work. There are two major types of energy: kinetic and potential.
- 13. Kinetic energy is the energy of motion. Potential energy is stored energy that results from the position or structure of an object. Conversions from potential to kinetic energy are not 100 percent efficient; every energy exchange produces heat.
- A chemical reaction may be classified as a decomposition, synthesis, or exchange reaction.

- 15. Cells gain energy to power their functions through catabolism, the breakdown of complex molecules. Much of this energy supports anabolism, the synthesis of new organic molecules.
- **16.** Reversible reactions consist of simultaneous synthesis and decomposition reactions. At **equilibrium** the rates of these two opposing reactions are in balance.

2-4 Enzymes catalyze specific biochemical reactions by lowering a reaction's activation energy *p. 64*

- 17. Activation energy is the amount of energy required to start a reaction. Molecules called enzymes control many chemical reactions within our bodies. Enzymes are catalysts that take part in reactions without themselves being permanently changed. (*Figure 2-8*)
- **18. Exergonic** reactions release energy; **endergonic** reactions absorb energy.

2-5 Inorganic compounds usually lack carbon, and organic compounds always contain carbon *p. 64*

- **19. Nutrients** and **metabolites** can be broadly classified as **organic** or **inorganic compounds**.
- **20.** Living cells in the body consume oxygen and generate carbon dioxide.

2-6 Physiological systems depend on water p. 65

- **21.** Water is the most important inorganic component of the body.
- **22.** Water is an excellent solvent, has a high heat capacity, and participates in the metabolic reactions of the body.
- **23.** Many inorganic compounds undergo **dissociation**, or **ionization**, in water to form ions. (*Figure 2-9*)

2-7 Body fluid pH is vital for homeostasis *p. 66*

- **24.** The **pH** of a solution indicates the concentration of hydrogen ions it contains. Solutions are classified as neutral (pH = 7), acidic (pH < 7), or basic (alkaline) (pH > 7) on the basis of pH. (*Figure 2-10*)
- **25. Buffers** maintain pH within normal limits (7.35–7.45 in most body fluids) by releasing or absorbing hydrogen ions.

2-8 Acids, bases, and salts have important physiological roles *p. 67*

- **26.** An **acid** releases hydrogen ions into a solution, and a **base** removes hydrogen ions from a solution.
- 27. A salt is an ionic compound whose cation is not H⁺ and whose anion is not OH⁻. Acids, bases, and salts are electrolytes, compounds that dissociate in water and conduct an electrical current.

2-9 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio *p. 68*

- **28.** Organic compounds always contain carbon and hydrogen.
- **29. Carbohydrates** are most important as an energy source for metabolic processes. The three major types are **monosac-charides** (simple sugars), **disaccharides**, and **polysac-charides**. (*Figures 2-11, 2-12; Table 2-3*)

2-10 Lipids contain a carbon-to-hydrogen ratio of 1:2 p. 70

- **30.** Lipids are water-insoluble molecules that include fats, oils, and waxes. There are four important classes of lipids: fatty acids, fats, steroids, and phospholipids. (*Table 2-4*)
- **31. Triglycerides (fats)** consist of three fatty acid molecules attached to a molecule of **glycerol**. (*Figures* 2-13, 2-14)
- **32.** Cholesterol is a building block of steroid hormones and is a component of cell membranes. (*Figure 2-15*)
- **33.** Phospholipids are the most abundant components of cell membranes. (*Figure 2-16*)

2-11 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids p. 73

- 34. Proteins perform a great variety of functions in the body.
 Seven important types of proteins include structural proteins, contractile proteins, transport proteins, buffering proteins, enzymes, hormones, and antibodies.
- **35.** Proteins are chains of **amino acids**. Each amino acid consists of an amino group, a carboxyl group, a hydrogen atom, and an R group (variable side chain) attached to a central carbon atom. Amino acids are linked by **peptide bonds**. The sequence of amino acids and the interactions of their R groups influence the final shape of a protein molecule. (*Figures 2-17, 2-18*)
- **36.** The four levels of protein structure are **primary structure** (amino acid sequence), **secondary structure** (amino acid interactions, such as hydrogen bonding), **tertiary structure** (complex folding and interaction with water molecules), and **quaternary structure** (formation of protein complexes from individual subunits). **Fibrous proteins** are tough, durable, and generally insoluble in water. **Globular proteins** are generally rounded and soluble in water. *(Figure 2-18)*
- **37.** The shape of a protein determines its function. Each protein works best at an optimal combination of temperature and pH.
- **38.** The reactants in an enzymatic reaction, called **substrates**, interact to form a **product** by binding to the enzyme at the **active site**. (*Figure 2-19*)

2-12 DNA and RNA are nucleic acids p. 76

39. Nucleic acids store and process information at the molecular level. There are two kinds of nucleic acids: **deoxyribo-nucleic acid (DNA)** and **ribonucleic acid (RNA)**. (*Figure* 2-20; *Table* 2-5)

See the blue Answers tab at the back of the book.

40. Nucleic acids are chains of nucleotides. Each nucleotide contains a sugar, a **phosphate group**, and a **nitrogenous** base. The sugar is always ribose or deoxyribose. The nitrogenous bases found in DNA are adenine, guanine, cytosine, and thymine. In RNA, uracil replaces thymine.

2-13 ATP is a high-energy compound used by cells p. 78

41. Cells store energy in high-energy compounds. The most important high-energy compound is ATP (adenosine

triphosphate). When energy is available, cells make ATP by adding a phosphate group to ADP. When energy is needed, ATP is broken down to ADP and phosphate. (Figures 2-21, 2-22)

42. Biologically important organic compounds are composed of simple structural subunits. (Figure 2-23; Table 2-6)

2-14 Chemicals form functional units called cells p. 80

43. Biochemical building blocks form cells.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN B

COLUMN A

1. atomic number	a. $AB + CD \longrightarrow AD + CB$
2. covalent bond	b. synthesis
3. ionic bond	c. catalyst
4. catabolism	d. sharing of electrons
5. anabolism	e. $A + B \Longrightarrow AB$
6. exchange reaction	f. stabilizes pH
7. reversible reaction	g. number of protons
8. acid	h. decomposition
9. enzyme	i. carbohydrates, lipids, and proteins
10. buffer	j. electrical attraction
11. organic compounds	k. water, NaCl
12. inorganic compounds	I. H^+ donor

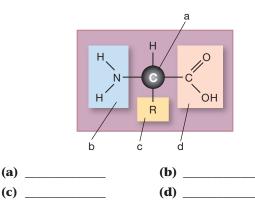

13. An oxygen atom has eight protons. (a) In the following diagram, sketch in the arrangement of electrons around the nucleus of the oxygen atom. (b) How many more electrons will it take to fill the outermost electron shell?

- 14. An element's chemical properties are determined by the
 - (a) number of protons and electrons it has.
 - (b) total number of electrons.
 - (c) number of electrons in its outer shell.
 - (d) number of electron shells.

- **15.** Atoms that share electrons to form a molecule are held by (a) covalent bonds. (b) hydrogen bonds.
 - (c) ionic bonds. (d) double bonds.
- 16. The mass of an atom is the total number of its
 - (a) protons and electrons.
 - (b) protons and neutrons.
 - (c) neutrons and electrons.
 - (d) protons, neutrons, and electrons.
- **17.** Explain how the polysaccharides glycogen and cellulose differ as an energy source for human bodies.
- **18.** Which type of bond exists between the carbon and oxygen atoms in carbon dioxide gas?
- 19. What are the nitrogenous bases found in DNA?
- **20.** List the four levels of structural complexity that proteins can have.

2 21. Identify the components of an amino acid in the following diagram.

Level 2 Reviewing Concepts

- **22.** The mass number of hydrogen (1 proton and 1 electron) is 1, and the mass number of its isotope tritium is 3. How many protons does tritium contain?
 - (a) 1 (b) 2
 - (c) 3 (d) 4
- **23.** Complementary base pairing occurs between
 - (a) cytosine and adenine.
 - (b) cytosine and guanine.
 - (c) cytosine and thymine.
 - (d) cytosine and uracil.
- **24.** The high-energy bonds in adenosine triphosphate are found between
 - (a) adenine and ribose.
 - (b) adenine and phosphate.
 - (c) ribose and phosphate.
 - (d) phosphate groups.
- **25.** Explain the differences among nonpolar covalent bonds, polar covalent bonds, and ionic bonds.
- **26.** What does it mean to say a solution has a neutral pH?
- **27.** How much more acidic or less acidic is a solution of pH 2 compared to one with a pH of 6?
- **28.** An organic molecule contains the following elements: carbon, hydrogen, oxygen, nitrogen, and phosphorus. On the basis of this information, is the molecule a carbohydrate, a lipid, a protein, or a nucleic acid?

Level 3 Critical Thinking and Clinical Applications

- **29.** People with lactose intolerance are deficient in lactase, an enzyme that breaks down lactose. How will the absorption of lactose be affected when they drink milk?
- **30.** An important buffer system in the human body involves carbon dioxide (CO₂), carbonic acid (H₂CO₃), and bicarbonate ions (HCO₃⁻) as shown:

 $CO_2 + H_2O \Longrightarrow H_2CO_3 \Longrightarrow H^+ + HCO_3^-$

If a person becomes excited and exhales large amounts of CO₂, how will his or her body's pH be affected?

Cell Structure and Function

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **3-1** List the main points of the cell theory.
- **3-2** Describe the functions of the plasma membrane and the structures that enable it to perform those functions.
- **3-3** Describe the processes of cellular diffusion and osmosis, and explain their physiological roles.
- **3-4** Describe carrier-mediated transport and vesicular transport processes used by cells to absorb or remove specific substances.
- **3-5** Describe the organelles of a typical cell and indicate their specific functions.
- **3-6** Explain the functions of the cell nucleus.
- **3-7** Summarize the process of protein synthesis.
- **3-8** Describe the stages of the cell life cycle, including interphase, mitosis, and cytokinesis, and explain their significance.
- **3-9** Discuss the relationship between cell division and cancer.
- **3-10** Define cellular differentiation, and explain its importance.

Clinical Notes

Spotlights

Anatomy of a Model Cell, pp. 88–89 Protein Synthesis, Processing, and Packaging, pp. 104–105

An Introduction to Cell Structure and Function

Cells are very small. A typical cell is only about 0.1 mm in diameter, similar to the thickness of a human hair. As a result, no one could actually examine the structure of a cell until effective microscopes were invented in the 17th century. In 1665, Robert Hooke inspected thin slices of cork and found that they were made up of millions of small, walled openings. Hooke used the term *cell* because the many, small bare spaces reminded him of the rooms, or cells, in a prison or monastery. Hooke saw only the outlines of cells, not the cells themselves, but he stimulated interest in the microscopic world and the nature of cellular life that continues to this day.

Build Your Knowledge

The Build Your Knowledge feature reminds you of what you already know and prepares you to learn new material. Be sure to read every Build Your Knowledge box or page so that you can build your knowledge—and confidence!

Recall that cells are the smallest living units that exhibit the basic functions of living things—responsiveness, growth, reproduction, movement, and metabolism (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). Cells make up the cellular level of organization in the human body. **Dp. 34**

3-1 The study of cells provides the foundation for understanding human physiology

Learning Outcome List the main points of the cell theory.

Just as atoms are the building blocks of molecules, **cells** are the building blocks of the human body. Over the years, biologists have developed the **cell theory**, which includes the following four basic concepts:

- **1.** Cells are the building blocks of all plants and animals.
- 2. Cells are the smallest functioning units of life.
- **3.** Cells are produced through the division of preexisting cells.
- 4. Each cell maintains homeostasis.

An individual organism maintains homeostasis only through the combined and coordinated actions of many different types of cells. **Figure 3-1** shows some of the variety of cell shapes and sizes in the human body.

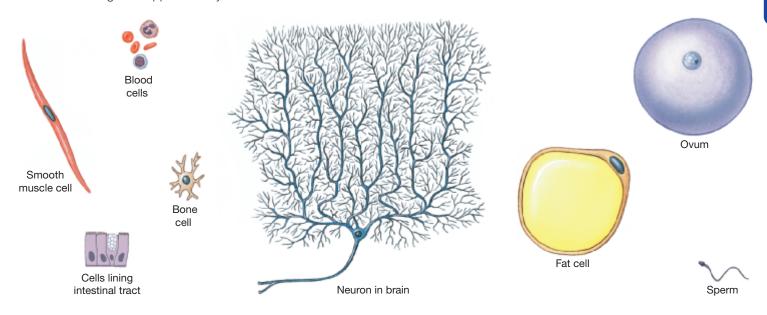

Numbering in the trillions, human body cells form anatomical structures and maintain them. Our cells allow us to perform activities as different as running and thinking. Thus an understanding of how the human body functions requires a familiarity with the nature of cells.

The Study of Cells

The study of the structure and function of cells is called **cytology** (sī-TOL-ō-jē; *cyto-*, cell + *-logy*, the study of). What we have learned over the last 60 years has provided new insights into the physiology of cells and their means of homeostatic control. This knowledge resulted from improved equipment for viewing cells and new experimental techniques. It came not only from biology but also from chemistry and physics.

The two most common methods used to study cell and tissue structure are light microscopy and electron microscopy. Before the 1950s, cells were viewed through light microscopes. Using a series of glass lenses, *light microscopy* can magnify cellular structures about 1000 times. Light microscopy typically involves looking at thin sections sliced from a larger piece of tissue. A photograph taken through a light microscope is called a *light micrograph* (*LM*).

Many fine details of cell structure are too small to be seen with a light microscope. These details remained a mystery until cell biologists began using *electron microscopy*, a technique that replaced light with a focused beam of electrons. *Transmission electron micrographs* (*TEMs*) are photographs of very thin sections (slices), and they can reveal fine details of cell membranes and structures within the cell. Figure 3-1 The Diversity of Cells in the Human Body. The cell types shown here have the dimensions they would have if magnified approximately 500 times.

Scanning electron micrographs (SEMs) provide less magnification but reveal the three-dimensional nature of cell structures. An SEM provides a surface view of a cell, a portion of a cell, or structures outside the cell rather than a detailed sectional view.

You will see examples of light micrographs and both kinds of electron micrographs in figures throughout this text. The abbreviations LM, TEM, and SEM are followed by a number that tells you the total magnification of the image. For example, "LM \times 160" indicates that the structures shown in a light micrograph have been magnified 160 times.

An Overview of Cell Anatomy

The "typical" cell is like the "average" person: Any such description masks enormous individual variations. Our representative, or model, cell shares features with most cells of the body without being identical to any specific one. **Spotlight Figure 3-2** summarizes the structures and functions of a model cell. We will refer to it during our discussion of the parts of a cell.

We begin our discussion of the cell with its **plasma membrane**, or **cell membrane**, which separates the cell contents, or **cytoplasm**, from its watery, surrounding environment. As noted in **Spotlight Figure 3-2**, this watery environment is called *extracellular fluid*. We then consider some of the ways cells interact with their external environment, as well as the activities of their specialized structures. We conclude with how typical body cells reproduce.

CHECKPOINT

- **1.** The cell theory was developed over many years. What are its four basic concepts?
- 2. The study of cells is called _____
- See the blue Answers tab at the back of the book.

3-2 The plasma membrane separates the cell from its surrounding environment and performs various functions

Learning Outcome Describe the functions of the plasma membrane and the structures that enable it to perform those functions.

We begin our look at cell structure with the plasma membrane. Its general functions include:

- *Physical isolation.* The plasma membrane is a physical barrier that separates the inside of the cell from the surrounding extracellular fluid. Conditions inside and outside the cell are very different. Those differences must be maintained to preserve homeostasis.
- *Regulation of exchange with the environment.* The plasma membrane controls the entry of ions and nutrients, the elimination of wastes, and the release of secretions.
- **Sensitivity to the environment.** The plasma membrane is the first part of the cell affected by changes in the extracellular fluid. It also contains a variety of molecules that act as receptors, enabling the cell to recognize and respond to specific molecules in its environment.

SPOTLIGHT Figure 3-2 ANATOMY OF A MODEL CELL

In our model cell, a *plasma membrane* separates the cell contents, called the *cytoplasm*, from its surroundings. The cytoplasm can be subdivided into the *cytosol*, or intracellular fluid, and intracellular structures collectively known as *organelles* (or-ga-NELZ). Organelles are structures suspended within the cytosol that perform specific functions within the cell and can be further subdivided into membranous and nonmembranous organelles. Cells are surrounded by a watery medium known as the **extracellular** fluid. The extracellular fluid in most tissues is called **interstitial** (in-ter-STISH-ul) **fluid**.

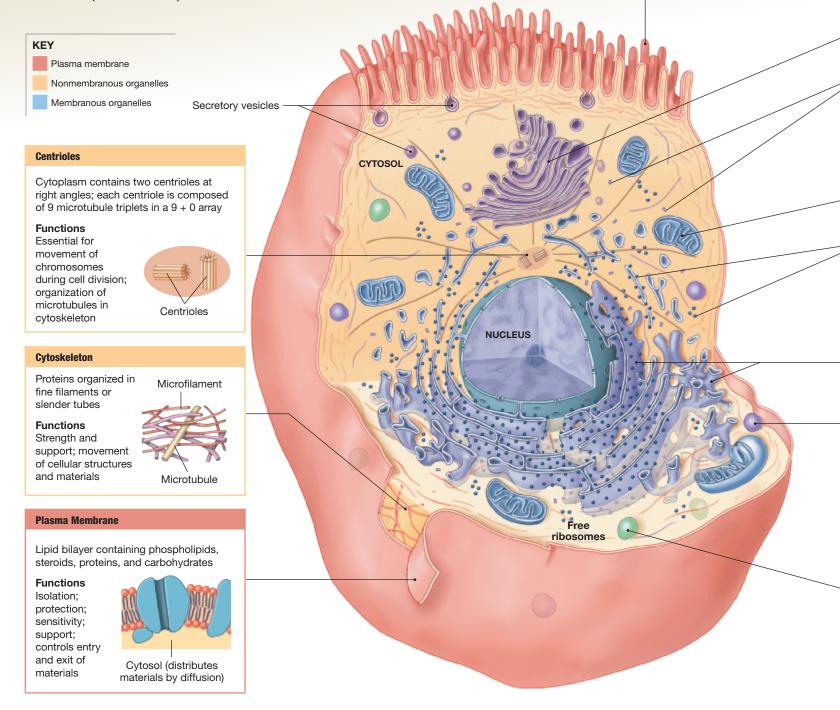

Microvilli

Plasma membrane extensions containing microfilaments

Function

Increase surface area to aid absorption of extracellular materials

Cilia (not shown in model cell)

Cilia are long extensions of the plasma membrane containing microtubules. There are two types: motile and primary.

Multiple motile cilia move materials over cell surfaces. A solitary primary cilium acts as a sensor.

Proteasomes

Functions Breakdown and

Function

Hollow cylinders of proteolytic enzymes with regulatory proteins at their ends

recycling of damaged or abnormal intracellular proteins

Peroxisomes

Functions

Vesicles containing

degradative enzymes

of toxic compounds

Catabolism of fatty acids and other organic compounds, neutralization

generated in the process

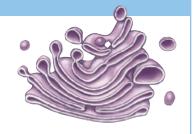

RNA + proteins; fixed ribosomes bound to rough endoplasmic reticulum, free ribosomes scattered in cytoplasm Function Protein synthesis

Golgi apparatus

Stacks of flattened membranes (cisternae) containing chambers

Functions

Storage, alteration, and packaging of secretory products and lysosomal enzymes

Mitochondria

Double membrane, with inner membrane folds (cristae) enclosing important metabolic enzymes

Functions Produce 95% of the ATP required by the cell

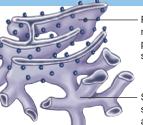

channels extending throughout the cytoplasm

Functions

Synthesis of secretory products; intracellular storage and transport

Network of membranous

Rough ER modifies and packages newly synthesized proteins

Smooth ER synthesizes lipids and carbohydrates

Chromatin Nuclear envelope NUCLEOPLASM Nucleolus (site of rRNA synthesis and assembly of ribosomal subunits) Nuclear pore

NUCLEUS

Nucleoplasm containing nucleotides, enzymes, nucleoproteins, and chromatin; surrounded by a double membrane, the nuclear envelope

Functions

Control of metabolism; storage and processing of genetic information; control of protein synthesis

Lysosomes

Vesicles containing digestive enzymes

Functions

Intracellular removal of damaged organelles or pathogens

• **Structural support.** Specialized connections between plasma membranes, or between membranes and materials outside the cell, give tissues a stable structure.

The plasma membrane is extremely thin, ranging from 6 nm to 10 nm in thickness. This membrane contains lipids, proteins, and carbohydrates (**Figure 3-3**).

Membrane Lipids

Phospholipids are a major component of plasma membranes. \bigcirc p. 72 In a phospholipid, a phosphate group (PO₄³⁻) serves as a link between a diglyceride (a glycerol molecule bonded to two fatty acid "tails") and a nonlipid "head."

The phospholipids in a plasma membrane lie in two distinct layers. For this reason, the plasma membrane is called a **phospholipid bilayer** (Figure 3-3). In each half of the bilayer, the phospholipids lie with their heads at the membrane surface and their tails on the inside. The heads are soluble in water, or **hydrophilic** (hī-drō-FŌ-lik; *hydro-*, water + *philos*, loving). The tails are insoluble in water, or **hydrophobic** (hī-drō-FŌB-ik; *hydro-*, + *phobos*, fear). In this arrangement, the hydrophilic heads of the two layers are in contact with watery environments on both sides of the membrane—the extracellular fluid on the outside of the cell and the *intracellular fluid* on the inside of the cell.

The hydrophobic lipid tails will not associate with water or charged molecules. This characteristic enables the plasma membrane to act as a selective physical barrier. Lipid-soluble molecules and compounds such as oxygen and carbon dioxide are able to cross the lipid portion of a plasma membrane, but ions and water-soluble compounds cannot pass. As a result, the plasma membrane isolates the cytoplasm from the surrounding extracellular fluid.

Mixed in with the fatty acid tails are cholesterol molecules and small quantities of other lipids. Cholesterol is present in a ratio of almost one cholesterol molecule for each phospholipid molecule. \bigcirc p. 72 Cholesterol "stiffens" the plasma membrane, making it less fluid and less permeable.

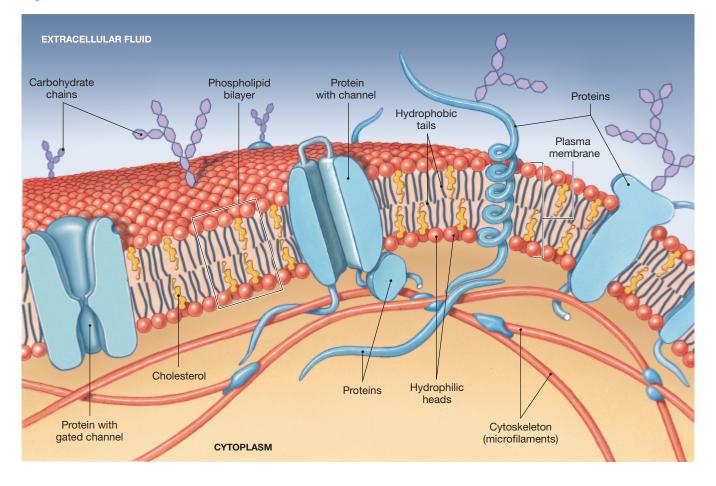

Figure 3-3 The Plasma Membrane.

3

3

Table 3-1	Types of Membrane Proteins			
Class	Function	Example		
Receptor proteins	Sensitive to specific extracellular materials that bind to them and trigger a change in a cell's activity.	Binding of the hormone insulin to membrane receptors increases the rate of glucose absorption by the cell.		
Channel proteins	Form a central pore, or channel, that permits water, ions, and other solutes to bypass lipid portion of plasma membrane.	Calcium ion movement through channel proteins is crucial to muscle contraction and the propagation of nerve impulses.		
Carrier proteins	Bind and transport solutes across the plasma membrane. This process may or may not require ATP energy.	Carrier proteins bring glucose into the cytoplasm and also transport sodium, potassium, and calcium ions into and out of the cell.		
Enzymes	Catalyze reactions in the extracellular fluid or cytosol (intracellular fluid).	Dipeptides are broken down into amino acids by enzymes on exposed membranes of cells lining the intestinal tract.		
Anchoring protein	s Attach the plasma membrane to other structures and stabilize its position.	Inside the cell, anchor proteins bind to the cytoskeleton (netwo of supporting filaments). Outside the cell, anchor proteins atta the cell to extracellular protein fibers or to another cell.		
Recognition prote (Identifiers)	ins Identify a cell as self or nonself, normal or abnormal, to the immune system.	One group of such recognition proteins is the major histocomp ibility complex (MHC) (discussed in Chapter 14: The Lymphatic System and Immunity).		

Membrane Proteins

Several types of proteins are associated with the plasma membrane. The most common of these membrane proteins span the width of the membrane one or more times and are known as *transmembrane proteins*. Other membrane proteins are either partially embedded in the membrane's phospholipid bilayer or loosely bound to its inner or outer surface. Membrane proteins may function as *receptors*, *channels*, *carriers*, *enzymes*, *anchors*, or *identifiers*. **Table 3-1** provides a functional description and an example of each class of membrane protein.

Plasma membranes are not rigid, and their inner and outer surfaces differ in structure. Some embedded proteins always remain in specific areas of the membrane, but others drift from place to place along its surface like ice cubes in a punch bowl. In addition, the composition of the plasma membrane can change over time, as components of the membrane are added or removed.

Membrane Carbohydrates

Carbohydrates join with proteins and lipids to form complex molecules on the outer surface of the membrane. These complex molecules are known as *glycoproteins* and *glycolipids*. The carbohydrate portions function as cell lubricants and adhesives and act as receptors for compounds outside the cell. They also form part of a recognition system that keeps the immune system from attacking the body's own cells and tissues.

CHECKPOINT

- 3. List the general functions of the plasma membrane.
- **4.** Which component of the plasma membrane is primarily responsible for forming a physical barrier between the cell's internal and external environments?
- **5.** Which functional class of membrane proteins allows water and small ions to cross the plasma membrane?
- See the blue Answers tab at the back of the book.

3-3 Diffusion is a passive transport process that assists membrane passage

Learning Outcome Describe the processes of cellular diffusion and osmosis, and explain their physiological roles.

Permeability refers to the ease with which substances can cross a membrane. It is the property of the plasma membrane that determines precisely which substances can enter or leave the cytoplasm. If nothing can cross a membrane, it is described as **impermeable**. If any substance can cross without difficulty, the membrane is **freely permeable**. Plasma membranes are **selectively permeable**, permitting the free passage of some materials and restricting the passage of others. Whether or not a substance can cross the plasma membrane is based on the substance's size, electrical charge, molecular shape, lipid solubility, or some combination of these factors.

Movement across the membrane may be passive or active. **Passive processes** move ions or molecules across the plasma

membrane without any energy expenditure by the cell. **Active processes** require that the cell expend energy, generally from adenosine triphosphate (ATP). \supset p. 78

In this section we consider the passive process of *diffusion*, including a special type of diffusion called *osmosis*. In the next section we will examine some types of *carrier-mediated transport*, which includes both active and passive processes. We will consider *facilitated diffusion*, a passive carrier-mediated process, and *active transport*, an active carrier-mediated process. Finally, we will examine two active processes involving *vesicular transport*: endocytosis and exocytosis.

Diffusion

Ions and molecules are in constant motion, randomly colliding and bouncing off one another and off obstacles in their paths. Over time, one result of this motion is that the molecules in a given space tend to become evenly distributed, or spread out. **Diffusion** is the movement of molecules from an area of relatively high concentration (of many collisions) to an area of relatively low concentration (of fewer collisions). The difference between the high and low concentrations represents a **concentration gradient**. Diffusion is often described as proceeding "down a concentration gradient" or "downhill." As a result of diffusion, molecules eventually become uniformly distributed, and concentration gradients are eliminated. Diffusion in air and water is slow. It is most important over very short distances. A simple, everyday example can give you a mental image of how diffusion works. Think about a colored sugar cube dropped into a beaker of water (**Figure 3-4**). As the cube dissolves, its sugar and dye molecules set up a steep concentration gradient with the surrounding clear water. Eventually, dissolved molecules of both types spread through the water until they are distributed evenly. (However, compared to a cell, a beaker of water is enormous. Additional factors which we will ignore—account for dye and sugar distribution over distances of centimeters as opposed to micrometers.)

Diffusion is important in body fluids because it tends to eliminate local concentration gradients. For example, every cell in your body generates carbon dioxide, and its intracellular (within the cell) concentration is relatively high. Carbon dioxide concentrations are lower in the surrounding extracellular fluid, and lower still in the circulating blood. Plasma membranes are freely permeable to carbon dioxide. As a result, carbon dioxide diffuses down its concentration gradient, traveling from the cell's interior into the surrounding interstitial fluid, and then into the bloodstream, for delivery to the lungs.

Diffusion across Plasma Membranes

In extracellular fluids of the body, water and dissolved solutes diffuse freely. A plasma membrane, however, acts as a barrier that selectively restricts diffusion. Some substances can pass through

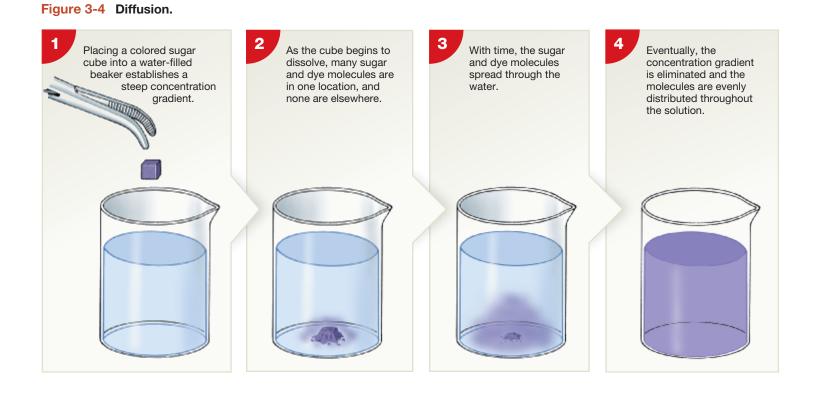

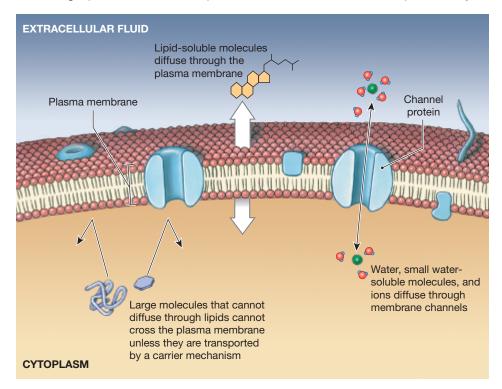

Figure 3-5 Diffusion across the Plasma Membrane. The path a substance takes in crossing a plasma membrane depends on the substance's size and lipid solubility.

easily, but others cannot penetrate the membrane at all. An ion or molecule can independently diffuse across a plasma membrane only by (1) crossing the lipid portion of the membrane or (2) passing through a channel protein in the membrane. For this reason, the primary factors determining whether a substance can diffuse across a plasma membrane are its lipid solubility and its size relative to the sizes of membrane channels (**Figure 3-5**).

Alcohol, fatty acids, and steroids can enter cells easily because they can diffuse through the lipid portions of the membrane. Lipid-soluble drugs and dissolved gases such as oxygen and carbon dioxide also enter and leave cells by diffusing through the phospholipid bilayer.

Ions and most water-soluble compounds are not lipid soluble, so they must pass through membrane channels to enter the cytoplasm. These channels are very small, about 0.8 nm in diameter. Water molecules can enter or exit these channels freely, as can ions such as sodium and potassium. Water molecules may also enter or leave the cytoplasm through water channels called *aquaporins*. However, even a small organic molecule, such as glucose, is too big to fit through the channels.

Osmosis: A Special Case of Diffusion

The diffusion of water across a selectively permeable membrane is called **osmosis** (oz-MŌ-sis; *osmos*, thrust). Both intracellular and extracellular fluids are solutions that contain a variety of dissolved materials, or solutes. \bigcirc p. 65 Each solute tends to diffuse as if it were the only substance in solution. Thus, changes in the concentration of potassium ions, for example, have no effect on the rate or direction of sodium ion diffusion. Some ions and molecules (solutes) diffuse into the cytoplasm, others diffuse out, and a few, such as proteins, are unable to diffuse across a plasma membrane. Yet if we ignore the individual identities and simply count ions and molecules, we find that the total concentration of ions and molecules on either side of the plasma membrane stays the same.

Why does this state of solute equilibrium persist? The reason is because *the plasma membrane is freely permeable to water.* Whenever a solute concentration gradient exists across a plasma membrane, a concentration gradient for water exists also. Dissolved solute molecules occupy space that would otherwise be taken up by water molecules, so the higher the

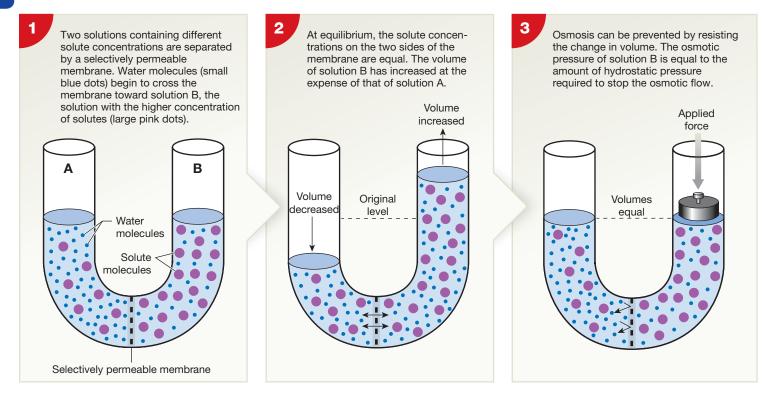

solute concentration, the lower the water concentration. As a result, *water molecules tend to flow across a membrane toward the solution containing the higher solute concentration*. This movement is down the concentration gradient for water molecules. Water will move until water concentrations—and thus, solute concentrations—are the same on either side of the membrane.

Three characteristics of osmosis are important to remember:

- **1.** Osmosis is the diffusion of water molecules across a selectively permeable membrane.
- **2.** Osmosis takes place across a selectively permeable membrane that is freely permeable to water but is not freely permeable to solutes.
- **3.** In osmosis, water flows across a selectively permeable membrane toward the solution that has the higher concentration of solutes, because that is where the concentration of water is lower.

OSMOSIS AND OSMOTIC PRESSURE. Figure 3-6 diagrams the process of osmosis. 1 shows two solutions (A and B), with different solute concentrations, separated by a selectively permeable membrane. As osmosis takes place, water molecules cross the membrane until the solute concentrations in the two solutions are identical 2. Thus, the volume of solution B increases

Figure 3-6 Osmosis. The osmotic flow of water can create osmotic pressure across a selectively permeable membrane. The osmotic pressure of solution B is equal to the amount of hydrostatic pressure required to stop the osmotic flow.

while that of solution A decreases. The greater the initial difference in solute concentrations, the stronger is the osmotic flow.

The **osmotic pressure** of a solution is an indication of the force of water movement *into that solution* as a result of solute concentration. As the solute concentration of a solution increases, so does its osmotic pressure. Osmotic pressure can be measured in several ways. For example, an opposing pressure can prevent the entry of water molecules. Pushing against a fluid generates *hydrostatic pressure*. In (3), hydrostatic pressure opposes the osmotic pressure of solution B, so no net osmotic flow takes place.

Solutions of various solute concentrations are described as *isotonic, hypotonic,* or *hypertonic* with regard to their effects on the shape or tension of the plasma membrane of living cells. The effects of various osmotic solutions are difficult to see in most tissues, but they are readily seen in red blood cells (RBCs) (**Figure 3-7**).

In an **isotonic** (*iso-*, equal + *tonos*, tension) solution—one that does not cause a net movement of water into or out of the cell—red blood cells retain their normal dimpled appearance (**Figure 3-7a**). In this case, an equilibrium exists: As one water molecule moves out of the cell, another moves in to replace it.

When a red blood cell is placed in a **hypotonic** (*hypo-,* below) solution, water will flow into the cell, causing it to swell

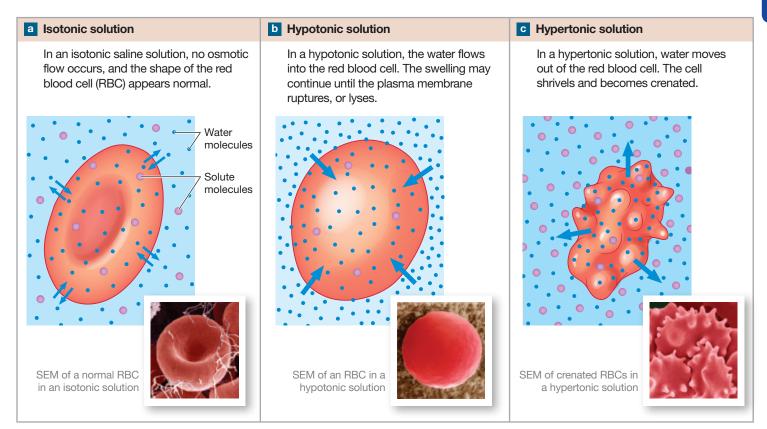

up like a balloon (**Figure 3-7b**). Eventually the cell may burst, or *lyse*. In the case of red blood cells, this event is known as **hemolysis** (*hemo-*, blood + *lysis*, a loosening).

Red blood cells in a **hypertonic** (*hyper-*, above) solution will lose water by osmosis. As they do, they shrivel and dehydrate. The shrinking of red blood cells is called **crenation** (**Figure 3-7c**).

Build Your Knowledge

Recall that water is an excellent solvent (as you saw in **Chapter 2: The Chemical Level of Organization**). This property is due to the polar nature of water molecules. As a result of their polarity, water molecules can surround ions and keep them in solution by preventing ionic bonds from forming. Because of hydrogen bonding, water molecules can also link with many organic molecules containing polar covalent bonds and keep them in solution. **D p. 60** As a solvent that can diffuse through selectively permeable membranes, water also affects the osmotic pressure of living cells. **D p. 65**

Figure 3-7 Osmotic Flow across a Plasma Membrane. The smaller paired arrows indicate an equilibrium and no net water movement. The larger arrows indicate the direction of osmotic water movement.

It is often necessary to give patients large volumes of fluid after severe blood loss or dehydration. One fluid frequently administered is a 0.9 percent (0.9 g/dL) solution of sodium chloride (NaCl). This solution approximates the normal *osmotic concentration* (total solute concentration) of extracellular fluids and is called *normal saline*. It is used because sodium and chloride are the most abundant ions in the body's extracellular fluid. Little net movement of either type of ion occurs across plasma membranes, so normal saline is essentially isotonic with respect to body cells.

CHECKPOINT

- **6.** What is meant by "selectively permeable," when referring to a plasma membrane?
- 7. Define diffusion.
- **8.** How would a decrease in the concentration of oxygen in the lungs affect the diffusion of oxygen into the blood?
- 9. Define osmosis.
- **10.** Relative to a surrounding hypertonic solution, the cytosol of a red blood cell is _____.

See the blue Answers tab at the back of the book.

3-4 Carrier-mediated and vesicular transport processes assist membrane passage

Learning Outcome Describe carrier-mediated transport and vesicular transport processes used by cells to absorb or remove specific substances.

Besides diffusion, substances are brought into or removed from cells in two additional ways. *Carrier-mediated transport* uses specialized membrane proteins. It can be passive or active, depending on the substance being moved and the nature of the transport process. *Vesicular transport* involves the movement of materials within small membrane-enclosed sacs, or *vesicles*. Vesicular transport is always an active process.

Carrier-Mediated Transport

In **carrier-mediated transport**, membrane proteins bind specific ions or organic substrates and carry them across the plasma membrane. These proteins share several characteristics with enzymes. They may be used repeatedly, and they can only bind to specific substrates. For example, the carrier protein that transports glucose will not carry other simple sugars. Carrier-mediated transport can be passive (no ATP required) or active (ATP dependent). In *passive transport*, solutes are typically carried from an area of high concentration to an area of low concentration. *Active transport* may follow or oppose an existing concentration gradient.

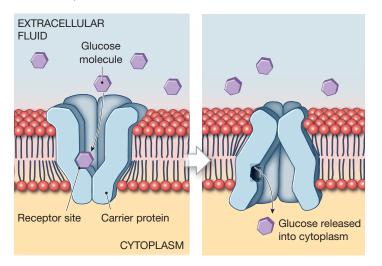

Many carrier proteins transport one ion or molecule at a time, but some move two solutes simultaneously. In *cotransport,* the carrier transports the two substances in the same direction, either into or out of the cell. In *countertransport,* one substance is moved into the cell while the other is moved out. Next we discuss two major examples of carrier-mediated transport—*facilitated diffusion* and *active transport.*

Facilitated Diffusion

Many essential nutrients, including glucose and amino acids, are insoluble in lipids and too large to fit through membrane channels. However, these compounds can be passively transported across the membrane by carrier proteins in a process called **facilitated diffusion** (**Figure 3-8**). First, the molecule to be transported binds to a **receptor site** on the carrier protein. The shape of the protein then changes, moving the molecule across the plasma membrane and releasing it into the cytoplasm. This process takes place without ever creating a continuous open channel between the cell's exterior and interior.

Just as in the process of diffusion across a plasma membrane, no ATP is expended in facilitated diffusion. In each case, molecules move from an area of higher concentration to one of lower concentration. However, facilitated diffusion also differs from simple diffusion. The rate of transport cannot increase indefinitely. The reason is that only a limited number

Figure 3-8 Facilitated Diffusion. In this process, an extracellular molecule, such as glucose, binds to a specific receptor site on a carrier protein. This binding permits the molecule to diffuse across the plasma membrane.

Build Your Knowledge

Recall that cations are atoms that have lost an electron and so have a positive electrical charge (as you saw in **Chapter 2: The Chemical Level of Organization**). Atoms that have gained electrons have a negative electrical charge and are called anions. ⊃ **p. 58**

of carrier proteins are available in the membrane. Once all of them are operating, any further increase in the solute concentration in the extracellular fluid will have no effect on the rate of movement into the cell.

Active Transport

In **active transport**, the high-energy bond in ATP provides the energy needed to move ions or molecules across the membrane. Despite the energy cost, active transport offers one great advantage: It is not dependent on a concentration gradient. This means that the cell can import or export specific materials *regardless of their intracellular or extracellular concentrations*.

All cells contain carrier proteins called **ion pumps** that actively transport the cations sodium (Na⁺), potassium (K⁺), calcium (Ca²⁺), and magnesium (Mg²⁺) across plasma membranes. Specialized cells have carrier proteins that can transport other ions, including iodide (I⁻), chloride (CI⁻), and iron (Fe²⁺). Many of these carrier proteins move a specific cation or anion in one direction only, either into or out of the cell. In a few cases, one carrier protein will move more than one ion at a time. The carrier protein is called an **exchange pump** if one kind of ion is moved in one direction and the other is moved in the opposite direction (countertransport).

A major function of exchange pumps is to maintain cell homeostasis. Sodium and potassium ions are the principal cations in body fluids. Sodium ion concentrations are high in the extracellular fluids but low in the cytoplasm. The distribution of potassium in the body is just the opposite—low in the extracellular fluids and high in the cytoplasm. Because of the presence of channel proteins in the membrane that are always open (so-called *leak channels*), sodium ions slowly diffuse into the cell, and potassium ions diffuse out.

Homeostasis within the cell depends on maintaining sodium and potassium ion concentration gradients with the extracellular fluid. The **sodium-potassium exchange pump** maintains these gradients by ejecting sodium ions and recapturing lost potassium ions (**Figure 3-9**). For each ATP molecule consumed, the pump ejects three sodium ions and recaptures

Figure 3-9 The Sodium–Potassium Exchange Pump. The operation of the sodium–potassium exchange pump is an example of active transport. For each ATP converted to ADP, this carrier protein pump carries three Na⁺ out of the cell and two K⁺ into the cell.

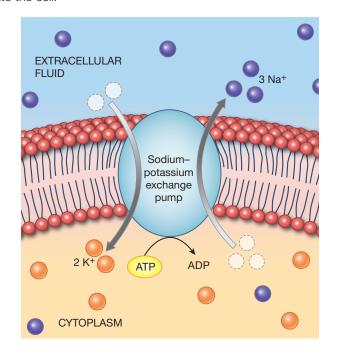

Figure 3-10 Receptor-Mediated Endocytosis.

two potassium ions. The energy demands are impressive: The sodium–potassium exchange pump may use up to 40 percent of the ATP produced by a resting cell!

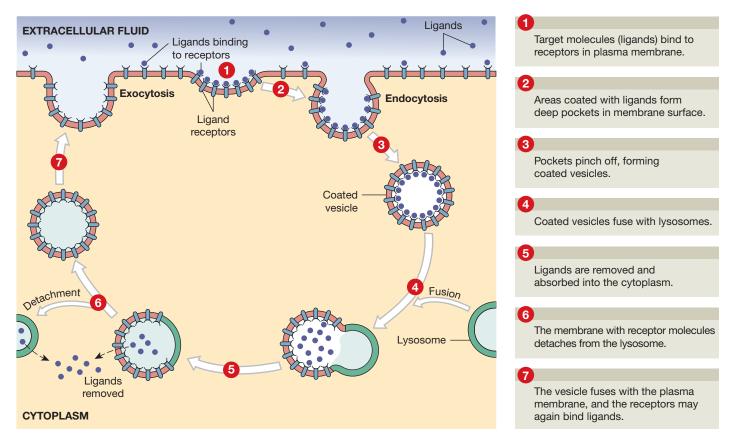

Vesicular Transport

In **vesicular transport**, materials move into or out of the cell in vesicles, small membrane-enclosed sacs that form at, or fuse with, the plasma membrane. The two major kinds of vesicular transport are *endocytosis* and *exocytosis*.

Endocytosis

The process called **endocytosis** (EN-dō-sī-TŌ-sis; *endo-*, inside + cyte, cell) is the packaging of extracellular materials in a vesicle at the cell surface for import *into* the cell. Relatively large volumes of extracellular material may be involved. There are three major types of endocytosis: *receptor-mediated endocytosis*, *pinocytosis*, and *phagocytosis*. All three are active processes that require ATP or other sources of energy.

• **Receptor-mediated endocytosis** produces vesicles containing a specific target molecule in high concentrations. Receptor-mediated endocytosis begins when molecules in the extracellular fluid bind to receptors on the plasma membrane surface (**Figure 3-10**). The receptors bind to

specific target molecules, called **ligands** (LĪ-gandz), such as a transport protein (described below) or hormone, and then cluster together on the plasma membrane. The area of the membrane with the bound receptors pinches off to form a vesicle. This vesicle is surrounded by the cytoplasmic surface of the plasma membrane and is called a *coated vesicle*.

Many important substances, such as cholesterol and iron ions (Fe²⁺), are carried throughout the body attached to special transport proteins. These transport proteins are too large to pass through membrane channels but can enter cells through receptor-mediated endocytosis.

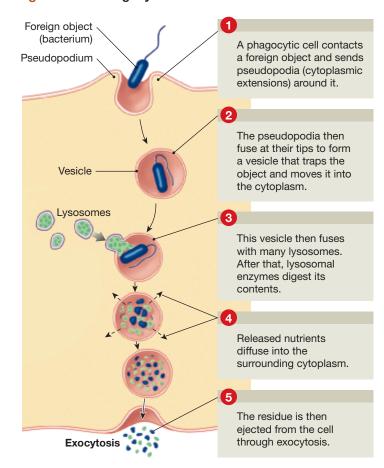

- **Pinocytosis** (pi-nō-sī-TŌ-sis; *pinein*, to drink), or "cell drinking," is the formation of small vesicles filled with extracellular fluid. This process is common to most cells. A deep groove or pocket forms in the plasma membrane and then pinches off. No receptor proteins are involved. For this reason, pinocytosis is not as selective a process as receptor-mediated endocytosis.
- *Phagocytosis* (FAG-ō-sī-TŌ-sis; *phagein*, to eat), or "cell eating," produces vesicles containing solid objects that may be as large as the cell itself (Figure 3-11). Cytoplasmic extensions called **pseudopodia** (soo-dō- PŌ-dē-ah; *pseudo-*, false + *podon*, foot) surround the object, and their membranes fuse to form a vesicle. This vesicle then fuses with many *lysosomes*. The vesicle contents are broken down by the lysosomal digestive enzymes.

Most cells carry out pinocytosis, but phagocytosis is performed only by specialized cells that protect tissues by engulfing bacteria, cell debris, and other abnormal materials. (We will consider phagocytic cells in chapters dealing with blood cells [Chapter 11] and the immune response [Chapter 14].)

Exocytosis

The process called **exocytosis** (ek-sō-sī-TŌ-sis; *exo-*, outside) is the functional reverse of endocytosis. In exocytosis, a vesicle created inside the cell fuses with the plasma membrane and discharges its contents into the extracellular environment. The ejected material may be secretory products such as a *hormone* (a compound that circulates in the blood and affects cells in other parts of the body) or mucus components, or waste products from the recycling of damaged organelles.

Figure 3-11 Phagocytosis.

At any given moment, various transport processes are moving materials into and out of the cell. These processes are summarized in **Table 3-2**.

CHECKPOINT

- **11.** What is the difference between active and passive transport processes?
- 12. During digestion, the concentration of hydrogen ions (H⁺) in the stomach rises to many times that within the cells lining the stomach, where H⁺ are produced. Is the type of transport process involved passive or active?
- **13.** When certain types of white blood cells encounter bacteria, they are able to engulf them and bring them into the cell. What is this process called?

See the blue Answers tab at the back of the book.

3

Table 3-2 A Summary of Passive and Active Membrane Transport Processes				
Process	Description	Factors Affecting Rate of Movement	Substances Involved	
DIFFUSION	Passive: molecular movement of solutes; direction determined by relative concentrations	Steepness of concentration gradient, molecular size, electric charge, lipid solubility, temperature, and presence of channel proteins	Small inorganic ions; most gases and lipid-soluble materials (all cells)	
Osmosis	Passive; movement of water molecules toward solution containing a relatively higher solute concentration across a selectively permeable membrane	Concentration gradient, opposing osmotic or hydrostatic pressure	Water only (all cells)	
CARRIER-MEDIATED TRANSPORT				
Facilitated diffusion	 Passive; carrier proteins passively transport solutes down a concentration gradient 	Steepness of gradient, temperature, and availability of carrier proteins	Glucose and amino acids (all cells)	
Active transport	Active: carrier proteins actively transport solutes regardless of any concentration gradients	Availability of carrier proteins, substrate, and ATP	Na ⁺ , K ⁺ , Ca ²⁺ , Mg ²⁺ (all cells); other solutes by specialized cells	
VESICULAR TRANSPORT				
Endocytosis	Active; formation of vesicles containing extracellular fluid or solid material	Type depends on substance being moved into cell; requires ATP	Fluids, nutrients (all cells); debris, pathogens (specialized cells)	
Exocytosis	Active; fusion of intracellular vesicles with plasma membrane to release fluids and/or solids from the cell	Type depends on substance being carried; requires ATP	Fluids, debris (all cells)	

3-5 Organelles within the cytoplasm perform specific functions

Learning Outcome Describe the organelles of a typical cell and indicate their specific functions.

Cytoplasm is a general term for the material between the plasma membrane and the membrane that surrounds the nucleus. The cytoplasm contains cytosol and organelles.

The Cytosol

The **cytosol**, or *intracellular fluid*, contains dissolved nutrients, ions, soluble and insoluble proteins, and waste products. The most important differences between the cytosol and the extracellular fluid that surrounds most of the cells in the body are as follows:

- **Potassium and sodium ions.** The concentration of potassium ions is higher in the cytosol than in the extracellular fluid. Conversely, the concentration of sodium ions is much lower in the cytosol than in the extracellular fluid.
- **Proteins.** The cytosol contains a higher concentration of suspended proteins than does the extracellular fluid. Many of the proteins are enzymes that regulate metabolic operations. Others are associated with various structures within the cell. These proteins give the cytosol a consistency that varies between that of thin maple syrup and almost-set gelatin.

• **Carbohydrates, amino acids, and lipids.** The cytosol usually contains small quantities of carbohydrates and small reserves of amino acids and lipids. The extracellular fluid is a transport medium only, and no amino acids or lipids are stored there. The carbohydrates are broken down to provide energy, and the amino acids are used to manufacture proteins. The lipids are used primarily as an energy source when carbohydrates are unavailable.

The cytosol may also contain insoluble materials known as **inclusions**. Examples include stored nutrients (such as glycogen granules in muscle and liver cells) and lipid droplets (in fat cells).

The Organelles

Organelles (or-gan-ELZ; "little organs") are internal structures that perform specific functions essential to normal cell structure, maintenance, and metabolism (see **Spotlight Figure 3-2** on pp. 88–89). Many organelles are membranous (membrane-enclosed). These organelles include the *nucleus, mitochondria, endoplasmic reticulum, Golgi apparatus, lysosomes,* and *peroxisomes*. The membrane isolates the organelle from the cytosol, so that the organelle can manufacture or store secretions, enzymes, or toxins that might otherwise damage the cell. Nonmembranous organelles include the *cytoskeleton, microvilli, centrioles, cilia, flagella, ribosomes,* and *proteasomes.* Because they are not surrounded by membranes, their parts are in direct contact with the cytosol.

The Cytoskeleton

The **cytoskeleton** serves as the cell's skeleton. It is an internal protein framework of threadlike filaments and hollow tubules that gives the cytoplasm strength and flexibility (**Figure 3-12**). The cytoskeleton of all cells is made of microfilaments, intermediate filaments, and microtubules. Muscle cells contain these cytoskeletal parts plus thick filaments.

MICROFILAMENTS. The thinnest strands of the cytoskeleton are **microfilaments**, which are usually composed of the protein **actin**. In most cells, they form a dense layer just inside the plasma membrane. Microfilaments attach the plasma membrane to the underlying cytoplasm by forming connections with proteins of the plasma membrane. In muscle cells, actin microfilaments interact with **thick filaments**, made of the protein **myosin**, to produce powerful contractions.

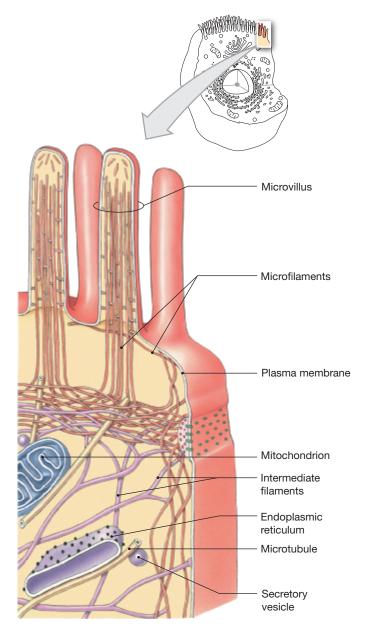

INTERMEDIATE FILAMENTS. These cytoskeletal filaments are intermediate in size between microfilaments and the thick filaments of muscle cells. Their protein composition varies among cell types. Intermediate filaments strengthen the cell. They also stabilize its position with respect to surrounding cells through specialized attachments to the plasma membrane. Many cells contain intermediate filaments with unique functions. For example, keratin fibers in the superficial layers of the skin are intermediate filaments that make these layers strong and able to resist stretching.

MICROTUBULES. All body cells contain **microtubules**, hollow tubes built from the globular protein **tubulin**. Microtubules form the primary components of the cytoskeleton, giving the cell strength and rigidity, and anchoring the positions of major organelles. In size, they are the largest components of the cytoskeleton.

During cell division, microtubules form the *spindle apparatus*, which distributes the duplicated chromosomes to opposite ends of the dividing cell. We will consider this process in a later section.

Microvilli

Microvilli are small, finger-shaped projections of the plasma membrane on the exposed surfaces of many cells (**Spotlight Figure 3-2**). An internal core of microfilaments supports the microvilli and connects them to the cytoskeleton (**Figure 3-12**). Microvilli increase the surface area of the membrane. For this reason, they are common features of cells actively engaged in absorbing materials from the extracellular fluid. Examples include the cells of the digestive tract and kidneys. **Figure 3-12 The Cytoskeleton.** The cytoskeleton provides strength and structural support for the cell and its organelles. Interactions between cytoskeletal components are also important in moving organelles and changing the shape of the cell.

Centrioles, Cilia, and Flagella

In addition to functioning individually in the cytoskeleton, microtubules also interact to form more complex structures known as *centrioles, cilia,* and *flagella*.

CENTRIOLES. A **centriole** is a cylindrical structure composed of triplets of microtubules (**Spotlight Figure 3-2**). All animal cells that are capable of dividing contain a pair of centrioles arranged perpendicular to each other. The centrioles produce the spindle fibers that move DNA strands during cell division. Mature red blood cells, skeletal muscle cells, cardiac muscle cells, and typical neurons lack centrioles. As a result, these cells cannot divide.

CILIA. Cilia (SIL-ē-uh; singular *cilium*) are relatively long, slender extensions of the plasma membrane (**Spotlight Figure 3-2**). **Motile cilia** are supported internally by a cylindrical array of pairs of microtubules surrounding a centrally located pair. Multiple motile cilia make coordinated active movements that require energy from ATP. Their coordinated actions move fluids or secretions across the cell surface. For example, motile cilia lining the respiratory passageways beat in a synchronized manner to move sticky mucus and trapped dust particles toward the throat and away from delicate respiratory surfaces. If these cilia are damaged or immobilized by heavy smoking or a metabolic problem, the cleansing action is lost, and the irritants will no longer be removed. As a result, a chronic cough and respiratory infections develop.

A single, nonmotile **primary cilium** is found on a wide variety of cells. It lacks the central pair of microtubules present in motile cilia. A primary cilium acts as a signal sensor, sensing the surrounding environment.

FLAGELLA. Organelles called **flagella** (fla-JEL-uh; singular *flagellum*, whip) resemble motile cilia but are much longer. Flagella move a cell through a surrounding fluid, rather than moving the fluid past a stationary cell. A sperm is the only human cell that has a flagellum. If the flagella of sperm are paralyzed or otherwise abnormal, the individual will be sterile, because immotile sperm cannot carry out fertilization.

Ribosomes

Ribosomes are organelles that manufacture proteins, using information from the DNA of the nucleus. Each ribosome consists of a small and a large subunit composed of a form of RNA called *ribosomal RNA* and protein. Ribosomes are found in all cells, but their number varies depending on the type of cell and its activities. For example, liver cells, which manufacture blood proteins, have many more ribosomes than do fat cells, which synthesize triglycerides.

There are two major types of ribosomes. **Free ribosomes** are scattered throughout the cytoplasm. The proteins that they manufacture enter the cytosol. **Fixed ribosomes** are attached to the *endoplasmic reticulum* (ER), a membranous organelle. Proteins manufactured by fixed ribosomes enter the endoplasmic reticulum, where they are modified and packaged for use within the cell or eventual secretion from the cell.

Proteasomes

Proteasomes are small organelles that remove proteins within the cytoplasm (**Spotlight Figure 3-2**). These organelles contain an assortment of protein-breaking, or proteolytic, enzymes called *proteases*. Proteasomes remove and recycle damaged or denatured proteins and break down abnormal proteins such as those produced within cells infected by viruses.

The Endoplasmic Reticulum

The **endoplasmic reticulum** (en-dō-PLAZ-mik re-TIK-ū-lum; *reticulum*, a network), or **ER**, is a network of intracellular membranes continuous with the membranous *nuclear envelope* surrounding the nucleus (**Spotlight Figure 3-2**). The ER forms hollow tubes, flattened sheets, and chambers called **cisternae** (sis-TUR-nē; singular, *cisterna*, a reservoir for water). The ER has four major functions:

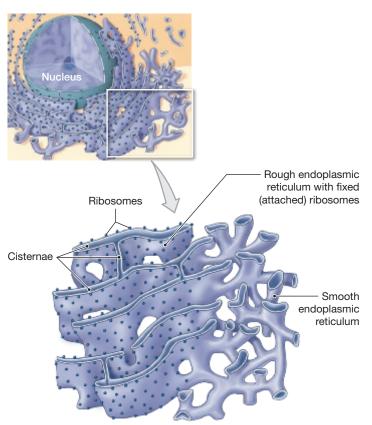

- **1.** *Synthesis.* Specialized regions of the ER manufacture proteins, carbohydrates, and lipids.
- **2.** *Storage.* The ER can store synthesized molecules or materials absorbed from the cytosol without affecting other cellular operations.
- **3.** *Transport.* Materials can travel from place to place in the ER.
- **4.** *Detoxification.* The ER can absorb drugs or toxins and neutralize them with enzymes.

There are two types of endoplasmic reticulum: **smooth endoplasmic reticulum (SER)** and **rough endoplasmic reticulum (RER) (Figure 3-13)**. The term *smooth* refers to the fact that no ribosomes are associated with the SER. The SER is where lipids and carbohydrates are produced. The membranes of the RER contain fixed ribosomes, giving the RER a beaded or rough appearance. The ribosomes take part in protein synthesis.

SER functions include (1) the synthesis of the phospholipids and cholesterol needed for maintenance and growth of the plasma membrane, ER, nuclear membrane, and Golgi apparatus in all cells; (2) the synthesis of steroid hormones, such as *testosterone* and *estrogen* (sex hormones) in cells of the reproductive organs; (3) the synthesis and storage of glycerides, especially triglycerides, in liver cells and fat cells; and (4) the synthesis and storage of glycogen in skeletal muscle and liver cells.

The rough endoplasmic reticulum (RER) functions as a combination workshop and shipping warehouse. The fixed ribosomes on its outer surface release newly synthesized proteins into the cisternae of the RER. Some proteins remain in the RER and function as enzymes. Others are chemically modified and packaged into small membrane-bound sacs that

Figure 3-13 The Endoplasmic Reticulum. The three-dimensional relationships between the rough and smooth endoplasmic reticula are shown here.

pinch off from the tips of the ER. The sacs, called *transport vesicles*, deliver the proteins to the Golgi apparatus, another membranous organelle. There the proteins are processed further (see **Spotlight Figure 3-15**).

The amount of endoplasmic reticulum and the ratio of RER to SER vary with the type of cell and its activities. For example, pancreatic cells that manufacture digestive enzymes contain an extensive RER, and their SER is relatively small. The proportions are just the reverse in reproductive system cells that synthesize steroid hormones.

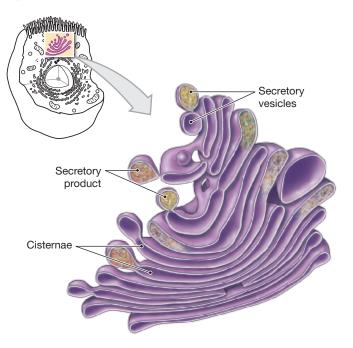

The Golgi Apparatus

The **Golgi** (GOL-je) **apparatus** consists of a set of five or six flattened membranous discs called *cisternae*. A single cell may contain several of these organelles, each resembling a stack of dinner plates (Figure 3-14).

A Golgi apparatus has three major functions (**Spotlight Figure 3-15** on pp. 104–105). It

- **1.** modifies and packages secretions, such as hormones or enzymes, for release from the cell;
- 2. renews or modifies the plasma membrane; and

Figure 3-14 The Golgi Apparatus.

3. packages special enzymes within vesicles (lysosomes) for use in the cytoplasm.

Lysosomes

Lysosomes (LĪ-sō-sōmz; *lyso-*, a loosening + *soma*, body) are vesicles filled with digestive enzymes. Lysosomes perform cleanup and recycling functions within the cell. One such function involves removing damaged organelles. Lysosomal enzymes are activated when lysosomes fuse with the membranes of damaged organelles, such as mitochondria or fragments of the endoplasmic reticulum. The activated enzymes break down the lysosomal contents. Nutrients re-enter the cytosol through passive or active transport processes. The remaining material is eliminated by exocytosis.

Lysosomes also function in defense against disease. Through endocytosis, immune system cells may engulf bacteria, fluids, and organic debris in their surroundings and isolate them within vesicles. $\bigcirc p. 98$ Lysosomes fuse with vesicles created in this way. The digestive enzymes then break down the contents and free up usable substances such as sugars or amino acids.

Lysosomes also do essential recycling functions inside the cell. For example, when muscle cells are inactive, lysosomes gradually break down their contractile proteins. If the cells become active once again, this destruction ends. However, in damaged or dead cells, lysosome membranes disintegrate, releasing active enzymes into the cytosol. These enzymes rapidly destroy the proteins and organelles of the cell, a process called **autolysis** (aw-TOL-i-sis; *auto-*, self). Because the breakdown of lysosomal membranes can destroy a cell, lysosomes have been called cellular "suicide packets." We do not know how to control lysosomal activities or why the enclosed enzymes do not digest the lysosomal membranes unless the cell is damaged.

Problems in producing lysosomal enzymes cause more than 30 serious inherited diseases affecting children. In these conditions, called *lysosomal storage disease*, the lack of a specific enzyme results in the buildup of waste products that lysosomes normally remove and recycle. Affected individuals may die when vital cells, such as those of the heart, can no longer function.

Peroxisomes

Peroxisomes are vesicles that are smaller than lysosomes and carry a different group of enzymes (**Spotlight Figure 3-2**). In contrast to lysosomes, which are produced at the Golgi apparatus, new peroxisomes arise from the growth and subdivision of existing peroxisomes. Peroxisomes absorb and break down fatty acids and other organic compounds. In the process, they generate hydrogen peroxide (H_2O_2), a potentially dangerous *free radical.* **Free radicals** are ions or molecules that contain unpaired electrons. They are highly reactive and enter additional reactions that can damage vital compounds such as proteins. Other enzymes in peroxisomes break down hydrogen peroxide into oxygen and water, thus protecting the cell from the damaging effects of free radicals produced during catabolism. Found in all cells, peroxisomes are most abundant in metabolically active cells, such as liver cells.

Mitochondria

Mitochondria (mī-tō-KON-drē-uh; singular *mitochondrion; mitos*, thread + *chondrion*, granule) are small organelles that provide energy for the cell (**Spotlight Figure 3-2**). The number of mitochondria in a particular cell varies with the cell's energy demands. Red blood cells, for example, have no mitochondria, but these organelles may account for 30 percent of the volume of a heart muscle cell.

Mitochondria have an unusual double membrane (Figure 3-16, p. 106). Each membrane consists of a phospholipid bilayer. The outer membrane surrounds the entire organelle. The inner membrane contains numerous folds called **cristae**, which surround the fluid contents, or **matrix**. Cristae increase the inner membrane surface area in contact with the matrix of the mitochondria. Metabolic enzymes in the matrix catalyze energy-producing reactions.

Most of the chemical reactions that release energy take place in the mitochondria, but most of the cellular activities that require energy occur in the surrounding cytoplasm. For this reason, cells must store energy in a form that can be moved from place to place. Energy is stored and transferred in the high-energy bond of ATP. \bigcirc p. 78 Living cells break the highenergy phosphate bond under controlled conditions, reconverting ATP to ADP and releasing energy for the cell's use.

MITOCHONDRIAL ENERGY PRODUCTION. Most cells generate ATP and other high-energy compounds through the breakdown of carbohydrates, especially glucose. Most of the actual energy production occurs inside mitochondria, but the first steps take place in the cytosol. In this reaction sequence, called *glycolysis*, six-carbon glucose molecules are broken down into three-carbon *pyruvate* molecules. These molecules are then absorbed by the mitochondria. If glucose or other carbohydrates are not available, mitochondria can absorb and use small carbon chains produced by the breakdown of lipids or proteins. As long as oxygen is present, these molecules will be broken down to carbon dioxide, which diffuses out of the cell, and hydrogen atoms, which take part in a series of energy-releasing steps resulting in the enzymatic conversion of ADP to ATP.

Because the key reactions involved in mitochondrial activity consume oxygen, the process of mitochondrial energy production is known as **aerobic** (*aero-*, air + *bios*, life) **metabolism**, or *cellular respiration*. Aerobic metabolism in mitochondria produces about 95 percent of the energy a cell needs to stay alive. (We discuss aerobic metabolism in more detail in Chapters 7 and 17.)

Mitochondria contain their own DNA (mtDNA) and ribosomes. The mtDNA codes for small numbers of RNA and polypeptide molecules. The polypeptides serve as enzymes in energy production. Although mitochondria contain their own DNA, their functions depend on imported proteins coded by nuclear DNA.

CLINICAL NOTE

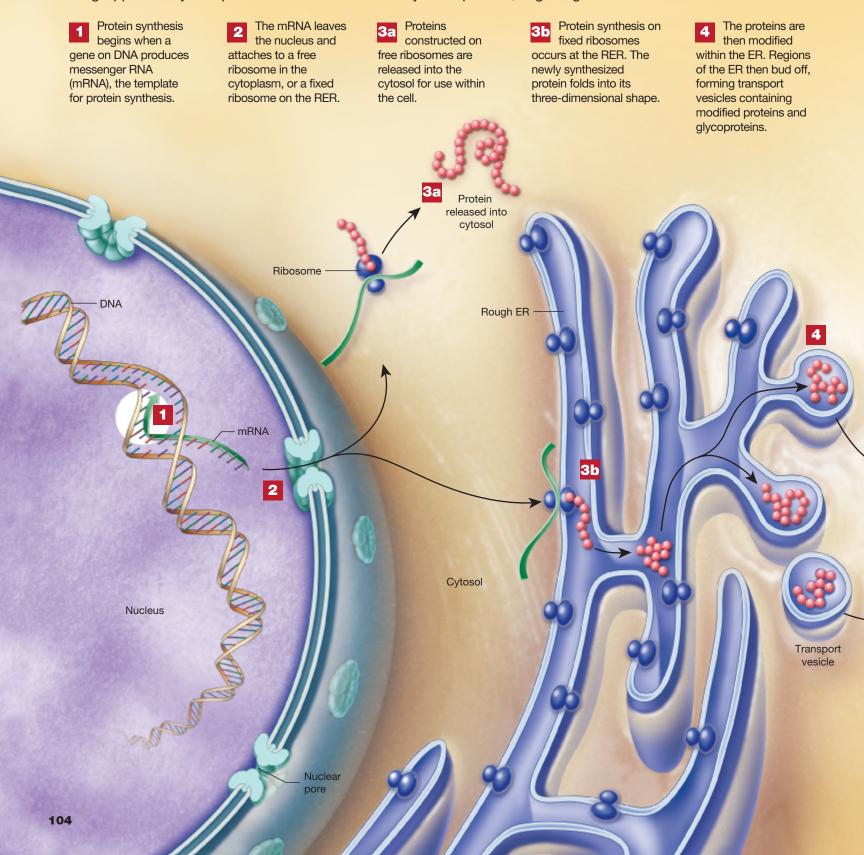

Inheritable Mitochondrial Disorders

Several inheritable disorders result from abnormal mitochondrial activity. Mitochondria have DNA and ribosomes to manufacture some of their own proteins. However, most of their proteins are coded by nuclear DNA and imported from the cytosol. For this reason, abnormal nuclear DNA or mtDNA may result in defective enzymes that reduce the efficiency of ATP production. A mitochondrial disorder may affect a single organ or involve many organ systems that affect cells throughout the body. Symptoms involving muscle cells, nerve cells, and the light receptor cells in the eye are most common. The reason is because these cells have especially high energy demands.

3

SPOTLIGHT Figure 3-15 PROTEIN SYNTHESIS, PROCESSING, AND PACKAGING

The Golgi apparatus plays a major role in modifying and packaging newly synthesized proteins. Some proteins and glycoproteins synthesized in the rough endoplasmic reticulum (RER) are delivered to the Golgi apparatus by transport vesicles. Here's a summary of the process, beginning with DNA.

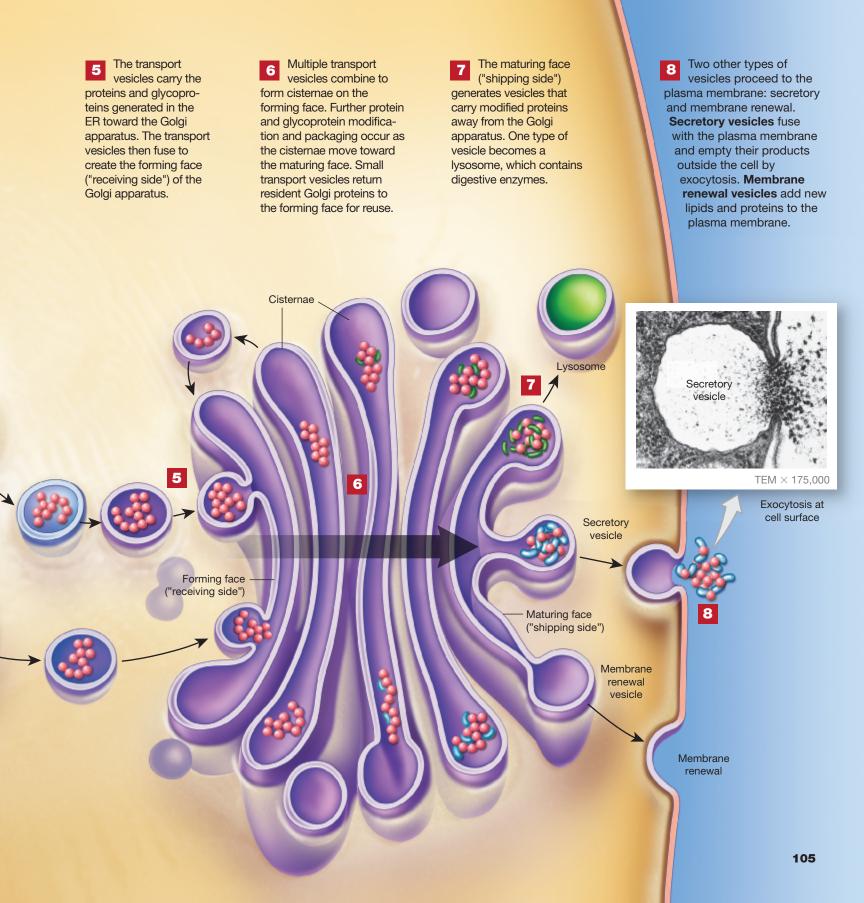

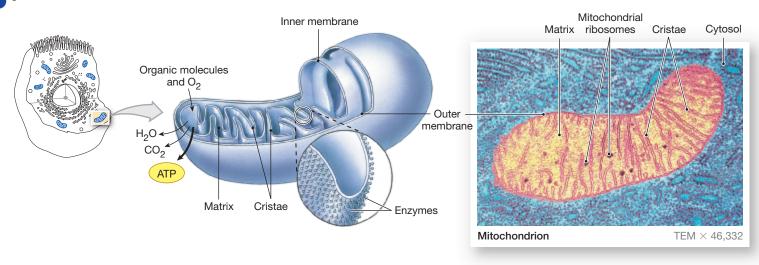

Figure 3-16 Mitochondria. Shown here is the three-dimensional organization of a typical mitochondrion and a color-enhanced TEM of a mitochondrion in section. Mitochondria absorb short carbon chains and oxygen, and generate carbon dioxide, ATP, and water.

CHECKPOINT

- **14.** Describe the difference between the cytoplasm and the cytosol.
- **15.** Identify the membranous organelles and list their functions.
- **16.** Cells lining the small intestine have numerous fingerlike projections on their free surface. What are these structures, and what is their function?
- 17. How does the absence of centrioles affect a cell?
- **18.** Explain why certain cells in the ovaries and testes contain large amounts of smooth endoplasmic reticulum (SER).
- **19.** What does the presence of many mitochondria imply about a cell's energy requirements?

See the blue Answers tab at the back of the book.

3-6 The nucleus contains DNA and enzymes essential for controlling cellular activities

Learning Outcome Explain the functions of the cell nucleus.

The **nucleus** is usually the largest and most conspicuous structure in a cell (**Spotlight Figure 3-2**). It is the control center for cellular operations. A single nucleus stores all the information needed to control the synthesis of the more than 100,000 different proteins in the human body. The nucleus determines the structure of the cell and the functions the cell can perform. The nucleus does so by controlling which proteins are synthesized, under what circumstances, and in what amounts.

Nuclear Structure and Contents

Most cells contain a single nucleus, but exceptions exist. For example, skeletal muscle cells have many nuclei, and mature red blood cells have none. **Figure 3-17** shows the structure of a typical nucleus. A **nuclear envelope** consisting of a double membrane surrounds the nucleus and separates its fluid contents—called *nucleoplasm*—from the cytosol. The nucleoplasm contains ions, enzymes, RNA and DNA nucleotides, proteins, small amounts of RNA, and DNA.

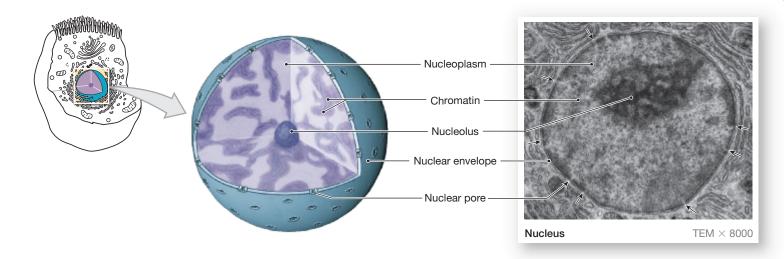

Chemical communication between the nucleus and the cytosol takes place through **nuclear pores**. These pores are large enough to allow the movement of ions and small molecules, yet small enough to regulate the transport of proteins and RNA.

Most nuclei have several **nucleoli** (noo-KLĒ-ō-lī; singular, *nucleolus*). Nucleoli are organelles that synthesize **ribosomal RNA (rRNA)**, and assemble the small and large ribosomal subunits. These subunits pass through the nuclear pores into the cytoplasm, where they will form functional ribosomes. For this reason, they are most prominent in cells that manufacture large amounts of proteins, such as muscle and liver cells.

The DNA in the nucleus stores instructions for protein synthesis. This DNA is contained in **chromosomes** (*chroma*, color). The nuclei of human body cells contain 23 pairs of chromosomes. One chromosome in each pair is derived from the mother and one from the father.

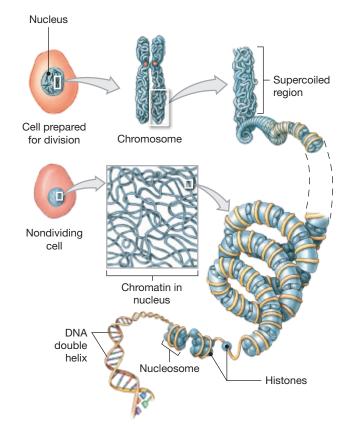

The structure of a typical chromosome is shown in **Figure 3-18**. Each chromosome contains DNA strands wrapped around proteins called *histones*. At intervals, the DNA and histones form a complex known as a *nucleosome*. The tightness of

Figure 3-17 The Nucleus. The diagram and electron micrograph show important nuclear structures. The arrows on the TEM indicate the locations of nuclear pores.

DNA coiling determines whether the chromosome is long and thin or short and fat. In cells that are not dividing, the nucleosomes are loosely coiled, forming a tangle of fine filaments

Figure 3-18 DNA Organization and Chromosome Structure. DNA strands wound around histone proteins (at bottom) form coils that may be very tight or rather loose. In cells that are not dividing, the DNA is loosely coiled, forming a tangled network known as chromatin. When the coiling becomes tighter, as it does in preparation for cell division, the DNA becomes visible as distinct structures called chromosomes.

known as **chromatin**. Chromosomes in a dividing cell contain very tightly coiled DNA. These chromosomes can be seen clearly as separate structures in light or electron micrographs.

Information Storage in the Nucleus

Each protein molecule consists of a unique sequence of amino acids. \bigcirc p. 73 Any "recipe" for a protein, therefore, must specify the order of the amino acids it contains. This information is stored in the chemical structure of the DNA strands in the nucleus. The chemical "language" the cell uses is known as the **genetic code**. An understanding of the genetic code has enabled researchers to determine how cells build proteins and how various structural and functional traits, such as hair color or blood type, are inherited from generation to generation.

How does the genetic code work? Recall the basic structure of nucleic acids described in Chapter 2. \bigcirc p. 77 A single DNA molecule consists of a pair of DNA strands held together by hydrogen bonding between complementary nitrogenous bases. Information is stored in the sequence of nitrogenous bases (adenine, A; thymine, T; cytosine, C; and guanine, G) along the length of the DNA strands.

The genetic code is called a *triplet code* because a sequence of three nitrogenous bases represents a single amino acid. For example, the DNA triplet adenine–cytosine–adenine (ACA) codes for the amino acid cysteine.

A **gene** is the functional unit of heredity. Each proteincoding gene consists of all the triplets in the proper sequence needed to produce a specific protein. The number of triplets varies from gene to gene, depending on the size of the protein that will be produced. Each gene also contains special segments responsible for regulating its own activity. In effect these are

CLINICAL NOTE

DNA Fingerprinting

Every nucleated cell in the body carries a set of 46 chromosomes identical to the set formed at fertilization. Not all the DNA of these chromosomes codes for proteins. Within the DNA that does not code for proteins are regions called Short Tandem Repeats (STRs), which contain the same nucleotide sequence repeated over and over. The number of STRs and the number of repetitions vary among individuals.

In the United States, 13 core STRs are used to identify individuals. The individual differences are reflected in the different lengths of these STRs. The chance that any two individuals, other than identical twins, will have the same length and pattern of repeating DNA segments in 13 STRs is approximately one in 575 trillion. For this reason, individuals can be identified on the basis of their DNA pattern, just as they can on the basis of a fingerprint. Skin scrapings, blood, semen, hair roots, or other tissues can serve as the DNA source. Information from **DNA fingerprinting** has been used to convict or acquit people accused of violent crimes, such as rape or murder. The U.S. Crime Act of 1994 mandates that DNA fingerprints of individuals convicted of certain crimes be kept in searchable criminal justice DNA databases. The science of molecular biology has become a useful addition to the crime-fighting toolbox.

triplets of nucleotides that say, "Do (or do not) read this message," "Message starts here," or "Message ends here." These "read me," "don't read me," and "start" signals form a special region of the DNA called the *promoter*, or control segment, at the start of each gene. Each gene ends with a "stop" signal.

Not all genes code for proteins. Some genes contain instructions for the synthesis of ribosomal RNA or another type we will discuss shortly, *transfer RNA*. Some regulate other genes, and others have no apparent function.

21. What is a gene?

See the blue Answers tab at the back of the book.

3-7 DNA controls protein synthesis, cell structure, and cell function

Learning Outcome Summarize the process of protein synthesis.

Each DNA molecule contains thousands of genes and, therefore, holds the information needed to synthesize thousands of proteins. Normally, the genes are tightly coiled, and bound histones keep the genes inactive, thus preventing the synthesis of proteins. Before a gene can be activated, enzymes must temporarily break the weak hydrogen bonds between its nitrogenous bases and temporarily remove the histone that guards the *promoter* segment at the start of each gene.

The process of gene activation is only partially understood, but more is known about protein synthesis. The process of **protein synthesis** is divided into two main parts. *Transcription* is the production of RNA from a single strand of DNA. *Translation* is the assembly of a protein by ribosomes, using the information carried by the RNA molecule. Transcription takes place within the nucleus, and translation occurs in the cytoplasm.

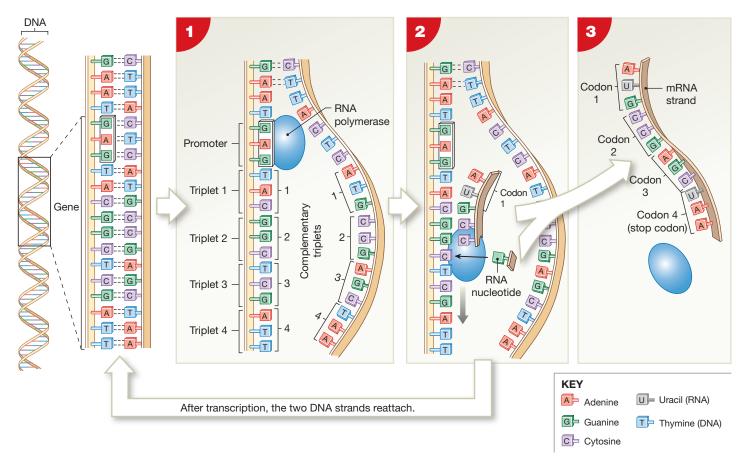

Transcription

Ribosomes, the organelles of protein synthesis, are located in the cytoplasm, but the genes are confined to the nucleus. This problem of a separation between the protein manufacturing site and the DNA's protein blueprint is solved with a single strand of RNA known as **messenger RNA (mRNA)**. The process of mRNA formation is called **transcription (Figure 3-19**). Transcription means "copying" or "rewriting." This term makes sense because the newly formed mRNA is a transcript (a copy) of the information contained in the gene. The information that is "copied" is the sequence of nucleotides of the gene.

Transcription begins when an enzyme, *RNA polymerase*, binds to the promoter of a gene (1) in Figure 3-19). This enzyme catalyzes the synthesis of an mRNA strand, using nucleotides complementary to those in the gene (2). The nucleotides involved are those typical of RNA, not those of DNA. RNA polymerase may use adenine, guanine, cytosine, or uracil (U), but never thymine. Thus, wherever an A occurs in the DNA strand, RNA polymerase attaches a U, not a T. The resulting mRNA strand contains a sequence of nucleotides that are complementary to those of the gene. A sequence of three nitrogenous bases along the new mRNA strand represents a **codon** (KŌ-don) that is complementary to the corresponding DNA triplet along the gene (3). At the DNA "stop" signal, the enzyme and the mRNA strand detach, and the complementary DNA strands reattach.

The mRNA formed in this way may be altered, or edited, before it leaves the nucleus. For example, some regions (called *introns*) may be removed and the remaining segments (called *exons*) spliced together. This modification creates a shorter, functional mRNA strand that enters the cytoplasm through a nuclear pore. We now know that by removing different introns, a single gene can produce mRNAs that code for several different proteins. How this variable editing is regulated is unknown.

Figure 3-19 **Transcription.** In this figure, only a small portion of a single DNA molecule, containing a single gene, is undergoing transcription. 1 The two DNA strands separate, and RNA polymerase binds to the promoter of the gene. 2 The RNA polymerase moves from one nucleotide to the next along the length of the gene. At each site, complementary RNA nucleotides form hydrogen bonds with the DNA nucleotides of the gene. The RNA polymerase then bonds the arriving nucleotides together into a strand of mRNA. 3 On reaching the stop codon at the end of the gene, the RNA polymerase and the mRNA strand detach, and the two DNA strands reattach.

Translation

Translation is the synthesis of a protein using the information provided by the sequence of codons along the mRNA strand. Every amino acid has at least one unique and specific codon. **Table 3-3** includes several examples of DNA triplets and their corresponding mRNA codons and amino acids. During translation, the sequence of codons determines the sequence of amino acids in the protein. (For a complete table of mRNA codons, the amino acids, and the start or stop signals they represent, see the Appendix at the back of the book.)

Translation begins when the newly synthesized mRNA leaves the nucleus and binds with a ribosome in the cytoplasm. Molecules of a third form of RNA known as **transfer RNA (tRNA)** then deliver amino acids that will be used by the ribosome to assemble a protein. There are more than 20 different types of transfer RNA, at least one for each amino acid used in protein synthesis. Each tRNA molecule contains a triplet of nitrogenous bases, known as an **anticodon**, that is complementary to a specific codon on the mRNA and will bind to it.

Table 3-3		Examples of the Genetic Code		
DNA Triplet	mRNA Codon	tRNA Anticodon	Amino Acid (and/or instruction)	
AAA	UUU	AAA	Phenylalanine	
AAT	UUA	AAU	Leucine	
ACA	UGU	ACA	Cysteine	
CAA	GUU	CAA	Valine	
GGG	CCC	GGG	Proline	
CGA	GCU	CGA	Alanine	
TAC	AUG	UAC	Methionine; start codon	
ATT	UAA	[none]	Stop codon	

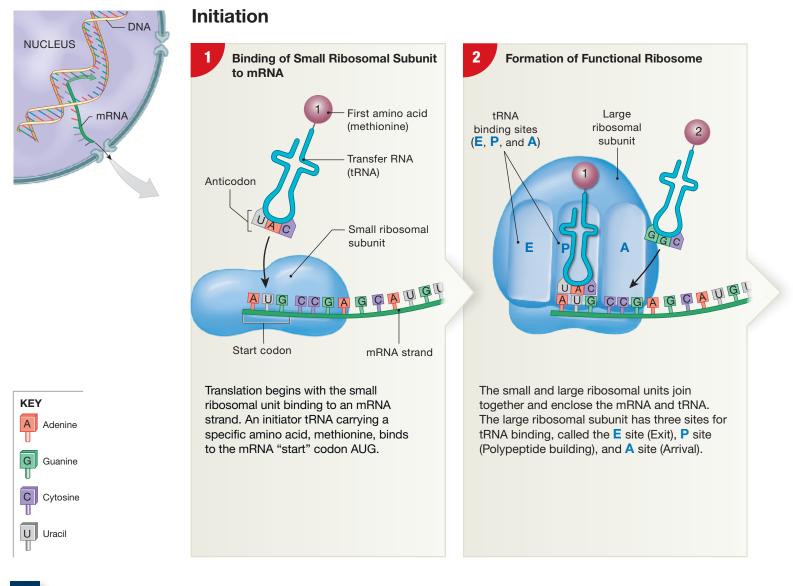

Figure 3-20 illustrates the three phases of the translation process: *initiation, elongation, and termination*. During **initia**tion (1) and (2), a functional ribosome forms as its two subunits (small and large) are joined, along with an mRNA strand and amino acid-carrying tRNA molecule. In **elongation** (3) and (4), amino acids are added one by one to the growing polypeptide chain. At **termination** (5), the polypeptide chain is released, and the ribosomal subunits separate, freeing an intact mRNA strand. The freed mRNA strand can interact with other ribosomes and create additional copies of the same polypeptide chain or protein.

A protein is a polypeptide containing 100 or more amino acids (as you may recall from Chapter 2). \bigcirc p. 73 Translation proceeds swiftly, producing a typical protein (about 1000 amino acids) in around 20 seconds. The protein begins as a simple linear strand, but a more complex structure develops as it grows longer.

CHECKPOINT

- 22. How does the nucleus control the cell's activities?
- **23.** What process would be affected by the lack of the enzyme RNA polymerase?
- **24.** During the process of transcription, a nucleotide was deleted from an mRNA sequence that coded for a protein. What effect would this deletion have on the amino acid sequence of the protein?
- See the blue Answers tab at the back of the book.

Figure 3-20 Translation. Once transcription has been completed, the mRNA diffuses into the cytoplasm and interacts with a ribosome to assemble a protein or polypeptide.

3-8 Stages of a cell's life cycle include interphase, mitosis, and cytokinesis

Learning Outcome Describe the stages of the cell life cycle, including interphase, mitosis, and cytokinesis, and explain their significance.

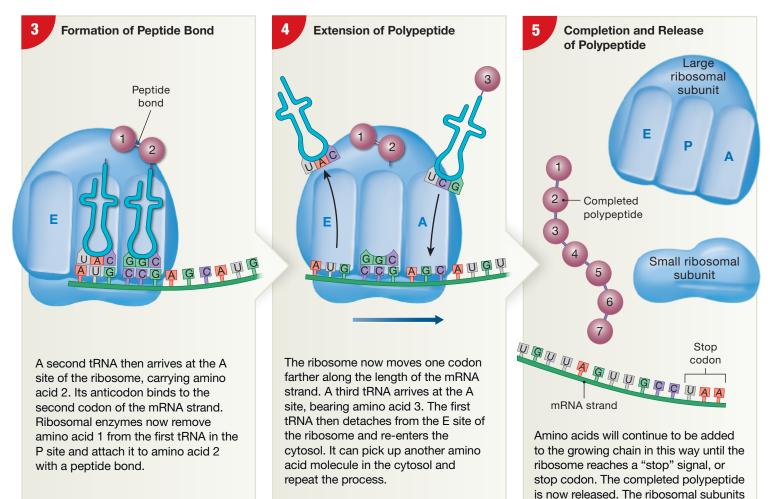

During the time between fertilization and physical maturity, the number of cells making up an individual increases from a single cell to roughly 75 trillion cells. This amazing increase in numbers takes place through a form of cellular reproduction called **cell division**. Even when development has been completed, cell division continues to be essential to survival because it replaces old and damaged cells. For cell division to be successful, the genetic material in the nucleus must be duplicated accurately, and each daughter cell must receive a complete copy. The duplication of the cell's genetic material is called *DNA replication*. Nuclear division is called **mitosis** (mī-TŌ-sis). Mitosis takes place during the division of **somatic** (*soma*, body) **cells**, which include the vast majority of the cells in the body. The production of sex cells—sperm and oocytes (immature ova, or egg cells) involves a different process, called **meiosis** (mī-Ō-sis), which we will describe in Chapter 19.

Figure 3-21 represents the life cycle of a typical cell. Most cells spend only a small part of their life cycle in cell division. For most of their lives, cells are in **interphase**, the period of time between cell divisions when they perform normal functions.

Elongation

Termination

then separate, freeing the mRNA strand.

CLINICAL NOTE

Mutations and Mosaicism

Mutations are permanent changes in the nucleotide sequence of a cell's DNA. Mutations may involve changes in the number or structure of chromosomes and their long segments of DNA, or they may involve only single nucleotides. Chromosomal mutations can involve deletions, insertions, or inversions of DNA segments. Such changes may disrupt only the chromosome undergoing the change or may affect multiple chromosomes as one gains DNA and another loses DNA. The simplest mutation is called a *point mutation*, a change in a single nucleotide that affects one codon.

With roughly 3 billion pairs of nucleotides in the DNA of a human cell, a single mistake might seem relatively unimportant. Yet several hundred inherited disorders have been traced to abnormalities in enzyme or protein structure that reflect single changes in nucleotide sequence. In some disorders, a single change in the amino acid sequence of a structural protein or enzyme can prove fatal. For example, several cancers and two potentially lethal blood

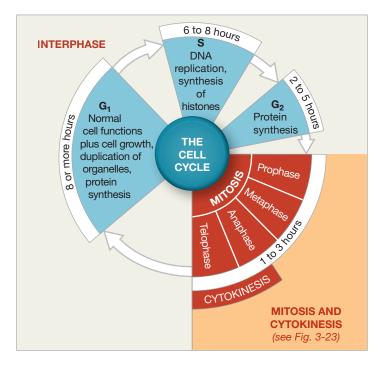

Figure 3-21 Stages of a Cell's Life Cycle.

disorders, *thalassemia* and *sickle cell anemia*, result from variations in a single nucleotide. Other mutations resulting from the addition or deletion of nucleotides can affect multiple codons in one gene, in several adjacent genes, or in the structure of one or more chromosomes.

Most mutations occur during DNA replication, when cells are preparing for cell division. A single cell or group of daughter cells may be affected. If the mutations take place early in development, however, subsets of cells or every cell in the body may be affected. **Mosaicism** occurs when a person's cells do not all have the same genetic makeup. Some amount of mosaicism is present in all of us.

If a mutation affects the DNA of an individual's sex cells, however, that mutation can be inherited by that individual's children. Our growing understanding of gene structure and genetic engineering is opening the possibility of diagnosing and correcting some of these problems.

in the nucleus are activated. The genetically controlled death of cells is called **apoptosis** (ap-op- $T\bar{O}$ -sis; *apo-*, or ap- \bar{O} - $T\bar{O}$ -sis separated from + *ptosis*, a falling). Apoptosis is a key process in homeostasis. During an immune response, for example, some types of white blood cells activate genes in abnormal or infected cells that tell the cell to self-destruct.

A cell ready to divide first enters the G_1 phase. In this phase, the cell makes enough organelles and cytosol for two functional cells. These preparations may take just eight hours in cells dividing at top speed, or days to weeks to complete, depending on the type of cell and the situation. For example, certain cells in the lining of the digestive tract divide every few days throughout life, but specialized cells in other tissues divide only under special circumstances, such as following an injury.

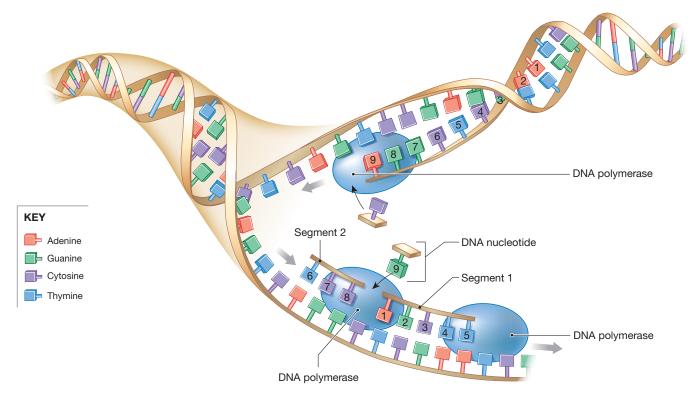

Once these preparations have been completed, the cell enters the S phase and replicates the DNA in its nucleus. This process takes six to eight hours. The goal of **DNA replication** is to copy the genetic information in the nucleus so that one set of chromosomes can be given to each of the two cells produced.

DNA replication starts when the complementary DNA strands begin to separate and unwind (**Figure 3-22**). Molecules of the enzyme *DNA polymerase* then bind to the exposed nitrogenous bases. As a result, complementary nucleotides present in the nucleoplasm attach to the exposed nitrogenous bases of the DNA strands and form a pair of identical DNA molecules.

Shortly after DNA replication is a brief G_2 phase for protein synthesis and for the completion of centriole replication. The cell then begins mitosis.

Interphase

Somatic cells differ in the length of time spent in interphase and their frequency of cell division. For example, unspecialized cells known as *stem cells* divide repeatedly with very brief interphase periods. In contrast, mature skeletal muscle cells and most nerve cells never undergo mitosis or cell division. Certain other cells appear to be programmed to self-destruct after a certain period of time because specific "suicide genes" **Figure 3-22 DNA Replication.** In replication, the DNA strands unwind, and DNA polymerase begins attaching complementary DNA nucleotides along each strand. The complementary copy of one original strand is produced as a continuous strand. The other copy is produced as short segments, which are then spliced together. The end result is that two identical copies of the original DNA molecule are produced.

Mitosis

Mitosis is a process that separates the duplicated chromosomes of the original cell into two identical nuclei. Division of the cytoplasm to form two distinct cells involves a separate, but related, process known as *cytokinesis* (sī-tō-ki-NĒ-sis; *cyto-*, cell + *kinesis*, motion). Mitosis is divided into four stages: *prophase, metaphase, anaphase,* and *telophase* (Figure 3-23).

Stage 1: Prophase

Prophase (PRŌ-fāz; *pro-*, before) begins when the DNA is coiled so tightly that the chromosomes become visible under a light microscope. As a result of DNA replication, there are now two copies of each chromosome. Each copy, called a **chromatid** (KRŌ-ma-tid), is connected to its duplicate copy at a single point, the **centromere** (SEN-trō-mēr).

As the chromosomes appear, the nucleoli disappear and the two pairs of centrioles begin moving toward opposite ends of the cell. An array of microtubules, called **spindle fibers**, extends between the centriole pairs. Late in prophase, the nuclear envelope disappears, and the chromatids become attached to the spindle fibers.

Stage 2: Metaphase

Metaphase (MET-a-fāz; *meta-*, after) begins as the chromosomes move to a narrow central zone called the **metaphase plate**. Metaphase ends when all the chromosomes are aligned in the plane of the metaphase plate. At this time, each chromosome still consists of a pair of chromatids.

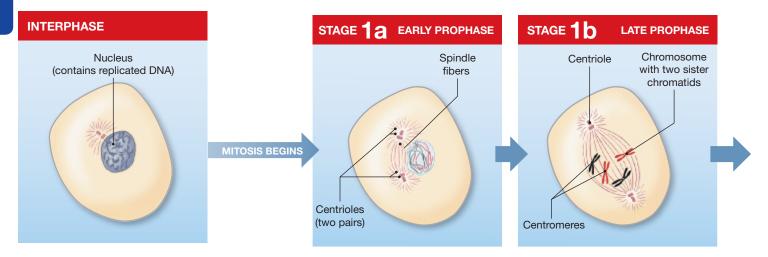

Stage 3: Anaphase

Anaphase (AN-a-fāz; *ana-*, apart) begins when the centromere of each chromatid pair splits and the chromatids separate. The two resulting **daughter chromosomes** are now pulled toward opposite ends of the cell. Anaphase ends when the daughter chromosomes arrive near the centrioles at opposite ends of the cell.

Stage 4: Telophase

During **telophase** (TĒL-ō-fāz; *telos*, end), the cell prepares to return to interphase. The nuclear membranes re-form, the nuclei enlarge, and the chromosomes gradually uncoil. Once the fine filaments of chromatin become visible, nucleoli reappear and the nuclei resemble those of interphase cells. This stage marks the end of mitosis.

Figure 3-23 Interphase, Mitosis, and Cytokinesis.

Cytokinesis

At the end of mitosis, the daughter cells have not yet completed their physical separation. **Cytokinesis** is the division of the cytoplasm into two daughter cells (**Figure 3-21**). It usually begins in late anaphase. As the daughter chromosomes near the ends of the spindle fibers, the cytoplasm constricts along the plane of the metaphase plate, forming a *cleavage furrow*. Cytokinesis continues throughout telophase, and is usually completed after a nuclear membrane has re-formed around each daughter nucleus. The completion of cytokinesis marks the end of cell division.

CHECKPOINT

- **25.** Give the biological terms for (a) cellular reproduction and (b) cell death.
- **26.** Describe interphase, and identify its stages.
- **27.** Define mitosis, and list its four stages.
- **28.** What would happen if spindle fibers failed to form in a cell during mitosis?
- See the blue Answers tab at the back of the book.

3-9 Tumors and cancers are characterized by abnormal cell growth and division

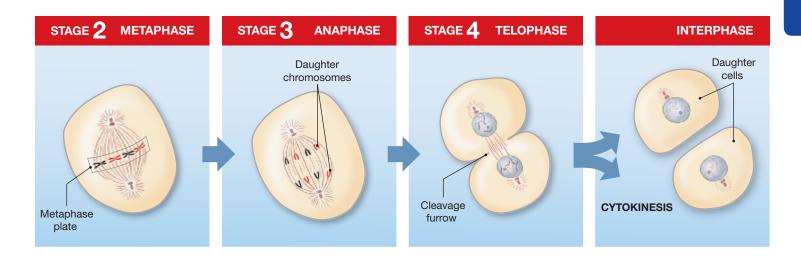

Learning Outcome Discuss the relationship between cell division and cancer.

Cancer cells result from mutations that disrupt the normal control processes that regulate cell division and growth. When the rates of cell division and growth exceed the rate of cell death, a tissue begins to enlarge. A **tumor**, or *neoplasm*, is a mass or swelling produced by abnormal cell growth and division. In a **benign tumor**, the cells usually remain in one place—within the epithelium (one of the four primary tissue types) or a connective tissue capsule. Such a tumor is seldom life threatening. It can usually be surgically removed if its size or position disturbs tissue function.

Cells in a **malignant tumor** no longer respond to normal controls. These cells do not remain within the epithelium or connective tissue capsule, but spread into surrounding tissues. The tumor of origin is called the *primary tumor* (or *primary neoplasm*). The spreading process is called **invasion**. Malignant cells may also travel to distant tissues and organs and produce *secondary tumors*. This migration, called **metas-tasis** (me-TAS-ta-sis; *meta-*, after + *stasis*, standing still), is difficult to control.

Cancer is an illness characterized by gene mutations leading to the formation of malignant cells and metastasis. Malignant cancer cells lose their resemblance to normal cells. The secondary tumors they form are extremely active metabolically. Their presence stimulates the growth of blood vessels into the area. The increased blood supply provides additional nutrients to the cancer cells, further accelerating tumor growth and metastasis.

As malignant tumors grow, organ function begins to deteriorate. The malignant cells may no longer perform their original functions, or they may perform normal functions in an abnormal way. Cancer cells do not use energy very efficiently. They grow and multiply at the expense of healthy tissues, competing for space and nutrients with normal cells. This competition accounts for the starved appearance of

many patients in the late stages of cancer. Death may result from the compression of vital organs when nonfunctional cancer cells have killed or replaced the healthy cells in those organs, or when the cancer cells have starved normal tissues of essential nutrients.

CHECKPOINT

- **29.** An illness characterized by mutations that disrupt normal control processes and produce potentially malignant cells is termed _____.
- **30.** Define metastasis.

See the blue Answers tab at the back of the book.

3-10 Cellular differentiation is cellular specialization as a result of gene activation or repression

Learning Outcome Define cellular differentiation and explain its importance.

All of an individual's somatic cells have the same chromosomes and genes. Why then are liver cells, fat cells, and nerve cells so unlike in appearance and function? The differences exist because, in each case, a different set of genes has been repressed, or turned *off*. In other words, these cells differ because liver cells have one set of genes accessible for transcription, or activation, and fat cells have another. When a gene is functionally eliminated, the cell loses its ability to make a particular protein and to perform any functions involving that protein. As more genes are switched off, the cell's functions become more restricted or specialized. This development of specific cellular characteristics and functions that are different from the original cell is called **cellular differentiation**.

Fertilization produces a single cell with all its genetic potential intact. Repeated cell divisions follow, and cellular differentiation begins as the number of cells increases. Cellular differentiation produces specialized cells with limited capabilities. These cells form organized collections known as *tissues*, each with different functional roles. (In the next chapter we examine the structure and function of tissues, and the role of tissue interactions in maintaining homeostasis.)

CHECKPOINT

31. Define cellular differentiation.

• See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

carcinogen (kar-SIN-ō-jen): A cancer-causing agent. **chemotherapy:** The administration of drugs that either kill cancerous tissues or prevent mitotic divisions.

oncologists (on-KOL-o-jists): Physicians who specialize in identifying and treating cancers. **recombinant DNA:** DNA created by inserting (splicing) a specific gene from one organism into the DNA strand of another organism.

remission: A stage in which a tumor stops growing or becomes smaller; a major goal of cancer treatment.

3

Chapter Review

Summary Outline

3-1 The study of cells provides the foundation for understanding human physiology *p. 86*

- Modern cell theory includes several basic concepts: (1)
 Cells are the building blocks of all plants and animals; (2) cells are the smallest functioning units of life; (3) cells are produced by the division of preexisting cells; and (4) each cell maintains homeostasis. (*Figure 3-1*)
- **2.** Light and electron microscopes are important tools used in **cytology**, the study of the structure and function of cells.
- 3. A cell is surrounded by **extracellular fluid**—specifically, **interstitial fluid**. The cell's outer boundary, the **plasma membrane (cell membrane)**, separates the **cytoplasm**, or cell contents, from the extracellular fluid. (*Spotlight Figure 3-2*)

3-2 The plasma membrane separates the cell from its surrounding environment and performs various functions *p. 87*

- **4.** The functions of the plasma membrane include (1) physical isolation, (2) control of the exchange of materials with the cell's surroundings, (3) sensitivity, and (4) structural support.
- **5.** The plasma membrane, or cell membrane, contains lipids, proteins, and carbohydrates. Its major components, lipid molecules, form a **phospholipid bilayer**. (*Figure* 3-3)
- **6.** Membrane proteins may function as receptors, channels, carriers, enzymes, anchors, or identifiers. *(Table 3-1)*

3-3 Diffusion is a passive transport process that assists membrane passage *p. 91*

- 7. Plasma membranes are selectively permeable.
- 8. **Diffusion** is the movement of a substance from an area where its concentration is relatively high to an area where its concentration is lower. Diffusion occurs until the **concentration gradient** is eliminated. (*Figures* 3-4, 3-5)
- **9. Osmosis** is the diffusion of water across a selectively permeable membrane in response to differences in concentration. The force of movement is **osmotic pressure**. (*Figures* 3-6, 3-7)

3-4 Carrier-mediated and vesicular transport processes assist membrane passage *p. 95*

- **10. Facilitated diffusion** is a type of **carrier-mediated transport** and requires the presence of carrier proteins in the membrane. (*Figure 3-8*)
- **11. Active transport** processes consume ATP and are independent of concentration gradients. Some **ion pumps** are **exchange pumps**. (*Figure 3-9*)
- 12. In vesicular transport, material moves into or out of a cell in membranous sacs. Movement into the cell occurs through endocytosis, an active process that includes receptor-mediated endocytosis, pinocytosis ("cell-drinking"), and phagocytosis ("cell-eating"). Movement of material out of the cell occurs through exocytosis. (*Figures 3-10, 3-11; Table 3-2*)

3-5 Organelles within the cytoplasm perform specific functions *p. 99*

- **13.** The *cytoplasm* surrounds the nucleus and contains a fluid cytosol and intracellular structures called organelles.
- **14.** The **cytosol** (*intracellular fluid*) differs in composition from the extracellular fluid that surrounds most cells of the body.
- **15.** Membrane-enclosed **organelles** are surrounded by phospholipid membranes that isolate them from the cytosol. Membranous organelles include the endoplasmic reticulum, the nucleus, the Golgi apparatus, lysosomes, and mitochondria. *(Spotlight Figure 3-2)*
- **16.** Nonmembranous organelles are always in contact with the cytosol. They include the cytoskeleton, microvilli, centrioles, cilia, flagella, proteasomes, and ribosomes. *(Spotlight Figure 3-2)*
- **17.** The **cytoskeleton** gives the cytoplasm strength and flexibility. Its main components are **microfilaments**, **intermediate filaments**, and **microtubules**. (*Figure 3-12*)
- **18. Microvilli** are small projections of the plasma membrane that increase the surface area exposed to the extracellular environment. (*Figure 3-12*)

- **19. Centrioles** direct the movement of chromosomes during cell division.
- **20.** Multiple **motile cilia** move fluids or secretions across the cell surface by beating rhythmically. A single **primary cilium** is sensitive to environmental stimuli.
- **21. Flagella** move a cell through surrounding fluid. The only human cell that has a flagellum is a sperm.
- **22.** A **ribosome** manufactures proteins. **Free ribosomes** are in the cytoplasm, and **fixed ribosomes** are attached to the endoplasmic reticulum.
- **23. Proteasomes** remove and break down damaged or abnormal proteins.
- 24. The endoplasmic reticulum (ER) is a network of intracellular membranes. Rough endoplasmic reticulum (RER) contains ribosomes and is involved in protein synthesis. Smooth endoplasmic reticulum (SER) does not contain ribosomes. It is involved in lipid and carbohydrate synthesis. (*Figure 3-13; Spotlight Figure 3-15*)
- **25.** The **Golgi apparatus** forms **secretory vesicles** and new membrane components, and it packages *lysosomes*. Secretions are discharged from the cell by exocytosis. (*Spotlight Figure 3-2; Figure 3-14; Spotlight Figure 3-15*)
- **26. Lysosomes** are vesicles filled with digestive enzymes. Their functions include ridding the cell of bacteria and debris.
- **27. Mitochondria** are responsible for 95 percent of the ATP production within a typical cell. The **matrix**, or fluid contents of a mitochondrion, lies inside **cristae**, or folds of an inner mitochondrial membrane. (*Figure 3-16*)

3-6 The nucleus contains DNA and enzymes essential for controlling cellular activities *p. 106*

- **28.** The **nucleus** is the control center for cellular activities. It is surrounded by a **nuclear envelope**, through which it communicates with the cytosol by way of **nuclear pores**. (*Figure 3-17*)
- **29.** The nucleus controls the cell by directing the synthesis of specific proteins using information stored in the DNA of **chromosomes**. (*Figure 3-18*)
- **30.** The cell's information storage system, the **genetic code**, is called a *triplet code* because a sequence of three nitrogenous bases identifies a single amino acid. Each **gene** consists of all the DNA triplets needed to produce a specific protein. (*Table 3-3*)

3-7 DNA controls protein synthesis, cell structure, and cell function *p. 108*

31. Protein synthesis includes both *transcription*, which occurs in the nucleus, and *translation*, which occurs in the cytoplasm.

- **32.** During **transcription**, a strand of **messenger RNA** (**mRNA**) is formed and carries protein-making instructions from the nucleus to the cytoplasm. (*Figure 3-19*)
- **33.** During **translation**, a functional protein is constructed using the information contained in an mRNA strand. Each triplet of nitrogenous bases along the mRNA strand is a **codon**. The sequence of codons determines the sequence of amino acids in the protein.
- 34. During translation, complementary base pairing of anticodons and mRNA codons occurs, and transfer RNA (tRNA) molecules bring amino acids to the ribosome. Translation includes three phases: initiation, elongation, and termination.

3-8 Stages of a cell's life cycle include interphase, mitosis, and cytokinesis *p. 111*

- **35. Cell division** is the reproduction of cells. **Apoptosis** is the genetically controlled death of cells. **Mitosis** is the nuclear division of **somatic** (body) **cells**.
- **36.** Most somatic cells are in **interphase** most of the time. Cells preparing for mitosis undergo **DNA replication** in this phase. (*Figures 3-21, 3-22*)
- **37.** Mitosis proceeds in four stages: **prophase, metaphase, anaphase**, and **telophase**. (*Figure* 3-23)
- **38.** During **cytokinesis**, the cytoplasm divides, producing two identical daughter cells.

3-9 Tumors and cancers are characterized by abnormal cell growth and division *p. 114*

39. Produced by abnormal cell growth and division, a tumor, or *neoplasm*, can be benign (non-cancerous) or malignant (able to invade other tissues). Cancer is a disease characterized by the presence of malignant tumors. Over time, cancer cells tend to spread to new areas of the body.

3-10 Cellular differentiation is cellular specialization as a result of gene activation or repression *p. 115*

40. Cellular differentiation is a process of specialization that produces cells with limited capabilities. These specialized cells form organized collections called *tissues*, each of which has specific functional roles.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

Membrane Transport

The Tissue Level of Organization

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **4-1** Identify the body's four basic types of tissues and describe their roles.
- **4-2** Describe the characteristics and functions of epithelial cells.
- **4-3** Describe the relationship between form and function for each type of epithelium.
- **4-4** Compare the structures and functions of the various types of connective tissues.
- **4-5** Explain how epithelial and connective tissues combine to form four types of tissue membranes, and specify the functions of each.
- **4-6** Describe the three types of muscle tissue and the special structural features of each.
- **4-7** Discuss the basic structure and role of nervous tissue.
- **4-8** Describe how injuries affect the tissues of the body.
- **4-9** Describe how aging affects the tissues of the body.

Inflammation and Regeneration, p. 146

An Introduction to the Tissue Level of Organization

In this chapter, we discuss how a variety of cell types arranged in various combinations form tissues, which are structures with distinct structural and functional properties. Tissues in combination form organs, such as the heart or liver, and in turn organs can be grouped into 11 organ systems.

Build Your Knowledge

The Build Your Knowledge feature reminds you of what you already know and prepares you to learn new material. Be sure to read every Build Your Knowledge box or page so that you can build your knowledge—and confidence!

Recall that a tissue is made up of similar cells working together to perform a specific function (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). Our example there was cardiac muscle tissue. This tissue combines with other tissues to form the heart. The heart, blood, and blood vessels are the components of the cardiovascular system. \bigcirc **p. 34**

4-1 The four tissue types are epithelial, connective, muscle, and nervous

Learning Outcome Identify the body's four basic types of tissues and describe their roles.

No single cell is able to perform the many functions of the human body. Instead, through differentiation, each cell specializes to perform a relatively restricted range of functions. There are trillions of individual cells in the human body, but only about 200 different types of cells. These cell types combine to form **tissues**, collections of specialized cells and cell products that perform a limited number of functions.

Recall that cellular differentiation is the development of specific cellular characteristics and functions that are different from the original cell. This cellular specialization occurs as different genes are activated or repressed (as you saw in **Chapter 3: The Cellular Level of Organization**). This process underlies why cells such as liver cells, fat cells, and nerve cells differ in appearance and function. \supset **p. 115** **Histology** (*histos*, tissue) is the study of tissues. Histologists recognize four basic *types* of tissues: *epithelial tissue, connective tissue, muscle tissue,* and *nervous tissue* (**Figure 4-1**).

CHECKPOINT

- **1**. Define histology.
- **2.** List the four basic types of tissues in the body.
- See the blue Answers tab at the back of the book.

4-2 Epithelial tissue covers body surfaces, lines cavities and tubular structures, and serves essential functions

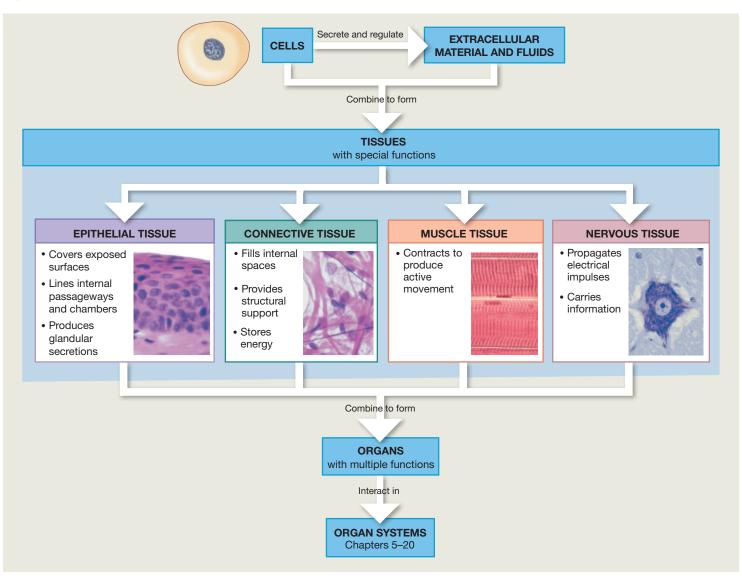

Learning Outcome Describe the characteristics and functions of epithelial cells.

Our discussion begins with *epithelial tissue*, because it includes a familiar feature—the surface of your skin. **Epithelial tissue** includes epithelia and *glands*. **Epithelia** (ep-i-THĒ-lē-a; singular, *epithelium*) are layers of cells that cover internal or external surfaces. **Glands** are composed of fluid-secreting cells derived from epithelia.

Epithelia have the following important characteristics:

• Cells that are bound closely together. In other tissue types, the cells are often widely separated by extracellular materials.

Figure 4-1 An Orientation to the Body's Tissues.

- A free (apical) surface exposed to the environment or to an internal chamber or passageway.
- Attachment to underlying connective tissue by a *basement membrane*.
- The absence of blood vessels. Because of this **avascular** (ā-VAS-kū-lar; *a*-, without + *vas*, vessel) condition, epithelial cells must obtain nutrients across their attached surface from deeper tissues or across their exposed surfaces.
- Continual replacement or regeneration of epithelial cells that are damaged or lost at the exposed surface.

Epithelia cover both external and internal body surfaces. In addition to covering the skin, epithelia line internal passageways that open to the outside world, such as the digestive, respiratory, reproductive, and urinary tracts. These epithelia form selective barriers that separate the deep tissues of the body from the external environment.

Epithelia also line internal cavities and passageways, such as the body cavities surrounding the lungs and heart; the fluidfilled chambers in the brain, eye, and internal ear; and the inner surfaces of the heart and blood vessels. These epithelia prevent friction, regulate the fluid composition of internal cavities, and restrict communication between the blood and tissue fluids.

Functions of Epithelia

Epithelia perform four essential functions. They:

- 1. *Provide physical protection*. Epithelia protect exposed and internal surfaces from abrasion, dehydration, and destruction by chemical or biological agents. For example, as long as it remains intact, the epithelium of your skin resists impacts and scrapes, restricts water loss, and prevents bacteria from invading underlying structures.
- **2.** *Control permeability.* Any substance that enters or leaves the body must cross an epithelium. Some epithelia are relatively impermeable; others are easily crossed by compounds as large as proteins.
- **3.** *Provide sensation.* Specialized epithelial cells can detect changes in the environment and relay information about such changes to the nervous system. For example, touch receptors in the deepest layers of the epithelium of the skin respond to touch by stimulating neighboring sensory nerves.
- **4.** *Produce specialized secretions.* Epithelial cells that produce secretions are called **gland cells**. Individual gland cells are typically scattered among other cell types in an epithelium. In a **glandular epithelium**, most or all of the cells actively produce secretions. These secretions are classified according to where they are discharged:
 - **Exocrine** (*exo*-, outside + *krinein*, to secrete) secretions are discharged onto the surface of the epithelium. Examples include enzymes entering the digestive tract, perspiration on the skin, and milk produced by mammary glands.
 - Endocrine (*endo*-, inside) secretions are released into the surrounding tissue (interstitial) fluid and blood. These secretions, called *hormones*, act as chemical messengers and regulate or coordinate the activities of other tissues, organs, and organ systems. (We discuss hormones further in Chapter 10.) Endocrine secretions are produced in such organs as the pancreas, and thyroid and pituitary glands.

Intercellular Connections

To be effective in protecting other tissues, epithelial cells must remain firmly attached to the basement membrane and to one another to form a complete cover or lining. If an epithelium is damaged or the connections are broken, it is no longer an effective barrier. For example, when the epithelium of the skin is damaged by a burn or an abrasion, bacteria can enter underlying tissues and cause an infection. Undamaged epithelia form effective barriers because of intercellular connections that involve either large areas of opposing plasma membranes or specialized attachment sites. The large areas of opposing plasma membranes are interconnected by transmembrane proteins called *cell adhesion molecules (CAMs)*. These proteins bind to each other and extracellular materials by a thin layer of *proteoglycans* (a protein-polysaccharide mixture).

More specialized attachment sites that attach a cell to another cell or to extracellular materials are known as **cell junctions**. Three common cell junctions are *tight junctions, gap junctions,* and *desmosomes* (Figure 4-2).

At a **tight junction**, the lipid layers of adjacent plasma membranes are tightly bound together by interlocking membrane proteins (**Figure 4-2a,c**). Inferior to the tight junctions, a continuous *adhesion belt* forms a band that encircles cells and binds them to their neighbors. The bands are connected to a network of actin filaments in the cytoskeleton.

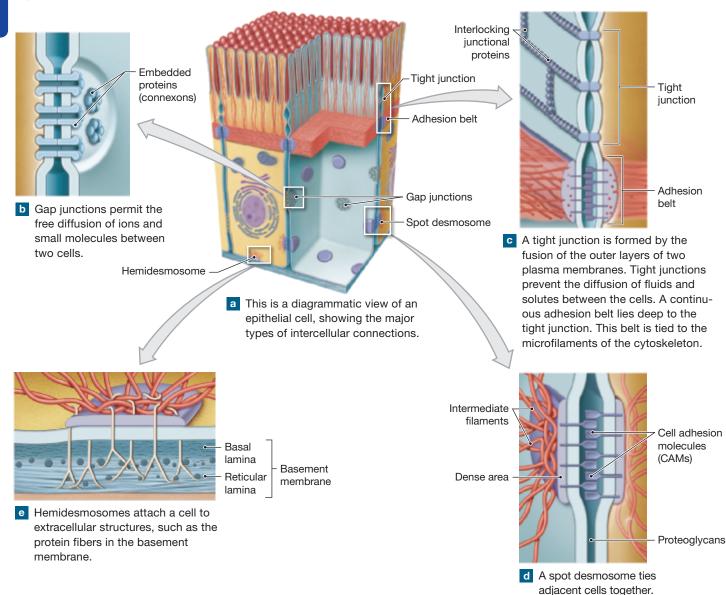

Tight junctions prevent the passage of water and solutes between cells. These junctions are common between epithelial cells exposed to harsh chemicals or powerful enzymes. For example, tight junctions between epithelial cells lining the digestive tract keep digestive enzymes, stomach acids, or waste products from damaging underlying tissues.

Some epithelial functions require rapid intercellular communication. At a **gap junction**, two cells are held together by embedded membrane proteins called *connexons* (Figure 4-2b). Together, the connexons form a narrow passageway that lets small molecules and ions pass from cell to cell. Gap junctions are most abundant in cardiac muscle and smooth muscle tissue, where they are essential to the coordination of muscle contractions. They also interconnect cells in ciliated epithelia (discussed shortly).

Most epithelial cells are subject to mechanical stresses such as stretching, bending, twisting, or compression. For this reason, they must have durable interconnections. At a **desmosome** (DEZ-mō-sōm; *desmos*, ligament + *soma*, body), the plasma membranes of two cells are locked together by CAMs and proteoglycans between the opposite dense areas of each cell. Each *dense area* is linked to the cytoskeleton by a network of intermediate filaments (**Figure 4-2d**).

Desmosomes that form a small disc are called *spot desmosomes*. *Hemidesmosomes* resemble half of a spot desmosome and attach a cell to the basement membrane (Figure 4-2e). Desmosomes are abundant between cells in the superficial layers of the skin. As a result, damaged skin cells are usually lost in sheets rather than as individual cells. (That is why your skin peels after a sunburn, rather than coming off as a powder.)

Figure 4-2 Cell Junctions.

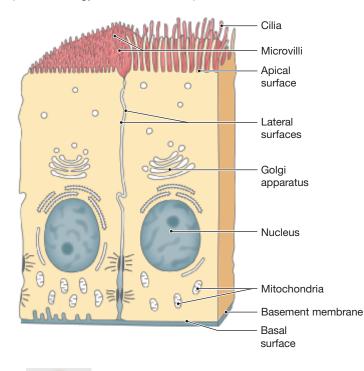

The Epithelial Surface

The *apical surface* of epithelial cells is exposed to an internal or external environment. The surfaces of these cells often have specialized structures unlike other body cells (**Figure 4-3**). Many epithelia that line internal passageways have microvilli on their exposed surfaces. $\bigcirc p$. 100 Microvilli may vary in number from just a few to so many that they carpet the entire surface. They are especially abundant on epithelial surfaces where absorption and secretion take place, such as portions of the digestive system and kidneys. The epithelial cells in these locations are transport specialists. A cell with microvilli has at least 20 times the surface area of a cell without them. The greater the surface area of the plasma membrane, the more transport proteins are exposed to the extracellular environment.

Motile cilia are characteristic of surfaces covered by a *ciliated epithelium*. \supset p. 101 A typical ciliated cell has roughly 250 cilia that beat in a coordinated manner to move materials across the epithelial surface. For example, the ciliated epithelium that lines the respiratory tract moves mucus-trapped irritants away from the lungs and toward the throat.

The Basement Membrane

Epithelial cells not only must adhere to one another but also must remain firmly connected to the rest of the body. This function is performed by the **basement membrane**, which lies between the epithelium and underlying connective tissues (**Figure 4-3**). There are no cells within the basement **Figure 4-3 The Surfaces of Epithelial Cells.** The surfaces of most epithelia are specialized for specific functions. In this diagram of a generalized epithelium, the free (apical) surfaces of different cells bear microvilli or cilia. Mitochondria are shown concentrated near the basal surface of the cells, where they likely provide energy for the cell's transport activities.

Epithelial cells of certain body surfaces are transport specialists. Recall that the transport of materials across plasma membranes involves passive and active processes (as you saw in **Chapter 3: The Cellular Level of Organization**). Active processes require the cell to expend energy. The three main transport processes involved in getting substances into and out of cells are (1) diffusion, (2) carrier-mediated transport, and (3) vesicular transport. Diffusion is a passive process. Carrier-mediated transport includes both passive and active processes. Vesicular transport is an active process. **`p.99**

membrane, which consists of a network of protein fibers. The epithelial cells adjacent to the basement membrane are firmly attached to these protein fibers by hemidesmosomes. In addition to providing strength and resisting distortion, the basement membrane also acts as a barrier. It restricts proteins and other large molecules from moving from the underlying connective tissue into the epithelium.

Epithelial Renewal and Repair

An epithelium must continually repair and renew itself. Epithelial cells may survive for just a day or two, because they are lost or destroyed by exposure to disruptive enzymes, toxic chemicals, pathogenic microorganisms, or mechanical abrasion. The only way the epithelium can maintain its structure over time is through the continuous division of unspecialized cells known as **stem cells**, or *germinative cells*. These cells are found in the deepest layers of the epithelium, near the basement membrane.

CHECKPOINT

- **3.** List five important characteristics of epithelial tissue.
- **4.** Identify four essential functions of epithelial tissue.
- **5.** Identify the three main types of epithelial cell junctions.
- **6.** What physiological functions are enhanced by the presence of microvilli or cilia on epithelial cells?

See the blue Answers tab at the back of the book.

4-3 Cell shape and number of layers determine the classification of epithelia

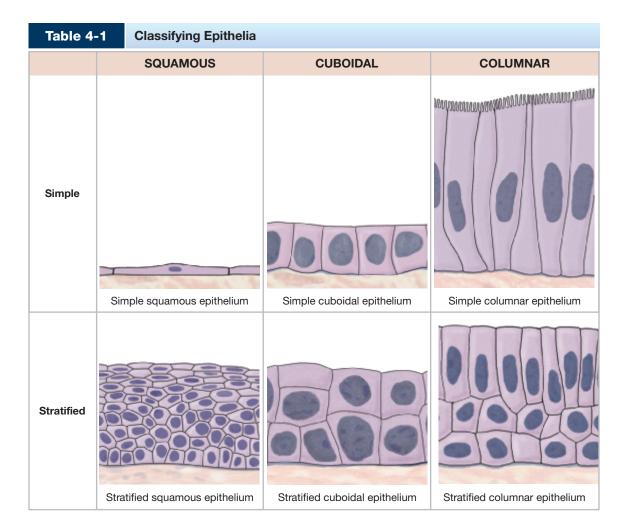

Learning Outcome Describe the relationship between form and function for each type of epithelium.

There are many different specialized types of epithelia. They can easily be classified according to the number of cell layers and the shape of the exposed cells. This classification scheme recognizes two types of layering—*simple* and *stratified*—and three cell shapes—*squamous, cuboidal,* and *columnar* (Table 4-1).

Cell Layers

A **simple epithelium** consists of a single layer of cells covering the basement membrane. Simple epithelia are thin. A single layer of cells is fragile and cannot provide much mechanical protection. For this reason, simple epithelia are found only in protected areas inside the body. They line internal compartments and passageways, including the pleural, pericardial, and peritoneal cavities, the heart chambers, and blood vessels.

Simple epithelia are also characteristic of regions where secretion or absorption occurs. Examples are the lining of the intestines and the gas-exchange surfaces of the lungs. In these places, thinness is an advantage. It reduces the time for materials to cross the epithelial barrier.

A **stratified epithelium** provides greater protection because it has several layers of cells above the basement membrane. Stratified epithelia are usually found in areas exposed to mechanical or chemical stresses. Examples include the surface of the skin and the lining of the mouth.

Cell Shapes

In sectional view (perpendicular to the exposed surface and basement membrane), cells at the surface of the epithelium usually have one of three basic shapes.

- **1.** *Squamous.* In a **squamous epithelium** (SKWĀ-mus; *squama,* plate or scale), the cells are thin and flat. The nucleus occupies the thickest portion of each cell. Viewed from the surface, the cells look like fried eggs laid side by side.
- **2.** *Cuboidal.* The cells of a **cuboidal epithelium** resemble little hexagonal (six-sided) boxes when seen from their free, apical surfaces, In typical sectional view, they appear square. The round nuclei lie near the center of each cell, and the distance between neighboring nuclei is about equal to the height of the epithelium.

3. *Columnar.* In a *columnar epithelium*, the cells are also hexagonal but taller and more slender, resembling rectangles in sectional view. The nuclei are crowded into a narrow band close to the basement membrane. The height of the epithelium is several times the distance between two nuclei.

Classification of Epithelia

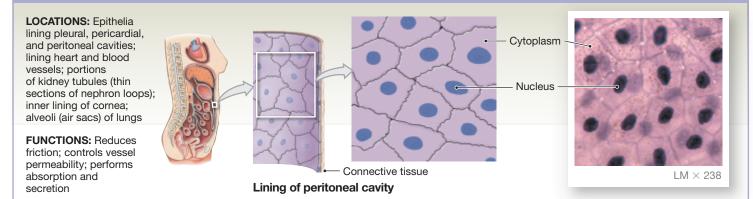

The two basic epithelial arrangements (simple and stratified) and the three possible cell shapes (squamous, cuboidal, and columnar) enable us to describe almost every epithelium in the body. We will focus here on only a few major types of epithelia.

Simple Squamous Epithelia

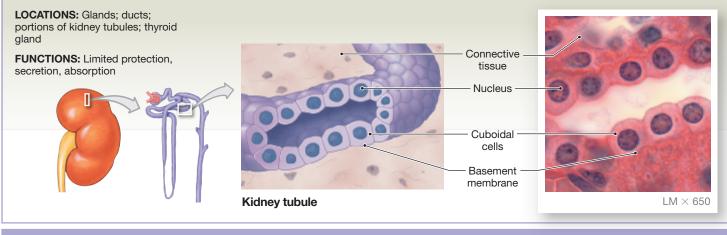

A **simple squamous epithelium** is found in protected regions where absorption takes place or where a slippery surface reduces friction (**Figure 4-4a**). Examples are portions of the kidney tubules, the gas-exchange surfaces of the lungs, the linings of the pericardial, pleural, and peritoneal cavities, blood vessels, and the inner surfaces of the heart.

Figure 4-4 Simple Epithelia.

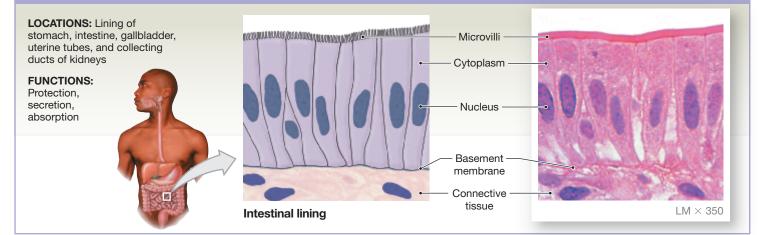

a Simple Squamous Epithelium

b Simple Cuboidal Epithelium

c Simple Columnar Epithelium

Δ

Simple Cuboidal Epithelia

A **simple cuboidal epithelium** provides limited protection and occurs where secretion or absorption takes place (**Figure 4-4b**). These functions are enhanced by larger cells, which have more room for the necessary organelles. Simple cuboidal epithelia in the pancreas and salivary glands secrete enzymes and buffers and line the ducts that discharge these secretions. Simple cuboidal epithelia also line portions of the kidney tubules involved in producing urine.

Simple Columnar Epithelia

A **simple columnar epithelium** provides some protection and may also occur in areas of absorption or secretion (**Figure 4-4c**). This type of epithelium lines the stomach, the intestinal tract, and many excretory ducts.

Stratified Squamous Epithelia

A **stratified squamous epithelium** is found where mechanical stresses are severe. Examples include the surface of the skin and the lining of the mouth, tongue, esophagus, and anus (**Figure 4-5a**).

Stratified Cuboidal Epithelia

Stratified cuboidal epithelium is relatively rare. It occurs along the ducts of sweat glands and in the larger ducts of the mammary glands. (It is not shown with the other stratified epithelia.)

Stratified Columnar Epithelia

Stratified columnar epithelium is also relatively rare. It is found along portions of the pharynx, epiglottis, anus, urethra, and a few, large excretory ducts. If more than two layers are present, only the superficial cells are columnar. (It is also not shown with the other stratified epithelia.)

Pseudostratified Epithelia

Portions of the respiratory tract contain **pseudostratified columnar epithelium**, a columnar epithelium that includes a mixture of cell types. The distances between the cell nuclei and the exposed surface vary, so the epithelium appears layered, or stratified (**Figure 4-5b**). It is not truly stratified, though, because all the cells contact the basement membrane.

Epithelial cells of this tissue typically possess cilia. A pseudostratified ciliated columnar epithelium lines most of the nasal cavity, the trachea (windpipe) and bronchi, and portions of the male reproductive tract.

Transitional Epithelia

A **transitional epithelium** is a stratified epithelium that tolerates repeated cycles of stretching and recoiling. It is called transitional because the appearance of the epithelium changes as stretching takes place. It lines the ureters and urinary bladder, where large changes in volume occur (**Figure 4-5c**). In an empty urinary bladder, the epithelium is layered, and the outermost cells appear plump and cuboidal. In a full urinary bladder, when the volume of urine has stretched the lining to its limits, the epithelium appears flattened. It looks more like a stratified squamous epithelium.

Glandular Epithelia

Many epithelia contain gland cells that produce exocrine or endocrine secretions. Exocrine secretions are produced by exocrine glands, which discharge their products through a *duct*, or tube, onto some external or internal surface. Endocrine secretions (*hormones*) are produced by ductless endocrine glands and released into blood or tissue fluids.

Based on their structure, exocrine glands can be categorized as unicellular glands (called *mucous* or *goblet cells*) or as multicellular glands. The simplest multicellular exocrine gland is a *secretory sheet*, such as the epithelium of mucin-secreting cells that lines the stomach and protects it from its own acids and enzymes. Multicellular glands are further classified according to the branching pattern of the duct and the shape and branching pattern of the secretory portion of the gland. Additionally, exocrine glands can be classified according to their *method of secretion* or *type of secretion*.

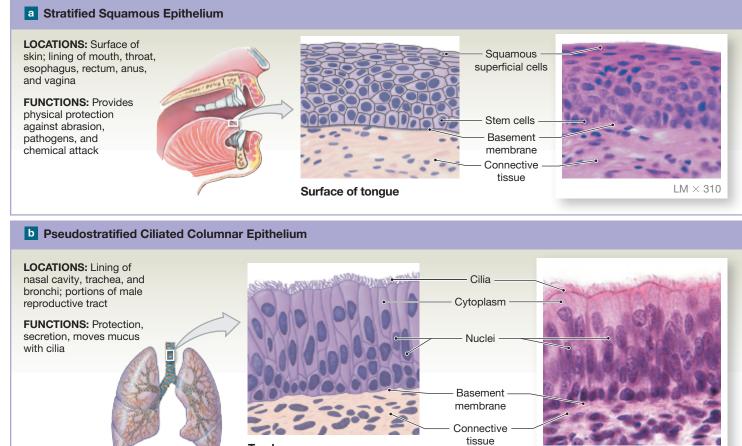

Method of Secretion

A glandular epithelial cell releases its secretions by (1) *merocrine secretion*, (2) *apocrine secretion*, or (3) *holocrine secretion* (Figure 4-6).

In **merocrine secretion** (MER-u-krin; *meros*, part + *krinein*, to secrete), the product is released from secretory vesicles by exocytosis. (Figure 4-6a). \supset p. 98 This is the most common method of exocrine secretion. One product of merocrine secretion, *mucin*, mixes with water to form **mucus**. Mucus is an effective lubricant, a protective barrier, and a sticky trap for foreign particles and microorganisms.

Apocrine secretion (AP-ō-krin; *apo-*, off) involves the loss of both cytoplasm and the secretory product (**Figure 4-6b**). The outermost portion of the cytoplasm becomes packed with secretory vesicles before it is shed. Milk production in the mammary glands involves both merocrine and apocrine secretions.

Figure 4-5 Stratified Epithelia.

c Transitional Epithelium

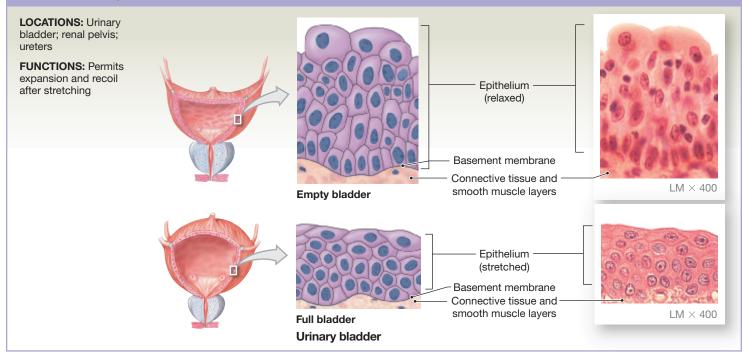

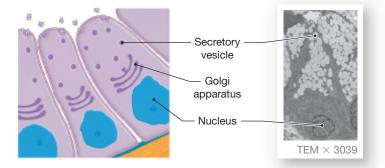

Figure 4-6 Methods of Glandular Secretion.

Automatic Salivary gland Mammary gland Hair Sebaceous gland Hair follicle

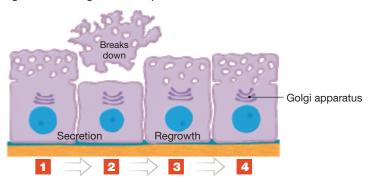

a Merocrine secretion

In merocrine secretion, the product is released from secretory vesicles at the apical surface of the gland cell by exocytosis.

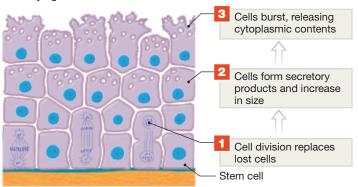

b Apocrine secretion

Apocrine secretion involves the loss of apical cytoplasm. Inclusions, secretory vesicles, and other cytoplasmic components are shed in the process. The gland cell then grows and repairs itself before it releases additional secretions.

C Holocrine secretion

Holocrine secretion occurs as superficial gland cells burst. Continued secretion involves the replacement of these cells through the divisions of underlying stem cells.

Merocrine and apocrine secretions leave a cell intact and able to continue secreting.

Holocrine secretion (HOL-ō-krin; *holos*, entire) does not leave a cell intact. Instead, the entire cell becomes packed with

secretory vesicles and then bursts, releasing the secretion, but killing the cell (**Figure 4-6c**). Sebaceous glands, associated with hair follicles, produce an oily hair coating by holocrine secretion.

Table 4-2	A Classification of Exocrine Glands			
Feature	Description	Examples		
METHOD OF SECRETION				
Merocrine	Secretion occurs through exocytosis.	Saliva from salivary glands; mucus in digestive and respiratory tracts; perspiration on the skin; milk in breasts		
Apocrine	Secretion occurs through loss of cytoplasm containing secretory product.	Milk in breasts; viscous underarm perspiration		
Holocrine	Secretion occurs through loss of entire cell containing secretory product.	Skin oils and waxy coating of hair (produced by sebaceous glands of the skin)		
TYPE OF SECRETION				
Serous	Watery solution containing enzymes	Secretions of parotid salivary gland		
Mucous	Thick, slippery mucus	Secretions of sublingual salivary gland		
Mixed	Contains more than one type of secretion	Secretions of submandibular salivary gland (serous and mucous)		

Type of Secretion

There are many kinds of exocrine secretions, all performing a variety of functions. Examples are enzymes entering the digestive tract, perspiration on the skin, and the milk produced by mammary glands.

Based on the type or types of secretions produced, exocrine glands can also be categorized as serous, mucous, or mixed. The secretions can have a variety of functions. *Serous glands* secrete a watery solution containing enzymes. *Mucous glands*

CLINICAL NOTE

Exfoliative Cytology

Exfoliative cytology (eks-FO-lē-a-tiv; ex-, from + folium, leaf) is the study of cells shed or removed from epithelial surfaces. The cells are examined for a variety of reasons—for example, to check for cellular changes that indicate cancer or to do genetic screening of a fetus. The cells are collected by sampling the fluids that cover the epithelia lining the respiratory, digestive, urinary, or reproductive tracts; by removing fluid from the pericardial, peritoneal, or pleural cavities; or by removing cells from an epithelial surface.

A common example of exfoliative cytology is a *Pap test*, named after Dr. George Papanicolaou, who pioneered its use. The most familiar Pap test is that for cervical cancer. The test involves scraping a small number of cells from the tip of the *cervix*, the portion of the uterus that projects into the vagina.

Amniocentesis is another important test involving exfoliative cytology. In this procedure, epithelial cells that have been shed are collected from a sample of *amniotic fluid*, the fluid that surrounds and protects a developing fetus. Examination of these cells can determine whether the fetus has a genetic abnormality, such as *Down syndrome*, that affects the number or structure of chromosomes. secrete mucins that form a thick, slippery mucus. *Mixed glands* contain more than one type of gland cell. They may produce two different exocrine secretions, one serous and the other mucous.

 Table 4-2 summarizes the classification of exocrine glands

 according to their method of secretion and type of secretion.

CHECKPOINT

- **7.** Identify the three cell shapes characteristic of epithelial cells.
- **8.** Using a light microscope, a tissue appears as a simple squamous epithelium. Can this be a sample of the skin surface? Why or why not?
- **9.** Name the two primary types of glandular epithelia.
- 10. The secretory cells of sebaceous glands fill with secretions and then rupture, releasing their contents. Which method of secretion occurs in sebaceous glands?
- **11.** Which type of gland releases its secretions directly into the extracellular fluid?

See the blue Answers tab at the back of the book.

4-4 Connective tissue provides a protective structural framework for other tissue types

Learning Outcome Compare the structures and functions of the various types of connective tissues.

Connective tissue is the most diverse tissue of the body. Bone, blood, and fat are familiar connective tissues with very different functions and characteristics. All connective tissues have three basic components: (1) specialized cells, (2) extracellular

protein fibers, and (3) a fluid known as **ground substance**. The extracellular fibers and ground substance form the **matrix** that surrounds the cells. This extracellular matrix accounts for most of the volume of connective tissues. Connective tissue differs in this way from epithelial tissues, which consist almost entirely of cells.

Connective tissues occur throughout the body but are never exposed to the outside environment. Many connective tissues are highly vascular (that is, they have many blood vessels). They also contain sensory receptors that detect pain, pressure, temperature, and other stimuli. Connective tissue functions include:

- **Support and protection.** The minerals and fibers produced by connective tissue cells form a strong structural framework for the body, protect delicate organs, and surround and interconnect other tissue types.
- **Transportation of materials.** Fluid connective tissues move dissolved materials efficiently from one region of the body to another.
- **Storage of energy reserves.** Fats are stored in connective tissue cells called *adipose cells* until needed.
- **Defense of the body.** Specialized connective tissue cells respond to invasions by microorganisms through cell-to-cell interactions and the production of *antibodies*.

Based on their physical properties, connective tissues are classified into three major types (**Figure 4-7**):

- **1. Connective tissue proper** consists of many cell types within a matrix containing extracellular fibers and a syrupy ground substance. Examples are the tissue that underlies the skin, fatty tissue, and *tendons* and *ligaments*.
- **2. Fluid connective tissues** have a distinctive population of cells suspended in a matrix of watery ground substance containing dissolved proteins. The two fluid connective tissues are *blood* and *lymph*.
- **3. Supporting connective tissues** have a less diverse cell population than connective tissue proper, and a matrix of dense ground substance and closely packed fibers. The body contains two supporting connective tissues: *cartilage* and *bone*. The fibrous matrix of bone is said to be calcified because it contains mineral deposits (primarily calcium salts) that give the bone strength and rigidity.

Connective Tissue Proper

Connective tissue proper contains a varied cell population, extracellular fibers, and a syrupy ground substance (Figure 4-8). Some cells of connective tissue proper are "permanent residents." Others are not always present because they leave to defend and repair areas of injured tissue.

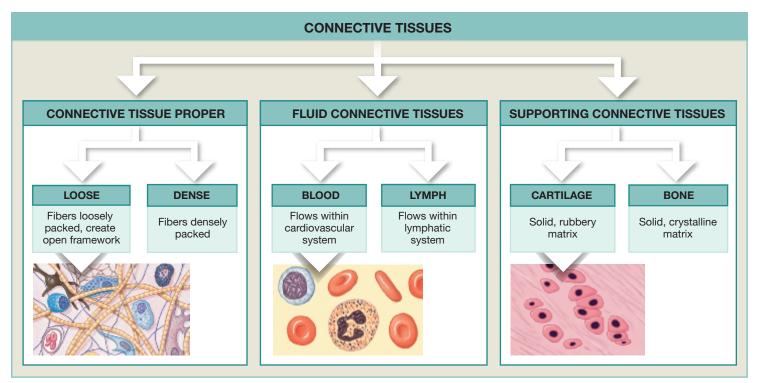

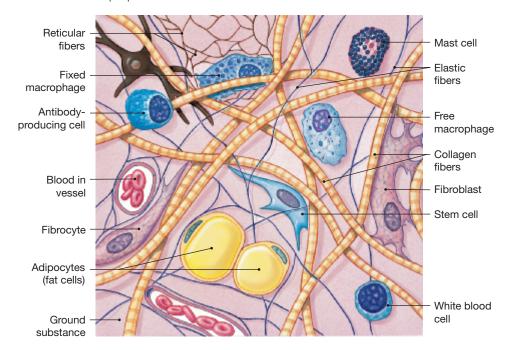

Figure 4-7 Major Types of Connective Tissue.

Figure 4-8 Cells and Fibers of Connective Tissue Proper. This diagrammatic view shows the common cell types and fibers of connective tissue proper.

Cells of Connective Tissue Proper

Connective tissue proper includes these four major cell types:

- **Fibroblasts** (FĪ-brō-blasts) are the only cells that are always present in connective tissue proper. They are also the most abundant permanent, or fixed, cells in connective tissue proper. Fibroblasts produce connective tissue fibers and ground substance. **Fibrocytes** (FĪ-brō-sīts) are next in abundance and differentiate from fibroblasts. Fibrocytes maintain the connective tissue fibers of connective tissue proper.
- **Macrophages** (MAK-rō-fā-jez; *phagein*, to eat) are large phagocytic cells (*phagocytes*) scattered throughout the matrix. These "big eater" cells engulf, or *phagocytize*, damaged cells or pathogens that enter the tissue. They also release chemicals that mobilize the immune system, attracting additional macrophages and other cells involved in tissue defense. ⊃ p. 98 Macrophages that spend long periods of time in connective tissue are known as *fixed macrophages*. When an infection occurs, migrating macrophages (called *free macrophages*) are drawn to the affected area.
- **Fat cells**, also known as adipose cells or **adipocytes** (AD-ipō-sīts), are permanent residents. A typical fat cell contains a large lipid droplet that squeezes the nucleus and other organelles to one side of the cell. The number of fat cells varies from one connective tissue to another, from one region of the body to another, and among individuals.

• **Mast cells** are small, motile connective tissue cells often found near blood vessels. The cytoplasm of a mast cell is packed with granules filled with *histamine* and *heparin*. These chemicals are released to begin the body's defensive activities after an injury or infection (as we will discuss later in the chapter).

In addition to mast cells and free macrophages, both phagocytic and antibody-producing white blood cells may move through connective tissue proper. Their numbers increase markedly if the tissue is damaged, as does the production of **antibodies**, proteins that destroy invading microorganisms or foreign substances. *Stem cells* also respond to local injury by dividing to produce daughter cells that differentiate into fibroblasts, macrophages, or other connective tissue cells.

Connective Tissue Fibers

The three basic types of fibers—*collagen, elastic,* and *reticular* are formed from protein subunits secreted by fibroblasts (**Figure 4-8**):

- **1. Collagen fibers** are long, straight, and unbranched. These strong but flexible fibers are the most common fibers in connective tissue proper.
- **2. Elastic fibers** contain the protein *elastin*. Elastic fibers are branched and wavy. After stretching, they return to their original length.

3. Reticular fibers (*reticulum*, a network) are made up of the same protein subunits as collagen fibers, but arranged differently. The least common of the three fibers, they are thinner than collagen fibers. Reticular fibers form a branching, interwoven framework in various organs.

Ground Substance

Ground substance fills the spaces between cells and surrounds connective tissue fibers (**Figure 4-8**). In normal connective tissue proper, it is clear, colorless, and similar in consistency to maple syrup. This dense consistency slows the movement of bacteria and other pathogens, making them easier for phagocytes to catch.

Types of Connective Tissue Proper

Connective tissue proper is categorized as either *loose connective tissues* or *dense connective tissues* on the basis of the relative proportions of cells, fibers, and ground substance. Loose connective tissues are the "packing materials" of the body. They fill spaces between organs, provide cushioning, and support epithelia. They also anchor blood vessels and nerves, store lipids, and provide a route for the diffusion of materials. Dense connective tissues are tough, strong, and durable. They resist tension and distortion and interconnect bones and muscles.

CLINICAL NOTE

Marfan Syndrome

Marfan syndrome is an inherited condition caused by the production of an abnormally weak form of *fibrillin*, a carbohydrate–protein complex important to normal connective tissue strength and elasticity. The effects of this defect are widespread because most organs contain connective tissues. The most visible sign of Marfan syndrome involves the skeleton. Most individuals with this condition are tall and have abnormally long arms, legs, and fingers. The most serious consequences, affecting roughly

90 percent of individuals with Marfan syndrome, are structural abnormalities in their cardiovascular systems. The most dangerous possibility is that the weakened connective tissues in the walls of major arteries, such as the aorta, may burst, causing a sudden, fatal loss of blood. Worldwide, the incidence of Marfan syndrome is about 1 in 5000. Most cases have a family history of the disorder, but about one-fourth of the cases do not, and these result from a new mutation in the fibrillin gene.

Loose Connective Tissues

Areolar tissue (*areola*, little space) is the least specialized connective tissue in adults (**Figure 4-9a**). It contains all the cells and fibers found in any connective tissue proper, as well as an extensive blood supply.

Areolar tissue forms a layer that separates the skin from deeper structures. In addition to providing padding, its elastic properties allow a considerable amount of independent movement. Pinching the skin of your arm, for example, does not distort the underlying muscle. Conversely, a contracting muscle does not pull against the skin. As the muscle bulges, the areolar tissue stretches. The ample blood supply in this tissue carries wandering cells to and from the tissue and provides for the metabolic needs (oxygen and nutrients) of nearby epithelial tissue.

Adipose tissue, or fat, is a loose connective tissue containing large numbers of fat cells, or adipocytes (Figure 4-9b). The difference between loose connective tissue and adipose tissue is one of degree. A loose connective tissue is called adipose tissue when it becomes dominated by fat cells. Adipose tissue is another source of padding and shock absorption for the body. It also serves as insulation that slows heat loss through the skin, and it stores energy.

Adipose tissue is common under the skin of the flanks (between the last rib and the hips), buttocks, and breasts. It fills the bony sockets behind the eyes and surrounds the kidneys. It is also common beneath the epithelial lining of the pericardial and peritoneal cavities.

Reticular tissue is a loose connective tissue whose reticular fibers form a complex three-dimensional network (**Figure 4-9c**). They stabilize the positions of functional cells in lymph nodes and bone marrow and in organs such as the spleen and liver. Fixed macrophages, fibroblasts, and fibrocytes are associated with the reticular fibers. These cells are seldom visible, however, because specialized cells with other functions dominate the organs.

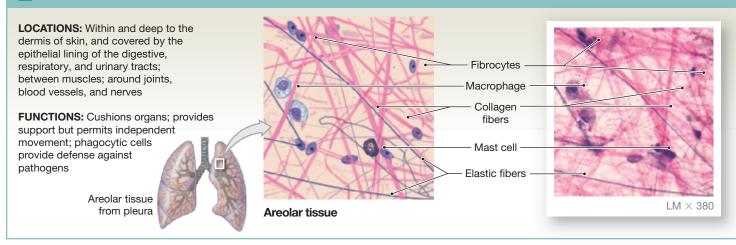

Dense Connective Tissues

Dense connective tissues consist mostly of collagen fibers. For this reason, they are also called *fibrous*, or *collagenous* (ko-LAJ-e-nus), tissues. The body has two types of dense connective tissues.

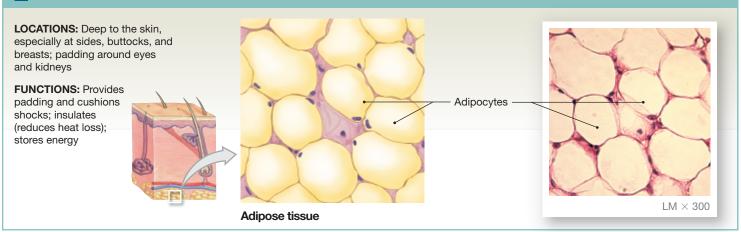

In **dense regular connective tissue**, the collagen fibers are parallel to each other, packed tightly, and aligned with the forces applied to the tissue. **Tendons** are cords of dense regular connective tissue that attach skeletal muscles to bones (**Figure 4-10a**). Their collagen fibers run along the length of the tendon and transfer the pull of the contracting muscle to the bone. **Ligaments** (LIG-a-ments) resemble tendons but connect one bone to another. Ligaments often contain elastic fibers as well as collagen fibers and thus can tolerate a modest amount of stretching.

Figure 4-9 Loose Connective Tissues.

a Areolar Tissue

b Adipose Tissue

c Reticular Tissue

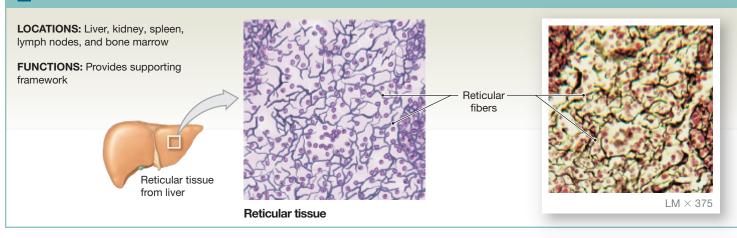

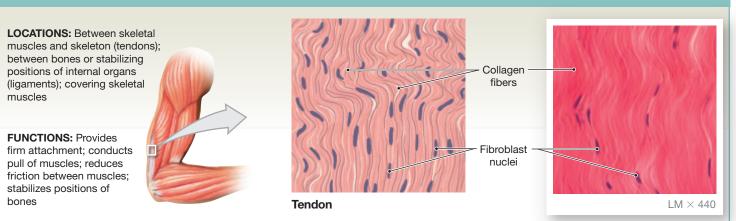

Figure 4-10 Dense Connective Tissues.

a Dense Regular Connective Tissue

b Dense Irregular Connective Tissue

In contrast, the fibers of dense irregular connective tissue (Figure 4-10b) form an interwoven meshwork in no consistent pattern. This tissue strengthens and supports areas subjected to stresses from many directions. Dense irregular connective tissue gives skin its strength and covers bone and cartilage (except at joints). It also forms a thick fibrous layer, or **capsule**, which surrounds internal organs such as the liver, kidneys, and spleen and encloses joint cavities.

Fluid Connective Tissues

Blood and lymph are connective tissues that contain distinctive collections of cells in a fluid matrix. Under normal conditions, the proteins dissolved in this watery matrix do not form large insoluble fibers. In blood, the watery matrix is called **plasma**.

A single cell type, the **red blood cell**, accounts for almost half the volume of blood. Red blood cells transport oxygen in

CLINICAL NOTE

Adipocytes are metabolically active cells. Their lipids are continually being broken down and replaced. When nutrients are scarce, adipocytes deflate like collapsing balloons. This deflation occurs during a weight-loss program. Because the cells are not killed but merely reduced in size, the lost weight can easily be regained in the same areas of the body.

In adults, adipocytes cannot divide. However, an excess of circulating lipids can stimulate connective tissue stem cells to divide. These cells then differentiate into additional fat cells. As a result, areas of areolar tissue can become adipose tissue after chronic overeating. In the procedure known as liposuction, unwanted adipose tissue is surgically removed. Because adipose tissue can regenerate through differentiation of stem cells, liposuction provides only a temporary and potentially risky solution to the problem of excess weight.

the blood. Blood also contains small numbers of **white blood cells**, important cells of the immune system, and **platelets**, cell fragments that play a role in blood clotting.

Together, plasma, lymph, and interstitial fluid make up most of the extracellular fluid of the body. Plasma is confined to the blood vessels of the cardiovascular system and is kept in constant motion by contractions of the heart. As blood flows through body tissues within thin-walled vessels called *capillaries*, water and small solutes move from the plasma into the interstitial fluid surrounding the body's cells. Lymph forms as interstitial fluid drains into small passageways, or *lymphatic vessels*, that eventually return it to the cardiovascular system. Along the way, cells of the immune system monitor the composition of the lymph and respond to signs of injury and infection. This recirculation of fluid is essential for homeostasis.

Supporting Connective Tissues

Cartilage and bone are called supporting connective tissues because they provide a strong framework that supports the rest of the body. In these connective tissues the matrix contains numerous fibers and, in some cases, deposits of solid calcium salts.

Cartilage

The matrix of **cartilage** is a firm gel containing embedded fibers. **Chondrocytes** (KON-drō-sīts) are the only cells found within the cartilage matrix. They occupy small pockets known as *lacunae* (la-KOO-nē; *lacus*, pool). Unlike other connective tissues, cartilage is avascular, so chondrocytes must obtain nutrients and eliminate waste products by diffusion through the matrix. This lack of a blood supply also limits the repair capabilities of cartilage. Structures of cartilage are covered and set apart from surrounding tissues by a **perichondrium** (per-i-KON-drē-um; *peri-*, around + *chondros*, cartilage) made up of an inner cellular layer and an outer fibrous layer.

The three major types of cartilage are *hyaline cartilage, elastic cartilage*, and *fibrocartilage* (Figure 4-11):

1. Hyaline cartilage (HĪ-uh-lin; *hyalos,* glass) is the most common type of cartilage (**Figure 4-11a**). The matrix contains closely packed collagen fibers, making hyaline cartilage tough but somewhat flexible. This type of cartilage connects the ribs to the sternum (breastbone), supports the conducting passageways of the respiratory tract, and covers opposing bone surfaces within joints.

- 2. Elastic cartilage contains numerous elastic fibers that make it extremely resilient and flexible (Figure 4-11b). Elastic cartilage forms the external flap (the *auricle*, or *pinna*) of the external ear, the epiglottis, an airway to the middle ear (the *auditory tube*), and small cartilages in the larynx (voice box).
- **3. Fibrocartilage** has little ground substance, and its matrix is dominated by collagen fibers (**Figure 4-11c**). These fibers are densely interwoven, making this tissue extremely durable and tough. Pads of fibrocartilage lie between the spinal vertebrae, between the pubic bones of the pelvis, around tendons, and around or within a few joints. In these positions the pads resist compression, absorb shocks, and prevent damaging bone-to-bone contact. Cartilages heal poorly, and damaged fibrocartilage in joints such as the knee can interfere with normal movements.

Bone

Here we focus on significant differences between cartilage and bone. We will examine the detailed histology of **bone**, or **osseous** (OS-ē-us; *os*, bone) **tissue** in Chapter 6. The volume of ground substance in bone is very small. The matrix of bone consists mainly of hard calcium compounds and flexible collagen fibers. This combination gives bone truly remarkable properties, making it both strong and resistant to shattering. In its overall properties, bone can compete with the best steelreinforced concrete.

The general organization of bone is shown in **Figure 4-12**. Lacunae in the matrix contain bone cells, or **osteocytes** (OS-tē- \bar{o} -sīts; *os*, bone + *cyte*, cell). The lacunae surround the blood vessels that branch through the bony matrix.

CLINICAL NOTE

Cartilages and Joint Injuries

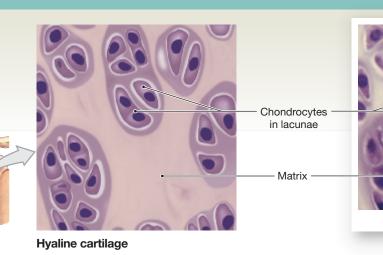

Several complex joints, including the knee, contain both hyaline cartilage and fibrocartilage. The hyaline cartilage covers bony surfaces. Fibrocartilage pads in the joint prevent bone-to-bone contact when movements are under way. Injuries to these joints can produce tears in the fibrocartilage pads that do not heal. This loss of cushioning places more strain on the cartilages within joints and leads to further joint damage. Eventually, joint mobility is severely reduced. Cartilages heal poorly because they are avascular. Joint cartilages heal even more slowly than other cartilages. Surgery to repair cartilage usually results in only a temporary or incomplete repair.

Figure 4-11 Types of Cartilage.

a Hyaline Cartilage

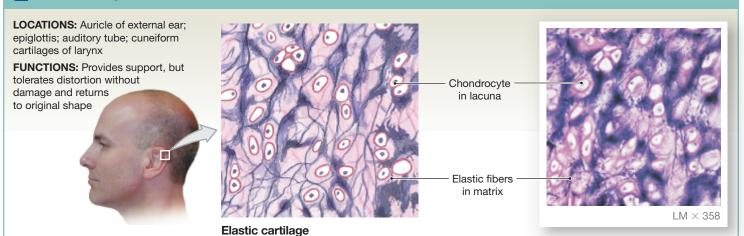

LOCATIONS: Between tips of ribs and bones of sternum; covering bone surfaces at freely movable (synovial) joints; supporting larynx (voice box), trachea, and bronchi; forming part of nasal septum

FUNCTIONS: Provides stiff but somewhat flexible support; reduces friction between bony surfaces

 $\rm LM imes 500$

b Elastic Cartilage

c Fibrocartilage

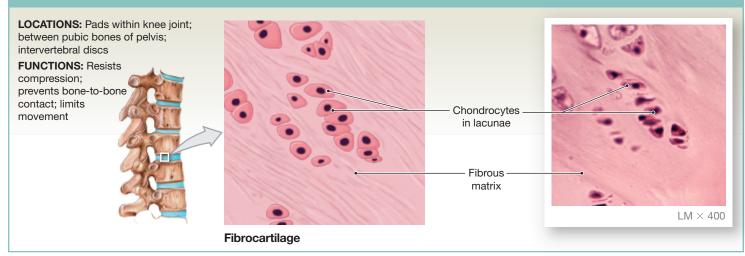

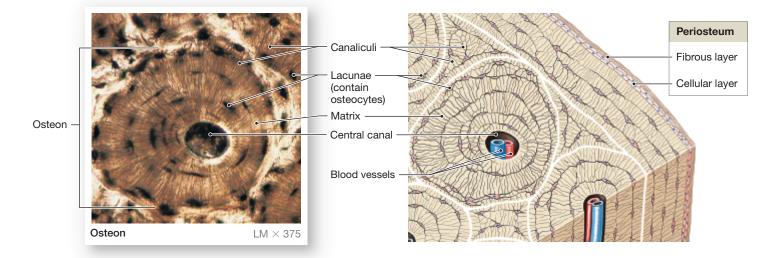

Figure 4-12 Bone. The osteocytes in bone are usually organized in groups around a central space that contains blood vessels. In the micrograph, bone dust produced during preparation of the bone section fills the lacunae and the central canal, making them appear dark.

Diffusion cannot take place through the bony matrix, but osteocytes obtain nutrients through cytoplasmic extensions that reach blood vessels and other osteocytes. These extensions run through a branching network within the matrix called **canaliculi** (kan-a-LIK-ū-lē; little canals).

Except in joint cavities, where a layer of hyaline cartilage covers bone, all other bone surfaces are surrounded by a **periosteum** (per-ē-OS-tē-um), a covering made up of fibrous (outer) and cellular (inner) layers. Unlike cartilage, bone is constantly being remodeled throughout life. Complete repairs can be made even after severe damage. **Table 4-3** summarizes the similarities and differences between cartilage and bone.

CHECKPOINT

- **12.** Identify several functions of connective tissues.
- **13.** List the three types of connective tissues.
- **14.** Which type of connective tissue contains primarily triglycerides?
- **15.** Lack of vitamin C in the diet interferes with the ability of fibroblasts to produce collagen. What effect might this interference have on connective tissue?
- **16.** Which two types of connective tissue have a fluid matrix?
- **17.** Identify the two types of supporting connective tissue.
- **18.** Why does cartilage heal more slowly than bone?
- See the blue Answers tab at the back of the book.

Table 4-3	Table 4-3 A Comparison of Cartilage and Bone		
Characteristic	Cartilage	Bone	
STRUCTURAL FEA	TURES		
Cells	Chondrocytes in lacunae	Osteocytes in lacunae	
Ground substance	Protein-polysaccharide gel and water	A small volume of liquid surrounding insoluble crystals of calcium salts (calcium phosphate and calcium carbonate)	
Fibers	Collagen, elastic, reticular fibers (proportions val	y) Collagen fibers predominate	
Vascularity (Blood	supply) None (avascular)	Extensive	
Covering	Perichondrium	Periosteum	
Strength	Limited: bends easily but difficult to break	Strong: resists distortion until breaking point is reached	
METABOLIC FEAT	JRES		
Oxygen demands	Low	High	
Nutrient delivery	By diffusion through matrix	By diffusion through cytoplasm and fluid in canaliculi	
Repair capabilities	Limited	Extensive	

4-5 Tissue membranes are physical barriers of four types: mucous, serous, cutaneous, and synovial

Learning Outcome Explain how epithelial and connective tissues combine to form four types of tissue membranes, and specify the functions of each.

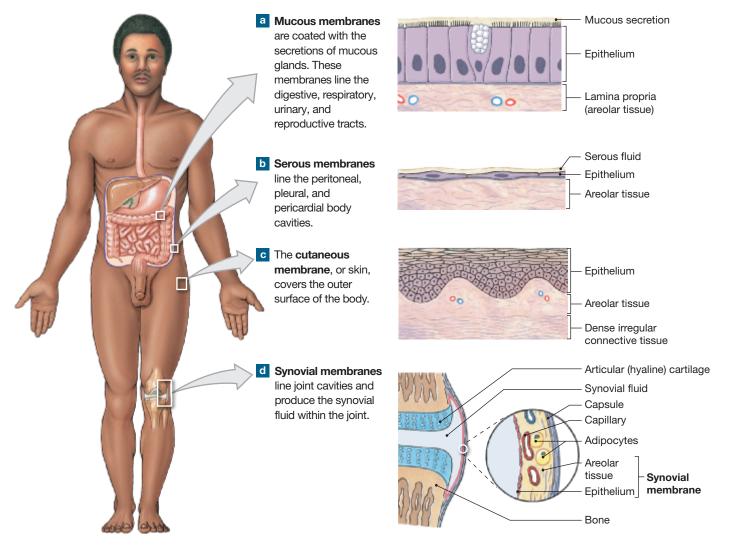

Some anatomical terms have more than one meaning, depending on the context. One such term is *membrane*. For example, at the cellular level, plasma membranes are lipid bilayers that restrict the passage of ions and other solutes. \bigcirc p. 90 A tissue membrane is a physical barrier. Tissue membranes line or cover body surfaces. Each consists of an epithelium supported by connective tissue. The body has four such membranes: *mucous membranes, serous membranes, the cutaneous membrane,* and *synovial membranes* (Figure 4-13).

Mucous Membranes

Mucous membranes, or **mucosae** (mū-KŌ-sē), line passageways and chambers that open to the exterior, including those in the digestive, respiratory, reproductive, and urinary tracts (**Figure 4-13a**). The epithelial surfaces are kept moist at all times, either by mucus produced by mucous cells or multicellular glands, or by fluids such as urine or semen. The areolar tissue portion of a mucous membrane is called the *lamina propria* (PRŌ-prē-uh).

Many mucous membranes contain simple epithelia with absorptive or secretory functions, such as the simple columnar epithelium of the digestive tract. However, other types of epithelia may be involved. For example, a stratified squamous epithelium is part of the mucous membrane of the mouth. Also, the mucous membrane along most of the urinary tract has a transitional epithelium.

Figure 4-13 Tissue Membranes.

Serous Membranes

A **serous membrane** consists of a simple epithelium supported by areolar tissue (**Figure 4-13b**). Serous membranes line the sealed, internal cavities of the trunk, which are not open to the exterior. There are three serous membranes. The **pleura** (PLOO-ra; *pleura*, rib) lines the pleural cavities and covers the lungs. The **peritoneum** (per-i-tō-NĒ-um; *peri,* around + *teinein*, to stretch) lines the peritoneal cavity and covers the surfaces of enclosed organs such as the liver and stomach. The **serous pericardium** (per-i-KAR-dē-um) lines the pericardial cavity and covers the heart.

A serous membrane has *parietal* and *visceral* layers that are in close contact at all times. \supset p. 47 The parietal layer lines the inner surface of the cavity. The visceral layer, or *serosa*, covers the outer surface of organs projecting into the body cavity. For example, the visceral layer of serous pericardium covers the heart, and the parietal layer of serous pericardium lines the inner surfaces of the fibrous tissue that surrounds the pericardial cavity. The primary function of any serous membrane is to reduce friction between the opposing parietal and visceral surfaces when an organ moves or changes shape. Friction is reduced by a watery, *serous fluid* formed by fluids diffusing from underlying tissues.

The Cutaneous Membrane

The **cutaneous membrane** is the skin that covers the surface of your body (Figure 4-13c). It consists of a stratified squamous epithelium and a layer of areolar tissue reinforced by underlying dense irregular connective tissue. In contrast to serous or mucous membranes, the cutaneous membrane is thick, relatively waterproof, and usually dry. (We discuss the skin in detail in Chapter 5.)

Synovial Membranes

Bones contact one another at joints, or **articulations** (ar-tik-ū-LĀ-shuns). Joints that allow free movement are surrounded by a fibrous capsule and contain a joint cavity lined by a **synovial** (si-NŌ-vē-ul) **membrane** (**Figure 4-13d**). Unlike the other three membranes, the synovial membrane consists primarily of areolar tissue and an incomplete layer of epithelial tissue.

In freely movable joints, the bony surfaces do not come into direct contact with one another. If they did, impacts and abrasion would damage the opposing surfaces, and smooth movement would become almost impossible. Instead, the ends of the bones are covered with hyaline cartilage and separated by a viscous *synovial fluid* produced by fibroblasts in the connective tissue of the synovial membrane. The synovial fluid helps lubricate the joint and permits smooth movement.

CHECKPOINT

- **19.** Identify the four types of tissue membranes found in the body.
- **20.** How does a plasma (cell) membrane differ from a tissue membrane?
- **21.** What is the function of fluids produced by serous membranes?
- **22.** The lining of the nasal cavity is normally moist, contains numerous mucous cells, and rests on a layer of areolar tissue. Which type of membrane is this?

See the blue Answers tab at the back of the book.

4-6 The three types of muscle tissue are skeletal, cardiac, and smooth

Learning Outcome Describe the three types of muscle tissue and the special structural features of each.

Muscle tissue is specialized for contraction. Muscle cells contract due to interaction between filaments of the proteins *myosin* and *actin*. ⊃ p. 100 These two proteins are found in the cytoskeletons of many cells, but in muscle cells, the filaments are more numerous and arranged so that their interaction produces a contraction of the entire cell.

There are three types of muscle tissue in the body—*skeletal, cardiac,* and *smooth muscle tissues* (Figure 4-14). The contraction process is the same in all of them, but the organization of their actin and myosin filaments differs. In this discussion we will focus on general characteristics rather than specific details (which we will examine in Chapter 7).

Skeletal Muscle Tissue

Skeletal muscle tissue contains very large, multinucleated cells (**Figure 4-14a**). A skeletal muscle cell may be 100 micrometers (μ m; 1 μ m = 0.001 mm = 1/25,000 in.) in diameter and up to 0.3 m (1 ft) long. The individual muscle cells are usually called *muscle fibers* because they are relatively long and slender. Skeletal muscle fibers are incapable of dividing, but new muscle fibers are produced through the divisions of stem cells in adult skeletal muscle tissue. As a result, at least partial repairs can take place after an injury.

In skeletal muscle fibers, actin and myosin filaments are organized into repeating patterns that give the cells a

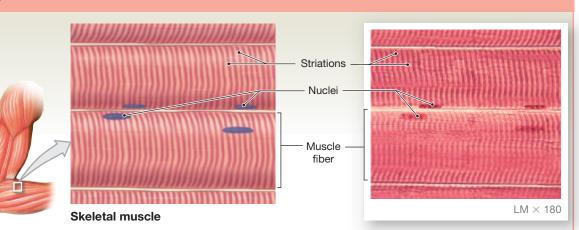

Figure 4-14 Muscle Tissue.

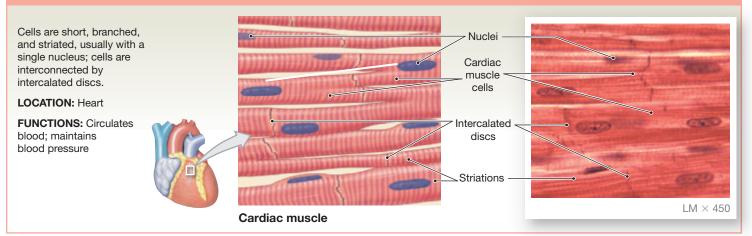

Cells are long, cylindrical, striated, and multinucleate.

LOCATIONS: Combined with connective tissues and nervous tissue in skeletal muscles

FUNCTIONS: Moves or stabilizes the position of the skeleton; guards entrances and exits to the digestive, respiratory, and urinary tracts; generates heat; protects internal organs

b Cardiac Muscle Tissue

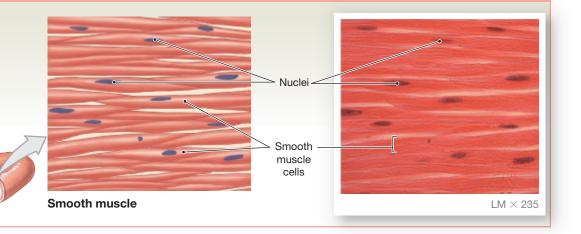

C Smooth Muscle Tissue

Cells are short, spindleshaped, and nonstriated, with a single, central nucleus.

LOCATIONS: Found in the walls of blood vessels and in digestive, respiratory, urinary, and reproductive organs

FUNCTIONS: Moves food, urine, and reproductive tract secretions; controls diameter of respiratory passageways; regulates diameter of blood vessels

4

striated, or banded, appearance. The *striations,* or bands, are easy to see in light micrographs. Skeletal muscle fibers will not usually contract unless stimulated by nerves. Because the nervous system provides voluntary control over its activities, skeletal muscle is described as *striated voluntary muscle*.

Cardiac Muscle Tissue

Cardiac muscle tissue is found in the heart. Like skeletal muscle tissue, cardiac muscle tissue is striated. A typical cardiac muscle cell, or *cardiocyte*, is much smaller than a skeletal muscle fiber and usually has only a single nucleus (**Figure 4-14b**). Cardiac muscle cells branch and form extensive connections with one another. These cells are interconnected at **intercalated** (in-TER-ka-lā-ted) **discs**, specialized attachment sites containing gap junctions and desmosomes. Cardiac muscle cells thus form a network that efficiently conducts the stimulus and force for contraction from one area of the heart to another. Cardiac muscle tissue has a very limited ability to repair itself. Stem cells are lacking. Some cardiac muscle cells do divide after an injury to the heart, but the repairs are incomplete.

Cardiac muscle cells do not rely on nerve activity to start a contraction. Instead, specialized *pacemaker cells* establish a regular rate of contraction. The nervous system can alter the rate of pacemaker activity, but it does not provide voluntary control over individual cardiac muscle cells. For this reason, cardiac muscle is called *striated involuntary muscle*.

Smooth Muscle Tissue

Smooth muscle tissue is found in the walls of blood vessels; around hollow organs such as the urinary bladder; and in layers around the respiratory, circulatory, digestive, and reproductive tracts.

A smooth muscle cell is small and slender. It tapers to a point at each end and contains a single nucleus (Figure 4-14c). Unlike skeletal and cardiac muscle, smooth muscle cells have no striations. The reason is because their actin and myosin filaments are scattered throughout the cytoplasm. Smooth muscle cells can divide, so smooth muscle tissue can regenerate after injury.

Smooth muscle cells may contract on their own, or their contractions may be triggered by neural activity. The nervous system usually does not provide voluntary control over smooth muscle contractions, so smooth muscle is known as *nonstriated involuntary muscle*.

CHECKPOINT

- **23.** Identify the three types of muscle tissue in the body.
- **24.** Voluntary control of muscle contractions is restricted to which type of muscle tissue?
- **25.** Which type of muscle tissue has small, tapering cells with single nuclei and no obvious striations?
- See the blue Answers tab at the back of the book.

4-7 Nervous tissue responds to stimuli and propagates electrical impulses throughout the body

Learning Outcome Discuss the basic structure and role of nervous tissue.

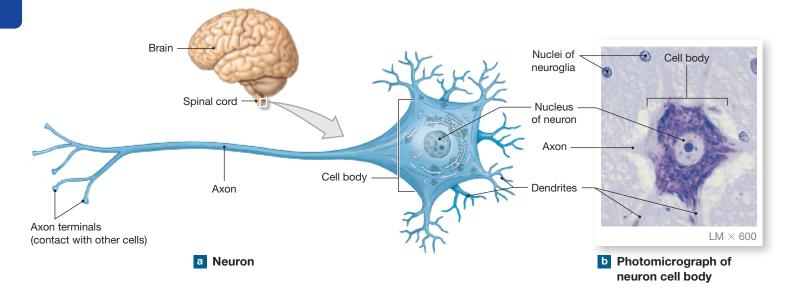

Nervous tissue is specialized for the propagation (movement) of electrical impulses from one region of the body to another. Most nervous tissue (98 percent) is concentrated in the brain and spinal cord, the control centers for the nervous system.

Nervous tissue contains two basic types of cells: (1) **neurons** (NOO-ronz; *neuro*-, nerve) and (2) several different kinds of supporting cells, or **neuroglia** (noo-ROG-lē-uh; *glia*, glue). Our conscious and unconscious thought processes are due to communication among neurons in the brain. Neurons communicate through electrical events that affect their plasma membranes. The neuroglia provide physical support for nervous tissue, maintain the chemical composition of the nervous tissue fluids, supply nutrients to neurons, and defend the tissue from infection.

The longest cells in your body are neurons. Many reach up to a meter (39 in.) long. Most neurons cannot divide under normal circumstances, so they have a very limited ability to repair themselves after injury.

A typical neuron has three main parts: (1) a **cell body** containing a large nucleus, (2) numerous branching projections called **dendrites** (DEN-drīts; *dendron*, tree), and (3) one projection called an **axon** (Figure 4-15). Dendrites receive information, typically from other neurons, and axons carry that information to other cells. Axons are also called *nerve fibers* because they tend to be very long and slender. Each axon ends at *axon terminals*, where the neuron communicates with other cells. (In Chapter 8 we consider the properties of nervous tissue.) Δ

Figure 4-15 Nervous Tissue.

CHECKPOINT

- **26.** A tissue contains irregularly shaped cells with many projections, including some several centimeters long. These are probably which type of cell?
- **27.** Why are both skeletal muscle cells and axons also called fibers?
- See the blue Answers tab at the back of the book.

4-8 The response to tissue injury involves inflammation and regeneration

Learning Outcome Describe how injuries affect the tissues of the body.

The different tissues in the body are not isolated from each other. They combine to form organs with diverse functions. Any injury will affect several tissue types at the same time. The repair process depends on the coordinated response of these tissues to restore homeostasis.

Restoring homeostasis after a tissue injury involves two related processes: *inflammation* and *regeneration*. First, the area is isolated from neighboring healthy tissue while damaged cells, tissue components, and any dangerous microorganisms are cleaned up. This phase, which coordinates the activities of several different tissues, is called **inflammation**, or the *inflammatory response*. It produces several familiar signs and symptoms, including swelling, heat (warmth), redness, and pain.

Many stimuli can produce inflammation. They include impact, abrasion, chemical irritation, infection (invasion and presence of pathogens, such as harmful bacteria or viruses), and extreme temperatures (hot or cold). When any of these stimuli either kill cells, damage fibers, or injure tissues, they trigger the inflammatory response by stimulating mast cells. \supset p. 133 The mast cells release chemicals (*histamine* and *heparin*) that cause local blood vessels to *dilate* (enlarge in diameter) and become more permeable. As a result, increased blood flow to the injured region makes it red and warm to the touch, and the diffusion of blood plasma causes the injured area to swell. The abnormal tissue conditions and chemicals released by the mast cells also stimulate sensory nerve endings that produce sensations of pain. These local circulatory changes increase the delivery of nutrients, oxygen, phagocytic white blood cells, and blood-clotting proteins. They also speed up the removal of waste products and toxins. Over a period of hours to days, this coordinated response generally succeeds in eliminating the inflammatory stimulus. (We will examine inflammation further in Chapter 14.)

In the second phase following injury, damaged tissues are replaced or repaired to restore normal function. This repair process is called **regeneration**. During regeneration, fibroblasts produce a dense network of collagen fibers known as *scar tissue* or *fibrous tissue*. Over time, scar tissue gradually assumes a more normal appearance.

4

Each organ has a different tissue organization, and this organization affects its ability to regenerate after injury. Epithelia, connective tissues (except cartilage), and smooth muscle tissue usually regenerate well. Other muscle tissues and nervous tissue regenerate relatively poorly, if at all.

Your skin, which is made up mostly of epithelia and connective tissues, regenerates rapidly. (We will examine the regeneration of skin in Chapter 5.) In contrast, damage to the heart is more serious. Although its connective tissue can be repaired, most of the damaged cardiac muscle cells are replaced only by fibrous connective tissue. Such permanent replacement of normal tissues is called **fibrosis** (fī-BRŌ-sis). Fibrosis may occur in muscle and other tissues in response to injury, disease, or aging. **Spotlight Figure 4-16** shows the tissue response to injury and the process of tissue regeneration.

CHECKPOINT

- **28.** Identify the two phases in the response to tissue injury.
- **29.** What signs and symptoms are associated with inflammation?
- **30.** What is fibrosis?
- See the blue Answers tab at the back of the book.

4-9 With advancing age, tissue repair declines and cancer rates increase

Learning Outcome Describe how aging affects the tissues of the body.

Aging has two important effects on tissues. The body's ability to repair damage to tissues decreases, and cancer is more likely to occur.

Aging and Tissue Structure

Tissues change with age. The speed and effectiveness of tissue repairs decrease. Maintenance and repair activities throughout the body slow down, and energy consumption generally declines. These changes reflect various hormonal alterations that take place with age, often coupled with reduced physical activity and a more sedentary lifestyle. These factors combine to alter the structure and chemical composition of many tissues. Epithelia get thinner and connective tissues more fragile. Individuals bruise more easily and bones become brittle. Joint pain and broken bones are common in the elderly. Cardiac muscle fibers and neurons cannot be replaced, and cumulative losses from relatively minor damage can contribute to major health problems, such as cardiovascular disease or deterioration in mental functioning.

Some of the effects of aging are genetically programmed. For example, as people age, their chondrocytes produce a slightly different form of the gelatinous compound making up the cartilage matrix. This difference probably accounts for the thinner and less resilient cartilage of older people.

Other age-related changes in tissue structure have multiple causes. The age-related reduction in bone strength in women is a condition called *osteoporosis*. It is often caused by a combination of inactivity, low dietary calcium intake, and a reduction in circulating estrogens (sex hormones). A program of exercise, calcium supplements, and in some cases medication can generally maintain normal bone structure for many years.

Aging and Cancer Rates

Cancer rates increase with age, and roughly 25 percent of all people in the United States develop cancer at some point in their lives. It has been estimated that 70–80 percent of cancer cases result from mutations due to chemical exposure, environmental factors, or some combination of the two, and 40 percent of these cancers are caused by cigarette smoke. Each year in the United States, over 500,000 individuals die of cancer. It is second only to heart disease as a cause of death.

Build Your Knowledge

Recall that cancer is an illness characterized by gene mutations leading to the formation of malignant cells and metastasis (as you saw in **Chapter 3: The Cellular Level of Organization**). Cancer cells result when these mutations lead to disruptions in the control of normal cycles of cell division and growth. \bigcirc **p. 114**

- CHECKPOINT

- **31.** Identify some age-related factors that affect tissue repair and structure.
- See the blue Answers tab at the back of the book.

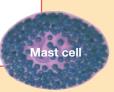

SPOTLIGHT Figure 4-16 INFLAMMATION AND REGENERATION

Go to **Mastering A&P** > Study Area > Spotlight Figure Videos

Tissues are not isolated, and they combine to form organs with diverse functions. Therefore, any injury affects several types of tissue at the same time. To preserve homeostasis, the tissues must respond in a coordinated way. Restoring homeostasis involves two related processes: inflammation and regeneration.

Mast Cell Activation

When an injury damages connective tissue, mast cells release a variety of chemicals. This process, called **mast cell activation**, stimulates inflammation.

Histamine Heparin

>

Inflammation produces several familiar indications of injury, including swelling, redness, heat (warmth), pain, and sometimes loss of function. Inflammation may also result from the presence of pathogens, such as harmful bacteria, within the tissues. The invasion and presence of these pathogens is an **infection**.

Increased Blood Flow Increased Vesse			Permeability	Pain		
In response to the released chemicals, blood vessels dilate, increasing blood flow through the damaged tissue.		ermeability of Plasma now red tissue,	The abnormal conditions within the tissue and the chemicals released by mast cells stimulate nerve endings that produce the sensation of pain.			
Increased Local Temperature	Increas and Nu	sed Oxygen utrients	Increased Phagocytosis	Removal of Toxins and Wastes		
The increased blood flow and permeability causes the tissue to become warm and red.	Vessel dilation, increased blood flow, and increased vessel permeability result in enhanced delivery of oxygen and nutrients.		Phagocytes in the tissue are activated, and they begin engulfing tissue debris and pathogens.	Enhanced circulation carries away toxins and wastes, distribut- ing them to the kidneys for excretion, or to the liver for inactivation.		
	0 ₂			Toxins		

Regeneration

Regeneration is the repair that occurs after the damaged tissue has been stabilized and the inflammation has subsided. Fibroblasts move into the area, laying down a collagenous framework known as **scar tissue**. Over time, scar tissue is usually "remodeled" and gradually assumes a more normal appearance.

Inflammation Subsides

Over a period of hours to days, the cleanup process generally succeeds in eliminating the inflammatory stimuli.

Exposure to Pathogens and Toxins

concentration of pathogens, toxins, wastes, and the chemicals from injured cells.

RELATED CLINICAL TERMS

adhesions: Restrictive fibrous connections that can result from surgery, infection, or other injuries to serous membranes.

anaplasia (a-nuh-PLĀ-zē-uh): An irreversible change in the size and shape of tissue cells.

dysplasia (dis-PLĀ-zē-uh): A change in the normal shape, size, and organization of tissue cells.

metaplasia (me-tuh-PLĀ-zē-uh): A structural change in cells that alters the character of a tissue.

necrosis (ne-KRŌ-sis): Tissue destruction that occurs after cells have been injured or killed.

pericarditis: An inflammation of the pericardial lining that may lead to the accumulation of pericardial fluid (*pericardial effusion*).

peritonitis: An inflammation of the peritoneum after infection or injury.

pleural effusion: The accumulation of fluid within the pleural cavities as a result of chronic infection or inflammation of the pleura.

pleuritis (*pleurisy*): An inflammation of the pleural cavities.

Chapter Review

Summary Outline

4-1 The four tissue types are epithelial, connective, muscle, and nervous *p. 121*

 Tissues are collections of specialized cells and cell products that are organized to perform a relatively limited number of functions. The four tissue types are epithelial tissue, connective tissues, muscle tissue, and nervous tissue. Histology is the study of tissues. (*Figure 4-1*)

4-2 Epithelial tissue covers body surfaces, lines cavities and tubular structures, and serves essential functions *p. 121*

- 2. An **epithelium** is an **avascular** layer of cells that forms a barrier that covers internal or external surfaces. **Glands** are secretory structures derived from epithelia.
- **3.** Epithelia provide physical protection, control permeability, provide sensations, and produce specialized secretions.
- Gland cells are epithelial cells that produce secretions.
 Exocrine secretions are released onto body surfaces; endocrine secretions, known as hormones, are released by gland cells into the surrounding tissue fluid.
- **5.** The individual cells that make up tissues connect to one another or to extracellular protein fibers by means of *cell adhesion molecules (CAMs)* and/or proteoglycans, or at specialized attachment sites called **cell junctions**. The three major types of cell junctions are **tight junctions**, **gap junctions**, and **desmosomes**. (*Figure 4-2*)
- **6.** Many epithelial cells have microvilli that increase absorptive surface area. The coordinated beating of the motile cilia on the cells of a ciliated epithelium moves materials across the epithelial surface. *(Figure 4-3)*

- **7.** The basal surface of each epithelium is connected to a noncellular **basement membrane.**
- **8.** Divisions by **stem cells**, or *germinative cells*, continually replace the short-lived epithelial cells.

4-3 Cell shape and number of layers determine the classification of epithelia *p. 125*

- **9.** Epithelia are classified on the basis of the number of cell layers and the shape of the exposed cells. (*Table 4-1*)
- **10.** A **simple epithelium** has a single layer of cells covering the basement membrane; a **stratified epithelium** has several layers. In a **squamous epithelium** the cells are thin and flat. Cells in a **cuboidal epithelium** resemble little boxes; those in a **columnar epithelium** are taller and more slender. (*Figures 4-4, 4-5*)
- **11.** A glandular epithelial cell may release its secretions by *merocrine, apocrine,* or *holocrine* secretory methods. (*Figure 4-6*)
- 12. In merocrine secretion (the most common method of secretion), the product is released through exocytosis. Apo-crine secretion involves the loss of both secretory product and cytoplasm. Holocrine secretion destroys the cell, which becomes packed with secretions before it finally bursts.
- **13.** Exocrine secretion types may be serous (watery, usually containing enzymes), mucous (thick and slippery), or mixed (containing enzymes and lubricants). (*Table 4-2*)

4-4 Connective tissue provides a protective structural framework for other tissue types *p. 131*

14. All **connective** tissues have specialized cells and a **matrix**, composed of extracellular protein fibers and a **ground substance**.

- **15.** Connective tissues are internal tissues with many important functions: establishing a structural framework; transporting fluids and dissolved materials; protecting delicate organs; supporting, surrounding, and interconnecting tissues; storing energy reserves; and defending the body from microorganisms.
- **16. Connective tissue proper** refers to connective tissues that contain varied cell populations and fiber types surrounded by a syrupy ground substance. (*Figure 4-7*)
- 17. Fluid connective tissues have a distinctive population of cells suspended in a watery ground substance containing dissolved proteins. The two types are *blood* and *lymph*. (*Figure 4-7*)
- **18. Supporting connective tissues** have a less diverse cell population than connective tissue proper and a dense matrix that contains closely packed fibers. The two types of supporting connective tissues are cartilage and bone. *(Figure 4-7)*
- 19. Connective tissue proper contains fibers, a viscous ground substance, and a varied cell population, including fibroblasts, fibrocytes, macrophages, fat cells, mast cells, and various white blood cells. (*Figure 4-8*)
- **20.** There are three types of fibers in connective tissue: **collagen fibers, elastic fibers,** and **reticular fibers.**
- 21. Connective tissue proper is classified as **loose** or **dense connective tissue.** Loose connective tissues include **areolar tissue, adipose tissue,** and **reticular tissue.** (*Figure 4-9*)
- **22.** Most of the volume in dense connective tissue consists of fibers. **Dense regular connective tissue** forms **tendons** and **ligaments**. **Dense irregular connective tissue** forms organ capsules, bone and cartilage sheaths, and the deep dermis of the skin. (*Figure 4-10*)
- **23. Blood** and **lymph** are connective tissues that contain distinctive collections of cells in a fluid matrix.
- **24.** Blood contains **red blood cells**, white blood cells, and **platelets**; the watery ground substance is called **plasma**.
- **25.** Lymph forms as *interstitial fluid* enters the *lymphatic vessels,* which return lymph to the cardiovascular system.
- **26.** Cartilage and bone are called supporting connective tissues because they support the rest of the body.
- 27. The matrix of **cartilage** consists of a firm gel and cells called **chondrocytes**. A fibrous **perichondrium** separates cartilage from surrounding tissues. The three types of cartilage are **hyaline cartilage**, **elastic cartilage**, and **fibrocartilage**. (*Figure 4-11*)
- **28.** Chondrocytes obtain nutrients by diffusion through the avascular matrix.
- **29. Bone**, or **osseous tissue**, has a matrix consisting primarily of collagen fibers and calcium salts, which give it unique properties. (*Figure 4-12; Table 4-3*)
- **30. Osteocytes** depend on diffusion through **canaliculi** for nutrient intake.

31. Each bone is surrounded by a **periosteum** with fibrous and cellular layers.

4-5 Tissue membranes are physical barriers of four types: mucous, serous, cutaneous, and synovial *p. 140*

- **32.** Membranes form a barrier or interface. Epithelia and connective tissues combine to form membranes that cover and protect other structures and tissues. (*Figure 4-13*)
- **33. Mucous membranes** line passageways and chambers that communicate with the exterior. Their surfaces are normally moistened by mucous secretions.
- **34. Serous membranes** line the body's sealed internal cavities of the trunk. They form a fluid that prevents friction between the inner surface of the cavity and the surfaces of visceral organs projecting into the cavity.
- **35.** The **cutaneous membrane**, or skin, covers the body surface. Unlike serous and mucous membranes, it is relatively thick, waterproof, and usually dry.
- **36. Synovial membranes,** located at joints (articulations), produce *synovial fluid* in joint cavities. Synovial fluid helps lubricate the joint and promotes smooth movement.

4-6 The three types of muscle tissue are skeletal, cardiac, and smooth *p. 141*

- **37.** Muscle tissue is specialized for contraction. (*Figure 4-14*)
- **38. Skeletal muscle tissue** contains large cells, or *muscle fibers*, that are multinucleate and have a banded (striated) appearance. Because we can control the contraction of skeletal muscle fibers through the nervous system, skeletal muscle is considered *striated voluntary muscle*.
- **39. Cardiac muscle tissue** is found only in the heart. The nervous system does not provide voluntary control over cardiac muscle cells. Thus, cardiac muscle is *striated involuntary muscle*.
- **40. Smooth muscle tissue** is found in the walls of blood vessels, around hollow organs, and in layers around various tracts (respiratory, circulatory, digestive, and reproductive). It is classified as *nonstriated involuntary muscle*.

4-7 Nervous tissue responds to stimuli and propagates electrical impulses throughout the body *p. 143*

- **41. Nervous tissue** is specialized to propagate electrical impulses that convey information from one area of the body to another.
- **42.** Cells in nervous tissue are either neurons or neuroglia. **Neurons** transmit information as electrical impulses in their plasma membranes. Several kinds of **neuroglia** serve both supporting and defense functions. (*Figure 4-15*)
- **43.** A typical neuron has a **cell body, dendrites,** and an **axon,** which ends at *axon terminals.*

See the blue Answers tab at the back of the book.

4

4-8 The response to tissue injury involves inflammation and regeneration p. 144

- **44.** Any injury affects several tissue types at the same time, and they respond in a coordinated manner. Homeostasis is restored through two processes: inflammation and regeneration.
- 45. Inflammation, or the inflammatory response, isolates the injured area while damaged cells, tissue components, and any dangerous microorganisms are cleaned up. (Spotlight *Figure* 4-16)
- 46. Regeneration is the repair process that restores normal function. (Spotlight Figure 4-16)

4-9 With advancing age, tissue repair declines and cancer rates increase p. 145

- 47. Tissues change with age. Repair and maintenance grow less efficient, and the structure and chemical composition of many tissues are altered.
- 48. Cancer rates increase with age; roughly three-quarters of all cases are due to mutations caused by exposure to chemicals or by other environmental factors, such as cigarette smoke.

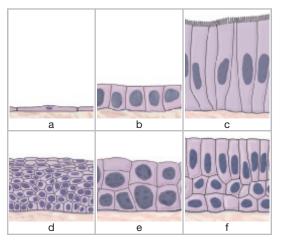

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A	COLUMN B		
1. histology	a. striated, voluntary		
2. microvilli	b. repair and renewal		
3. gap junction	c. ligament		
4. tight junction	d. endocrine secretion		
5. stem cells	e. enhance absorption and secretion		
6. destroys gland cell	f. fat cells		
7. hormones	g. holocrine secretion		
8. adipocytes	h. study of tissues		
9. bone-to-bone attachment	i. tendon		
10. muscle-to-bone attachment	j. prevents the passage of water and solutes between cells		
11. skeletal muscle tissue	k. permits ions to pass from cell to cell		
12. cardiac muscle tissue	I. intercalated discs		

13. Identify the six categories of epithelial tissue shown in the drawing below.

(f) _____ (e) _____

- **14.** Sweat glands are derived from the
 - (a) connective tissue.
 - (b) epithelial tissue.
 - (c) muscle tissue.
 - (d) neural tissue.
- 15. Cells in the epithelium are attached to the underlying basement membrane by
 - (a) desmosomes. (c) hemidesmosomes.
- (b) gap junctions.
- (d) tight junctions.
- 16. A simple squamous epithelium is found in the
 - (a) stomach.
 - (b) trachea.
 - (c) urinary bladder.

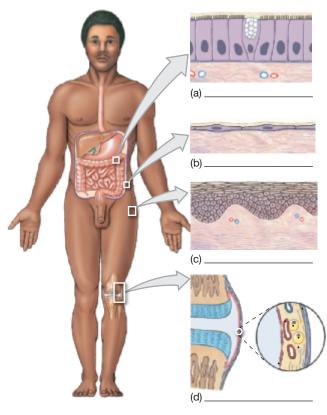

(a) adipose tissue.

- (d) blood vessel.
- **17.** Ligament is an example of the
 - (b) areolar tissue.
 - (c) dense connective tissue. (d) reticular tissue.
- 18. Matrix is characteristic of which type of tissue?
 - (a) epithelial (c) muscle
- (b) nervous (d) connective

- **19.** Apocrine secretion produces
 - (a) milk in the mammary glands.
 - (b) mucus in the digestive tract.
 - (c) saliva from the salivary glands.
 - (d) skin oils.

(c) serous.

- 20. Cartilage differs from bone as it has
 - (a) no blood supply.
 - (b) high oxygen demands.
 - (c) extensive repair capabilities.
 - (d) greater strength.
- 21. Striations are not seen in smooth muscles because the cells have
 - (a) actin but not myosin filaments.
 - (b) myosin but not actin filaments.
 - (c) neither actin nor myosin filaments.
 - (d) actin and myosin filaments scattered throughout the cytoplasm.
- **22.** Pleura is a membrane.
 - (a) cutaneous. (b) mucous.
 - (d) synovial.
- 23. Parts of a typical neuron include the following *except*
 - (a) an axon. (b) a cell body.
 - (c) a dendrite. (d) an intercalated disc.
- 24. Identify the four kinds of tissue membranes shown in the drawing below.

- 25. What two types of layering make epithelial tissue recognizable?
- **26.** Which interacting proteins allow muscle cells to contract?
- 27. Which fluid connective tissues and supporting connective tissues are found in the human body?

28. What two cell populations make up nervous tissue? What is the function of each?

Level 2 Reviewing Concepts

- **29.** Which type of epithelium in the urinary bladder is able to tolerate repeated stretching and recoiling of the organ? (a) Pseudostratified epithelium.
 - (b) Simple columnar epithelium.
 - (c) Stratified squamous epithelium.
 - (d) Transitional epithelium.
- 30. Why does holocrine secretion require continuous cell division?
- **31.** What is the functional significance of tight junctions in epithelial integrity?
- 32. Explain why tendons and ligaments have a regular arrangement of collagen fibers, whereas the arrangement is irregular in muscle sheaths and the dermis.
- **33.** Why are infections always a serious threat after a severe burn or an abrasion?
- 34. What characteristics make the cutaneous membrane different from serous and mucous membranes?

Level 3 Critical Thinking and Clinical Applications

- 35. Your friend's finger is bleeding from a paper cut. He is curious to know if the shallow wound is confined to the epithelial tissue. How would you decide?
- 36. You are asked to develop a scheme that can be used to identify the three types of muscle tissue in just two steps. What would the two steps be?

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **5-1** Describe the main structural features of the epidermis, and explain the functional significance of each.
- **5-2** Explain what accounts for individual differences in skin color, and discuss the response of melanocytes to sunlight exposure.
- **5-3** Describe the interaction between sunlight and vitamin D_3 production.
- **5-4** Describe the structure and functions of the dermis.
- **5-5** Describe the structure and functions of the subcutaneous layer.
- **5-6** Describe the processes that produce hair and the structural basis for hair texture and color.
- **5-7** Discuss the various kinds of glands in the skin, and list the secretions of those glands.
- **5-8** Describe the anatomical structure of nails, and explain how they are formed.
- **5-9** Explain how the skin responds to injury and repairs itself.

An Introduction to the Integumentary System

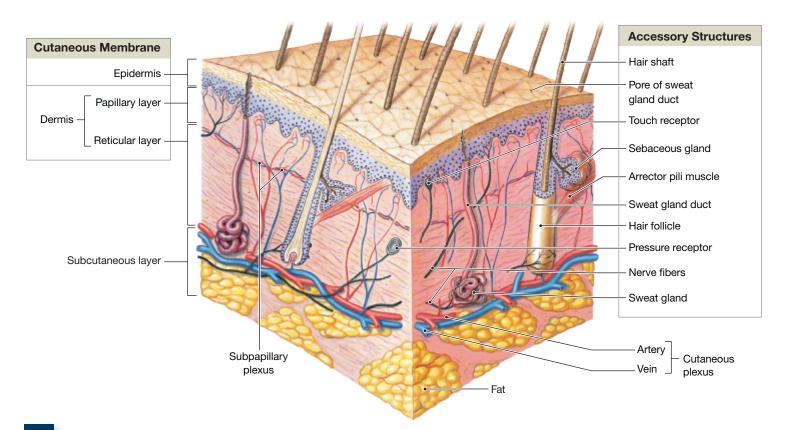

The integumentary system consists of the skin, hair, nails, and various glands. It is the most visible organ system of the body. We devote a lot of time to improving its appearance. Washing your face and hands, brushing or trimming your hair, clipping your nails, showering, and applying deodorant—all these activities modify the appearance or properties of the skin. And when something goes wrong with your skin, the effects are immediately apparent. You may notice a minor skin condition or blemish at once, yet ignore more serious problems in other organ systems. Physicians also pay attention to the skin because changes in its color, flexibility, or sensitivity can be important clues about a disorder in another body system.

The **integumentary system**, or simply the **integument** (in-TEG-ū-ment), has two major parts: the cutaneous membrane and accessory structures (**Figure 5-1**). The **cutaneous membrane**, or *skin*, is an organ composed of the superficial epithelium, or **epidermis** (*epi-*, above), and the underlying connective tissues of the **dermis**. The **accessory structures** include hair, exocrine glands, and nails. They are located primarily in the dermis and protrude through the epidermis to the skin surface.

Beneath the dermis, the loose connective tissue of the **subcutaneous layer**, or *hypodermis*, separates the integument from deeper tissues and organs. It is often not considered to be part of the integumentary system, but we include it here because its connective tissue fibers are interwoven with those of the dermis. The integument has five major functions:

- **1.** *Protection.* The skin covers and protects underlying tissues and organs from impacts, chemicals, and infections. It also prevents the loss of body fluids.
- **2.** *Temperature maintenance.* The skin maintains normal body temperature by regulating heat exchange with the environment.
- **3.** *Synthesis and storage of nutrients.* The epidermis synthesizes vitamin D₃, a steroid building block for a hormone that aids calcium uptake. The dermis stores large reserves of lipids in adipose tissue.
- **4.** *Sensory reception.* Receptors in the integument detect touch, pressure, pain, and temperature stimuli and relay that information to the nervous system.

Figure 5-1 The General Structure of the Integumentary System. This diagrammatic section of skin shows the relationships among the major parts of the integumentary system (with the exception of nails, shown in Figure 5-8).

Build Your Knowledge

The Build Your Knowledge feature reminds you of what you already know and prepares you to learn new material. Be sure to read every Build Your Knowledge box or page so that you can build your knowledge—and confidence!

Recall that the epidermis is a stratified squamous epithelium and is found where mechanical stresses are severe (as you saw in **Chapter 4: The Tissue Level of Organization**). Such an epithelium provides physical protection against abrasion and chemical attack, and helps keep microorganisms outside the body. **D 129**

5. *Excretion and secretion.* Integumentary glands excrete salts, water, and organic wastes. Also, specialized integumentary glands of the breasts secrete milk.

We will explore these functions more fully as we discuss the individual components of the integument. We begin with the superficial layer of the skin: the epidermis.

CHECKPOINT

List five major functions of the integumentary system.
 See the blue Answers tab at the back of the book.

5-1 The epidermis is composed of strata (layers) with various functions

Learning Outcome Describe the main structural features of the epidermis, and explain the functional significance of each.

Like all other epithelia, the epidermis is avascular and contains no blood vessels. For this reason, epidermal cells must rely on the diffusion of nutrients and oxygen from capillaries within the underlying dermis. As a result, the epidermal cells with the highest metabolic demands lie closest to the basement membrane, where diffusion distance is short. The outer, superficial cells far removed from the source of nutrients are dead.

Keratinocytes (ke-RAT-i-nō-sīts) are the body's most abundant epithelial cells. They dominate the epidermis. They form several layers of cells and contain the protein keratin (discussed shortly). **Thick skin**, found on the palms of the hands and soles of the feet, contains five layers of cells. Only four layers make up **thin skin**, which covers the rest of the body. The words *thin* and *thick* refer to the relative thickness of the epidermis only, not to that of the integument as a whole.

Spotlight Figure 5-2b shows the five cell layers, or **strata** (singular *stratum*), in a section of thick skin. In order, from the basement membrane toward the free surface, they are the

stratum basale, three intermediate layers (the *stratum spino-sum,* the *stratum granulosum,* and the *stratum lucidum*), and the *stratum corneum.*

Stratum Basale

The deepest epidermal layer is called the **stratum basale** (STRA-tum buh-SAL-āy; *basis*, base), or *stratum germinativum* (STRA-tum jer-mi-na-TĒ-vum; *stratum*, layer + *germinare*, to start growing). Hemidesmosomes attach the cells of this layer firmly to the basement membrane. \bigcirc p. 123 The basement membrane separates the epidermis from the areolar connective tissue of the adjacent dermis.

The stratum basale forms **epidermal ridges**, which extend into the dermis. Between the ridges, dermal projections called *dermal papillae* (singular *papilla;* a nipple-shaped mound) extend upward into the epidermis (**Spotlight Figure 5-2a,c**). The combination of ridges and papillae increases the area of contact between the two regions and strengthens the bond between them. It also increases the surface area for diffusion of nutrients between the dermis and epidermis.

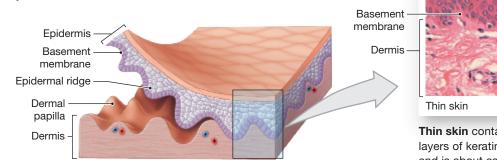

The contours of the skin surface follow the ridge patterns, which vary from small cone-shaped pegs (in thin skin) to the complex whorls on the thick skin of the palms and soles. The superficial ridges on the palms and soles (which overlie the dermal papillae) increase the surface area of the skin and increase friction, ensuring a secure grip. The ridge patterns on the tips of the fingers are also the basis of fingerprints. These ridge shapes are determined partly by genes and partly by the environment inside the uterus. That is, during fetal development, contact with amniotic fluid, another fetus (in the case of twins), or the uterine wall will affect the fingerprint pattern of a fetus. For this reason, identical twins do not have identical fingerprints. The pattern of your epidermal ridges is unique and does not change over the course of a lifetime.

SPOTLIGHT Figure 5-2 THE EPIDERMIS

BASIC ORGANIZATION OF THE EPIDERMIS

The epidermis consists of stratified squamous epithelium. It is separated from the dermis by a basement membrane.

The stratum basale and the underlying dermis interlock, strengthening the bond between the two. The epidermis forms epidermal ridges, which extend into the dermis and are adjacent to dermal papillae that project into the epidermis.

Thin skin contains four layers of keratinocytes and is about as thick as the wall of a plastic sandwich bag (about 0.08 mm).

 $LM \times 200$

Stratum

corneum

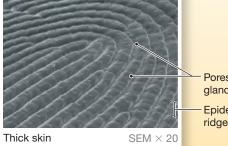

LAYERS OF THE EPIDERMIS

The layers of the epidermis are best shown in a sectional view of thick skin. **Thick skin** contains a fifth layer, the *stratum lucidum*. Because thick skin also has a much thicker superficial layer (the *stratum corneum*), it is about as thick as a standard paper towel (about 0.5 mm).

EPIDERMAL RIDGES OF THICK SKIN

Fingerprints reveal the pattern of epidermal ridges. The scanning electron micrograph to the right shows the ridges on a fingertip.

154

CLINICAL NOTE

Drug Administration through the Skin

Drugs dissolved in oils or other lipid-soluble solvents can be carried across the plasma membranes of the epidermal cells. The movement is slow, particularly through the stratum corneum, but

once a drug reaches the underlying tissues, it will be absorbed into the circulation.

A useful technique for long-term drug administration involves putting a sticky, drugcontaining patch over an area of thin skin. To overcome the slow rate of diffusion, the patch must contain an extremely high concentration of the drug. This technique, called *transdermal*

administration, has the advantage that a single patch may work for several days, making daily pills unnecessary. Two drugs routinely administered transdermally are:

- Scopolamine, which can control the nausea associated with motion sickness by affecting the nervous system.
- Nicotine, the addictive compound in tobacco, for suppressing the craving for a cigarette. The transdermal dosage of nico-tine can gradually be reduced in small controlled steps.

Other transdermal procedures include so-called "active" patches containing sharp microneedles and procedures using a brief pulse of electricity to the skin.

Large stem cells, called **basal cells** or *germinative cells*, dominate the stratum basale. Their continuous division replaces cells that are lost or shed at the epithelial surface. The stratum basale also contains *Merkel cells* (specialized epithelial cells sensitive to touch) and *melanocytes*, squeezed between or deep to the cells in this layer. Melanocytes synthesize *melanin*, a red-yellow to brown-black pigment that colors the epidermis.

Intermediate Strata

The cells in the three layers of the intermediate strata are progressively displaced from the basal layer as they become specialized to form the outer protective barrier of the skin. Each time a stem cell divides, one of the resulting daughter cells enters the next layer, the **stratum spinosum** (spiny layer). There it may continue to divide and add to the thickness of the epithelium. This stratum consists of keratinocytes held together by desmosomes. It also contains branched *dendritic cells* that take part in the immune response.

Build Your Knowledge

To form an effective barrier that protects underlying tissues, the epithelial cells of the skin must hold onto one another and also be connected to the rest of the body. They do this with specialized cell junctions known as desmosomes and hemidesmosomes (as you saw in **Chapter 4: The Tissue Level of Organization**). Desmosomes lock together the plasma membranes of epithelial cells forming the different strata of the epidermis. Hemidesmosomes firmly attach the deepest cells of the stratum basale to the extracellular basement membrane. **D p. 123**

The **stratum granulosum** (grainy layer) consists of cells displaced from the stratum spinosum. They have stopped dividing and have begun making large amounts of the protein **keratin** (KER-a-tin; *keros*, horn). \bigcirc p. 74 Keratin is extremely durable and water-resistant. In humans, keratin not only coats the surface of the skin but also forms the basic structure of hair, calluses, and nails. In various other animals, it forms structures such as horns and hooves, feathers, and baleen plates (in the mouths of filter-feeding whales).

In the thick skin of the palms and soles, a glassy **stratum lucidum** (clear layer) covers the stratum granulosum. The cells in this layer are flattened, densely packed, and filled with keratin.

Stratum Corneum

At the exposed surface of the skin is the **stratum corneum** (KOR-nē-um; *cornu*, horn). It normally contains 15–30 layers of flattened and dead epithelial cells packed with filaments of keratin. Such cells are said to be **keratinized** (ker-A-tin-īzed), or **cornified** (KŌ-ni-fīd; *cornu*, horn + *facere*, to make). The dead cells in each layer of the stratum corneum remain tightly connected by desmosomes. As a result, these cells are generally shed in large groups or sheets rather than individually.

It takes seven to ten days for a cell to move from the stratum basale to the stratum corneum. During this time, the cell is displaced from its oxygen and nutrient supply, becomes filled with keratin, and finally dies. The dead cells usually remain in the stratum corneum for two more weeks before they are shed or washed away. As superficial layers are lost, new layers arrive from the underlying strata. Thus, the deeper layers of the epithelium and underlying tissues remain protected by a barrier of dead, durable, and expendable cells. Normally, the surface of the stratum corneum is relatively dry, so it is unsuitable for the growth of many microorganisms.

CLINICAL NOTE

Disorders of Keratin Production

The excessive production of keratin is called **hyperkeratosis** (hī-per-ker-a-T \overline{O} -sis). Calluses and corns are easily observed examples. Calluses are thickened areas that appear on already thick-skinned areas, such as the palms of the hands or the soles or heels of the feet. They form in response to chronic abrasion

and distortion. Corns are more localized areas of excessive keratin production that form in areas of thin skin on or between the toes. In **psoriasis** (so-RĪ-a-sis), basal

cells (stem cells) in the stratum basale are unusually active, causing hyperkeratosis in specific

areas, such as the scalp, elbows, palms, soles, groin, or nails. Normally, an individual stem cell divides once about every 20 days, but in psoriasis it may divide every day and a half. Keratinization is abnormal and typically incomplete by the time the outer layers are shed. The affected areas have red bases covered with vast numbers of small, silvery scales that continuously flake off. Psoriasis develops in 20–30 percent of individuals with an inherited tendency for the condition. Roughly 5 percent of the U.S. population has psoriasis to some degree. It is frequently aggravated by stress and anxiety. Most cases are painless and controllable, but not curable.

CHECKPOINT

- 2. Identify the five layers of the epidermis.
- **3.** Dandruff is caused by excessive shedding of cells from the outer layer of skin in the scalp. Thus, dandruff is composed of cells from which epidermal layer?
- **4.** Some criminals sand their fingertips to avoid leaving recognizable fingerprints. Would this practice permanently remove fingerprints? Why or why not?

See the blue Answers tab at the back of the book.

5-2 Epidermal pigmentation and dermal circulation influence skin color

Learning Outcome Explain what accounts for individual differences in skin color, and discuss the response of melanocytes to sunlight exposure.

One of the most obvious differences among humans is skin color. What gives skin its various colors? Here we examine how pigments in the epidermis and blood flow in the dermis influence skin color.

The Role of Pigmentation

The epidermis contains variable amounts of two pigments, carotene and melanin. **Carotene** (KAR-uh-tēn) is an orangeyellow pigment that normally accumulates in epidermal cells. It is found in a variety of orange-colored vegetables, such as carrots and squashes. Eating lots of carrots can actually cause the skin of light-skinned individuals to turn orange. The color change is less striking in the skin of darker individuals. Carotene can be converted to vitamin A, which is required for the normal maintenance of epithelial tissues and the synthesis of photoreceptor pigments in the eye.

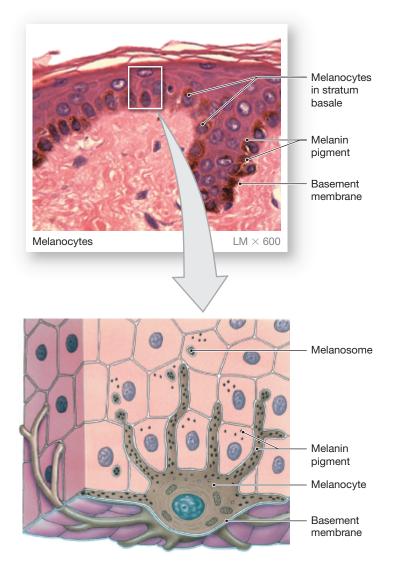

Melanin is a pigment made by pigment-producing cells called **melanocytes** (me-LAN-ō-sīts). There are two types of melanin, a red-yellow form and a brown-black form. Melanocytes manufacture and store melanin within intracellular vesicles called *melanosomes* (Figure 5-3). These vesicles are transferred to the epithelial cells of the stratum basale, coloring the entire epidermis. Melanocyte activity slowly increases in response to sunlight exposure, peaking around 10 days after the initial exposure. *Freckles* are small pigmented spots that appear on the skin of pale-skinned individuals. Freckles represent areas of greater-than-average melanin production. They tend to be most abundant on surfaces exposed to the sun, such as the face.

The ratio of melanocytes to basal cells ranges between 1:4 and 1:20, depending on the region of the body. The skin covering most areas of the body has about 1000 melanocytes per square millimeter. The cheeks and forehead, the nipples, and the genital region (the scrotum in males and labia majora in females) have about twice that density.

People of all skin colors produce both types of melanin. The differences in skin pigmentation among individuals are due to the amount of each type produced. A deficiency or absence of melanin production leads to a disorder known as *albinism*. Individuals with albinism have a normal abundance and distribution of melanocytes, but these cells are not able to produce melanin.

Sunlight contains significant amounts of **ultraviolet (UV) radiation**. A small amount of UV radiation is beneficial because it stimulates the synthesis of vitamin D_3 in the epidermis. (We discuss this process in a later section.) Too much ultraviolet radiation, however, produces immediate effects of mild or even serious burns. Melanin helps prevent skin damage by absorbing UV radiation before it reaches the deep layers of the epidermis and dermis. Within epidermal cells, melanin concentrates around the nuclear envelope. There it absorbs UV radiation before it can damage nuclear DNA.

Despite the presence of melanin, long-term damage can result from repeated exposure to sunlight, even in dark-skinned individuals. Over time, cumulative UV damage to the skin can

harm fibroblasts, impairing maintenance of the dermis. The result is premature wrinkling. In addition, skin cancers can result from chromosomal damage in stem cells of the stratum basale or in melanocytes. One of the major consequences of the global depletion of the ozone layer in the upper atmosphere is likely to be a sharp increase in the rate of skin cancers (such as malignant melanoma). For this reason, it makes sense to limit your UV exposure by wearing protective clothing and sunscreens during outdoor activities.

The Role of Dermal Circulation

Blood with abundant oxygen is bright red, so blood vessels in the dermis normally give the skin a reddish tint that is most apparent in lightly pigmented individuals. If those vessels dilate (widen), the red tones become much more pronounced. For example, skin becomes flushed and red when body temperature rises because the superficial blood vessels dilate so that the skin can act like a radiator and lose heat. \supset p. 41 When the vessels are temporarily constricted, as when you are fright- 5 ened, the skin becomes relatively pale.

During a sustained reduction in circulatory supply, the blood in the skin loses oxygen to surrounding tissues and takes on a darker red tone. Seen from the surface, the skin then takes on a bluish coloration called cyanosis (sī-uh-NŌ-sis; kyanos, blue). In individuals of any skin color, cyanosis is most apparent in areas of thin skin, such as the lips, ears, or beneath the nails. It can be a response to extreme cold or a result of circulatory or respiratory disorders, such as heart failure or severe asthma.

CHECKPOINT

- 5. Name the two pigments in the epidermis.
- 6. Why does exposure to sunlight or sunlamps darken skin?
- 7. Why does the skin of a light-skinned person appear red during exercise in hot weather?
- See the blue Answers tab at the back of the book.

5-3 Sunlight has beneficial and detrimental effects on the skin

Learning Outcome Describe the interaction between sunlight and vitamin D_3 production.

In this section we briefly consider how interactions between sunlight and skin cells regularly produce an important vitamin, and can sometimes result in skin cancers.

The Epidermis and Vitamin D₃

Too much sunlight can damage epithelial cells and deeper tissues, but limited exposure to sunlight is beneficial. When exposed to UV radiation, epidermal cells in the stratum spinosum and stratum basale convert a cholesterol-related steroid into vitamin D_3 . The liver then converts vitamin D_3 into an intermediary product used by the kidneys to synthesize the hormone calcitriol. Calcitriol is essential for the absorption of calcium and phosphorus in the small intestine. An inadequate supply of vitamin D₃ can lead to abnormally weak and flexible bones.

Skin Cancers

Almost everyone has several benign tumors of the skin. Moles and warts are common examples. Skin cancers, however, are more dangerous. They are the most common form

Figure 5-4 Skin Cancers.

a Basal cell carcinoma

b Melanoma

of cancer. Any cancer of epithelial tissue is called a **carcinoma** (kar-si-NŌ-mah). The most common *skin* cancer is **basal cell carcinoma**, which often looks like a waxy bump (**Figure 5-4a**). This cancer originates in the stratum basale. Less common are **squamous cell carcinomas**, which involve more superficial layers of epidermal cells. Metastasis seldom occurs in either cancer, and most people survive these cancers. The usual treatment involves surgical removal of the tumor.

Compared with these common and seldom life-threatening cancers, **malignant melanomas** (mel-a-NŌ-maz) are extremely dangerous (**Figure 5-4b**). In this condition, cancerous melanocytes grow rapidly and metastasize through the lymphatic system. A melanoma usually begins from a mole but may appear anywhere in the body. The outlook for longterm survival depends on when the condition is detected and treated. Avoiding exposure to UV radiation in sunlight (especially during the middle of the day) and using a sunblock (not a tanning oil) would largely prevent all three forms of cancer.

CHECKPOINT

- **8.** Explain the relationship between sunlight exposure and vitamin D₃ synthesis.
- 9. What is the most common skin cancer?
- See the blue Answers tab at the back of the book.

5-4 The dermis is the tissue layer that supports the epidermis

Learning Outcome Describe the structure and functions of the dermis.

The dermis lies between the epidermis and the subcutaneous layer. It has two major layers: a superficial *papillary layer* and a deeper *reticular layer* (Figure 5-1).

The **papillary layer**, named after the dermal papillae, consists of areolar tissue that supports and nourishes the epidermis. This region contains the capillaries, lymphatic vessels, and sensory neurons that supply the surface of the skin.

The deeper **reticular layer** consists of an interwoven meshwork of dense irregular connective tissue containing both *elastic fibers* and *collagen fibers*. The elastic fibers provide flexibility, and the collagen fibers limit that flexibility to prevent damage to the tissue. Bundles of collagen fibers blend into those of the papillary layer above, blurring the boundary between these layers. Collagen fibers of the reticular layer also extend into the underlying subcutaneous layer.

In addition to protein-based elastic and collagen fibers, the dermis contains the mixed cell populations of connective tissue proper. The dominant cell type of the dermis is the fibroblast. \bigcirc p. 133 Accessory structures derived from the epidermis, such as hair follicles and sweat glands, extend into the dermis (Figure 5-1).

CLINICAL NOTE

Dermatitis

Inflammation is a complex process that helps defend the body against pathogens and injury. D p. 144 Skin inflammation can be very painful because skin contains an abundance of sensory receptors.

Dermatitis (der-muh-TĪ-tis) is an inflammation of the skin that mainly involves the papillary layer of the dermis. The inflammation typically begins in an area of the skin exposed to infection or irritated by chemicals, radiation, or mechanical stimuli, such as scratching. Dermatitis may cause no discomfort, or it may produce an annoying itch. Sometimes the condition can be quite painful, and the inflammation can spread rapidly across the entire integument.

Dermatitis has many forms. Some of them are common:

- **Contact dermatitis** generally occurs in response to strong chemical irritants. It produces an itchy rash that may spread to other areas. One example is poison ivy.
- **Eczema** (EK-se-muh) can be triggered by temperature changes, fungi, chemical irritants, greases, detergents, or stress. Hereditary factors, environmental factors, or both can promote its development.
- **Diaper rash** is a localized dermatitis caused by a combination of moisture, irritating chemicals from fecal or urinary wastes, and microorganisms, frequently the yeast *Candida*, which is a fungus.
- **Urticaria** (ur-ti-KAR-ē-uh), also called *hives*, is an extensive allergic response to a food, drug, insect bite, infection, stress, or some other stimulus.

Other organ systems interact with the skin through their connections to the dermis. For example, both dermal layers contain a network of blood vessels (cardiovascular system), lymphatic vessels (lymphatic system), and nerve fibers (nervous system).

Arteries supplying the skin lie deep in the subcutaneous layer. Branches of the arteries form two networks, or *plexuses*, in the dermis. The deeper network lies along the border of the subcutaneous layer with the reticular layer of the dermis. This network is called the cutaneous plexus (Figure 5-1). Branches of these arteries supply both the adipose tissue in the subcutaneous layer and the tissues of the integument. As small arteries travel toward the epidermis, branches supply the hair follicles, sweat glands, and other structures in the dermis.

On reaching the papillary layer, the small arteries form another network called the *subpapillary plexus* (Figure 5-1). It provides blood to capillary loops that follow the contours of the epidermis-dermis boundary. (Capillaries are the smallest blood vessels. They are where nutrients and oxygen are exchanged for carbon dioxide and waste products. \bigcirc p. 137) The capillaries empty into small veins of the subpapillary plexus. These small veins, in turn, drain into veins accompanying arteries of the cutaneous plexus. This network connects to larger veins in the deep subcutaneous layer.

Both the blood vessels and the lymphatic vessels in the dermis help local tissues defend and repair themselves after injury or infection. The nerve fibers control blood flow, adjust gland secretion rates, and monitor sensory receptors in the dermis and the deeper layers of the epidermis. These receptors provide sensations of touch, pain, pressure, and temperature. (We will describe them in Chapter 9.)

CHECKPOINT

- **10.** Describe the location of the dermis.
- **11.** Where are the capillaries that supply the epidermis located?

See the blue Answers tab at the back of the book.

5-5 The subcutaneous layer connects the dermis to underlying tissues

Learning Outcome Describe the structure and functions of the subcutaneous layer.

The subcutaneous layer, or hypodermis, lies deep to the dermis (Figure 5-1). The boundary between the two is generally indistinct because the connective tissue fibers of the reticular layer are interwoven with those of the subcutaneous layer. The subcutaneous layer is not a part of the integument, but it is important in stabilizing the position of the skin relative to underlying tissues, such as skeletal muscles or other organs, while permitting them to move independently.

The subcutaneous layer consists of areolar tissue with many 5 fat cells. These adipose cells provide infants and small children with a layer of "baby fat," which helps to reduce heat loss. Subcutaneous fat also serves as an energy reserve and a shock absorber for the rough-and-tumble activities of our early years.

As we grow and mature, the distribution of subcutaneous fat changes. The greatest change takes place in response to circulating sex hormones. Beginning at puberty, men accumulate subcutaneous fat at the neck, upper arms, along the lower back, and over the buttocks. Women do so in the breasts, buttocks, hips, and thighs. Both women and men, however, may accumulate distressing amounts of adipose tissue in the abdominal region, producing a prominent "potbelly." An excessive amount of such abdominal fat is strongly correlated with cardiovascular disease.

The subcutaneous layer is quite elastic. Its superficial region contains the large blood vessels of the cutaneous plexus. Below this region, the subcutaneous layer contains few capillaries and no vital organs. The lack of vital organs makes subcutaneous injection a useful method for administering drugs using a hypodermic needle.

CHECKPOINT

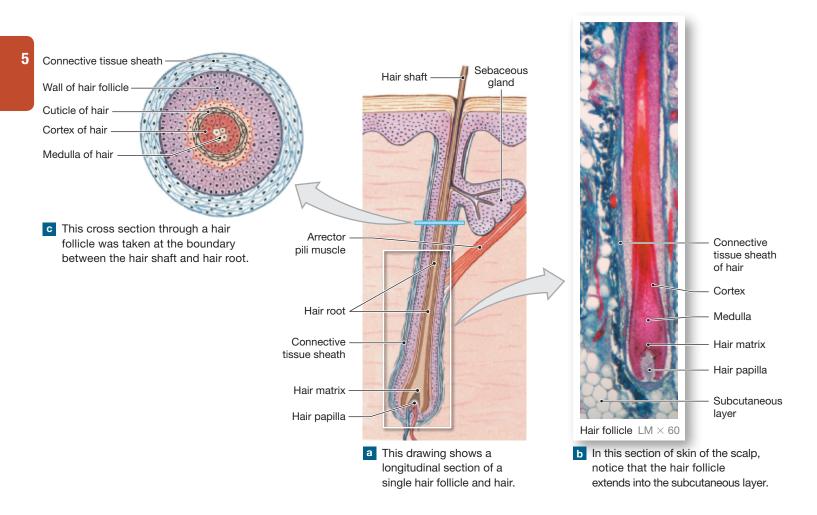

- 12. List the two terms for the tissue that connects the dermis to underlying tissues.
- **13.** Describe the subcutaneous layer.
- See the blue Answers tab at the back of the book.

5-6 Hair is composed of dead, keratinized cells that have been pushed to the skin surface

Learning Outcome Describe the processes that produce hair and the structural basis for hair texture and color.

Hair and several other structures-hair follicles, sebaceous and sweat glands, and nails-are considered accessory structures of the integument. During embryonic development, these structures originate from the epidermis.

Hairs are nonliving, keratinized structures produced in organs called hair follicles (Figure 5-5a). Hairs project above the surface of the skin almost everywhere. We do not have

hairs on the sides and soles of the feet, the palms of the hands, the sides of the fingers and toes, the lips, and portions of the external genital organs.

The Structure of Hair and Hair Follicles

Hair follicles project deep into the dermis and usually into the underlying subcutaneous layer (**Figure 5-5b**). The walls of each follicle contain all the cell layers found in the epidermis. The epithelium at the base of a follicle forms a cap over the **hair papilla**, a peg of connective tissue containing capillaries and nerves. Hair is formed by the repeated divisions of epithelial stem cells in the **hair matrix** surrounding the hair papilla. As the daughter cells are pushed toward the surface, the hair lengthens, and the cells undergo keratinization and die. The point at which this occurs is about halfway to the skin surface and marks the boundary between the **hair root** (the portion that anchors the hair into the skin) and the **hair shaft** (the part we see on the surface) (**Figure 5-5a**).

Each hair shaft consists of three layers of dead, keratinized cells (**Figure 5-5c**). The surface layer, or **cuticle**, is made up of an overlapping shingle-like layer of cells. The underlying layer is called the **cortex**, and the **medulla** makes up the core of the hair. The medulla contains a flexible *soft keratin*. The cortex and cuticle contain thick layers of *hard keratin*, which give the hair its stiffness.

Hairs grow and are shed according to a *hair growth cycle* based on the activity level of hair follicles. In general, a hair in the scalp grows for two to five years, at a rate of about 0.3 mm per day. Then its follicle may become inactive for a similar period of time. When another growth cycle begins, the follicle produces a new hair, and the old hair gets pushed toward the surface to be shed. Variations in growth rate and in the length of the hair growth cycle account for individual differences in the length of uncut hair.

CLINICAL NOTE

Hair Loss

Some people feel anxious when they find hairs clinging to their hairbrush instead of to their heads. On the average, we lose about 50 hairs from the head each day, but several factors may affect this rate. Sustained losses of over 100 hairs per day generally indicate a net loss of hair. The absence or loss of hair is called *alopecia* (al-ō-PĒ-shē-uh). Temporary increases in hair loss can result from drugs (including chemotherapeutic agents), radiation, dietary factors, high fever, stress, or hormonal factors related to pregnancy.

In males, changes in the level of circulating sex hormones can affect the scalp, causing a shift in production from normal hair to fine "peach fuzz" hairs, beginning at the temples and the crown of the head. This alteration is called *male pattern baldness*. Some cases of male pattern baldness respond to drug therapies, such as topical application of *minoxidil (Rogaine)*.

Chemotherapy and radiation therapy for cancer treatment can cause hair loss because both cancer cells and normal cells,

notably hair matrix stem cells, are affected. Such hair loss is generally not permanent, but may

affect all the hair on the body. In treatment with radiation, only the hair in the area receiving the radiation is affected. Radiation therapy to the head often causes hair loss from the scalp.

Not all drugs administered during chemotherapy cause hair loss. However, when hair loss does occur, it most often begins within a few weeks and generally increases up to two months into

treatment. Hair usually begins to regrow a few months after treatment ends, with complete regrowth within a year. The color, thickness, and texture of the new hair may be different from the original hair.

What makes hair curly or straight? These differences result from the cross-sectional shape of the hair shaft and its hair follicle. A curly hair and its follicle are oval or flattened. A straight hair and its follicle are round.

Functions of Hair

The 2.5 million hairs on the human body have important functions. The roughly 500,000 hairs on the head protect the scalp from UV light, help cushion a light blow to the head, and provide insulation for the skull. The hairs guarding the entrances to the nostrils and external ear canals help keep out foreign particles. The eyelashes perform a similar function for the surface of the eye.

A sensory nerve fiber is associated with the base of each hair follicle. As a result, you can even feel the movement of a single hair shaft. This sensitivity provides an early-warning system that may help prevent injury. For example, you may be able to swat a mosquito before it reaches the surface of your skin.

A bundle of smooth muscle cells forms the **arrector pili** (a-REK-tor PI-lē) muscle. It extends from the papillary dermis to the connective tissue sheath around each hair follicle (**Figure 5-5a**). When stimulated, the arrector pili pulls on the follicle, forcing the hair to stand up. Contraction may be caused by emotional states (such as fear or rage) or a response to cold, producing "goose bumps."

Hair Color

Hair color reflects differences in the type and amount of pigment produced by melanocytes at the hair papilla. The two different forms of melanin produce hair colors that can range from black to blond. These pigment differences are genetically determined, but hormonal and environmental factors also influence the condition of your hair.

What about gray hair? As pigment production decreases with age, hair color lightens. White hair results from both a lack of pigment and the presence of air bubbles within the hair shaft. As the proportion of white hairs increases, the individual's hair color is described as gray. Because each hair is dead and inert, changes in color are gradual. Unless bleach is used, it is not possible for hair to "turn white overnight," as some horror stories would have us believe.

CHECKPOINT

- **14.** Describe a typical strand of hair.
- **15.** What happens when the arrector pili muscle contracts?
- **16.** If a burn on the forearm destroys the epidermis and the deep dermis and then heals, will hair grow again in the affected area?
- See the blue Answers tab at the back of the book.

5-7 Sebaceous glands and sweat glands are exocrine glands found in the skin

Learning Outcome Discuss the various kinds of glands in the skin, and list the secretions of those glands.

The integument contains two types of exocrine glands: *sebaceous glands* and *sweat glands*.

Sebaceous (Oil) Glands

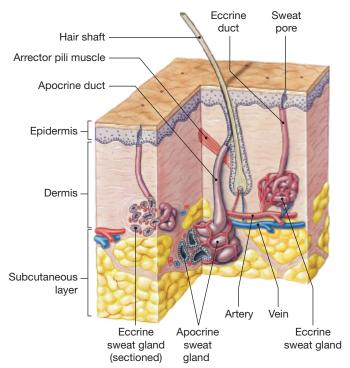

Sebaceous (se-BĀ-shus) glands, or *oil glands*, discharge an oily lipid secretion into hair follicles or, in some cases, onto the skin (Figure 5-6). The gland cells produce large quantities of lipids as they mature. The lipid is released through holocrine secretion, a process that involves the rupture and death of the cells. ⊃ p. 130 The contraction of the arrector pili muscle that elevates a hair also squeezes the sebaceous gland, forcing the oily secretions into the hair follicle and onto the surrounding skin. This secretion, called **sebum** (SĒ-bum), inhibits the growth of bacteria, lubricates the hair, and conditions the surrounding skin. Sebaceous follicles are large sebaceous glands that discharge sebum directly onto the skin. They are located on the face, back, chest, nipples, and external genitalia.

Sebaceous glands are sensitive to changes in the concentrations of sex hormones. Their secretions accelerate at puberty. For this reason, individuals with large sebaceous glands may be especially prone to develop **acne** during adolescence. In acne, sebaceous ducts become blocked and secretions accumulate, causing inflammation and a raised "pimple." The trapped secretions provide a fertile environment for bacterial infection.

Sweat Glands

The skin contains two types of sweat glands, or *sudoriferous glands: apocrine sweat glands* and *eccrine sweat glands* (Figure 5-7).

Figure 5-7 Sweat Glands. Eccrine sweat glands secrete directly onto the skin. Apocrine sweat glands secrete into hair follicles.

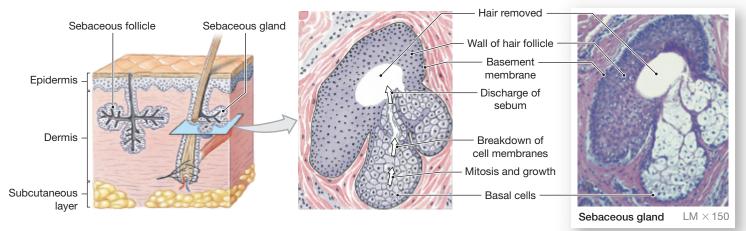

Apocrine Sweat Glands

Apocrine sweat glands secrete their products into hair follicles in the armpits, around the nipples, and in the pubic region. The name *apocrine* was originally chosen because it was thought these gland cells use an apocrine method of secretion. \bigcirc p. 128 We now know that they rely on merocrine secretion, but the name has not changed.

At puberty, these glands begin discharging a sticky, cloudy, and potentially odorous secretion. The sweat is a food source for bacteria, which intensify its odor. In other mammals, this odor is an important form of communication. In our culture, whatever function it might have is

masked by products such as deodorants. Other products, such as antiperspirants, contain astringent compounds that contract the skin and its sweat gland openings, thereby decreasing the quantity of both apocrine and eccrine secretions.

Eccrine Sweat Glands

Eccrine (EK-rin) **sweat glands** are also known as *merocrine sweat glands*. These coiled tubular glands discharge their secretions directly onto the surface of the skin. They are far more numerous and widely distributed than apocrine glands. The skin of an adult contains 2–5 million eccrine glands. Palms and soles have the highest numbers. It has been estimated that the palm of the hand has about 500 glands per square centimeter (3000 per square inch).

The perspiration, or sweat, produced by eccrine glands is 99 percent water. Sweat also contains a mixture of electrolytes (chiefly sodium chloride), organic nutrients, and waste products such as urea. Sodium chloride gives sweat its salty taste.

The primary function of eccrine gland activity and perspiration is to cool the surface of the skin and lower body temperature. When a person is sweating in the hot sun, all the eccrine glands are working together. The blood vessels beneath the epidermis are dilated and flushed with blood, the skin reddens in light-colored individuals, and the skin surface becomes warm and wet. As the moisture evaporates, the skin cools. If body temperature then falls below normal, perspiration ceases, and blood flow to the skin is reduced. The skin surface then cools and dries, releasing little heat into the environment. (We considered the roles of the skin and negative feedback in thermoregulation, or temperature control, in Chapter 1 on p. 40. In Chapter 17 we will examine this process in greater detail.)

Perspiration results in the loss of water and electrolytes from the body. For this reason, excessive perspiration to maintain normal body temperature can lead to problems. For example, when all the eccrine sweat glands are working at maximum, perspiration may exceed a gallon (about 4 liters) per hour, and dangerous fluid and electrolyte losses can occur. For this reason, marathoners and other endurance athletes must drink fluids at regular intervals.

Sweat also provides protection from environmental hazards. Sweat dilutes harmful chemicals in contact with the skin and flushes microorganisms from its surface. The presence of dermicidin, a small peptide molecule with antibiotic properties, provides additional protection from microorganisms.

The skin also contains other types of modified sweat glands with specialized secretions. For example, the mammary glands

Build Your Knowledge

Recall that exocrine glands secrete their products onto an epithelial surface (as you saw in **Chapter 4: The Tissue Level of Organization**). These secretions reach the surface either directly (mucous cells) or through tubular ducts that open onto the surface of the skin or onto an epithelium lining an internal passageway that connects to the exterior. **p. 128**

of the breasts are structurally related to apocrine sweat glands but secrete milk. Another example is the *ceruminous glands* in the passageway of the external ear. Their secretions combine with those of nearby sebaceous glands to form a mixture called *cerumen*, or earwax.

CHECKPOINT

- **17.** Identify two types of exocrine glands found in the skin.
- 18. What are the functions of sebaceous secretions?
- **19.** Deodorants are used to mask the effects of secretions from which type of skin gland?
- See the blue Answers tab at the back of the book.

5-8 Nails are keratinized epidermal cells that protect the tips of fingers and toes

Learning Outcome Describe the anatomical structure of nails, and explain how they are formed.

Nails protect the dorsal surfaces of the tips of the fingers and toes (**Figure 5-8a**). They also help limit distortion of the digits when they are subjected to mechanical stress—for example, when you run or grasp objects. The **nail body** is the visible portion of the nail. It consists of a dense mass of dead, kera-tinized cells. The nail body covers an area of epidermis called the **nail bed** (**Figure 5-8b**). The nail body is recessed beneath the level of the surrounding epithelium and is bordered by **lateral nail folds**.

The nail is produced at the **nail root**, an epithelial fold not visible from the surface. The deepest portion of the nail root lies very close to the bone of the fingertip. A portion of the stratum corneum of the fold extends over the exposed nail nearest the root, forming the **cuticle**, or *eponychium* (ep- \bar{o} -NIK- \bar{e} -um; *epi-*, over + *onyx*, nail) (**Figure 5-8c**).

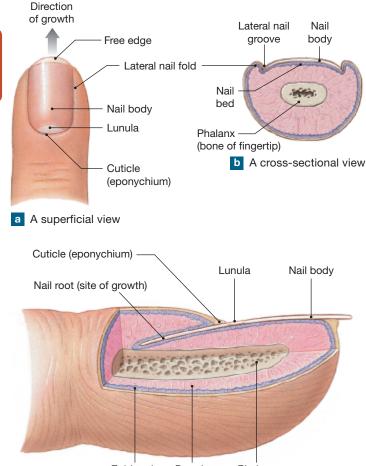

Figure 5-8 The Structure of a Nail.

Epidermis Dermis Phalanx c A longitudinal section

Underlying blood vessels give the nail its pink appearance. Near the root these vessels may be obscured, leaving a pale crescent known as the **lunula** (LOO-nū-la; *luna*, moon).

CHECKPOINT

- 20. What substance makes nails hard?
- **21.** Where does nail growth take place?
- See the blue Answers tab at the back of the book.

5-9 After an injury, the integument is repaired in several phases

Learning Outcome Explain how the skin responds to injury and repairs itself.

The integumentary system can respond directly and independently to many local influences or stimuli, without involving the nervous or endocrine systems. For example, when the skin is subjected to mechanical stresses, stem cells in the stratum basale divide more rapidly, and the thickness of the epithelium increases. That is why calluses form on your palms when you perform manual labor. After an injury to the skin, you can see a more dramatic example of a local response.

Repair of Skin Injuries

The skin can regenerate effectively even after considerable damage because stem cells are present in both its epithelial and connective tissues. Division of stem cells of the stratum basale replaces epithelial cells. Connective tissue stem cells divide to replace cells lost from the dermis. This process can be slow. When large surface areas are involved, infection and fluid loss complicate the repair process.

The relative speed and effectiveness of skin repair vary, depending on the type of wound. A slender, straight cut, or *incision*, may heal relatively quickly. A scrape, or *abrasion*, which involves a much greater area, may heal more slowly.

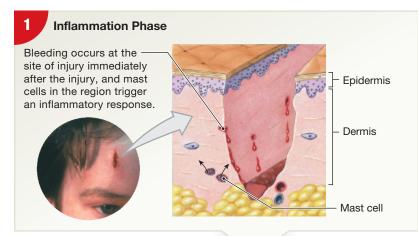

The skin regenerates in four phases after an injury: an inflammation phase, a migration phase, a proliferation phase, and a scarring phase (Figure 5-9).

When damage extends through the epidermis and into the dermis, bleeding, along with swelling, redness, and pain occur. Mast cells in the region trigger an inflammatory response that enhances blood flow and attracts phagocytes. This is the *inflammation phase* **1**.

A blood clot, or **scab**, forms at the surface as part of the *migration phase*. The scab temporarily restores the integrity of the epidermis and restricts the entry of additional microorganisms **2**. Most of the clot consists of an insoluble network of *fibrin*, a fibrous protein that forms from blood proteins during the clotting response. Cells of the stratum basale rapidly divide and begin to migrate along the sides of the wound to replace the missing epidermal cells. Meanwhile, fixed macrophages and newly arriving phagocytes patrol the damaged area of the dermis and clear away debris and pathogens.

If the wound covers an extensive area or involves a region covered by thin skin, dermal repairs must be under way before epithelial cells can cover the surface. Fibroblasts and connective tissue stem cells divide to produce motile cells that invade the deeper areas of injury. Epithelial cells lining damaged blood vessels also begin to divide, and capillaries follow the fibroblasts, enhancing circulation. The combination of blood clot, fibroblasts, and an extensive capillary network is called **granulation tissue**.

Figure 5-9 Repair of Injury to the Skin.

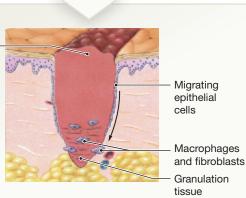

З

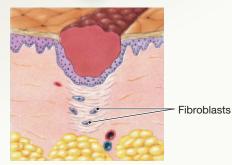

Migration Phase

After several hours, a scab has formed and cells of the stratum basale are migrating along the edges of the wound. Phagocytic cells are removing debris, and more of these cells are arriving with the enhanced circulation in the area. Clotting around the edges of the affected area partially isolates the region.

Proliferation Phase

About a week after the injury, the scab has been undermined by epidermal cells migrating over the collagen fiber meshwork produced by fibroblast activity. Phagocytic activity around the site has almost ended, and the fibrin clot is dissolving.

Scarring Phase

After several weeks, the scab has been shed, and the epidermis is complete. A shallow depression marks the injury site, but fibroblasts in the dermis continue to create scar tissue that will gradually elevate the overlying epidermis.

Over time, deeper portions of the clot dissolve and the number of capillaries declines in the proliferation *phase* **(3)**. Fibroblast activity has formed an extensive meshwork of collagen fibers in the dermis. These repairs do not restore the integument to its original condition, 5 however, because the dermis now contains an abnormally large number of collagen fibers and relatively few blood vessels. Severely damaged hair follicles, sebaceous or sweat glands, muscle cells, and nerves are seldom repaired. Instead, they are replaced by fibrous tissue.

In the scarring phase, the formation of rather inflexible, fibrous, noncellular scar tissue completes the repair process, but without restoring the tissue to its original condition (4). The process of scar tissue formation is highly variable. For example, surgical procedures performed on a fetus do not leave scars. In some adults, most often those with dark skin, scar tissue formation may continue beyond what is needed for tissue repair. The result is a flattened mass of scar tissue that begins at the injury site and grows into the surrounding dermis. This thickened area of scar tissue, called a keloid (KE-loyd), is covered by a shiny, smooth epidermal surface (Figure 5-10). Keloids most commonly develop on the upper back, shoulders, anterior chest, and earlobes. They are harmless. Some aboriginal cultures intentionally produce keloids as a form of body decoration.

Effects of Burns

Burns are relatively common injuries. They result from exposure of the skin to heat, radiation, electrical shock, or strong chemical agents. The severity of a burn depends on the depth of penetration and the total area affected, as detailed in Clinical Note: Burns on p. 166.

Figure 5-10 A Keloid. A keloid is an area of raised fibrous scar tissue.

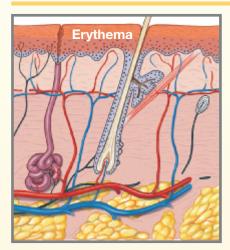

CLINICAL NOTE BURNS

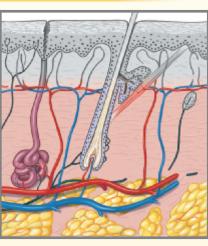

Burns are relatively common injuries that result from skin exposure to heat, friction, radiation, electrical shock, or strong chemical agents. According to a report published by the World Health Organization in 2018, globally, around 180,000 people die from burns each year. In evaluating burns in a clinical setting, two key factors must be determined: the depth of the burn and the percentage of skin surface area that has been burned.

Classification by Depth of Burn

Partial-thickness Burns

In a **first-degree burn**, only the surface of the epidermis is affected. In this type of burn, which includes most sunburns, the skin reddens and can be painful. The redness, a sign called **erythema** (er-i-THĒ-muh), results from inflammation of the sun-damaged tissues.

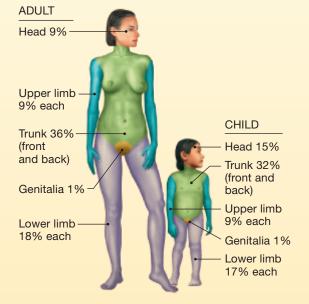

In a **second-degree burn**, the entire epidermis and perhaps some of the dermis are damaged. Accessory structures such as hair follicles and glands are generally not affected, but blistering, pain, and swelling occur. If the blisters rupture at the surface, infection can easily develop. Healing typically takes one to two weeks, and some scar tissue may form.

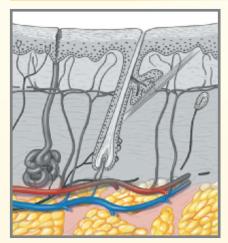

Estimation of Surface Burn Area

A simple method for estimating burn area is the **rule of nines**. The surface area in adults is divided into multiples of 9 and then the damaged regions are totaled. This rule is modified for children because their body proportions are different.

The depth of the burn can be quickly assessed with a pin. Because loss of sensation is characteristic of a full-thickness burn, the absence of a reaction to a pin prick indicates the presence of third-degree damage.

Full-thickness Burns

Third-degree burns, or full-thickness burns, destroy the epidermis and dermis, extending into the hypodermis. Despite swelling, these burns are less painful than second-degree burns, because sensory nerves are destroyed. Extensive third-degree burns cannot repair themselves, because granulation tissue cannot form and epithelial cells are unable to cover the injury. Skin grafting is usually necessary.

Burns and Skin Function

Burns that cover more than 20 percent of the skin surface threaten critical homeostatic functions of the skin.

Skin Functions Affected by Burns

- Fluid and Electrolyte Balance. Burns cause the skin to lose its effectiveness as a barrier to fluid and electrolyte loss. In full-thickness burns, the rate of fluid loss through the skin may reach five times the normal level.
- **Thermoregulation**. Increased fluid loss means increased evaporative cooling. As a result, more energy must be expended to keep body temperature within acceptable limits.
- **Protection from Infection**. Widespread bacterial infection, or **sepsis** (*sepsis*, rotting), is the leading cause of death in burn victims.

The most common classification of burns is based on the depth of penetration. The larger the area affected, the greater the impact on integumentary function.

CHECKPOINT

- **22.** What term describes the combination of fibrin clots, fibroblasts, and the extensive network of capillaries in healing tissue?
- **23.** Why can skin regenerate effectively even after considerable damage?

See the blue Answers tab at the back of the book.

5-10 Effects of aging include dermal thinning, wrinkling, and reduced melanocyte activity

Learning Outcome Summarize the effects of aging on the skin.

Aging affects all parts of the integumentary system. Major agerelated changes include the following:

- *Skin injuries and infections become more common.* Such problems are more likely because the epidermis thins as stem cell activity declines, and connections between the epidermis and dermis weaken.
- *The sensitivity of the immune system is reduced.* The number of macrophages and dendritic cells in the skin decreases to about one-half the levels seen at maturity (roughly, age 21). This loss further encourages skin damage and infection.
- *Muscles become weaker, and bone strength decreases.* Such changes are related to reduced calcium and phosphate absorption due to a decline in vitamin D₃ production of around 75 percent.
- *Sensitivity to sun exposure increases.* Less melanin is produced because melanocyte activity declines. The skin of light-skinned individuals becomes very pale, and sunburn is more likely.

- *The skin becomes dry and often scaly.* Glandular activity declines, reducing sebum production and perspiration.
- *Hair thins and changes color*. Follicles stop functioning or produce finer hairs. With decreased melanocyte activity, these hairs are gray or white.
- *Sagging and wrinkling of the skin occur.* The dermis becomes thinner, and the elastic fiber network decreases in size. The integument therefore becomes weaker and less resilient. Sagging and wrinkling are most noticeable in areas exposed to the sun.
- **The ability to lose heat decreases.** The blood supply to the dermis is reduced just as the sweat glands become less active. This combination makes elderly people less able than younger people to lose body heat. As a result, overexertion or overexposure to high temperatures (as in a sauna or hot tub) can cause dangerously high body temperatures.
- Skin repairs take place more slowly. For example, it takes three to four weeks to repair an uninfected blister site in a young adult. The same repairs could take six to eight weeks at ages 65–75. Recurrent infections may result because repairs are slow.

The Build Your Knowledge figure on p. 168 reviews the integumentary system. Such reviews appear after each body system to gradually build your understanding of the interconnections among all body systems. Because we have covered only one body system so far, references to body systems to be discussed in upcoming chapters are not included.

CHECKPOINT

- **24.** Older individuals do not tolerate summer heat as well as they did when they were young, and they are more prone to heat-related illnesses. What accounts for these changes?
- **25.** Why does hair turn gray or white with age? See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

biopsy(BĪ-op-sē): The removal and examination of tissue from the body for the diagnosis of disease.

cavernous hemangioma (strawberry nevus): A mass of large blood vessels that can occur in the skin or other organs in the body; a "port wine stain" birthmark generally lasts a lifetime. **lesions**(LĒ-zhuns): Changes in tissue structure caused by injury or disease. **pruritus** (proo-RĪ-tus): An irritating itching sensation, common in skin conditions such as psoriasis or dermatitis. **ulcer:** A localized shedding of an epithelium. **xerosis** (ze-RŌ-sis): "Dry skin," a common complaint of older persons and almost anyone living in an arid climate.

Build Your Knowledge

How the INTEGUMENTARY SYSTEM integrates with the other body systems presented so far

5

Integumentary System

The integumentary system performs five major functions for the human body. It:

- covers and protects underlying tissues and organs from impacts, chemicals, and infections, and it prevents the loss of body fluids
- maintains normal body temperature by regulating heat exchange with the environment
- synthesizes vitamin D₃ in the epidermis, which aids calcium uptake, and stores large reserves of lipids in the dermis
- detects touch, pressure, pain, and temperature stimuli
- excretes salts, water, and organic wastes; in females, specialized integumentary glands secrete milk

ABOUT THE BUILD YOUR KNOWLEDGE FIGURES

Since each organ system, or simply, body system, interacts with all the others, no one system can be completely understood in isolation. Their integration allows the human body to function seamlessly, and when disease or injury strikes, multiple systems must respond for healing to occur. Homeostasis depends on all the body systems working as one.

These figures will introduce the body systems one by one and show how each influences the others to make them function more effectively. As we progress through the systems, you will *build your knowledge* about the functional relationships between the various body systems.

Chapter Review

Summary Outline

5

An Introduction to the Integumentary System p. 152

- 1. The integumentary system, or integument, consists of the cutaneous membrane, which includes the epidermis and dermis, and the accessory structures. Beneath it lies the subcutaneous layer (*hypodermis*). (*Figure 5-1*)
- **2.** Major functions of the integument include *protection*, *temperature maintenance*, *synthesis and storage of nutrients*, *sensory reception*, and *excretion and secretion*.

5-1 The epidermis is composed of strata (layers) with various functions *p. 153*

- **3. Thin skin**, made up of four layers of **keratinocytes**, covers most of the body. Heavily abraded body surfaces may be covered by **thick skin**. (*Spotlight Figure 5-2*)
- 4. Cell divisions by basal cells (stem cells) that make up most of the stratum basale replace more superficial cells. As epidermal cells age, they move up through the stratum spinosum, the stratum granulosum, the stratum lucidum (in thick skin), and the stratum corneum. In the process, they accumulate large amounts of keratin. Ultimately, the cells are shed or lost. (Spotlight Figure 5-2)
- **5. Epidermal ridges** interlock with the dermal papillae of the dermis. Together, they form superficial ridges on the palms and soles that improve the gripping ability of the hands and feet and are the basis of fingerprints. (*Spotlight Figure 5-2*)

5-2 Epidermal pigmentation and dermal circulation influence skin color *p. 156*

6. The color of the epidermis depends on two factors: blood supply and the concentrations of the pigments melanin and carotene. Melanocytes protect stem cells from ultraviolet (UV) radiation. (Figure 5-3)

5-3 Sunlight has beneficial and detrimental effects on the skin *p. 157*

7. Epidermal cells synthesize **vitamin D**₃ when exposed to sunlight.

8. Skin cancer is the most common form of cancer. **Basal cell** carcinoma and squamous cell carcinoma are not as dangerous as melanoma. (*Figure 5-4*)

5-4 The dermis is the tissue layer that supports the epidermis *p. 158*

- **9.** The dermis consists of the **papillary layer** and the deeper **reticular layer**.
- **10.** The papillary layer of the dermis contains blood vessels, lymphatic vessels, and sensory nerves. This layer supports and nourishes the overlying epidermis. The reticular layer consists of a meshwork of collagen and elastic fibers oriented to resist tension in the skin.
- **11.** Components of other organ systems (cardiovascular, lymphatic, and nervous) that communicate with the skin are in the dermis. Arteries to the skin form the *cutaneous plexus* within the superficial region of the subcutaneous layer. The *subpapillary plexus* is at the base of the papillary layer of the dermis.

5-5 The subcutaneous layer connects the dermis to underlying tissues *p. 159*

12. The **subcutaneous layer**, or hypodermis, stabilizes the skin's position against underlying organs and tissues.

5-6 Hair is composed of dead, keratinized cells that have been pushed to the skin surface *p. 159*

- 13. Hairs originate in complex organs called hair follicles. Each hair has a shaft composed of dead, keratinized cells. Hairs have a central medulla of soft keratin surrounded by a cortex and an outer cuticle of hard keratin. (*Figure 5-5*)
- 14. Each arrector pili muscle can raise a single hair.
- **15.** Hairs grow and are shed according to the *hair growth cycle*. A single hair grows for two to five years and is then shed after a period of inactivity in the hair follicle.

5-7 Sebaceous glands and sweat glands are exocrine glands found in the skin *p. 162*

- **16.** Typical **sebaceous glands** discharge waxy **sebum** into hair follicles. *Sebaceous follicles* are sebaceous glands that empty directly onto the skin. (*Figure 5-6*)
- **17. Apocrine sweat glands** produce an odorous secretion; the more numerous **eccrine sweat glands** produce perspiration, a watery secretion. (*Figure 5-7*)

5-8 Nails are keratinized epidermal cells that protect the tips of fingers and toes *p. 163*

18. The **nail body** of a **nail** covers the **nail bed**. Nail production occurs at the **nail root**, which is covered by the **cuticle**. (*Figure 5-8*)

5-9 After an injury, the integument is repaired in several phases *p. 164*

- **19.** The skin can regenerate effectively even after considerable damage. (*Figures 5-9, 5-10*)
- **20.** Burns are relatively common injuries characterized by damage to layers of the epidermis and perhaps the dermis.

5-10 Effects of aging include dermal thinning, wrinkling, and reduced melanocyte activity *p. 167*

21. With aging, the integument thins, blood flow decreases, cellular activity decreases, and repairs occur more slowly.

See the blue Answers tab at the back of the book.

Review Questions

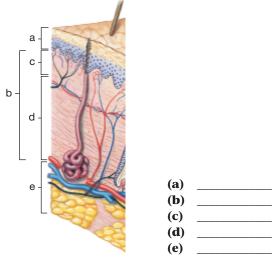

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A		COLUMN B	
	1. cutaneous membrane	a.	epidermal layer containing stem cells
:	2. carotene	b.	arrector pili
;	3. melanocytes	c.	cyanosis
4	4. stratum basale	d.	perspiration
:	5. merocrine (eccrine) glands	e.	sebum
	6. stratum corneum	f.	epidermal layer of flat- tened and dead cells
	7. bluish skin	g.	skin
8	8. sebaceous glands	h.	orange-yellow pigment
9	9. smooth muscle	i.	bone growth
10	0. vitamin D_3	j.	pigment cells

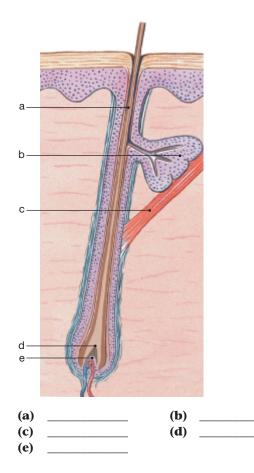

- 11. Multiple layers of dead keratinocytes are found in the
 - (a) stratum corneum.
 - (b) stratum lucidum.
 - (c) stratum spinosum.
 - (d) stratum basale.
- **12.** The epidermis of thin skin does not possess the layer called
 - (a) stratum basale. (b) stratum spinosum.
 - (c) stratum granulosum. (d) stratum lucidum.

13. Identify the different portions (a–d) of the cutaneous membrane and the underlying layer of loose connective tissue (e) in the following diagram.

- 14. The papillary layer of the dermis is made up of
 - (a) areolar tissue.
 - (b) reticular tissue.
 - (c) elastic tissue.
 - (d) smooth muscle.
- **15.** The hypodermis
 - (a) lies between the epidermis and dermis.
 - (b) consists of a papillary layer and a reticular layer.
 - (c) contains areolar tissue with many fat cells.
 - (d) synthesizes vitamin D₃ in the presence of sunlight.

- 16. Synthesis of melanin in melanocytes takes place in the (a) centrioles. (b) melanosomes.
 - (c) mitochondria. (d) nucleus.
- **17.** Hair is formed by repeated division of stem cells found in the
 - (a) hair cortex.
 - **(b)** hair cuticle.
 - (c) hair matrix.
 - (d) hair medulla.
- **18.** Identify the different portions (a–e) of a hair and hair follicle.

- **19.** What are the three layers of a hair shaft?
- 20. Touch is detected in the stratum basale by
 (a) basal cells.
 (b) keratinocytes.
 (c) Merkel cells.
 (d) melanocytes.
- **21.** Which layers of the skin are affected in a second-degree burn?

Level 2 Reviewing Concepts

- 22. Which of the following affects skin color?
 - (a) the amount of melanin and carotene in the epidermis
 - (b) the amount of blood flow in the dermal vasculature
 - (c) the amount of oxygen present in the blood
 - (d) all of the above

- **23.** In clinical practice, drugs can be delivered by diffusion across the skin. This delivery method is called transdermal administration. Why are fat-soluble drugs more desirable for transdermal administration than drugs that are water soluble?
- **24.** In our society, a tanned body is associated with good health. However, medical research constantly warns about the dangers of excessive exposure to the sun. What are the benefits of a tan?
- **25.** In some cultures, women must be covered completely, except for their eyes, when they go outside. These women exhibit a high incidence of bone problems. Why?
- **26.** Why don't identical twins have identical fingerprint patterns?
- 27. Why does skin sag and wrinkle as a person ages?

Level 3 Critical Thinking and Clinical Applications

- **28.** A new mother notices that her 6-month-old son has a yellow-orange complexion. Fearful that the child may have jaundice (a condition caused by bilirubin, a toxic yellow-orange pigment produced during the destruction of red blood cells), she takes him to her pediatrician. After examining the child, the pediatrician declares him perfectly healthy and advises the mother to watch the child's diet. Why?
- **29.** Vanessa notices that even though her 80-year-old grandmother keeps her thermostat set at 80°F, she still wears a sweater in her house. When Vanessa asks her grandmother why, her grandmother says she is cold. Vanessa can't understand this. How would you explain it to her?
- **30.** Despite more severe injury, a patient with third-degree burns may report less pain than another patient with second-degree burns. How could this be explained?

The Skeletal System

Clinical Notes Types of Fractures and Steps in Repair, pp. 180–181 Osteoporosis, p. 182

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **6-1** Describe the major functions of the skeletal system.
- **6-2** Classify bones according to shape, and compare the structures and functions of compact and spongy bone.
- **6-3** Compare the processes of intramembranous ossification and endochondral ossification.
- **6-4** Describe the remodeling and homeostatic processes of the skeletal system.
- **6-5** Summarize the effects of aging on the skeletal system.
- **6-6** Define a bone marking and name the components and functions of the axial and appendicular skeletons.
- **6-7** Identify the bones of the skull, discuss the differences in structure and function of the various vertebrae, and describe the roles of the thoracic cage.
- **6-8** Identify the bones of the pectoral and pelvic girdles and the upper and lower limbs, and describe their various functions.
- **6-9** Contrast the major categories of joints, and link their structural features to joint functions.
- **6-10** Describe how the structure and functions of synovial joints permit the movements of the skeleton.
- **6-11** Explain the relationship between joint structure and mobility of representative axial and appendicular joints.
- **6-12** Describe the interactions between the skeletal system and other body systems.

Rheumatism and Arthritis, p. 206 Hip Fractures, p. 214 **Spotlight** Synovial Joints, p. 210

6

An Introduction to the Skeletal System

The skeleton has many functions. The most obvious is supporting the weight of the body. This support is provided by bones, structures as strong as reinforced concrete but considerably lighter. Unlike concrete, bones can be remodeled and reshaped to meet changing metabolic demands and patterns of activity. Bones work with muscles to maintain body position and to produce controlled, precise movements. With the skeleton to pull against, contracting muscles can make us sit, stand, walk, or run.

Recall that bone is a supporting connective tissue (as you saw in **Chapter 4: The Tissue Level of Organization**). All of the features and properties of the skeletal system

ultimately depend on the unique and constantly changing properties of bone. **> p. 132**

6-1 The skeletal system has five major functions

Learning Outcome Describe the major functions of the skeletal system.

The skeletal system includes the bones of the skeleton and the cartilages, joints, ligaments, and other connective tissues that stabilize or connect the bones. This system has five major functions:

- **1.** *Support*. The skeletal system provides structural support for the entire body. Individual bones or groups of bones provide a framework for the attachment of soft tissues and organs.
- **2.** *Storage of minerals and lipids*. The calcium salts of bone serve as a valuable mineral reserve that maintains normal concentrations of calcium and phosphate ions in body fluids. In addition, bones store lipids as energy reserves in areas filled with *yellow bone marrow*.
- **3.** *Blood cell production*. Red blood cells, white blood cells, and other blood elements are produced within the *red bone marrow*, which fills the internal cavities of many bones.
- **4.** *Protection*. Skeletal structures surround many soft tissues and organs. The ribs protect the heart and lungs, the skull encloses the brain, the vertebrae shield the spinal cord, and the pelvis cradles delicate digestive and reproductive organs.
- **5.** *Leverage*. Many bones function as levers that change the magnitude (size) and direction of the forces generated by skeletal muscles. The resulting movements range from the delicate motion of a fingertip to powerful changes in the position of the entire body.

CHECKPOINT

1. Name the five major functions of the skeletal system. See the blue Answers tab at the back of the book.

6-2 Bones are classified according to shape and structure

Learning Outcome Classify bones according to shape, and compare the structures and functions of compact and spongy bone.

Bone, or **osseous tissue**, is a supporting connective tissue that contains specialized cells and a matrix consisting of extracellular protein fibers and a ground substance. $\bigcirc p$. 137 The distinctive texture of bone results from the calcium salts deposited within the matrix. Calcium phosphate, Ca₃(PO₄)₂, accounts for almost two-thirds of the weight of bone. The remaining third is dominated by collagen fibers. Osteocytes and other cell types make up only around 2 percent of the mass of a bone.

Build Your Knowledge

Recall that a salt is an ionic compound made up of any cation except a hydrogen ion (H⁺) and any anion except a hydroxide ion (OH⁻) (as you saw in **Chapter 2: The Chemical Level of Organization**). Calcium phosphate Ca₃(PO₄)₂ is a calcium salt. The cation is a calcium ion (Ca²⁺), and the anion is a phosphate ion (PO₄³⁻). \supset **p. 67**

Macroscopic Features of Bone

The typical human skeleton contains 206 major bones. They have four general shapes: long, short, flat, and irregular (**Figure 6-1**). **Long bones** are longer than they are wide. In **short bones** these dimensions are roughly equal. Examples of long bones are bones of the limbs, such as the bones of the arm (*humerus*) and thigh (*femur*). Short bones include the bones of the wrist (*carpal bones*) and ankles (*tarsal bones*). **Flat bones** are thin and relatively broad, such as the *parietal bones* of the skull, the ribs, and the shoulder blades (*scapulae*). **Irregular bones** have complex shapes that do not fit easily into any other category. Examples include the vertebrae of the spinal column and several bones of the skull.

Figure 6-2 shows the typical features of a long bone on the humerus. A long bone has a central shaft, or **diaphysis** (dī-AF-i-sis), that surrounds a central space called the **marrow cavity**, or *medullary cavity* (*medulla*, innermost part). This space contains **bone marrow**, a soft, fatty tissue. The expanded portions at each end are called **epiphyses** (ē-PIF-i-sēz). They are covered by *articular cartilages*. Each epiphysis (ē-PIF-i-sis) of a long bone articulates with an adjacent bone at a joint.

Two types of bone tissue are visible in **Figure 6-2**. **Compact bone** is relatively dense and solid. **Spongy bone**, or *trabecular*(tra-bek-YŪ-lar) *bone*, consists of an interlacing network of bony rods or struts separated by spaces. Compact bone forms the wall of the diaphysis, and spongy bone fills the

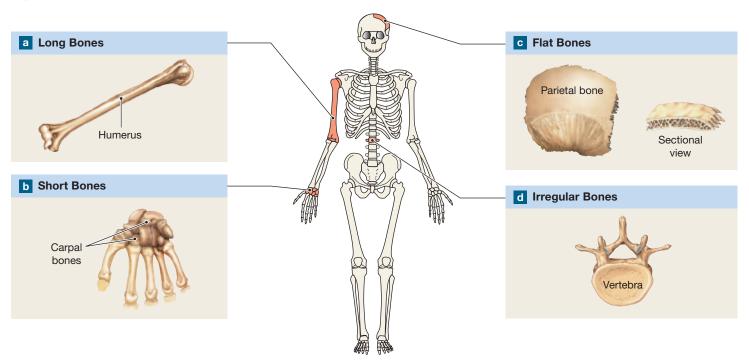

epiphyses and lines the marrow cavity. A thin layer of compact bone covers the spongy bone of each epiphysis.

The outer surface of a bone is covered by a **periosteum** (**Figure 6-2**). The periosteum consists of an outer fibrous layer and an inner cellular layer. The fibers of *tendons* and *ligaments* intermingle with those of the fibrous layer of the periosteum. Tendons attach skeletal muscles to bones, and ligaments attach one bone to another. The periosteum isolates the bone from surrounding tissues, provides a route for blood vessels and nerves, and takes part in bone growth and repair.

Within the bone, a cellular **endosteum** covers the spongy bone of the marrow cavity and other inner surfaces. The endosteum is active during bone growth and during repair or remodeling.

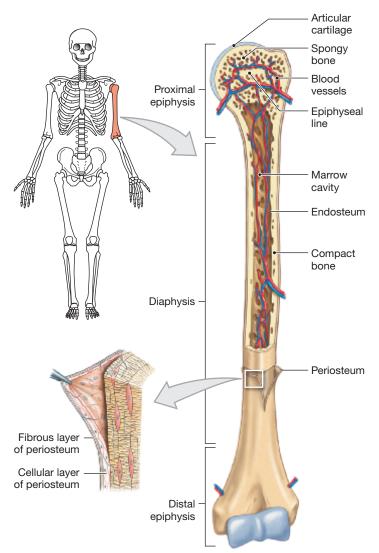

Microscopic Features of Bone

Bone is a supporting connective tissue. We introduced its general histology in Chapter 4. **Figure 6-3** presents further details of the microscopic structure of bone. Both compact bone and spongy bone contain bone cells, or **osteocytes** (OS-tē-ō-sīts; *osteon*, bone), in small pockets called **lacunae** (la-KOO-nē) (**Figure 6-3a,b**). Lacunae are found between narrow sheets of calcified matrix that are known as **lamellae** (lah-MEL-lē; *lamella*, thin plate). Small channels, called **canaliculi** (ka-na-LIK-ū-lē), radiate through the matrix. They interconnect lacunae and link them to nearby blood

vessels. The canaliculi contain cytoplasmic extensions of the osteocytes. Nutrients from the blood and waste products from osteocytes diffuse through the extracellular fluid that surrounds these cells, as well as through their cytoplasmic extensions.

Compact and Spongy Bone

The basic functional unit of compact bone is the **osteon** (OS-tē-on), or *Haversian system* (Figure 6-3a,b). Within an osteon, the osteocytes are arranged in concentric layers around a **central canal**, or *Haversian canal*, that contains one or more blood vessels. The lamellae of each osteon form a series of nested cylinders around the central canal. The central canals generally run parallel to the surface of the bone. **Perforating canals** provide passageways that link the blood vessels of the central canals with those of the periosteum and the marrow cavity.

6

Spongy bone has no osteons and a different arrangement of lamellae. Its lamellae form rods or plates called **trabeculae** (tra-BEK-ū-lē; *trabecula*, wall). Frequent branchings of the thin trabeculae create an open network. Canaliculi radiating from the lacunae of spongy bone end at the exposed surfaces of the trabeculae, where nutrients and wastes diffuse between the marrow and osteocytes.

A layer of compact bone covers bone surfaces everywhere except inside *joint capsules*, where articular cartilages protect opposing surfaces. Compact bone is usually found where stresses come from a limited range of directions. The limb bones, for example, are built to withstand forces applied at either end. Because osteons are parallel to the long axis of the shaft, a limb bone does not bend when a force (even a large one) is applied to either end. However, a much smaller force applied to the side of the shaft can break the bone.

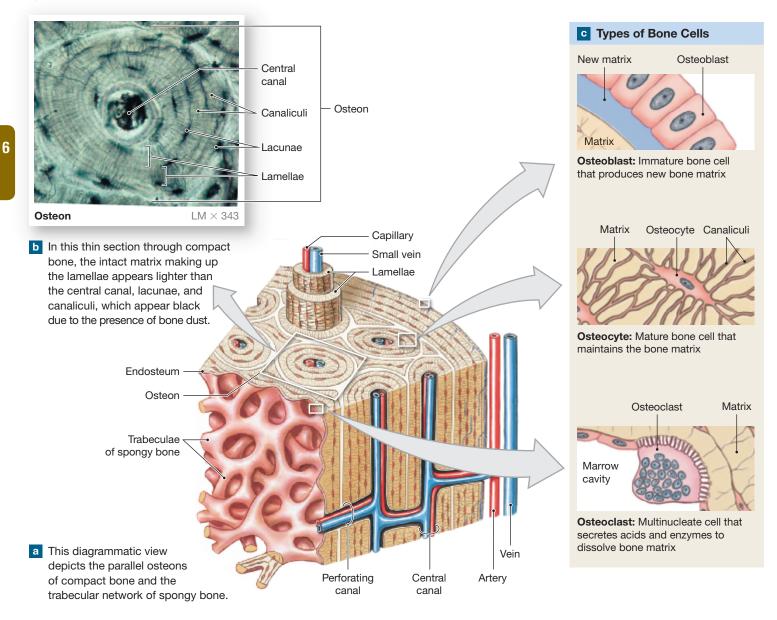

In contrast, spongy bone is found where bones are not heavily stressed or where stresses arrive from many directions. For example, spongy bone is present in the epiphyses of long bones, where stresses are transferred across joints. It is also much lighter than compact bone. Spongy bone reduces the weight of the skeleton, making it easier for muscles to move the bones. Finally, the trabecular network of spongy bone supports and protects the cells of red bone marrow, where blood cells form.

Cells in Bone

Osteocytes are the most abundant cells in bone, but other cells types are also present (**Figure 6-3c**). These cells, called *osteo-blasts* and *osteoclasts*, are associated with the endosteum that lines the inner cavities of both compact and spongy bone, and with the cellular layer of the periosteum. The three primary cell types are:

- **1. Osteoblasts** (OS-tē-ō-blasts; *blast*, precursor) produce new bone, in a process called **ossification**. They produce new bone matrix and promote the deposition of calcium salts in the organic matrix. When an osteoblast becomes completely surrounded by calcified matrix, it differentiates into an osteocyte.
- **2. Osteocytes** are mature bone cells. They maintain normal bone structure by recycling the calcium salts in the bony matrix and by assisting in repairs.
- **3. Osteoclasts** (OS-tē-ō-clasts; *clast*, break) are giant cells with 50 or more nuclei. They secrete acids and enzymes that dissolve the bony matrix and release the stored minerals through *osteolysis* (os-tē-OL-i-sis), or *resorption*. This process helps regulate calcium and phosphate concentrations in body fluids. At any given moment, osteoclasts are removing matrix and osteoblasts are adding to it.

Figure 6-3 The Microscopic Structure of a Typical Bone.

CHECKPOINT

- 2. Identify the four general shapes of bones.
- **3.** How would a bone's strength be affected if the ratio of collagen to calcium increased?
- **4.** A sample of a long bone shows concentric layers surrounding a central canal. Is it from the shaft or the end of the bone?
- Mature bone cells are known as ______, bone-building cells are called ______, and ______ are bone-resorbing cells.
- **6.** If the activity of osteoclasts exceeds that of osteoblasts in a bone, how will the mass of the bone be affected?
- See the blue Answers tab at the back of the book.

6-3 Ossification and appositional growth are processes of bone formation and enlargement

Learning Outcome Compare the processes of intramembranous ossification and endochondral ossification.

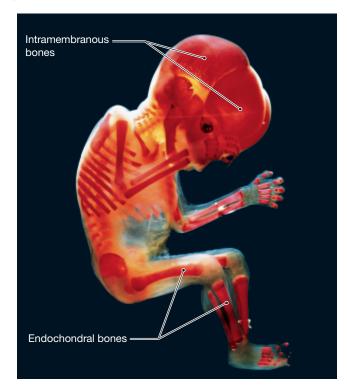

The growth of your skeleton determines the size and proportions of your body. The bony skeleton begins to form about six weeks after fertilization, when an embryo is about 12 mm (0.5 in.) long. (At this time, all skeletal elements are made of cartilage.) Bone growth continues through adolescence, and portions of the skeleton generally do not stop growing until about age 25. During development, bone replaces cartilage or other connective tissues. The process of replacing other tissues with bone is called **ossification**. (**Calcification** is the deposition of calcium salts. It occurs during ossification, but it can also take place in tissues other than bone.) There are two forms of ossification. In *intramembranous ossification*, bone develops within sheets or membranes of connective tissue. In *endochondral ossification*, bone replaces existing cartilage. **Figure 6-4** shows some of the bones formed by these two processes in a 16-week-old fetus.

Intramembranous Ossification

Intramembranous (in-tra-MEM-bra-nus) **ossification** begins when osteoblasts differentiate within embryonic or fetal fibrous connective tissue. This type of ossification takes place in the deeper layers of the dermis. The osteoblasts differentiate from connective tissue stem cells after the organic components of the matrix secreted by the stem cells become calcified. Ossification first occurs in an **ossification center**. As ossification proceeds and new bone branches outward, some osteoblasts become trapped inside bony pockets and change into osteocytes.

Bone growth is an active process, and osteoblasts require oxygen and a supply of nutrients. Blood vessels begin to grow into the area to meet these demands and over time become trapped within the developing bone. At first, the intramembranous bone resembles spongy bone. Further remodeling around

Figure 6-4 Bone Formation in a 16-Week-Old Fetus.

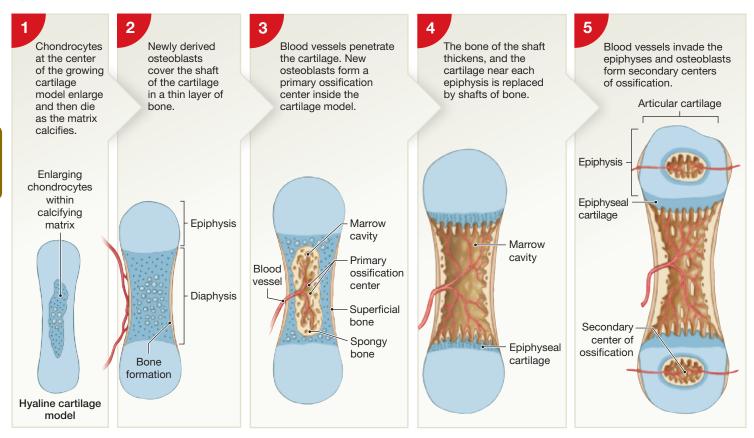

the trapped blood vessels can produce osteons typical of compact bone. The flat bones of the skull, the lower jaw (*mandible*), and the collarbones (*clavicles*) form this way.

Endochondral Ossification

Most bones of the skeleton form through **endochondral** (en-dō-KON-drul; *endo*, **inside** + *chondros*, cartilage) **ossification** of existing hyaline cartilage. The cartilages develop first, serving as miniature models of the future bone (Figure 6-4). By the time an embryo is six weeks old, these cartilage models begin to be replaced by true bone. Steps in the growth and ossification of a limb bone are diagrammed in Figure 6-5:

- 1 Endochondral ossification starts as chondrocytes within the growing cartilage model enlarge and their surrounding matrix begins to calcify. The chondrocytes die because the calcified matrix slows the diffusion of nutrients.
- 2 Bone formation first occurs at the shaft surface. Blood vessels grow around the edges of the cartilage, and the cells of the perichondrium differentiate into osteoblasts. The osteoblasts begin producing a superficial layer of bone around the shaft surface. D p. 175
- 3 Blood vessels invade the inner region of the cartilage, along with migrating fibroblasts that differentiate into osteoblasts. The new osteoblasts form spongy bone within the center of the shaft at a *primary ossification center*. Bone development proceeds toward either end, filling the shaft with spongy bone.
- As the bone enlarges, osteoclasts break down some of the spongy bone and create a marrow cavity. The **epiphyseal cartilages**, or *epiphyseal plates*, on the ends continue to enlarge, increasing the length of the developing bone. Osteoblasts from the shaft continuously invade the epiphyseal cartilages, but the bone grows longer because new cartilage is continuously added in front of the advancing osteoblasts. This situation is like a pair of joggers, one in front of the other: As long as they run at the same speed, the one in back will never catch the one in front.
- The centers of the epiphyses begin to calcify. As blood vessels and osteoblasts enter these areas, *secondary ossification centers* form. The epiphyses eventually become filled with spongy bone. A thin cap of the original cartilage model remains exposed to the joint cavity as the **articular cartilage**. At this stage, the bone of the shaft and the bone of each epiphysis are still separated by epiphyseal cartilage. As long as the rate of cartilage growth keeps pace with the rate of osteoblast invasion, the epiphyseal cartilage persists, and the bone continues to grow longer.

Figure 6-5 Endochondral Ossification.

When sex hormone production increases at puberty, bone growth speeds up. The osteoblasts begin to produce bone faster than the epiphyseal cartilages expand. As a result, the epiphyseal cartilages at each end of the bone get increasingly narrow, until they disappear. In adults, the former location of the epiphyseal cartilage is marked by a distinct **epiphyseal line** (**Figure 6-2**) that can be seen in x-rays. The end of epiphyseal growth is called *epiphyseal closure*.

While the bone lengthens, its diameter also enlarges. This enlargement process, called **appositional growth**, occurs as cells of the periosteum develop into osteoblasts and produce additional bony matrix (**Figure 6-6**). As new bone is deposited on the outer surface of the shaft, the inner surface is eroded by osteoclasts, and the marrow cavity gradually enlarges.

Bone Growth and Body Proportions

The timing of epiphyseal closure varies from bone to bone and individual to individual. Ossification of the toes may be complete by age 11, but portions of the pelvis or the wrist may enlarge until age 25. The epiphyseal cartilages in the arms and legs usually close by age 18 (women) or 20 (men). Differences in sex hormones account for variations in body size and proportions between men and women.

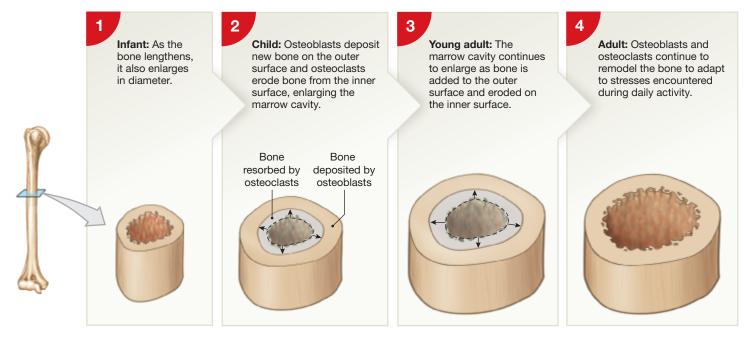

Requirements for Normal Bone Growth

Normal bone growth and maintenance depend on a reliable source of minerals, especially calcium salts. During prenatal development these minerals are absorbed from the mother's bloodstream. The demands are so great that the maternal skeleton often loses bone mass during pregnancy. From infancy to adulthood, the diet must provide adequate amounts of calcium and phosphate. The body must also be able to absorb and transport these minerals to sites of bone formation.

Vitamin D_3 plays an important role in normal calcium metabolism. This vitamin can be manufactured by epidermal cells exposed to UV radiation or obtained from dietary supplements. D p. 157 After vitamin D_3 is processed in the liver, the kidneys convert a derivative of this vitamin into *calcitriol*, a hormone that stimulates the absorption of calcium and phosphate ions in the digestive tract. A deficiency of vitamin D_3 can lead to softening of bones as a result of poor mineralization. This disorder is called *osteomalacia* in adults and *rickets* in children. In growing children, affected individuals develop a bowlegged appearance as the leg bones bend laterally under the weight of the body.

Vitamin A and *vitamin C* are also essential for normal bone growth and maintenance. For example, a deficiency of vitamin C can cause *scurvy*. In this condition, a reduction in osteoblast activity leads to weak and brittle bones. Various hormones

Figure 6-6 Appositional Bone Growth.

are also essential to normal skeletal growth and development. They include growth hormone, thyroid hormones, sex hormones, and hormones involved in calcium metabolism.

CHECKPOINT

- **7.** During intramembranous ossification, which type of tissue is replaced by bone?
- **8.** How could x-rays of the femur be used to determine if a person had reached full height?
- **9.** A child who enters puberty several years later than the average age is generally taller than average as an adult. Why?
- **10.** Why are pregnant women given calcium supplements and encouraged to drink milk even though their skeletons are fully formed?

See the blue Answers tab at the back of the book.

6-4 Bone growth and development depend on a balance between bone formation and resorption, and on calcium availability

Learning Outcome Describe the remodeling and homeostatic processes of the skeletal system.

The process of **remodeling** continuously recycles and renews the organic and mineral components of the bone matrix. Two of the five major functions of the skeleton, support and storage of minerals, depend on this dynamic nature of bone. In adults, osteocytes maintain the matrix surrounding their lacunae, continually removing and replacing calcium salts. But osteoclasts and osteoblasts also remain active, even after the epiphyseal cartilages have closed. Normally, their activities are balanced. As one osteon forms through the activity of osteoblasts, another is destroyed by osteoclasts.

The turnover rate for bone is quite high. In young adults almost one-fifth of the skeleton is recycled and replaced, or remodeled, each year. Not every part of every bone is affected. For example, the spongy bone in the head of the femur may be replaced two or three times each year, yet the compact bone along the shaft remains largely untouched.

The Role of Remodeling in Support

Regular mineral turnover gives each bone the ability to adapt to new stresses. Heavily stressed bones become thicker and stronger and develop more pronounced surface ridges. Bones not subjected to ordinary stresses become thin and brittle. For this reason, regular exercise is an important stimulus in maintaining normal bone structure.

Degenerative changes take place in the skeleton after even brief periods of inactivity. For example, using a crutch while wearing a cast takes the weight off the injured leg. After a few weeks, the unstressed leg will lose up to about a third of its bone mass. However, the bones rebuild just as quickly once they again carry their normal weight.

The Skeleton as a Calcium Reserve

The bones of the skeleton are important mineral reserves especially for calcium, the most abundant mineral in the human body. A typical human body contains 1–2 kg (2.2–4.4 lb) of calcium, with 99 percent deposited in the skeleton.

CLINICAL NOTE TYPES OF FRACTURES AND STEPS IN REPAIR

TYPES OF FRACTURES

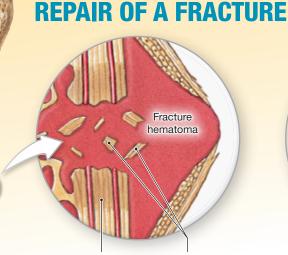

Fractures are named according to their external appearance, their location, and the nature of the crack or break in the bone. Important types of fractures are shown here by representative x-rays. The broadest general categories are closed fractures and open fractures. Closed, or simple, fractures are completely internal. They can be seen only on x-rays, because they do not involve a break in the skin. Open, or compound, fractures project through the skin. These fractures, which are obvious on inspection, are more dangerous than closed fractures, due to the possibility of infection or uncontrolled bleeding. Many fractures fall into more than one category, because the terms overlap.

Transverse fractures, such as this fracture of the ulna, break a bone shaft across its long axis. Displaced fractures produce new and abnormal bone arrangements. Nondisplaced fractures retain the normal alignment of the bones or fragments. **Compression fractures** occur in vertebrae subjected to extreme stresses, such as those produced by the forces that arise when you land on your seat in a fall. Compression fractures are often associated with osteoporosis.

Spiral fractures, such as this fracture of the tibia, are produced by twisting stresses that spread along the length of the bone.

Cartilage of

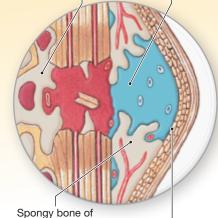

external callus

Dead bone

Bone fragments

Fracture hematoma formation. Immediately after the fracture, extensive bleeding occurs. A large blood clot, or **fracture hematoma** (*hemato-*, blood; + *tumere*, to swell), soon closes off the injured vessels and leaves a fibrous meshwork in the damaged area. The lack of blood flow kills local osteocytes, broadening the area affected. Dead bone soon extends along the shaft in either direction.

Spongy bone of

internal callus

external callus

Periosteum

2 Callus formation. The cells of the intact endosteum and periosteum undergo rapid cycles of cell division, and the daughter cells migrate into the fracture zone. An internal callus (callum, hard skin) forms as a network of spongy bone unites the inner edges of the fracture. An external callus of cartilage and bone encircles and stabilizes the outer edges of the fracture.

Comminuted fracture

Epiphyseal fractures, such as this fracture of the femur, tend to occur where the bone matrix is undergoing calcification and chondrocytes are dying. A clean transverse fracture along this line generally heals well. Unless carefully treated, fractures between the epiphysis and the epiphyseal cartilage can permanently stop growth at this site.

Comminuted fractures, such as this fracture of the femur, shatter the affected area into a multitude of bony fragments.

External callus

In a greenstick fracture, such as this fracture of the radius, only one side of the shaft is broken, and the other is bent. This type of fracture generally occurs in children, whose long bones have yet to ossify fully.

A Colles fracture, a break in the distal portion of the radius, is typically the result of reaching out to cushion a fall.

A Pott's fracture, also called a bimalleolar fracture, occurs at the ankle and affects both the medial malleolus of the distal tibia and the lateral malleolus of the distal fibula.

Internal callus

External callus

Spongy bone formation.

3 Osteoblasts replace the central cartilage of the external callus with spongy bone, which then unites the broken ends. Fragments of dead bone and the areas of bone closest to the break are resorbed and replaced. The ends of the fracture are now held firmly in place and can withstand normal stresses from muscle contractions.

Compact bone formation. 4 A swelling marks the location of the fracture. Over time, this region will be remodeled by osteoblasts and osteoclasts, and little evidence of the fracture will remain. The repair may be "good as new" or the bone may be slightly thicker and stronger than normal at the fracture site. Under comparable stresses, a second fracture will generally occur at a different site.

Calcium ions play an important role in many physiological processes, so calcium ion concentrations must be closely controlled. Even small variations from the normal concentration affect cellular operations. Larger changes can cause a clinical crisis.

The hormones *parathyroid hormone* (PTH) from the parathyroid glands and *calcitriol* from the kidneys work together to increase calcium ion levels in body fluids. Their actions are opposed by *calcitonin* (CT), a hormone from the thyroid gland that decreases calcium ion levels in body fluids. (We discuss these hormones and their regulation in Chapter 10.)

By providing a calcium reserve, the skeleton helps maintain calcium ion homeostasis in body fluids. This function can directly affect the shape and strength of the bones in the skeleton. When large numbers of calcium ions are released from the bones, the bones become weaker. When calcium salts are deposited, the bones become denser and stronger.

Repair of Fractures

Despite its strength, bone will crack or even break if subjected to extreme loads, sudden impacts, or stresses from unusual directions. Such bone damage is called a **fracture**. Most fractures heal even after severe damage, as long as the blood supply remains and the cellular components of the endosteum and periosteum survive. Steps in the repair process may take from four months to well over a year. The different types of fractures and the repair process are described in the Clinical Note: Types of Fractures and Steps in Repair on pp. 180-181.

CHECKPOINT

- **11.** Describe bone remodeling.
- **12.** Why would you expect the arm bones of a weight lifter to be thicker and heavier than those of a jogger?
- **13.** What general effects do the hormones PTH, calcitriol, and calcitonin have on blood calcium levels?
- **14.** What is the difference between a closed fracture and an open fracture?
- See the blue Answers tab at the back of the book.

6-5 Osteopenia has a widespread effect on aging skeletal tissue

Learning Outcome Summarize the effects of aging on the skeletal system.

Bones become thinner and relatively weaker as a normal part of aging. Inadequate ossification is called **osteopenia** (os-tē-ō-PĒ-nē-uh; *penia*, lacking). All of us become slightly osteopenic as we age. The reduction in bone mass begins between ages 30 and 40. Osteoblast activity begins to decline, while osteoclast activity continues at previous levels. Once the reduction begins, women lose roughly 8 percent of their skeletal mass every decade. Men lose less—about 3 percent per decade. Not all parts of the skeleton are equally affected. Epiphyses, vertebrae, and the jaws lose more than their fair share. The result is fragile limbs, a reduction in height, and the loss of teeth.

CLINICAL NOTE

Osteoporosis

Osteoporosis (os-tē-ō-po-RŌ-sis; *porosus*, porous) is a condition that reduces bone mass so much that normal function is compromised. The difference between the "normal" osteopenia of aging and osteoporosis is a matter of degree.

Sex hormones are important in maintaining normal rates of bone deposition. Over age 45, an estimated 29 percent of women and 18 percent of men have osteoporosis. In women, the condition accelerates after menopause because circulating estrogens (female sex hormones) decline. Severe osteoporosis is less common in men under age 60 than in women under 60 because men continue to produce androgens (male sex hormones) until late in life.

Osteoporotic bones break easily and do not repair well. Fractures frequently occur in the hip, wrist, and spine. Vertebrae may collapse and create pressure on spinal nerves.

CHECKPOINT

- **15.** Define osteopenia.
- **16.** Why is osteoporosis more common in older women than in older men?
- See the blue Answers tab at the back of the book.

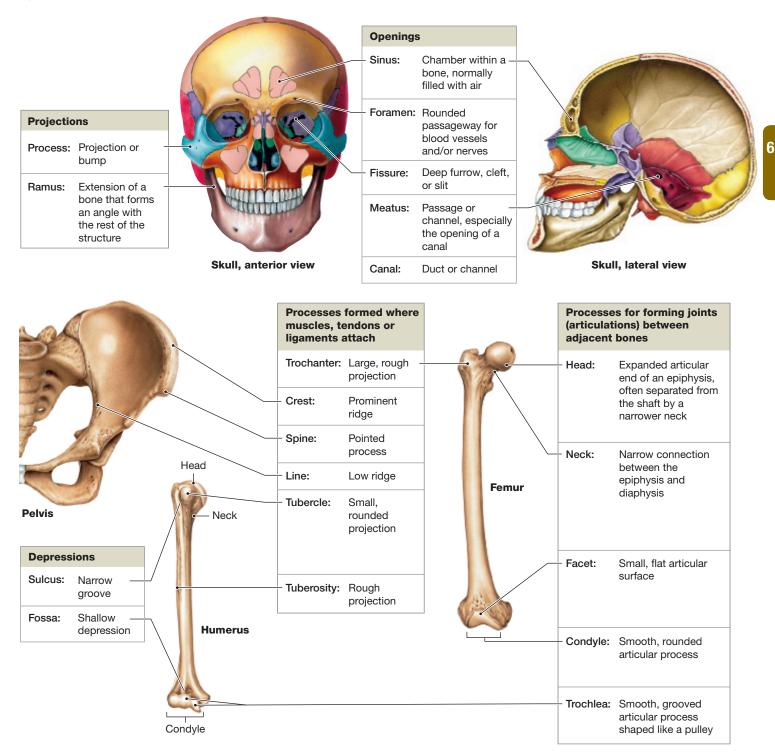

6-6 The bones of the skeleton are distinguished by bone markings and grouped into two skeletal divisions

Learning Outcome Define a bone marking and name the components and functions of the axial and appendicular skeletons.

Bone Markings (Surface Features)

The surfaces of each bone in your body have characteristic features related to specific functions. Projections form where muscles, tendons, or ligaments attach, and where adjacent

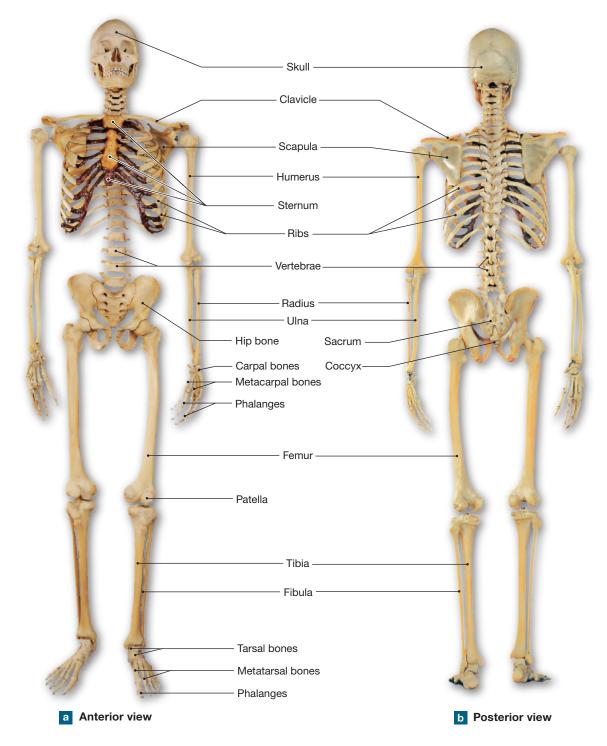

bones form at joints. *Depressions, grooves, and openings* indicate sites where blood vessels and nerves run alongside or penetrate the bone. These landmarks are called **bone markings**, or *surface features*. **Figure 6-7** lists and illustrates the most common terms used to describe bone markings.

Skeletal Divisions

The skeletal system consists of 206 separate bones and associated cartilages (**Figure 6-8**). It is divided into axial and appendicular divisions (**Figure 6-9**).

Figure 6-8 The Skeleton.

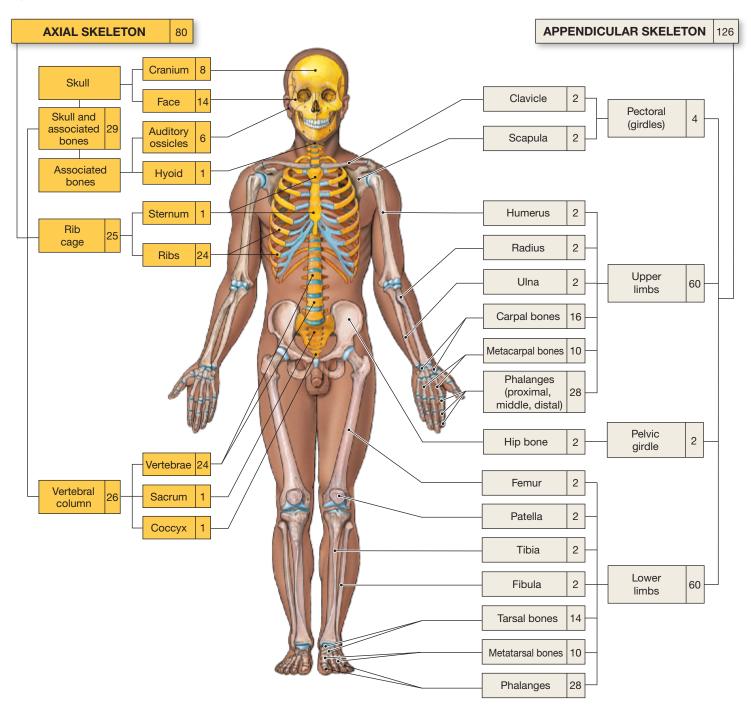

Figure 6-9 The Axial and Appendicular Divisions of the Skeleton.

The **axial skeleton** forms the longitudinal axis of the body. This division has 80 bones (Figure 6-9). They can be subdivided into four groups:

- 1. The 22 bones of the **skull** (8 *cranial bones* and 14 *facial bones*).
- 2. The 7 bones associated with the skull (6 auditory ossicles [*ear bones*] and the hyoid bone).
- 3. The 25 bones of the **rib cage** (24 *ribs* and the *sternum*).
- 4. The 26 bones of the vertebral column.

Collectively, the rib cage and the 12 thoracic vertebrae form the *thoracic cage*, which surrounds the thoracic cavity.

The **appendicular skeleton** includes the bones of the limbs and those of the **pectoral** and **pelvic girdles**, which attach the limbs to the trunk. All together there are 126 appendicular bones. Of these, 32 are associated with each upper limb, and 31 with each lower limb.

CHECKPOINT

17. Define a bone marking.

18. Identify the bones of the axial skeleton.

See the blue Answers tab at the back of the book.

6-7 The bones of the skull, vertebral column, and thoracic cage make up the axial skeleton

Learning Outcome Identify the bones of the skull, discuss the differences in structure and function of the various vertebrae, and describe the roles of the thoracic cage.

The **axial skeleton** creates a framework that supports and protects the brain, the spinal cord, and the thoracic and abdominal organs. It also provides an extensive surface area for the attachment of muscles that (1) adjust the positions of the head, neck, and trunk; (2) perform respiratory movements; and (3) stabilize or position elements of the appendicular skeleton.

The Skull

The bones of the skull protect the brain and guard the entrances to the digestive and respiratory systems. The skull also houses special sense organs for smell, taste, hearing, balance, and sight. The skull is made up of 22 bones: 8 form the **cranium**, and 14 are associated with the face. Seven additional

bones are associated with the skull: 6 *auditory ossicles*, tiny bones involved in sound detection, are encased by the *temporal bones* of the cranium; and the *hyoid bone* is connected to the inferior surface of the skull by a pair of ligaments.

The cranium encloses the **cranial cavity**, a chamber that supports the brain. Membranes that stabilize the position of the brain are attached to the inner surface of the cranium. The outer surface of the cranium provides an extensive area for the attachment of muscles that move the eyes, jaws, and head.

The Bones of the Cranium

THE FRONTAL BONE. The **frontal bone** of the cranium forms the forehead and the roof of the **orbits**, or eye sockets (**Figures 6-10** and **6-11a**). A **supra-orbital foramen** pierces the bony ridge above each orbit, forming a passageway for blood vessels and nerves passing to or from the eyebrows and eyelids (**Figure 6-10**). (Sometimes the foramen is incomplete, and the vessels then cross the rim of the orbit in a deep groove, called the *supra-orbital notch*.)

Above the orbit, the frontal bone contains air-filled chambers that connect with the nasal cavity. These **frontal sinuses** make the bone lighter and produce mucus that cleans and moistens the nasal cavities (**Figure 6-12b**).

THE PARIETAL BONES. On either side of the skull, a **parietal** (pa-RĪ-e-tal) **bone** is posterior to the frontal bone (**Figures 6-11a** and **6-12**). Together the parietal bones form the roof and the superior walls of the cranium. The parietal bones interlock along the **sagittal suture**, which extends along the midline of the cranium (**Figure 6-11a**). Anteriorly, the two parietal bones articulate with the frontal bone along the **coronal suture** (**Figure 6-10**).

THE OCCIPITAL BONE. The **occipital bone** forms the posterior and inferior portions of the cranium (**Figures 6-10** and **6-11b**). Along its superior margin, the occipital bone contacts the two parietal bones at the **lambdoid** (LAMdoyd) **suture.** The **foramen magnum** connects the cranial cavity with the vertebral canal, which is enclosed by the vertebral column. This passageway surrounds the connection between the brain and spinal cord. On either side of the foramen magnum are the **occipital condyles**, the sites of articulation between the skull and the first vertebra of the neck.

THE TEMPORAL BONES. The **temporal bones** form part of both the sides of the cranium and the zygomatic arches.

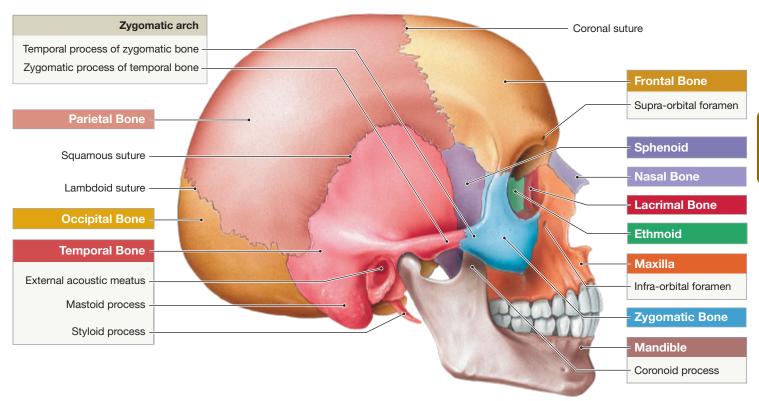

Figure 6-10 The Adult Skull, Part I. The adult skull is shown in lateral view.

The temporal bones contact the parietal bones along the **squamous** (SKWĀ-mus) **suture** on each side (**Figure 6-10**).

The temporal bones have a number of distinctive surface features. One of them, the **external acoustic meatus**, leads to the *tympanic membrane*, or eardrum. The eardrum separates the external acoustic meatus from the *middle ear*, an air-filled chamber which contains the *auditory ossicles*, or *ear bones*. (We will consider structures of the ear in Chapter 9.)

Anterior to the external acoustic meatus is a transverse depression, the **mandibular fossa**, which marks the point of articulation with the lower jaw (mandible) (**Figure 6-11b**). The prominent bulge just posterior and inferior to the entrance to the external acoustic meatus is the **mastoid process.** It is a site of the attachment of muscles that rotate or extend the head. Next to the base of the mastoid process is the long, sharp **styloid** (STĪ-loyd; *stylos*, pillar) **process.** Ligaments that support the hyoid bone are attached to the styloid process. It also anchors muscles associated with the tongue and pharynx.

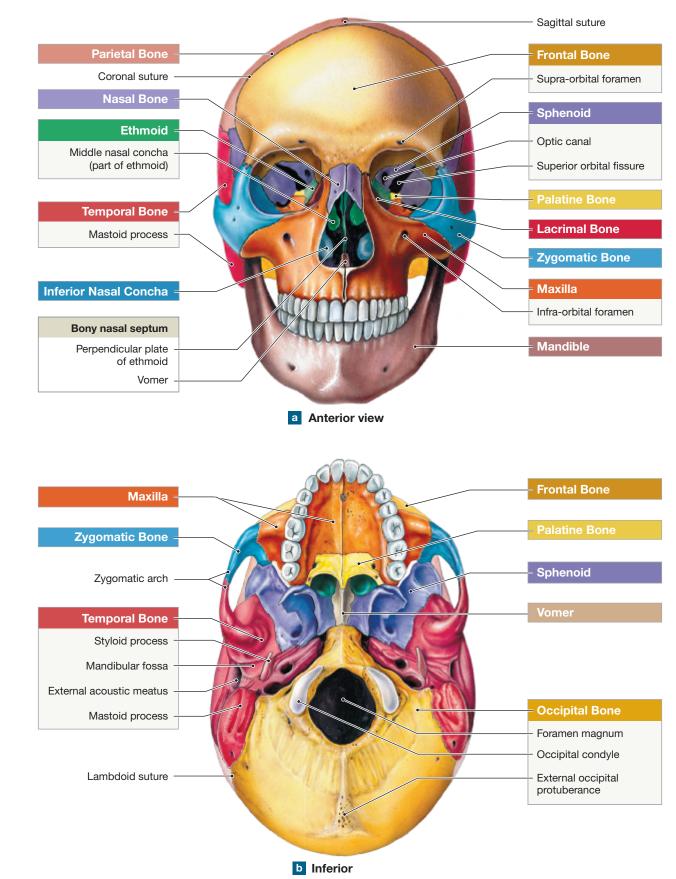

THE SPHENOID BONE. The **sphenoid** (SFE-noyd) **bone** forms part of the floor of the cranium (**Figure 6-12b**). It also acts like

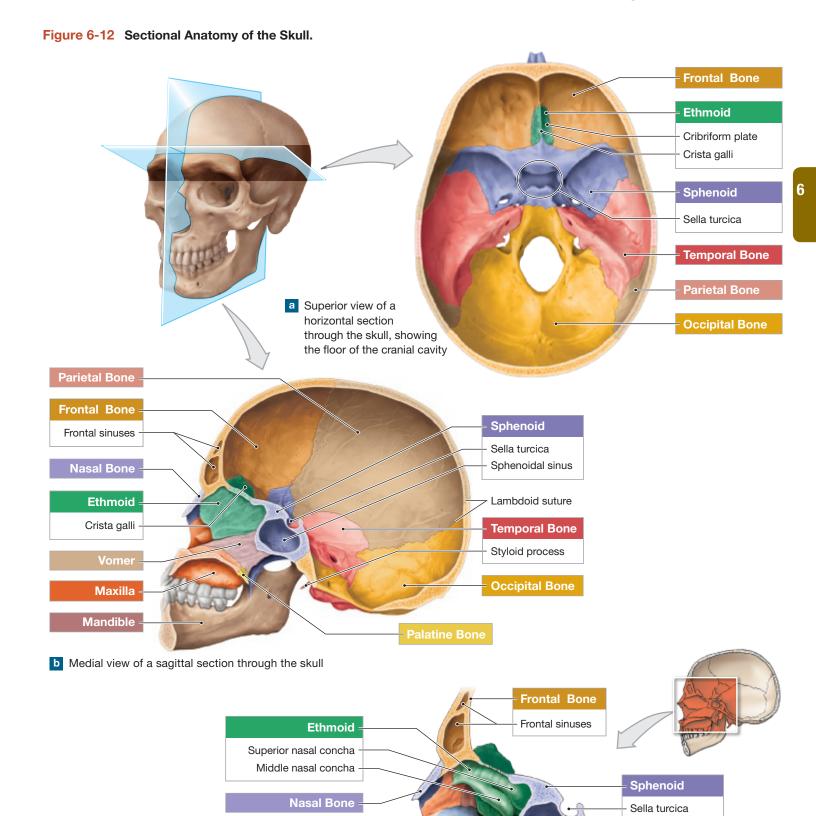

a bridge, uniting the cranial and facial bones, and it braces the sides of the skull. The general shape of the sphenoid is like a giant bat with wings extended (**Figure 6-12a**). Viewed anteriorly (**Figure 6-11a**) or laterally (**Figure 6-10**), the sphenoid is covered by other bones. Like the frontal bone, the sphenoid bone also contains a pair of sinuses, called **sphenoidal sinuses** (**Figure 6-12b,c**).

The lateral "wings" of the sphenoid extend to either side from a central depression called the **sella turcica** (TUR-sikuh) (Turk's saddle) (**Figure 6-12a,b**). It encloses the pituitary gland, which is connected to the inferior surface of the brain by a narrow stalk of neural tissue.

THE ETHMOID BONE. The **ethmoid bone** is anterior to the sphenoid bone. The ethmoid consists of two honeycombed masses of bone. It forms part of the cranial floor, contributes to the medial surfaces of the orbit of each eye, and forms the roof and sides of the nasal cavity (**Figures 6-11a** and **6-12b**). A prominent ridge, the **crista galli**, or "cock's comb," projects above the superior surface of the ethmoid (**Figure 6-12a,b**). Holes in the **cribriform plate** (*cribrum*, sieve) permit passage of the olfactory nerves, which provide the sense of smell.

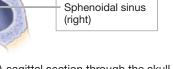

Figure 6-11 The Adult Skull, Part II.

Inferior Nasal Concha

Maxilla (bony palate)

c A sagittal section through the skull, with the nasal septum removed to show major features of the wall of the right nasal cavity The lateral portions of the ethmoid bone contain the **ethmoidal cells**, sinuses which drain into the nasal cavity. Projections called the **superior** and **middle nasal conchae** (KONG-kē; singular *concha*, shell) extend into the nasal cavity toward the *nasal septum* (*septum*, wall), which divides the nasal cavity into left and right portions (**Figures 6-11a** and **6-12b,c**). The superior and middle nasal conchae, along with the paired inferior nasal conchae bones, slow and break up the airflow through the nasal cavity. This allows time for the air to be cleaned, moistened, and warmed before it reaches the delicate portions of the respiratory tract. These bones also direct air into contact with olfactory (smell) receptors in the superior portions of the nasal cavity. The **perpendicular plate** of the ethmoid bone extends inferiorly from the crista galli, passing between the conchae to help form the nasal septum (**Figure 6-11a**).

The Bones of the Face

The facial bones protect and support the entrances to the digestive and respiratory tracts. They are sites for the attachment of muscles that control our facial expressions and help us manipulate food. Of the 14 facial bones, only the lower jaw, or mandible, is movable.

THE MAXILLAE. The **maxillae**, or *maxillary* (MAK-si-ler-ē) *bones*, articulate with all other facial bones except the mandible. The maxillae are the largest facial bones. The maxillary bones form (1) the floor and medial portion of the rim of the orbit (**Figure 6-11a**); (2) the walls of the nasal cavity; and (3) the anterior roof of the mouth, or *bony palate* (**Figure 6-12c**). The **maxillary sinuses** in these bones produce mucus that flushes the inferior surfaces of the nasal cavities. These sinuses lighten the portion of the maxillae above the embedded teeth. Infections of the gums or teeth can sometimes spread into the maxillary sinuses, increasing pain and making treatment more complicated. The **infra-orbital foramen** is an opening for a major sensory nerve from the face (**Figures 6-10** and **6-11a**).

THE PALATINE BONES. The paired **palatine bones** form the posterior surface of the *bony palate*, or *hard palate*—the "roof of the mouth" (Figures 6-11b and 6-12b,c). The superior surfaces of the horizontal portion of each palatine bone contribute to the floor of the nasal cavity. The superior tip of the vertical portion of each palatine bone forms part of the floor of each orbit.

THE VOMER. The inferior margin of the **vomer** articulates with the paired palatine bones (**Figures 6-11b** and **6-12b**). The vomer supports a prominent partition that forms part of the *nasal septum*, along with the ethmoid bone (**Figures 6-11a** and **6-12b**).

THE ZYGOMATIC BONES. On each side of the skull, a **zygomatic** (zī-gō-MA-tik) **bone** articulates with the frontal bone and the maxilla to complete the lateral wall of the orbit (**Figures 6-10** and **6-11a**). Along its lateral margin, each zygomatic bone gives rise to a slender *temporal process* that curves laterally and posteriorly to meet the *zygomatic process* of the temporal bone. Together these processes form the **zygomatic arch**, or *cheekbone* (**Figure 6-10**).

THE NASAL BONES. The **nasal bones** form the bridge of the nose midway between the orbits. They articulate with the frontal bone and the maxillary bones (**Figures 6-10** and **6-11a**).

THE LACRIMAL BONES. The **lacrimal** (*lacrimae*, tears) **bones** are located within the orbit on its medial surface. They articulate with the frontal, ethmoid, and maxillary bones (**Figures 6-10** and **6-11a**).

THE INFERIOR NASAL CONCHAE. The paired **inferior nasal conchae** project from the lateral walls of the nasal cavity (**Figures 6-11a** and **6-12c**). They slow airflow and deflect inhaled air toward the olfactory (smell) receptors located near the upper portions of the nasal cavity.

THE NASAL COMPLEX. The **nasal complex** includes the bones that form the superior and lateral walls of the nasal cavities and the sinuses that drain into them.

The ethmoid bone and vomer form the bony portion of the **nasal septum**, which separates the left and right portions of the nasal cavity (**Figure 6-11a**).

The air-filled chambers of the frontal, sphenoid, ethmoid, palatine, and maxillary bones are collectively known as the **paranasal sinuses** (Figure 6-13). (The tiny palatine sinuses, not shown, open into the sphenoidal sinuses.) These sinuses lighten the skull and provide an extensive area of mucous epithelium. Their mucous secretions are released into the nasal cavities, where the ciliated epithelium passes the mucus back toward the throat. There it is swallowed or expelled by coughing. Incoming air is humidified and warmed as it flows across this carpet of mucus. Dust and bacteria become trapped in the sticky mucus and are swallowed or expelled. This mechanism helps protect delicate portions of the respiratory tract.

THE MANDIBLE. The broad **mandible** is the bone of the lower jaw. It forms a broad, horizontal curve with vertical processes at either side. Each vertical process, or **ramus**, bears two processes. The more posterior **condylar process** ends at the *mandibular condyle*, a curved surface that articulates with the mandibular fossa of the temporal bone on that side. This

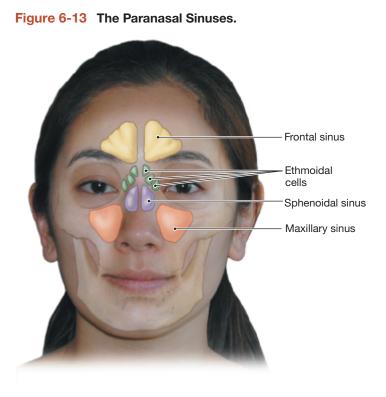

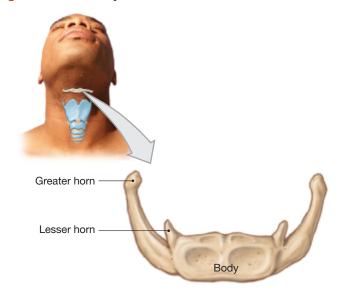

Figure 6-14 The Hyoid Bone.

joint is quite mobile. A disadvantage of such mobility is that the jaw is easily dislocated. The anterior **coronoid** (kor-Ōnoyd) **process** (**Figure 6-10**) is the attachment point for the *temporalis muscle*, a powerful muscle that closes the jaws.

The Hyoid Bone

The small, U-shaped **hyoid bone** is suspended below the skull (**Figure 6-14**). Ligaments extend from the styloid processes of the temporal bones to the *lesser horns*. The hyoid (1) a base for muscles associated with the *larynx* (voicebox), tongue, and pharynx. It also (2) supports and stabilizes the larynx.

The Skulls of Infants and Children

Many different centers of ossification are involved in forming the skull. During development, the centers fuse into a smaller number of composite bones. For example, the sphenoid begins as 14 separate ossification centers. At birth, there are two frontal bones, four occipital bones, and several sphenoid and temporal elements.

The skull organizes around the developing brain. The brain enlarges rapidly prior to birth, but the bones of the skull fail to keep pace. At birth the cranial bones are connected by areas of fibrous connective tissue (Figure 6-15). The connections are quite flexible, so the skull can be distorted without damage. During delivery, changes in head shape ease the passage of the infant along the birth canal. The largest fibrous areas between the cranial bones are known as **fontanelles** (fon-tah-NELZ; sometimes spelled *fontanels*). The anterior fontanelle is the "soft spot" on newborns. By about age four these areas disappear, and skull growth is completed.

The Vertebral Column and Thoracic Cage

The rest of the axial skeleton consists of the vertebral column and the thoracic cage. The **vertebral column**, or **spine**, consists of 26 bones: the 24 **vertebrae**, the *sacrum* (SĀ-krum), and the *coccyx* (KOK-siks) or *tailbone*. The vertebrae provide a column of support. They bear the weight of the head, neck, and trunk, and ultimately transfer the weight to the appendicular skeleton of the lower limbs. The vertebrae also protect the spinal cord and help maintain an upright body position when sitting or standing.

The vertebral column is subdivided on the basis of vertebral structure (**Figure 6-16**). The **cervical region** of the vertebral column consists of the seven **cervical vertebrae** of the neck (abbreviated as C_1 to C_7). The cervical region begins at the articulation of C_1 with the occipital condyles of the skull. This region extends inferiorly to the articulation of C_7 with the first thoracic vertebra. The **thoracic region** consists of the 12 **thoracic vertebrae** (T_1 to T_{12}). Each articulates with one or more pairs of ribs. The **lumbar region** contains the five **lumbar vertebrae** (L_1 to L_5). The first lumbar vertebra articulates with T_{12} , and the fifth lumbar vertebra articulates with the **sacrum**. The sacrum is a single bone formed by the fusion of the five embryonic vertebrae of the **sacral region**. The **coccygeal region** is made up of the small **coccyx**, which also consists of fused vertebrae. The total length of the adult vertebral column averages 71 cm (28 in.).

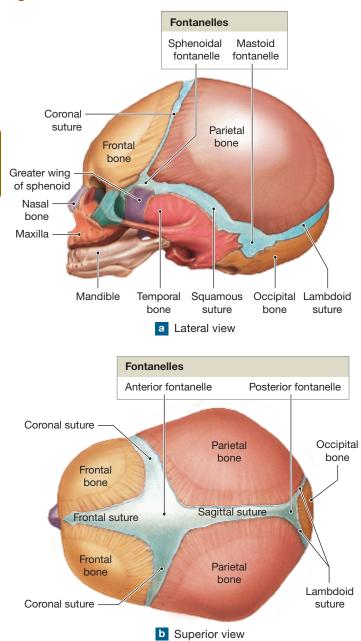

Figure 6-15 The Skull of an Infant.

Spinal Curvature

Even when we stand up straight, the vertebral column is not straight and rigid. A lateral view shows four **spinal curves** (Figure 6-16). The *thoracic* and *sacral curves* are called **primary curves** because they are present at birth. The C-shape of an infant's body axis results from these primary curves. The *cervical* and *lumbar curves*, known as **secondary curves**, develop several months after birth. All four spinal curves are fully developed by age 10.

Several abnormal distortions of spinal curvature may appear before adulthood. Three examples are (1) **kyphosis**

(kī-FŌ-sis; *kyphos*, humpbacked, bent), caused by an exaggerated thoracic curvature; (2) **lordosis** (lor-DŌ-sis; *lordosis*, a bending backward), an exaggerated lumbar curvature; and (3) **scoliosis** (skō-lē-Ō-sis; *scoliosis*, crookedness), an abnormal lateral curvature.

Vertebral Anatomy

Figure 6-17 shows representative vertebrae from three different regions of the vertebral column. All vertebrae have a *vertebral body*, a *vertebral arch*, and *articular processes*. The **vertebral body** is the more massive, weight-bearing portion. An **intervertebral disc** of fibrocartilage lies between the bony faces of the vertebral bodies, preventing contact. Intervertebral discs are not found in the sacrum and coccyx, where the vertebrae have fused, or between the first and second cervical vertebrae.

The **vertebral arch** forms the posterior margin of each **vertebral foramen** (plural, *foramina*). Together, the vertebral foramina of successive vertebrae form the **vertebral canal**, which encloses the spinal cord. The vertebral arch has walls, called *pedicles* (PED-i-kulz), and a roof formed by flat layers called *laminae* (LAM-i-nē; singular, *lamina*, a thin plate). *Transverse processes* project laterally or dorsolaterally from the pedicles and are sites for muscle attachment. A *spinous process,* or spinal process, projects posteriorly from where the laminae fuse together. The spinous processes form the bumps that can be felt along the midline of your back.

The **articular processes** arise at the junction between the pedicles and laminae. Each side of a vertebra has a *superior* and *inferior articular process*. The articular processes of successive vertebrae contact one another at the **articular facets**. Gaps between the pedicles of successive vertebrae—the *intervertebral foramina*—permit the passage of nerves running to or from the enclosed spinal cord.

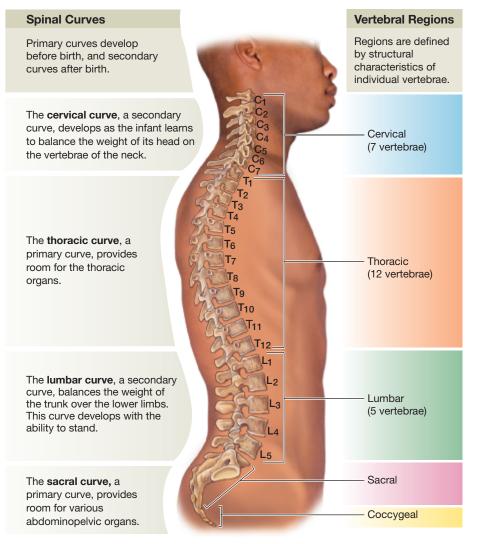

Some structural differences among vertebrae reflect differences in function, as we discuss next.

The Cervical Vertebrae

The seven cervical vertebrae extend from the head to the thorax. A typical cervical vertebra is shown in **Figure 6-17a**. Notice that the body of the vertebra is not much larger than the vertebral foramen.

Distinctive features of a typical cervical vertebra include (1) an oval, concave vertebral body; (2) a relatively large vertebral foramen; (3) a stumpy spinous process, usually with a notched tip; and (4) round **transverse foramina** within the transverse processes. These foramina protect blood vessels supplying the brain.

Figure 6-16 The Vertebral Column. The major regions of the vertebral column and the four spinal curves are shown in this lateral view.

same time, the vertebral bodies gradually enlarge, because they must bear more weight. Distinctive features of a thoracic vertebra include (1) a characteristic heart-shaped body that is more massive than that of a cervical vertebra; (2) a large, slender spinous process that points inferiorly; and (3) *costal facets* on the body (and, in most cases, on the transverse processes) for articulating with the head of one or two pairs of ribs.

The Lumbar Vertebrae

The five lumbar vertebrae are the largest vertebrae (**Figure 6-17c**). Their distinctive features include (1) a vertebral body that is thicker and more oval than that of a thoracic vertebra; (2) a relatively massive, stumpy spinous process that projects posteriorly, providing a surface for the attachment of the lower back muscles; and (3) bladelike transverse processes that lack articulations for ribs.

These vertebrae support most of the body weight. With increasing weight, the intervertebral discs become increasingly important as shock absorbers. The lumbar discs, which are subjected to the most pressure, are the thickest of all.

The Sacrum and Coccyx

The sacrum consists of the fused parts of five sacral vertebrae. It protects the reproductive, digestive, and excretory organs. Through paired articulations, it attaches the axial skel-

The first two cervical vertebrae have unique characteristics that allow for specialized movements. The **atlas** (C_1) holds up the head, articulating with the occipital condyles of the skull. It is named after Atlas, who, according to Greek myth, holds the world on his shoulders. The articulation between the occipital condyles and the atlas permits you to nod (as when indicating "yes"). The atlas forms a pivot joint with the **axis** (C_2) through a projection on the axis called the **dens** (*denz;* tooth), or *odontoid process*. This articulation permits rotation (as when shaking your head "no") (Figure 6-18).

The Thoracic Vertebrae

There are 12 thoracic vertebrae (Figure 6-17b). From the first thoracic vertebra to the sacrum, the diameter of the spinal cord decreases, and so does the size of the vertebral foramen. At the

eton to the pelvic girdle of the appendicular skeleton. The broad surface area of the sacrum provides an extensive area for the attachment of muscles, especially those used for leg movement (Figure 6-19).

Notice that the sacrum resembles a triangle. The narrow caudal portion is called the **apex**. The broad superior surface is the **base**. The superior articular processes of the first sacral vertebra articulate with the last lumbar vertebra. The **sacral canal** is a passageway that begins between those processes and extends the length of the sacrum. Nerves and the membranes that line the vertebral canal in the spinal cord continue into the sacral canal. Its inferior end, the *sacral hiatus* (hī-Ā-tus), is covered by connective tissues. A prominent bulge at the anterior tip of the base is the **sacral promontory**. It is an important landmark in females during pelvic examinations and during labor and delivery.

6

6

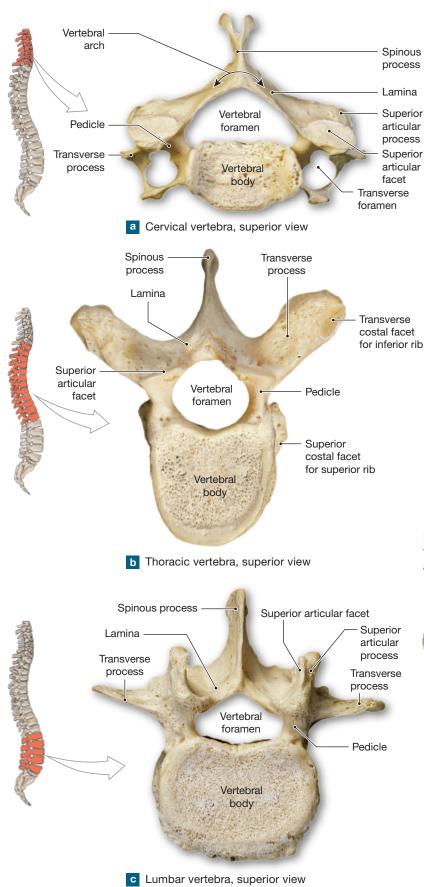

Figure 6-17 Typical Vertebrae of the Cervical, Thoracic, and Lumbar Regions.

The sacral vertebrae begin fusing shortly after puberty. They are typically completely fused at ages 25–30. Their fused spinal processes form a series of elevations along the *median sacral crest*. Four pairs of **sacral foramina** open on either side of the median sacral crest.

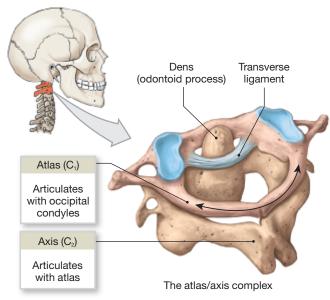

The coccyx provides an attachment site for a muscle that closes the anal opening. The fusion of the three to five (most often four) coccygeal vertebrae is not complete until late in adulthood. In elderly people, the coccyx may also fuse with the sacrum.

The Thoracic Cage

The skeleton of the chest, or **thoracic cage**, consists of the thoracic vertebrae, the ribs, and the sternum (**Figure 6-20**). It provides bony support for the walls of the thoracic cavity. The ribs and the sternum form the *rib cage*. The thoracic cage protects the heart, lungs, and other internal organs. It also serves as a base for muscles involved in respiration.

Ribs, or *costal bones,* are long, curved, flattened bones that originate on or between the thoracic vertebrae and end in the wall of the thoracic cavity. Each of us, regardless of sex, has 12 pairs of ribs. The first seven pairs are called **true ribs**, or *vertebrosternal ribs*.

Figure 6-18 The Atlas and Axis. The arrows indicate the direction of rotation at the articulation between the atlas (C_1) and the axis (C_2) .

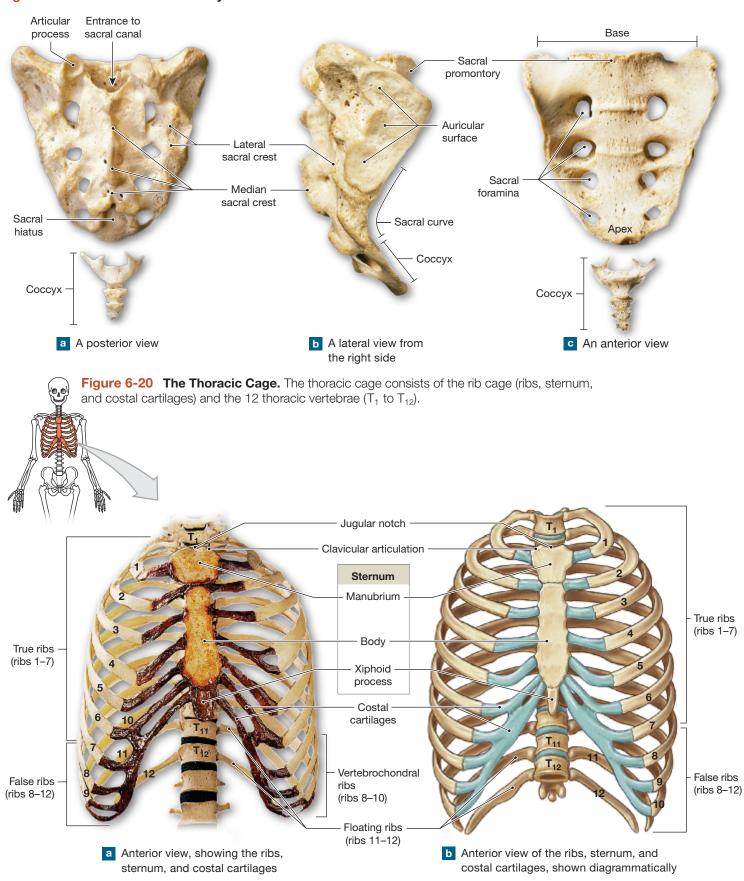

Figure 6-19 The Sacrum and Coccyx.

These ribs reach the anterior body wall and are connected to the sternum by separate cartilaginous extensions, the **costal cartilages.** Ribs 8–12 are called the **false ribs** because they do not attach directly to the sternum. The costal cartilages of ribs 8–10, the *vertebrochondral ribs*, fuse together and merge with the cartilages of rib pair 7 before they reach the sternum. The last two pairs of ribs (11 and 12) are called **floating ribs** because they have no connection with the sternum.

The ribs provide attachment sites for muscles of the pectoral girdles and trunk, and between individual ribs. With their complex musculature, dual articulations at the vertebrae (ribs 2–9), and flexible connection to the sternum, the ribs are quite mobile. Because they are curved, their movements affect both the width and the depth of the thoracic cavity (chest cavity), increasing or decreasing its volume.

The adult **sternum**, or breastbone, has three parts. The broad, triangular **manubrium** (ma-NOO-brē-um) articulates with the *clavicles* of the appendicular skeleton and with the cartilages of the first pair of ribs. The *jugular notch* is the shallow indentation on the superior surface of the manubrium. The elongated **body** ends at the slender **xiphoid** (ZI-foyd) **process**.

Ossification of the sternum begins at six to ten different centers. Fusion is not complete until at least age 25. The xiphoid process is usually the last part to ossify and fuse. Its connection to the body of the sternum can be broken by impact or strong pressure, creating a spear of bone that can severely damage the liver. Cardiopulmonary resuscitation (CPR) training strongly emphasizes the proper positioning of the hand to avoid breaking ribs or the xiphoid process.

CHECKPOINT

- **19.** The mastoid and styloid processes are found on which skull bones?
- **20.** What bone contains the depression called the sella turcica? What is located in this depression?
- **21.** Which bone of the cranium articulates directly with the vertebral column?
- **22.** During baseball practice, a ball hits Casey in the eye, fracturing the bones directly above and below the orbit. Which bones were broken?
- **23.** What are the functions of the paranasal sinuses?
- **24.** Why would a fracture of the coronoid process of the mandible make it difficult to close the mouth?
- **25.** What signs would you expect to see in a person suffering from a fractured hyoid bone?
- **26.** Joe suffered a hairline fracture at the base of the dens. Which bone is fractured, and where would you find it?

- **27.** In adults, five large vertebrae fuse to form what single structure?
- **28.** Why are the bodies of lumbar vertebrae so large?
- **29.** What are the differences between true ribs and false ribs?
- **30.** Improper administration of CPR (cardiopulmonary resuscitation) could result in a fracture of which bone(s)?
- See the blue Answers tab at the back of the book.

6-8 The pectoral girdles and upper limb bones, and the pelvic girdle and lower limb bones, make up the appendicular skeleton

Learning Outcome Identify the bones of the pectoral and pelvic girdles and the upper and lower limbs, and describe their various functions.

The appendicular skeleton includes the bones of the upper and lower limbs, and the supporting bones of the pectoral and pelvic girdles that connect the limbs to the trunk.

The Pectoral Girdles

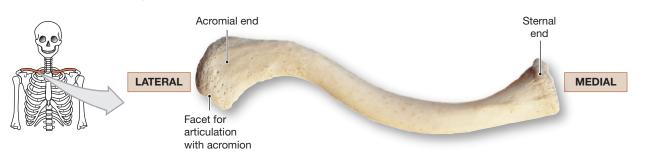

Each upper limb articulates with the trunk at a **pectoral girdle**, or *shoulder girdle*. The pectoral girdles consist of two broad, flat **scapulae** (SKAP-ū-lē; singular, *scapula*, SKAP-ū-luh) or shoulder blades and two slender, curved **clavicles** (KLAV-i-kulz; collarbones) (**Figure 6-9**). Each clavicle articulates with the manubrium of the sternum. These joints are the only direct connections between the pectoral girdles and the axial skeleton. Skeletal muscles support and position each scapula, which has no bony or ligamentous connections to the thoracic cage.

Movements of the clavicle and scapula position the shoulder joint and provide a base for arm movement. Once the shoulder joint is in position, muscles that originate on the pectoral girdle help to move the arm. The surfaces of the scapulae and clavicles are, therefore, extremely important as sites for muscle attachment.

The Clavicles

Each S-shaped clavicle articulates with the manubrium of the sternum at its *sternal end* and with a process of the scapula, the *acromion* (a-KRŌ-mē-on), at its *acromial end* (**Figure 6-21**). The smooth superior surface of the clavicle lies just beneath

the skin. The rough inferior surface of the acromial end has prominent lines and tubercles, attachment sites for muscles and ligaments.

The clavicles are relatively small and fragile, so fractures are fairly common. For example, you can fracture a clavicle in a simple fall if you land on your hand with your arm outstretched. Fortunately, most fractures of the clavicle heal rapidly without a cast.

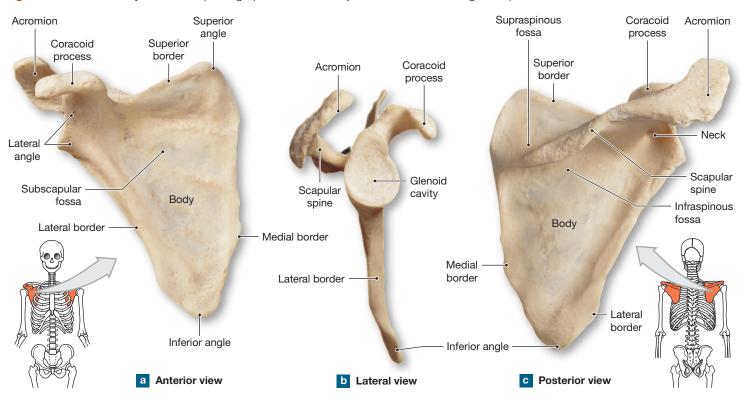

The Scapulae

The anterior surface of the *body* of each scapula forms a broad triangle bounded by **superior**, **medial**, and **lateral borders** (**Figure 6-22**). Muscles that position the scapula attach along

these edges. The three tips are called the *superior angle, inferior angle,* and *lateral angle*. The lateral angle, or *head,* of the scapula forms a broad process that supports the shallow, cup-shaped **glenoid cavity,** or *glenoid fossa* (FOS-sah). \bigcirc p. 183 At the glenoid cavity, the scapula forms the *shoulder joint* with the humerus, the proximal bone of the upper limb. The depression in the anterior surface of the body of the scapula is called the **subscapular fossa.** The *subscapularis muscle* attaches here and to the humerus.

Figure 6-22b shows a lateral view of the scapula and the two large processes that extend over the glenoid cavity. The smaller, anterior projection is the **coracoid** (KOR-uh-koyd) **process.** The **acromion** is the larger, posterior process. If you run your fingers along the superior surface of the shoulder

Figure 6-22 The Scapula. These photographs show the major landmarks on the right scapula.

joint, you will feel this process. The acromion articulates with the distal end of the clavicle.

The **scapular spine** divides the posterior surface of the scapula into two regions (**Figure 6-22c**). The area superior to the spine is the **supraspinous fossa** (*supra-*, above); the *supraspinatus muscle* attaches here. The region below the spine is the **infraspinous fossa** (*infra-*, beneath), where the *infraspinatus muscle* attaches. Both muscles are also attached to the humerus.

The Upper Limb

The skeleton of each upper limb consists of the bones of the arm, forearm, wrist, and hand. Anatomically, the term *arm* refers only to the proximal portion of the upper limb (from shoulder to elbow), not to the entire limb. $\bigcirc p$. 44 The arm, or *brachium*, contains a single bone, the **humerus**, which extends from the scapula to the elbow.

The Humerus

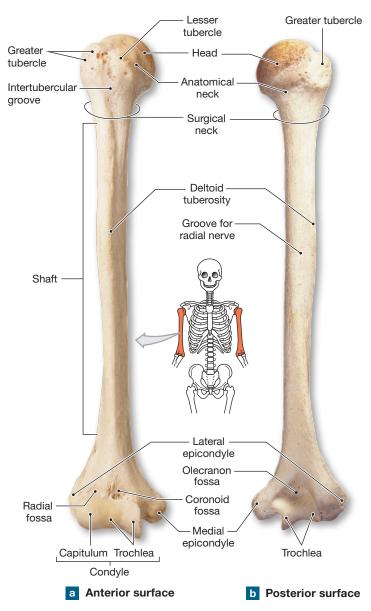

At its proximal end, the round **head** of the humerus articulates with the scapula. The prominent **greater tubercle** of the humerus is a rounded projection near the lateral surface of the head (**Figure 6-23**). It establishes the lateral contour of the shoulder. The **lesser tubercle** lies more anteriorly, separated from the greater tubercle by a deep *intertubercular groove*. Muscles are attached to both tubercles, and a large tendon runs along the groove. The *anatomical neck* lies between the tubercles and below the surface of the head. Distal to the tubercles, the narrow *surgical neck* corresponds to the region of growing bone, the *epiphyseal cartilage*. \bigcirc p. 177 The surgical neck earned its name because it is a common fracture site.

The proximal shaft of the humerus is round in section. The elevated **deltoid tuberosity** that runs along the lateral border of the shaft is named after the *deltoid muscle*, which attaches to it.

Distally, the posterior surface of the shaft flattens, and the humerus expands to either side, forming a broad triangle. **Medial** and **lateral epicondyles** project to either side, providing additional surface area for muscle attachment. The smooth **condyle** dominates the inferior surface of the humerus. At the condyle, the humerus articulates with the bones of the forearm, the *radius* and *ulna*.

A low ridge crosses the condyle, dividing it into two distinct regions. The **trochlea** is the large medial portion shaped like a spool or pulley (*trochlea*, a pulley). The trochlea extends from the base of the **coronoid** (*corona*, crown) **fossa** on the anterior surface to the **olecranon** (ō-LEK-ruh-non) **fossa** on

the posterior surface. These depressions accept projections from the ulna as the elbow reaches its limits of motion. The **capitulum** forms the lateral region of the condyle. A shallow **radial fossa** proximal to the capitulum accommodates a small projection on the radius.

The Radius and Ulna

The **radius** and **ulna** are the bones of the forearm (Figure 6-24). In the anatomical position, the radius lies along the lateral (thumb) side of the forearm while the ulna provides medial support of the forearm (Figure 6-24a).

6

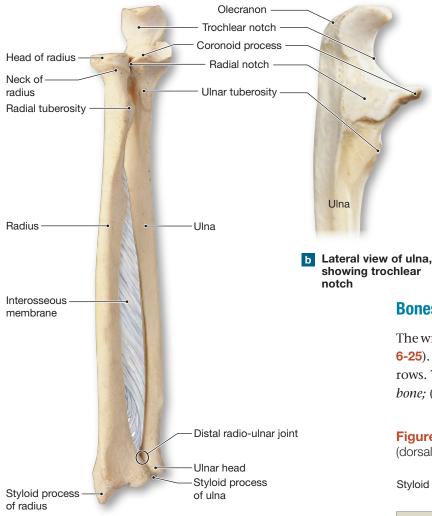

Figure 6-24 The Right Radius and Ulna.

The **olecranon** of the ulna is the point of the elbow. On its anterior surface, the **trochlear notch** articulates with the trochlea of the humerus at the elbow joint. **Figure 6-24b** shows the trochlear notch in a lateral view. The olecranon forms the superior lip of the notch, and the **coronoid process** forms its inferior lip. At the limit of *extension*, when the arm and forearm form a straight line, the olecranon swings into the olecranon fossa on the posterior surface of the humerus. At the limit of *flexion*, when the arm and forearm form a V, the coronoid process projects into the coronoid fossa on the anterior surface of the humerus.

a Anterior view

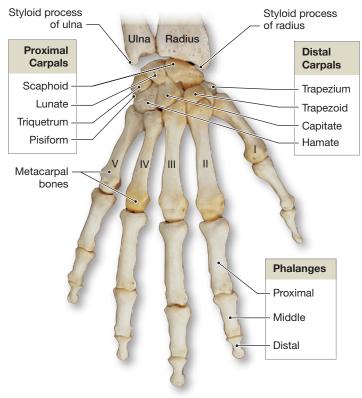

A fibrous sheet, or *interosseus membrane*, connects the lateral margin of the ulna to the radius along its length. Near the wrist, the ulnar shaft ends at a disc-shaped head whose posterior margin bears a short **styloid process.** The distal end of the ulna is separated from the wrist joint by a pad of cartilage, and only the large distal portion of the radius participates in the wrist joint. The styloid process of the radius stabilizes the joint by preventing lateral movement of the bones of the wrist (*carpal bones*). The lateral surface of the ulnar head articulates with the distal end of the radius at the *distal radio-ulnar joint*.

A narrow *neck* extends from the head of the radius to the **radial tuberosity**, which marks the attachment site of the *biceps brachii*, a large muscle on the anterior surface of the arm. The disc-shaped head of the radius articulates with the capitulum of the humerus at the elbow joint and with the ulna at the **radial notch**. This articulation with the ulna, the *proximal radio-ulnar joint*, allows the radius to roll across the ulna, rotating the palm in a movement known as *pronation*. The reverse movement, which returns the forearm to the anatomical position, is called *supination*.

Bones of the Wrist and Hand

The wrist, palm, and fingers are supported by 27 bones (**Figure 6-25**). The eight **carpal bones** of the wrist, or *carpus,* form two rows. There are four proximal carpal bones: (1) the *scaphoid bone;* (2) the *lunate bone;* (3) the *triquetrum bone;* and (4) the

Figure 6-25 The Bones of the Wrist and Hand. A posterior (dorsal) view of the right hand is shown.

200 SKELETAL SYSTEM

pisiform (PIS-i-form) *bone*. There are also four distal carpal bones: (1) the *trapezium;* (2) the *trapezoid bone;* (3) the *capitate bone;* and (4) the *hamate bone.* Joints between the carpal bones permit a limited degree of sliding and twisting.

Five **metacarpal** (met-uh-KAR-pul) **bones** articulate with the distal carpal bones and form the palm of the hand. The metacarpal bones in turn articulate with the finger bones, or **phalanges** (fa-LAN-jēz; singular, *phalanx*). Each hand has 14 phalangeal bones. Four of the fingers contain three phalanges each (proximal, middle, and distal). The thumb, or **pollex** (POL-eks), has only two phalanges (proximal and distal).

The Pelvic Girdle

6

The **pelvic girdle** articulates with the thigh bones (**Figure 6-9**). Because of the stresses involved in weight bearing and locomotion, the bones of the pelvic girdle and lower limbs are more massive than those of the pectoral girdles and upper limbs. The pelvic girdle is also much more firmly attached to the axial skeleton.

The pelvic girdle consists of two large **hip bones**, or **coxal bones**. Each hip bone forms by the fusion of three bones: an **ilium** (IL-ē-um), an **ischium** (IS-kē-um), and a **pubis** (PŪ-bis) (**Figure 6-26a,c,d**). Posteriorly, the hip bones articulate with the sacrum at the **sacro-iliac joints** (**Figure 6-26d**). Anteriorly, the hip bones are connected by a pad of fibrocartilage at a joint called the *pubic symphysis*. At the hip joint on either side, the head of the femur (thigh bone) articulates with the curved surface of the **acetabulum** (as-e-TAB-ū-lum; *acetabulum*, a vinegar cup).

The Hip Bone (Coxal Bone)

The ilium is the most superior and largest component of the hip bone (Figure 6-26). Above the acetabulum, the ilium forms

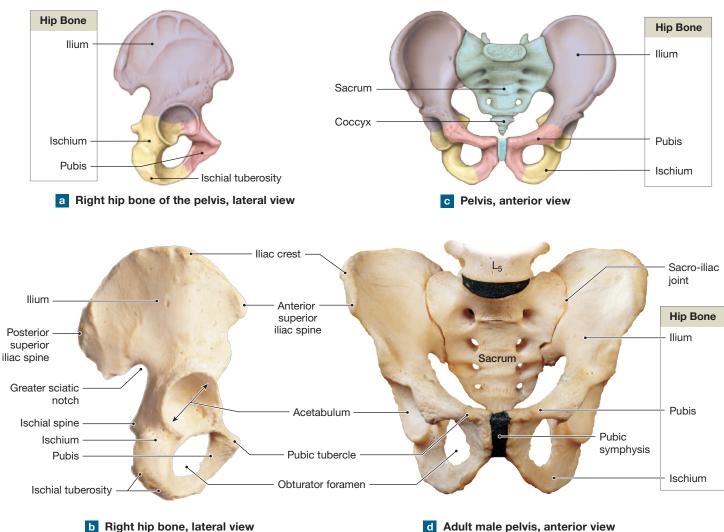

Figure 6-26 The Hip Bones and the Pelvis.

a broad, curved surface that provides an extensive area for the attachment of muscles, tendons, and ligaments. The superior margin of the ilium, the **iliac crest**, marks the sites of attachments of both ligaments and muscles (**Figure 6-26b,d**). Near the superior and posterior margin of the acetabulum, the ilium fuses with the ischium. A roughened projection at the posterior and lateral edge of the ischium, called the *ischial tuberosity*, supports the body's weight when sitting.

The fusion of a narrow branch of the ischium with a branch of the pubis completes the encirclement of the **obturator** (OB-tū-rā-tor) **foramen.** This space is closed by a sheet of collagen fibers whose inner and outer surfaces provide a base for the attachment of muscles of the hip.

The anterior and medial surface of the pubis contains a roughened area that marks the **pubic symphysis**, an articulation with the pubis of the opposite side. This joint limits movement between the two pubic bones.

The Pelvis

The **pelvis** consists of the two hip bones, the sacrum, and the coccyx (**Figure 6-26c,d**). It includes portions of both the appendicular and axial skeletons. An extensive network of ligaments connects the sacrum with the iliac crests, the ischia, and the pubic bones. Other ligaments tie the ilia to the posterior lumbar vertebrae. These interconnections increase the structural stability of the pelvis.

The shape of the pelvis of a female is somewhat different from that of a male (Figure 6-27). Some differences

result from variations in body size and muscle mass. For example, in females the pelvis is generally smoother, lighter in weight, and has less prominent markings. Other differences are adaptations for childbearing. They help to support the weight of the developing fetus and to ease its passage through the pelvic outlet during delivery. The *pelvic outlet* is the inferior opening of the pelvis. Compared to males, females have a relatively broad, low pelvis; a larger pelvic outlet; and a broader *pubic angle* (the angle between the pubic bones).

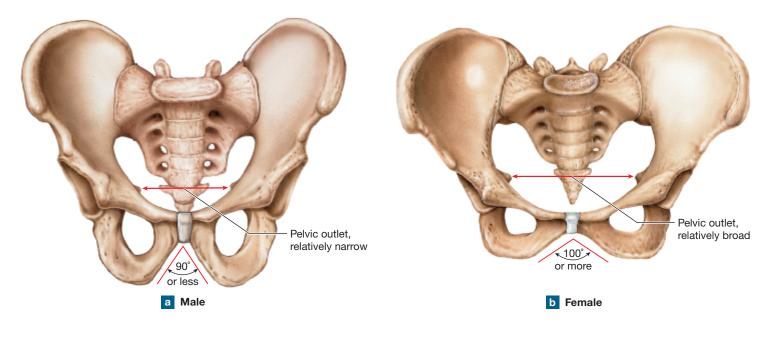

The Lower Limb

The skeleton of each lower limb consists of a *femur* (thigh bone), a *patella* (kneecap), a *tibia* and a *fibula* (leg), and the bones of the ankle and foot.

The Femur

The **femur** is the longest and heaviest bone in the body (**Figure 6-28**). The rounded epiphysis, or head, of the femur articulates with the pelvis at the acetabulum. The **greater** and **lesser trochanters** are large, rough projections that extend laterally from the juncture of the neck and the shaft. Both trochanters develop where large tendons attach to the femur. On the posterior surface of the femur is a prominent ridge, the **linea aspera.** It marks the attachment of powerful muscles that pull the shaft of the femur toward the midline, a movement called *adduction (ad-,* toward + duco, to lead).

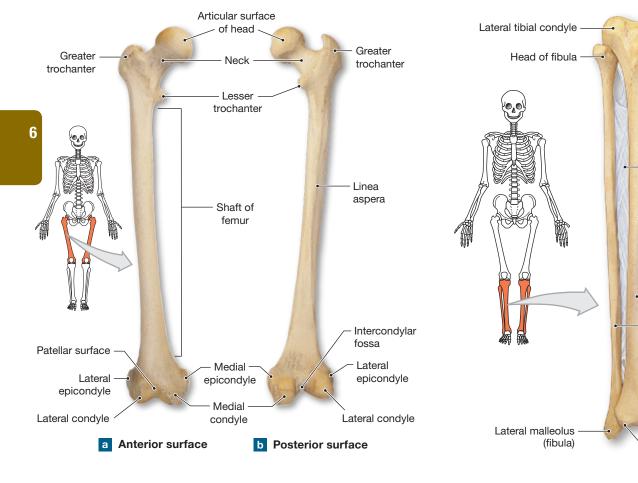

Figure 6-28 The Femur. The labels indicate the various bone markings on the right femur.

Figure 6-29 The Right Tibia and Fibula. These bones are shown in an anterior view.

Medial tibial

Tibial tuberosity

condyle

Interosseous membrane

Anterior margin

Tibia

Fibula

Medial malleolus

Inferior articular surface

(tibia)

The proximal shaft of the femur is round in cross section. More distally, the shaft becomes more flattened and ends in two large **epicondyles** (**lateral** and **medial**). The inferior surfaces of the epicondyles form the **lateral** and **medial condyles**. They form part of the knee joint.

The **patella** (*kneecap*) glides over the smooth anterior surface, or *patellar surface*, between the lateral and medial condyles. \supset p. 185 The patella forms within the tendon of the *quadriceps femoris*, a group of muscles that straighten the knee.

The Tibia and Fibula

The **tibia** (TIB-ē-uh), or *shinbone,* is the large medial bone of the leg (**Figure 6-29**). The lateral and medial condyles of the femur articulate with the *lateral* and *medial condyles* of the tibia. The *patellar ligament* connects the patella to the **tibial tuberosity** just below the knee joint.

A projecting **anterior margin** extends almost the entire length of the anterior tibial surface. The tibia broadens at its distal end into a large process, the **medial malleolus** (ma-LĒ-o-lus; *malleolus*, hammer), which provides medial support for the ankle. The inferior surface of the tibia forms a joint with the proximal bone of the ankle.

The slender **fibula** (FIB-ū-luh) parallels the lateral border of the tibia. The fibula articulates with the tibia inferior to the lateral condyle of the tibia. The fibula does not articulate with the femur or help transfer weight to the ankle and foot. However, it is an important surface for muscle attachment, and the distal **lateral malleolus** provides lateral stability to the ankle. An interosseus membrane between the two bones stabilizes their relative positions and provides additional surface area for muscle attachment.

Bones of the Ankle and Foot

The ankle, or *tarsus*, includes seven separate **tarsal bones** (Figure 6-30a): (1) the *talus*, (2) the *calcaneus*, (3) the *navicular bone*, (4) the *cuboid bone*, and (5–7) the *medial*, *intermediate*, and *lateral cuneiform bones*. Only the **talus** articulates with the tibia and fibula. It passes the body's weight from the tibia toward the toes.

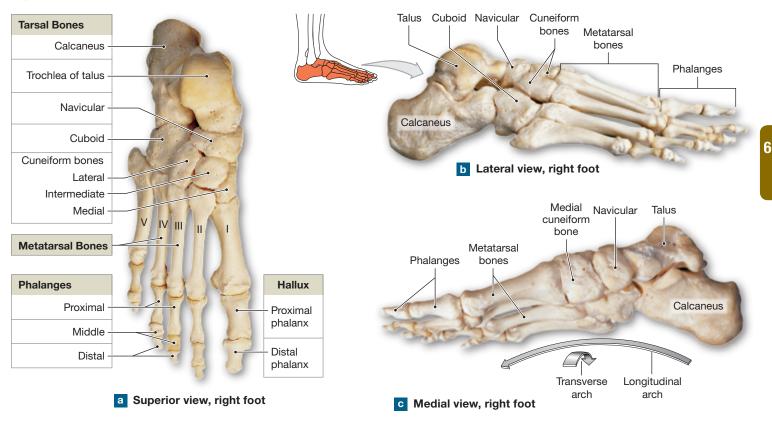

Figure 6-30 The Bones of the Ankle and Foot.

When you stand normally, most of your weight is transmitted to the ground through the talus to the large **calcaneus** (kal-KĀ-nē-us), or *heel bone* (**Figure 6-30b,c**). The posterior projection of the calcaneus is the attachment site for the *calcaneal tendon*, or *Achilles tendon*, which arises from the calf muscles. These muscles raise the heel and depress the sole, as when you stand on tiptoes. The rest of the body weight is passed through the cuboid bone and cuneiform bones to the **metatarsal bones**, which support the sole of the foot.

The basic organization of the metatarsals and phalanges of the foot resembles that of the hand. The metatarsals are numbered by Roman numerals I to V from medial to lateral, and their distal ends form the ball of the foot. Like the thumb, the great toe (or **hallux**) has two phalanges. Like the fingers, the other toes have three.

Weight is transferred along the *longitudinal arch* of the foot (**Figure 6-30c**). Ligaments and tendons maintain this arch by tying the calcaneus to the distal portions of the metatarsal bones. However, the lateral portion of this arch has less curvature than the medial portion. Part of the reason is that there is more elasticity in the medial portion. As a result, the medial plantar surface of the foot remains elevated and the muscles, nerves, and blood vessels that supply the inferior surface are not squeezed between the metatarsal bones and the ground. In the condition known as *flatfeet*, normal arches are "lost" or never form. The *transverse arch* describes the degree of curvature change from the medial to lateral borders of the foot.

CHECKPOINT

- **31.** How would a broken clavicle affect the mobility of the scapula?
- **32.** The rounded projections on either side of the elbow are parts of which bone?
- **33.** Which of the two bones of the forearm is lateral in the anatomical position?
- 34. Which three bones make up a hip bone?
- **35.** The fibula neither participates in the knee joint nor bears weight. When it is fractured, however, walking becomes difficult. Why?
- **36.** While jumping off the back steps at his house, 10-yearold Cesar lands on his right heel and breaks his foot. Which bone is most likely broken?

6-9 Joints are categorized according to their range of motion or anatomical organization

Learning Outcome Contrast the major categories of joints, and link their structural features to joint functions.

Joints, or articulations, exist wherever two bones meet. The structure of a joint determines the type of movement that may take place. Each joint reflects a compromise between the need for strength and stability and the need for movement. When movement is not required or could be dangerous, joints can be very strong. For example, the sutures of the skull lock the bones together as if they were a single bone. At other joints, movement is more important than strength. For example, the shoulder joint permits a range of arm movement that is limited more by the surrounding muscles than by joint structure. The joint itself is relatively weak, so shoulder injuries are rather common.

Joints can be classified according to their structure or function. The structural classification is based on their anatomy. Joints are described as **fibrous**, **cartilaginous**, or **synovial** (si- $N\bar{O}$ - $v\bar{e}$ -ul). The first two reflect the type of connective tissue binding them together. Such joints permit either no movement or only slight movements. Synovial joints permit free movement. They are surrounded by fibrous tissue, and the ends of bones are covered by cartilage that prevents bone-tobone contact.

In a functional classification—one we will emphasize joints are classified according to *range of motion*, the amount of movement possible. An immovable joint is a **synarthrosis**

Build Your Knowledge

Recall that a synovial membrane lines the cavity of a freely movable joint (as you in saw **Chapter 4: The Tissue Level of Organization**). The synovial fluid it secretes lubricates the joint and permits smooth movement **D p. 141**

(sin-ar-THRŌ-sis; *syn-*, together + *arthros*, joint). A slightly movable joint is an **amphiarthrosis** (am-fē-ar-THRŌ-sis; *amphi-*, on both sides). A freely movable joint is a **diarthrosis** (dī-ar-THRŌ-sis; *dia-*, through), or *synovial joint*. **Table 6-1** presents a functional classification, relates it to the structural classification scheme, and provides examples.

Immovable Joints (Synarthroses)

At a synarthrosis, the bony edges are quite close together and may even interlock. A synarthrosis can be fibrous or cartilaginous. Two examples of fibrous immovable joints can be found in the skull. In a **suture** (*sutura*, a sewing together), the bones of the skull are interlocked and bound together by dense connective tissue. In a **gomphosis** (gom-FŌ-sis; *gomphosis*, a bolting together), a ligament binds each tooth in the mouth within a bony cavity or socket (*tooth alveolus*.).

A rigid, cartilaginous connection is called a **synchondrosis** (sin-kon-DR \overline{O} -sis; *syn*, together + *chondros*, cartilage). The connection between the first pair of ribs and the sternum is a

Table 6-1	A Functional and S	Functional and Structural Classification of Joints			
Functional Category	Structural Catego	ory and Type	Description	Example	
SYNARTHROSIS (NO MOVEMENT)					
	Fibrous	Suture	Fibrous connections plus interlocked surfaces	Between the bones of the skull	
	Fibrous	Gomphosis	Fibrous connections plus insertion in bony socket (tooth alveolus)	Between the teeth and bony sockets in the maxillae and mandible	
	Cartilaginous	Synchondrosis	Interposition of cartilage bridge or plate	Between the first pair of ribs and the sternum; epiphyseal cartilages	
AMPHIARTHROSIS (LITTLE MOVEMENT					
	Fibrous	Syndesmosis	Ligamentous connection	Between the tibia and fibula	
	Cartilaginous	Symphysis	Connection by a fibrocartilage pad	Between the two pubic bones; between adjacent vertebrae of spinal column	
DIARTHROSIS (FREE MOVEMENT)					
	Synovial		Complex joint bounded by joint capsule and containing synovial fluid	Numerous; subdivided by range of motion (Spotlight Figure 6-35)	

6

synchondrosis. Another example is the epiphyseal cartilage that connects the diaphysis and epiphysis in a growing long bone. \bigcirc p. 177

Slightly Movable Joints (Amphiarthroses)

An amphiarthrosis permits very limited movement. The bones are usually farther apart than in a synarthrosis. Structurally, an amphiarthrosis can be fibrous or cartilaginous.

A **syndesmosis** (sin-dez-MŌ-sis; *desmos*, a band or ligament) is a fibrous joint connected by a ligament. The distal articulation between the two bones of the leg, the tibia and fibula, is an example. A **symphysis** is a cartilaginous joint between bones separated by a broad disc or pad of fibrocartilage. The articulations between the spinal vertebrae (at an *intervertebral disc*) and the joint between the two pubic bones are examples of a symphysis.

Freely Movable Joints (Diarthroses)

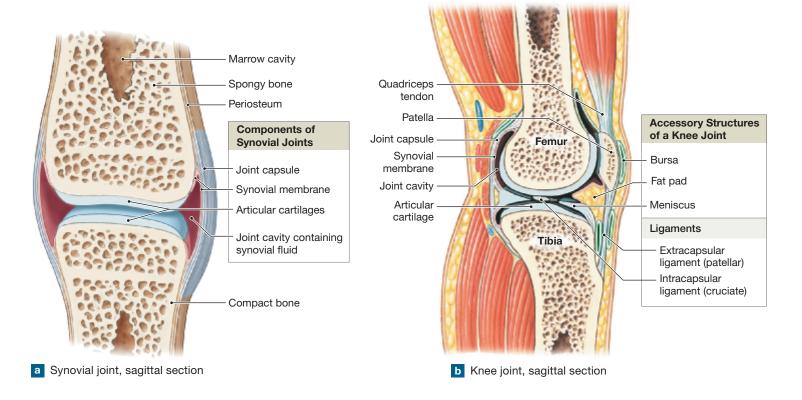

Diarthroses, or **synovial joints**, permit a wide range of motion (**Figure 6-31a**).

Synovial joints are typically found at the ends of long bones, such as those of the arms and legs. Under normal conditions the bony surfaces are not in contact, for they are covered with special **articular cartilages.** Although they resemble hyaline cartilage, articular cartilages have no perichondrium and their matrix contains more water than other cartilages. The joint is surrounded by a fibrous **joint capsule**, or *articular capsule*. A synovial membrane lines the joint cavity. **Synovial fluid** in the joint cavity lubricates moving surfaces in the joint and reduces friction.

Some complex joints have additional padding between the opposing surfaces. An example of such shock-absorbing, fibrocartilage pads are the **menisci** (me-NIS-kē; singular *meniscus*, crescent) in the knee (**Figure 6-31b**). Such joints also have **fat pads** which protect the articular cartilages and act as packing material. When the bones move, the fat pads fill in the spaces created as the joint cavity changes shape.

The joint capsule surrounding the entire joint is continuous with the periostea of the articulating bones. In addition, **ligaments** join bone to bone outside or inside the joint capsule. **Bursae** (BUR-sē; singular *bursa*, a pouch) are small packets of connective tissue containing synovial fluid. They form where a tendon or ligament rubs against other tissues. They reduce friction and act as shock absorbers. Bursae are characteristic of many synovial joints. They may also be found surrounding a tendon, covering a bone, or within other connective tissues exposed to friction or pressure.

CLINICAL NOTE

Rheumatism and Arthritis

Problems with joints are relatively common, especially in older people. Rheumatism (ROOmuh-tiz-um) is a general term for pain and stiffness in the skeletal or muscular systems, or both. Arthritis (ar-THRĪ-tis) includes all the rheumatic diseases that affect synovial joints. It always involves

damage to the articular cartilages. Causes can be bacterial or viral infection, injury to the joint, metabolic problems, or severe physical stresses.

Osteoarthritis (os-tē-ō-ar-THRĪ-tis), or *degenerative arthritis* or *degenerative joint disease (DJD)*, is the most common form of

arthritis. It generally affects individuals age 60 or older. It can result from wear and tear at

the joint surfaces or from genetic factors affecting collagen formation. According to the 2013 Global Burden of Disease report, around 242 million people in

the world were suffering from osteoarthritis.

Globally, around 20 million cases of rheumatoid arthritis, an inflammatory condition, were reported in 2017. At least some cases result when the immune response mis-

takenly attacks the joint tissues. Allergies, bacteria, viruses, and genetic factors have all been proposed as contributing to or triggering the destructive inflammation.

CHECKPOINT

- **37.** Name and describe the three types of joints as classified by their range of motion.
- **38.** In a newborn, the large bones of the skull are joined by fibrous connective tissue but later form immovable joints. Structurally, which type of joints are these?
- See the blue Answers tab at the back of the book.

6-10 The structure and functions of synovial joints enable various skeletal movements

Learning Outcome Describe how the structure and functions of synovial joints permit the movements of the skeleton.

Synovial joints are involved in all of our day-to-day movements. In everyday speech we use phrases such as "bend the leg" or "raise the arm," but anatomists use more precise language to describe types of movement and types of synovial joints.

Types of Movements at Synovial Joints Plane

In a plane movement, two opposing surfaces glide past each other in one plane. Gliding occurs between articulating carpal bones and articulating tarsal bones, and between the clavicles and sternum. The movement is slight but can take place in almost any direction. The joint capsule and ligaments usually prevent rotation.

Angular Movement

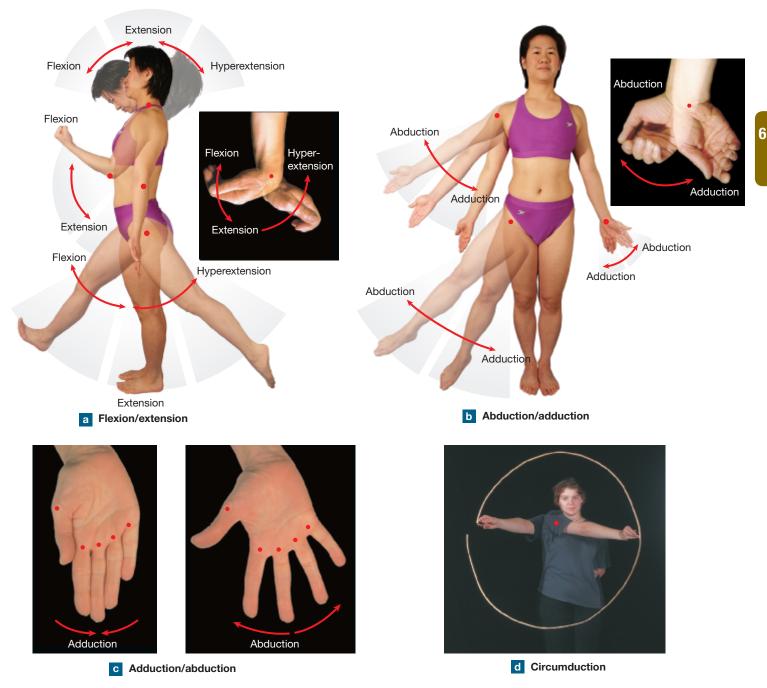

Angular movements include *flexion, extension, adduction, abduction, and circumduction.* The description of each movement refers to an individual in the anatomical position.

Flexion (FLEK-shun) is movement in the anterior-posterior, or sagittal, plane that decreases the angle between articulating bones (**Figure 6-32a**). **Extension** occurs in the same plane, but it increases the angle between articulating bones. Flexion at the shoulder joint or hip joint moves the limbs forward (*anteriorly*). Extension moves them back (*posteriorly*). Flexion of the wrist joint moves the hand forward, and extension moves it back.

Flexion and extension usually describe movements of the long bones, but they are also used for movements of the axial skeleton. For example, when you bring your head toward your chest, you flex the intervertebral joints of the neck. When you bend at the waist to touch your toes, you flex the entire vertebral column. Extension reverses these movements. In these examples, extension can continue past the anatomical position. In these cases, **hyperextension** occurs. When you gaze at the ceiling, you hyperextend the neck. Ligaments, bony processes, or soft tissues prevent hyperextension of other joints.

Abduction (*ab-*, from) is movement *away* from the longitudinal axis of the body in the frontal plane. For example,

swinging the upper limb to the side is abduction of the limb (**Figure 6-32b**). Moving it back to the anatomical position is **adduction** (*ad*, to). Adduction of the wrist moves the heel of the hand toward the body, and abduction moves it farther away. Spreading the fingers or toes apart abducts them, because they move *away* from a central digit (finger or toe), as in **Figure 6-32c**. Bringing fingers or toes together is

adduction. Abduction and adduction always refer to movements of the appendicular skeleton, not to those of the axial skeleton.

Circumduction (*circum*, around) is another type of angular movement. An example is moving your arm in a loop, as when drawing a large circle on a chalkboard (**Figure 6-32d**).

Rotation

Rotation involves turning around the longitudinal axis of the body or a limb (**Figure 6-33**). For example, you may rotate your head to look to one side or rotate your arm to screw in a lightbulb.

The articulations between the radius and ulna permit the rotation of the distal end of the radius across the anterior

6 Figure 6-33 Rotational Movements.

surface of the ulna. This rotation moves the wrist and hand from palm-facing-front to palm-facing-back. This motion is called **pronation** (pr \bar{o} -N \bar{A} -shun) (**Figure 6-33b**). The opposing movement, in which the palm is turned forward, is **supination** (soo-pi-N \bar{A} -shun).

Special Movements

Some specific terms describe unusual or special types of movement (Figure 6-34).

- **Inversion** (*in-*, into + *vertere*, to turn) is a twisting motion of the foot that turns the sole inward, elevating the medial edge of the sole. The opposite movement is called **eversion** (ē-VER-zhun; *e-*, out).
- **Dorsiflexion** is flexion at the ankle joint and elevation of the sole, as when you dig in your heel. **Plantar flexion** (*planta,* sole) is extension at the ankle joint and elevation of the heel, as when you stand on tiptoe.
- **Opposition** is the movement of the thumb toward the palm or fingertips. It enables you to grasp and hold an object. **Reposition** returns the thumb from opposition.
- **Protraction** occurs when you move a part of the body anteriorly in the horizontal plane. **Retraction** is the reverse movement. You protract your jaw when you grasp your upper lip with your lower teeth, and you protract your clavicles when you cross your arms.
- Elevation and depression take place when a structure moves in a superior or inferior direction, respectively. You depress your mandible when you open your mouth and elevate it as you close it.
- **Lateral flexion** occurs when your vertebral column bends to the side.

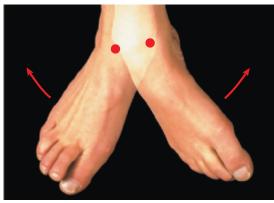

Types of Synovial Joints

Based on the shapes of the articulating surfaces, anatomists describe synovial joints as *plane (gliding), hinge, condylar, saddle, pivot,* or *ball-and-socket joints*. Each one permits a different type and range of motion. **Spotlight Figure 6-35** lists the categories and the types of movement each joint permits.

CHECKPOINT

- **39.** Give the proper term for each of the following types of motion: (a) moving the humerus away from the longitudinal axis of the body, (b) turning the palms so that they face forward, and (c) bending the elbow.
- **40.** Which movements are associated with hinge joints? See the blue Answers tab at the back of the book.

Figure 6-34 Special Movements.

Eversion

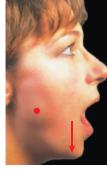

Inversion

Opposition

Lateral flexion

Retraction Protraction

Depres

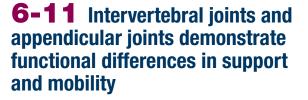

Depression

Elevation

Except for the first cervical vertebra, the vertebrae are separated and cushioned by pads called **intervertebral discs**. Each intervertebral disc has a tough outer layer of fibrocartilage. The collagen fibers of that layer attach the discs to adjacent vertebrae. The fibrocartilage surrounds a soft, elastic, and gelatinous core. The core gives intervertebral discs resiliency and enables them to act as shock absorbers, compressing and distorting when stressed. This resiliency prevents bone-tobone contact that might damage the vertebrae or jolt the spinal cord and brain.

Shortly after physical maturity, the gelatinous mass within each disc begins to degenerate, and the "cushion" becomes less effective. Over the same period, the outer fibrocartilage loses its elasticity. If the stresses are great enough, the inner mass may break through the surrounding fibrocartilage and protrude beyond the intervertebral space. This condition, called a *herniated disc*, further reduces disc function. The term *slipped disc* is often used to describe this problem, although the disc does not actually slip.

The discs make a significant contribution to an individual's height. They account for about one-quarter of the length of the spinal column above the sacrum. As we grow older, the

Learning Outcome Explain the relationship between joint structure and mobility of representative axial and appendicular joints.

In this section, we describe examples of joints that demonstrate important functional principles.

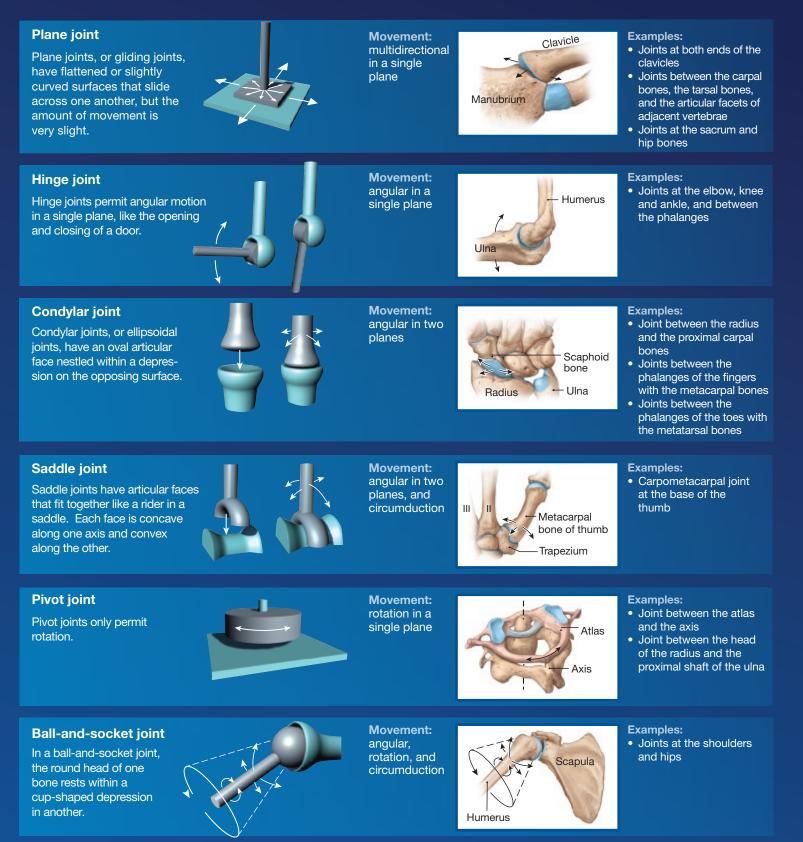

Intervertebral Joints

From the axis to the sacrum, the vertebrae articulate with one another in two ways: (1) at plane (gliding) joints (diarthroses) between the *superior* and *inferior articular processes*, and (2) at *symphyseal joints* (amphiarthroses) between the vertebral bodies (Figure 6-36). Joints between the superior and inferior articular processes of adjacent vertebrae permit small movements during flexion and rotation of the vertebral column. Little movement occurs between adjacent vertebral bodies.

SPOTLIGHT Figure 6-35 SYNOVIAL JOINTS

Go to Mastering A&P > Study Area > (myA&P) > Spotlight Figure Videos

Synovial joints are described as plane, hinge, condylar, saddle, pivot, or ball-and-socket on the basis of the shapes of the articulating surfaces. Each type permits a different range and type of motion.

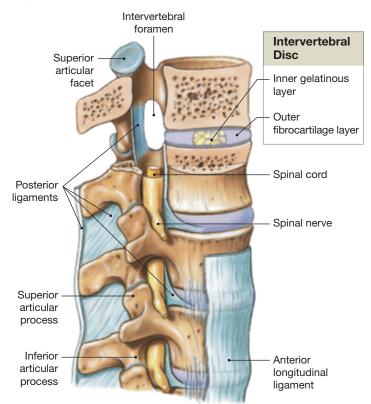

Figure 6-36 Intervertebral Joints.

water content of each disc decreases. This loss causes the vertebral column to shorten, accounting for the characteristic decrease in height with advancing age.

Joints of the Upper Limb

The shoulder, elbow, and wrist work together to position the hand, which performs precise and controlled movements. The shoulder has great mobility, the elbow has great strength, and the wrist makes fine adjustments in the orientation of the palm and fingers.

The Shoulder Joint

The shoulder joint permits the greatest range of motion of any joint in the body. Because it is also the most frequently dislocated joint, it demonstrates the principle that stability must be sacrificed to obtain mobility.

The shoulder joint is a ball-and-socket joint (**Figure 6-37**). The relatively loose joint capsule extends from the scapular neck to the humerus. This oversized capsule permits an extensive range of motion.

Bursae at the shoulder, like those at other joints, reduce friction where large muscles and tendons pass across the joint capsule. The bursae of the shoulder are especially large and

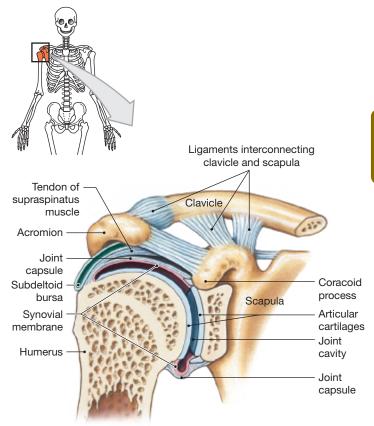

Figure 6-37 The Shoulder Joint. The structure of the right shoulder joint is visible in this anterior view of a frontal section.

numerous. Several bursae are associated with the capsule, the processes of the scapula, and large shoulder muscles. Inflammation of any of these bursae—a condition called *bursitis*— can restrict motion and produce pain.

The muscles that move the humerus do more to stabilize the shoulder joint than all its ligaments and capsular fibers combined. Powerful muscles originating on the trunk, shoulder girdle, and humerus cover the anterior, superior, and posterior surfaces of the capsule. These muscles form the *rotator cuff*, a group of muscles that swing the arm through an impressive range of motion.

The Elbow Joint

The elbow joint consists of two articulations: between the humerus and ulna and between the humerus and radius (**Figure 6-38**). The larger and stronger articulation is between the humerus and the ulna. This hinge joint provides stability and limits movement at the elbow joint.

The elbow joint is extremely stable because (1) the bony surfaces of the humerus and ulna interlock, (2) the joint capsule is very thick, and (3) the capsule is reinforced by

212 SKELETAL SYSTEM

Figure 6-38 The Elbow Joint. This longitudinal section reveals the anatomy of the right elbow joint.

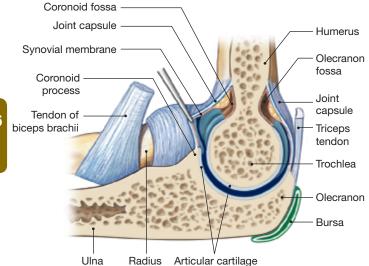

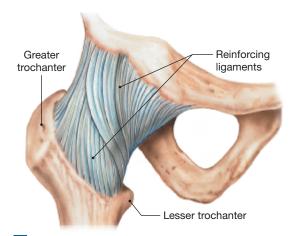

Figure 6-39 The Hip Joint.

a The hip joint is extremely strong and stable, in part because of the massive joint capsule and surrounding ligaments.

strong ligaments. Nevertheless, severe impacts or unusual stresses can damage the joint. If you fall on your hand with a partially flexed elbow, contractions of the muscles that extend the elbow may break the ulna at the center of the trochlear notch.

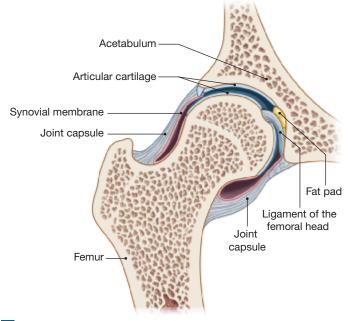

Joints of the Lower Limb

The joints of the hip, ankle, and foot are sturdier than those at corresponding locations in the upper limb, and they have smaller ranges of motion. The knee has a range of motion comparable to that of the elbow, but the knee is subjected to much greater forces. For this reason, it is less stable.

The Hip Joint

The hip joint is a ball-and-socket diarthrosis (Figure 6-39). The articulating surface of the acetabulum has a fibrocartilage pad along its edges, a fat pad covered by synovial membrane in its central portion, and a central, intracapsular ligament. This structural combination resists compression, absorbs shocks, and stretches and distorts without damage.

The joint capsule of the hip joint is denser and stronger than that of the shoulder. It extends from the lateral and inferior surfaces of the pelvic girdle to the femur and encloses both the femoral head and neck. This arrangement helps keep the head from moving away from the acetabulum. Three broad ligaments reinforce the joint capsule, while a fourth, the *ligament of the femoral head* (the *ligamentum teres*), is inside the acetabulum and attaches to the center of the

b This sectional view of the right hip shows the structure of the joint and the position of the ligament of the femoral head.

femoral head. Additional stabilization comes from the bulk of the surrounding muscles.

The combination of an almost complete bony socket, a strong joint capsule, supporting ligaments, and muscular padding makes this an extremely stable joint. However, this ball-and-socket joint is not directly aligned with the weight distribution along the shaft. As a result, *hip fractures* (fractures of the femoral neck or between the trochanters) are actually more common than *hip dislocations* (articulating surfaces are forced out of position). Flexion, extension, adduction,

6

abduction, and rotation are permitted, but the total range of motion is considerably less than that of the shoulder. Flexion is the most important normal hip movement, and range of flexion is primarily limited by the surrounding muscles. Other directions of movement are restricted by ligaments and the joint capsule.

The Knee Joint

The hip joint passes weight to the femur, and at the knee joint the femur transfers the weight to the tibia. The knee functions as a hinge joint, but the articulation is far more complex than that of the elbow or even the ankle. The rounded condyles of the femur roll across the top of the tibia, so the points of contact are constantly changing.

Structurally, the knee combines three separate articulations. There are two between the femur and tibia (medial condyle to medial condyle, and lateral condyle to lateral condyle), and one between the patella and the femur. There is no single unified joint capsule, nor is there a common synovial cavity. A pair of fibrocartilage pads, the **medial** and **lateral menisci**, lies between the femoral and tibial surfaces (**Figures 6-31b** and **6-40b**). The pads act as cushions and conform to the shape of the articulating surfaces as the femur changes position. Fat pads provide padding around the margins of the joint and assist the bursae in reducing friction between the patella and other tissues.

Ligaments stabilize the anterior, posterior, medial, and lateral surfaces of this joint. A complete dislocation of the knee is an extremely rare event. The tendon from the muscles responsible for extending the knee passes over the anterior surface of the joint. The patella lies within this tendon, and the **patellar ligament** continues its attachment on the anterior surface of the tibia (Figures 6-31b and 6-40a). This ligament provides support to the front of the knee joint. Posterior ligaments between the femur and the heads of the tibia and fibula reinforce the back of the knee joint. The *fibular collateral ligament*, also called the *lateral collateral ligament (LCL)*, reinforces the lateral surface of the knee joint. The *tibial collateral ligament*, also called the *medial collateral ligament (MCL)*, reinforces the medial surface of the knee joint. Together, they stabilize the joint at full extension.

Additional ligaments are found inside the joint capsule (**Figure 6-40b**). Inside the joint, the *anterior cruciate ligament* (*ACL*) and *posterior cruciate ligament* (*PCL*) cross each other as they attach the tibia to the femur. (The term *cruciate* is derived

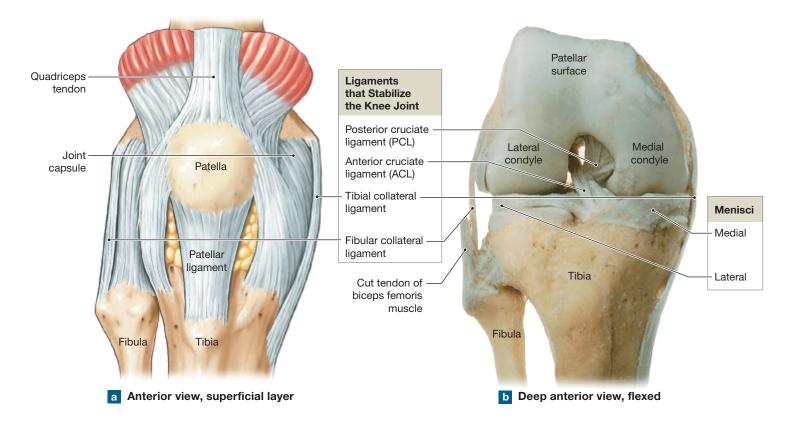

Figure 6-40 The Knee Joint.

214 SKELETAL SYSTEM

from the Latin word *crucialis,* meaning a cross.) These ligaments limit the anterior and posterior movement of the femur. Rupture of the anterior cruciate ligament (ACL) is a common sports injury. It affects women two to five times more often than men. ACL injuries are frequently caused by twisting an extended weight-bearing knee. This movement is common in football, basketball, and skiing. A strong hit or force to the lateral surface of the knee, as in a football tackle or a flying hockey puck, may damage both the ACL and the medial collateral ligament (MCL).

6

CHECKPOINT

- **41.** Would a tennis player or a jogger be more likely to develop inflammation of the subdeltoid bursa? Why?
- **42.** Daphne falls on her hands with her elbows slightly flexed. After the fall, she can't move her left arm at the elbow. If a fracture exists, which bone is most likely broken?
- **43.** Why is a complete dislocation of the knee joint an infrequent event?
- See the blue Answers tab at the back of the book.

6-12 The skeletal system supports and stores energy and minerals for other body systems

Learning Outcome Describe the interactions between the skeletal system and other body systems.

Bones may seem inert, but by now you know they are quite dynamic. They undergo continuous remodeling. The balance

between bone formation and bone recycling involves interactions between the skeletal system and other organ systems. Bones provide attachment sites for muscles. Bones are extensively interconnected with the cardiovascular and lymphatic systems. They are largely under the physiological control of the endocrine system. The digestive and urinary systems provide calcium and phosphate minerals for bone growth. Build Your Knowledge: How the SKELETAL SYSTEM integrates with the other body systems presented so far on p. 215 reviews the major functional relationships between the skeletal and integumentary systems.

CHECKPOINT

- **44.** Describe the functional relationship between the skeletal system and the integumentary system.
- See the blue Answers tab at the back of the book.

CLINICAL NOTE

Hip Fractures

Hip fractures most often occur in individuals over the age of 60, when osteoporosis has weakened the thigh bones. These injuries may be accompanied by dislocation of the hip or by pelvic fractures. In individuals with osteoporosis, such fractures heal very slowly. In addition, the powerful muscles that surround the joint can easily prevent proper alignment of the bone fragments. Trochanteric fractures usually heal well if the joint can be stabilized. Steel frames, pins, screws, or some combination of these items may be required to preserve alignment and permit normal healing.

RELATED CLINICAL TERMS

ankylosis (ang-ki-LŌ-sis): An abnormal fusion between articulating bones in response to trauma and friction within a joint.

arthroscopy: Insertion of a narrow tube containing optical fibers and a tiny camera (arthroscope) directly into the joint for visual examination.

gigantism: A condition of extreme height resulting from an overproduction of growth hormone before puberty.

luxation (luks-Ā-shun): A dislocation; a condition in which the articulating surfaces are forced out of position.

orthopedics (or-tho-PĒ-diks): A branch of surgery concerned with disorders of the bones and joints and their associated muscles, tendons, and ligaments.

osteomyelitis (os-tē-ō-mī-e-LĪ-tis)**:** A painful infection in a bone, generally caused by bacteria.

spina bifida (SPĪ-nuh BI-fi-duh): A birth defect resulting from the failure of the vertebral laminae to unite during development; commonly associated with developmental abnormalities of the brain and spinal cord.

sprain: A condition in which a ligament is stretched to the point at which some of the collagen fibers are torn. The ligament remains functional, and the structure of the joint is not affected.

whiplash: An injury resulting when a sudden change in body position injures the cervical vertebrae.

Build Your Knowledge:

How the SKELETAL SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System removes excess body heat, synthesizes vitamin D₃ for calcium and phosphate ion absorption, and protects underlying bones and joints
- The skeletal system provides structural support for the skin

Skeletal System

The skeletal system performs five major functions for the human body. It:

- provides structural support for the body
 stores calcium, phosphate, and other minerals necessary for many functions in
- other organ systems, and lipids as energy reserves
- produces blood cells and other blood elements in red bone marrow
- protects many soft tissues and organs
- provides leverage for movements generated by skeletal muscles

An Introduction to the Skeletal System p. 173

1. The components of the skeletal system have a variety of purposes, such as providing a framework for body posture and allowing for precise movements.

6-1 The skeletal system has five major functions p. 173

2. The skeletal system includes the bones of the skeleton and the cartilages, ligaments, and other connective tissues that stabilize or interconnect bones. Its major functions include structural support, storage of minerals and lipids, blood cell production, protection, and leverage.

6-2 Bones are classified according to shape and structure *ρ. 173*

- **3. Bone**, or **osseous tissue**, is a supporting connective tissue with a solid *matrix*.
- **4.** General categories of bones are **long bones**, **short bones**, **flat bones**, and **irregular bones**. (*Figure 6-1*)
- **5.** The features of a long bone include a **diaphysis**, two **epiphyses**, and a central *marrow cavity*. (*Figure 6-2*)
- 6. The two types of bone tissue are **compact bone** and **spongy** (*trabecular*) **bone**.
- **7.** A bone is covered by a **periosteum** and lined with an **endosteum**.
- 8. Both types of bone tissue contain **osteocytes** in **lacunae**. Layers of calcified matrix are **lamellae**, interconnected by **canaliculi**. (*Figure 6-3a,b*)
- **9.** The basic functional unit of compact bone is the **osteon**, containing osteocytes arranged around a **central canal**.
- 10. Spongy bone contains **trabeculae**, often in an open network.
- **11.** Compact bone is located where stresses come from a limited range of directions. Spongy bone is located where stresses are few or come from many different directions.
- 12. Cells other than osteocytes are also present in bone. Osteoblasts synthesize the matrix in the process of *ossification*. Osteoclasts dissolve the bony matrix through the process of *osteolysis* or *resorption*. (*Figure 6-3c*)

6-3 Ossification and appositional growth are processes of bone formation and enlargement *p. 176*

- 13. Ossification is the process of converting other tissues to bone.
- **14. Intramembranous ossification** begins when stem cells in connective tissue differentiate into osteoblasts and produce spongy or compact bone. (*Figure 6-4*)

- **15. Endochondral ossification** begins with the formation of a cartilage model of a bone that is gradually replaced by bone. In this process, bone length also increases. (*Figure 6-5*)
- **16.** Bone diameter increases through **appositional growth.** (*Figure 6-6*)
- **17.** The timing of epiphyseal closure differs among bones and among individuals.
- **18.** Normal ossification requires a reliable source of minerals, vitamins, and hormones.

6-4 Bone growth and development depend on a balance between bone formation and resorption, and on calcium availability *p. 179*

- **19.** The organic and mineral components of bone are continuously recycled and renewed through the process of **remodeling.**
- **20.** The shapes and thicknesses of bones reflect the stresses applied to them. Mineral turnover enables bone to adapt to new stresses.
- **21.** Calcium is the most abundant mineral in the human body, with roughly 99 percent of it located in the skeleton. The skeleton acts as a calcium reserve.
- 22. A fracture is a crack or break in a bone. Closed fractures are internal. Open fractures project through the skin. Repair of a fracture involves the formation of a fracture hematoma, an external callus, and an internal callus. (Clinical Note: Types of Fractures and Steps in Repair)

6-5 Osteopenia has a widespread effect on aging skeletal tissue *p. 182*

23. The effects of aging on the skeleton can include **osteopenia** and **osteoporosis**.

6-6 The bones of the skeleton are distinguished by bone markings and grouped into two skeletal divisions *p. 182*

- **24.** A **bone marking** (*surface feature*) is an area on the surface of a bone with a specific function. Bone markings can be used to describe and identify specific bones. (*Figure 6-7*)
- 25. The axial skeleton can be subdivided into the skull and associated bones (including the auditory ossicles, or ear bones, and the hyoid); the rib cage, composed of the ribs and sternum and the vertebral column. The thoracic cage consists of the rib cage and thoracic vertebrae. (Figures 6-8, 6-9)
- **26.** The **appendicular skeleton** includes the bones of the upper and lower limbs and the **pectoral** and **pelvic girdles**.

6-7 The bones of the skull, vertebral column, and thoracic cage make up the axial skeleton *p. 186*

- **27.** The **cranium** encloses the **cranial cavity**, which encloses the brain.
- **28.** The **frontal bone** forms the forehead and superior surface of each **orbit.** (*Figures 6-10, 6-11, 6-12*)
- **29.** The **parietal bones** form the upper sides and roof of the cranium. (*Figures 6-10, 6-12*)
- **30.** The **occipital bone** surrounds the **foramen magnum** and articulates with the sphenoid, temporal, and parietal bones to form the back of the cranium. (*Figures 6-10, 6-11, 6-12*)
- **31.** The **temporal bones** help form the sides and base of the cranium and fuse with the parietal bones along the **squamous suture.** (*Figures 6-10, 6-11, 6-12*)
- **32.** The **sphenoid bone** acts like a bridge that unites the cranial and facial bones. (*Figures 6-10, 6-11, 6-12*)
- **33.** The **ethmoid bone** stabilizes the brain and forms the roof and sides of the nasal cavity. Its **cribriform plate** contains perforations for olfactory nerves, and the **perpendicular plate** forms part of the bony *nasal septum*. (*Figures 6-10, 6-11, 6-12*)
- **34.** The left and right **maxillae**, or *maxillary bones*, articulate with all the other facial bones except the *mandible*. (*Figures* 6-10, 6-11, 6-12)
- **35.** The **palatine bones** form the posterior portions of the hard palate and contribute to the walls of the nasal cavity and to the floor of each orbit. *(Figures 6-11, 6-12)*
- **36.** The **vomer** forms the inferior portion of the bony nasal septum. (*Figures 6-11, 6-12*)
- **37.** The **zygomatic bones** help complete the orbit and together with the temporal bones form the **zygomatic arch** (*cheekbone*). (*Figures 6-10, 6-11*)
- **38.** The **nasal bones** articulate with the frontal bone and the maxillary bones. (*Figures 6-10, 6-11, 6-12*)
- **39.** The **lacrimal bones** are within the orbit on its medial surface. (*Figures 6-10, 6-11*)
- **40.** The **inferior nasal conchae** inside the nasal cavity aid the **superior** and **middle nasal conchae** of the ethmoid bone in slowing incoming air. (*Figures 6-11a, 6-12c*)
- **41.** The **nasal complex** includes the bones that form the superior and lateral walls of the nasal cavity and the sinuses that drain into them. The **nasal septum** divides the nasal cavities. Together, the **frontal, sphenoidal, palatine,** and **maxillary sinuses,** and **ethmoidal cells** make up the **paranasal sinuses**. (*Figures 6-11, 6-12, 6-13*)
- **42.** The **mandible** is the bone of the lower jaw. (*Figures 6-10*, *6-11*, *6-12*)
- **43.** The **hyoid bone** is suspended below the skull by ligaments from the styloid processes of the temporal bones. (*Figure 6-14*)
- **44.** Fibrous tissue connections called **fontanelles** permit the skulls of infants and children to continue growing. *(Figure 6-15)*

- **45.** The **vertebral column** consists of the vertebrae, sacrum, and coccyx. We have 7 **cervical vertebrae**, 12 **thoracic vertebrae**, and 5 **lumbar vertebrae**. The **sacrum** and **coccyx** consist of fused vertebrae. (*Figure 6-16*)
- **46.** The spinal column has four **spinal curves**, which accommodate the unequal distribution of body weight and keep it in line with the body axis. (*Figure 6-16*)
- **47.** A typical vertebra has a **body** and a **vertebral arch**; it articulates with other vertebrae at the **articular processes**. Adjacent vertebrae are separated by an **intervertebral disc.** (*Figure 6-17*)
- **48.** Cervical vertebrae are distinguished by the oval body and **transverse foramina** on either side. (*Figures 6-17, 6-18*)
- **49.** Thoracic vertebrae have distinctive heart-shaped bodies and articulate with the ribs. (*Figure 6-17*)
- **50.** The lumbar vertebrae are the most massive, least mobile, and are subjected to the greatest strains. (*Figure 6-17*)
- 51. The sacrum protects reproductive, digestive, and excretory organs. At its **apex**, the sacrum articulates with the coccyx. At its **base**, the sacrum articulates with the last lumbar vertebra. (*Figure 6-19*)
- **52.** The skeleton of the chest, or **thoracic cage**, consists of the thoracic vertebrae, the ribs, and the sternum. The **ribs** and **sternum** form the *rib cage*. (*Figure 6-20*)
- **53.** Ribs 1 to 7 are **true ribs.** Ribs 8 to 12 lack direct connections to the sternum and are called **false ribs**; they include two pairs of **floating ribs.** The medial end of each rib articulates with a thoracic vertebra. (*Figure 6-20*)
- **54.** The sternum consists of a **manubrium**, a **body**, and a **xiphoid process**. (*Figure 6-20*)

6-8 The pectoral girdles and upper limb bones, and the pelvic girdle and lower limb bones, make up the appendicular skeleton *p. 196*

- **55.** Each arm articulates with the trunk at a **pectoral girdle**, or *shoulder girdle*, which consists of a **scapula** and **a clavicle**. (*Figures 6-8, 6-9, 6-21, 6-22*)
- **56.** The clavicle and scapula position the shoulder joint, help move the arm, and provide a base for arm movement and muscle attachment. (*Figures 6-21, 6-22*)
- **57.** Both the **coracoid process** and the **acromion** are attached to ligaments and tendons. The **scapular spine** crosses the posterior surface of the scapular body. (*Figure 6-22*)
- **58.** The **humerus** articulates with the scapula at the shoulder joint. The **greater tubercle** and **lesser tubercle** of the humerus are important sites for muscle attachment. Other prominent landmarks include the **deltoid tuberosity**, the **medial** and **lateral epicondyles**, and the articular **condyle**. (*Figure 6-23*)
- **59.** Distally, the humerus articulates with the radius and ulna. The medial **trochlea** extends from the **coronoid fossa** to the **olecranon fossa**. (*Figure 6-23*)

218 SKELETAL SYSTEM

- **60.** The **radius** and **ulna** are the bones of the forearm. The olecranon fossa accommodates the **olecranon process** during extension of the arm. The coronoid and radial fossae accommodate the **coronoid process** of the ulna. (*Figure 6-24*)
- **61.** The bones of the wrist form two rows of **carpal bones.** The distal carpal bones articulate with the **metacarpal bones** of the palm. The metacarpal bones articulate with the proximal **phalanges**, or finger bones. Four of the fingers contain three phalanges; the **pollex**, or thumb, has only two. (*Figure 6-25*)
- **62.** The **pelvic girdle** consists of two **hip bones**, or **coxal bones**. (*Figures 6-8, 6-9, 6-26*)
- **63.** The largest part of the hip bone, the **ilium**, fuses with the **ischium**, which in turn fuses with the **pubis**. The **pubic symphysis** limits movement between the pubic bones of the left and right hip bones. (*Figure 6-26*)
- **64.** The **pelvis** consists of the hip bones, the sacrum, and the coccyx. (*Figures 6-26, 6-27*)
- **65.** The **femur**, or *thigh bone*, is the longest bone in the body. It articulates with the **tibia** at the knee joint. The patellar ligament from the **patella** (the *kneecap*) attaches at the **tibial tuberosity.** (*Figures 6-28, 6-29*)
- **66.** Other tibial landmarks include the **anterior margin** and the **medial malleolus.** The **head** of the **fibula** articulates with the tibia below the knee, and the **lateral malleolus** stabilizes the ankle. (*Figure 6-29*)
- **67.** The ankle includes seven **tarsal bones;** only the **talus** articulates with the tibia and fibula. When we stand normally, most of our weight is transferred to the **calcaneus**, or *heel bone*, and the rest is passed on to the **metatarsal bones.** (*Figure 6-30*)
- **68.** The basic organizational pattern of the metatarsals and phalanges of the foot resembles that of the hand.

6-9 Joints are categorized according to their range of motion or anatomical organization *p. 204*

- **69.** Joints, or articulations, exist wherever two bones interact. Immovable joints are **synarthroses**, slightly movable joints are **amphiarthroses**, and those that are freely movable are called **diarthroses**. (*Table 6-1*)
- **70.** Examples of synarthroses are a **suture**, a **gomphosis**, and a **synchondrosis**.
- **71.** Examples of amphiarthroses are a **syndesmosis** and a **symphysis.**
- **72.** The bony surfaces at diarthroses, or **synovial joints**, are covered by **articular cartilages**, lubricated by **synovial fluid**, and enclosed within a **joint capsule**. Other synovial structures include **menisci**, **fat pads**, **bursae**, and various **ligaments**. (*Figure 6-31*)

6-10 The structure and functions of synovial joints enable various skeletal movements p. 206

- **73.** Important terms that describe movements at synovial joints are **flexion**, **extension**, **hyperextension**, **abduction**, **adduction**, **circumduction**, and **rotation**. (*Figures 6-32*, *6-33*)
- **74.** The bones in the forearm permit **pronation** and **supination.** (*Figure 6-33*)
- 75. Movements of the foot include **inversion** and **eversion**. The ankle undergoes flexion and extension, also known as **dorsiflexion** and **plantar flexion**, respectively. **Opposition** is the thumb movement that enables us to grasp and hold objects. **Reposition** is the opposite of opposition. (*Figure 6-34*)
- **76. Protraction** involves moving a part of the body forward; **retraction** involves moving it back. **Depression** and **elevation** occur when we move a structure inferiorly and superiorly, respectively. *(Figure 6-34)*
- **77.** Major types of synovial joints include plane (gliding) joints, hinge joints, pivot joints, condylar joints, saddle joints, and ball-and-socket joints. (*Spotlight Figure 6-35*)

6-11 Intervertebral joints and appendicular joints demonstrate functional differences in support and mobility *p. 209*

- **78.** The articular processes of adjacent vertebrae form plane (gliding) joints. *Symphyseal joints* connect adjacent vertebral bodies and are separated by **intervertebral discs**. (*Figure 6-36*)
- **79.** The shoulder joint is formed by the **glenoid cavity** and the head of the humerus. This ball-and-socket joint is extremely mobile and, for that reason, it is also unstable and easily dislocated. *(Figure 6-37)*
- **80.** Bursae at the shoulder joint reduce friction from muscles and tendons during movement. (*Figure 6-37*)
- **81.** The elbow joint permits only flexion and extension. It is extremely stable because of extensive ligaments and the shapes of the articulating bones. (*Figure 6-38*)
- **82.** The hip joint is formed by the union of the **acetabulum** with the head of the femur. This ball-and-socket joint permits flexion and extension, adduction and abduction, circumduction, and rotation. (*Figure 6-39*)
- **83.** The knee joint is a complicated hinge joint. The joint permits flexion-extension and limited rotation. (*Figure 6-40*)

6-12 The skeletal system supports and stores energy and minerals for other body systems *p. 214*

84. Growth and maintenance of the skeletal system is supported by the integumentary system. The skeletal system also interacts with the muscular, cardiovascular, lymphatic, digestive, urinary, and endocrine systems.

- 33. Which spinal curves are present at birth?
- **34.** What two primary functions are performed by the thoracic cage?
- **35.** Which two large scapular processes are associated with the shoulder joint?

Level 2 Reviewing Concepts

- **36.** Why are stresses or impacts to the side of the shaft of a long bone more dangerous than stress applied along the long axis of the shaft?
- **37.** During the growth of a long bone, how is the epiphysis forced farther from the shaft?
- **38.** Why are ruptured intervertebral discs more common in lumbar vertebrae, and dislocations and fractures more common in cervical vertebrae?
- **39.** What are the factors that help to make the hip joint extremely stable?
- **40.** What is the difference in skeletal structure between the pelvic girdle and the pelvis?
- **41.** Why does the shape of a female's pelvis differ from that of a male's?
- **42.** The cranial bones of the fetus are connected by connective tissue. How is this helpful in the birth process?

Level 3 Critical Thinking and Clinical Applications

43. While examining the x-ray of a young boy's ankle, a medical student noticed a transverse radiolucent line in the lower

end of the tibia, even though the boy did not have a fracture. What could be the cause of the radiolucent line?

- **44.** Tess is diagnosed with a disease that affects the membranes surrounding the brain. The physician tells Tess's family that the disease is caused by an airborne virus. Explain how this virus could have entered the cranium.
- **45.** While working at an excavation, an archaeologist finds several small skull bones. She examines the frontal, parietal, and occipital bones and concludes that the skulls are those of children not yet one year old. How can she tell their ages from examining these bones?
- **46.** Frank Fireman is fighting a fire in a building when part of the ceiling collapses and a beam strikes him on his left shoulder. He is rescued by his friends, but he has a great deal of pain in his shoulder and cannot move his arm properly, especially anteriorly. His clavicle is not broken, and his humerus is intact. What is the probable nature of Frank's injury?
- **47.** Ed "turns over" his ankle while playing tennis. He experiences swelling and pain, but after examination he is told that there are no torn ligaments and that the structure of the ankle is not affected. On the basis of the signs and symptoms and the examination results, what do you think happened to Ed's ankle?

The Muscular System

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **7-1** Specify the functions of skeletal muscle tissue.
- **7-2** Describe the organization of muscle at the tissue level.
- **7-3** Identify the structural components of a sarcomere.
- **7-4** Explain the key steps in the contraction of a skeletal muscle fiber beginning at the neuromuscular junction.
- **7-5** Compare the different types of muscle contractions.
- **7-6** Describe the processes by which muscles obtain the energy to power contractions.
- **7-7** Relate the types of muscle fibers to muscle performance, and distinguish between aerobic and anaerobic endurance.
- **7-8** Contrast the structures and functions of skeletal, cardiac, and smooth muscle tissues.
- **7-9** Explain how the name of a muscle can help identify its location, appearance, or function.
- **7-10** Identify the main axial muscles of the body and their origins, insertions, and actions.
- **7-11** Identify the main appendicular muscles of the body and their origins, insertions, and actions.
- **7-12** Describe the effects of aging on muscle tissue.
- **7-13** Discuss the interactions between the muscular system and other body systems when the body is at rest, and explain the homeostatic responses to exercise by the muscular system and various other body systems.

An Introduction to Muscle Tissue

Muscle tissue is one of the four primary tissue types. It consists of elongated muscle cells that are highly specialized for contraction. We introduced the three types of muscle tissue—*skeletal muscle, cardiac muscle,* and *smooth muscle*—in Chapter 4. D p. 141 Without these muscle tissues, nothing in the body would move, and the body itself could not move. We would not be able to sit, stand, walk, speak, or grasp objects. Our blood would not circulate, because we would have no heartbeat to propel it through the vessels. Our lungs could not empty and fill, nor could food move through the digestive tract.

We begin this chapter by discussing skeletal muscle tissue, the most abundant muscle tissue in the body. We then give an overview of the differences among skeletal, cardiac, and smooth muscle tissue. Finally, we describe the gross anatomy of the muscular system and look at the working relationships between the muscles and bones of the body.

Build Your Knowledge

Recall that skeletal muscle tissue is described as striated voluntary muscle tissue (as you saw in **Chapter 4: The Tissue Level of Organization).** This description is based on the presence of regularly repeating groups of

actin and myosin filaments within skeletal muscle cells. It also refers to the fact that the nervous system provides voluntary control over this tissue. **D p. 143**

7-1 Skeletal muscle performs five primary functions

Learning Outcome Specify the functions of skeletal muscle tissue.

Skeletal muscles are organs composed primarily of skeletal muscle tissue, but they also contain connective tissues, nerves, and blood vessels. These muscles are directly or indirectly attached to the bones of the skeleton. The muscular system includes approximately 700 skeletal muscles that perform the following functions:

- 1. *Move the skeleton.* When skeletal muscles contract, they pull on tendons and thereby move the bones. These contractions may produce a simple motion, such as extending the arm, or the highly coordinated movements of swimming, skiing, or typing.
- 2. *Maintain posture and body position.* Continuous muscle contractions maintain body posture. Without this constant action, you could not sit upright without collapsing, or stand without toppling over.
- **3.** *Support soft tissues.* The abdominal wall and the floor of the pelvic cavity consist of layers of skeletal muscle. These muscles support the weight of our visceral organs and shield our internal tissues from injury.
- **4.** *Guard entrances and exits.* Skeletal muscles encircle openings of the digestive and urinary tracts. These muscles give us voluntary control over swallowing, defecating, and urinating.

5. *Maintain body temperature.* Muscle contractions use energy, and whenever energy is used in the body, some of it is converted to heat. The heat from working muscles keeps body temperature in the range required for normal functioning.

To understand how skeletal muscle contracts, we must study the structure of skeletal muscle. We begin with the organ-level structure of skeletal muscle and then describe its cellular-level structure. In the following discussions you will often see the Greek words *sarkos* (flesh) and *mys* (muscle) as word roots in the names of the structural features of muscles and their components.

CHECKPOINT

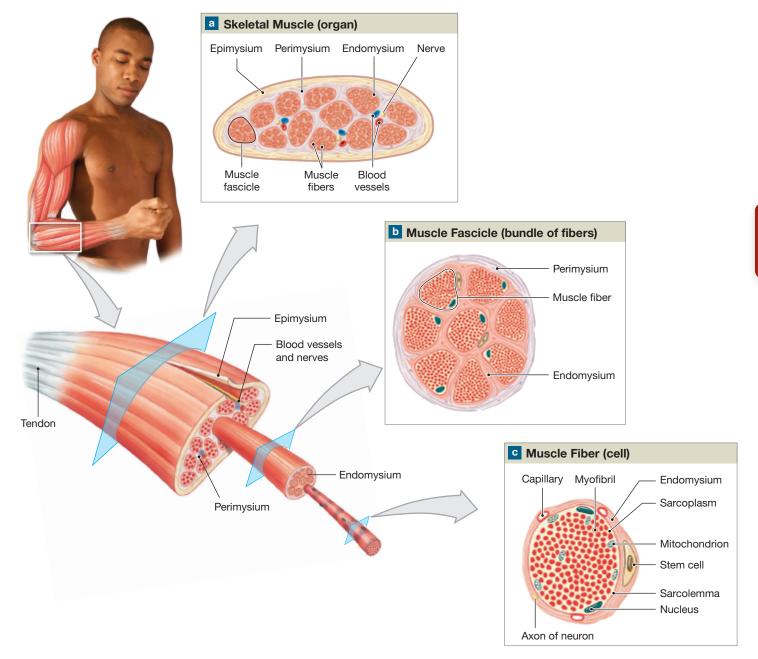

1. What are the five primary functions of skeletal muscle? See the blue Answers tab at the back of the book.

7-2 A skeletal muscle contains muscle tissue, connective tissues, blood vessels, and nerves

Learning Outcome Describe the organization of muscle at the tissue level.

Figure 7-1 illustrates the organization of a typical skeletal muscle. A skeletal muscle contains skeletal muscle tissue as well as connective tissues, blood vessels, and nerves. Each cell in skeletal muscle tissue is a single muscle *fiber*.

Connective Tissue Organization

Three layers of connective tissue support each muscle: (1) the epimysium, (2) the perimysium, and (3) the endomysium.

The **epimysium** (ep-i-MIZ- \bar{e} -um; *epi*-, on + *mys*, muscle) is a layer of collagen fibers that surrounds the entire muscle (**Figure 7-1a**). It separates the muscle from surrounding tissues and organs.

The connective tissue fibers of the **perimysium** (per-i-MIZē-um; *peri-*, around) divide the skeletal muscle into compartments. Each compartment contains a bundle of muscle fibers called a **fascicle** (FAS-i-kl; *fasciculus*, a bundle) (**Figure 7-1b**). In addition to collagen and elastic fibers, the perimysium contains blood vessels and nerves that supply the fascicles.

Within a fascicle, the **endomysium** (en-dō-MIZ-ē-um; *endo-*, inside) surrounds each skeletal muscle fiber (cell) and ties adjacent muscle fibers together (**Figure 7-1c**). Stem cells scattered among the fibers help repair damaged muscle tissue. The endomysium also contains capillaries that supply blood to the muscle fibers, and nerve fibers (axons) that control the muscle.

At each end of the muscle, the collagen fibers of all three layers come together to form either a bundle known as a **tendon**, or a broad sheet called an **aponeurosis** (ap-ō-noo-RŌ-sis).

Tendons are bands of collagen fibers that attach skeletal muscles to bones, and aponeuroses connect different skeletal muscles. \bigcirc p. 134 The tendon fibers are interwoven into the periosteum of the bone, providing a firm attachment. Any contraction of the muscle exerts a pull on its tendon and in turn on the attached bone.

Blood Vessels and Nerves

The connective tissues of the epimysium and perimysium provide a passageway for the blood vessels and nerves that are necessary for muscle fibers to function. Muscle contraction uses tremendous amounts of energy. An extensive network of blood vessels delivers the necessary oxygen. It also carries away the metabolic wastes generated by active skeletal muscles.

Skeletal muscles contract only when they are stimulated by the central nervous system. *Axons* (nerve fibers) penetrate the epimysium, branch through the perimysium, and enter the endomysium to control individual muscle fibers. Skeletal muscles are often called *voluntary muscles* because we have voluntary control over their contractions. Many skeletal muscles may also be controlled at a subconscious level. For example, skeletal muscles involved with breathing, such as the *diaphragm*, usually work outside our conscious awareness.

CHECKPOINT

- **2.** Describe the connective tissue layers associated with a skeletal muscle.

7-3 Skeletal muscle fibers have distinctive features

Learning Outcome Identify the structural components of a sarcomere.

Skeletal muscle fibers are quite different from the "typical" cell we described in Chapter 3. \bigcirc p. 87 One major difference is size. A skeletal muscle fiber from a leg muscle, for example, could have a diameter of 100 μ m and a length equal to that of the entire muscle (up to 60 cm, or 24 in.). In addition, each skeletal muscle fiber contains hundreds of nuclei just beneath the plasma membrane. For this reason, it is said to be *multi-nucleate*. In the next sections we examine the components of a typical skeletal muscle fiber.

The Sarcolemma and Transverse Tubules

The basic structure of a muscle fiber is shown in **Figure 7-2a**. The plasma membrane, or **sarcolemma** (sar-kō-LEM-uh; *sarkos*, flesh + *lemma*, husk), of a muscle fiber surrounds the cytoplasm, or **sarcoplasm** (SAR-kō-plazm). Openings scattered across the surface of the sarcolemma lead into a network of narrow tubules called **transverse tubules**, or **T tubules**. Filled with extracellular fluid, the T tubules form passageways through the muscle fiber, like a series of tunnels through a mountain.

The T tubules play a major role in making all regions of the muscle fiber contract at the same time. A muscle fiber contraction takes place through the orderly interaction of both electrical and chemical events. Electrical impulses propagated by the sarcolemma trigger a contraction by altering the chemical environment everywhere inside the muscle fiber. These electrical impulses reach the cell's interior by traveling along the transverse tubules that extend deep into the sarcoplasm of the muscle fiber.

Myofibrils

Inside each muscle fiber, branches of T tubules encircle cylinder-shaped structures called **myofibrils** (Figure 7-2a). A myofibril is $1-2 \mu m$ in diameter and as long as the entire muscle fiber. Each muscle fiber contains hundreds to thousands of myofibrils. Myofibrils are bundles of **myofilaments**, protein filaments made primarily of the proteins *actin* and *myosin* (Figure 7-2a). Actin molecules are found in **thin filaments**, and myosin molecules in **thick filaments**. \supset p. 100

Myofibrils can actively shorten. As they do so, they create muscle fiber contraction. Because they are attached to the sarcolemma at each end of the cell, their contraction shortens the entire cell. Scattered among the myofibrils are mitochondria and granules of glycogen, a source of glucose. The breakdown of glucose and the activity of mitochondria provide the ATP that powers muscular contractions.

The Sarcoplasmic Reticulum

The **sarcoplasmic reticulum (SR)** is a specialized form of smooth endoplasmic reticulum (**Figure 7-2a**). The SR forms a tubular network around each myofibril and is tightly bound to T tubules. Expanded chambers of the SR called *terminal cisternae* (singular: *cisterna*) lie on either side of T tubules that encircle a myofibril, forming a *triad*.

The terminal cisternae contain high concentrations of calcium ions. The calcium ion concentration in the cytosol

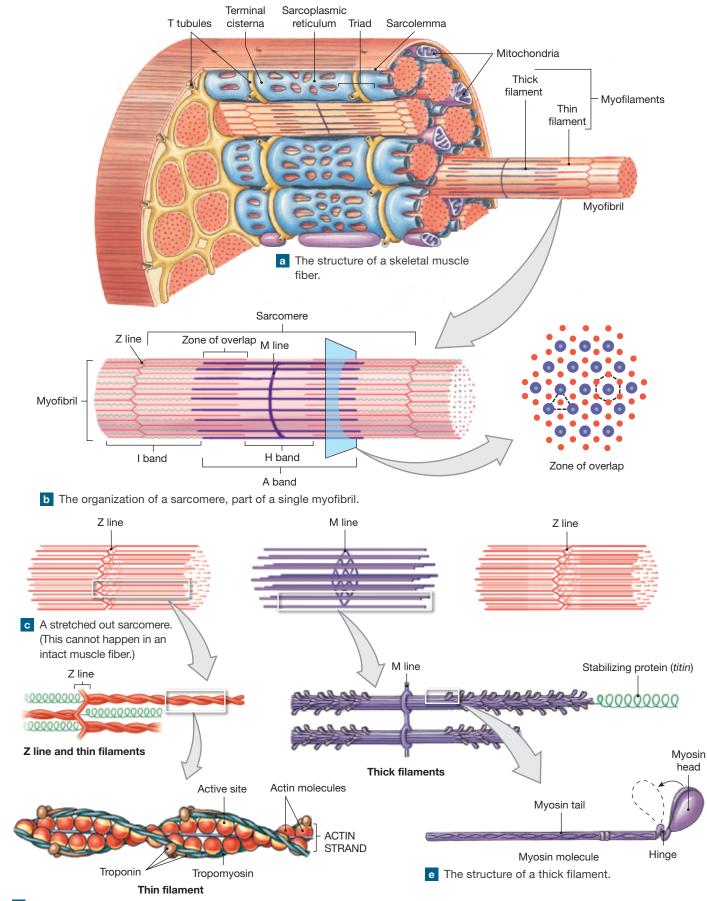

Figure 7-2 The Organization of a Skeletal Muscle Fiber.

d The structure of a thin filament.

of all cells is kept very low. Most cells, including skeletal muscle fibers, pump calcium ions across their plasma membranes and into the extracellular fluid. Skeletal muscle fibers, however, also actively transport calcium ions into the terminal cisternae of the sarcoplasmic reticulum. A muscle contraction begins when these stored calcium ions are released into the cytosol of the sarcoplasm.

Build Your Knowledge

Calcium is the most abundant mineral in the human body. Calcium ions (Ca²⁺) are important in many physiological processes, not the least of which is muscle contraction. Recall that the skin plays an important role in calcium metabolism by synthesizing vitamin D_3 (as you saw in **Chapter 5: The Integumentary System**). This vitamin is modified by the liver and converted by the kidneys into calcitriol, the hormone essential for calcium and phosphate absorption by the small intestine. \bigcirc **p. 157** Our bones also have a role in calcium metabolism (as you saw in **Chapter 6: The Skeletal System**). They provide a mineral reserve for maintaining normal concentrations of calcium (and phosphate) ions in body fluids. \bigcirc **p. 173**

Sarcomeres

The myofilaments (thin and thick filaments) that make up myofibrils are organized into repeating functional units called **sarcomeres** (SAR-kō-mērz; *sarkos*, flesh + *meros*, part) (**Figure 7-2b**). Each myofibril consists of approximately 10,000 sarcomeres arranged end to end. The sarcomere is the smallest functional unit of the muscle fiber. Interactions between the thick and thin filaments of sarcomeres are responsible for muscle contraction.

The arrangement of thick and thin filaments within a sarcomere produces a banded appearance. All the myofibrils lie parallel to the long axis of the cell, with their sarcomeres lying side by side. As a result, the entire muscle fiber has a banded, or *striated*, appearance corresponding to the bands of the individual sarcomeres (Figure 7-2a).

Figure 7-2b diagrams the external and internal structure of a single sarcomere. Each sarcomere has a resting length of about $2 \mu m$. Neither type of filament spans the entire length of a sarcomere. The thick filaments (purple) lie in the center of the sarcomere. Thin filaments (red) at either end of the sarcomere are attached to interconnecting proteins that make up the **Z lines**, the boundaries of each sarcomere.

Differences in the sizes and densities of thick and thin filaments account for the banded appearance of the sarcomere. The dark **A band** is the area containing thick filaments. The light region between two successive A bands—including the Z line—is the **I band**. (It may help you to remember that in a light micrograph, the A band appears d**A**rk and the I band is l**I**ght.)

From the Z lines, the thin filaments extend toward the center of the sarcomere, passing among the thick filaments in the *zone of overlap*. Strands of another protein (*titin*) extend from the Z lines to the ends of the thick filaments and keep both types of filaments aligned. The **M line** is made up of proteins that connect the central portions of each thick filament to its neighbors. An **H band** includes the M line and light regions on either side of the M line. It contains only thick filaments. The relationships of Z lines and M lines are shown in **Figure 7-2c**.

Thin and Thick Filaments

Each thin filament consists of a twisted strand of actin molecules (**Figure 7-2d**). Each actin molecule has an **active site** that can interact with myosin. In a resting muscle, the active sites along the thin filaments are covered by strands of the protein **tropomyosin** (trō-pō-MĪ-ō-sin; *trope*, turning). The tropomyosin strands are held in position by molecules of **troponin** (TRŌ-pō-nin) that are bound to the actin strand.

Thick filaments are composed of myosin molecules, each with a *tail* and a globular *head* (Figure 7-2c,e). The myosin molecules are oriented away from the center of the sarcomere, with the heads projecting outward. During a contraction, the myosin heads attach to actin molecules. This interaction takes place only when the troponin changes position, moving the tropomyosin and uncovering the active sites on actin.

Calcium is the "key" that "unlocks" the active sites and starts a contraction. When calcium ions bind to troponin, the protein changes shape, swinging the tropomyosin away from the active sites. Myosin–actin binding can then occur, and a contraction begins. The source of the calcium is the terminal cisternae of the sarcoplasmic reticulum.

Sliding Filaments and Cross-Bridges

When a sarcomere contracts, the I bands get smaller, the Z lines move closer together, the H bands decrease, and the zones of overlap get larger, but the length of the A bands does not change (Figure 7-3). These observations make sense only if the thin filaments slide toward the center of the sarcomere, alongside the stationary thick filaments. This explanation for sarcomere contraction is called the *sliding filament theory*.

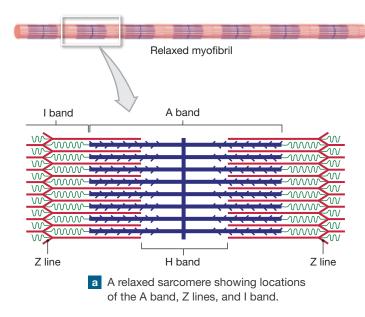

Figure 7-3 Changes in the Appearance of a Sarcomere during Contraction of a Skeletal Muscle Fiber.

The mechanism responsible for sliding filaments involves the binding of the myosin heads of thick filaments to active sites on the thin filaments. When the myosin heads interact with thin filaments during a contraction, they are called **cross-bridges**. When a cross-bridge binds to an active site, it pivots toward the center of the sarcomere (**Figure 7-2e**), pulling the thin filament in that direction. The cross-bridge then detaches and returns to its original position, ready to repeat a cycle of "attach, pivot, detach, and return," like a person pulling in a rope one-handed.

CHECKPOINT

- **4.** Describe the basic structure of a sarcomere.
- **5.** Why do skeletal muscle fibers appear striated when viewed through a light microscope?
- **6.** Where would you expect the greatest concentration of calcium ions to be in a resting skeletal muscle fiber?

The Neuromuscular Junction

Each skeletal muscle fiber is controlled by a nerve cell called a *motor neuron*. A single axon of this neuron branches within the perimysium to form a number of fine branches. Each branch ends at an expanded **axon terminal**. $\bigcirc p$. 143 The axon terminal becomes part of a neuromuscular junction midway along the fiber's length.

The cytoplasm of the axon terminal contains mitochondria and vesicles filled with molecules of **acetylcholine** (as-ē-til-KŌ-lēn), or **ACh**. Acetylcholine is a *neurotransmitter*, a chemical released by a neuron to communicate with other cells. The release of ACh from the axon terminal results in changes in the sarcolemma that trigger the contraction of the muscle fiber.

A narrow space, the **synaptic cleft**, separates the axon terminal from the sarcolemma. This portion of the sarcolemma, known as the **motor end plate**, contains receptors that bind ACh. Both the synaptic cleft and the motor end plate contain the enzyme **acetylcholinesterase** (**AChE**, or *cholinesterase*), which breaks down molecules of ACh.

Neurons control skeletal muscle fibers by stimulating the generation of an **action potential**, or electrical impulse, in the sarcolemma. The steps in this process are shown in **Spotlight Figure 7-4**.

7 line

SPOTLIGHT Figure 7-4 EVENTS AT THE NEUROMUSCULAR JUNCTION

A single axon may branch to control more than one skeletal muscle fiber, but each muscle fiber has only one neuromuscular junction (NMJ). At the NMJ, the axon terminal of the neuron lies near the motor end plate of the muscle fiber.

Path of electrical impulse (action potential) 🔪

Axon

Neuromuscular junction

Motor end plate ____ Myofibril _____

Axon terminal

> The cytoplasm of the axon terminal contains vesicles filled with molecules of acetylcholine, or ACh. Acetylcholine is a *neurotransmitter*, a chemical released by a neuron to change the permeability or other properties of another cell's plasma membrane. The synaptic cleft and the motor end plate contain molecules of the enzyme acetylcholinesterase (AChE), which breaks down ACh.

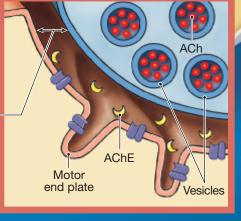

Motor end plate

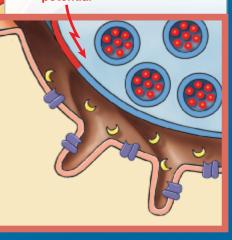

2

The stimulus for ACh release is the arrival of an electrical impulse, or action potential, at the axon terminal. The action potential arrives at the NMJ after traveling along the length of the axon.

Arriving action potential

The synaptic cleft, a – narrow space, separates the axon terminal of the neuron from the opposing motor end plate.

Go to Mastering A&P > Study Area > Menu > MP3 Tutor Session > Events at the Neuromuscular Junction

Muscle Fiber

The action potential generated at the motor end plate now sweeps across the entire membrane surface. The effects are almost immediate because an action potential is an electrical event that flashes like a spark across the surface of the sarcolemma. The effects are brief because the ACh has been removed, and no further stimulus acts upon the motor end plate until another action potential arrives at the axon terminal.

3

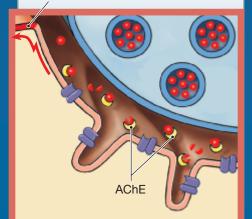

When the action potential reaches the neuron's axon terminal, permeability changes in the membrane trigger the exocytosis of ACh into the synaptic cleft. Exocytosis occurs as vesicles fuse with the neuron's plasma membrane. ACh molecules diffuse across the synaptic cleft and bind to ACh receptors on the surface of the motor end plate. ACh binding alters the membrane's permeability to sodium ions. Because the extracellular fluid contains a high concentration of sodium ions (Na⁺), and sodium ion concentration inside the cell is very low, sodium ions rush into the cytosol.

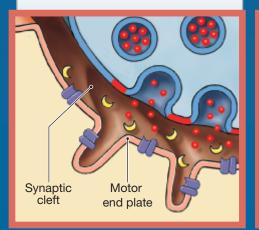

Δ

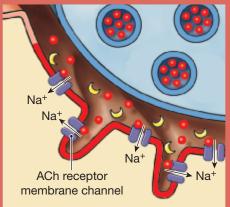

5

The sudden inrush of sodium ions results in the generation of an action potential in the sarcolemma. AChE quickly breaks down the ACh on the motor end plate and in the synaptic cleft. This removal closes the ACh receptor membrane channels. The muscle fiber shown above indicates the propagation of the action potential.

Action potential spreads across membrane surface

Build Your Knowledge

Recall that neurons communicate through electrical events that affect their plasma membranes (as you saw in Chapter 4: The Tissue Level of Organization). **D** p. 143 These events also occur in the sarcolemma of skeletal muscle fibers. (We discuss these electrical events in detail in Chapter 8: The Nervous System.)

CLINICAL NOTE

Interference at the NMJ and **Muscular Paralysis**

Any condition that interferes with the generation of an action potential in the sarcolemma will cause muscular paralysis. Two examples are worth noting.

Botulism is a disease that results from the consumption of foods (often canned or smoked) contaminated with a bacterial toxin. The toxin prevents the release of ACh at the axon terminals, leading to a severe, potentially fatal muscular paralysis.

The progressive muscular paralysis seen in the autoimmune disease myasthenia gravis (mī-as-THĒ-nē-uh GRA-vis) results from the loss of ACh receptors at the motor end plate. The primary cause is a misguided attack on ACh receptors by the immune system. Genetic factors play a role in predisposing individuals to develop this condition. Estimates of the incidence of myasthenia gravis in the United States range from 2 to 10 cases per 100,000 population.

CLINICAL NOTE

Rigor Mortis

Upon death, circulation ceases, depriving skeletal muscles of nutrients and oxygen. Within a few hours, skeletal muscle fibers run out of ATP. The sarcoplasmic reticulum then can no longer remove calcium ions from the cytosol. Calcium ions diffusing into the cytosol from the extracellular fluid or leaking out of the sarcoplasmic reticulum trigger a sustained contraction. Without ATP, the cross-bridges cannot detach from the active sites, and the muscle locks in the contracted position. All of the body's skeletal muscles are involved, and the individual becomes "stiff as a board." This physical state-called rigor mortis-lasts until the lysosomal enzymes released by autolysis break down the myofilaments. Rigor mortis begins two to seven hours after death and ends after one to six days or when decomposition begins. The timing is dependent on environmental factors, such as temperature.

The Contraction Cycle

The link between the generation of an action potential in the sarcolemma and the start of a muscle contraction occurs at the triads. There, the passage of the action potential along the T tubules triggers a massive release of calcium ions from the terminal cisternae. The presence of the calcium ions begins muscle contraction. The interlocking steps of the contraction cycle are shown in Spotlight Figure 7-5 (pp. 232-233).

Figure 7-6 (p. 234) provides a summary of the contraction process, beginning with ACh release and ending with relaxation.

CHECKPOINT

- 7. Describe the neuromuscular junction.
- 8. How would a drug that blocks acetylcholine release affect muscle contraction?
- 9. What would you expect to happen to a resting skeletal muscle if the sarcolemma suddenly became very permeable to calcium ions?
- See the blue Answers tab at the back of the book.

7-5 Sarcomere shortening and muscle fiber stimulation produce tension

Learning Outcome Compare the different types of muscle contractions.

Now that you are familiar with the contraction of individual muscle fibers, let's examine the performance of skeletal muscles. In this section we consider the coordinated contractions of an entire population of muscle fibers.

The individual muscle cells in muscle tissue are surrounded and tied together by connective tissue. When muscle cells contract, they pull on collagen fibers, producing an active force called **tension**. Tension applied to an object tends to pull the object toward the source of the tension. However, before movement can take place, the applied tension must overcome the object's **resistance**, a passive force that opposes movement. The amount of resistance can depend on an object's weight and shape, friction, and other factors. In contrast, **compression**—a push applied to an object-tends to force the object away from the source of compression. Muscle cells can only contract (that is, shorten and generate tension). They cannot actively lengthen and generate compression.

The amount of tension produced by an individual muscle fiber depends solely on the number of pivoting cross-bridges it contains. All the sarcomeres of the fiber are involved. There is no way to regulate the amount of tension produced in that contraction by changing the number of contracting sarcomeres. The muscle fiber is either "on" (producing tension) or "off" (relaxed).

Tension does vary, however. It depends on

- 1. the muscle fiber's resting length at the time of stimulation, which determines the degree of overlap between thick and thin filaments, and
- **2.** the frequency of stimulation, which affects the internal concentration of calcium ions and thus the amount bound to troponin molecules.

An entire skeletal muscle contracts when its component muscle fibers are stimulated. The amount of tension produced in the skeletal muscle *as a whole* is determined by

- 1. the frequency of muscle fiber stimulation, and
- **2.** the number of muscle fibers activated.

Frequency of Muscle Fiber Stimulation

A **twitch** is a single stimulus-contraction-relaxation sequence in a muscle fiber. Its duration can be as brief as 7.5

msec, as in an eye muscle fiber, or up to 100 msec in fibers of the *soleus*, a small calf muscle. A *myogram* is a graph of tension development in a muscle fiber during a twitch. **Figure 7-7** is a myogram of the phases of a 40-msec twitch in a fiber from the *gastrocnemius muscle*, a prominent calf muscle:

- The **latent period** begins at stimulation and typically lasts about 2 msec. Over this period the action potential sweeps across the sarcolemma, and calcium ions are released by the sarcoplasmic reticulum. No tension is produced by the muscle fiber because contraction has yet to begin.
- In the **contraction phase**, tension rises to a peak. Throughout this period the cross-bridges are interacting with the active sites on the actin filaments. Maximum tension is reached roughly 15 msec after stimulation.
- During the **relaxation phase**, muscle tension falls to resting levels as calcium levels drop, active sites are being covered, and the number of cross-bridges declines. This phase lasts about 25 msec.

A single stimulation produces a single twitch, but twitches in a skeletal muscle do not accomplish anything useful. All normal activities involve sustained muscle contractions. Such contractions result from repeated stimulations.

CLINICAL NOTE

Tetanus

Children are often told to be careful around rusty nails. Parents should worry most not about the rust or the nail, but about infection with a very common bacterium, *Clostridium tetani*. This bacterium can cause the disease called **tetanus**. Although they share a name, the disease tetanus has no relation to the normal muscle response to neural stimulation. The *Clostridium* bacteria are found virtually everywhere but thrive only in tissues that contain abnormally low amounts of oxygen. For this reason, a deep puncture wound, such as that from a nail, carries a much greater risk than a shallow, open cut that bleeds freely.

When active in body tissues, these bacteria release a powerful toxin that affects the central nervous system. Motor

neurons, which control skeletal muscles throughout the body, are particularly sensitive to it. The toxin suppresses the mechanism that inhibits motor neuron activity. The result is a sustained, powerful contraction of skeletal muscles throughout the body.

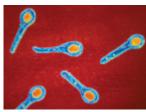

The incubation period (the time between exposure and the onset of symptoms) is usually less than two weeks. The most common early complaints are headache, muscle stiffness, and difficulty swallowing. Because it soon becomes difficult to open the mouth, this disease is also called *lockjaw*. Widespread muscle spasms usually develop within two to three days of the initial symptoms and continue for a week before subsiding. After two to four weeks, surviving

Severe tetanus has a 40–60 percent mortality rate, but immunization is effective in preventing the disease. Of the approximately 500,000 cases of tetanus worldwide each year, only about 100 occur in the United States, thanks to an effective immunization

program. ("Tetanus shots," with booster shots every 10 years, are recommended.) Severe symptoms in unimmunized patients can be prevented by early administration of an antitoxin, usually *human tetanus immune globulin*. However, this treatment does not reduce symptoms that have already appeared.

patients recover with no aftereffects.

Clostridium tetani

SPOTLIGHT Figure 7-5 THE CONTRACTION CYCLE

Contraction Cycle Begins

The contraction cycle, which involves a series of interrelated steps, begins with the arrival of calcium ions within the zone of overlap.

2

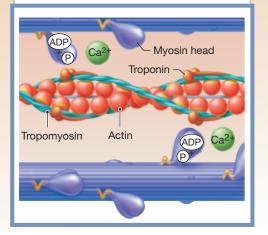

Active-Site Exposure

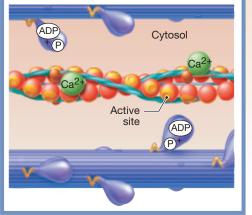

Calcium ions bind to troponin, weakening the bond between actin and the troponin–tropomyosin complex. This reaction leads to the exposure of the active sites on the actin molecules of the thin filaments.

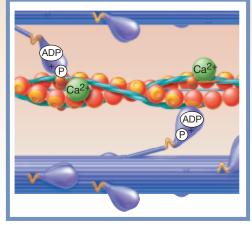

3

Cross-Bridge Formation

Once the active sites are exposed, the energized myosin heads bind to them, forming cross-bridges.

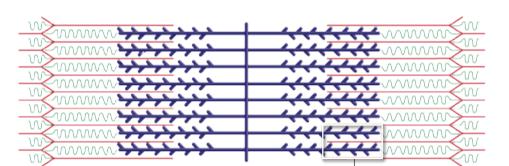

Resting Sarcomere

In the resting sarcomere, each myosin head is already "energized"-charged with the energy that will be used to power a contraction. Each myosin head points away from the M line. In this position, the myosin head is "cocked" like the spring in a mousetrap. Cocking the myosin head requires energy, which is obtained by breaking down ATP. At the start of the contraction cycle, the breakdown products, ADP and phosphate (often represented as P), remain bound to the myosin head.

Zone of Overlap (shown in sequence above)

Myosin Head Pivoting

After cross-bridge formation, the stored energy is used to pivot the myosin head toward the M line. This action is called the power stroke; when it occurs, the bound ADP and phosphate group are released.

5

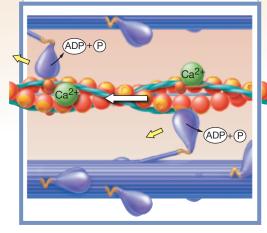

Cross-Bridge Detachment

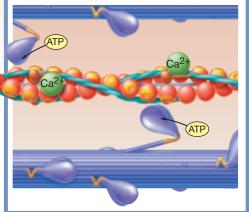

When another ATP binds to the myosin head, the link between the myosin head and the active site on the actin molecule is broken. The active site is now exposed and able to form another cross-bridge.

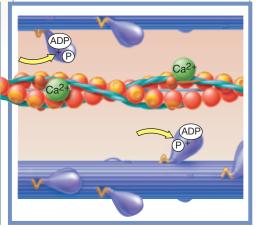

6

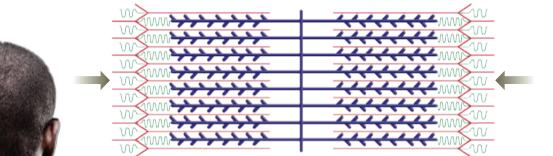

Myosin Reactivation

Myosin reactivation occurs when the free myosin head splits ATP into ADP and P. The energy released is used to recock the myosin head.

Contracted Sarcomere

The entire cycle is repeated several times each second, as long as Ca²⁺ concentrations remain elevated and ATP reserves are sufficient. Calcium ion levels will remain elevated only as long as action potentials continue to pass along the T tubules and stimulate the terminal cisternae. Once that stimulus is removed, calcium ion pumps pull Ca²⁺ from the cytosol and store it within the terminal cisternae. Troponin molecules then shift position, swinging the tropomyosin strands over the active sites and preventing further

cross-bridge formation.

7

Figure 7-6 Steps Involved in Skeletal Muscle Contraction and Relaxation.

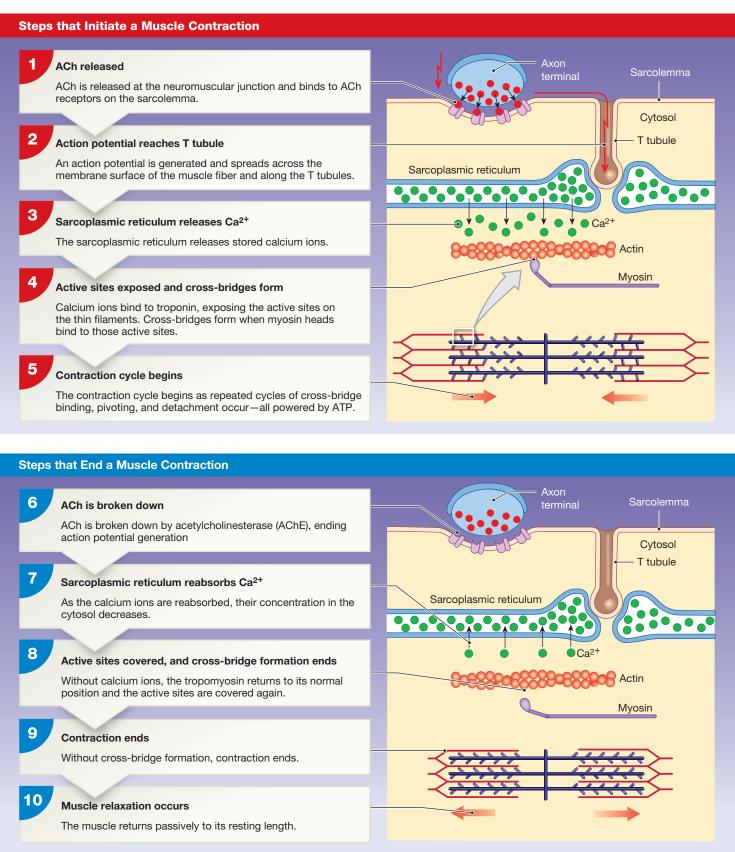

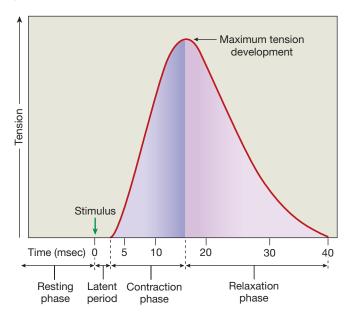

Figure 7-7 The Development of Tension in a Twitch.

Summation and Incomplete Tetanus

If a second stimulus arrives before the relaxation phase has ended, a second, more powerful contraction occurs. The addition of one twitch to another in this way is called **summation** (Figure 7-8a). If the muscle fiber is stimulated repeatedly and is never allowed to relax completely, the tension rises and peaks (Figure 7-8b). A muscle fiber producing almost peak tension during rapid cycles of contraction and relaxation is said to be in **incomplete tetanus** (*tetanos*, convulsive tension). Virtually all normal muscular contractions involve incomplete tetanus of the participating muscle fibers.

Complete Tetanus

Complete tetanus occurs when the rate of stimulation is increased until the relaxation phase is completely eliminated, producing maximum tension (**Figure 7-8c**). In complete tetanus, the action potentials are arriving so fast that the sarcoplasmic reticulum does not have time to reclaim calcium ions. The high calcium ion concentration in the cytosol prolongs the contraction, making it continuous.

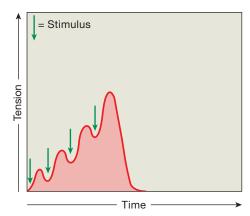

Number of Muscle Fibers Activated

We have a remarkable ability to control the amount of tension exerted by our skeletal muscles so that our muscles contract smoothly during a normal movement, not jerkily. Such control is accomplished by controlling the number of stimulated muscle fibers in the skeletal muscle.

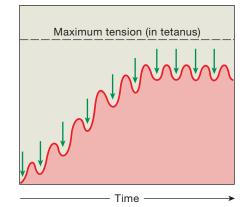

A typical skeletal muscle contains thousands of muscle fibers. Some motor neurons control a single muscle fiber, but most control hundreds or thousands of muscle fibers through multiple axon terminals. A **motor unit** is a single motor neuron and all the muscle fibers it controls.

The size of a motor unit indicates how fine the control of movement can be. In the muscles of the eye, where precise control is extremely important, a motor neuron may control two or three muscle fibers. We have much less precise control over our leg muscles, where up to 2000 muscle fibers may respond to stimulation by a single motor neuron.

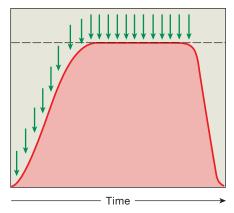

Figure 7-8 Effects of Repeated Stimulations.

a Summation. Summation of twitches occurs when successive stimuli arrive before the relaxation phase has been completed.

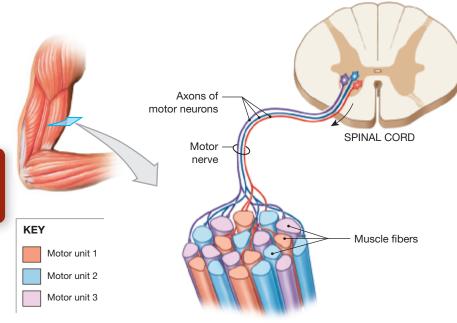

b Incomplete tetanus. Incomplete tetanus occurs if the stimulus frequency increases further. Tension production rises to a peak, and the periods of relaxation are very brief.

c Complete tetanus. During complete tetanus, the stimulus frequency is so high that the relaxation phase is eliminated; tension plateaus at maximal levels.

Figure 7-9 The Arrangement of Motor Units in a Skeletal Muscle. Each motor unit is a single motor neuron and all the muscle fibers it controls. Muscle fibers of different motor units are intermingled, so the forces applied to the tendon remain roughly balanced regardless of which muscle groups are stimulated.

The muscle fibers of each motor unit are intermingled with those of other motor units (**Figure 7-9**). This mixing ensures that the direction of pull on a tendon does not change when the number of activated motor units varies. When you decide to perform a specific arm movement, specific groups of motor neurons within the spinal cord are stimulated. The contraction begins with the activation of the smallest motor units in the stimulated muscle. Over time, the number of activated motor units gradually increases. The activation of more and more motor units is called **recruitment**, and the result is a smooth, steady increase in muscular tension.

Peak tension production occurs when all the motor units in the muscle are contracting in complete tetanus. Such contractions do not last long, however, because the muscle fibers soon use up their available energy supplies. During a sustained contraction, motor units are activated on a rotating basis, so that some are resting while others are contracting. As a result, when your muscles contract for sustained periods, they produce slightly less than maximal tension.

Muscle Tone

Some of the motor units within any particular muscle are always active, even when the entire muscle is not contracting. Their contractions do not produce enough tension to cause movement, but they do tense and firm the muscle. This resting tension in a skeletal muscle is called **muscle tone**. A muscle with little muscle tone is limp and flaccid, but one with moderate muscle tone is quite firm and solid. Resting muscle tone stabilizes the positions of bones and joints. For example, in muscles involved with balance and posture, enough motor units are stimulated to produce the tension needed to maintain body position.

A skeletal muscle that is not regularly stimulated by a motor neuron will **atrophy** (AT-rō-fē; *a*, without + *-trophy*, nourishing): Its muscle fibers will become smaller and weaker. Individuals paralyzed by spinal injuries or other damage to the nervous system gradually lose muscle size and tone in the areas affected. Even a temporary reduction in muscle use can lead to muscular atrophy. Compare, for example, arm muscles after a cast has been worn to the same muscles in the other arm. Muscle atrophy is reversible at first, but dying muscle fibers are not replaced. In extreme atrophy the func-

tional losses are permanent. That is why physical therapy is so important for patients who are temporarily unable to move normally.

Isotonic and Isometric Contractions

We can classify muscle contractions on the basis of their pattern of tension production. In an **isotonic** (*iso-*, equal + *tonos*, tension) contraction, tension rises and the skeletal muscle's length changes. Tension in the muscle remains at a constant level until relaxation takes place. Lifting an object off a desk, walking, and running involve isotonic contractions.

In an **isometric** (*metron*, **measure**) **contraction**, the muscle as a whole does not change length, and the tension produced never exceeds the load. Examples of isometric contractions are pushing against a closed door and trying to pick up a car. These examples are rather unusual, but many of the everyday reflexive muscle contractions that keep your body upright when you stand or sit involve isometric contractions of muscles that oppose the force of gravity.

Normal daily activities involve a combination of isotonic and isometric muscular contractions. As you sit reading this text, isometric contractions of postural muscles stabilize your vertebrae and maintain your upright position. When you turn a page, isotonic contractions move your arm, forearm, hand, and fingers.

Muscle Elongation Following Contraction

Recall that no active mechanism for muscle fiber elongation exists. \bigcirc p. 230 Contraction is active, but elongation is passive. After a contraction, a muscle fiber usually returns to its original length through a combination of *elastic forces*, the *movements of opposing muscles*, and *gravity*.

Elastic forces are generated when a muscle fiber contracts and tugs on the flexible extracellular fibers of the endomysium, perimysium, epimysium, and tendons. These fibers are also somewhat elastic, and their recoil gradually helps return the muscle fiber to its original resting length.

Much more rapid returns to resting length result from the contraction of opposing muscles. For example, contraction of the *biceps brachii* muscle on the anterior part of your arm flexes your elbow, and contraction of the *triceps brachii* muscle on the posterior surface of your arm extends your elbow. When the biceps brachii contracts, the triceps brachii is stretched. When the biceps brachii relaxes, contraction of the triceps brachii extends the elbow and stretches the muscle fibers of the biceps brachii to their original length.

Gravity may also help lengthen a muscle after a contraction. For example, imagine your biceps brachii muscle fully contracted with your elbow pointing at the ground. When the muscle relaxes, gravity will pull your forearm down and stretch the muscle.

CHECKPOINT

- **10.** What factors are responsible for the amount of tension a skeletal muscle develops?
- 11. A motor unit from a skeletal muscle contains 1500 muscle fibers. Would this muscle be involved in fine, delicate movements or in powerful, gross movements? Explain.
- **12.** Can a skeletal muscle contract without shortening? Explain.

See the blue Answers tab at the back of the book.

7-6 ATP is the energy source for muscle contraction

Learning Outcome Describe the processes by which muscles obtain the energy to power contractions.

Muscle contraction requires large amounts of energy. For example, an active skeletal muscle fiber may require some 600 trillion molecules of ATP each second, not including the energy needed to pump the calcium ions back into the sarcoplasmic reticulum. This enormous amount of energy is not available before a contraction begins in a resting muscle fiber. Instead, a resting muscle fiber contains only enough energy reserves to sustain a contraction until additional ATP can be generated. Throughout the rest of the contraction, the muscle fiber will generate ATP at roughly the same rate as it is used. This section discusses how muscle fibers meet the demand for ATP.

Build Your Knowledge

Recall that the most important high-energy compound in the body is adenosine triphosphate, or ATP (as you saw in **Chapter 2: The Chemical Level of Organization**). ATP is made up of the nucleotide adenosine monophosphate (AMP) connected with two phosphate groups by high energy bonds. Cells most often obtain energy by removing one phosphate group from ATP, forming adenosine diphosphate, or ADP. ADP can be converted back to ATP by attaching another phosphate group. **`D p. 78**

ATP and CP Reserves

The primary function of ATP is the transfer of energy from one location to another, not the long-term storage of energy. At rest, a skeletal muscle fiber produces more ATP than it needs. Under these conditions, ATP transfers energy to *creatine* (KRĒ-uh-tēn), a small molecule that muscle cells assemble from fragments of amino acids. As **Figure 7-10a** shows, the energy transfer creates another high-energy compound, **creatine phosphate (CP)**:

 $ATP + creatine \rightarrow ADP + creatine phosphate$

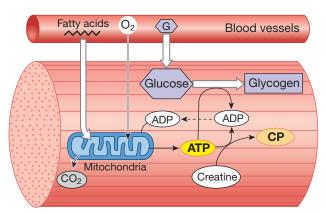

During a contraction, each cross-bridge breaks down ATP, producing ADP and a phosphate group. Then the energy stored in creatine phosphate is used to "recharge" the ADP back to ATP through the reverse reaction:

ADP + creatine phosphate \rightarrow ATP + creatine

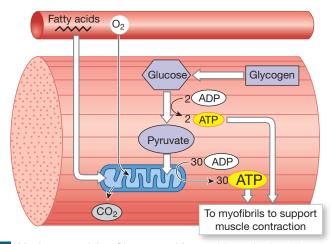

The enzyme that regulates this reaction is **creatine phosphokinase (CPK or CK)**. When muscle cells are damaged, CPK leaks into the bloodstream. For this reason, a high blood level of CPK usually indicates serious muscle damage.

A resting skeletal muscle fiber contains about six times as much creatine phosphate as ATP. But when a muscle fiber is undergoing a sustained contraction, these energy reserves are exhausted in about 15 seconds. The muscle fiber must then rely on other processes to convert ADP to ATP.

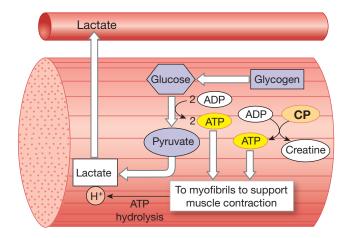

Figure 7-10 Muscle Metabolism.

a **Resting:** Fatty acids are broken down; the ATP produced is used to build energy reserves of ATP, CP, and glycogen.

b Moderate activity: Glucose and fatty acids are broken down; the ATP produced is used to power contraction.

Peak activity: Most ATP is produced through glycolysis, with lactate and hydrogen ions as by-products. Mitochondrial activity (not shown) now provides only about one-third of the ATP consumed.

ATP Generation

Cells in the body generate ATP through *aerobic* (oxygen-requiring) *metabolism* in mitochondria and through *glycolysis* in the cytoplasm. **`**p. 103 Glycolysis is an **anaerobic** (non-oxygen-requiring) process.

Aerobic Metabolism

Aerobic metabolism normally provides 95 percent of the ATP needed by a resting cell. In this process, mitochondria absorb oxygen, ADP, phosphate ions, and organic substrate molecules from the surrounding cytoplasm. The organic substrates are carbon chains produced by the breakdown of carbohydrates, lipids, or proteins. The molecules enter the citric acid cycle (also known as the tricarboxylic acid cycle or the Krebs cycle) and are then completely disassembled by a series of chemical reactions. In brief, the carbon atoms and oxygen atoms are released as carbon dioxide (CO₂). The hydrogen atoms are shuttled to respiratory complexes in the inner mitochondrial membrane, where their electrons are removed. The protons and electrons thus produced ultimately recombine with oxygen to form water (H_2O) . Along the way, large amounts of energy are released and used to make ATP. The aerobic metabolism of a common carbohydrate substrate, pyruvate, is quite efficient: For each pyruvate molecule "fed" into the citric acid cycle, the cell gains 15 ATP molecules.

Resting skeletal muscle fibers rely primarily on the aerobic metabolism of fatty acids to make ATP (Figure 7-10a). These fatty acids are absorbed from the circulation. When the muscle starts contracting, the mitochondria begin breaking down molecules of pyruvate instead of fatty acids. The pyruvate is provided through the process of glycolysis (discussed shortly).

The maximum rate of ATP generation within mitochondria is limited by the availability of oxygen. A sufficient supply of oxygen becomes a problem as the energy demands of the muscle fiber increase. Oxygen consumption and energy production by mitochondria can increase to 40 times resting levels, but the energy demands of the muscle fiber may increase by 120 times. Thus, at peak levels of exertion, mitochondrial activity provides only around one-third of the required ATP.

Glycolysis

Glycolysis is the anaerobic breakdown of glucose to pyruvate in the cytoplasm of the cell. The ATP yield of glycolysis is much lower than that of aerobic metabolism. However, glycolysis can proceed without oxygen. For this reason, glycolysis can continue to provide ATP when the availability of oxygen limits the rate of mitochondrial ATP production.

The glucose broken down under these conditions comes from glycogen reserves in the sarcoplasm. Glycogen is a polysaccharide chain of glucose molecules. **Dp.** 69 Typical skeletal muscle fibers contain large glycogen reserves in the form of insoluble granules. When the muscle fiber begins to run short of ATP and CP, enzymes break the glycogen molecules apart, releasing glucose that can be used to generate more ATP.

Energy Use and the Level of Muscle Activity

The demand for ATP is low in a resting skeletal muscle cell. More than enough oxygen is available for mitochondria to meet this demand and produce a surplus of ATP. The extra ATP is used to build up reserves of CP and glycogen (Figure 7-10a).

At moderate levels of activity, the demand for ATP increases (Figure 7-10b). As the rate of mitochondrial ATP production rises, so does the rate of oxygen consumption. So long as sufficient oxygen is available, the mitochondria can meet the demand for ATP. The amount of ATP provided by glycolysis remains relatively minor.

At peak levels of activity, oxygen cannot diffuse into the muscle fiber fast enough to enable the mitochondria to produce the required ATP. Mitochondrial activity can provide only about one-third the ATP needed, and glycolysis becomes the primary source of ATP (Figure 7-10c). The anaerobic process of glycolysis enables the cell to continue generating ATP when mitochondrial activity alone cannot meet the demand.

This pathway has two drawbacks. First, any underutilized pyruvate molecules produced through glycolysis are converted to lactate, a related three-carbon molecule. At the same time, the hydrolytic breakdown of ATP during muscle contraction releases hydrogen ions. During aerobic metabolism, these hydrogen ions are absorbed by the mitochondria. However, when ATP production is relying on glycolysis, the hydrogen ions are not absorbed. At peak activity, both hydrogen ions and lactate build up. This results in an increased lactate blood level and metabolic acidosis, often referred to as lactic acidosis.

Second, glycolysis is also an inefficient way to generate ATP. Under anaerobic conditions, each glucose generates 2 pyruvate molecules, which are converted to 2 lactate molecules. In return, the cell gains 2 ATP molecules. If those 2 pyruvate molecules had been broken down aerobically in a mitochondrion, the cell would have gained 30 additional ATP molecules.

Muscle Fatigue

A skeletal muscle fiber is said to be fatigued when it can no longer perform at the required level of activity despite continued neural stimulation. Muscle fatigue is caused by the depletion of energy reserves or the decline in pH due to the buildup of hydrogen ions that can alter the normal functioning of key enzymes.

If the muscle contractions use ATP at or below the maximum rate of mitochondrial ATP generation, the muscle fiber can function aerobically. Under these conditions, fatigue does not occur until glycogen and other reserves such as lipids and amino acids are depleted. This type of fatigue affects the muscles of endurance athletes, such as marathon runners, after hours of exertion. 7

When a muscle produces a sudden, intense burst of activity, the ATP is provided by glycolysis. After a relatively short time (seconds to minutes), the buildup of hydrogen ions lower the tissue pH, and the muscle can no longer function normally. Athletes running sprints, such as the 100-yard dash, suffer from this type of muscle fatigue.

The Recovery Period

When a muscle fiber contracts, conditions in the sarcoplasm change: Energy reserves are consumed, heat is released, and lactate and H⁺ may be produced. During the **recovery period**, conditions within muscle fibers return to normal pre-exertion levels. Lactate and H⁺ are removed and intracellular energy reserves are restored. The body as a whole loses the heat generated during intense muscular contraction.

Lactate Recycling

The reaction that converts pyruvate to lactate is freely reversible. During the recovery period, when oxygen is available, lactate can be recycled by converting it back to pyruvate. This pyruvate can then be used as a building block to synthesize glucose or be used by mitochondria to generate ATP. The ATP is used to convert creatine to creatine phosphate and to store the newly synthesized glucose as glycogen.

During the recovery period, the body's oxygen demand remains elevated above normal resting levels. The oxygen **debt** is the additional oxygen required during the recovery period to restore normal pre-exertion conditions in muscle tissue. Liver cells and muscle cells consume most of the extra oxygen. The liver cells produce ATP for recycling lactate absorbed from the blood back to glucose, and muscle cells restore their reserves of ATP, creatine phosphate, and glycogen. Other cells, including sweat gland cells, also increase their rate of oxygen use and ATP generation. While the oxygen debt is being repaid, breathing rate and depth are increased. That is why you continue to breathe heavily for a time after you stop exercising.

Heat Loss

Muscular activity generates substantial amounts of heat that warms the sarcoplasm, interstitial fluid, and circulating blood. Muscle contractions play an important role in maintaining normal body temperature because muscle makes up a large portion of total body mass. Shivering, for example, can help keep you warm in a cold environment. But when skeletal muscles are contracting at peak levels, body temperature soon begins to climb. In response, blood flow to the skin increases, promoting heat loss through processes described in Chapters 1 and 5. ⊃ pp. 40, 163

Build Your Knowledge

A primary function of the integumentary system is to help maintain normal body temperature by regulating heat exchange with the environment (as you saw in **Chapter 5: The Integumentary System**). Excess body heat may be lost from the skin when superficial blood vessels dilate (widen) and merocrine sweat glands secrete perspiration. The heat released by the superficial blood flow warms and evaporates the sweat on the skin, cooling the skin and lowering body temperature. **D pp. 157, 163**

CHECKPOINT

- 13. How do muscle cells continuously synthesize ATP?
- 14. What is muscle fatigue?
- **15.** Define oxygen debt.

See the blue Answers tab at the back of the book.

7-7 Muscle performance depends on muscle fiber type and physical conditioning

Learning Outcome Relate the types of muscle fibers to muscle performance, and distinguish between aerobic and anaerobic endurance.

We can consider muscle performance in terms of **force**, the maximum amount of tension produced by a particular muscle

or muscle group, and **endurance**, the amount of time over which the individual can perform a particular activity. Two major factors determine the performance capabilities of a particular skeletal muscle: the types of muscle fibers within the muscle, and physical conditioning or training.

Types of Skeletal Muscle Fibers

The human body contains two contrasting types of skeletal muscle fibers: fast (or fast-twitch) fibers and slow (or slow-twitch) fibers.

Fast Fibers

Most of the skeletal muscle fibers in the body are called **fast fibers** because they can reach peak twitch tension in 0.01 second or less after stimulation. Fast fibers are large in diameter and contain densely packed myofibrils, large glycogen reserves, and relatively few mitochondria. The tension produced by a muscle fiber is directly proportional to the number of myofibrils, so fast-fiber muscles produce powerful contractions. However, fast fibers fatigue rapidly because their contractions use ATP very quickly and they have few mitochondria to produce ATP. As a result, their activity is primarily supported by glycolysis.

Slow Fibers

Slow fibers are only about half the diameter of fast fibers, and they take three times as long to reach peak tension after stimulation. These fibers are specialized to contract for extended periods, long after a fast muscle would have become fatigued. Three specializations make this possible. They are related to the availability and use of oxygen:

- **1.** *Oxygen supply.* Slow muscle tissue contains a more extensive network of capillaries than does typical fast muscle tissue, so oxygen supply is dramatically increased.
- 2. Oxygen storage. Slow muscle fibers contain the red pigment myoglobin (MĪ-ō-glō-bin). This globular protein is structurally related to hemoglobin, the oxygen-carrying pigment found in blood, and also binds oxygen molecules. ⊃ p. 74 For this reason, resting slow muscle fibers contain oxygen reserves that can be mobilized during a contraction.
- **3.** *Oxygen use.* Slow muscle fibers contain a relatively larger number of mitochondria than do fast muscle fibers.

The Distribution of Muscle Fibers and Muscle Performance

The percentages of fast and slow muscle fibers can vary considerably among skeletal muscles. Muscles dominated by fast fibers appear pale, and they are often called **white muscles**. Chicken breasts contain "white meat" because chickens use their wings only briefly, as when fleeing a predator. The power for their flight comes from the anaerobic process of glycolysis in the fast fibers of their breast muscles. In contrast, slow muscle fibers have a reddish color due to extensive blood vessels and myoglobin, and muscles dominated by slow fibers are known as **red muscles**. Chickens walk around all day, and these movements are powered by aerobic metabolism in the slow muscle fibers of the "dark meat" of their legs.

What about human muscles? Most contain a mixture of fiber types and so appear pink. However, there are no slow fibers in muscles of the eye and hand, where swift, but brief, contractions are required. Many back and calf muscles are dominated by slow fibers. These muscles contract almost continuously to keep us upright. The percentage of fast versus slow fibers in each muscle is genetically determined, but athletic training can increase the fatigue resistance of fast muscle fibers.

Physical Conditioning

Physical conditioning and training schedules enable athletes to improve both power and endurance. In practice, the training schedule varies depending on whether the activity is primarily supported by aerobic or anaerobic energy production.

Anaerobic endurance is the length of time muscle contractions can be supported by glycolysis and existing energy reserves of ATP and CP. Examples of activities that require anaerobic endurance are a 50-yard dash or swim, a pole vault, and a weightlifting competition. Such activities involve contractions of fast muscle fibers. Athletes training to develop anaerobic endurance do frequent, brief, intense workouts. The net effect is an enlargement, or **hypertrophy** (hī-PER-trō-fē), of the stimulated muscles, as seen in champion weight lifters or bodybuilders. The number of muscle fibers does not change, but the muscle as a whole gets larger because each muscle fiber increases in diameter.

Aerobic endurance is the length of time a muscle can continue to contract while supported by mitochondrial activities. Aerobic endurance is determined by the availability of substrates for aerobic metabolism from the breakdown of carbohydrates, lipids, or amino acids. Aerobic activities do not promote muscle hypertrophy. Training to improve aerobic endurance usually involves sustained low levels of muscular activity. Examples are jogging, distance swimming, and other exercises that do not require peak tension production. Because glucose is a preferred energy source, endurance athletes often "load up" on carbohydrates ("carboload") for the three days before an event. They may also consume glucose-rich "sports drinks" during a competition.

CHECKPOINT

- **16.** Why would a sprinter experience muscle fatigue before a marathon runner would?
- **17.** Which activity would be more likely to create an oxygen debt in an individual who regularly exercises: swimming laps or lifting weights?
- **18.** Which type of muscle fibers would you expect to dominate in the large leg muscles of someone who excels at endurance activities such as cycling or long-distance running?
- See the blue Answers tab at the back of the book.

7-8 Cardiac and smooth muscle tissues differ in structure and function from skeletal muscle tissue

Learning Outcome Contrast the structures and functions of skeletal, cardiac, and smooth muscle tissues.

We introduced cardiac muscle tissue and smooth muscle tissue previously (Chapter 4). Here we consider their structural and functional properties in greater detail.

Cardiac Muscle Tissue

Cardiac muscle tissue is found only in the heart. Cardiac muscle cells are relatively small and usually have a single, centrally placed nucleus.

Like skeletal muscle fibers, cardiac muscle cells contain an orderly arrangement of myofibrils and are striated, but

Build Your Knowledge

Cardiac muscle is described as striated involuntary muscle because of its regular arrangement of actin and myosin filaments forming striations and the lack of voluntary nervous control over its contraction (as you saw in **Chapter 4: The Tissue Level of Organization**). Smooth muscle is known as nonstriated involuntary muscle because it lacks striations and the nervous system does not provide voluntary control over its contractions. \supset **p. 143**

significant differences exist in their structures and functions. The most obvious structural difference is that cardiac muscle cells are branched, and each cardiac cell contacts several others at specialized sites called **intercalated** (in-TER-ka-lā-ted) **discs** (Figure 7-11a). These cellular connections contain gap junctions that allow the movement of ions and small molecules and the rapid passage of action potentials from cell to cell, resulting in their simultaneous contraction. The cells "pull together" quite efficiently because the myofibrils are also attached to the intercalated discs.

Cardiac muscle and skeletal muscle also have these important functional differences:

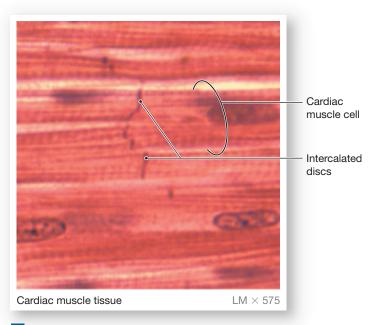

- *Automaticity.* Cardiac muscle tissue contracts without neural stimulation, a property called *automaticity*. Specialized cardiac muscle cells called **pacemaker cells** normally determine the timing of contractions.
- **Longer contractions.** Cardiac muscle cell contractions last roughly 10 times longer than those of skeletal muscle fibers.
- **No tetanus.** The properties of cardiac muscle plasma membranes differ from those of skeletal muscle fibers. As a result, cardiac muscle tissue cannot undergo tetanus (sustained contraction). This property is important because a heart in tetany could not pump blood.
- *Extracellular calcium ions.* An action potential not only triggers the release of calcium ions from the sarcoplasmic reticulum but also increases the permeability of the plasma membrane to extracellular calcium ions.
- **Reliance on aerobic metabolism.** Cardiac muscle cells rely on aerobic metabolism for the energy needed to continue contracting. The sarcoplasm contains large numbers of mitochondria and abundant reserves of myoglobin that store oxygen.

Smooth Muscle Tissue

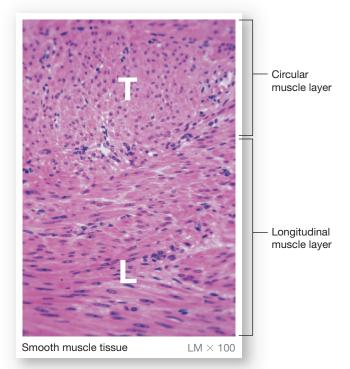

Smooth muscle cells are similar in size to cardiac muscle cells. They also contain a single, centrally located nucleus within each spindle-shaped cell (Figure 7-11b). Smooth muscle tissue is found within almost every organ, forming sheets, bundles, or sheaths around other tissues. Smooth muscles around blood vessels regulate blood flow through vital organs in the skeletal, muscular, nervous, and endocrine systems. Rings of smooth muscles, called *sphincters*, regulate movement of materials along internal passageways in the digestive and urinary systems.

Actin and myosin are present in all three muscle types. However, the internal organization of a smooth muscle cell differs from that of skeletal or cardiac muscle cells in these ways:

Figure 7-11 Cardiac and Smooth Muscle Tissues.

a A light micrograph of cardiac muscle tissue.

- b Many visceral organs contain several layers of smooth muscle tissue oriented in different directions. Here, a single sectional view shows smooth muscle cells in both longitudinal (L) and transverse (T) sections.
- **No sarcomeres.** Smooth muscle tissue lacks myofibrils, sarcomeres, or striations.
- **Scattered thick filaments.** In smooth muscle cells, the thick filaments are scattered throughout the sarcoplasm.

The thin filaments are anchored within the cytoplasm and to the sarcolemma. The anchoring sites on the sarcolemma are not arranged in straight lines. As a result, when a contraction takes place, the muscle cell twists like a corkscrew.

• **Cells bound together.** Adjacent smooth muscle cells are bound together at these anchoring sites, thereby transmitting the contractile forces throughout the tissue.

Functionally, smooth muscle tissue differs from other muscle types in several major ways:

- **Contractions triggered differently.** Calcium ions trigger contractions through a different mechanism than that found in other muscle types. Also, most of the calcium ions that trigger contractions enter the cell from the extracellular fluid.
- **Contraction over a greater range of lengths.** Smooth muscle cells are able to contract over a greater range of lengths than skeletal or cardiac muscle because the actin and myosin filaments are not rigidly organized. This property is important because layers of smooth muscle are found in the walls of organs that undergo large changes in volume, such as the urinary bladder and stomach. Like skeletal muscle fibers, smooth muscle fibers can undergo sustained contractions.
- Automaticity or neural or hormonal stimulation. Many smooth muscle cells are not innervated by motor neurons. Instead, these muscle cells contract either automatically (in response to *pacesetter cells*) or in response to environmental or hormonal stimulation. When smooth muscle fibers are innervated by motor neurons, the neurons involved are not under voluntary control.

 Table 7-1 summarizes the structural and functional properties of skeletal, cardiac, and smooth muscle tissue.

CHECKPOINT

- **19.** How do intercalated discs enhance the functioning of cardiac muscle tissue?
- **20.** Extracellular calcium ions are important for the contraction of what type(s) of muscle tissue?
- **21.** Why can smooth muscle contract over a wider range of resting lengths than skeletal muscle?

See the blue Answers tab at the back of the book.

7-9 Descriptive terms are used to name skeletal muscles

Learning Outcome Explain how the name of a muscle can help identify its location, appearance, or function.

The **muscular system** includes all the skeletal muscles (**Figure 7-12**). The general appearance of each of the nearly 700 skeletal muscles provides clues to its primary function. Muscles involved with locomotion and posture work across joints, producing movement of the skeleton. Those that support soft tissue form slings or sheets between relatively stable bony parts. Muscles that guard an entrance or an exit completely encircle the opening.

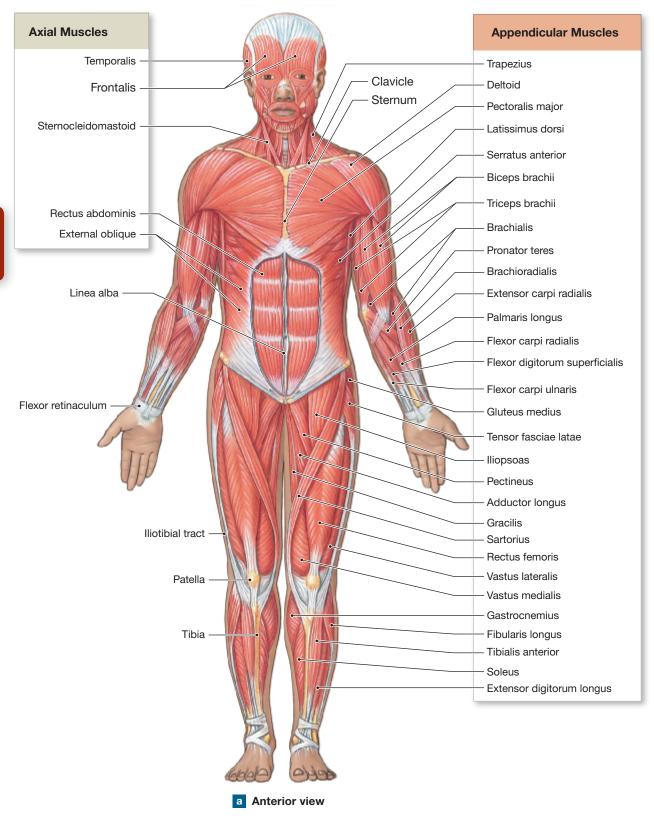

The separation of the skeletal system into axial and appendicular divisions provides a useful guideline for subdividing the muscular system as well:

• The **axial muscles** arise on the axial skeleton. They position the head and spinal column and also move the rib cage, assisting in the movements that make breathing possible. They do not play a role in movement or support of the pectoral or pelvic girdles or the limbs. This category includes roughly 60 percent of the skeletal muscles in the body.

Table 7-1 A Comparison of Skeletal, Cardiac, and Smooth Muscle Tissues				
Property		Skeletal Muscle Fiber	Cardiac Muscle Cell	Smooth Muscle Cell
Fiber dimensions (diameter \times length	1)	100 μ m $ imes$ up to 60 cm	10–20 μ m $ imes$ 50–100 μ m	5–10 μ m $ imes$ 30–200 μ m
Nuclei		Multiple, near sarcolemma	Usually single, centrally located	Single, centrally located
Filament organizat	tion	In sarcomeres along myofibrils	In sarcomeres along myofibrils	Scattered throughout sarcoplasm
Control mechanism	n	Neural, at single neuromuscular junction	Automaticity (pacemaker cells)	Automaticity (pacesetter cells), neural or hormonal control
Ca ²⁺ source		Release from SR	Extracellular fluid and release from SR	Extracellular fluid and release from SR
Contraction		Rapid onset; tetanus can occur; rapid fatigue	Slower onset; tetanus cannot occur; resistant to fatigue	Slow onset; tetanus can occur; resistant to fatigue
Energy source		Aerobic metabolism at moderate lev- els of activity; glycolysis (anaerobic during peak activity)	Aerobic metabolism, usually lipid or carbohydrate substrates	Primarily aerobic metabolism

244 MUSCULAR SYSTEM

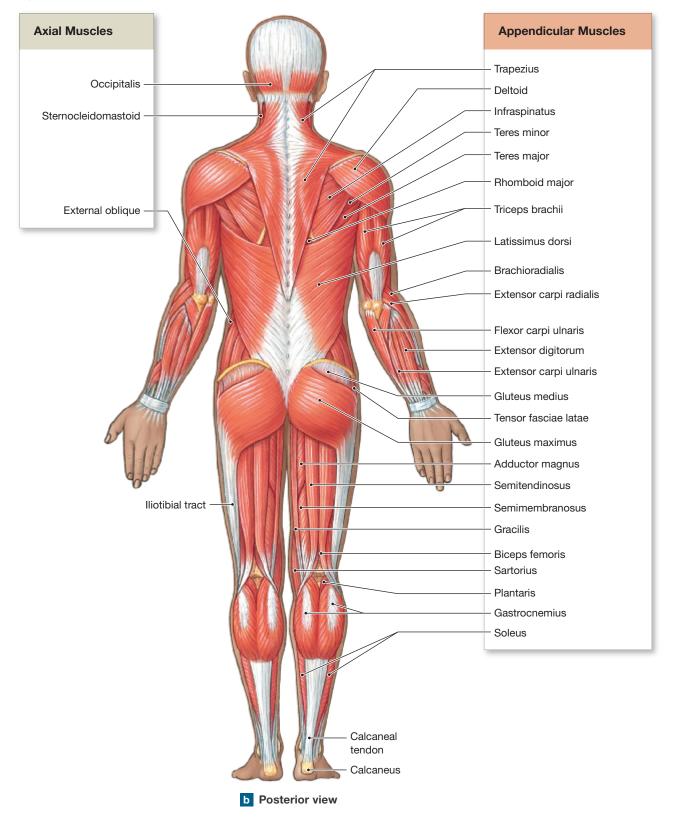

Figure 7-12 An Overview of the Major Skeletal Muscles. (continued)

• The **appendicular muscles** stabilize or move components of the appendicular skeleton.

Here we consider several features of muscles that are used to name them: their attachment sites, known as origins and insertions, and their actions.

Origins, Insertions, and Actions

Each muscle begins at an **origin**, ends at an **insertion**, and contracts to produce a specific **action**. In general, a muscle's origin remains stationary while the insertion moves. For example, the *gastrocnemius* muscle (in the calf) has its origin on the distal portion of the femur and inserts on the calcaneus. Its contraction pulls the insertion closer to the origin, resulting in the action called *plantar flexion*. The determinations of origin and insertion are usually based on movement from the anatomical position.

Almost all skeletal muscles either originate or insert on the skeleton. When they contract, they may produce *flexion, extension, adduction, abduction, protraction, retraction, elevation, depression, rotation, circumduction, pronation, supination, inversion,* or *eversion*.(You may wish to review Figures 6-32 to 6-34, pp. 207–209.)

We can describe actions of muscles in two ways. The first describes muscle actions in terms of the bone affected. Accordingly, we say the *biceps brachii* muscle performs "flexion of the forearm." The second way, which is increasingly used by specialists of human motion (*kinesiologists*), describes muscle action in terms of the joint involved. Thus, we say the biceps brachii muscle performs "flexion at (or of) the elbow." We will primarily use the second way.

We can also describe muscles by their **primary actions**:

- A **prime mover**, or **agonist** (AG-o-nist), is a muscle whose contraction is chiefly responsible for producing a particular movement. The *biceps brachii* muscle is a prime mover that flexes the elbow.
- An **antagonist** (an-TAG-o-nist) is a muscle whose action opposes the movement produced by another muscle. An antagonist may also be a prime mover. For example, the *triceps brachii* muscle is a prime mover that extends the elbow. It is, therefore, an antagonist of the biceps brachii, and the biceps brachii is an antagonist of the triceps brachii. Agonists and antagonists are functional opposites—if one produces flexion, the other's primary action is extension.
- A **synergist** (*syn*-, together + *ergon*, work) is a muscle that helps a prime mover work efficiently. Synergists may either provide additional pull near the insertion or stabilize the point of origin. For example, the *deltoid muscle*

acts to lift the arm away from the body (abduction). A smaller muscle, the *supraspinatus muscle*, assists the deltoid in starting this movement. **Fixators** are synergists that stabilize the origin of a prime mover by preventing movement at another joint.

Names of Skeletal Muscles

You need not learn the name of every skeletal muscle, but you should become familiar with the most important ones. Fortunately, the names of muscles provide clues to their identification. **Table 7-2** summarizes muscle terminology and can be a useful reference as you go through the rest of this chapter. (With the exception of the platysma and the diaphragm, the complete name of every muscle includes the word *muscle*. For simplicity, we have not included the word *muscle* in figures and tables.)

Some names, often those with Greek or Latin roots, refer to the orientation of the muscle fascicles. For example, *rectus* means "straight," and *rectus muscles* are parallel muscles whose fascicles run parallel to the long axis of the muscle, as in the *rectus abdominis muscle*. In a few cases, a muscle is such a prominent feature that the regional name alone can identify it, such as the *temporalis muscle* of the head.

Other muscles are named after structural features. For example, a biceps muscle has two tendons of origin (*bi*-, two + *caput*, head), and the *triceps* has three. Table 7-2 also lists names reflecting shape, length, or size, or whether a muscle is visible at the body surface (*externus, superficialis*) or lies beneath (*internus, profundus*). Superficial muscles that position or stabilize an organ are called *extrinsic muscles*. Those that operate within an organ are called *intrinsic muscles*.

The first part of many names indicates the muscle's origin, and the second part its insertion. The *sternohyoid muscle*, for example, originates at the sternum and inserts on the hyoid bone. Other names may also indicate the primary function of the muscle. For example, the *extensor carpi radialis muscle* is found along the radial (lateral) border of the forearm, and its contraction produces extension at the wrist (carpal) joint.

CHECKPOINT

- **22.** Identify the kinds of descriptive information used to name skeletal muscles.
- 23. Which muscle is the antagonist of the biceps brachii?
- **24.** What does the name *flexor carpi radialis longus* tell you about this muscle?
- See the blue Answers tab at the back of the book.

Table 7-9	Muscla

Muco	Lo Tom	minol	
Musc	le ler	mino	logy

Terms Indicating Specific	Terms Indicating Position, Direction,	Terms Indicating Structural	
Regions of the Body*	or Fascicle Arrangement	Characteristics of the Muscle	Terms Indicating Actions
Abdominal (abdomen)	Anterior (front)	NATURE OF ORIGIN	GENERAL
Ancon (elbow)	External (on the outside)	Biceps (two heads)	Abductor (movement away)
Auricular (ear)	Extrinsic (outside the structure)	Triceps (three heads)	Adductor (movement toward)
Brachial (arm)	Inferior (below)	Quadriceps (four heads)	Depressor (lowering movement)
Capitis (head)	Internal (away from the surface)		Extensor (straightening movement)
Carpi (wrist)	Intrinsic (within the structure)	SHAPE	Flexor (bending movement)
Cervicis (neck)	Lateral (on the side)	Deltoid (triangle)	Levator (raising movement)
Coccygeus (coccyx)	Medial (middle)	Orbicularis (circle)	Pronator (turning into prone
Cleido-/-clavius (clavicle)	Oblique (slanting)	Pectinate (comblike)	position)
Costal (rib)	Posterior (back)	Piriformis (pear-shaped)	Supinator (turning into supine
Cutaneous (skin)	Profundus (deep)	Platysma (flat plate)	position) Tensor (tensing movement)
Femoris (thigh))	Rectus (straight)	Pyramidal (pyramid)	Tensor (tensing movement)
Genio- (chin)	Superficial (toward the surface)	Rhomboid (parallelogram)	SPECIFIC
Glossal (tongue)	Superioris (toward the head)	Serratus (serrated)	
Hallux (great toe)	Transverse (crosswise)	Splenius (bandage)	Buccinator (trumpeter)

Nasalis (nose)		OTHER STRIKING FEATURES	
Nuchal (back of neck)		Alba (white)	
Ocular (eye)		Brevis (short)	
Oris (mouth)		Gracilis (slender)	
Palpebra (eyelid)		Latae (wide)	
Pollex (thumb)		Latissimus (widest)	
Popliteal (posterior to knee)		Longissimus (longest)	
Psoas (loin)		Longus (long)	
Radial (forearm)		Magnus (large)	
Scapular (scapula)		Major (larger)	
Temporal (temple)		Maximus (largest)	
Thoracic (thorax)		Minimus (smallest)	
Tibial (tibia; shin)		Minor (smaller)	
Ulnar (ulna)		Vastus (great)	
*For other regional terms, refer to Figure	1-6, p. 44, which shows anatomical landmarks.		

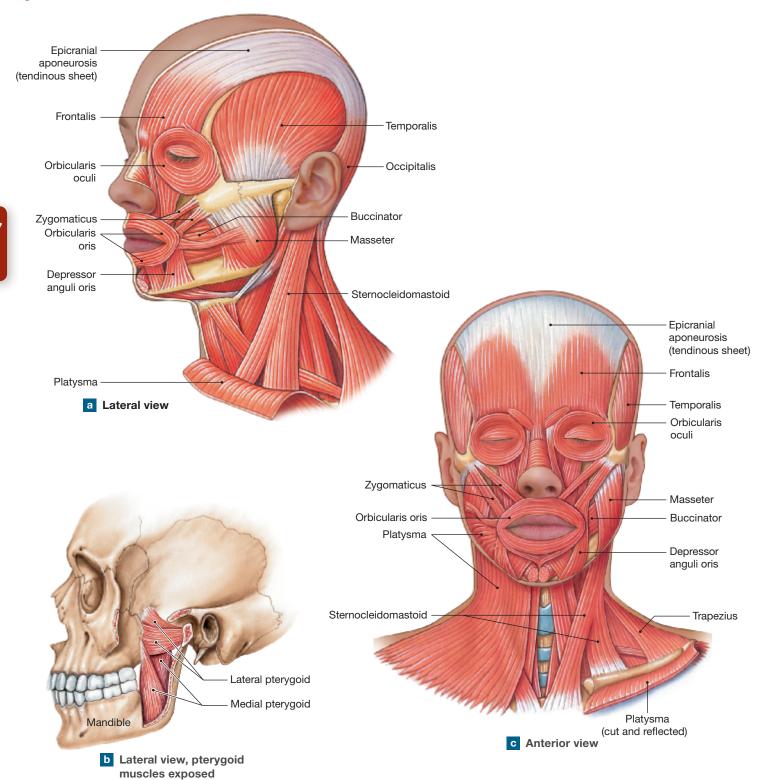

7-10 Axial muscles are muscles of the head and neck, vertebral column, trunk, and pelvic floor

Learning Outcome Identify the main axial muscles of the body and their origins, insertions, and actions.

The axial muscles fall into four logical groups based on location, function, or both:

- **1.** *Muscles of the head and neck.* These muscles include those responsible for facial expression, chewing, and swallowing.
- 2. *Muscles of the spine.* This group includes flexors and extensors of the head, neck, and spinal column.
- **3.** *Muscles of the trunk.* The *oblique* and *rectus* muscles form the muscular walls of the thoracic and abdominopelvic cavities.
- **4.** *Muscles of the pelvic floor.* These muscles extend between the sacrum and pelvic girdle and form the muscular *perineum*, which closes the pelvic outlet.

Figure 7-13 Muscles of the Head and Neck.

Muscles of the Head and Neck

The muscles of the head and neck are shown in **Figure 7-13** and **7-14** (p. 250) and detailed in **Table 7-3**. The muscles of

the face originate on the surface of the skull and insert into the dermis of the skin. When they contract, the skin moves.

The largest group of facial muscles is associated with the mouth. The **orbicularis oris** constricts the opening, and

Table 7-3	Muscles of the Head and Neck		
Region/Muscle	Origin	Insertion	Action
MOUTH			
Buccinator	Maxillary bone and mandible	Blends into fibers of orbicularis oris	Compresses cheeks
Orbicularis oris	Maxillary bone and mandible	Lips	Compresses, purses lips
Depressor anguli ori	s Anterolateral surface of mandible	Skin at angle of mouth	Depresses corner of mouth
Zygomaticus	Zygomatic bone	Angle of mouth; upper lip	Draws corner of mouth back and up
EYE			
Orbicularis oculi	Medial margin of orbit	Skin around eyelids	Closes eye
SCALP			
Frontalis	Epicranial aponeurosis	Skin of eyebrow and bridge of nose	Raises eyebrows, wrinkles forehead
Occipitalis	Occipital bone	Epicranial aponeurosis	Tenses and retracts scalp
LOWER JAW			
Masseter	Zygomatic arch	Lateral surface of mandible	Elevates mandible
Temporalis	Along temporal lines of skull	Coronoid process of mandible	Elevates mandible
Pterygoids	Inferior processes of sphenoid	Medial surface of mandible	Elevate, protract, and/or move mandible to either side
NECK			
Platysma	From cartilage of second rib to acromion of scapula	Mandible and skin of cheek	Tenses skin of neck, depresses mandible
Digastric	Mastoid region of temporal bone and inferior surface of mandible	Hyoid bone	Depresses mandible and/or elevates larynx
Mylohyoid	Medial surface of mandible	Median connective tissue band that runs to hyoid bone	Elevates floor of mouth and hyoid, and/or depresses mandible
Omohyoid	Superior border of scapula	Hyoid bone	Depresses hyoid bone and larynx
Sternohyoid	Clavicle and sternum	Hyoid bone	Depresses hyoid bone and larynx
Sternothyroid	Dorsal surface of sternum and 1st rib	Thyroid cartilage of larynx	Depresses hyoid bone and larynx
Stylohyoid	Styloid process of temporal bone	Hyoid bone	Elevates larynx
Sternocleidomastoic	Superior margins of sternum and clavicle	Mastoid region of skull	Both sides together flex the neck; one side alone bends head toward shoulder and turns face to opposite side

other muscles move the lips or the corners of the mouth. The **buccinator** (BUK-si-nā-tor) muscle compresses the cheeks, as when pursing the lips and blowing forcefully. (*Buccinator* translates as "trumpeter.") During chewing, contraction and relaxation of the buccinators move food back across the teeth from the space inside the cheeks. In infants, the buccinator produces suction for suckling at the breast. The chewing motions are primarily produced by contractions of the **masseter**, assisted by the **temporalis** and the **pterygoid** muscles used in various combinations.

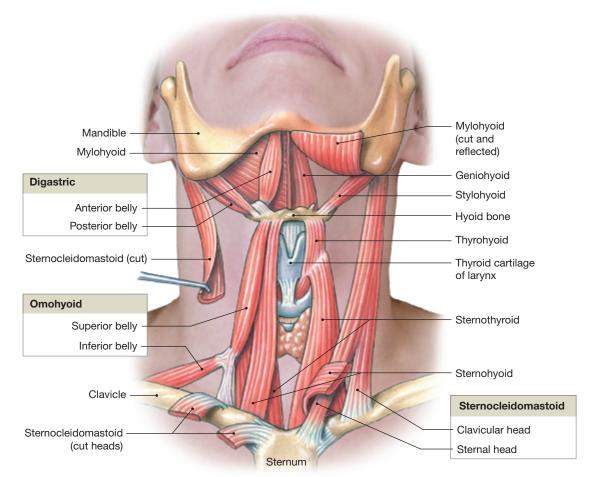

Smaller groups of muscles control movements of the eyebrows and eyelids, the scalp, the nose, and the external ear. The **epicranium** (ep-i-KRĀ-nē-um), or *scalp*, contains a two-part muscle, the *occipitofrontalis*. The anterior **frontalis**

muscle and the posterior **occipitalis** muscle of the occipitofrontalis are separated by an *aponeurosis*, or tendinous sheet, called the **epicranial aponeurosis**. The **platysma** (pla-TIZ-muh; *platys*, flat) covers the ventral surface of the neck, extending from the base of the neck to the mandible and the corners of the mouth.

The muscles of the neck control the position of the larynx, depress the mandible, tense the floor of the mouth, and provide a stable foundation for muscles of the tongue and pharynx (**Figure 7-14**). These muscles include the following:

• The **digastric**, which has two bellies (*di*-, two + *gaster*, stomach), opens the mouth by depressing the mandible.

- The broad, flat **mylohyoid** provides a muscular floor to the mouth and supports the tongue.
- The **stylohyoid** forms a muscular connection between the hyoid bone and the styloid process of the skull.
- The **sternocleidomastoid** (ster-nō-klī-dō-MAS-toyd) extends from the clavicle and the sternum to the mastoid region of the skull. It can rotate the head or flex the neck.
- The **omohyoid** attaches to the scapula, the clavicle and first rib, and the hyoid bone. Its superior and inferior bellies join at a central tendon anchored to the clavicle and first rib.

Muscles of the Spine

The muscles of the spine are covered by more superficial back muscles, such as the trapezius and latissimus dorsi (Figure 7-12b). The most superior of the spinal muscles

CLINICAL NOTE

Hernias

When the abdominal muscles contract forcefully, pressure in the abdominopelvic cavity can increase dramatically. That pressure is applied to internal organs. The pressure is relieved if an individual exhales at the same time, because the diaphragm can move upward as the lungs collapse. But during vigorous isometric exercises or when lifting a weight while holding one's breath, pressure in the abdominopelvic cavity can rise high enough to cause a variety of problems. Among them is the development of a hernia.

A **hernia** develops when an organ protrudes through an abnormal opening in the surrounding body cavity wall. The most common hernias are inguinal hernias and diaphragmatic hernias. *Inguinal hernias* typically occur in males, at the *inguinal canal*. This canal is the site where blood vessels, nerves, and reproductive ducts pass through the abdominal wall to reach the testes. Elevated abdominal pressure can force open the inguinal canal and push a portion of the intestine into the pocket created. *Diaphragmatic hernias* develop when visceral organs, such as a portion of the stomach, are forced into the thoracic cavity. If herniated structures become trapped or twisted, surgery may be required to prevent serious complications. are the posterior neck muscles: the superficial **splenius capitis** and the deeper **semispinalis capitis** (Figure 7-15 and Table 7-4). When the left and right pairs of these muscles contract together, they assist each other in extending the head. When both contract on one side, they assist in tilting the head. Due to its more lateral insertion, contraction of the splenius capitis also acts to rotate the head.

The *spinal extensors*, or **erector spinae**, act to maintain an erect spinal column and head. Moving laterally from the spine, these muscles can be subdivided into **spinalis**, **longissimus**, and **iliocostalis** divisions. In the lower lumbar and sacral regions, the border between the longissimus and iliocostalis muscles is indistinct, and they are sometimes known as the *sacrospinalis* muscles. When contracting together, these muscles extend the spinal column. When only the muscles on one side contract, the spine is bent laterally (lateral flexion). Deep to the spinalis muscles, smaller muscles interconnect and stabilize the vertebrae. In the lumbar region, the large **quadratus lumborum** muscles flex the spinal column and depress the ribs.

The extensor muscles of the vertebral column outnumber its flexor muscles. Fewer flexor muscles are needed because many large trunk muscles flex the vertebral column. Also, most of the body weight lies anterior to the vertebral column, so gravity tends to flex the spine.

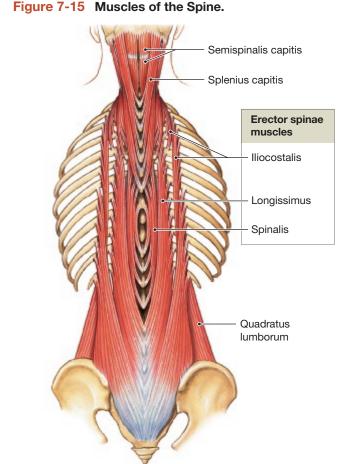

Table 7-4	Muscles of the Spine		
Region/Muscle	Origin	Insertion	Action
SPINAL EXTENSO	RS		
Splenius capitis	Spinous processes of lower cervical and upper thoracic vertebrae	Mastoid process, base of the skull, and upper cervical vertebrae	The two sides act together to extend the neck; either alone rotates and laterally flexes head to that side
Semispinalis capitis	Spinous processes of lower cervical and upper thoracic vertebrae	Base of skull, upper cervical vertebrae	The two sides act together to extend the neck; either alone laterally flexes head to that side
Spinalis group	Spinous processes and transverse pro- cesses of cervical, thoracic, and upper lumbar vertebrae	Base of skull and spinous processes of cervical and upper thoracic vertebrae	The two sides act together to extend vertebral column; either alone extends neck and laterally flexes head or rotates vertebral column to that side
Longissimus group	Processes of lower cervical, thoracic, and upper lumbar vertebrae	Mastoid process of temporal bone, transverse process of cervical vertebrae, and inferior surfaces of ribs	The two sides act together to extend vertebral column; either alone rotates and laterally flexes head or vertebral column to that side
lliocostalis group	Superior borders of ribs and iliac crest	Transverse processes of cervical verte- brae and inferior surfaces of ribs	Extends vertebral column or moves laterally to that side; moves ribs
SPINAL FLEXOR			
Quadratus lumboru	m Iliac crest	Last rib and transverse processes of lumbar vertebrae	Together they depress ribs, flex vertebral column; one side acting alone produces lateral flexion

The Axial Muscles of the Trunk

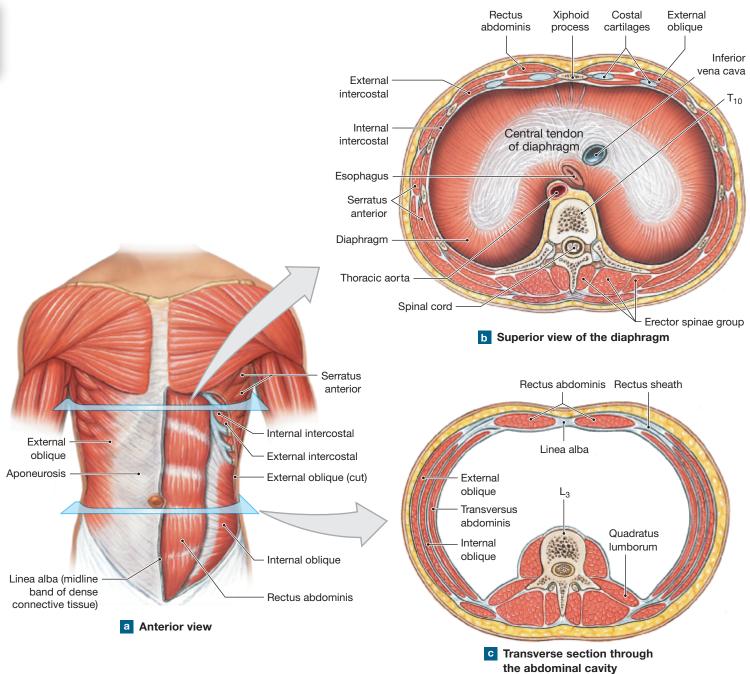

The *oblique muscles* and the *rectus muscles* form the muscular walls of the thoracic and abdominopelvic cavities between the first thoracic vertebra and the pelvis. In the thoracic area, these muscles are partitioned by the ribs, but over the abdominal surface they form broad muscular sheets (Figure 7-16 and Table 7-5). The oblique muscles can compress underlying structures or rotate the spinal column, depending on whether

Figure 7-16 Oblique and Rectus Muscles and the Diaphragm.

Build Your Knowledge

The pelvic cavity lies inferior to the abdominal cavity (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). It contains the urinary bladder, various reproductive organs, and the distal portion of the large intestine. **Dp. 48**

7

Table 7-5	Axial Muscles of the Trunk		
Region/Muscle	Origin	Insertion	Action
THORACIC REGIO	N		
External intercosta	Inferior border of each rib	Superior border of next rib	Elevate ribs
Internal intercosta	Is Superior border of each rib	Inferior border of the preceding rib	Depress ribs
Diaphragm	Xiphoid process, cartilages of ribs 4–10, and anterior surfaces of lumbar vertebrae	Central tendinous sheet	Contraction expands thoracic cavity, compresses abdominopelvic cavity
ABDOMINAL REGI	ON		
External oblique	Lower eight ribs	Linea alba and iliac crest	Compresses abdomen, depresses ribs, flexes or laterally flexes vertebral column
Internal oblique	lliac crest and adjacent connective tissues	Lower ribs, xiphoid of sternum, and linea alba	Compresses abdomen, depresses ribs, flexes or laterally flexes vertebral column
Transversus abdor	ninis Cartilages of lower ribs, iliac crest, and adjacent connective tissues	Linea alba and pubis	Compresses abdomen
Rectus abdominis	Superior surface of pubis around symphysis	Inferior surfaces of costal cartilages (ribs 5–7) and xiphoid process	Depresses ribs, flexes vertebral column

one or both sides are contracting. The rectus muscles are important flexors of the spinal column; they oppose the erector spinae.

The axial muscles of the trunk include (1) the **external** and **internal intercostals**, (2) the muscular **diaphragm** that separates the thoracic and abdominopelvic cavities, (3) the **external** and **internal obliques**, (4) the **transversus abdominis**, (5) the **rectus abdominis**, (commonly called the "abs") and (6) the muscles that form the floor of the pelvic cavity.

Muscles of the Pelvic Floor

The floor of the pelvic cavity is called the **perineum** (Figure 7-17 and Table 7-6). It is formed by a broad sheet of muscles that connects the sacrum and coccyx to the ischium and pubis. These muscles support the organs of the pelvic cavity, flex the coccyx, and control the movement of materials through the urethra and anus.

CLINICAL NOTE

Intramuscular Injections

Drugs are commonly injected into tissues rather than directly into the bloodstream. This method makes it possible to introduce a large amount of a drug at one treatment, yet have it enter the circulation gradually. An **intramuscular (IM) injection** introduces the drug into the mass of a large skeletal muscle. Uptake is usually faster and accompanied by less tissue irritation than when drugs are administered *intradermally* or *subcutaneously*

(injected into the dermis or subcutaneous layer, respectively). D p. 159 Up to 5 mL of fluid may be injected at one time, and multiple injections are possible.

The most common complications involve accidental injection into a blood vessel or the piercing of a nerve. The sudden entry of massive quantities of a drug into the bloodstream can have unpleasant or even fatal effects.

Damage to a nerve can cause motor paralysis or sensory loss. For these reasons, the injection site must be selected with care.

Bulky muscles that contain few large vessels or nerves make ideal injection sites. The gluteus medius or the posterior, lateral, superior portion of the gluteus maximus is often selected. The deltoid muscle of the arm, about 2.5 cm (1 in.) distal to the acromion, is another common site.

Probably the most satisfactory site from a technical point of view is the vastus lateralis of the thigh. An injection into this thick muscle will not encounter vessels or nerves. This injection site is preferred in infants and young children, who have relatively small gluteal and deltoid muscles. This site is also used in elderly patients or others with atrophied gluteal and deltoid muscles.

254 MUSCULAR SYSTEM

Figure 7-17 Muscles of the Pelvic Floor.

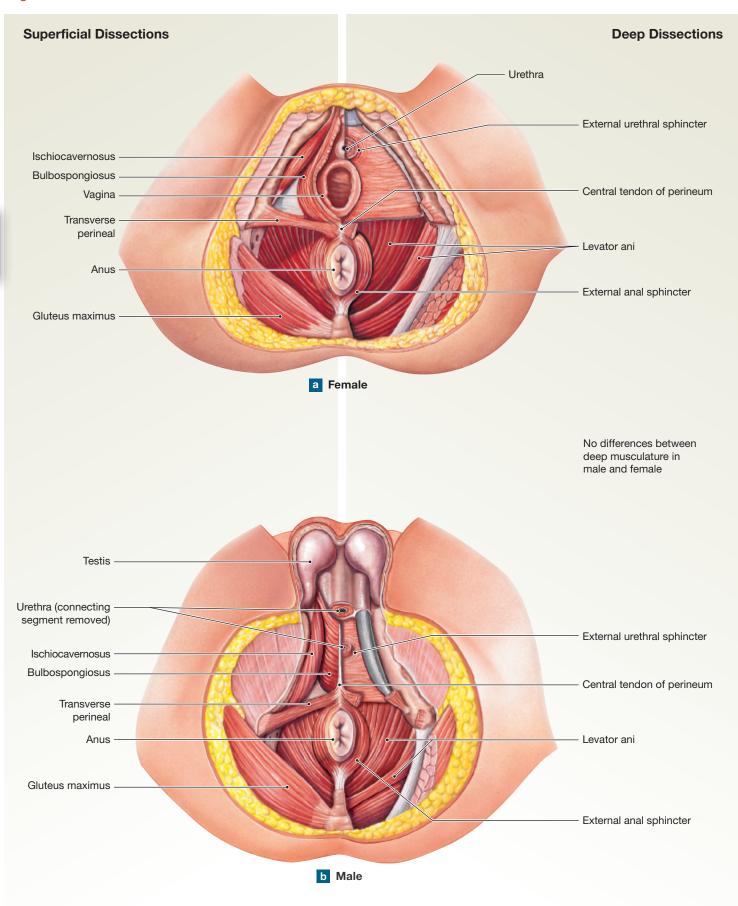

Table 7-6	Muscles of the Pelvic Floor		
Muscle	Origin	Insertion	Action
SUPERFICIAL MUS	SCLES		
Bulbospongiosus			
Males	Base of penis; fibers cross over urethra	Midline and central tendon of perineum	Compresses base and stiffens penis; ejects urine or semen
Females	Base of clitoris; fibers run on either side of urethral and vaginal openings	Central tendon of perineum	Compresses and stiffens clitoris; narrows vaginal opening
Ischiocavernosus	Inferior medial surface of ischium	Symphysis pubis anterior to base of penis or clitoris	Compresses and stiffens penis or clitoris
Transverse perinea	I Inferior medial surface of ischium	Central tendon of perineum	Stabilizes central tendon of perineum
DEEP MUSCLES			
External Urethral Sphincter			
Males	Inferior medial surfaces of ischium and pubis	Midline at base of penis; inner fibers encircle urethra	Closes urethra, compresses prostate and bulbo-urethral glands
Females	Inferior medial surfaces of ischium and pubis	Midline; inner fibers encircle urethra	Closes urethra, compresses vagina and greater vestibular glands
External anal sphincter	By tendon from coccyx	Encircles anal opening	Closes anal opening
Levator ani	Ischial spine, pubis	Соссух	Tenses floor of pelvis, supports pelvic organs, flexes coccyx, elevates and retracts anus

CHECKPOINT

- **25.** If you were contracting and relaxing your masseter muscle, what would you probably be doing?
- **26.** Which facial muscle would you expect to be well developed in a trumpet player?
- **27.** Damage to the external intercostal muscles would interfere with what important process?
- **28.** If someone were to hit you in your rectus abdominis muscle, how would your body position change?

See the blue Answers tab at the back of the book.

7-11 Appendicular muscles are muscles of the shoulders, upper limbs, pelvic girdle, and lower limbs

Learning Outcome Identify the main appendicular muscles of the body and their origins, insertions, and actions.

The appendicular musculature includes (1) the muscles of the shoulders and upper limbs and (2) the muscles of the pelvic girdle and lower limbs. The two groups have very different functions and ranges of motion. The muscular connections between the pectoral girdle and the axial skeleton increase the mobility of the upper limb and must also act as shock absorbers. For example, people can still perform delicate hand

movements while jogging. The reason is that the muscular connections between the axial and appendicular skeleton smooth out the bounces in their stride. In contrast, the pelvic girdle has evolved to transfer weight from the axial to the appendicular skeleton. A muscular connection would reduce the efficiency of the transfer, and the emphasis is on sheer power rather than mobility.

Muscles of the Shoulders and Upper Limbs Muscles That Position the Pectoral Girdle

The large, superficial **trapezius** muscles cover the back and portions of the neck, reaching to the base of the skull. These muscles form a broad diamond (**Figure 7-18a** and **Table 7-7**). Its actions are quite varied because specific regions can be made to contract independently. The **rhomboid** muscles and the **levator scapulae** are covered by the trapezius. Both originate on vertebrae and insert on the scapula. Contraction of the rhomboids adducts (retracts) the scapula, pulling it toward the center of the back. The levator scapulae elevates the scapula, as when you shrug your shoulders.

On the chest, the **serratus anterior** originates along the anterior surfaces of several ribs (**Figure 7-18b**) and inserts along the vertebral border of the scapula. When the serratus anterior contracts, it abducts (protracts) the scapula and

7

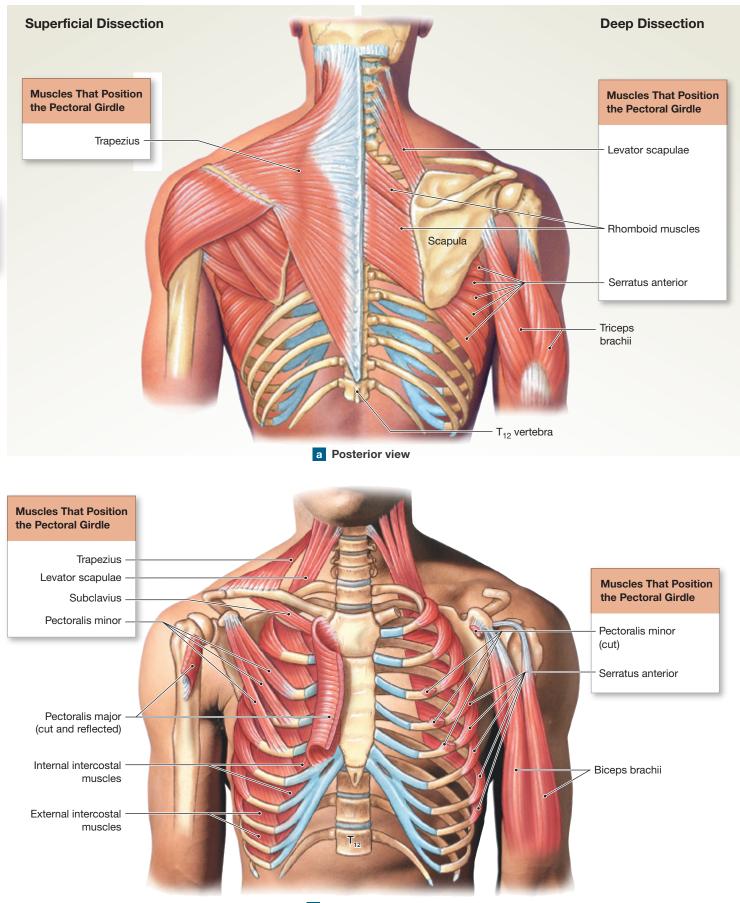

Table 7-7	Muscles That Position the Pectoral Girdle		
Muscle	Origin	Insertion	Action
Levator scapulae	Transverse processes of first 4 cervical vertebrae	Vertebral border of scapula	Elevates scapula
Pectoralis minor	Anterior surfaces of ribs 3–5	Coracoid process of scapula	Depresses and abducts (protracts) shoulder; rotates scapula laterally (downward); elevates ribs if scapula is stationary
Rhomboid muscles	Spinous processes of lower cervical and upper thoracic vertebrae	Vertebral border of scapula	Adducts (retracts) and rotates scapula laterally (downward)
Serratus anterior	Anterior and superior margins of ribs 1–9	Anterior surface of vertebral border of scapula	Protracts shoulder, abducts and medially rotates scapula (upward)
Subclavius	First rib	Clavicle	Depresses and protracts shoulder
Trapezius	Occipital bone and spinous processes of thoracic vertebrae	Clavicle and scapula (acromion and scapular spine)	Depends on active region and state of other muscles; may elevate, adduct, depress, or rotate scapula and/or elevate clavicle; can also extend or hyperextend neck

swings the shoulder anteriorly. The **pectoralis minor** attaches to the coracoid process of the scapula. The **subclavius** (sub-KLĀ-vē-us; *sub*, below + *clavius*, clavicle) inserts on the inferior border of the clavicle. The contraction of each of these muscles depresses and protracts the scapula.

Muscles That Move the Arm

The muscles that move the arm (Figure 7-19 and Table 7-8) are easiest to remember when grouped by primary actions:

- The **deltoid** is the major abductor of the arm, and the **supraspinatus** assists at the start of this movement.
- The subscapularis, teres major, infraspinatus, and teres minor rotate the arm.
- The **pectoralis major**, which extends between the chest and the greater tubercle of the humerus, produces flexion at the shoulder joint. The **latissimus dorsi**, which extends between the thoracic vertebrae and the intertubercular groove of the humerus, produces extension. The two muscles also work together to produce adduction and rotation of the humerus.

These muscles provide substantial support for the shoulder joint. The tendons of the supraspinatus, infraspinatus, teres minor, and subscapularis blend with and support the capsular fibers that enclose the shoulder joint. They are the muscles of the *rotator cuff*, a common site of sports injuries. Sports that involve throwing a ball, such as a baseball or football, place considerable strain on the muscles of the rotator cuff. A **muscle strain** (a tear or break in the muscle), *bursitis*, and other painful injuries can result.

Muscles That Move the Forearm and Wrist

Most of the muscles that insert on the forearm and wrist (Figure 7-20 and Table 7-9) originate on the humerus, but there are two notable exceptions. The **biceps brachii** and the *long head* tendon of the **triceps brachii** originate on the scapula and insert on the bones of the forearm. Their primary actions are at the elbow, although their contractions can have a secondary effect on the shoulder. The triceps brachii extends the elbow when, for example, you do pushups. The biceps brachii both flexes the elbow and supinates the forearm. With the forearm pronated (palm facing back), the biceps brachii cannot function effectively. As a result, you are strongest when you flex your elbow with a supinated forearm. You will see that the biceps brachii then makes a prominent bulge.

Other important muscles include the following:

- The **brachialis** and **brachioradialis** also flex the elbow, opposed by the triceps brachii.
- The **flexor carpi radialis**, the **flexor carpi ulnaris**, and the **palmaris longus** are superficial muscles that work together to produce flexion of the wrist. Because they originate on opposite sides of the humerus, the flexor carpi radialis flexes and abducts the wrist, whereas the flexor carpi ulnaris flexes and adducts the wrist.
- The **extensor carpi radialis** muscles and the **extensor carpi ulnaris** have a similar relationship. The former produces extension and abduction at the wrist. The latter produces extension and adduction.
- The **pronators** and the **supinator** rotate the radius at its proximal and distal articulations with the ulna. They do not flex or extend the elbow.

258 MUSCULAR SYSTEM

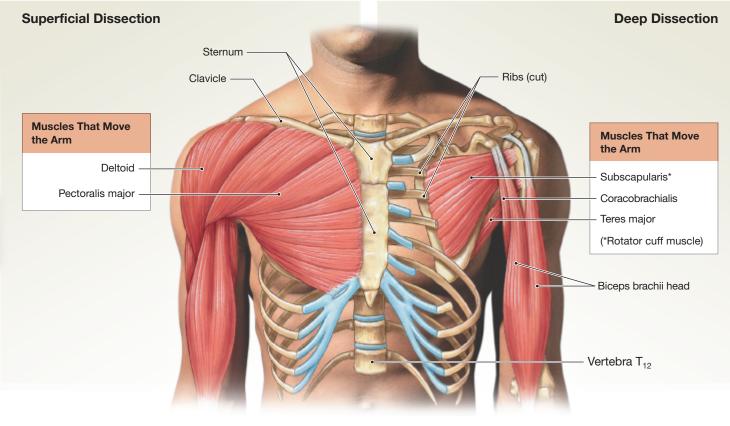

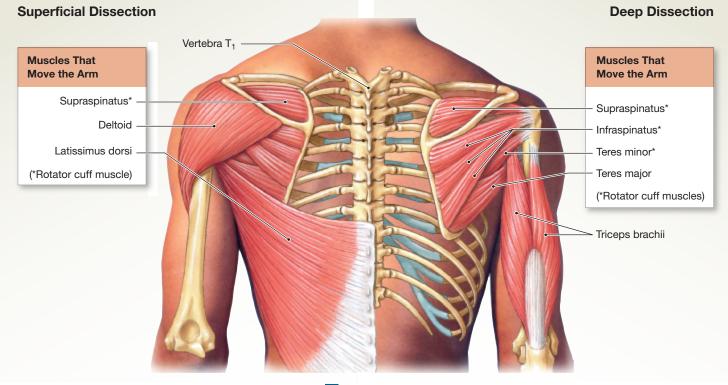

Figure 7-19 Muscles That Move the Arm. The four muscles of the rotator cuff are marked by an asterisk (*).

a Anterior view

b Posterior view

Table 7-8	Muscles That Move the Arm		
Muscle	Origin	Insertion	Action
Coracobrachialis	Coracoid process of scapula	Medial margin of shaft of humerus	Adduction and flexion at shoulder
Deltoid	Clavicle and scapula (acromion and adjacent scapular spine)	Deltoid tuberosity of humerus	Abduction at shoulder
Latissimus dorsi	Spinous processes of lower thoracic vertebrae, ribs, and lumbar vertebrae	Intertubercular groove of humerus	Extension, adduction, and medial rotation at shoulder
Pectoralis major	Cartilages of ribs 2–6, body of sternum, and clavicle	Greater tubercle of humerus	Flexion, adduction, and medial rotation at shoulder
Supraspinatus*	Supraspinous fossa of scapula	Greater tubercle of humerus	Abduction at shoulder
Infraspinatus*	Infraspinous fossa of scapula	Greater tubercle of humerus	Lateral rotation at shoulder
Subscapularis*	Subscapular fossa of scapula	Lesser tubercle of humerus	Medial rotation at shoulder
Teres minor*	Lateral border of scapula	Greater tubercle of humerus	Lateral rotation at shoulder
Teres major	Inferior angle of scapula	Intertubercular groove of humerus	Adduction and medial rotation at shoulder
*Rotator cuff muscles			

Muscles That Move the Hand and Fingers

The muscles of the forearm flex and extend the finger joints (**Table 7-9**). These muscles end before reaching the hand, and only their tendons cross the wrist. These are relatively large muscles, and keeping them clear of the joints ensures maximum mobility at both the wrist and hand. Wide bands of connective tissue cross the posterior and anterior surfaces of the wrist. The *extensor retinaculum* (ret-i-NAK-ū-lum; plural, *retinacula*) holds the tendons of the extensor muscles in place. The *flexor retinaculum* does the same for the flexor muscles. Both groups of tendons pass through *synovial tendon sheaths*, wide tubular bursae that reduce friction. \supset p. 205

Inflammation of the retinacula and synovial tendon sheaths can restrict movement and irritate the *median nerve*, a nerve that innervates the palm of the hand. Chronic pain, often associated with weakness in the hand muscles, is the result. This condition is known as **carpal tunnel syndrome**. A common cause is repetitive hand or wrist movements. Fine control of the hand involves small *intrinsic muscles*, which originate on the carpal and metacarpal bones. No muscles originate on the phalanges, and only tendons extend across the distal joints of the fingers.

CHECKPOINT

- 29. Which muscle do you use to shrug your shoulders?
- **30.** Sometimes baseball pitchers suffer rotator cuff injuries. Which muscles are involved in this type of injury?

- **31.** Injury to the flexor carpi ulnaris would impair which two movements?
- See the blue Answers tab at the back of the book.

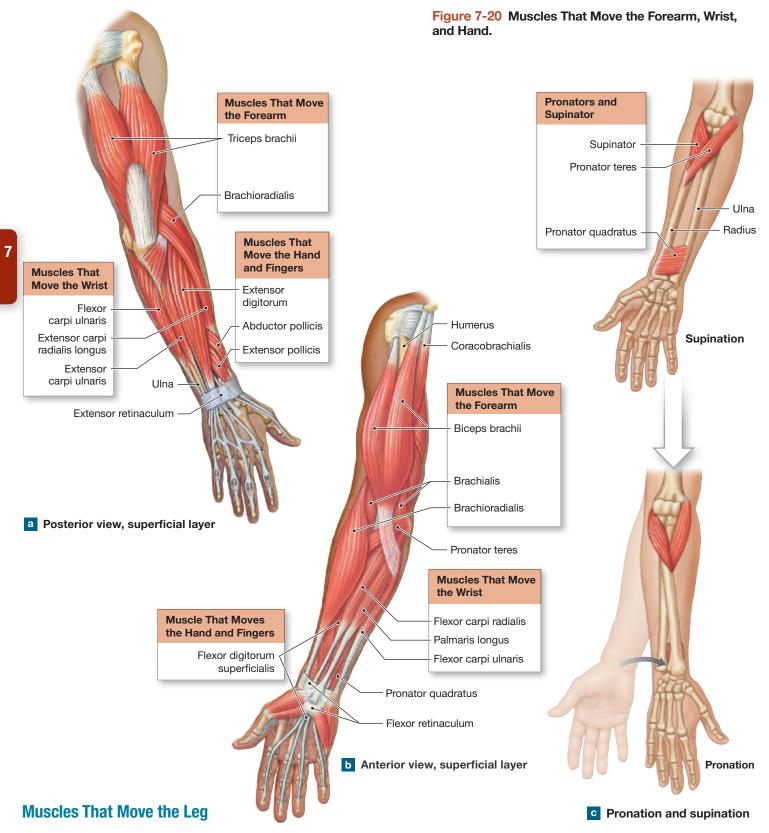

Muscles of the Pelvis and Lower Limbs

The muscles of the pelvis and the lower limb can be divided into three functional groups: (1) muscles that work across the hip joint to move the thigh; (2) muscles that work across the knee joint to move the leg; and (3) muscles that work across the various joints of the foot to move the ankles, feet, and toes.

Muscles That Move the Thigh

The muscles that move the thigh are detailed in **Figure 7-21** and **Table 7-10**.

- **Gluteal muscles** cover the lateral surfaces of the ilia (Figure 7-21a,b). The **gluteus maximus** is the largest and most posterior of the gluteal muscles. They produce extension, rotation, and abduction at the hip joint.
- The adductors of the thigh include the **adductor magnus**, the **adductor brevis**, the **adductor longus**, the **pectineus** (pek-ti-NĒ-us), and the **gracilis** (GRAS-i-lis) (Figure 7-21c). When an athlete suffers a *pulled groin*, the problem is a *strain*—a muscle tear—in one of these adductor muscles.
- The largest hip flexor is the **iliopsoas** (il-ē-ō-SŌ-us) muscle (**Figure 7-21c**). The iliopsoas is really two muscles, the **psoas major** and the **iliacus** (il-Ī-ah-kus). They share a common insertion at the lesser trochanter of the femur.

The pattern of muscle distribution in the lower limb is like that in the upper limb: Extensors are found along the anterior and lateral surfaces of the limb, and flexors lie along the posterior and medial surfaces (**Figure 7-22**).

• The flexors of the knee include three muscles collectively known as the *hamstrings*. They are the **biceps femoris** (FEM-or-is), the **semimembranosus** (sem-ē-mem-bra-NŌ-sus),

Table 7-9	Muscles That Move the Forearm, Write	st, and Hand	
Muscle	Origin	Insertion	Action
ACTION AT THE EL	BOW		
lexors			
Biceps brachii	Short head from the coracoid process and <i>long head</i> from the supraglenoid tubercle (both on the scapula)	Tuberosity of radius	Flexion at shoulder and elbow; supination
Brachialis	Anterior, distal surface of humerus	Tuberosity of ulna	Flexion at elbow
Brachioradialis	Lateral epicondyle of humerus	Styloid process of radius	Flexion at elbow
Extensors			
Triceps brachii	Superior, posterior, and lateral margins of humerus, and the scapula	Olecranon of ulna	Extension at elbow
PRONATORS/SUPI	NATOR		
Pronator quadratus	Medial surface of distal portion of ulna	Anterior and lateral surface of distal portion of radius	Pronation
Pronator teres	Medial epicondyle of humerus and coronoid process of ulna	Distal lateral surface of radius	Pronation
Supinator	Lateral epicondyle of humerus and ulna	Anterior and lateral surface of radius distal to the radial tuberosity	Supination
ACTION AT THE WI	RIST		
Flexors			
Flexor carpi radialis	Medial epicondyle of humerus	Bases of 2nd and 3rd metacarpal bones	Flexion and abduction at wrist
Flexor carpi ulnaris	Medial epicondyle of humerus and adjacent surfaces of ulna	Pisiform bone, hamate bone, and base of 5th metacarpal bone	Flexion and adduction at wrist
Palmaris longus	Medial epicondyle of humerus	A tendinous sheet on the palm	Flexion at wrist
Extensors			
Extensor carpi radi	alis Distal lateral surface and lateral epicondyle of humerus	Bases of 2nd and 3rd metacarpal bones	Extension and abduction at wrist
Extensor carpi ulna	ris Lateral epicondyle of humerus and adjacent surface of ulna	Base of 5th metacarpal bone	Extension and adduction at wrist
ACTION AT THE HA	ND		
Extensor digitorum	Lateral epicondyle of humerus	Posterior surfaces of the phalanges, fingers 2–5	Extension at finger joints and wrist
Flexor digitorum	Medial epicondyle of humerus; anterior surfaces of ulna and radius; medial and posterior surfaces of ulna	Distal phalanges of fingers 2–5	Flexion at finger joints and wrist
Abductor pollicis	Proximal dorsal surfaces of ulna and radius	Lateral margin of 1st metacarpal bone	Abduction at thumb joints and wrist
Extensor pollicis	Distal shaft of radius and the interosseus membrane	Base of phalanges of the thumb	Extension at thumb joints; abduction at wrist

and the semitendinosus (sem-ē-ten-di-NŌ-sus)—and the sartorius (sar-TOR-ē-us) (Figure 7-22a). The sartorius muscle crosses both the hip and knee joints. It produces flexion at the knee and lateral rotation at the hip when you cross your legs. A *pulled hamstring* is a relatively common sports injury caused by a strain affecting one of the hamstring muscles.

• Collectively the *knee extensors* are known as the **quadri**ceps femoris. The three vastus muscles and the rectus femoris insert on the patella, which is attached to the tibial tuberosity by the patellar ligament (Figure 7-22b). (Because the vastus intermedius lies under the other quadriceps femoris muscles, it is not visible in Figure 7-22.)

• When you stand, a slight lateral rotation of the tibia can lock the knee joint in the extended position. This enables you to stand for long periods with minimal muscular effort, but the locked knee cannot be flexed. The small **popliteus** (pop-LI-tē-us) muscle unlocks the joint by medially rotating the tibia back into its normal position (Figure 7-22a).

The muscles that move the leg are detailed in Table 7-11.

262 MUSCULAR SYSTEM

Group/Muscle	Origin	Insertion	Action
GLUTEAL GROUP			
Gluteus maximus	lliac crest of ilium, sacrum, and coccyx	lliotibial tract and gluteal tuberosity of femur	Extension and lateral rotation at hip
Gluteus medius	Anterior iliac crest and lateral surface of ilium	Greater trochanter of femur	Abduction and medial rotation at hip
Gluteus minimus	Lateral surface of ilium	Greater trochanter of femur	Abduction and medial rotation at hip
Tensor fasciae latae	lliac crest and surface of ilium between anterior iliac spines	lliotibial tract	Flexion and medial rotation at hip; tenses fas ciae latae, which laterally supports the knee
ADDUCTOR GROUP			
Adductor brevis	Inferior ramus of pubis	Linea aspera of femur	Adduction, flexion, and medial rotation at hip
Adductor longus	Inferior ramus of pubis anterior to adductor brevis	Linea aspera of femur	Adduction, flexion, and medial rotation at hip
Adductor magnus	Inferior ramus of pubis posterior to adductor brevis	Linea aspera of femur	Adduction at hip joint; superior portion produces flexion; inferior portion produces extension
Pectineus	Superior ramus of pubis	Inferior to lesser trochanter of femur	Adduction, flexion, and medial rotation at hip joint
Gracilis	Inferior ramus of pubis	Medial surface of tibia inferior to medial condyle	Flexion at knee; adduction and medial rota- tion at hip
ILIOPSOAS GROUP			
lliacus	Medial surface of ilium	Femur distal to lesser trochanter; tendon fused with that of psoas major	Flexion at hip
Psoas major	Anterior surfaces and transverse pro- cesses of T ₁₂ and lumbar vertebrae	Lesser trochanter in company with iliacus	Flexion at hip or lumbar intervertebral joints

Table 7-11	Muscles That Move the Leg		
Muscle	Origin	Insertion	Action
FLEXORS			
Biceps femoris*	Ischial tuberosity and linea aspera of femur	Head of fibula, lateral condyle of tibia	Flexion at knee, extension and lateral rotation at hip
Semimembranosus	* Ischial tuberosity	Posterior surface of medial condyle of tibia	Flexion at knee; extension and medial rotation at hip
Semitendinosus*	Ischial tuberosity	Proximal medial surface of tibia	Flexion at knee; extension and medial rotation at hip
Sartorius	Anterior superior spine of ilium	Medial surface of tibia near tibial tuberosity	Flexion at knee; flexion and lateral rotation at hip
Popliteus	Lateral condyle of femur	Posterior surface of proximal tibial shaft	Rotates tibia medially (or rotates femur laterally); flexion at knee
EXTENSORS			
Rectus femoris	Anterior inferior iliac spine and superior acetabular rim of ilium	Tibial tuberosity by way of patellar ligament	Extension at knee, flexion at hip
Vastus intermedius	Anterior and lateral surface of femur along linea aspera	Tibial tuberosity by way of patellar ligament	Extension at knee
Vastus lateralis	Anterior and inferior to greater trochanter of femur and along linea aspera	Tibial tuberosity by way of patellar ligament	Extension at knee
Vastus medialis	Entire length of linea aspera of femur	Tibial tuberosity by way of patellar ligament	Extension at knee
*Hamstring muscles

CHECKPOINT

- 32. You often hear of athletes suffering a "pulled hamstring." To what does this phrase refer?
- **33.** How would a torn calcaneal tendon affect movement of the foot?
- 34. Which three functional groups make up the muscles of the lower limbs?
- 35. Which muscle of the leg crosses both the hip and knee joints?
- See the blue Answers tab at the back of the book.

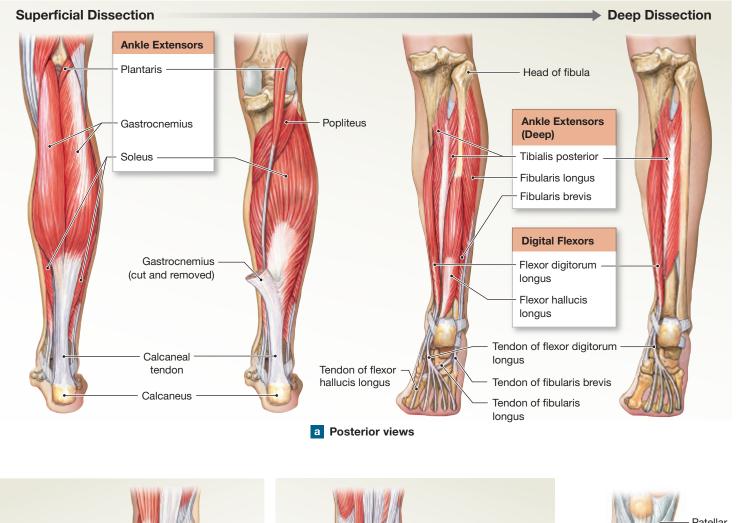

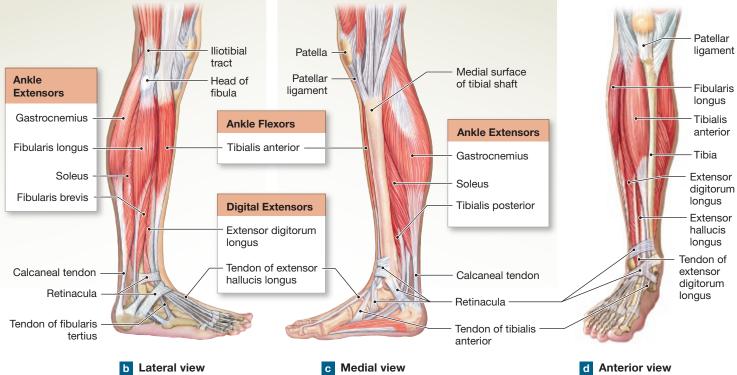

Figure 7-23 Muscles That Move the Foot and Toes.

7

Muscle	Origin	Insertion	Action
ACTION AT THE ANKLE			
Flexors (Dorsiflexors)			
Tibialis anterior	Lateral condyle and proximal shaft of tibia	Base of 1st metatarsal bone	Flexion (dorsiflexion) at ankle; inversion of foot
Fibularis tertius	Distal anterior surface of fibula and interosseus membrane	Dorsal surface of 5th metatarsal bone	Flexion (dorsiflexion) at ankle; eversion of foot
Extensors (Plantar flexors)			
Gastrocnemius	Femoral condyles	Calcaneus by way of calcaneal tendon	Extension (plantar flexion) at ankle; inversion and adduction of foot; flexion at knee
Fibularis brevis	Midlateral margin of fibula	Base of 5th metatarsal bone	Eversion of foot and extension (plantar flexion) at ankle
Fibularis longus	Lateral condyle of tibia, head and proximal shaft of fibula	Base of 1st metatarsal bone and medial cuneiform bone	Eversion of foot and extension (plantar flexion) at ankle
Plantaris	Lateral supracondylar ridge of femur	Posterior calcaneus	Extension (plantar flexion) at ankle; flexion at knee
Soleus	Head and proximal shaft of fibula, and adjacent shaft of tibia	Calcaneus by way of calcaneal tendon	Extension (plantar flexion) at ankle; adduction of foot
Tibialis posterior	Interosseus membrane and adjacent shafts of tibia and fibula	Tarsal and metatarsal bones	Adduction and inversion of foot; extension (plantar flexion) at ankle
ACTION AT THE TOES			
Flexors			
Flexor digitorum longus	Posterior and medial surface of tibia	Inferior surface of phalanges, toes 2-5	Flexion at joints of toes 2-5
Flexor hallucis longus	Posterior surface of fibula	Inferior surface, distal phalanx of great toe	Flexion at joints of great toe; assists in extension (plantar flexion) at ankle
Extensors			
Extensor digitorum longus	Lateral condyle of tibia, anterior surface of fibula	Superior surfaces of phalanges, toes 2–5	Extension at joints of toes 2-5
Extensor hallucis longus	Anterior surface of fibula	Superior surface, distal phalanx of great toe	Extension at joints of great toe

7-12 The size and power of muscle tissue decrease with advancing age

Learning Outcome Describe the effects of aging on muscle tissue.

The effects of aging on the muscular system can be summarized as follows:

- 1. Skeletal muscle fibers become smaller in diameter. The reduction in size reflects a decrease in the number of myofibrils. In addition, muscle fibers contain smaller ATP, CP, and glycogen reserves and less myoglobin. Overall, muscle strength and endurance are reduced, and muscles tend to fatigue rapidly. Also, blood flow to active muscles does not increase with exercise as rapidly as it does in younger people because cardiovascular performance decreases with age.
- 2. Skeletal muscles become less elastic. Aging skeletal muscles develop increasing amounts of fibrous connective tissue, a process called *fibrosis*. Fibrosis makes the muscle

less flexible, and the collagen fibers can restrict movement and circulation.

- 3. Tolerance for exercise decreases. A lower tolerance for exercise as age increases results in part from the tendency to tire quickly and in part from reduced thermoregulation (described in Chapters 1 and 5).
 > pp. 40, 157 Individuals over age 65 cannot eliminate heat generated by muscles as effectively as younger people, which leads to overheating.
- **4.** *The ability to recover from muscular injuries decreases.* When an injury occurs, repair capabilities are limited. As a result, scar tissue usually forms.

The *rate* of decline in muscular performance is the same in all people, regardless of their exercise patterns or lifestyle. For this reason, to be in good shape late in life, an individual must be in *very* good shape early in life. Regular exercise helps control body weight, strengthens bones, and generally improves the quality of life at all ages. Extremely demanding exercise is

not as important as regular exercise. In fact, extreme exercise in the elderly can damage tendons, bones, and joints.

CHECKPOINT

36. Describe general age-related effects on skeletal muscle tissue.

See the blue Answers tab at the back of the book.

7-13 Exercise produces responses in multiple body systems

Learning Outcome Discuss the interactions between the muscular system and other body systems when the body is at rest, and explain the homeostatic responses to exercise by the muscular system and various other body systems.

Even when the body is at rest, the muscular system is interacting with other body systems. Build Your Knowledge: How the MUSCULAR SYSTEM integrates with the other body systems presented so far on p. 268 summarizes the major functional relationships between it and the integumentary and skeletal systems.

To work at maximum efficiency and maintain homeostasis, the muscular system must be supported by many other systems. The changes that take place during exercise are a good example of such interactions. Responses of the muscular system and other organ systems to exercise include the following:

• *Muscular system.* Active muscles consume oxygen and generate carbon dioxide and heat.

- **Cardiovascular system.** Blood vessels in active muscles and in the skin dilate, and heart rate increases. These adjustments speed delivery of oxygen and removal of carbon dioxide at the muscle. They also bring heat to the skin where it can pass into the environment.
- **Respiratory system.** The rate and depth of respiration increase during exercise. Air moves into and out of the lungs more quickly, keeping pace with the increased rate of blood flow through the lungs.
- **Integumentary system.** Blood vessels dilate, and sweat gland secretion increases. This combination promotes evaporation at the skin surface and removes the excess heat generated by muscular activity.
- *Nervous and endocrine systems.* These systems direct the responses of other organ systems by controlling heart rate, respiratory rate, sweat gland activity, and the release of stored energy reserves.

CHECKPOINT

- **37.** What major function does the muscular system perform for the body as a whole?
- **38.** Identify the physiological effects of exercise on the cardiovascular, respiratory, and integumentary systems. What is the relationship between these physiological effects and the nervous and endocrine systems?

See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

compartment syndrome: Ischemia (defined shortly) resulting from accumulated blood and fluid trapped within limb muscle compartments formed by partitions of dense connective tissue.

ischemia (is-KĒ-mē-uh): A deficiency of blood ("blood starvation") in a body part, sometimes due to compression of regional blood vessels.

muscle cramps: Prolonged, involuntary, painful muscular contractions.

muscular dystrophies (DIS-trō-fēz): A varied collection of inherited diseases that produce progressive muscle weakness and deterioration. The most familiar is *Duchenne muscular dystrophy*, which typically develops in males ages three to seven years.

myalgia (mī-AL-jē-uh): Muscular pain; a common symptom of a wide variety of conditions and infections.

myoma: A benign tumor of muscle tissue.

myositis (mī-ō-SĪ-tis): Inflammation of muscle tissue.

polio: A viral disease in which the destruction of motor neurons produces paralysis and atrophy of motor units.

sarcoma: A malignant tumor of mesoderm-derived tissue (muscle, bone, or other connective tissue).

tendinitis: Inflammation of the connective tissue surrounding a tendon.

Build Your Knowledge

How the MUSCULAR SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System removes excess body heat; synthesizes vitamin D₃ for calcium and phosphate absorption; protects underlying muscles
- The muscular system includes facial muscles that pull on the skin of the face to produce facial expressions

7

Skeletal System

- The Skeletal System provides mineral reserves for maintaining normal calcium and phosphate levels in body fluids; supports skeletal muscles; and provides sites of muscle attachment
- The muscular system provides skeletal movement and support; stabilizes bones and joints; stresses exerted by tendons of contracting skeletal muscles help to maintain normal bone structure and mass

Muscular System

The muscular system performs five primary functions for the human body. It:

- produces skeletal movement
- helps maintain posture and body position
- supports soft tissues
- guards entrances and exits to the body
- helps maintain body temperature

Chapter Review

Summary Outline

An Introduction to Muscle Tissue p. 222

1. The three types of muscle tissue are *skeletal muscle, cardiac muscle*, and *smooth muscle*. The muscular system includes all of the body's skeletal muscles, which can be controlled voluntarily.

7-1 Skeletal muscle performs five primary functions *p. 222*

2. Skeletal muscles attach to bones directly or indirectly. They (1) produce movement of the skeleton, (2) maintain posture and body position, (3) support soft tissues, (4) guard entrances and exits, and (5) maintain body temperature.

7-2 A skeletal muscle contains muscle tissue, connective tissues, blood vessels, and nerves p. 222

3. Each muscle fiber is surrounded by an **endomysium**. Bundles of muscle fibers are sheathed by a **perimysium**, and the entire muscle is covered by an **epimysium**. At the ends of the muscle is a **tendon** or **aponeurosis**. (*Figure 7-1*)

7-3 Skeletal muscle fibers have distinctive features *p. 224*

- 4. A muscle cell has a sarcolemma (plasma membrane), sarcoplasm (cytoplasm), and a sarcoplasmic reticulum, similar to the smooth endoplasmic reticulum of other cells. Transverse tubules (T tubules) and myofibrils have roles in contraction. Filaments in a myofibril are organized into repeating functional units called sarcomeres. (Figure 7-2a-c)
- **5. Myofilaments** consist of **thin filaments** (*actin*) and **thick filaments** (*myosin*). (*Figure 7-2d,e*)
- **6.** As a myofilament contracts and shortens, the **Z lines** of adjacent sarcomeres move closer together as the thin filaments slide past the thick filaments. (*Figure 7-3*)
- 7. The explanation for sarcomere contraction is the *sliding filament theory*. The process involves **active sites** on thin filaments and **cross-bridges** of the thick filaments. At rest, the necessary interactions are prevented by **tropomyosin** and **troponin** proteins on the thin filaments.

7-4 The nervous system and skeletal muscles communicate at neuromuscular junctions p. 227

- **8.** Neural control of muscle function links electrical activity in the sarcolemma with the initiation of a contraction.
- **9.** A neuron controls the activity of a muscle fiber at a **neuromuscular junction (NMJ)**. (*Spotlight Figure 7-4*)

- **10.** When an **action potential** arrives at the axon terminal, acetylcholine is released into the synaptic cleft. The binding of ACh to receptors on the motor end plate leads to the generation of an action potential in the sarcolemma. The passage of an action potential along a transverse tubule triggers the release of calcium ions from the *terminal cisternae* of the sarcoplasmic reticulum. (*Spotlight Figure 7-4*)
- **11.** A contraction involves a repeated cycle of "attach, pivot, detach, and return." It begins when calcium ions are released by the sarcoplasmic reticulum. The calcium ions bind to troponin, which changes position and moves tropomyosin away from the active sites of actin. Cross-bridge binding of myosin heads to actin can then occur. After binding, each myosin head pivots at its base, pulling the actin filament toward the center of the sarcomere. (*Spotlight Figure 7-5*)
- **12.** A summary of the contraction process, from ACh release to the end of the contraction and relaxation, is shown in *Figure 7-6*.

7-5 Sarcomere shortening and muscle fiber stimulation produce tension *p. 230*

- **13.** The amount of tension produced by a muscle fiber depends on the number of cross-bridges formed.
- **14.** Both the number of activated muscle fibers and their rate of stimulation control the tension of a skeletal muscle.
- **15.** A muscle fiber **twitch** is a cycle of contraction and relaxation produced by a single stimulus. (*Figure 7-7*)
- 16. Repeated stimulation before the relaxation phase ends can result in the addition of twitches (known as summation). The result can be either incomplete tetanus (in which tension peaks because the muscle is never allowed to relax completely) or complete tetanus (in which the relaxation phase is completely eliminated). (*Figure 7-8*)
- **17.** The number and size of a muscle's **motor units** indicate how precisely the muscle's movements are controlled. *(Figure 7-9)*
- Muscle tension is increased by increasing the number of motor units involved—a process called **recruitment**.
- **19.** Resting **muscle tone** stabilizes bones and joints. Inadequate stimulation causes muscles to **atrophy**.
- **20.** Normal activities usually include both **isotonic contractions** (a muscle's tension remains constant as it shortens) and **isometric contractions** (a muscle's tension rises but its length remains constant).
- **21.** Elongation of a muscle fiber is passive. Elongation can result from elastic forces, the contraction of opposing muscles, or the effects of gravity.

7-6 ATP is the energy source for muscle contraction p. 237

- **22.** Muscle contractions require large amounts of energy from ATP.
- 23. ATP is an energy-transfer molecule, not an energy-storage molecule. Creatine phosphate (CP) can release stored energy to convert ADP to ATP. A resting muscle cell contains many times more CP than ATP. (Figure 7-10a)
- 24. At rest or moderate levels of activity, aerobic metabolism in mitochondria can provide most of the ATP required to support muscle contractions.
- 25. When a muscle fiber runs short of ATP and CP, enzymes can break down glycogen molecules to release glucose that can be broken down by glycolysis. (Figure 7-10b)
- 26. At peak levels of activity the cell relies heavily on the anaerobic process of glycolysis to generate ATP, because the mitochondria cannot obtain enough oxygen to meet the existing ATP demands. (Figure 7-10c)
- 27. Muscle fatigue occurs when a muscle can no longer contract, because of a drop in the pH due to the buildup of hydrogen ions from the hydrolytic breakdown of ATP, a lack of energy resources, or other factors.
- 28. The **recovery period** begins after a period of muscle activity and continues until conditions inside the muscle have returned to pre-exertion levels. The oxygen debt is the amount of oxygen used to restore normal conditions.

7-7 Muscle performance depends on muscle fiber type and physical conditioning p. 240

- 29. Muscle performance can be considered in terms of force (the maximum amount of tension produced by a particular muscle or muscle group) and endurance (the duration of muscular activity).
- **30.** The two types of human skeletal muscle fibers are **fast** fibers and slow fibers.
- **31.** Fast fibers are large in diameter, contain densely packed myofibrils, large reserves of glycogen, and few mitochondria. They produce rapid and powerful contractions of relatively short duration.
- 32. Slow fibers are smaller in diameter and take three times as long to contract after stimulation. An extensive capillary supply, abundant mitochondria, and high concentrations of **myoglobin** enable them to contract for long periods of time.
- **33.** Anaerobic endurance is the time over which a muscle can support sustained, powerful contractions anaerobically. Training to develop anaerobic endurance can lead to hypertrophy (enlargement) of the stimulated muscles.
- 34. Aerobic endurance is the time over which a muscle can continue to contract while supported by mitochondrial activities.

7-8 Cardiac and smooth muscle tissues differ in structure and function from skeletal muscle tissue p. 241

- 35. Cardiac muscle cells differ from skeletal muscle fibers in that they are smaller, typically have a single central nucleus, rely more greatly on aerobic metabolism when contracting at peak levels, and have **intercalated discs**. (Figure 7-11a; Table 7-1)
- 36. Cardiac muscle cells have *automaticity* and do not require neural stimulation to contract. Their contractions last longer than those of skeletal muscles, and cardiac muscle cannot undergo tetanus.
- 37. Smooth muscle is nonstriated, involuntary muscle tissue that can contract over a greater range of lengths than skeletal muscle cells. (Figure 7-11b; Table 7-1)
- 38. Many smooth muscle cells lack direct connections to motor neurons. If innervated, they are not under voluntary control.

7-9 Descriptive terms are used to name skeletal muscles p. 243

- 39. The muscular system includes approximately 700 skeletal muscles, which can be voluntarily controlled. (Figure 7-12)
- 40. The axial muscles arise on the axial skeleton; they position the head and spinal column and move the rib cage. The appendicular muscles stabilize or move components of the appendicular skeleton.
- **41.** Each muscle can be identified by its **origin**, **insertion**, and primary action. A muscle can be classified by its primary action as a prime mover, or agonist; as a synergist; or as an antagonist.
- **42.** The names of muscles often provide clues to their location, fascicle orientation, or function. (Table 7-2)

7-10 Axial muscles are muscles of the head and neck, vertebral column, trunk, and pelvic floor p. 247

- **43.** The axial muscles fall into four groups based on location and/or function: muscles of (a) the head and neck, (b) the spine, (c) the trunk, and (d) the pelvic floor.
- 44. The muscles of the head include the **frontalis**, orbicularis oris, buccinator, masseter, temporalis, and pterygoids. (Figure 7-13; Table 7-3)
- 45. The muscles of the neck include the platysma, digastric, mylohyoid, stylohyoid, omohyoid, and sternocleidomastoid. (Figure 7-13, 7-14; Table 7-3)
- 46. The splenius capitis and semispinalis capitis are the most superior muscles of the spine. The extensor muscles of the spine, or erector spinae, can be classified into the spinalis, longissimus, and iliocostalis groups. In the lower lumbar and sacral regions, the longissimus and iliocostalis are sometimes called the sacrospinalis muscles. (Figure 7-15; Table 7-4)

- 47. The muscles of the trunk include the **oblique** and rectus muscles. The thoracic region muscles include the intercostal and transversus muscles. Also important to respiration is the **diaphragm**. (Figure 7-16; Table 7-5)
- **48.** The muscular floor of the pelvic cavity is called the **perineum**. These muscles support the organs of the pelvic cavity and control the movement of materials through the urethra and anus. (Figure 7-17; Table 7-6)

7-11 Appendicular muscles are muscles of the shoulders, upper limbs, pelvic girdle, and lower limbs p. 255

- 49. Together, the trapezius and the sternocleidomastoid affect the position of the shoulder, head, and neck. Other muscles inserting on the scapula include the **rhomboids**, the levator scapulae, the serratus anterior, and the pectoralis minor. (Figure 7-18; Table 7-7)
- 50. The **deltoid** and the **supraspinatus** produce abduction of the arm at the shoulder. The **subscapularis**, **teres major**, infraspinatus, and teres minor rotate the arm at the shoulder. (Figure 7-19; Table 7-8)
- **51.** The **pectoralis major** flexes the shoulder joint, and the latissimus dorsi extends it. Both of these muscles adduct and rotate the arm at the shoulder joint. (Figure 7-19; Table 7-8)
- 52. The primary actions of the biceps brachii and the triceps brachii affect the elbow. The brachialis and brachioradialis flex the elbow. The flexor carpi radialis, the flexor carpi ulnaris, and the palmaris **longus** cooperate to flex the wrist. They are opposed by the extensor carpi radialis and the extensor carpi ulnaris. The **pronator** muscles pronate the forearm, opposed by the supinator and the biceps brachii. (Figure 7-20; Table 7-9)
- 53. Gluteal muscles cover the lateral surfaces of the ilia. They produce extension, abduction, and rotation at the hip. (Figure 7-21a,b; Table 7-10)

- 54. Adductors of the thigh work across the hip joint. These muscles include the adductor magnus, adductor brevis, adductor longus, pectineus, and gracilis. (Figure 7-21c; Table 7-10)
- 55. The psoas major and the iliacus merge to form the iliopsoas muscle, a powerful flexor of the hip. (Figure 7-21c; Table 7-10)
- **56.** The flexors of the knee include the hamstrings (**biceps** femoris, semimembranosus, and semitendinosus) and sartorius. The popliteus aids flexion by unlocking the knee. (Figure 7-22; Table 7-11)
- **57.** The *knee extensors* are known as the **quadriceps femoris**. This group includes the three **vastus** muscles and the rectus femoris. (Figure 7-22; Table 7-11)
- 58. The gastrocnemius and soleus muscles produce plantar flexion (ankle extension). A pair of fibularis muscles produces eversion as well as plantar flexion and a third also produces dorsiflexion (ankle flexion). The tibialis anterior performs dorsiflexion. (Figure 7-23; Table 7-12)
- **59.** The phalanges are controlled by muscles originating at the tarsal bones and at the metatarsal bones. (Table 7-12)

7-12 The size and power of muscle tissue decrease with advancing age p. 266

60. Aging reduces the size, elasticity, and power of all muscle tissues. Both exercise tolerance and the ability to recover from muscular injuries decrease with age.

7-13 Exercise produces responses in multiple body **systems** *p. 267*

61. Exercise integrates the muscular system with the cardiovascular, respiratory, integumentary, nervous, and endocrine systems.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A

- a. contains ACh receptors
- **c.** contractile units
- **d.** thin filaments
- **e.** surrounds muscle fiber
- **f.** muscle enlargement
- g. surrounds muscle
- **h.** slow fibers

i. thick filaments

See the blue Answers tab at the back of the book.

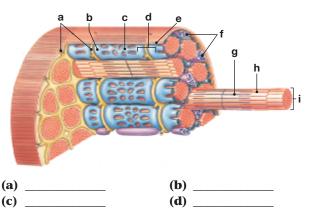

- i. bundle of muscle fibers
- **k.** hamstring muscles
- **1.** covers active sites on actin
- **m.** transmits action potentials
- **n.** fast fibers
- **o.** quadriceps muscles
- p. multiple motor units

1. epimysium 9. sarcomeres **2.** fascicle **10.** tropomyosin _____ **3.** endomysium _____ **11.** recruitment _____ **4.** motor end plate **12.** muscle tone **5.** transverse tubule **13.** white muscles **6.** actin **14.** flexors of the leg 7. myosin **15.** red muscles **8.** extensors of the knee _____ **16.** hypertrophy

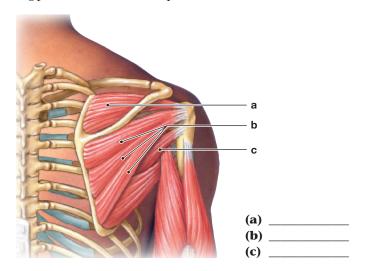

COLUMN B

- **b.** resting muscle tension

17. Identify the structures in the following figure.

- (e) _____ (f) ____ (g) ____ (h) ____
- (g) ____ (i)
- 18. In comparison to fast fibers in skeletal muscles, slow fibers(a) have larger diameters.
 - **(b)** are rich in myoglobin.
 - (c) contain relatively fewer mitochondria.
 - (d) are the predominating fiber type in the eye muscles.
- **19.** Label the three visible muscles of the rotator cuff in the following posterior view of the deep muscles that move the arm.

- **20.** How does isotonic contraction differ from isometric contraction in a muscle?
- **21.** What is the role of calcium ions in skeletal muscle contraction?
- **22.** List the muscles involved when tightening a screw with the right hand.

Level 2 Reviewing Concepts

- **23.** Contraction of a muscle fiber results in the shortening of the
 - (a) A and H bands. (b) A and I bands.
 - (c) H and I bands. (d) A, H, and I bands.
- **24.** Describe the basic sequence of events that occurs at a neuro-muscular junction.

- **25.** Why is it important for slow muscle fibers to have a high concentration of myoglobin?
- **26.** The muscles of the spine include many dorsal extensors but few ventral flexors. Why?
- 27. How does shivering help us when we feel cold?
- **28.** How will the eye be affected if the orbicularis oculi muscle is paralyzed?

Level 3 Critical Thinking and Clinical Applications

- **29.** Many potent insecticides contain toxins called *organophosphates*, which interfere with the action of the enzyme acetylcholinesterase. Terry is using an insecticide containing organophosphates and is very careless. He does not use gloves or a mask, so he absorbs some of the chemical through his skin and inhales a large amount as well. What signs would you expect to observe in Terry as a result of organophosphate poisoning?
- **30.** The time of a murder victim's death is commonly estimated by the flexibility or stiffness of the body. Explain why this is possible.
- **31.** Injecting botulinum toxin can help to reduce facial wrinkles. How is this possible?

The Nervous System

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **8-1** Describe the anatomical and functional divisions of the nervous system.
- **8-2** Distinguish between neurons and neuroglia on the basis of structure and function.
- **8-3** Describe the events involved in the generation and propagation of an action potential.
- **8-4** Describe the structure of a synapse, and explain the process of nerve impulse transmission at a synapse.
- **8-5** Describe the three meningeal layers that surround the central nervous system.
- **8-6** Discuss the roles of gray matter and white matter in the spinal cord.
- **8-7** Name the major regions of the brain, and describe the locations and functions of each.
- **8-8** Name the cranial nerves, relate each pair of cranial nerves to its principal functions, and relate the distribution pattern of spinal nerves to the regions they innervate.
- **8-9** Describe the steps in a reflex arc.
- **8-10** Identify the principal sensory and motor pathways, and explain how it is possible to distinguish among sensations that originate in different areas of the body.
- **8-11** Describe the structures and functions of the sympathetic and parasympathetic divisions of the autonomic nervous system.
- **8-12** Summarize the effects of aging on the nervous system.
- **8-13** Give examples of interactions between the nervous system and other body systems presented so far.

An Introduction to the Nervous System

Two organ systems coordinate organ system activities to maintain homeostasis in response to changing environmental conditions. They are the *nervous system* and the *endocrine system*. The nervous system responds relatively swiftly but briefly to stimuli. In contrast, responses by the endocrine system develop more slowly but last much longer. (We consider the endocrine system in Chapter 10.)

The nervous system is your most complex organ system. For example, right now you are consciously reading these words and thinking about them. At the subconscious level (outside your awareness), it is doing much more. Your nervous system is also monitoring the external environment and your internal systems and issuing commands as needed to maintain homeostasis. Yet in a few hours—at mealtime or while you are sleeping—your pattern of nervous system activity will be very different. The change from one pattern of activity to another can take place in almost an instant because neural function relies on electrical events that proceed at great speed.

In this chapter we examine the structure and function of the nervous system. We consider its cells through their organization into two major divisions: the *central nervous system* and the *peripheral nervous system*.

Build Your Knowledge

Recall that the nervous system directs immediate responses to stimuli (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). It usually does so by coordinating the activities of other organ systems. It also provides and interprets sensory information about internal and external conditions. \bigcirc **p. 37**

8-1 The nervous system has anatomical and functional divisions

Learning Outcome Describe the anatomical and functional divisions of the nervous system.

The **nervous system** carries out three main functions. It (1) monitors the body's internal and external environments, (2) integrates sensory information, and (3) coordinates voluntary and involuntary responses of many other organ systems.

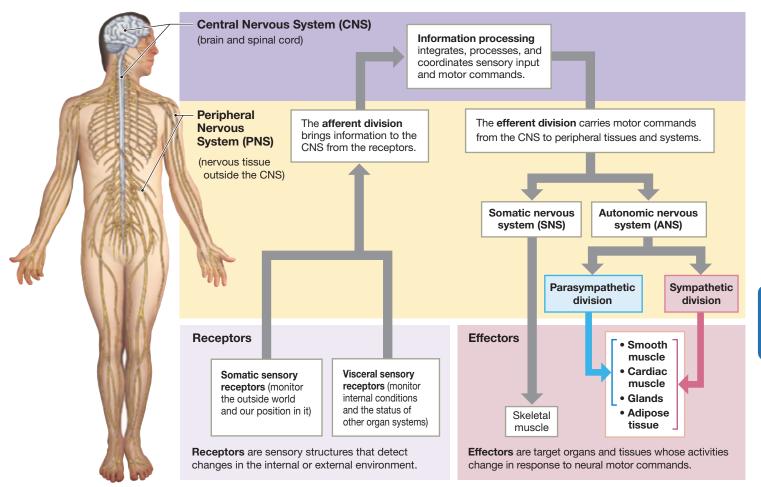

The nervous system has two major anatomical divisions. The **central nervous system (CNS)** consists of the *brain* and the *spinal cord*. It integrates and coordinates the processing of sensory data and the transmission of motor commands. The CNS is also the seat of higher functions, such as intelligence, memory, and emotion. All communication between the CNS and the rest of the body takes place through the **peripheral nervous system (PNS)**, which includes all the nervous tissue *outside* the CNS.

Figure 8-1 presents an overview of the functional relationships of the CNS and PNS. Notice that the PNS itself consists of two divisions. The **afferent division** (*afferens*, to bring to) of the PNS brings sensory information *to* the CNS from *receptors* in body tissues and organs. **Receptors** are sensory structures that either detect changes in the environment (internal or external) or respond to specific stimuli. The **efferent division** (*effero*, to bring out) of the PNS carries motor commands *from* the CNS to muscles and glands. These target organs and tissues respond by *doing* something and are called **effectors**.

The efferent division of the PNS has two parts. The **somatic nervous system (SNS)** controls skeletal muscle contractions. *Voluntary* contractions are under conscious control, such as when you lift a glass of water to your lips. *Involuntary* contractions are simple or complex movements controlled at the subconscious level. For example, if you accidentally place your hand on a hot stove, you will pull it back immediately, even before you notice any pain. This type of automatic response is called a *reflex*.

The **autonomic nervous system (ANS)**, or *visceral motor system*, automatically regulates smooth muscle, cardiac muscle, glandular secretions, and adipose tissue at the subconscious level. The ANS includes a *sympathetic division* and a *parasympathetic division*, which commonly have opposite effects. For example, activity of the sympathetic division speeds up your heart rate, but the parasympathetic division slows your heart rate.

The ANS also includes a third division, called the *enteric nervous system* (*ENS*). The ENS is the network of nervous tissue in the walls of the digestive tract. It helps control digestive functions independent of the CNS. We consider its role in Chapter 16.

CHECKPOINT

- **1.** Identify the two anatomical divisions of the nervous system.
- **2.** Identify the two functional divisions of the peripheral nervous system, and describe their primary functions.
- **3.** What would be the effect of damage to the afferent division of the PNS?

See the blue Answers tab at the back of the book.

8-2 Neurons are specialized for intercellular communication and are supported by cells called neuroglia

Learning Outcome Distinguish between neurons and neuroglia on the basis of structure and function.

The nervous system includes all the neural tissue in the body. Neural tissue (introduced in Chapter 4) consists of

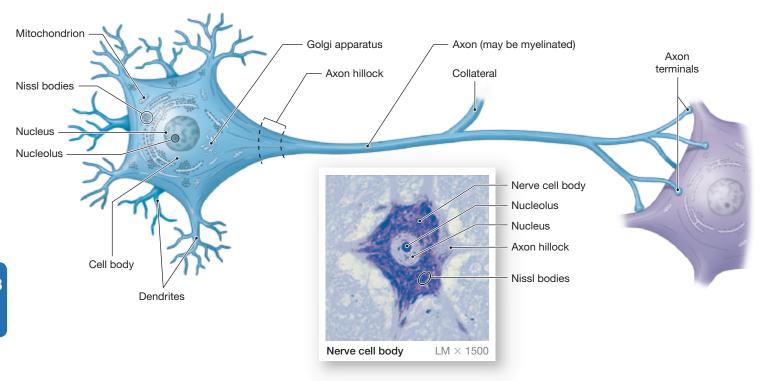

two kinds of cells, *neurons* and *neuroglia*. \supset p. 143 **Neurons** (*neuro*-, nerve) are the basic functional units of the nervous system. All neural functions involve the communication of neurons with one another and with other cells. The **neuro-glia** (noo-ROG-lē-uh; *glia*, glue) regulate the environment around neurons, provide a supporting framework for neural tissue, and act as phagocytes. Although they are much smaller cells, neuroglia (also called *glial cells*) far outnumber neurons. Unlike most neurons, most glial cells retain the ability to divide.

Neurons

The General Structure of Neurons

Neurons can have a variety of shapes. **Figure 8-2** shows a *multipolar neuron*, the most common type of neuron in the CNS. A multipolar neuron has (1) a cell body; (2) several branching, sensitive **dendrites**, which receive incoming

Figure 8-2 The Anatomy of a Representative Neuron. The relationships of the four parts of a neuron (dendrites, cell body, axon, and axon terminals) are shown in the multipolar neuron depicted here.

signals; and (3) a single long axon, which carries outgoing signals toward (4) one or more **axon terminals**.

The **cell body** contains a large, round nucleus with a prominent nucleolus. The cytoplasm of the cell body contains organelles that provide energy and synthesize organic compounds. The numerous mitochondria, free and fixed ribosomes, and membranes of the rough endoplasmic reticulum (RER) give the cytoplasm a coarse, grainy appearance. Clusters of RER and free ribosomes are known as **Nissl bodies**. They give a gray color to areas containing neuron cell bodies and account for the color of *gray matter* seen in brain and spinal cord dissections.

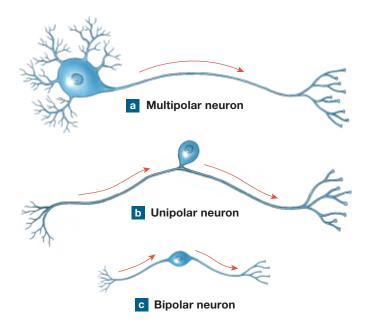

Projecting from the cell body are a variable number of dendrites and a single large axon. The plasma membrane of the dendrites and cell body is sensitive to chemical, mechanical, or electrical stimulation. In a process described later, such stimulation often leads to the generation of an electrical impulse, or *action potential*, that travels along the axon. Action potentials begin at a thickened region of the cell body called the **axon hillock**. The axon may branch along its length, producing branches called *collaterals*. Axon terminals (also called synaptic terminals and synaptic knobs) are found at the tips of each branch. An axon terminal is part of a **synapse**, a site where a neuron communicates with another cell. Most neurons lack centrioles, organelles involved in the movement of chromosomes during mitosis. \supset p. 100 As a result, typical CNS neurons cannot divide, so they cannot be replaced if lost to injury or disease. Neural stem cells are present in the adult nervous system, but they are typically inactive. Exceptions occur in the nose, where the regeneration of olfactory (smell) receptors maintains our sense of smell, and in the *hippocampus*, a portion of the brain involved in storing memories. Researchers are studying the processes that trigger neural stem cell activity, with the goal of preventing or reversing neuron loss due to trauma, disease, or aging.

Structural Classification of Neurons

The billions of neurons in the nervous system are variable in form. Based on the relationship of the dendrites to the cell body and axon, neurons are classified into three types (Figure 8-3):

1. A **multipolar neuron** has two or more dendrites and a single axon (Figure 8-3a). These are the most common neurons in the CNS. All the motor neurons that control skeletal muscles are multipolar. Their axons may be a meter or more in length.

Figure 8-3 A Structural Classification of Neurons. The neurons are not drawn to scale; bipolar neurons are many times smaller than typical unipolar and multipolar neurons. The arrows show the normal direction of an action potential.

- 2. In a unipolar neuron, the dendrites and axon are continuous, and the cell body lies off to one side (Figure 8-3b). In a unipolar neuron, the action potential begins at the base of the dendrites, and the rest of the process is considered an axon. Most sensory neurons of the peripheral nervous system are unipolar. Their axons can be as long as those of multipolar neurons.
- **3. Bipolar neurons** have only one dendrite and one axon, with the cell body between them (**Figure 8-3c**). Bipolar neurons are small and rare. They occur in special sense organs, where they relay information about sight, smell, or hearing from receptor cells to other neurons.

Functional Classification of Neurons

In terms of function, neurons are sorted into three groups: (1) *sensory neurons*, (2) *motor neurons*, and (3) *interneurons*.

SENSORY NEURONS. The approximately 10 million **sensory neurons**, or *afferent neurons*, in the human body form the afferent division of the PNS. Sensory neurons receive information from *sensory receptors* monitoring the external and internal environments and then relay the information to other neurons in the CNS (spinal cord or brain). The receptor may be a dendrite of a sensory neuron or specialized cells of other tissues that communicate with the sensory neuron. Receptors may be categorized according to the information they detect. Two types of **somatic sensory receptors** detect information about the outside world or our physical position within it.

- **1. External receptors** provide information about the external environment in the form of sensations of touch, pressure, pain, and temperature and the more complex senses of taste, smell, sight, equilibrium, and hearing.
- 2. Proprioceptors (prō-prē-ō-SEP-torz; *proprius*, one's own + *capio*, to take) monitor the position and movement of skeletal muscles and joints. Visceral receptors, or internal receptors, monitor the activities of the digestive, respiratory, cardiovascular, urinary, and reproductive systems. They provide sensations of distension, deep pressure, and pain.

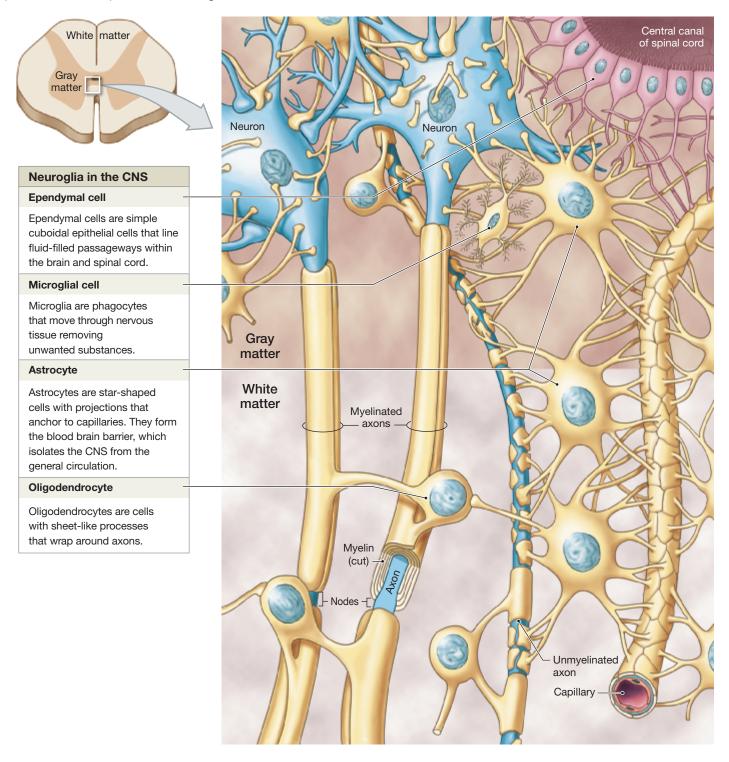

MOTOR NEURONS. The half million **motor neurons**, or *efferent neurons*, of the efferent division carry instructions from the CNS to other tissues, organs, or organ systems. These peripheral targets are called *effectors*. For example, a skeletal muscle is an effector that contracts when it receives neural stimulation. Neurons in the two efferent divisions of the PNS target separate classes of effectors. The **somatic motor neurons** of the somatic nervous system innervate skeletal muscles, and the **visceral motor neurons** of the autonomic nervous system innervate all other effectors, including cardiac muscle, smooth muscle, and glands.

INTERNEURONS. The 20 billion **interneurons**, or *association neurons*, are located entirely within the brain and the spinal cord. Interneurons, as the name implies (*inter*-, between), interconnect other neurons. They are responsible for distributing sensory information and coordinating motor activity. The more complex the response to a given stimulus, the greater the number of interneurons involved. Interneurons also play a role in all higher functions, such as memory, planning, and learning.

Neuroglia

Neuroglia are abundant and diverse. They make up about half of the volume of the nervous system. They are found in both the CNS and PNS, but the CNS has a greater variety of glial cells. The CNS contains four types of neuroglial cells (**Figure 8-4**):

1. Astrocytes (AS-trō-sīts; *astro*-, star + *cyte*, cell) are the largest and most numerous neuroglia. These starshaped cells have varied functions. Astrocytes maintain the *blood brain barrier* that isolates the CNS from the **Figure 8-4 Neuroglia in the CNS.** This diagrammatic view of nervous tissue in the CNS depicts the relationships between neuroglia and neurons.

body's general circulation. Cytoplasmic extensions of the astrocytes end in expanded "feet" that wrap around capillaries. The astrocytes secrete chemicals that cause the capillaries of the CNS to become impermeable to many compounds, such as hormones and amino acids that could interfere with neuron function. Astrocytes also create a structural framework for CNS neurons and perform repairs in damaged neural tissues. 2. Oligodendrocytes (ol-i-gō-DEN-drō-sīts; *oligo*-, few) have smaller cell bodies and fewer processes (cytoplasmic extensions) than astrocytes. The plasma membrane at the tip of each process forms a thin, expanded sheet that wraps around an axon. This membranous wrapping is called **myelin** (MĪ-e-lin). It serves as electrical insulation that increases the speed at which an action potential travels along the axon. Each oligodendrocyte myelinates short segments of several axons, so many oligodendrocytes are needed to coat an entire axon with myelin. Such

an axon is said to be **myelinated**. The areas covered in myelin are called **internodes**. The small gaps between adjacent cell processes are called **nodes**, or the *nodes of Ranvier* (rahn-vē-Ā).

Myelin is lipid-rich, and on dissection, areas of the CNS containing myelinated axons appear glossy white. Areas dominated by myelinated axons are known as the **white matter** of the CNS. Not every axon in the CNS is myelinated. Axons without a myelin coating are said to be **unmyelinated**. Areas containing neuron cell bodies, dendrites, and unmyelinated axons make up the **gray matter** of the CNS.

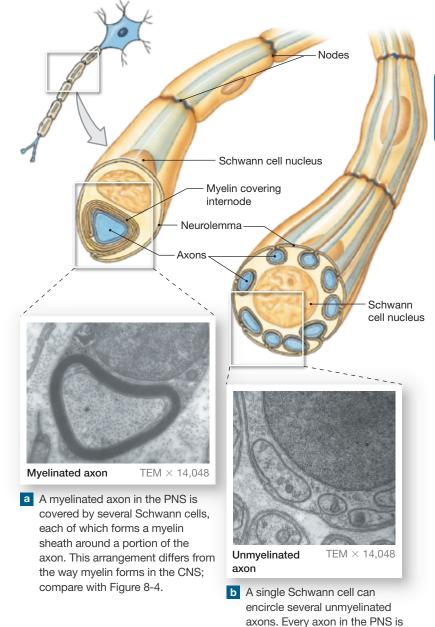

- **3. Microglia** (mī-KRŌG-lē-uh) are the smallest and least numerous of the neuroglia in the CNS. Microglia are phagocytic cells derived from white blood cells that migrated into the CNS as the nervous system formed. They perform protective functions such as engulfing cellular waste and pathogens.
- **4. Ependymal** (ep-EN-di-mul) **cells** are simple cuboidal epithelial cells that line cavities in the CNS filled with cerebrospinal fluid (CSF). These cavities include the *central canal* of the spinal cord and the chambers, or *ventricles*, of the brain. The lining of epithelial cells is called the **ependyma** (ep-EN-di-muh). Unlike other epithelia, it lacks a basement membrane. In some regions of the brain, the ependyma produces CSF. In other locations, the cilia on ependymal cells help circulate this fluid within and around the CNS.

The PNS contains two types of neuroglia. **Satellite cells** surround and support neuron cell bodies in the peripheral nervous system, much as astrocytes

do in the CNS. The other glial cells in the PNS are **Schwann cells**, also called *neurolemmocytes* (**Figure 8-5a**).

Schwann cells cover every axon outside the CNS. Wherever a Schwann cell covers an axon, the outer surface of the Schwann cell is called the *neurolemma* (nū-rō-LEM-uh). Unlike an oligodendrocyte in the CNS, which may myelinate portions of several axons, a Schwann cell can myelinate only one segment of a single axon (**Figure 8-5a**). However, a Schwann cell can enclose portions of several different unmyelinated axons (**Figure 8-5b**).

Figure 8-5 Schwann Cells and Peripheral Axons.

completely enclosed by Schwann cells.

Organization of Neurons in the Nervous System

Neuron cell bodies and their axons are not randomly scattered in the CNS and PNS. Instead, they are organized into masses or bundles that have distinct anatomical boundaries and are identified by specific terms (**Figure 8-6**). We will use these terms again, so you may find a brief overview here helpful.

In the PNS:

- Neuron cell bodies (gray matter) are located in **ganglia** (singular, *ganglion*). The neuron cell bodies are surrounded by satellite cells.
- The white matter of the PNS contains axons bundled together in **nerves**. *Spinal nerves* are connected to the spinal cord, and *cranial nerves* are connected to the brain. Both sensory and motor axons may be present in the same nerve.

- A collection of neuron cell bodies (gray matter) with a common function is called a **center**. A center with a discrete boundary is called a **nucleus**. Portions of the brain surface are covered by a thick layer of gray matter called **neural cortex** (*cortex*, rind). The term *higher centers* refers to the most complex integration centers, nuclei, and areas of cortex in the brain.
- The white matter of the CNS contains bundles of axons that share common origins, destinations, and functions. These bundles are called **tracts**. Tracts in the spinal cord form larger groups called **columns**.
- **Pathways** include both gray matter and white matter. They link the centers of the brain with the rest of the body. For example, **sensory** (*ascending*) **pathways** distribute information from sensory receptors to processing centers in the brain. **Motor** (*descending*) **pathways** begin at CNS centers for motor activity and end at the skeletal muscles they control.
- **CENTRAL NERVOUS SYSTEM** GRAY MATTER ORGANIZATION PERIPHERAL Neural Cortex Centers **NERVOUS SYSTEM** Gray matter on the Collections of neuron cell bodies surface of the brain **GRAY MATTER** in the CNS; each Ganglia center has specific processing functions Collections of Nuclei neuron cell bodies Collections of in the PNS **Higher Centers** neuron cell bodies in the interior of The most complex WHITE MATTER the CNS centers in the brain Nerves WHITE MATTER ORGANIZATION Bundles of axons in the PNS Tracts Columns Bundles of CNS Several tracts that axons that share form an anatomically a common origin, distinct mass destination, and RECEPTORS function PATHWAYS Centers and tracts that connect the brain with other organs and systems in the body **EFFECTORS** Ascending (sensory) pathway Descending (motor) pathway

8

Figure 8-6 Anatomical Organization of the Nervous System.

CLINICAL NOTE

Demyelination Disorders

Demyelination is the progressive destruction of myelin sheaths, both in the CNS and PNS. The result is a gradual loss of sensation and motor control that leaves affected body regions numb and paralyzed. One demyelination disorder is **multiple sclerosis** (skler-Ō-sis; sklerosis, hardness), or **MS**. It affects axons in the optic nerve, brain, and/or spinal cord. Common signs and symptoms of MS include partial loss of vision and problems with speech, balance, and general motor coordination. Other important demyelination disorders include *heavy metal poisoning, Charcot-Marie-Tooth disease*, and *Guillain-Barré syndrome*.

CHECKPOINT

- **4.** Name the structural components of a typical neuron.
- **5.** Examination of a tissue sample reveals unipolar neurons. Are these more likely to be sensory neurons or motor neurons?
- 6. Identify the neuroglia of the central nervous system.
- **7.** Which type of glial cell would increase in number in the brain tissue of a person with a CNS infection?
- In the PNS, neuron cell bodies are located in
 <u>and surrounded by neuroglial cells</u>
 called
 cells.

8-3 In neurons, a change in the plasma membrane's electrical potential may result in an action potential (nerve impulse)

Learning Outcome Describe the events involved in the generation and propagation of an action potential.

The sensory, integrative, and motor functions of the nervous system are dynamic and ever changing. All communications between neurons and other cells take place through their membrane surfaces. These membrane changes are electrical events that proceed at great speed.

The Membrane Potential

A characteristic feature of all living cells is a *polarized* plasma membrane. An undisturbed, or unstimulated, cell has a plasma membrane that is polarized because the membrane separates an excess of positive charges outside the cell from an excess of negative charges inside the cell. When positive and negative charges are held apart, a *potential difference* is said to exist between them. This potential difference is called a **membrane potential**, or *transmembrane potential*, because the charges are separated by a plasma membrane.

The unit of measurement of potential difference is the *volt* (V). Most cars, for example, have 12 V batteries. The membrane potential of cells is much smaller and is usually reported in *millivolts* (mV, thousandths of a volt). The membrane potential of an unstimulated, resting cell is known as its **resting membrane potential**. The resting membrane potential of a neuron is -70 mV. The minus sign indicates that the cytoplasmic surface of the plasma membrane contains an excess of negative charges compared to the extracellular surface.

Factors Responsible for the Membrane Potential

Many factors influence membrane potential. In addition to an imbalance of electrical charges, the intracellular and extracellular fluids differ markedly in chemical and ionic composition. For example, the extracellular fluid contains relatively high concentrations of sodium ions (Na⁺) and chloride ions (Cl⁻). The intracellular fluid contains high concentrations of potassium ions (K⁺) and negatively charged proteins (Pr⁻).

The selective permeability of the plasma membrane maintains these differences between the intracellular and extracellular fluids. The proteins within the cytoplasm are too large to cross the membrane. The ions can enter or leave the cell only with the aid of membrane channels and/or carrier proteins. \bigcirc p. 91 There are many different types of membrane channels:

- Some, called *leak channels*, are always open.
- Others, called *gated channels*, open or close under specific circumstances. For example, gated channels may open or close due to the presence of a specific chemical, ion, or a change in membrane potential, or voltage.

Both passive and active processes act across the plasma membrane to determine the membrane potential at any moment. The passive forces are chemical and electrical. Chemical concentration gradients move potassium ions out of the cell and sodium ions into the cell. (These ions move through separate leak channels.) However, it is easier for potassium ions to diffuse through a potassium channel than for sodium ions to diffuse through sodium channels. As a result, potassium ions diffuse out of the cell faster than sodium ions enter the cell. Electrical forces across the membrane also affect the passive movement of sodium and potassium ions. The overall positive charge on the outer surface of the plasma membrane repels positively charged potassium ions. At the same time, the negatively charged inner membrane surface attracts the positively charged sodium ions. Potassium ions continue to leave the cell, however, because its chemical concentration gradient is stronger than the repelling electrical force.

To maintain a potential difference across the plasma membrane, active processes work both to overcome the combined chemical and electrical forces driving sodium ions into the cell and to maintain the potassium concentration gradient. The resting potential remains stable over time because of the actions of a carrier protein, the sodium–potassium exchange pump. \supset p. 96 This ion pump exchanges three intracellular sodium ions for two extracellular potassium ions. At the normal resting membrane potential of -70 mV, sodium ions are ejected as fast as they enter the cell. The cell, therefore, undergoes a net loss of positive charges. As a result, the interior surface of the plasma membrane maintains an excess of negative charges, primarily from negatively charged proteins. **Figure 8-7** shows the plasma membrane at the resting membrane potential.

Changes in the Membrane Potential

Any stimulus that (1) alters membrane permeability to sodium or potassium ions or (2) alters the activity of the exchange pump will disturb the resting membrane potential of a cell. Some stimuli that can affect membrane potential include exposure to specific chemicals, mechanical pressure, changes in temperature, or shifts in the extracellular ion concentrations. Any change in the resting potential can have an immediate effect on the cell. For example, permeability changes in the sarcolemma of a skeletal muscle fiber trigger a contraction. \bigcirc p. 229

In most cases, a stimulus opens gated ion channels that are closed when the plasma membrane is at its resting membrane potential. The opening of these channels speeds up ion movement across the plasma membrane and changes the membrane potential. For example, the opening of gated sodium ion channels speeds up the entry of sodium ions (Na⁺) into the cell. As the number of positively charged ions on the inner surface of the plasma membrane increases, the membrane potential shifts toward 0 mV. A shift in this direction is called a **depolarization** of the membrane.

On the other hand, a stimulus that opens gated potassium ion channels shifts the membrane potential away from 0 mV,

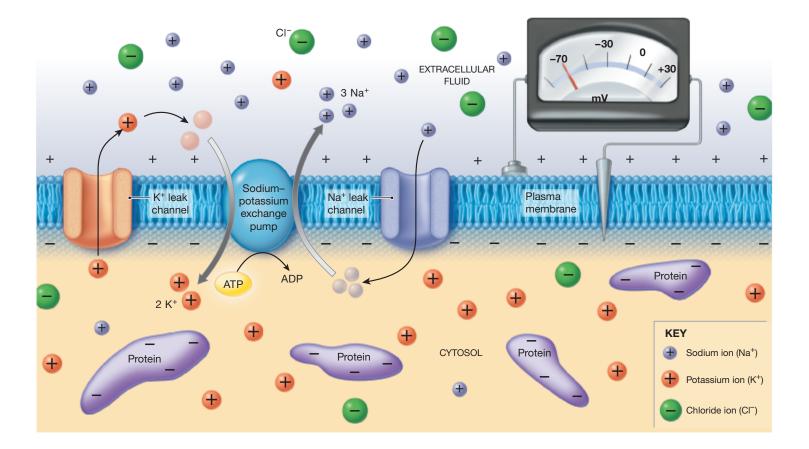

Figure 8-7 The Resting Membrane Potential.

because additional potassium ions (K⁺) will leave the cell. Such a change may take the membrane potential from -70 mV to -80 mV. This kind of shift is called a **hyperpolarization**.

Information transfer between neurons and other cells involves two types of change in membrane potential: graded potentials and action potentials. **Graded potentials**, or *local potentials*, are changes in the membrane potential that cannot spread far from the site of stimulation. For example, if a chemical stimulus to the plasma membrane of a neuron opens gated sodium ion channels at a single site, the Na⁺ entering the cell will depolarize the membrane at that location. Attracted to surrounding negative ions, the Na⁺ move along the inner surface of the membrane in all directions. The degree of depolarization decreases with distance from the stimulation site. Why? This happens because the cytosol resists ion movement and because some sodium ions are lost as they move back out across the membrane through leak channels.

Graded potentials occur in the plasma membranes of all cells in response to environmental stimuli. They often trigger specific cell functions. For example, a graded potential in the membrane of a gland cell may trigger secretion. However, graded potentials affect too small an area to have an effect on the activities of such large cells as skeletal muscle fibers or neurons. In these cells, graded potentials can influence activities in distant portions of the cell only if they generate an *action potential*, an electrical signal that affects the surface of the entire membrane.

An **action potential** is a propagated change in the membrane potential of excitable cells. Only *excitable cells* have an electrically *excitable membrane* that can be stimulated to propagate action potentials. Excitable membranes contain *voltage-gated ion channels* that open or close in response to changes in the membrane potential. Skeletal muscle fibers, cardiac muscle cells, and the axons of neurons have excitable membranes.

In a skeletal muscle fiber, the action potential begins at the neuromuscular junction and travels along the entire membrane surface, including the T tubules. \bigcirc p. 234 The resulting ion movements trigger a contraction.

In an axon, an action potential usually begins near the axon hillock and travels along the length of the axon toward the axon terminals, where its arrival activates the synapses. An action potential in a neuron is also known as a **nerve impulse**. (We discuss action potentials in cardiac muscle cells in Chapter 12.)

Action potentials are generated by the opening and closing of voltage-gated Na⁺ channels and voltage-gated K⁺ channels in response to a graded potential. This local depolarization acts like pressure on the trigger of a gun. A gun fires only after a certain minimum pressure has been applied to the trigger. It does not matter whether the pressure builds gradually or is exerted suddenly—when the pressure reaches a critical point, the gun will fire. Whenever the gun fires, the forces that were

Build Your Knowledge

Recall that a single axon of a motor neuron may branch to control more than one skeletal muscle fiber (as you saw in **Chapter 7: The Muscular System**). Each branch ends in an axon terminal that is part of a neuromuscular junction. Each skeletal muscle fiber has only one neuromuscular junction. A motor unit is a single motor neuron and all the muscle fibers it innervates. **`p. 235**

applied to the trigger have no effect on the speed of the bullet leaving the gun. In an axon, the graded potential is the pressure on the trigger, and the action potential is like the firing of the gun. An action potential will not appear unless the membrane depolarizes to a level known as the **threshold**.

Every stimulus (whether minor or extreme) that brings the membrane to threshold will generate an identical action potential. This concept is called the **all-or-none principle** because a given stimulus either triggers a typical action potential or none at all. The all-or-none principle applies to all excitable membranes.

The Generation of an Action Potential

How is an action potential generated? An action potential begins when the first portion of the excitable axon membrane, called the *initial segment*, depolarizes to threshold. The steps involved in generating an action potential begin with a graded depolarization to threshold (from -70 mV to -60 mV) and end with a return to the resting membrane potential (-70 mV). The steps are illustrated in **Spotlight Figure 8-8**.

The membrane cannot respond normally to further stimulation during most of these steps. This period is known as the **refractory period** of the membrane. It lasts from the moment the voltage-gated sodium channels open at threshold until the return to the resting potential, or **repolarization**, is complete. The refractory period limits the rate at which action potentials can be generated in an excitable membrane. (The maximum rate of action potential generation is 500–1000 per second.)

Propagation of an Action Potential

An action potential initially involves a relatively small portion of the total membrane surface of the axon. But unlike graded potentials, which diminish rapidly with distance, action potentials affect the entire membrane surface. The basic processes of action potential propagation along unmyelinated and myelinated axons are shown in **Spotlight Figure 8-9** (p. 286).

SPOTLIGHT Figure 8-8 THE GENERATION OF AN ACTION POTENTIAL

A neuron receives information on its dendrites and cell body, and communicates that information to another cell at its axon terminal. Because the two ends of the neuron may be a meter apart, such long-range communication relies on action potentials.

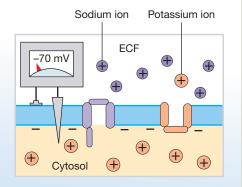

Action potentials are propagated changes in the membrane potential that, once started, affect the entire excitable membrane of the axon. Action potentials depend on the presence of voltage-gated sodium and potassium ion channels.

Axon hillock

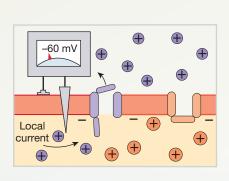

Initial segment (first portion of excitable axon membrane to reach threshold)

Steps in the generation of an action potential in an axon. The first step is a graded depolarization caused by the opening of chemically gated sodium ion channels, usually at the axon hillock. The axon membrane colors in steps 1–4 match the colors of the line graph showing changes in the membrane potential.

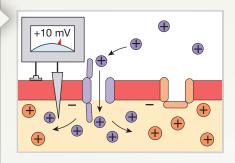

Resting Membrane Potential

The axon membrane contains both voltage-gated sodium channels and voltage-gated potassium channels that are closed when the membrane is at the resting membrane potential. **Depolarization to Threshold**

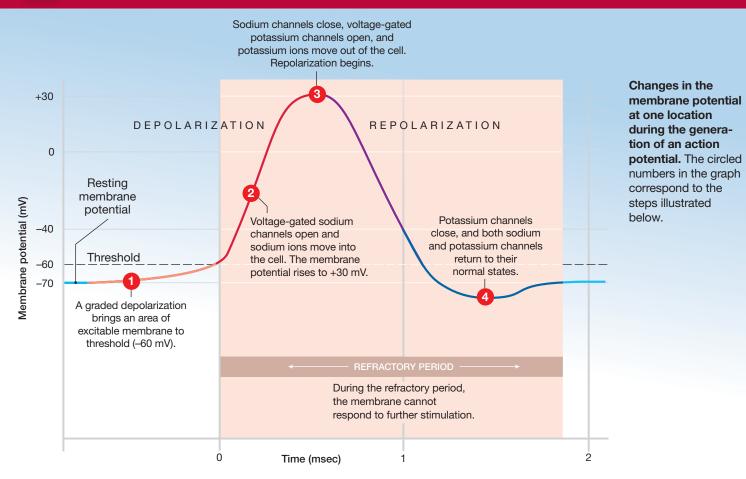

The stimulus that begins an action potential is a graded depolarization large enough to open voltage-gated sodium channels. The opening of the channels occurs at a membrane potential known as the threshold. Activation of Sodium Ion Channels and Rapid Depolarization

When the voltage-gated sodium channels open, sodium ions rush into the cytosol, and rapid depolarization occurs. The inner membrane surface now contains more positive ions than negative ones, and the membrane potential has changed from -60 mV to a positive value.

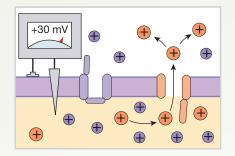

Go to **Mastering A&P** > Study Area > Menu > MP3 Tutor Session > Generation of an Action Potential

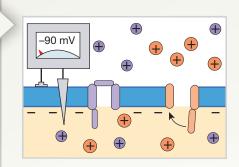

3 Inactiv

>

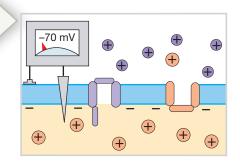

Inactivation of Sodium Ion Channels and Activation of Potassium Ion Channels

As the membrane potential approaches +30 mV, voltage-gated sodium channels close. This step coincides with the opening of voltage-gated potassium channels. Positively charged potassium ions move out of the cytosol, shifting the membrane potential back toward resting levels. Repolarization now begins. Closing of Potassium Ion Channels

The voltage-gated sodium channels remain inactivated until the membrane has repolarized to near threshold levels. The voltagegated potassium channels begin closing as the membrane reaches the normal resting potential (about –70 mV). Until all have closed, potassium ions continue to leave the cell. This produces a brief hyperpolarization. **Return to Resting Membrane Potential**

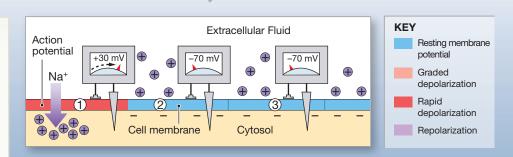

As the voltage-gated potassium channels close, the membrane potential returns to normal resting levels. The action potential is now over, and the membrane is once again at the resting membrane potential.

SPOTLIGHT Figure 8-9 PROPAGATION OF AN ACTION POTENTIAL

Continuous Propagation along an Unmyelinated Axon

In an unmyelinated axon, an action potential moves along by continuous propagation. The action potential spreads by depolarizing the adjacent region of the axon membrane. This process continues to spread as a chain reaction down the axon.

As an action potential develops at the initial segment ①, the membrane potential at this site depolarizes to +30 mV.

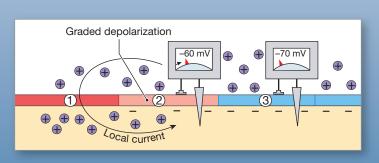

Axon hillock

Initial segment

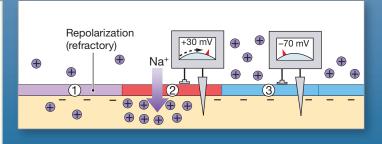

123

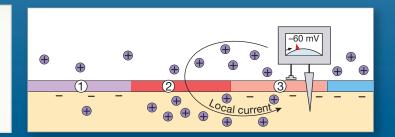

As the sodium ions entering at (1) spread away from the open voltage-gated channels, a graded depolarization quickly brings the membrane in segment (2) to threshold.

An action potential now occurs in segment ② while segment ① begins repolarization.

As the sodium ions entering at segment (2) spread laterally, a graded depolarization quickly brings the membrane in segment (3) to threshold, and the cycle is repeated.

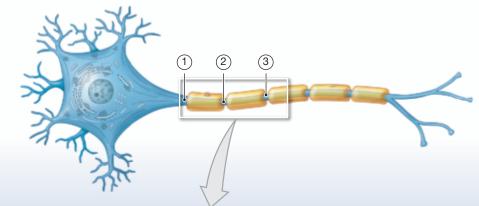

2

3

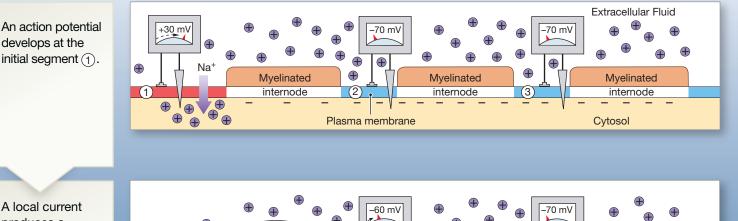

Δ

Saltatory Propagation along a Myelinated Axon

Because myelin limits the movement of ions across the axon membrane, the action potential must "jump" from node to node during propagation. This results in much faster propagation along the axon.

Repolarization (refractory) +30 m\ -70 mV \oplus Na⁺ Ð (1)(2) \oplus \oplus \oplus Ð Æ \oplus $\oplus \oplus \oplus \oplus$

A local current produces a graded depolarization that brings the axon membrane at node (3) to threshold.

For simplicity, think of the plasma membrane as a series of adjacent segments (**Spotlight Figure 8-9a**).

The action potential begins at the axon's initial segment. For a brief moment at the peak of the action potential, the membrane potential becomes positive rather than negative (1). A *local current* then develops as the sodium ions begin moving in the cytosol and the extracellular fluid (2). The local current of moving sodium ions spreads in all directions, depolarizing adjacent portions of the membrane. (The axon hillock cannot respond with an action potential because it does not have voltage-gated sodium ion channels.) The process then continues in a chain reaction (3 and 4).

Each time a local current develops, the action potential moves forward along the axon. *It does not move backward, because the previous segment of the axon is still in the refractory period.* As a result, an action potential always proceeds away from its generation site and cannot reverse direction. Eventually, it reaches the most distant portions of the plasma membrane. This form of action potential transmission is known as **continuous propagation**. You might compare continuous propagation to a person walking toward some destination by taking small "baby steps." Progress is made, but slowly. Continuous propagation takes place along unmyelinated axons at a speed of about 1 meter per second (2 mph).

In a myelinated fiber, the axon is wrapped in myelin. This wrapping is complete except at the nodes, where adjacent glial cells contact one another. Between the nodes, the lipids of the myelin sheath block the flow of ions across the membrane. As a result, continuous propagation cannot take place. Instead, when an action potential is initiated by the axon hillock, the local current skips the internode and depolarizes the closest node to threshold (**Spotlight Figure 8-9b**). In this way, the action potential jumps from node to node rather than proceeding in a series of small steps. This jumping process is called **saltatory propagation**. Its name comes from *saltare*, the Latin word meaning "to leap." Saltatory propagation carries nerve impulses along an axon at speeds ranging from 18–140 meters per second (40–300 mph). This faster process might be compared to a person jumping over puddles on the way to a destination.

CHECKPOINT

- **9.** What effect would a chemical that blocks the voltagegated sodium ion channels in the excitable axon membrane of a neuron have on its ability to depolarize?
- **10.** What effect would decreasing the concentration of extracellular potassium ions have on the membrane potential of a neuron?
- **11.** List the steps involved in the generation of an action potential.

12. Two axons are tested for propagation velocities (speeds). One carries action potentials at 50 meters per second, the other at 1 meter per second. Which axon is myelinated?

See the blue Answers tab at the back of the book.

8-4 At synapses, communication takes place among neurons or between neurons and other cells

Learning Outcome Describe the structure of a synapse, and explain the process of nerve impulse transmission at a synapse.

Recall that a synapse is a site where a neuron communicates with another cell. In the nervous system, information moves from one location to another in the form of action potentials (nerve impulses) along axons. At the end of an axon, the arrival of an action potential results in the transfer of information to another neuron or to an effector cell. The information transfer takes place through the release of chemicals called **neurotransmitters** from the axon terminal.

The synapse where one neuron communicates with another may be on a dendrite, on the cell body, or along the length of the axon. Synapses between a neuron and another cell type are called **neuroeffector junctions**. As you have learned, a neuron communicates with a muscle cell at a *neuromuscular junction*. \supset p. 227 At a *neuroglandular junction*, a neuron controls or regulates the activity of a secretory cell.

Structure of a Synapse

Communication between neurons and other cells takes place in only one direction across a synapse. At a synapse between two neurons, the nerve impulse passes from the axon terminal of the sending neuron, called the **presynaptic neuron**, to the receiving neuron, called the **postsynaptic neuron** (Figure 8-10). The opposing plasma membranes are separated by a narrow space called the **synaptic cleft**.

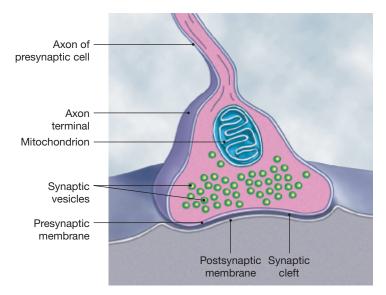

Each axon terminal contains synaptic vesicles. Each vesicle contains several thousand molecules of a specific neurotransmitter. Upon stimulation, many of these vesicles release their contents into the synaptic cleft. The neurotransmitter then diffuses across the synaptic cleft and binds to receptors on the postsynaptic membrane.

Synaptic Function and Neurotransmitters

There are many different neurotransmitters. The neurotransmitter **acetylcholine**, or **ACh**, is released at **cholinergic synapses**. These synapses are widespread inside and outside of

Figure 8-10 The Structure of a Typical Synapse.

A diagrammatic view of a typical synapse between two neurons.

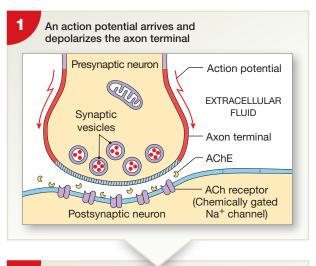

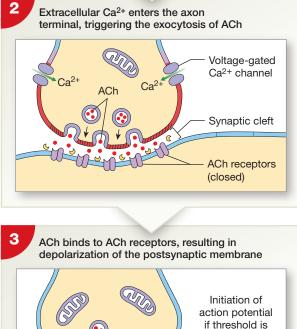

the CNS. The neuromuscular junction (described in Chapter 7) is one example. **Figure 8-11** shows the major events that take place at a cholinergic synapse after an action potential arrives at the presynaptic neuron:

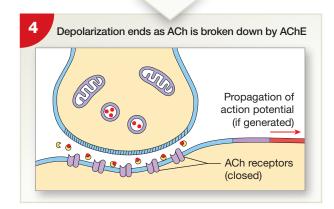

- **1**. An action potential arrives and depolarizes the axon terminal.
- 2. The axon terminal releases the neurotransmitter ACh. Depolarization of the presynaptic membrane causes voltage-gated calcium ion channels to open briefly, allowing extracellular calcium ions to enter the axon terminal. Their entry triggers the exocytosis of the synaptic vesicles and the release of ACh. ACh release stops very quickly, because active transport processes rapidly remove the calcium ions from the cytosol.
- **3.** ACh binds to ACh receptors and depolarizes the postsynaptic membrane. ACh binding causes these chemically gated Na⁺ channels to open and allow sodium ions to enter. If the resulting depolarization of the postsynaptic membrane reaches threshold, an action potential is generated.
- **4.** *ACh is removed by AChE.* The effects on the postsynaptic membrane are temporary. The reason is because the synaptic cleft and postsynaptic membrane contain the enzyme acetylcholinesterase (AChE). ⊃ p. 227 AChE removes ACh by breaking it into acetate and choline.

Another common neurotransmitter is **norepinephrine** (nor-ep-i-NEF-rin), or NE. It is important in the brain and in portions of the autonomic nervous system. NE is also called

Figure 8-11 The Events at a Cholinergic Synapse.

noradrenaline, and synapses releasing NE are described as **adrenergic**.

The neurotransmitters **dopamine** (DŌ-puh-mēn), **gamma aminobutyric** (GAM-ma a-MĒ-nō-bū-TĒR-ik) **acid** (also known as **GABA**), and **serotonin** (ser-o-TŌ-nin) function in the CNS. There are at least 50 other neurotransmitters whose functions are not well understood. In addition, two gases are important neurotransmitters: *nitric oxide* (*NO*) and *carbon monoxide* (*CO*).

The neurotransmitters released at a synapse may have excitatory or inhibitory effects. Both ACh and NE usually have an excitatory, depolarizing effect on postsynaptic neurons. Like ACh, NE has a temporary effect. It is broken down by an enzyme called *monoamine oxidase*. The effects of dopamine, GABA, and serotonin are usually inhibitory because they tend to hyperpolarize postsynaptic neurons.

Many drugs affect the nervous system by stimulating receptors that otherwise respond only to neurotransmitters. These drugs can have complex effects on perception, motor control, and emotional states.

Whether or not an action potential appears in the postsynaptic neuron depends on the balance between the depolarizing and hyperpolarizing stimuli arriving at any moment. For example, suppose that a neuron will generate an action potential if it receives 10 depolarizing stimuli. That could mean 10 active synapses if all release excitatory neurotransmitters. But if, at the same moment, 10 other synapses release inhibitory neurotransmitters, the excitatory and inhibitory effects will cancel one another out. As a result, no action potential would develop.

The activity of a neuron thus depends on the balance between excitation and inhibition. The interactions are extremely complex. Synapses at the cell body and dendrites may involve tens of thousands of other neurons. Some release excitatory neurotransmitters and others release inhibitory neurotransmitters.

Neuronal Pools

As noted earlier, the human body has about 10 million sensory neurons, 20 billion interneurons, and one-half million motor neurons. These individual neurons represent the simplest level of organization within the CNS. However, the integration of sensory and motor information to produce complex responses requires groups of interneurons acting together.

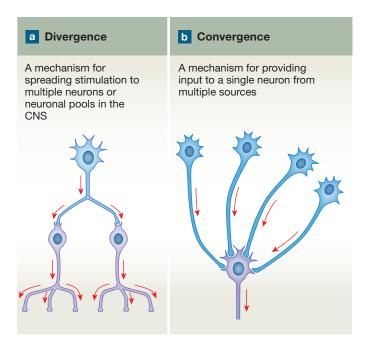

A **neuronal pool** is a group of interconnected interneurons with specific functions. Each neuronal pool has a limited number of input sources and output destinations. Also, each pool may contain excitatory and inhibitory neurons. The output of one pool may stimulate or depress the activity of other pools, or it may exert direct control over motor neurons or peripheral effectors.

Neurons and neuronal pools communicate with one another in several "wiring diagrams," or *neural circuits*. The two simplest circuit patterns are *divergence* and *convergence*. In **divergence**, information spreads from one neuron to several neurons, or from one neuronal pool to multiple neuronal pools (**Figure 8-12a**). Considerable divergence occurs when sensory neurons bring information into the CNS. The sensory information is distributed to different neuronal pools throughout the spinal cord and brain. For example, visual information from the eyes reaches your conscious awareness at the same time it is carried to areas of the brain that control posture and balance at the subconscious level.

Divergence is also involved when you step on a sharp object. That action stimulates sensory neurons that distribute information to a number of neuronal pools. As a result, you might withdraw your foot, shift your weight, move your arms, feel the pain, and shout "Ouch!"—all at the same time.

In **convergence** (Figure 8-12b), several neurons synapse on a single postsynaptic neuron. Convergence makes possible both voluntary and involuntary control of some body processes. For example, as you read this, the movements of your diaphragm and ribs are being involuntarily, or subconsciously, controlled by respiratory centers in your brain. These centers activate or inhibit motor neurons in your spinal cord that control your respiratory muscles. But those same movements can

Figure 8-12 Two Common Types of Neuronal Pools.

be controlled voluntarily, or consciously, as when you take a deep breath and hold it. Two neuronal pools are involved, and both synapse on the same motor neurons.

CHECKPOINT

- **13.** Describe the general structure of a synapse.
- **14.** What effect would blocking calcium ion channels at a cholinergic synapse have on synapse function?
- **15.** What type of neural circuit permits both conscious and subconscious control of the same motor neurons?

See the blue Answers tab at the back of the book.

8-5 The brain and spinal cord are surrounded by three layers of membranes called the meninges

Learning Outcome Describe the three meningeal layers that surround the central nervous system.

The central nervous system (CNS) consists of the spinal cord and brain. The nervous tissue of the CNS is delicate. It also has a very high metabolic rate and requires abundant nutrients and a constant supply of oxygen. At the same time, CNS tissue must

Figure 8-13 The Meninges of the Brain and Spinal Cord.

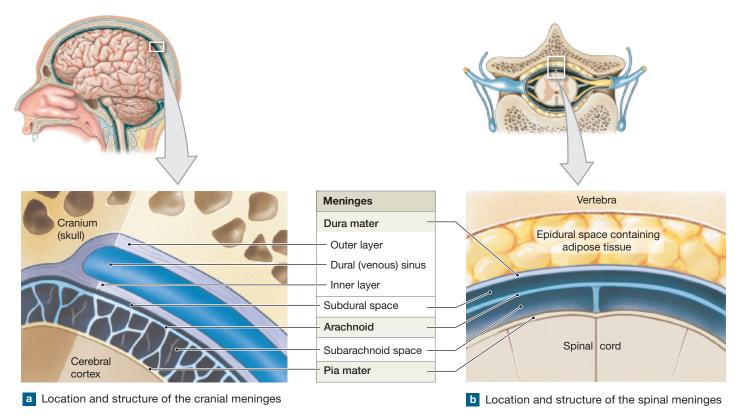

be isolated from a variety of compounds in the blood that could interfere with its complex operations. It also needs to be protected against damaging contact with the surrounding bones.

The **meninges** (me-NIN-jēz) are three layers of specialized membranes surrounding the brain and spinal cord (**Figure 8-13**). They provide the CNS tissue with physical stability and shock absorption. Blood vessels branching within these layers deliver needed oxygen and nutrients. At the foramen magnum of the skull, the *cranial meninges* covering the brain are continuous with the *spinal meninges* that surround the spinal cord. The meninges cover cranial nerves as they extend through foramina of the skull and spinal nerves that pass through the intervertebral foramina. The meninges then become continuous with the connective tissues surrounding the peripheral nerves.

The three meningeal layers are the *dura mater*, the *arachnoid*, and the *pia mater*.

The Dura Mater

The tough, fibrous **dura mater** (DOO-ruh MĀ-ter; *dura*, hard + *mater*, mother) forms the outermost covering of the central nervous system. The dura mater surrounding the brain consists of two fibrous layers. The outer layer is fused to the

periosteum of the skull. In some places, the inner layer is joined with the outer layer. Typically, the two layers are separated by a slender gap that contains tissue fluids and blood vessels (**Figure 8-13a**).

At several locations, the inner layer of the dura mater extends deep into the cranial cavity, forming folded membranous sheets called *dural folds*. The dural folds act like seat belts to hold the brain in position. Large collecting veins known as *dural sinuses* lie between the two layers of a dural fold.

In the spinal cord, the outer layer of the dura mater is not fused to bone. An **epidural space** lies between the dura mater of the spinal cord and the walls of the vertebral canal. This space contains areolar tissue, blood vessels, and adipose tissue (**Figure 8-13b**). Injecting an anesthetic into the epidural space produces a temporary sensory and motor paralysis known as an *epidural block*. This technique has the advantage of affecting only the spinal nerves in the immediate area of the injection. Epidural blocks in the lower lumbar or sacral regions may be used to control pain during childbirth.

The Arachnoid

A narrow **subdural space** separates the inner surface of the dura mater from the second meningeal layer, the **arachnoid** (a-RAK-noyd; *arachne*, spider). This intervening space contains a small quantity of lymphatic fluid, which reduces friction between the opposing surfaces. The arachnoid is a layer of squamous epithelial cells. Deep to this layer lies the **subarachnoid space**, which contains a delicate web of collagen and elastic fibers. The subarachnoid space is filled with *cerebrospinal fluid (CSF)*. This fluid acts as a shock absorber and transports dissolved gases, nutrients, chemical messengers, and waste products.

The Pia Mater

The subarachnoid space separates the arachnoid from the innermost meningeal layer, the **pia mater** (*pia*, delicate + *mater*, mother). The pia mater is bound firmly to the underlying neural tissue. The blood vessels servicing the brain and spinal cord run along the surface of this layer, within the subarachnoid space. The pia mater of the brain is highly vascular, and large blood vessels branch over the surface of the brain, supplying the superficial areas of neural cortex. This extensive blood supply is extremely important, for the brain has a very high rate of metabolism. At rest, the 1.4 kg (3.1 lb) brain uses as much oxygen as 28 kg (61.6 lb) of skeletal muscle.

CLINICAL NOTE

Epidural and Subdural Hemorrhages

A severe head injury may damage cerebral blood vessels and cause bleeding into the cranial cavity. If blood is forced between the dura mater and the skull, the condition is known as an *epidural hemorrhage*. A *subdural hemorrhage* is bleeding between the dura mater and the arachnoid mater. These conditions are serious because the blood entering the epidural or subdural spaces compresses and distorts the relatively soft tissues of the brain. The signs and symptoms vary depending on whether an artery or a vein is damaged. Because arterial blood pressure is higher, bleeding from an artery can cause more rapid and severe

distortion of neural tissue. There is good reason for adults and children to give their heads added protection by wearing helmets while biking, motorcycling, skiing, skateboarding, and playing various sports.

CHECKPOINT

16. Identify the three meninges surrounding the CNS. See the blue Answers tab at the back of the book.

8-6 The spinal cord contains gray matter surrounded by white matter and connects to 31 pairs of spinal nerves

Learning Outcome Discuss the roles of gray matter and white matter in the spinal cord.

The spinal cord serves as the major highway for sensory impulses passing to the brain and motor impulses coming from the brain. In addition, the spinal cord integrates information on its own. It controls *spinal reflexes*, automatic motor responses ranging from withdrawal from pain to complex reflex patterns involved in sitting, standing, walking, and running.

Gross Anatomy

The adult spinal cord (Figure 8-14a) is approximately 45 cm (18 in.) long and has a maximum width of roughly 14 mm (0.55 in.). With two exceptions, the diameter of the spinal cord decreases as it extends inferiorly. The two exceptions are regions concerned with the sensory and motor control of the limbs. The *cervical enlargement* supplies nerves to the shoulder girdles and upper limbs. The *lumbosacral*

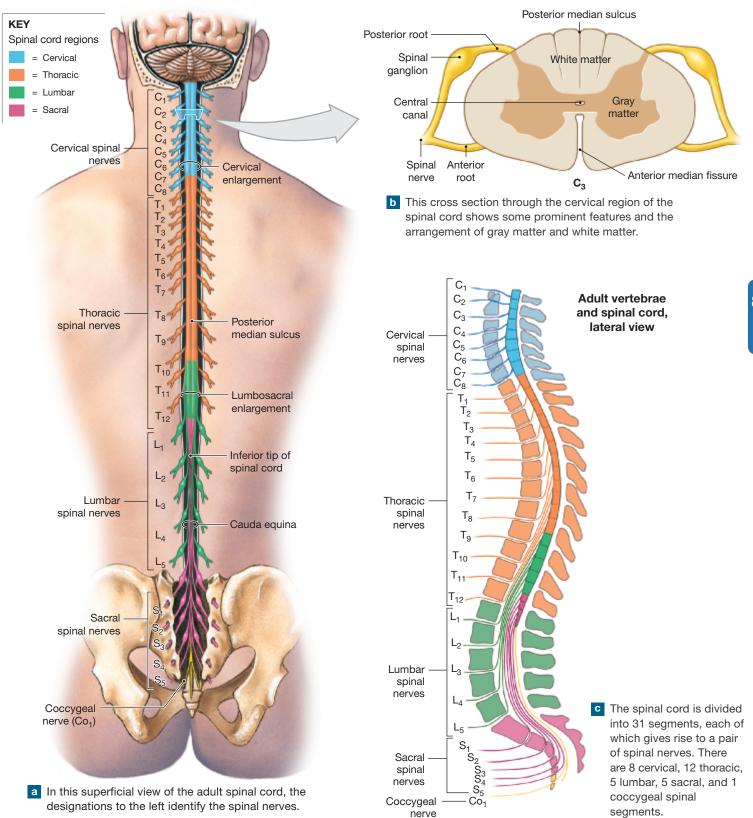

Figure 8-14 Gross Anatomy of the Spinal Cord.

8

enlargement provides innervation to the pelvis and lower limbs. Inferior to the lumbosacral enlargement, the spinal cord becomes tapered and conical. A slender strand of fibrous tissue extends from the inferior tip of the spinal cord to the coccyx, serving as an anchor that prevents upward movement.

The spinal cord has a **central canal**, a narrow internal passageway filled with cerebrospinal fluid (**Figure 8-14b**). The posterior surface of the spinal cord has a shallow groove, the *posterior median sulcus*. The anterior surface has a deeper groove, the *anterior median fissure*.

The entire spinal cord consists of 31 segments. Each gives rise to a pair of *spinal nerves*. There are 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal spinal segments (Figure 8-14c). Each pair of spinal nerves is identified by a letter and number (Figure 8-14a,c).

Every spinal segment is associated with a pair of **spinal ganglia** (singular: ganglion), which contain the cell bodies of sensory neurons (Figure 8-14b). The **posterior roots** contain the axons of these neurons and bring sensory information to the spinal cord. A pair of **anterior roots** contains the axons of CNS motor neurons that control muscles and glands. On either side, the posterior and anterior roots from each segment leave the vertebral column between adjacent vertebrae at the *intervertebral foramen*.

Distal to each spinal ganglion, the sensory (posterior) and motor (anterior) roots are bound together into a single **spinal**

nerve. All spinal nerves are classified as *mixed nerves* because they contain both sensory and motor fibers. The spinal nerves on either side form outside the vertebral canal, where the anterior and posterior roots unite. \bigcirc p. 192

The spinal cord continues to grow until a person is approximately four years old. After age four, the vertebral column continues to elongate, but the spinal cord does not. As a result, the posterior and anterior roots gradually grow longer and the correspondence between a spinal cord segment and its adjacent vertebra is lost. This explains why spinal cord segments S_1 — S_5 are level with vertebrae T_{12} — L_1 (Figure 8-14c).

The adult spinal cord extends only to the level of the first or second lumbar vertebrae. When seen in gross dissection, the long ventral and dorsal roots of spinal nerves inferior to the tip of the spinal cord, plus the cord's threadlike extensions, reminded early anatomists of a horse's tail. With that in mind, they called this complex the *cauda equina* (KAW-duh ek-WĪ-nuh; *cauda*, tail + *equus*, horse).

Sectional Anatomy

The anterior median fissure and the posterior median sulcus mark the division between left and right sides of the spinal cord (**Figure 8-15**). The *gray matter* is dominated by the cell bodies of neurons and glial cells. It forms a rough H, or a butterfly shape, around the narrow central canal. Projections of gray

CLINICAL NOTE

Spinal Cord Injuries

Injuries affecting the spinal cord or cauda equina produce symptoms of sensory loss or motor paralysis that reflect the specific nuclei, tracts, or spinal nerves involved. A general paralysis can result from severe damage to the spinal cord in an auto crash or other accident, and the damaged tracts seldom undergo even partial repairs. Extensive damage at the fourth or fifth cervical vertebra will eliminate sensation and motor control of the upper and lower limbs. The extensive paralysis produced is called *quadriplegia. Paraplegia*, the loss of motor control of the lower limbs, may follow damage to the thoracic vertebrae. According to the CDC, complete or partial paralysis due to spinal injury affects approximately 200,000 people in the United States.

The regeneration of spinal cord tissue was long thought to be impossible because mature nervous tissue had not been observed to grow or undergo mitosis. Biological cures by various means are being sought. One involves interfering with inhibitory factors in the spinal cord that slow the repair of neurons. Another involves implanting or stimulating unspecialized stem cells to grow and divide. Inactive neural stem cells have been found in mature human nervous tissues. This discovery is potentially significant because laboratory rats treated with embryonic stem cells at the site of a spinal cord injury have regained limb mobility and strength.

Work also continues on electronic methods of restoring some degree of motor control. In 2014, the FDA approved an electric-powered exoskeleton suit that may help paraplegic individuals walk again. The device consists of a fitted brace that supports the legs and part of the upper body; motors that provide movement at the hips, knees, and ankles; a tilt sensor; and a backpack containing a computer and power supply. Crutches are still needed for additional support. With assistance from a trainer, individuals wearing the exoskeleton will be able to sit, stand, and walk.

8

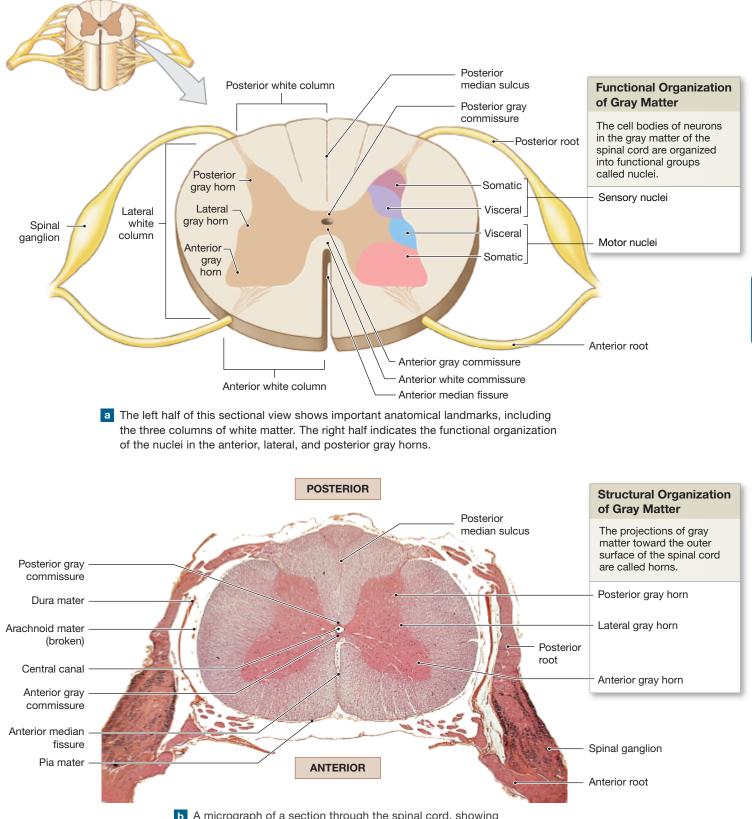

Figure 8-15 Sectional Anatomy of the Spinal Cord.

b A micrograph of a section through the spinal cord, showing major landmarks in and surrounding the cord.

matter, called **horns**, extend outward into the *white matter*, which contains large numbers of myelinated and unmyelinated axons.

Figure 8-15a shows the relationship between the function of a particular nucleus (a collection of sensory or motor cell bodies) and its relative position in the gray matter of the spinal cord. The *posterior gray horns* contain sensory nuclei. The *anterior gray horns* are involved in the motor control of skeletal muscles. Nuclei in the *lateral gray horns* contain the visceral motor neurons that control smooth muscle, cardiac muscle, and glands.

The *gray commissures* anterior and posterior to the central canal interconnect the horns on either side of the spinal cord. The gray and white commissures contain axons that cross from one side of the spinal cord to the other.

The white matter on each side can be divided into three regions, or **columns** (Figure 8-15a). The *posterior white columns* extend between the posterior gray horns and the posterior median sulcus. The *anterior white columns* lie between the anterior gray horns and the anterior median fissure. The anterior white columns are interconnected by the *anterior white commissure*. The white matter between the anterior and posterior columns makes up the *lateral white columns*.

Each column contains tracts whose axons carry either sensory information or motor commands. Small tracts carry sensory or motor signals between segments of the spinal cord, and larger tracts connect the spinal cord with the brain. **Ascending tracts** carry sensory information toward the brain. **Descending tracts** convey motor commands into the spinal cord.

CHECKPOINT

- **17.** Damage to which root of a spinal nerve would interfere with motor function?
- **18.** A person with polio has lost the use of his leg muscles. In which area of his spinal cord could you locate the poliovirus-infected motor neurons?
- 19. Why are spinal nerves also called mixed nerves?
- See the blue Answers tab at the back of the book.

8-7 The brain has several principal structures, each with specific functions

Learning Outcome Name the major regions of the brain, and describe the locations and functions of each.

The brain is far more complex than the spinal cord. Its responses to stimuli are also more versatile. The brain contains roughly 20 billion neurons organized into hundreds of

neuronal pools. Everything we do and everything we are is the result of brain activity.

The adult human brain contains almost 97 percent of the nervous tissue in the body. A "typical" adult brain weighs 1.4 kg (3 lb) and has a volume of 1200 cc (71 in.³). Brain size varies considerably among individuals. The brains of males are, on average, about 10 percent larger than those of females, because of differences in average body size. There is no correlation between brain size and intelligence. Individuals with the smallest brains (750 cc) or largest brains (2100 cc) are functionally normal.

The Major Regions of the Brain

The adult brain has six major regions: (1) the *cerebrum*, (2) the *diencephalon*, (3) the *midbrain*, (4) the *pons*, (5) the *medulla oblongata*, and (6) the *cerebellum*. Major landmarks are indicated in **Figure 8-16**.

The adult brain is dominated in size by the **cerebrum** (se-RĒ-brum or SER-e-brum). The cerebrum is made up of large, paired left and right **cerebral hemispheres** (Figure 8-16a). Conscious thoughts, sensations, intellectual functions, memory storage and processing, and complex movements originate in the cerebrum.

The hollow **diencephalon** (dī-en-SEF-a-lon; *dia*-, through + *encephalos*, brain) is connected to the cerebrum (**Figure 8-16c**). Its largest portion is the **thalamus** (THAL-a-mus). The thalamus contains relay and processing centers for sensory information. The **hypothalamus** (*hypo*-, below) is the floor of the diencephalon. It contains centers involved with emotions, autonomic function, and hormone production. A narrow stalk connects the hypothalamus to the *pituitary gland*. The pituitary gland is the primary link between the nervous and endocrine systems. (We will discuss it in Chapter 10.) The **epithalamus** contains another endocrine structure, the *pineal gland*.

The **brainstem** contains three major regions of the brain: the midbrain, pons, and medulla oblongata (**Figure 8-16c**). The brainstem contains important processing centers and relay stations for information headed to or from the cerebrum or cerebellum.

Nuclei in the **midbrain**, or *mesencephalon* (mez-en-SEF-a-lon; *meso-*, middle), process visual and auditory information and generate involuntary motor responses. This region also contains centers that help maintain consciousness.

The **pons** connects the cerebellum to the brainstem (*pons* refers to a bridge). In addition to tracts and relay centers, the pons also contains nuclei involved in somatic and visceral motor control.

8

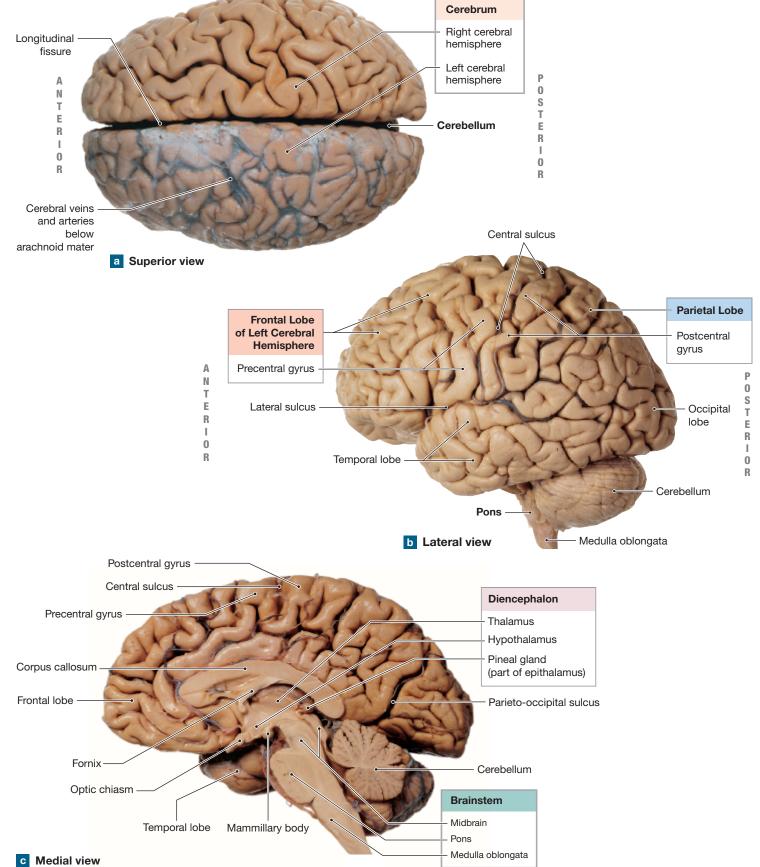

Figure 8-16 The Brain.

Go to **Mastering A&P** > Study Area > Menu > Dissection Video > Sheep Brain > Midsagittal Section >

The pons is also connected to the **medulla oblongata**, the segment of the brain that is attached to the spinal cord. The medulla oblongata relays sensory information to the thalamus and other brainstem centers. It also contains major centers that regulate autonomic function, such as heart rate, blood pressure, respiration, and digestive activities.

The large cerebral hemispheres and the smaller hemispheres of the **cerebellum** (ser-e-BEL-um) almost completely cover the brainstem (**Figure 8-16b**). The cerebellum adjusts voluntary and involuntary motor activities on the basis of sensory information and stored memories of previous movements.

The Ventricles of the Brain

Recall that the brain and spinal cord contain internal cavities filled with cerebrospinal fluid and lined by ependymal cells. **>** p. 279 The brain has a central passageway that expands to form four chambers called **ventricles** (VEN-tri-kls) (**Figure 8-17**). Each cerebral hemisphere contains a large **lateral ventricle**. These two lateral ventricles are not directly connected. Instead, each communicates with the **third ventricle** of the diencephalon through an opening, the *interventricular foramen*. Rather than a ventricle, the midbrain has a slender canal known as the *cerebral aqueduct*. This passageway connects the third ventricle with the **fourth ventricle**, which extends into the pons and upper portion of the medulla oblongata. Within the medulla oblongata, the fourth ventricle narrows and becomes continuous with the central canal of the spinal cord.

Cerebrospinal Fluid

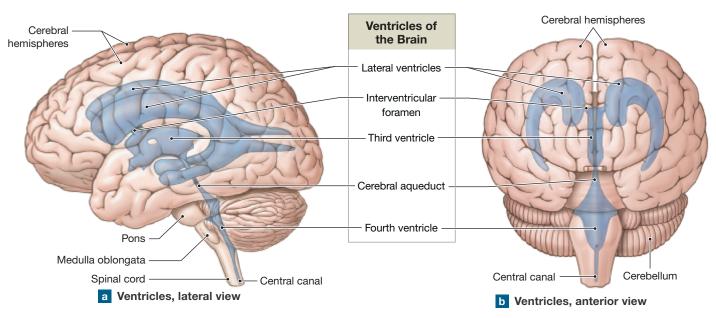

Cerebrospinal fluid, or **CSF**, fills the ventricles and completely surrounds and bathes the exposed surfaces of the CNS. The CSF has several important functions, including:

- Cushioning the brain and spinal cord against physical trauma.
- *Supporting the brain*. The brain essentially floats in the cerebrospinal fluid. A human brain weighs about 1400 g (3.1 lb) in air but only about 50 g (1.8 oz) when supported by cerebrospinal fluid.
- *Transporting nutrients, chemical messengers, and waste products.* Except at the *choroid plexus*, where CSF is produced, the ependymal lining is freely permeable. The CSF is in constant chemical communication with the interstitial fluid that surrounds the neurons and neuroglia of the CNS.

Because free exchange takes place between the interstitial fluid and CSF, changes in CNS function may produce changes in the composition of CSF. Samples of CSF can be obtained through a *lumbar puncture*, or *spinal tap*. Such samples provide useful clinical information about CNS injury, infection, or disease.

A **choroid plexus** (*choroid*, a vascular coat + *plexus*, a network) is a network of permeable capillaries within each ventricle that produces CSF (**Figure 8-18a**). The capillaries of the choroid plexuses are covered by large ependymal cells that secrete CSF at a rate of about 500 mL/day. The total volume

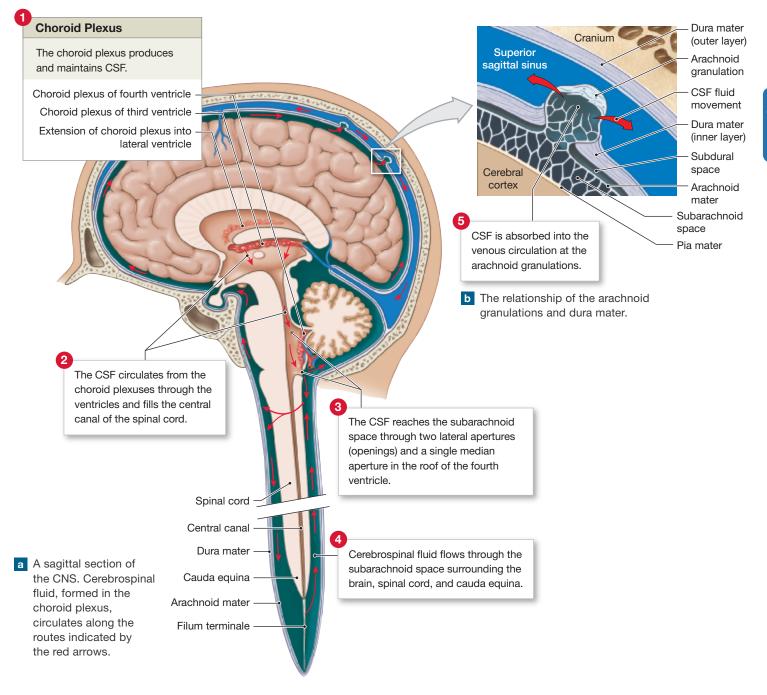

of CSF at any given moment is approximately 150 mL. This means that the entire volume of CSF is replaced roughly every 8 hours. Despite this rapid turnover, the composition of CSF is closely regulated. The rate of removal normally keeps pace with the rate of production. If it does not, a variety of clinical problems may appear.

The areas where cerebrospinal fluid is formed, its circulatory pathway around the CNS, and its absorption into the venous circulation are shown in **Figure 8-18a**. CSF formed at the

choroid plexuses circulates through the different ventricles and fills the central canal of the spinal cord (1) and (2). CSF enters the subarachnoid space through openings (*apertures*) in the roof of the fourth ventricle (3). Cerebrospinal fluid then flows through the subarachnoid space surrounding the brain, spinal cord, and cauda equina (4). Between the cerebral hemispheres, slender extensions of the arachnoid mater penetrate the inner layer of the dura mater. Clusters of these extensions form **arachnoid granulations**, which project into

the *superior sagittal sinus*, a large cerebral vein (**Figure 8-18b**). Diffusion across the arachnoid granulations returns excess cerebrospinal fluid to the venous circulation (**5**).

The Cerebrum

The cerebrum is the largest region of the brain. It is the site where conscious thought and intellectual functions originate. Much of the cerebrum is involved in receiving somatic sensory information and then exerting voluntary or involuntary control over somatic motor neurons. In general, we are aware of these events. However, most sensory processing and all visceral motor (autonomic) control occur elsewhere in the brain, usually outside our conscious awareness.

The cerebrum includes gray matter and white matter. Gray matter is found in a superficial layer of neural cortex, known as the **cerebral cortex**, and in deeper *basal nuclei*. The white matter lies beneath the neural cortex and surrounds the basal nuclei.

Structure of the Cerebral Hemispheres

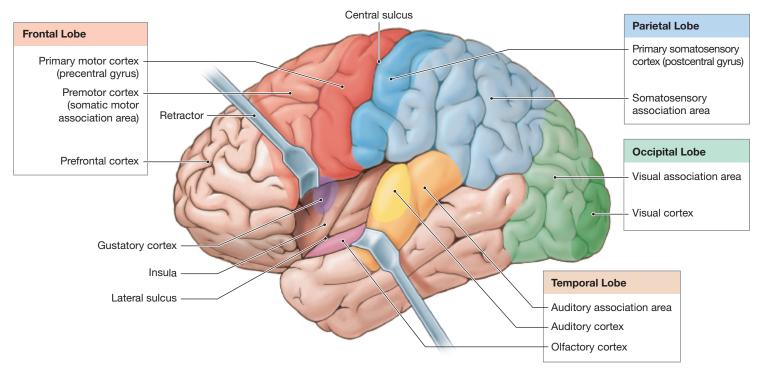

A blanket of cerebral cortex ranging from 1 to 4.5 mm (0.04 to 0.18 in.) thick covers the paired cerebral hemispheres

(**Figure 8-19**). This outer surface forms a series of folds, or **gyri** (JĪ-rī; singular, *gyrus*). The gyri are separated by shallow depressions, called **sulci** (SUL-sī), or by deeper grooves, called **fissures**. Gyri increase the surface area of the cerebrum, and thus the number of neurons in the cortex. The total surface area of the cerebral hemispheres is roughly equivalent to 2200 cm² (2.5 ft²) of flat surface.

The two cerebral hemispheres are separated by a deep longitudinal fissure (Figure 8-16a). Each hemisphere can be divided into well-defined regions, or lobes, named after the overlying bones of the skull (Figures 8-16b and 8-19). On each hemisphere, the central sulcus, a deep groove, divides the anterior frontal lobe from the more posterior parietal lobe. The horizontal lateral sulcus separates the frontal lobe from the temporal lobe. The temporal lobe overlaps the insula (IN-sū-luh), an "island" of cortex that is otherwise hidden (Figure 8-19). The more posterior parietooccipital sulcus separates the parietal lobe from the occipital lobe (Figure 8-16c).

In each lobe, some regions are concerned with sensory information and others with motor commands. Additionally, each hemisphere receives sensory information from, and sends motor commands to, the opposite side of the body. As a result, the left cerebral hemisphere controls the right

Figure 8-19 Motor, Sensory, and Association Areas of the Cerebral Cortex. Major anatomical landmarks on the surface of the left cerebral hemisphere are shown. (Retractors along the lateral sulcus reveal the insula.)

side of the body, and the right cerebral hemisphere controls the left side. This crossing over has no known functional significance.

Motor and Sensory Areas of the Cortex

The major motor and sensory regions of the cerebral cortex are shown in Figure 8-19. The central sulcus separates the motor and sensory portions of the cortex. The precentral gyrus of the frontal lobe forms the anterior margin of the central sulcus. The surface of this gyrus is the primary motor cortex. Neurons of the primary motor cortex direct voluntary movements by controlling somatic motor neurons in the brainstem and spinal cord.

The postcentral gyrus of the parietal lobe forms the posterior margin of the central sulcus. Its surface contains the primary somatosensory cortex. Neurons in this region receive somatic sensory information from touch, pressure, pain, and temperature receptors. We are aware of these sensations only when nuclei in the thalamus relay the information to the primary somatosensory cortex.

Sensations of sight, taste, sound, and smell arrive at other portions of the cerebral cortex. The visual cortex of the occipital lobe receives visual information. The gustatory cortex of the frontal lobe receives taste sensations. In the temporal lobe, the auditory cortex and olfactory cortex receive information about hearing and smell, respectively.

Association Areas

The sensory and motor regions of the cortex are connected to nearby association areas. These regions interpret incoming data or coordinate a motor response.

The somatosensory association area monitors activity in the primary somatosensory cortex. This area allows you to recognize a touch as light as a mosquito landing on your arm. The special senses of smell, sight, and hearing involve separate areas of sensory cortex. Each has its own association area.

The premotor cortex, or somatic motor association area, is responsible for coordinating learned movements. When you perform a voluntary movement, such as picking up a glass or scanning these lines of type, instructions are relayed to the primary motor cortex by the premotor cortex.

The functional distinctions between the motor and sensory association areas are most evident after localized brain damage has taken place. For example, someone with damage to the premotor cortex might understand written letters and words but be unable to read due to an inability to track along the lines on a printed page. In contrast, someone with a damaged visual association area can scan the lines of a printed page but cannot figure out what the letters mean.

Cortical Connections

The various regions of the cerebral cortex are interconnected by the white matter that lies beneath the cerebral cortex. Myelinated axons of different lengths interconnect gyri within a single cerebral hemisphere. Such axons also link the two hemispheres across the corpus callosum (Figure 8-16c). Other bundles of axons link the cerebral cortex with the diencephalon, brain stem, cerebellum, and spinal cord.

Cerebral Processing Centers

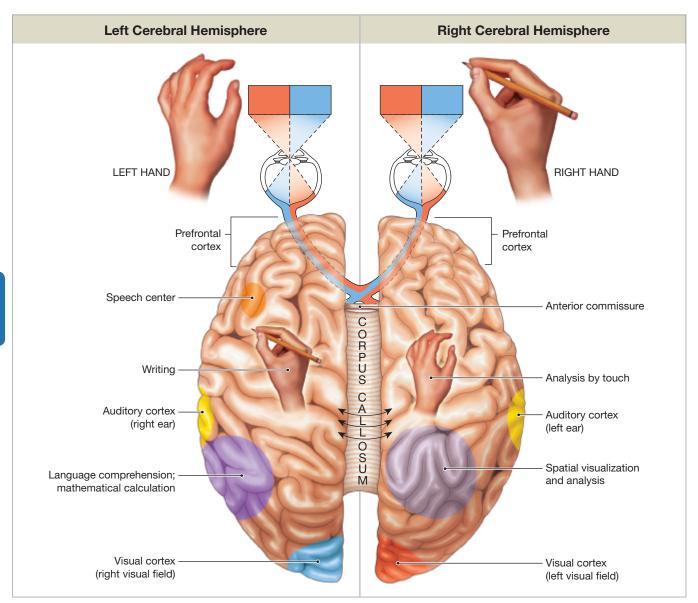

"Higher-order" integrative centers receive information from many different association areas. These integrative centers direct extremely complex motor activities and perform complicated analytical functions. Even though integrative centers may be found in both cerebral hemispheres, many are lateralized—largely restricted to either the left or the right hemisphere (Figure 8-20). Examples of lateralized integrative 8 centers are those concerned with complex processes such as speech, writing, mathematical computation, and understanding spatial relationships.

THE SPECIALIZED LANGUAGE AREAS IN THE BRAIN. Two important cortical areas related to human language are Wernicke's area and Broca's area. Both are primarily associated with the left cerebral hemisphere. Wernicke's (VER-nih-kēz) area is near the auditory cortex and is associated with language comprehension. This analytical center receives information from the sensory association areas and plays an important role in your personality by integrating sensory information and coordinating access to visual and auditory memories. Damage to this area affects the ability to interpret what is read or heard, even though the words are understood as individual entities. For example, you might still understand the meaning of the spoken words sit and here, because word recognition takes place in the auditory association areas. But you would be totally bewildered by the request sit here.

Broca's area (motor speech area), also called the speech center, is near the motor cortex and is associated with speech production. Broca's area regulates the patterns of breathing and vocalization needed for normal speech. A person with damage to this area can make sounds but not words.

The motor commands issued by the speech center are adjusted by feedback from the auditory association area. Damage there can cause a variety of speech-related problems. Some affected individuals have difficulty speaking, even though they know exactly which words to use. Others talk constantly but use all the wrong words.

Figure 8-20 Hemisphere Lateralization. Some functional differences between the left and right cerebral hemispheres are depicted.

THE PREFRONTAL CORTEX. The **prefrontal cortex** of the frontal lobe (Figure 8-20) coordinates information from the association areas of the entire cortex. In doing so, it performs such abstract intellectual functions as predicting the consequences of events or actions. Damage to this area leads to problems in estimating time relationships between events. Questions such as "How long ago did this happen?" or "What happened first?" become difficult to answer.

The prefrontal cortex also has connections with other cortical areas and with other portions of the brain. Feelings of frustration, tension, and anxiety are generated at the prefrontal cortex as it interprets ongoing events and makes predictions about future situations or consequences. If the connections between the prefrontal cortex and other brain regions are severed, the tensions, frustrations, and anxieties are removed. Early in the 1900s this rather drastic procedure, called a *prefrontal lobotomy*, was used to "cure" a variety of mental illnesses, especially those associated with violent or antisocial behavior.

Hemispheric Lateralization

As shown in **Figure 8-20**, each of the two cerebral hemispheres is responsible for specific functions that are not ordinarily performed by the opposite hemisphere. This specialization is called *hemispheric lateralization*. In most people, the left hemisphere contains Wernicke's and Broca's areas and is responsible for language-based skills (reading, writing, and speaking). In addition, the premotor cortex involved in the control of hand movements is larger on the left side in right-handed individuals than in left-handed ones. The left hemisphere is also important in performing analytical tasks, such as mathematical calculations and logical decision making. For these reasons, the left hemisphere has been called the dominant hemisphere, or the categorical hemisphere.

The right hemisphere, or *representational hemisphere*, is concerned with spatial relationships and analyses. It analyzes sensory information and relates the body to the sensory environment. Interpretive centers in this hemisphere enable you to identify familiar objects by touch, smell, sight, or taste. The right hemisphere plays a dominant role in recognizing faces and in understanding three-dimensional relationships. It is also important in analyzing the emotional context of a conversation—for instance, distinguishing between the threat "Get lost!" and the question "Get lost?"

Interestingly, there may be a link between handedness and sensory/spatial abilities. An unusually high percentage of musicians and artists are left-handed. The complex motor activities that they perform are directed by the primary motor cortex and association areas of the right cerebral hemisphere. These areas are near the association areas involved with spatial visualization and emotions.

Hemispheric lateralization does not mean that the two hemispheres function independently of each other. Recall that the white fibers of the corpus callosum link the two hemispheres, including their sensory information and motor commands. The corpus callosum alone contains over 200 million axons, carrying an estimated 4 billion impulses per second!

The Electroencephalogram (EEG)

Various methods have been used to map brain activity and function. The primary sensory cortex and the primary motor cortex have been mapped by direct stimulation in patients undergoing brain surgery. The behavioral changes that follow localized brain injuries or strokes can reveal the functions of other regions of the cerebrum. The activities of specific regions can be examined by noninvasive techniques such as a PET scan or sequential MRI scans. $\supset p. 50$

The electrical activity of the brain is commonly monitored to assess brain activity. Neural function depends on electrical events of the plasma membrane of neurons. The brain contains billions of nerve cells, and their activity generates an electrical field that can be measured by placing electrodes on the brain or on the outer surface of the skull. The electrical activity changes constantly as nuclei and cortical areas are stimulated or quiet down.

An **electroencephalogram (EEG)** is a printed record of this electrical activity over time. The electrical patterns are called **brain waves**, which can be correlated with the individual's level of consciousness. Electroencephalograms can also provide useful diagnostic information regarding brain disorders. Four types of brain wave patterns are shown in **Figure 8-21**.

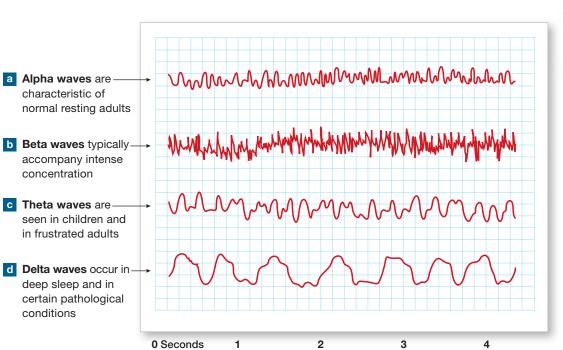

Figure 8-21 Brain Waves.

Patient being wired for EEG monitoring

CLINICAL NOTE

Aphasia and Dyslexia

Aphasia (*a*-, without + *phasia*, speech) is a disorder affecting the ability to speak or read. *Global aphasia* results from extensive damage to the general interpretive area or to the associated sensory tracts. Affected individuals cannot speak, read, understand, or interpret the speech of others. Global aphasia often accompanies a severe stroke or tumor that affects a large area of cortex, including the speech and language areas. Recovery is possible when the condition results from *edema* (an abnormal accumulation of fluid) or hemorrhage, but the process often takes months or even years. Lesser degrees of aphasia often follow minor strokes with no initial period of global aphasia. Such individuals can understand spoken and written words and may recover completely.

Dyslexia *(lexis,* diction) is a disorder affecting the comprehension and use of words. Developmental dyslexia affects children. Estimates are that up to 15 percent of children in the United States suffer from some degree of dyslexia. These children have difficulty reading and writing, although their other intellectual functions may be normal or above normal. Their writing looks uneven and unorganized. They typically

write letters in the wrong order (dig becomes gid) or reverse them (E becomes \exists). Recent evidence suggests that at least some forms of dyslexia result from problems in processing, sorting, and integrating visual or auditory information.

8

Memory

What was the topic of the last sentence you read? What is your social security number? How do you open a screw-top jar? To answer these questions, you access *memories*, stored bits of information gathered through experience. **Fact memories** are specific bits of information, such as the color of a stop sign. **Skill memories** are learned motor behaviors. You can probably remember how to light a match or throw a Frisbee, for example. With repetition, skill memories become incorporated at the unconscious level. Examples include the complex motor patterns involved in skiing or playing the violin. Skill memories related to programmed behaviors, such as eating, are stored in appropriate portions of the brain stem. Complex skill memories involve an integration of motor patterns in the cerebellum and the cerebral cortex.

Memories are often classified according to how long they last. **Short-term memories** do not last long, but while they persist the information can be recalled immediately. Shortterm memories contain small bits of information, such as a person's name or a telephone number. Repeating a phone number or other bit of information reinforces the original short-term memory and helps ensure its conversion to a longterm memory. **Long-term memories** remain for much longer periods, in some cases for an entire lifetime. The conversion from short-term to long-term memory is called *memory consolidation*. Some long-term memories fade with time and may require considerable effort to recall. Other long-term memories seem to be part of consciousness, such as your name or the contours of your own body. Most long-term memories are stored in the cerebral cortex. Conscious motor and sensory memories are referred to the appropriate association areas. For example, visual memories are stored in the visual association area, and memories of voluntary motor activity are kept in the premotor cortex. Special portions of the occipital and temporal lobes retain the memories of faces, voices, and words.

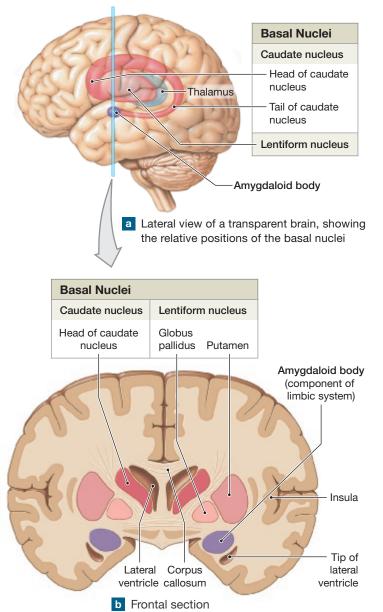

Amnesia refers to the loss of memory as a result of disease or trauma. The type of memory loss depends on the specific regions of the brain affected. For example, damage to the auditory association areas may make it difficult to remember sounds. Damage to thalamic and limbic structures, especially the *hippocampus*, affects memory storage and consolidation.

The Basal Nuclei

While your cerebral cortex is consciously active, other centers of your cerebrum, diencephalon, and brain stem are processing sensory information and issuing motor commands outside your conscious awareness. Many of these activities, which take place at the subconscious level, are directed by *cerebral nuclei* called basal nuclei. The **basal nuclei** are masses of gray matter deep within the brain. They lie beneath the lateral ventricles, surrounded by the white matter of each cerebral hemisphere (**Figure 8-22**).

The **caudate nucleus** has a massive head and slender, curving tail that follows the curve of the lateral ventricle. The head of the caudate nucleus lies anterior to the **lentiform** (*lensshaped*) **nucleus**. The lentiform nucleus consists of a medial **globus pallidus** (GLŌ-bus PAL-i-dus; pale globe) and a lateral

Figure 8-22 The Basal Nuclei.

putamen (pū-TĀ-men). Together, the caudate and lentiform nuclei are also called the *corpus striatum* (striated body). Inferior to the caudate and lentiform nuclei is another nucleus, the **amygdaloid** (ah-MIG-da-loyd; *amygdale*, almond) **body**, or *amygdala*. It is a component of the *limbic system* and is discussed in the next section.

The basal nuclei function in the subconscious control of skeletal muscle tone and the coordination of learned movement patterns. These nuclei do not start a movement—that decision is a voluntary one—but once a movement is under way, the basal nuclei provide the general pattern and rhythm.

CLINICAL NOTE

Seizures

A **seizure** is a temporary cerebral disorder accompanied by abnormal involuntary movements, unusual sensations, or inappropriate behavior. Clinical conditions characterized by seizures are known as seizure disorders, or *epilepsies*. Seizures of all kinds are accompanied by a marked change in the pattern of electrical activity seen in an electroencephalogram. The alteration begins in one portion of the cerebral cortex but may then spread across the entire cortical surface, like a wave on the surface of a pond. The nature of the signs and symptoms produced depends on the region of the cortex involved. If the seizure affects the primary motor cortex, the person will make involuntary movements. If it affects the auditory cortex, the person will hear strange sounds.

For example, when you walk, the basal nuclei control the cycles of arm and thigh movements that occur between the time you decide to "start" walking and the time you give the "stop" order.

The Limbic System

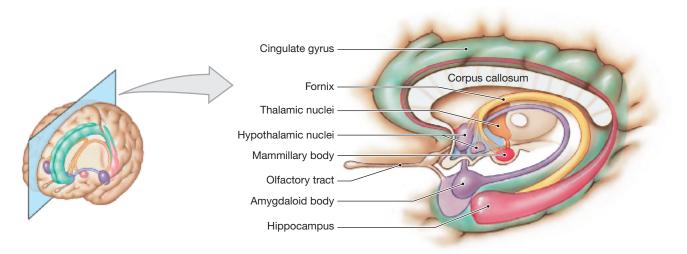

The **limbic system** (LIM-bik; *limbus*, border) includes the olfactory cortex, several nuclei, gyri, and tracts along the border between the cerebrum and diencephalon (**Figure 8-23**). This system is a functional grouping rather than an anatomical one. The functions of the limbic system include (1) establishing emotional states; (2) linking the conscious, intellectual functions of the cerebral cortex with the unconscious and autonomic functions of the brainstem; and (3) aiding long-term memory storage and retrieval. In short, the sensory cortex, motor cortex, and association areas of the cerebral cortex enable you to perform complex tasks, but it is largely the limbic system that makes you *want* to do them.

The amygdaloid bodies link the limbic system, the cerebrum, and various sensory systems. These cerebral nuclei play a role in regulating heart rate, responding to fear and anxiety, controlling the "fight or flight" response, and linking emotions with specific memories.

Another nucleus, the **hippocampus**, is important in learning and in storing long-term memories. Damage to the hippocampus in Alzheimer's disease interferes with memory storage and retrieval. The **fornix** (FOR-niks, *arch*) is a tract of white matter that connects the hippocampus with the hypothalamus (**Figures 8-16c** and **8-23**).

The limbic system also includes hypothalamic centers that control (1) emotional states, such as rage, fear, and sexual arousal, and (2) reflex movements that can be consciously

Figure 8-23 The Limbic System. This three-dimensional reconstruction of the limbic system shows the relationships among the system's major components.

activated. For example, the limbic system includes the *mammillary bodies* (MAM-i-lar-ē; *mamilla*, a little breast) of the hypothalamus, where many fibers of the fornix end. These nuclei process olfactory sensations and control reflex movements associated with eating, such as chewing, licking, and swallowing.

The Diencephalon

The diencephalon (**Figures 8-16c** and **8-24**) contains switching and relay centers that integrate conscious and unconscious sensory information and motor commands. It surrounds the third ventricle and consists of the *epithalamus, thalamus*, and *hypothalamus*.

The Epithalamus

The epithalamus lies superior to the third ventricle, where it forms the roof of the diencephalon. The anterior portion contains an extensive area of choroid plexus. The posterior portion contains the **pineal gland** (Figure 8-24b), an endocrine structure that secretes the hormone *melatonin*. Among other functions, melatonin is important in regulating daynight cycles.

The Thalamus

The left thalamus and right thalamus are separated by the third ventricle. Each contains a rounded mass of thalamic nuclei. The thalamus (Figures 8-16c and 8-24) is the final relay

point for all ascending sensory information, other than olfactory, that will reach our conscious awareness. It acts as a filter, passing on to the primary sensory cortex only a small portion of the arriving sensory information. The rest is relayed to the basal nuclei and centers in the brainstem. The thalamus also plays a role in coordinating voluntary and involuntary motor commands.

The Hypothalamus

The hypothalamus lies inferior to the third ventricle (**Figure 8-16c**). The hypothalamus contains important control and integrative centers in addition to those associated with the limbic system. Its diverse functions include:

- subconscious control of skeletal muscle contractions associated with rage, pleasure, pain, and sexual arousal;
- **2.** adjusting the activities of autonomic centers in the pons and medulla oblongata (such as heart rate, blood pressure, respiration, and digestive functions);
- **3.** coordinating activities of the nervous and endocrine systems;
- **4.** secreting a variety of hormones, including *antidiuretic hormone* (*ADH*) and *oxytocin* (*OXT*);
- producing the behavioral "drives" involved in hunger and thirst;
- 6. coordinating voluntary and autonomic functions;
- 7. regulating normal body temperature; and
- 8. coordinating the daily cycles of activity.

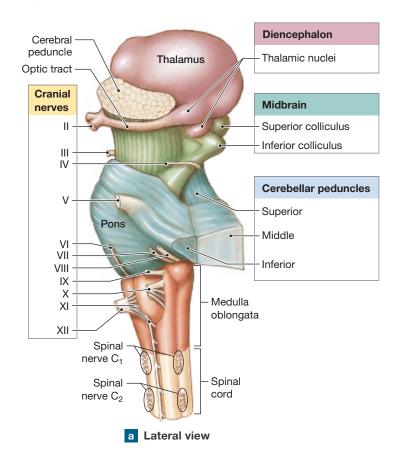

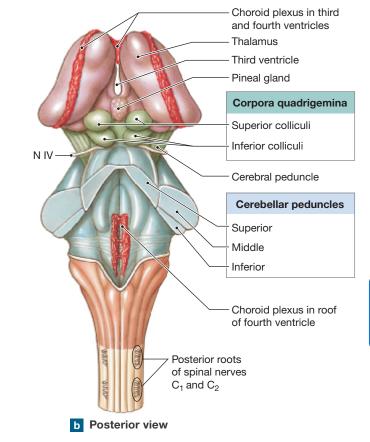

Figure 8-24 The Diencephalon and Brainstem.

The Midbrain

The midbrain (Figure 8-24) contains various nuclei and bundles of ascending and descending nerve fibers. It includes two pairs of sensory nuclei, or *colliculi* (ko-LIK-ū-lī; singular: *colliculus*, a small hill), involved in processing visual and auditory sensations. The *superior colliculi* control the reflex movements of the eyes, head, and neck in response to visual stimuli, such as a bright light. The *inferior colliculi* control reflex movements of the head, neck, and trunk in response to auditory stimuli, such as a loud noise.

The midbrain also contains motor nuclei for two of the cranial nerves (III, IV) involved in the control of eye movements. Descending bundles of nerve fibers on the ventrolateral surface of the midbrain make up the **cerebral peduncles** (*peduncles*, little feet). Some of the descending fibers go to the cerebellum by way of the pons. Others carry voluntary motor commands from the primary motor cortex of each cerebral hemisphere.

The midbrain is also headquarters to one of the most important brain stem components, the **reticular formation**, which regulates many involuntary functions. The reticular formation is a network of interconnected nuclei that extends the length of the brainstem. The reticular formation of the midbrain contains the *reticular activating system* (*RAS*). The output of this system directly affects the activity of the cerebral cortex. When the RAS is inactive, so are we. When the RAS is stimulated, so is our state of attention or wakefulness.

Midbrain nuclei that integrate information from the cerebrum and cerebellum control the maintenance of muscle tone and posture. Other midbrain nuclei play an important role in regulating the motor output of the basal nuclei. For example, the *substantia nigra* (NĪ-gruh; black) inhibit the activity of the basal nuclei by releasing the neurotransmitter dopamine. \bigcirc p. 290 If the substantia nigra are damaged or the neurons secrete less dopamine, the basal nuclei become more active. The result is a gradual increase in muscle tone and the appearance of symptoms characteristic of *Parkinson's disease*. Persons with Parkinson's disease have difficulty starting voluntary movements because opposing muscle groups do not relax. Instead, they must be overpowered. Once a movement is under way, every aspect must be voluntarily controlled through intense effort and concentration.

The Pons

The pons (Figure 8-24a) links the cerebellum with the midbrain, diencephalon, cerebrum, and spinal cord. One group of nuclei within the pons includes the sensory and motor nuclei for four of the cranial nerves (V–VIII). Other nuclei are concerned with the involuntary control of the pace and depth of respiration. Tracts passing through the pons link the cerebellum with the brain stem, cerebrum, and spinal cord.

The Cerebellum

The cerebellum (**Figure 8-16b,c**) is an automatic processing center. Like the cerebrum, the cerebellum is composed of white matter covered by a layer of neural cortex (gray matter) called the *cerebellar cortex*. The cerebellum has two important functions:

- 8
- **1.** *Adjusting the postural muscles of the body.* The cerebellum coordinates rapid, automatic adjustments to maintain balance and equilibrium.
- **2.** *Programming and fine-tuning movements controlled at the conscious and subconscious levels.* The cerebellum refines learned movement patterns, such as riding a bicycle or playing the piano.

These functions are performed indirectly by regulating activity along motor pathways at the cerebral cortex, basal nuclei, and brain stem. The cerebellum compares the motor commands with proprioceptive information (position sense) and makes adjustments needed to make the movement smooth. The tracts that link the cerebellum with these different regions are the **cerebellar peduncles** (Figure 8-24).

The cerebellum can be permanently damaged by trauma or stroke or temporarily affected by drugs such as alcohol. These alterations can produce *ataxia* (a-TAK-sē-uh; *ataxia*, a lack of order), a disturbance in balance.

The Medulla Oblongata

The medulla oblongata (Figure 8-24) connects the brain with the spinal cord. It is a very busy place—all communication between the brain and spinal cord involves tracts that ascend or descend through the medulla oblongata. These tracts often synapse in the medulla oblongata at sensory or motor nuclei that act as relay stations and processing centers. In addition to these nuclei, the medulla oblongata contains sensory and motor nuclei associated with five of the cranial nerves (VIII–XII).

The portion of the reticular system within the medulla oblongata contains nuclei and centers that regulate vital autonomic functions. These *reflex centers* receive inputs from cranial nerves, the cerebral cortex, and the brain stem. Their output controls or adjusts the activities of the cardiovascular and respiratory systems:

- The **cardiovascular center** adjusts heart rate, the strength of cardiac contractions, and the flow of blood through peripheral tissues. In terms of function, the cardiovascular center is subdivided into a *cardiac center* regulating the heart rate and a *vasomotor center* controlling peripheral blood flow.
- The **respiratory rhythmicity centers** set the basic pace for respiratory movements, and their activity is adjusted by the *respiratory centers* of the pons.

CHECKPOINT

- **20.** Describe one major function of each of the six regions of the brain.
- **21.** The pituitary gland links the nervous and endocrine systems. To which portion of the diencephalon is it attached?
- **22.** How would decreased diffusion across the arachnoid granulations affect the volume of cerebrospinal fluid in the ventricles?
- **23.** Mary suffers a head injury that damages her primary motor cortex. Where is this area located?
- **24.** Which senses would be affected by damage to the temporal lobes of the cerebrum?
- **25.** The thalamus acts as a relay point for all but what type of sensory information?
- **26.** Changes in body temperature stimulate which area of the diencephalon?
- **27.** The medulla oblongata is one of the smallest sections of the brain. Why can damage to it cause death, when similar damage in the cerebrum might go unnoticed?

See the blue Answers tab at the back of the book.

8-8 The PNS connects the CNS with the body's external and internal environments

Learning Outcome Name the cranial nerves, relate each pair of cranial nerves to its principal functions, and relate the distribution pattern of spinal nerves to the regions they innervate.

The peripheral nervous system (PNS) links the neurons of the central nervous system (CNS) to the rest of the body. All sensory information and motor commands are carried by axons of the PNS (Figure 8-1, p. 275). These axons are bundled together and wrapped in connective tissue, forming peripheral nerves, or simply nerves. Cranial nerves originate from the brain, and spinal nerves connect to the spinal cord. The PNS also includes both the cell bodies and the axons of sensory neurons and motor neurons of the autonomic nervous system.

The Cranial Nerves

Twelve pairs of **cranial nerves** connect to the brain (Figure 8-25). Each cranial nerve has a name related to its distribution or function. Each also has a designation consisting of the letters CN and a Roman numeral (for its position along the longitudinal axis of the brain). For example, CN II refers to the second pair of cranial nerves, the optic nerves. If the full name of the cranial nerve is given, then only the Roman numeral is needed, such as optic nerve (II).

Distribution and Function of Cranial Nerves

Functionally, each nerve can be classified as primarily sensory, primarily motor, or mixed (sensory and motor). Many cranial nerves, however, have secondary functions. For example, several cranial nerves (III, VII, IX, and X) also carry autonomic fibers to PNS ganglia, just as spinal nerves deliver them to ganglia along the spinal cord. Next we consider the distribution and functions of the cranial nerves.

Few people are able to remember the names, numbers, and functions of the cranial nerves without some effort. Many people use mnemonic phrases, such as "Oh, Once One Takes The Anatomy Final, Very Good Vacations Are Heavenly." The first letter of each word represents the name of a cranial nerve.

THE OLFACTORY NERVES (I). The first pair of cranial nerves, the olfactory nerves, are the only cranial nerves attached to the cerebrum. (The rest start or end within nuclei of the diencephalon or brainstem.) These nerves carry special sensory information responsible for the sense of smell. The olfactory nerves originate in the epithelium of the upper nasal cavity and penetrate the cribriform plate of the ethmoid bone to synapse in the *olfactory bulbs* of the brain. \bigcirc p. 187 From the olfactory bulbs, the axons of postsynaptic neurons travel within the *olfactory tracts* to the olfactory centers of the brain.

THE OPTIC NERVES (II). The optic nerves carry visual information from the eyes. After passing through the optic foramina of the orbits, these nerves intersect at the optic chiasm ("a crossing") (Figure 8-25a,b) before they continue as the optic tracts to nuclei of the left and right thalamus.

THE OCULOMOTOR NERVES (III). The midbrain contains the motor nuclei controlling the third and fourth cranial nerves. Each **oculomotor nerve** innervates four of the six extrinsic muscles that move an eyeball (the superior, medial, and inferior rectus muscles and the inferior oblique muscle). (Superficial muscles that position or stabilize an organ are called extrinsic muscles.) These nerves also carry autonomic fibers to intrinsic eye muscles that control the amount of light entering the eye and the shape of the lens. (Muscles located entirely within an organ are called *intrinsic muscles*.)

THE TROCHLEAR NERVES (IV). The trochlear (TRŌK-lē-ar; trochlea, a pulley) nerves, the smallest of the cranial nerves, innervate the superior oblique muscles of the eyes. The motor nuclei that control these nerves lie in the midbrain. The name trochlear refers to the pulley-shaped, ligamentous sling through which the tendon of the superior oblique muscle passes to reach its attachment on the eyeball (Figure 9-9a, 8 p. 346).

THE TRIGEMINAL NERVES (V). The pons contains the nuclei associated with cranial nerve V. The trigeminal (tri-JEM-inal) **nerves** are the largest of the cranial nerves. These nerves provide sensory information from the head and face and motor control over the chewing muscles, such as the temporalis and masseter.

The trigeminal has three major divisions. The ophthalmic *nerve* (V_1) provides sensory information from the orbit of the eye, the nasal cavity and sinuses, and the skin of the forehead, eyebrows, eyelids, and nose. The maxillary nerve (V_2) provides sensory information from the lower eyelid, upper lip, cheek, nose, upper gums and teeth, palate, and portions of the pharynx. The *mandibular nerve* (V_3) is the largest of the three. It provides sensory information from the skin of the temples, the lower gums and teeth, the salivary glands, and the anterior portions of the tongue. It also provides motor control over the chewing muscles (the temporalis, masseter, and pterygoid muscles). **D** p. 249

THE ABDUCENS NERVES (VI). The abducens (ab-DŪ-senz) nerves innervate only the lateral rectus, the sixth of the extrinsic eye muscles. The nuclei of the abducens nerves are in the pons. The nerves emerge at the border between the pons and the medulla oblongata and reach the orbit of the eve along with the oculomotor and trochlear nerves. The name abducens is based on the action of this nerve's innervated muscle, which abducts the eyeball, causing it to rotate laterally, away from the midline of the body.

Trochlear (IV)	Motor	Superior oblique muscle of the eye
 - Trigeminal (V)	Mixed	Sensory: orbital structures, nasal cavity, skin of forehead, eyelids, eyebrows, nose, lips, gums and teeth; cheek, palate, pharynx, and tongue <i>Motor:</i> chewing muscles (temporalis, masseter, pterygoids)
 Abducens (VI)	Motor	Lateral rectus muscle of the eye
- Facial (VII)	Mixed	Sensory: taste receptors on anterior 2/3 of tongue Motor: muscles of facial expression, lacrimal (tear) gland, and submandibular and sublingual salivary glands
 Vestibulocochlear (VIII)	Special sensory	Cochlea (receptors for hearing) Vestibule (receptors for motion and balance)
 Glossopharyngeal (IX)	Mixed	Sensory: posterior 1/3 of tongue; pharynx and palate (part); receptors for blood pressure, pH, oxygen, and carbon dioxide
 – Vagus (X)	Mixed	Sensory: pharynx, auricle and external acoustic meatus (portion of external ear), diaphragm, visceral organs in thoracic and abdominopelvic cavities <i>Motor:</i> palatal and pharyngeal muscles and visceral organs in thoracic and abdominopelvic cavities
 Accessory (XI)	Motor	Voluntary muscles of palate, pharynx, and larynx (with vagus nerve); sternocleidomastoid and trapezius muscles
 – Hypoglossal (XII)	Motor	Tongue muscles

THE FACIAL NERVES (VII). The facial nerves are mixed nerves of the face. Their sensory and motor roots emerge from the side of the pons. The sensory fibers monitor proprioceptors in the facial muscles, provide deep pressure sensations over the face, and provide taste information from receptors along the anterior two-thirds of the tongue. The motor fibers produce facial expressions by controlling the superficial muscles of the scalp and face and muscles near the ear. These nerves also carry autonomic fibers that result in control of the tear glands and salivary glands.

THE VESTIBULOCOCHLEAR NERVES (VIII). The vestibuloco-

chlear nerves monitor the sensory receptors of the internal ear. The pons and medulla oblongata contain nuclei associated with these nerves. Each vestibulocochlear nerve has two parts: (1) a vestibular nerve (vestibulum, a cavity), which originates at the vestibule (the portion of the internal ear concerned with balance sensations) and conveys information on position, movement, and balance; and (2) the cochlear (KOK-lē-ar; cochlea, snail shell) nerve, which monitors the receptors of the cochlea (the portion of the internal ear responsible for the sense of hearing).

THE GLOSSOPHARYNGEAL NERVES (IX). The glossopharyngeal (glos-ō-fah-RIN-jē-al; glossus, tongue) nerves are mixed nerves innervating the tongue and pharynx. The associated sensory and motor nuclei are in the medulla oblongata. The sensory portion of this nerve provides taste sensations from the posterior third of the tongue. It also monitors blood pressure and dissolved gas concentrations in major blood vessels. The motor portion controls the pharyngeal muscles involved in swallowing. These nerves also carry autonomic fibers that control the parotid salivary glands.

THE VAGUS NERVES (X). The **vagus** (VĀ-gus; *vagus*, wandering) nerves provide sensory information from each auricle and external acoustic meatus (auditory canal), the diaphragm, and taste receptors in the pharynx, and from visceral receptors along the esophagus, respiratory tract, and abdominal organs as far away as the last portions of the large intestine. The associated sensory and motor nuclei of the vagus are located in the medulla oblongata. The sensory information that is provided is vital to the autonomic control of visceral function. We are not consciously aware of these sensations because they are seldom relayed to the cerebral cortex. The motor components of the vagus nerves control skeletal muscles of the soft palate, pharynx, and esophagus and affect cardiac muscle, smooth muscle, and glands of the esophagus, stomach, intestines, and gallbladder.

THE ACCESSORY NERVES (XI). The accessory nerves, sometimes called the spinal accessory nerves, are motor nerves that innervate structures in the neck and back. These nerves differ from other cranial nerves in that some of their motor fibers originate in the lateral gray horns of the first five cervical segments of the spinal cord, as well as in the medulla oblongata. All these motor fibers join together in the cranium and exit as cranial nerve XI, which then divides into two branches. The internal branch joins the vagus nerve and innervates the voluntary swallowing muscles of the soft palate and pharynx, as well as the laryngeal muscles that control the vocal cords and produce speech. The external branch controls the sternocleidomastoid and trapezius muscles associated with the pectoral girdles. \bigcirc pp. 250, 255

THE HYPOGLOSSAL NERVES (XII). The hypoglossal (hī-pō-GLOS-al) nerves provide voluntary control over movements of the tongue. The nuclei for these motor nerves are located in the medulla oblongata.

The distribution (innervated structures) and functions of the cranial nerves are summarized in Figure 8-25b.

The Spinal Nerves

The 31 pairs of **spinal nerves** are grouped according to the region of the vertebral column from which they originate (Figure 8-26). They include 8 pairs of cervical nerves $(C_1 - C_8)$, 12 pairs of thoracic nerves (T_1-T_{12}) , 5 pairs of lumbar nerves (L_1-L_5) , 5 pairs of sacral nerves (S_1-S_5) , and 1 pair of coccygeal nerves (Co₁).

Each pair of spinal nerves monitors a specific region of the body surface known as a **dermatome** (Figure 8-27). Dermatomes are clinically important because damage or infection of a spinal nerve or of spinal ganglia produces a characteristic loss of sensation in the corresponding region of the skin. For example, in *shingles*, a virus that infects spinal ganglia causes a painful rash whose distribution corresponds to that of the affected sensory nerves.

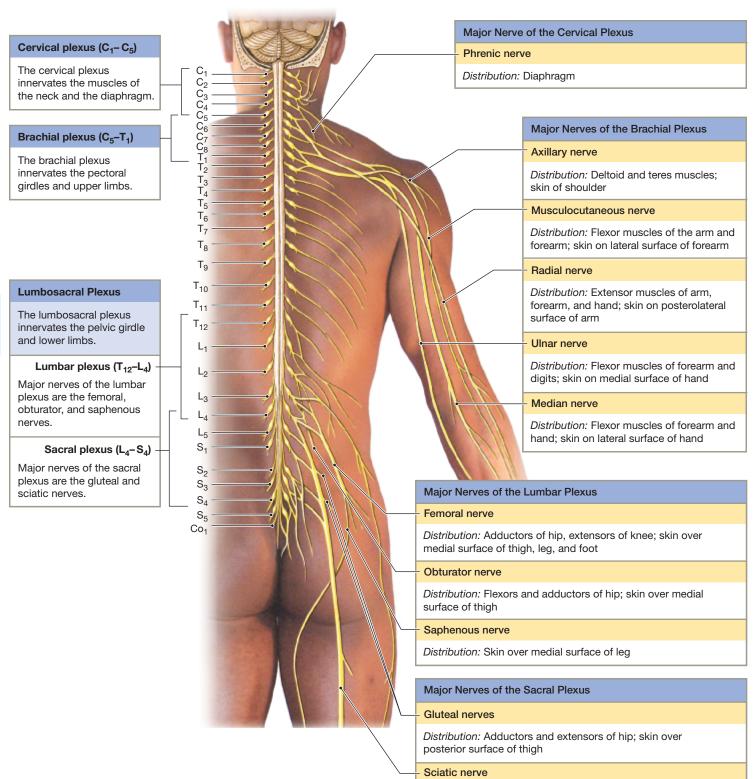

Nerve Plexuses

During development, skeletal muscles commonly fuse, forming larger muscles innervated by nerve trunks containing axons derived from several spinal nerves. These compound nerve trunks originate at networks called **nerve plexuses**. The four spinal nerve plexuses and the distribution of some of the major peripheral nerves are shown in Figure 8-26.

The **cervical plexus** innervates the muscles of the neck and extends into the thoracic cavity to control the

8

Figure 8-26 Peripheral Nerves and Nerve Plexuses.

Distribution: Flexors of knee and ankle, flexors and extensors of toes; skin over anterior and posterior surfaces of leg and foot

diaphragm, a key respiratory muscle. The **brachial plexus** innervates the pectoral girdles and upper limbs. The **lumbar plexus** and the **sacral plexus** supply the pelvic girdle and lower limbs. These plexuses are sometimes designated the *lumbosacral plexus*.

The nerves arising at the nerve plexuses contain sensory as well as motor fibers. *Peripheral nerve palsies*, also known as *peripheral neuropathies*, are characterized by regional losses of sensory and motor function as the result of nerve trauma or compression. You have experienced a mild, temporary palsy if your arm or leg has ever "fallen asleep."

CHECKPOINT

- **28.** What signs would you associate with damage to the abducens nerve (VI)?
- **29.** John is having trouble moving his tongue. His physician tells him it is due to pressure on a cranial nerve. Which cranial nerve is involved?
- **30.** Injury to which nerve plexus would interfere with the ability to breathe?
- See the blue Answers tab at the back of the book.

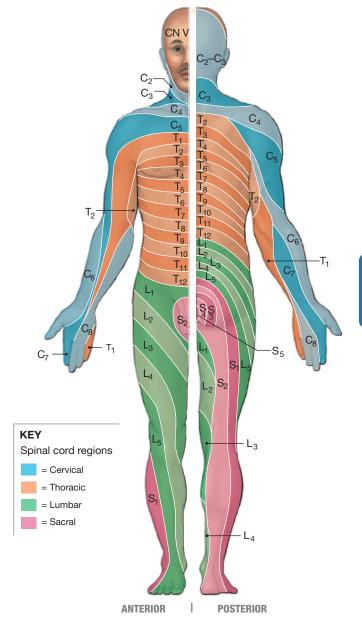

8-9 Reflexes are rapid, automatic responses to stimuli

Learning Outcome Describe the steps in a reflex arc.

We can study the central and peripheral nervous systems separately, but they work together. To consider the ways the CNS and PNS interact, we begin with simple reflex responses to stimulation. A **reflex** is a rapid, automatic response to a specific stimulus. Reflexes help preserve homeostasis by making rapid adjustments in the function of organs or organ systems. The response shows little variability. Whenever a particular reflex is activated, it usually produces the same motor response.

Simple Reflexes

A reflex involves sensory fibers delivering information from peripheral receptors to the CNS, and motor fibers carrying motor commands to peripheral effectors. The "wiring" of a single reflex is called a **reflex arc**. It begins at a receptor and ends at an effector such as a muscle fiber or gland cell. **Figure 8-28** diagrams the five steps involved in the action of a reflex arc: (1) the arrival of a stimulus and activation of a receptor, (2) the activation of a sensory neuron, (3) information processing by an interneuron, (4) the activation of a motor neuron, and (5) the response by a peripheral effector. **Figure 8-27 Dermatomes.** Distributions of dermatomes on the surface of the skin, as seen in the anterior and posterior view. The face is served by cranial nerves, not spinal nerves.

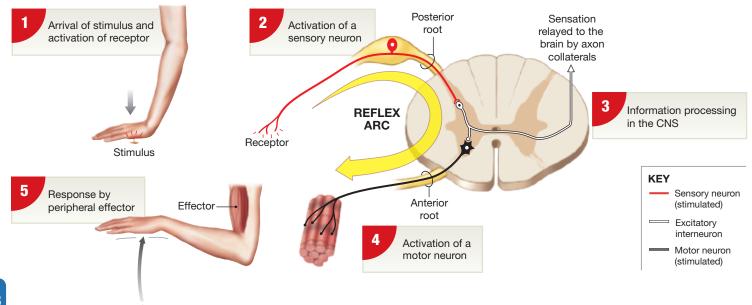

A reflex usually removes or opposes the original stimulus. In **Figure 8-28**, the contracting muscle pulls the hand away from the painful stimulus. This reflex arc is, therefore, an example of *negative feedback*. \bigcirc p. 40 By opposing potentially harmful changes in the internal or external environment, reflexes play an important role in maintaining homeostasis.

In the simplest reflex arc, a sensory neuron synapses directly on a motor neuron, which performs the information-processing function. Such a reflex is called a **monosynaptic reflex**. Because there is only one synapse, monosynaptic reflexes control the most rapid, stereotyped motor responses of the nervous system. The best-known example is the stretch reflex.

314 NERVOUS SYSTEM

Figure 8-28 Events in a Reflex Arc.

The **stretch reflex** provides automatic regulation of skeletal muscle length. The sensory receptors in the stretch reflex are called **muscle spindles**. They are bundles of small, specialized skeletal muscle fibers scattered throughout skeletal muscles. The stimulus (increasing muscle length) activates a sensory neuron that triggers an immediate motor response (contraction of the stretched muscle) that counteracts the stimulus.

Stretch reflexes are important in maintaining normal posture and balance and in making automatic adjustments in muscle tone. Physicians can use the sensitivity of the stretch reflex to test the general condition of the spinal cord, peripheral nerves, and muscles. For example, in the **patellar reflex**, or *knee-jerk reflex*, a sharp rap on the patellar tendon stretches muscle spindles in the quadriceps muscles (**Figure 8-29**). With so brief a stimulus, the reflexive contraction occurs unopposed and produces a noticeable kick. If this contraction shortens the muscle spindles to less than their original resting lengths, the sensory nerve endings are compressed, the sensory neuron is inhibited, and the leg drops back.

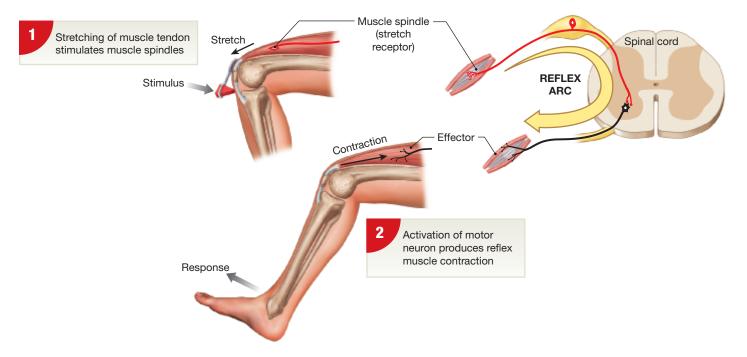

Complex Reflexes

Many spinal reflexes have at least one interneuron between the sensory (afferent) neuron and the motor (efferent) neuron (Figure 8-28). Because there are more synapses, such **polysynaptic reflexes** include a longer delay between stimulus and response. But they can produce far more responses because the interneurons can control several muscle groups simultaneously. Withdrawal reflexes move stimulated parts of the body away from a source of stimulation. Painful stimuli trigger the strongest withdrawal reflexes, but these reflexes are also initiated by the stimulation of touch or pressure receptors. A **flexor reflex** is a withdrawal reflex affecting the muscles of a limb. If you grab an unexpectedly hot pan on the stove, a dramatic flexor reflex occurs (**Figure 8-30**). When the pain receptors in your hand are stimulated, the sensory neurons activate interneurons in the spinal cord that stimulate motor neurons in the anterior gray horns. As a result, flexor muscles contract and yank your forearm and hand away from the stove. At the same time this response is taking place, pain sensations are ascending to the brain.

When a specific muscle contracts, opposing (antagonistic) muscles are stretched. For example, the flexor muscles that bend the elbow are opposed by extensor muscles, which straighten it out. A potential conflict exists here: Contraction of a flexor muscle should trigger a stretch reflex in the extensors that would cause them to contract, opposing the movement that is under way. Interneurons in the spinal cord prevent such competition through **reciprocal inhibition**. When one set of motor neurons is stimulated, those controlling antagonistic muscles are inhibited.

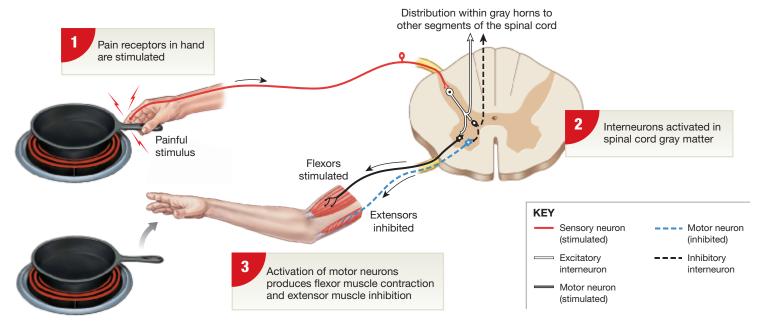

Integration and Control of Spinal Reflexes

Reflexes are automatic, but higher centers in the brain influence these responses. They do so by facilitating (assisting) or inhibiting the interneurons and motor neurons involved. **Figure 8-29 A Stretch Reflex.** The patellar reflex is a stretch reflex controlled by stretch receptors (muscle spindles) in the quadriceps muscles that straighten the knee. When a reflex hammer strikes the patellar tendon, the muscle spindles are stretched. This stretching results in a sudden increase in the activity of the sensory neurons, which synapse on motor neurons in the spinal cord. The activation of spinal motor neurons produces an immediate muscle contraction and a reflexive kick.

The sensitivity of a reflex can thus be modified. The facilitation of motor neurons involved in reflexes is called *reinforcement*. For example, a method used to overemphasize the patellar reflex is a distractive technique called the Jendrassik maneuver. To do this, the person hooks the hands together by interlocking the fingers and then tries to pull the hands apart while a light tap is applied to the patellar tendon. This reinforcement produces a big kick rather than a twitch. A larger reflex response occurs even if the individual realizes it is just a distraction.

Other descending fibers have an inhibitory effect on spinal reflexes. Stroking an infant's foot on the side of the sole produces a fanning of the toes known as the **Babinski reflex**. This response disappears as descending inhibitory synapses develop, so in adults the same stimulus produces a curling of the toes, called a **plantar reflex**, or *negative Babinski reflex*, after about a one-second delay. If either the higher centers or the descending tracts are damaged, the Babinski sign will reappear. As a result, clinicians often test this reflex if CNS injury is suspected.

Spinal reflexes produce consistent, stereotyped motor patterns that are triggered by specific external stimuli. However, the same motor patterns can also be activated as needed by higher centers in the brain. The use of preexisting motor patterns allows a relatively small number of descending fibers to control complex motor functions. For example, the motor patterns for walking, running, and jumping are directed primarily by neuronal pools in the spinal cord. The descending pathways from the brain facilitate, inhibit, or fine-tune the established patterns.

CHECKPOINT

- **31.** Define reflex.
- **32.** Which common reflex do physicians use to test the general condition of the spinal cord, peripheral nerves, and muscles?
- **33.** Why can polysynaptic reflexes produce more complex responses than can monosynaptic reflexes?
- **34.** After injuring his back lifting a sofa, Tom exhibits a positive Babinski reflex. What does this imply about Tom's injury?
- See the blue Answers tab at the back of the book.

Build Your Knowledge

Recall that sensory receptors are present in the dermis and deeper layers of the epidermis (as you saw in **Chapter 5: The Integumentary System**). Dermal nerve fibers monitor these sensory receptors, which provide sensations of touch, pain, pressure, and temperature. **D p. 159**

8-10 Separate pathways carry sensory information and motor commands

Learning Outcome Identify the principal sensory and motor pathways, and explain how it is possible to distinguish among sensations that originate in different areas of the body.

The communication among the CNS, the PNS, and organs and organ systems takes place over pathways, nerve tracts, and nuclei that relay sensory and motor information. $\supset p. 280$ The names of the major sensory (ascending) and motor (descending) tracts of the spinal cord are based on the destinations of the axons. If the name of a tract begins with *spino*-, the tract starts in the spinal cord and ends in the brain, and it therefore carries sensory information. If the name of a tract ends in *-spinal*, its axons start in the higher centers and end in the spinal cord, bearing motor commands. The rest of the tract's name indicates the associated nucleus or cortical area of the brain.

 Table 8-1 lists some examples of sensory and motor pathways, and their functions.

Table 8-1	Sensory and Motor Pathways			
Pathway		Function		
SENSORY				
Posterior column pathway		Delivers highly localized sensations of fine touch, pressure, vibration, and proprioception to the primary sensory cortex		
Spinothalamic pathway		Delivers poorly localized sensations of touch, pressure, pain, and temperature to the primary sensory cortex		
Spinocerebellar pathway		Delivers proprioceptive information concerning the positions of muscles, bones, and joints to the cerebellar cortex		
MOTOR				
Corticospinal pathway		Provides conscious control of skeletal muscles throughout the body		
Medial and lateral pathways		Provides subconscious regulation of skeletal muscle tone, controls reflexive skeletal muscle responses to equilibrium sensations and to sudden or strong visual and auditory stimuli		

Sensory Pathways

Sensory receptors monitor conditions in the body or the external environment. The information gathered by a sensory receptor arrives in the CNS in the form of action

Figure 8-31 The Posterior Column Pathway. The posterior column pathway carries fine-touch, pressure, vibration, and proprioception sensations to the primary somatosensory cortex of the cerebral hemisphere on the opposite side of the body. (For clarity, this figure shows only the pathway for sensations originating on the right side of the body.)

potentials in an afferent (sensory) fiber. The arriving information is called a **sensation**. Most processing of arriving sensations takes place in centers along the sensory pathways in the spinal cord or brainstem. Only about 1 percent of the arriving information reaches the cerebral cortex and our con-

> scious awareness. For example, we usually do not perceive, or feel, the clothes we wear or hear the hum of our car's engine.

The Posterior Column Pathway

One example of an ascending sensory pathway is the posterior column pathway (Figure 8-31). It sends highly localized ("fine") touch, pressure, vibration, and proprioception (position) sensations to the cerebral cortex. In the process, the information is relayed from one neuron to another.

Sensations travel along the axon of a sensory 8 neuron, reaching the CNS through the dorsal roots of spinal nerves (**1** in Figure 8-31). Within the spinal cord, the axons ascend within the posterior column pathway. They synapse in a sensory nucleus of the medulla oblongata. The axons of the neurons in this nucleus (the second neuron in this pathway) cross over to the opposite side of the brainstem before continuing to the thalamus (2). The location of the synapse in the thalamus depends on the region of the body involved. The thalamic (in this case, third) neuron then relays the information to an appropriate region of the primary somatosensory cortex (3).

The sensations arrive at particular locations in the primary somatosensory cortex. For example, sensory information from the toes reaches one end of the primary somatosensory cortex, and information from the head reaches the other. In effect, the primary somatosensory cortex contains a miniature map of the body surface called a sensory homunculus ("little man"). That map is distorted because the area of sensory cortex devoted to a particular region is proportional not to its size, but to the number of sensory receptors the region contains. In other words, it takes many more cortical neurons to process sensory information from the tongue, which has tens of thousands of taste and touch receptors, than it does to analyze sensations from the back, where touch receptors are few and far between.

Motor Pathways

In response to information from sensory systems, the CNS issues motor commands that are distributed by the *somatic nervous system* (*SNS*) and the *autonomic nervous system* (*ANS*) of the efferent division of the PNS (**Figure 8-1**, p. 275). The SNS, under voluntary control, issues somatic motor commands that direct the contractions of skeletal muscles. The motor commands of the ANS occur outside our conscious awareness. They control the smooth muscles, cardiac muscle, and glands.

Three motor pathways provide control over skeletal muscles: the corticospinal pathway, the medial pathway, and the lateral pathway. The corticospinal pathway provides conscious, voluntary control over skeletal muscles. The medial and lateral pathways exert more indirect, subconscious control. **Table 8-1** lists some examples and functions of these motor pathways. We begin our examination of motor pathways with the corticospinal pathway.

The Corticospinal Pathway

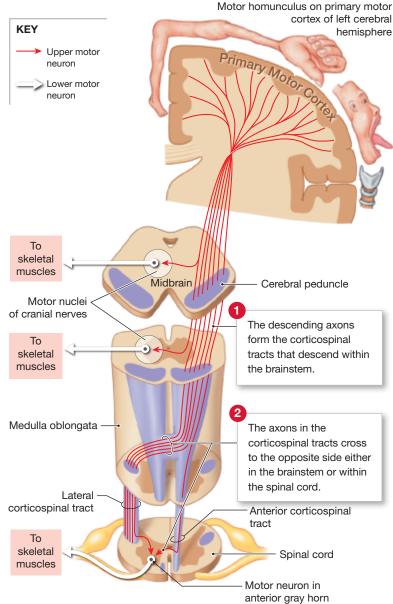

The **corticospinal pathway**, sometimes called the *py-ramidal system*, provides conscious, voluntary control of skeletal muscles. **Figure 8-32** shows the motor pathway providing voluntary control over the right side of the body. As in the case of the sensory homunculus, in the primary motor cortex the area devoted to a body part does not reflect the size of that part. Instead, the area reflects the number of motor units present in that part of the body. For example, the *motor homunculus* has grossly oversized hands. Their size is an indication of the large number of motor units involved in writing, grasping, and manipulating objects in our environment.

The corticospinal pathway begins at triangularshaped *pyramidal cells* of the cerebral cortex. The axons of these upper motor neurons extend into the brainstem and spinal cord, where they synapse on lower motor neurons (1) in Figure 8-32). All axons of the corticospinal tracts eventually cross over to reach motor neurons on the opposite side of the body (2). As a result, the right cerebral hemisphere controls the left side of the body, and the left cerebral hemisphere controls the right side.

The Medial and Lateral Pathways

The **medial and lateral pathways** provide subconscious, involuntary control of muscle tone and movements of

Figure 8-32 The Corticospinal Pathway. The corticospinal pathway originates at the primary motor cortex. Axons of the pyramidal cells of the primary motor cortex descend to reach motor nuclei in the brainstem and spinal cord. Most of the fibers cross over in the medulla oblongata before descending into the spinal cord as the corticospinal tracts.

the neck, trunk, and limbs. They also coordinate learned movement patterns and other voluntary motor activities (**Table 8-1**). Together, these pathways were known as the *extrapyramidal system* because it was thought that they operated independently of and parallel to the *pyramidal system* (the corticospinal pathway). We now know that the control of the body's motor functions is integrated among all three motor pathways. The components of the medial and lateral pathways are spread throughout the brain. These components include nuclei in the brainstem (midbrain, pons, and medulla oblongata), relay stations in the thalamus, the basal nuclei of the cerebrum, and the cerebellum. Output from the basal nuclei and cerebellum exerts the highest level of control. For example, their output can stimulate or inhibit (1) other nuclei of these pathways or (2) the activities of pyramidal cells in the primary motor cortex. Also, axons from the upper motor neurons in the medial and lateral pathways synapse on the same motor neurons innervated by the corticospinal pathway.

CLINICAL NOTE

Cerebral Palsy

The term **cerebral palsy** refers to a number of disorders affecting voluntary motor performance (including speech, movement, balance, and posture) that appear during infancy or childhood and persist throughout life. The cause may be trauma associated with premature or unusually stressful birth; maternal exposure to drugs, including alcohol; or a genetic defect that causes the motor pathways to develop improperly. Problems with labor and delivery result from the compression or interruption of placental circulation or oxygen supplies. If the oxygen concentration of fetal blood declines significantly for as little as 5–10 minutes, CNS

function can be permanently impaired. The cerebral cortex, cerebellum, basal nuclei, hippocampus, and thalamus are likely to be affected. Abnormalities in motor skills, posture and balance, memory, speech, and learning abilities may result.

CHECKPOINT

- **35.** As a result of pressure on her spinal cord, Jill cannot feel touch or pressure on her legs. What sensory pathway is being compressed?
- **36.** The primary motor cortex of the right cerebral hemisphere controls motor function on which side of the body?
- **37.** An injury to the superior portion of the primary motor cortex would affect the ability to control muscles of which parts of the body?

See the blue Answers tab at the back of the book.

8-11 The autonomic nervous system, composed of the sympathetic and parasympathetic divisions, is involved in the unconscious regulation of body functions

Learning Outcome Describe the structures and functions of the sympathetic and parasympathetic divisions of the autonomic nervous system.

Your conscious sensations, plans, and responses are only a tiny fraction of the activities of the nervous system. In practical terms, conscious activities have little to do with our immediate or long-term survival. The **autonomic nervous system (ANS)** makes adjustments that are much more important. Without the ANS, a simple night's sleep would be a life-threatening event.

Recall that both the ANS and the somatic nervous system (SNS) are parts of the efferent division of the PNS. As such, they carry motor commands to peripheral effectors. \supset p. 275 However, clear anatomical differences exist between them (Figure 8-33). In the SNS, lower motor neurons exert direct control over skeletal muscles (Figure 8-33a). In the ANS, a second motor neuron always separates the CNS and the peripheral effector (Figure 8-33b). We now turn to the ANS.

The ANS motor neurons in the CNS are known as **preganglionic neurons**. They send their axons, called *preganglionic fibers*, to autonomic ganglia outside the CNS. In these ganglia, the axons of preganglionic neurons synapse on **ganglionic neurons**. The axons of the ganglionic neurons are **postganglionic fibers**. These fibers leave the ganglia and innervate cardiac muscle, smooth muscles, glands, and, in some cases, fat cells (adipocytes).

The ANS has two divisions: the sympathetic division and the parasympathetic division. In the **sympathetic division**, preganglionic fibers leave the thoracic and lumbar segments of the spinal cord and synapse in ganglia near the spinal cord (**Figure 8-34**). In this division, the preganglionic fibers are short, and the postganglionic fibers are long. The sympathetic division is often called the "fight or flight" system because it usually stimulates tissue metabolism, increases alertness, and prepares the body to deal with emergencies.

In the **parasympathetic division** of the ANS, preganglionic fibers originate in the brainstem and the sacral segments of the spinal cord (**Figure 8-35**). They synapse on neurons in *terminal ganglia* very close to the target organs, or in *intramural ganglia* (*murus*, wall) embedded within the target organs. In this division, the preganglionic fibers are long, and the postganglionic fibers are short. The parasympathetic division is often regarded as the "rest and repose" or "rest and digest" system because it conserves energy and promotes sedentary activities, such as digestion.

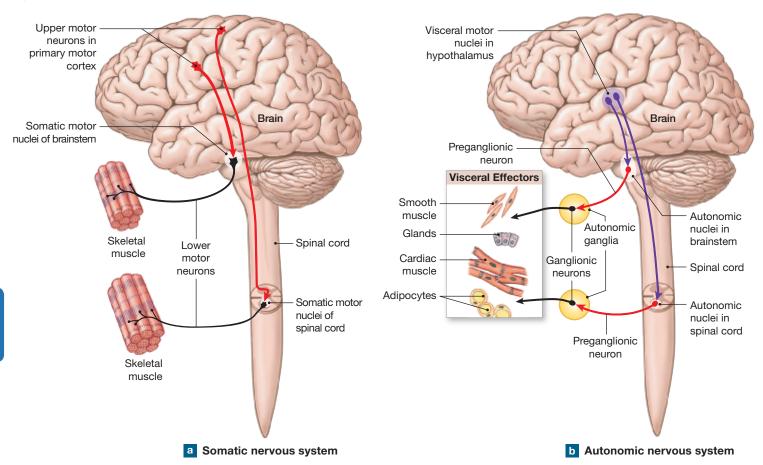

Figure 8-33 The Organization of the Somatic and Autonomic Nervous Systems.

Both divisions of the ANS affect target organs by releasing specific neurotransmitters from their postganglionic fibers. The result may be either stimulation or inhibition of activity, depending on the membrane receptor's response to the neurotransmitter. Some general patterns are worth noting:

- All preganglionic autonomic fibers are cholinergic: They release acetylcholine (ACh) at their axon terminals.
 p. 288 The effects are always excitatory.
- Postganglionic parasympathetic fibers are also cholinergic. However, the effects are excitatory or inhibitory, depending on the nature of the target cell receptor.
- Most postganglionic sympathetic fibers release norepinephrine (NE). Neurons that release NE are called *adrenergic*. D p. 290 The effects of NE are usually excitatory.

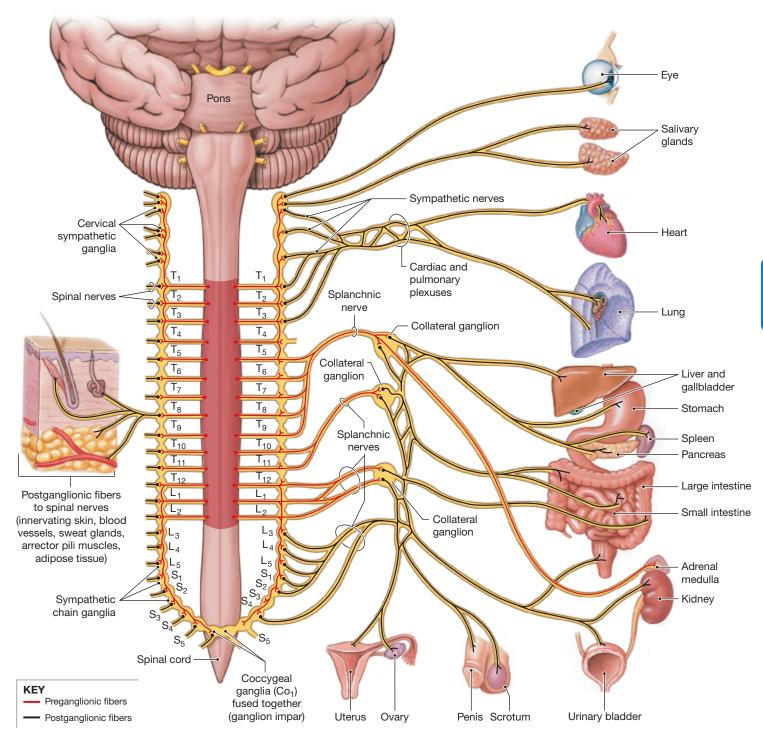

The Sympathetic Division

The sympathetic division of the ANS (**Figure 8-34**) consists of the following components:

- Preganglionic neurons located between segments
 T₁ and L₂ of the spinal cord. The cell bodies of these
 neurons are found in the lateral gray horns. Their short
 axons enter the anterior roots of these spinal segments.
- *Ganglionic neurons located in ganglia near the vertebral column.* Two types of sympathetic ganglia exist. Paired *sympathetic chain ganglia* lie on either side of the vertebral column. They contain neurons that control effectors in the body wall and inside the thoracic cavity. Unpaired *collateral ganglia* lie anterior to the vertebral column. They contain ganglionic neurons that innervate tissues and organs in the abdominopelvic cavity.
- **The adrenal medullae.** The center of each adrenal (*ad-*, near + *renal*, kidney) gland is known as the **adrenal medulla**. It is a modified sympathetic ganglion. Its ganglionic neurons have very short axons.

Organization of the Sympathetic Division

Figure 8-34 diagrams the distribution of sympathetic innervation. Note that this distribution is the same on both sides of the body. **Figure 8-34 The Sympathetic Division.** The distribution of sympathetic fibers is the same on both sides of the body. For clarity, the innervation of somatic structures is shown to the left, and the innervation of visceral structures to the right.

THE SYMPATHETIC CHAIN. From spinal segments T_1 to L_2 , sympathetic preganglionic fibers join the ventral root of each spinal nerve. All these fibers then exit the spinal nerve to enter the sympathetic chain ganglia (**Figure 8-34**). The fibers diverge extensively, with one preganglionic fiber synapsing on two dozen or more ganglionic neurons. For motor commands to the body wall, a synapse occurs at the chain ganglia, and then the postganglionic fibers return to the spinal nerve for distribution. For the thoracic cavity, a synapse also occurs at the chain ganglia, but the postganglionic fibers then form nerves that go directly to their targets.

THE COLLATERAL GANGLIA. The abdominopelvic tissues and organs receive sympathetic innervation over preganglionic fibers from lower thoracic and upper lumbar segments that pass through the sympathetic chain without synapsing. Instead, these fibers synapse within three unpaired **collateral ganglia** (**Figure 8-34**). The nerves traveling to the collateral ganglia are known as *splanchnic nerves*. The postganglionic fibers leave the collateral ganglia and innervate organs throughout the abdominopelvic cavity.

THE ADRENAL MEDULLAE. Preganglionic fibers enter each adrenal gland and proceed to its center, the adrenal medulla. The fibers then synapse on modified neurons with an endocrine function. When stimulated, these cells release the neurotransmitters norepinephrine (NE) and epinephrine (E) into the bloodstream. The bloodstream carries NE and E throughout the body, where they cause metabolic changes in many different cells. In general, the effects of these neurotransmitters resemble those produced by the stimulation of sympathetic postganglionic fibers.

General Functions of the Sympathetic Division

The sympathetic division stimulates tissue metabolism, increases alertness, and prepares the individual for sudden, intense physical activity. Sympathetic innervation by the spinal nerves stimulates sweat gland activity and arrector pili muscles (producing "goose bumps"), reduces circulation to the skin and body wall, speeds up blood flow to skeletal muscles, releases stored lipids from adipose tissue, and dilates the pupils. The activation of the sympathetic nerves to the thoracic cavity accelerates the heart rate, increases the force of cardiac contractions, and dilates the respiratory passageways.

The postganglionic fibers from the collateral ganglia reduce the blood flow to visceral organs that are not important to short-term survival (such as the digestive tract). These fibers also reduce energy use by these organs. In addition, the fibers stimulate the release of stored energy reserves.

The release of NE and E by the adrenal medullae broadens the effects of sympathetic activation to cells not innervated by sympathetic postganglionic fibers. The effects also last much longer than those produced by direct sympathetic innervation.

The Parasympathetic Division

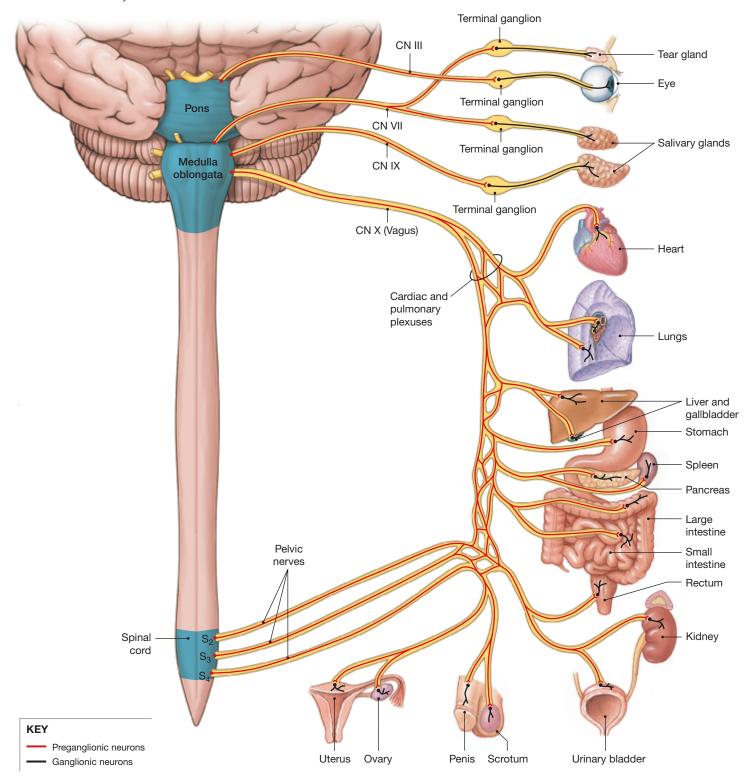

The parasympathetic division of the ANS (**Figure 8-35**) includes the following structures:

- **Preganglionic neurons in the brainstem and in sacral segments of the spinal cord.** The midbrain, pons, and medulla oblongata contain autonomic nuclei associated with cranial nerves III, VII, IX, and X. Other autonomic nuclei lie in the lateral gray horns of spinal cord segments S₂ to S₄.
- *Ganglionic neurons in peripheral ganglia within or adjacent to the target organs.* Preganglionic fibers of the parasympathetic division do not diverge as extensively as those of the sympathetic division. For this reason, the effects of parasympathetic stimulation are more localized and specific than those of the sympathetic division.

Organization of the Parasympathetic Division

Figure 8-35 diagrams the pattern of parasympathetic innervation. Preganglionic fibers leaving the brain travel within cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus). These fibers synapse in terminal ganglia located in peripheral tissues. Short postganglionic fibers then continue to their targets. The vagus nerves provide preganglionic parasympathetic innervation to ganglia in organs of the thoracic and abdominopelvic cavities. Some of these ganglia are as distant as the last segments of the large intestine. The vagus nerves provide roughly 75 percent of all parasympathetic outflow (efferent activity) and innervate most of those organs.

Preganglionic fibers in the sacral segments of the spinal cord carry the sacral parasympathetic output. They do not join the spinal nerves but instead form **pelvic nerves**. These nerves innervate intramural ganglia in the kidney and urinary bladder, the last segments of the large intestine, and the sex organs. **Figure 8-35** The Parasympathetic Division. The distribution of parasympathetic fibers is the same on both sides of the body.

General Functions of the Parasympathetic Division

The functions of the parasympathetic division center on relaxation, food processing, and energy absorption. For example, the parasympathetic division constricts the pupils, increases secretions by the digestive glands, increases smooth muscle activity of the digestive tract, stimulates defecation and urination, constricts respiratory passageways, and reduces heart rate and the force of cardiac contractions. This division has been called the *anabolic system* (*anabole*, a raising up), because its stimulation leads to a general increase in the nutrient content of the blood. In response, cells throughout the body absorb nutrients and use them in growth, cell division, and the storage of energy reserves. The effects of parasympathetic stimulation are usually brief and are restricted to specific organs and sites.

8

Relationships between the Sympathetic and Parasympathetic Divisions

The sympathetic division has widespread effects, reaching visceral and somatic structures throughout the body. In contrast, the parasympathetic division innervates areas serviced by the cranial nerves and organs in the thoracic and abdominopelvic cavities. Some organs are innervated by one division or the other, but most vital organs receive **dual innervation**. That is, they get instructions from both autonomic divisions. In these cases, the two divisions often have opposing effects. **Table 8-2** provides examples of the effects of either single or dual innervation on selected organs.

CHECKPOINT

- **38.** While out for a brisk walk, Megan is suddenly confronted by an angry dog. Which division of the ANS is responsible for the physiological changes that occur as she turns and runs from the animal?
- **39.** Why is the parasympathetic division of the ANS sometimes referred to as the anabolic system?
- **40.** What effect would loss of sympathetic stimulation have on the flow of air into the lungs?
- **41.** What physiological changes would you expect in a patient who is about to undergo a root canal procedure and is quite anxious about it?
- See the blue Answers tab at the back of the book.

8-12 Aging produces various structural and functional changes in the nervous system

Learning Outcome Summarize the effects of aging on the nervous system.

Age-related anatomical and physiological changes in the nervous system probably begin by age 30 and accumulate over time. An estimated 85 percent of individuals above age 65 lead relatively normal lives, but they exhibit noticeable changes in mental performance and in CNS function. Common agerelated anatomical changes include:

- *A reduction in brain size and weight.* This change results primarily from a decrease in the volume of the cerebral cortex. The brains of elderly individuals have narrower gyri and wider sulci than those of young people.
- *A reduction in the number of neurons.* Brain shrinkage has been linked to a loss of cortical neurons. Evidence indicates that the loss of neurons does not occur (at least to the same degree) in brainstem nuclei.
- *A decrease in blood flow to the brain.* With age, the gradual accumulation of fatty deposits in the walls of blood vessels reduces the rate of blood flow through arteries. (This process, called *arteriosclerosis*, affects arteries throughout the body. We discuss it further in Chapter 13.) The reduction in blood flow may not cause a cerebral crisis, but it does increase the chances that the individual will suffer a stroke.
- **Changes in the synaptic organization of the brain.** The number of dendritic branchings and interconnections appears to decrease. Synaptic connections are lost, and neurotransmitter production declines.
- Intracellular and extracellular changes in CNS neurons. Many neurons in the brain accumulate abnormal intracellular deposits (pigments or abnormal proteins) that have no apparent function. Extracellular accumulations of proteins (plaques) may also occur. These changes appear to take place in all aging brains. When present in excess, they seem to be associated with clinical abnormalities.

These anatomical changes are linked to impaired neural function. Memory consolidation—the conversion of short-term memory to long-term memory—often becomes more difficult. Other memories, especially those of the recent past, also become more difficult to recall. The sensory systems of the elderly (notably hearing, balance, vision, smell, and taste) become less acute.

Table 8-2 The Effects of the Sympathetic and Parasympathetic Divisions of the ANS on Various Body Structures					
Structure	Sympathetic Effects	Parasympathetic Effects			
EYE					
	Dilation of pupil	Constriction of pupil			
	Focusing for distance vision	Focusing for close vision			
Tear glands	None (not innervated)	Secretion			
SKIN					
Sweat glands	Increases secretion	None (not innervated)			
Arrector pili muscles	Contraction, erection of hairs	None (not innervated)			
CARDIOVASCULAR S	YSTEM				
Blood vessels	Vasoconstriction and vasodilation	None (not innervated)			
Heart	Increases heart rate, force of contraction, and blood pressure	Decreases heart rate, force of contraction, and blood pressure			
ADRENAL GLANDS					
	Secretion of epinephrine and norepinephrine by adrenal medullae	None (not innervated)			
RESPIRATORY SYSTE	M				
Airways	Increases diameter	Decreases diameter			
Respiratory rate	Increases rate	Decreases rate			
DIGESTIVE SYSTEM					
General level of activit	by Decreases activity	Increases activity			
Liver	Glycogen breakdown, glucose synthesis and release	Glycogen synthesis			
SKELETAL MUSCLES					
	Increases force of contraction, glycogen breakdown	None (not innervated)			
ADIPOSE TISSUE					
	Lipid breakdown, fatty acid release	None (not innervated)			
URINARY SYSTEM					
Kidneys	Decreases urine production	Increases urine production			
Urinary bladder	Constricts internal sphincter, relaxes urinary bladder	Tenses urinary bladder, relaxes internal sphincter to eliminate urine			
REPRODUCTIVE SYST	rem literature and the second s				
	Increased glandular secretions; ejaculation in males	Erection of penis (males) or clitoris (females)			

Light must be brighter, sounds louder, and smells stronger before they are perceived. Reaction times are slowed, and reflexes even some withdrawal reflexes—weaken or disappear. The precision of motor control decreases, so it takes longer to perform a given motor pattern than it did 20 years earlier.

For roughly 85 percent of the elderly population, these changes do not interfere with their abilities to function. But for as yet unknown reasons, some individuals become incapacitated by progressive CNS changes. These changes, which can include memory loss, an inability to recall new information, and emotional disturbances, are often lumped together as *dementia*. **Dementia** is a decline in mental ability characterized by deficits in memory, spatial orientation, language, or personality.

The most common cause of dementia is *Alzheimer's disease* (see the Clinical Note on the next page).

CHECKPOINT

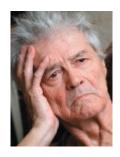

42. What is the major cause of age-related reduction, or shrinkage, of the brain?

See the blue Answers tab at the back of the book.

CLINICAL NOTE

Alzheimer's Disease

Alzheimer's disease is a progressive disorder characterized by the loss of higher cerebral functions. It is the most common cause of *dementia* in older people. Signs and symptoms may appear at

50–60 years of age or later, but the disease occasionally affects younger people. An estimated 5.5 million people in the United States have some form of the condition, including about 16 percent of those between ages 65 to 74, and 38 percent over age 85. The disease causes approximately 100,000 deaths each year. It can also have devastating emotional effects on the patient's immediate family. In its characteristic form, Alzheimer's disease produces a gradual deterioration of mental orga-

nization. The afflicted individual loses memories, verbal and reading skills, and emotional control. As memory losses continue to accumulate, problems become more severe. The affected person may forget relatives, a home address, or how to use the telephone.

The loss of memory affects both intellectual and motor abilities. A patient with severe Alzheimer's disease has difficulty performing even the simplest motor tasks. There is no cure for Alzheimer's disease. A few medications and supplements slow its progress in many patients.

8

8-13 The nervous system is closely integrated with other body systems

Learning Outcome Give examples of interactions between the nervous system and other body systems presented so far.

The nervous system monitors all other systems and issues commands that adjust their activities.

Build Your Knowledge: How the NERVOUS SYSTEM integrates with the other body systems presented so far on p. 327 reviews the major functional relationships between it and the integumentary, skeletal, and muscular systems.

CHECKPOINT

- **43.** Identify the relationships between the nervous system and the other body systems studied so far.
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

amyotrophic lateral sclerosis (ALS): A progressive, degenerative disorder affecting motor neurons of the spinal cord, brainstem, and cerebral hemispheres; commonly known as Lou Gehrig's disease. **cerebrovascular accident (CVA), or** *stroke:* A condition in which the blood supply to a portion of the brain is blocked off.

diphtheria (dif-THĒ-rē-uh): A disease that results from a bacterial infection of the respiratory tract. Among other effects, the bacterial toxins damage Schwann cells and cause PNS demyelination.

Hansen's disease *(leprosy):* A bacterial infection that begins in sensory nerves of the skin and gradually progresses to a motor paralysis of the same regions.

Huntington's disease: An inherited disease marked by a progressive deterioration of mental abilities and by motor disturbances.

meningitis: Inflammation of the meninges involving the spinal cord (*spinal meningitis*) and/or brain (*cerebral meningitis*). It is generally caused by bacterial or viral pathogens.

myelography: A diagnostic procedure in which a radiopaque dye is introduced into the cerebrospinal fluid to obtain an x-ray image of the spinal cord and cauda equina.

neurology: The branch of medicine that deals with the study of the nervous system and its disorders.

neurotoxin: A compound that disrupts normal nervous system function by interfering with the generation or propagation of action potentials. Examples include *tetrodotoxin (TTX), saxitoxin (STX), paralytic shellfish poisoning (PSP),* and *ciguatoxin (CTX).*

paresthesia: An abnormal tingling sensation, usually described as "pins and needles," that accompanies the return of sensation after a temporary palsy.

sciatica (sī-AT-i-kuh): The painful result of compression of the roots of the sciatic nerve.

shingles: A condition caused by the infection of neurons in spinal ganglia by the varicella-zoster virus. The primary symptom is a painful rash along the sensory distribution of the affected spinal nerves.

spinal shock: A period of depressed sensory and motor function following any severe injury to the spinal cord.

Build Your Knowledge

How the NERVOUS SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System provides sensations of touch, pressure, pain, vibration, and temperature; hair provides some protection and insulation for skull and brain; protects peripheral nerves
- The nervous system controls the contraction of arrector pili muscles and the secretion of sweat glands

Skeletal System

- The Skeletal System provides calcium for neural function and protects the brain and spinal cord
- The nervous system affects bone thickening and maintenance by controlling muscle contractions

Nervous System

- The Nervous System is your most complex organ system. It:
- monitors the body's internal and external environments
- integrates sensory information
- directs immediate responses to stimuli
- by coordinating voluntary and involuntary responses of many other organ systems

Muscular System

- The Muscular System expresses emotional states with facial muscles; intrinsic laryngeal muscles permit communication; muscle spindles provide proprioceptive sensations
- The nervous system controls voluntary and involuntary skeletal muscle contractions

Chapter Review

Summary Outline

8

An Introduction to the Nervous System p. 274

1. Two organ systems—the nervous and endocrine systems coordinate organ system activity. The nervous system provides swift but brief responses to stimuli. The endocrine system adjusts metabolic operations and directs long-term changes.

8-1 The nervous system has anatomical and functional divisions *p. 274*

- The nervous system includes all the nervous tissue in the body. Its major anatomical divisions include the central nervous system (CNS) (the brain and spinal cord) and the peripheral nervous system (PNS) (all the nervous tissue outside the CNS).
- 3. Functionally, the PNS can be divided into an **affer**ent division, which brings sensory information to the CNS, and an **efferent division**, which carries motor commands to muscles and glands. The efferent division includes the **somatic nervous system (SNS)** (voluntary control over skeletal muscle contractions) and the **autonomic nervous system (ANS)** (automatic, involuntary regulation of smooth muscle, cardiac muscle, glandular activity, and adipose tissue). (*Figure 8-1*)

8-2 Neurons are specialized for intercellular communication and are supported by cells called neuroglia *p. 275*

- **4.** There are two types of cells in nervous tissue: **neurons**, which are responsible for information transfer and processing, and **neuroglia**, or *glial cells*, which regulate the environment around neurons, provide a supporting framework, and act as phagocytes.
- 5. Sensory neurons form the afferent division of the PNS and deliver information to the CNS. Motor neurons stimulate or modify the activity of a peripheral tissue, organ, or organ system. Interneurons (association neurons) may be located between sensory and motor neurons; they analyze sensory inputs and coordinate motor outputs.
- **6.** A typical neuron has a cell body, an **axon**, several branching **dendrites**, and axon terminals. *(Figure 8-2)*
- 7. Neurons may be described as **unipolar**, **bipolar**, or **multipolar**. (*Figure 8-3*)

- 8. The four types of neuroglia in the CNS are (1) **astrocytes**, which are the largest and most numerous and maintain the blood brain barrier; (2) **oligodendrocytes**, which are responsible for the **myelination** of CNS axons; (3) **microglia**, phagocytic cells derived from white blood cells; and (4) **ependymal cells**, with functions related to the *cerebrospinal fluid* (CSF). (*Figure 8-4*)
- **9.** Nerve cell bodies in the PNS are clustered into **ganglia** (singular: *ganglion*). Their axons are covered by myelin wrappings of **Schwann cells**. (*Figure 8-5*)
- **10.** In the CNS, a collection of neuron cell bodies that share a particular function is called a **center**. A center with a discrete anatomical boundary is called a **nucleus**. Areas of the brain surface are covered by a thick layer of gray matter called the **neural cortex**. The white matter of the CNS contains bundles of axons, or **tracts**, that share common origins, destinations, and functions. Tracts in the spinal cord form larger groups, called *columns. (Figure 8-6)*
- Sensory (ascending) pathways carry information from peripheral sensory receptors to processing centers in the brain. Motor (descending) pathways extend from CNS centers concerned with motor control to the associated skeletal muscles. (Figure 8-6)

8-3 In neurons, a change in the plasma membrane's electrical potential may result in an action potential (nerve impulse) *p. 281*

- **12.** The **resting membrane potential** of an undisturbed nerve cell results from a balance between the rates of sodium ion gain and potassium ion loss achieved by the sodium–potassium exchange pump. Any stimulus that affects this balance will alter the resting potential of the cell. (*Figure 8-7*)
- **13.** An **action potential** appears when the membrane depolarizes to a level known as the **threshold**. The steps involved include depolarization to threshold, the opening of voltage-gated sodium ion channels and membrane depolarization, the closing of voltage-gated sodium ion channels and opening of voltage-gated potassium ion channels, and the return to normal permeability. *(Spotlight Figure 8-8)*
- **14.** In **continuous propagation**, an action potential spreads along the entire excitable membrane surface in a series of small steps. During **saltatory propagation**, the action potential appears to leap from node to node, skipping the intervening myelinated membrane surface. *(Spotlight Figure 8-9)*

8-4 At synapses, communication takes place among neurons or between neurons and other cells *p. 288*

- **15.** A **synapse** is a site where a neuron communicates with another cell through the release of chemicals called **neurotransmitters**. A synapse where neurons communicate with other cell types is a **neuroeffector junction**.
- **16.** Neural communication moves from the **presynaptic neuron** to the **postsynaptic neuron** across the **synaptic cleft**. (*Figure 8-10*)
- 17. Cholinergic synapses release the neurotransmitter acetylcholine (ACh). ACh is broken down in the synaptic cleft by the enzyme acetylcholinesterase (AChE). (*Figure 8-11*)
- 18. The roughly 20 billion interneurons are organized into neuronal pools (groups of interconnected neurons with specific functions). Divergence is the spread of information from one neuron to several neurons or from one neuronal pool to several pools. In convergence, several neurons synapse on the same postsynaptic neuron. (Figure 8-12)

8-5 The brain and spinal cord are surrounded by three layers of membranes called the meninges *p. 291*

- 19. The CNS is made up of the *spinal cord* and *brain*.
- **20.** Special covering membranes, the **meninges**, protect and support the spinal cord and the delicate brain. The *cranial meninges* (dura mater, arachnoid, and pia mater) are continuous with those of the spinal cord, the *spinal meninges*. (*Figure 8-13*)
- **21.** The **dura mater** covers the brain and spinal cord. The **epidural space** separates the spinal dura mater from the walls of the vertebral canal. The subarachnoid space of the arachnoid layer contains **cerebrospinal fluid** (the CSF), which acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemical messengers, and waste products. The **pia mater** is bound to the underlying neural tissue.

8-6 The spinal cord contains gray matter surrounded by white matter and connects to 31 pairs of spinal nerves *p. 292*

- **22.** In addition to relaying information to and from the brain, the spinal cord integrates and processes information on its own.
- **23.** The spinal cord has 31 segments, each associated with a pair of **spinal ganglia** and their **posterior roots**, and a pair of **anterior roots**. (*Figures 8-14; 8-15b*)
- **24.** The white matter contains myelinated and unmyelinated axons; the gray matter contains cell bodies of neurons and glial cells. The projections of gray matter toward the outer surface of the spinal cord are called **horns**. (*Figure 8-15a*)

8-7 The brain has several principal structures, each with specific functions *p. 296*

- **25.** There are six regions in the adult brain: cerebrum, diencephalon, midbrain, pons, medulla oblongata, and cerebellum. *(Figure 8-16)*
- **26.** The central passageway of the brain expands to form four chambers called **ventricles**. Cerebrospinal fluid (CFS) continuously circulates from the ventricles and central canal of the spinal cord into the subarachnoid space of the meninges that surround the CNS. *(Figures 8-17; 8-18)*
- 27. Conscious thought, intellectual functions, memory, and complex involuntary motor patterns originate in the cerebrum. (*Figure 8-16*)
- 28. The cortical surface of the cerebrum contains gyri (elevated ridges) separated by sulci (shallow depressions) or deeper grooves (fissures). The longitudinal fissure separates the two cerebral hemispheres. The central sulcus marks the boundary between the frontal lobe and the parietal lobe. Other sulci form the boundaries of the temporal lobe and the occipital lobe. (*Figures 8-16; 8-19*)
- 29. Each cerebral hemisphere receives sensory information and generates motor commands that concern the opposite side of the body. The **primary motor cortex** of the **precentral gyrus** directs voluntary movements. The **primary somatosensory cortex** of the **postcentral gyrus** receives somatic sensory information from touch, pressure, pain, and temperature receptors. Association areas, such as the visual association area and premotor cortex (somatic motor association area), control our ability to understand sensory information and coordinate a motor response. (*Figure 8-19*)
- **30.** The left hemisphere is usually the *categorical hemisphere*, which contains the **Wernicke's area** and **Broca's area** (speech center) and is responsible for language-based skills. The right hemisphere, or *representational hemisphere*, is concerned with spatial relationships and analyses. (*Figure 8-20*)
- **31.** An **electroencephalogram (EEG)** is a printed record of **brain waves**. (*Figure 8-21*)
- **32.** The **basal nuclei** lie within the central white matter and aid in the coordination of learned movement patterns and other somatic motor activities. (*Figure 8-22*)
- **33.** The **limbic system** is a functional grouping rather than an anatomical one. Among other structures, it includes the *hippocampus*, which is involved in memory and learning, and the *mammillary bodies*, which control reflex movements associated with eating. The functions of the limbic system involve establishing emotional states, linking the conscious, intellectual functions of the cerebral cortex with the unconscious and autonomic functions of the brainstem, and aid-ing long-term memory storage and retrieval. (*Figure 8-23*)
- **34.** The **diencephalon** provides the switching and relay centers needed to integrate the conscious and unconscious sensory and motor pathways. It is made up of the **epithalamus**,

which contains the *pineal gland* and *choroid plexus* (a vascular network that produces cerebrospinal fluid), the **thalamus**, and the **hypothalamus**. (*Figures 8-16c; 8-24*)

- **35.** The thalamus is the final relay point for ascending sensory information. Only a small portion of the arriving sensory information is passed to the cerebral cortex; the rest is relayed to the basal nuclei and centers in the brainstem. *(Figures 8-16c; 8-24)*
- **36.** The hypothalamus contains important control and integrative centers. It can produce emotions and behavioral drives, coordinate activities of the nervous and endocrine systems, secrete hormones, coordinate voluntary and autonomic functions, and regulate body temperature.
- **37.** Three regions make up the **brainstem**. (1) The **midbrain** processes visual and auditory information and generates involuntary somatic motor responses, and contains the *reticular activating system (RAS)*, which directly affects the activity of the cerebral cortex. (2) The **pons** connects the cerebellum to the brainstem and is involved with somatic and visceral motor control. (3) The spinal cord connects to the brain at the **medulla oblongata**, which relays sensory information and regulates autonomic functions. (*Figures 8-16c; 8-24*)
- **38.** The **cerebellum** oversees the body's postural muscles and programs and fine-tunes voluntary and involuntary movements. The **cerebellar peduncles** are tracts linking the cerebellum with the brainstem, cerebrum, and spinal cord. (*Figures 8-16; 8-24*)
- **39.** The medulla oblongata connects the brain to the spinal cord. Its nuclei relay information from the spinal cord and brainstem to the cerebral cortex. Its reflex centers, including the **cardiovascular center** and the **respiratory rhythmicity centers**, control or adjust the activities of one or more peripheral systems. (*Figure 8-24*)

8-8 The PNS connects the CNS with the body's external and internal environments *p. 308*

- **40.** The **peripheral nervous system (PNS)** links the central nervous system (CNS) with the rest of the body; all sensory information and motor commands are carried by axons of the PNS. The sensory and motor axons are bundled together into **peripheral nerves**, or nerves, and clusters of cell bodies, or *ganglia*.
- **41.** The PNS includes cranial nerves and spinal nerves.
- **42.** There are 12 pairs of **cranial nerves**, which connect to the brain, not to the spinal cord. (*Figure 8-25*)
- **43.** The **olfactory nerves (I)** carry sensory information for the sense of smell.
- **44.** The **optic nerves (II)** carry visual information from special sensory receptors in the eyes.
- **45.** The **oculomotor nerves (III)** are the primary sources of innervation for four of the six muscles that move the eyeball.

- **46.** The **trochlear nerves (IV)**, the smallest cranial nerves, innervate the superior oblique muscles of the eyes.
- **47.** The **trigeminal nerves (V)**, the largest cranial nerves, are mixed nerves with three divisions: the ophthalmic nerve, the maxillary nerve, and the mandibular nerve.
- **48.** The **abducens nerves (VI)** innervate the sixth extrinsic eye muscle, the lateral rectus.
- **49.** The **facial nerves (VII)** are mixed nerves that control muscles of the scalp and face. They provide pressure sensations over the face and receive taste information from the tongue.
- **50.** The **vestibulocochlear nerves (VIII)** contain the vestibular nerves, which monitor sensations of balance, position, and movement, and the cochlear nerves, which monitor hearing receptors.
- **51.** The **glossopharyngeal nerves (IX)** are mixed nerves that innervate the tongue and pharynx and control swallowing.
- **52.** The **vagus nerves (X)** are mixed nerves that are vital to the autonomic control of visceral function and have a variety of motor components.
- **53.** The **accessory nerves (XI)** have an internal branch, which innervates voluntary swallowing muscles of the soft palate and pharynx, and an external branch, which controls muscles associated with the pectoral girdles.
- **54.** The **hypoglossal nerves (XII)** provide voluntary control over tongue movements.
- **55.** There are 31 pairs of **spinal nerves:** 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Each pair monitors a region of the body surface known as a **dermatome**. (*Figures* 8-26; 8-27)
- 56. A nerve plexus is a complex, interwoven network of nerves. The four large plexuses are the cervical plexus, the brachial plexus, the lumbar plexus, and the sacral plexus. The latter two can be united into a *lumbosacral plexus*. (Figure 8-26)

8-9 Reflexes are rapid, automatic responses to stimuli p. 313

- **57.** A **reflex** is an automatic involuntary motor response to a specific stimulus.
- **58.** A **reflex arc** is the "wiring" of a single reflex. Five steps are involved in the action of a reflex arc: (1) arrival of a stimulus and activation of a receptor, (2) activation of a sensory neuron, (3) information processing, (4) activation of a motor neuron, and (5) response by an effector. (*Figure 8-28*)
- **59.** A **monosynaptic reflex** is the simplest reflex arc, in which a sensory neuron synapses directly on a motor neuron that acts as the processing center. A **stretch reflex** is a monosynaptic reflex that automatically regulates skeletal muscle length and muscle tone. The sensory receptors involved are **muscle spindles**. (*Figure 8-29*)

- **60. Polysynaptic reflexes**, which have at least one interneuron between the sensory afferent neuron and the motor efferent neuron, have a longer delay between stimulus and response than does a monosynaptic synapse. Polysynaptic reflexes can also produce more complex responses. A **flexor reflex** is a withdrawal reflex affecting the muscles of a limb. (*Figure 8-30*)
- **61.** The brain can facilitate or inhibit reflex motor patterns based in the spinal cord.

8-10 Separate pathways carry sensory information and motor commands *p. 316*

- **62.** The essential communication between the CNS and PNS occurs over pathways that relay sensory information and motor commands. *(Table 8-1)*
- **63.** A **sensation** arrives in the form of an action potential in an afferent fiber. The **posterior column pathway** carries fine touch, pressure, vibration, and proprioceptive sensations. The axons ascend within this pathway and synapse with neurons in the medulla oblongata. These axons then cross over and travel on to the thalamus. The thalamus sorts the sensations according to the region of the body involved and sends them to specific regions of the primary somatosensory cortex. (*Figure 8-31; Table 8-1*)
- **64.** The **corticospinal pathway** provides conscious skeletal muscle control. The **medial** and **lateral pathways** generally exert subconscious control over skeletal muscles. (*Figure 8-32; Table 8-1*)

8-11 The autonomic nervous system, composed of the sympathetic and parasympathetic divisions, is involved in the unconscious regulation of body functions *p. 319*

- **65.** The autonomic nervous system (ANS) coordinates cardiovascular, respiratory, digestive, excretory, and reproductive functions.
- **66. Preganglionic neurons** in the CNS send axons to synapse on **ganglionic neurons** in **autonomic ganglia** outside the CNS. The axons of the ganglionic neurons (postganglionic fibers) innervate cardiac muscle, smooth muscles, glands, and, in some cases, fat cells. (*Figure 8-33b*)
- **67.** Preganglionic fibers from the thoracic and lumbar segments form the **sympathetic division** ("fight or flight" system) of the ANS. Preganglionic fibers leaving the brain and sacral

segments form the **parasympathetic division** ("rest and repose" or "rest and digest" system).

- **68.** The sympathetic division consists of preganglionic neurons between spinal segments T_1 and L_2 , ganglionic neurons in ganglia near the vertebral column, and specialized neurons in the adrenal gland. Sympathetic ganglia are paired **sympathetic chain ganglia** or unpaired **collateral ganglia**. (*Figure 8-34*)
- **69.** Preganglionic fibers entering the adrenal glands synapse within the **adrenal medullae**. During sympathetic activation, these endocrine organs secrete epinephrine (E) and norepinephrine (NE) into the bloodstream.
- **70.** In a crisis, the entire sympathetic division responds, producing increased alertness, a feeling of energy, increased cardiovascular and respiratory activity, and elevation in muscle tone.
- **71.** The parasympathetic division includes preganglionic neurons in the brainstem and sacral segments of the spinal cord, and ganglionic neurons in peripheral ganglia located within or next to target organs. Preganglionic fibers leaving the sacral segments form **pelvic nerves**. (*Figure 8-35*)
- **72.** The effects produced by the parasympathetic division center on relaxation, food processing, and energy absorption; they are usually brief and restricted to specific sites.
- **73.** The sympathetic division has widespread effects, reaching visceral and somatic structures throughout the body. The parasympathetic division innervates only visceral structures either serviced by cranial nerves or lying within the abdominopelvic cavity. Organs with **dual innervation** receive instructions from both divisions. *(Table 8-2)*

8-12 Aging produces various structural and functional changes in the nervous system *p. 324*

74. Age-related changes in the nervous system include a reduction of brain size and weight, a reduction in the number of neurons, decreased blood flow to the brain, changes in synaptic organization of the brain, and intracellular and extracellular changes in CNS. For roughly 85 percent of the elderly population, these changes do not interfere with their abilities to function.

8-13 The nervous system is closely integrated with other body systems *p. 326*

75. The nervous system monitors all other body systems and issues commands that adjust their activities.

Review Questions

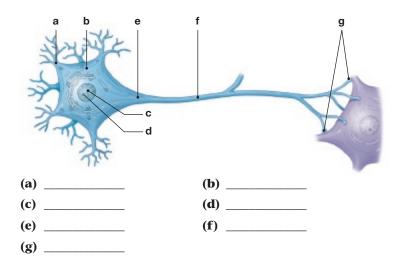

8

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A	COLUMN B		
1. neuroglia	a. "fight or flight" division		
2. autonomic nervous system	b. cover CNS axons with myelin		
3. sensory neurons	c. carry sensory information to the brain		
4. dual innervation	d. occurs along unmyelinated axons		
5. ganglia	e. outermost covering of brain and spinal cord		
6. oligodendrocytes	f. production of CSF		
7. ascending tracts	g. supporting cells		
8. descending tracts	h. controls smooth and cardiac muscle, glands, and fat cells		
9. saltatory propagation	i. occurs along myelinated axons		
10. continuous propagation	j. link between nervous and endocrine systems		
11. dura mater	k. carry motor commands to spinal cord		
12. monosynaptic reflex	1. efferent division of the PNS		
13. sympathetic division	m. controls contractions of skeletal muscles		
14. cerebellum	n. controls cardiovascular and respiratory output		
15. somatic nervous system	o. connects the brain to the spinal cord		
16. hypothalamus	p. stretch reflex		
17. medulla oblongata	q. efferent division of the PNS		
18. choroid plexus	r. maintains muscle tone and posture		
19. parasympathetic division	s. "rest and digest" division		
20. motor neurons	t. opposing effects		

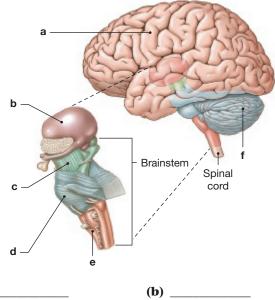

21. Label the structures in the following diagram of a neuron.

- **22.** What is the stimulus for the exocytosis of a neurotransmitter into the synaptic cleft?
 - (a) An influx of K⁺ ions into the presynaptic membrane throughout.
 - **(b)** An efflux of K⁺ ions from the postsynaptic membrane throughout.
 - (c) An influx of Ca^{2+} ions into the synaptic nob.
 - (d) An influx of Ca^{2+} ions into the postsynaptic neuron.
- **23.** Nissl bodies are formed by
 - (a) the nucleus and nucleolus.
 - (b) mitochondria.
 - (c) the rough endoplasmic reticulum and free ribosomes.
- (d) the Golgi apparatus and smooth endoplasmic reticulum. **24.** The myelin sheath of nerves in the peripheral nervous sys
 - tem originates from
 - (a) astrocytes. (b) microglial cells.
 - (c) oligodendrocytes. (d) Schwann cells.

8

25. Identify the six principal regions of the brain in the following diagram.

- (a) _____ (b) _____ (c) _____ (d) _____
- (e) _____ (f) _____
- **26.** Neuroglial cells in the central nervous system include the following except
 - (a) astrocytes.
 - **(b)** ependymal cells.
 - (c) oligodendrocytes.
 - (d) Schwann cells.
- 27. An example of an important gaseous neurotransmitter is(a) acetylcholine.
 - **(b)** dopamine.
 - (c) nitric oxide.
 - (d) serotonin.
- **28.** The epidural space is located
 - (a) exterior to the dura mater.
 - (b) between the dura and arachnoid mater.
 - (c) between the arachnoid and pia mater.
 - (d) deep to the pia mater.
- 29. The visual cortex is located in the
 - (a) frontal lobe.
 - (b) occipital lobe.
 - (c) parietal lobe.
 - (d) temporal lobe.

- **30.** The dorsal root ganglion contains the cell bodies of
 - (a) interneurons.(b) motor neurons.
 - (c) sensory neurons.
 - (d) each of the neurons listed above.
- **31.** The ability to think is a function of the
 - (a) cerebellum.
 - (b) cerebrum.
 - (c) diencephalon.
 - (d) brain stem.
- **32.** Return of cerebrospinal fluid to the venous circulation occurs via the
 - (a) arachnoid granulations.
 - **(b)** choroid plexus.
 - (c) lateral ventricles.
 - (d) central canal of the spinal cord.
- **33.** Impulses for voluntary contraction of the biceps brachii muscle are carried in the _____ pathway.
 - (a) corticospinal
 - (b) posterior column
 - (c) spinocerebellar
 - (d) spinothalamic
- **34.** State the all-or-none principle of action potentials.
- **35.** Which cranial nerves transmit motor impulses for movement of the eyeball?
- **36.** How do sensory neurons of the peripheral nervous system differ from motor neurons that control skeletal muscles?

Level 2 Reviewing Concepts

- 37. The patellar reflex begins with the stretching of the(a) motor neuron.
 - (**b**) muscle spindle.
 - (c) quadriceps muscle.
 - (d) sensory neuron.
- **38.** The sympathetic and parasympathetic divisions of the autonomic nervous system have opposing effects in regulating the following *except*
 - (a) airway diameter.
 - (b) heart rate.
 - (c) pupil size.
 - (d) adrenal medullary secretion.
- **39.** What is the main function of the primary motor cortex?

- **40.** Why is response time in a monosynaptic reflex much faster than response time in a polysynaptic reflex?
- **41.** Compare the general effects of the sympathetic and parasympathetic divisions of the ANS on mental alertness, metabolic rate, digestive/urinary function, use of energy reserves, respiratory rate, heart rate/blood pressure, and sweat gland activity.

Level 3 Critical Thinking and Clinical Applications

- **42.** If neurons in the central nervous system lack centrioles and are unable to divide, how can a person develop brain cancer?
- **43.** A police officer has just stopped Bill on suspicion of driving while intoxicated. The officer asks Bill to walk the yellow line on the road and then asks him to place the tip of his

index finger on the tip of his nose. Which part of the brain is being tested by these activities? How would these activities indicate Bill's level of sobriety?

- **44.** In some severe cases of stomach ulcers, the branches of the vagus nerve (X) that lead to the stomach are surgically severed. How might this procedure control the ulcers?
- **45.** Improper use of crutches can produce a condition known as crutch paralysis, which is characterized by a lack of response by the extensor muscles of the arm and a condition known as wrist drop. Which nerve is involved?
- **46.** A 60-year-old man had a stroke that affected his right cerebral hemisphere. He reported weakness in his left leg but not his right leg. How could this be explained?

The General and Special Senses

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **9-1** Explain how the organization of receptors for the general senses and the special senses affects their sensitivity.
- **9-2** Identify the receptors for the general senses, and describe how they function.
- **9-3** Describe the sensory organs of smell, and discuss the processes involved in olfaction.
- **9-4** Describe the sensory organs of taste, and discuss the processes involved in gustation.
- **9-5** Identify the internal and accessory structures of the eye, and explain their functions.
- **9-6** Explain how we form visual images and distinguish colors, and discuss how the central nervous system processes visual information.
- **9-7** Describe the parts of the external, middle, and internal ear, and the receptors they contain, and discuss the processes involved in the senses of equilibrium and hearing.
- **9-8** Describe the effects of aging on smell, taste, vision, equilibrium, and hearing.

Clinical Notes

Cataracts, p. 351 Visual Acuity, p. 356 Night Blindness, p. 357 Hearing Deficits, p. 366 **Spotlight** Refractive Problems, p. 354

An Introduction to General and Special Senses

Our knowledge of the world around us is limited to those characteristics that stimulate our sensory receptors. We may not realize it, but our picture of the environment is incomplete. Colors we cannot see guide insects to flowers. Sounds and smells we cannot detect provide important information to dolphins, dogs, and cats about their surroundings. Moreover, our senses are sometimes deceptive. In cases of phantom limb pain, for example, a person "feels" pain in a missing limb. During an epileptic seizure, a person may experience sights, sounds, or smells that have no physical basis. In this chapter we discuss the "general senses" that provide information about the body and its environment, and the "special senses" of smell, taste, sight, equilibrium (balance), and hearing.

Build Your Knowledge

What we perceive also varies with the state of our nervous system. Recall that the sympathetic nervous system is often called the "fight or flight" system (as you saw in **Chapter 8: The Nervous System**). During sympathetic activation, you experience an increased state of alertness. In other words, you have a heightened awareness of sensory information. **D p. 319**

9-1 Sensory receptors connect our internal and external environments with the nervous system

Learning Outcome Explain how the organization of receptors for the general senses and the special senses affects their sensitivity.

All sensory information is picked up by *sensory receptors*. **Sensory receptors** are specialized cells or cell processes (extensions) that monitor conditions inside or outside the body.

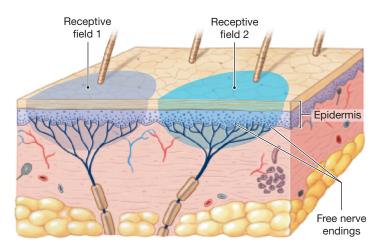

The simplest receptors are the dendrites (processes) of sensory neurons. The branching tips of these dendrites are called **free nerve endings**. Free nerve endings extend through a tissue the way grass roots extend into the soil. They are sensitive to many types of stimuli. As a result, free nerve endings provide little receptor specificity. For example, a given free nerve ending in the skin may provide the sensation of pain in response to chemicals, pressure, heat, or a cut.

Other receptors are sensitive to one kind of stimulus. For example, a touch receptor is very sensitive to pressure but insensitive to chemical stimuli. A taste receptor is sensitive to dissolved chemicals but insensitive to pressure. The most complex receptors, such as the visual receptors of the eye, are protected by accessory cells and layers of connective tissue. These cells are seldom exposed to any stimulus *except* light and so provide very specific information. The area monitored by a single receptor cell is its *receptive field* (Figure 9-1). Whenever a sufficiently strong stimulus arrives in the receptive field, the CNS receives the information "stimulus arriving at receptor X." The larger the receptive field, the poorer is your ability to localize a stimulus. A touch receptor on the general body surface, for example, may have a receptive field of 7 cm (2.75 in.) in diameter. As a result, you can describe a light touch there affecting only a general area, not an exact spot. On your tongue or fingertips, the receptive fields are less than a millimeter in diameter. In these areas, you can be very precise about the location of a stimulus.

All sensory information arrives at the CNS in the form of action potentials in a sensory (afferent) fiber. In general, the stronger the stimulus, the higher the frequency of action potentials. The arriving information is called a **sensation**.

When sensory information arrives at the CNS, it is routed according to the location and nature of the stimulus. For example, touch, pressure, pain, vibration, and temperature sensations arrive at the primary somatosensory cortex. Information from visual, auditory, olfactory, and taste receptors reaches the visual, auditory, olfactory, and gustatory regions of the cortex, respectively. A **perception** is the conscious awareness of a sensation.

The CNS interprets the nature of sensory information entirely on the basis of the area of the brain stimulated. The CNS cannot tell the difference between a "true" sensation Figure 9-1 Receptors and Receptive Fields. Each receptor cell monitors a specific area known as the receptive field.

and a "false" one. For instance, when rubbing your eyes, you may "see" flashes of light. Although the stimulus is physical rather than visual, any activity along the optic nerve is carried to the visual cortex and experienced as a visual perception.

Adaptation is a reduction in sensitivity in the presence of a constant stimulus. Familiar examples are stepping into a hot bath or jumping into a cold lake. Within moments neither temperature seems as extreme as it did at first. Adaptation reduces the amount of information arriving at the cerebral cortex. Most sensory information is routed to centers along the spinal cord or brainstem, potentially triggering such involuntary reflexes as the withdrawal reflexes. \supset p. 314 Only about 1 percent of the information provided by afferent fibers reaches the cerebral cortex and our conscious awareness.

Output from higher centers, however, can increase receptor sensitivity or facilitate transmission along a sensory pathway. For example, the *reticular activating system* (*RAS*) in the midbrain, which helps focus attention, can heighten or reduce awareness of arriving sensations. \supset p. 307 This adjustment of sensitivity can take place under conscious or unconscious direction. When we "listen carefully," our sensitivity to and awareness of auditory stimuli increase. The reverse occurs when we enter a noisy factory or walk along a crowded city street. There we automatically "tune out" the high level of background noise.

The **general senses** include temperature, pain, touch, pressure, vibration, and **proprioception** (body position). The receptors for the general senses occur throughout the body. The **special senses** are smell or **olfaction**, taste or **gustation**, vision, balance or **equilibrium**, and hearing. The receptors for these five special senses are confined to the head and concentrated within specific structures—the sense organs, such as the eye or the ear. In this chapter we explore both the general senses and the special senses.

CHECKPOINT

- **1.** What is adaptation?
- **2.** Receptor A has a circular receptive field on the skin with a diameter of 2.5 cm. Receptor B has a circular receptive field 7.0 cm in diameter. Which receptor provides more precise sensory information?
- **3.** List the five special senses.
- See the blue Answers tab at the back of the book.

9-2 General sensory receptors are classified by the type of stimulus that excites them

Learning Outcome Identify the receptors for the general senses, and describe how they function.

Receptors for the general senses are distributed throughout the body. They are relatively simple in structure. We classify them into four types by the nature of the stimulus that excites them: *nociceptors* (pain); *thermoreceptors* (temperature); *mechanoreceptors* (physical distortion); and *chemoreceptors* (chemical concentration).

Pain

Pain receptors, or **nociceptors** (nō-sē-SEP-tōrz; *noxa*, harm), are free nerve endings. They are especially common in the superficial portions of the skin, in joint capsules, within the periostea covering bones, and around blood vessel walls. Other deep tissues and most visceral organs contain few nociceptors. Pain receptors have large receptive fields (**Figure 9-1**). As a result, it is often difficult to determine the exact source of a painful sensation.

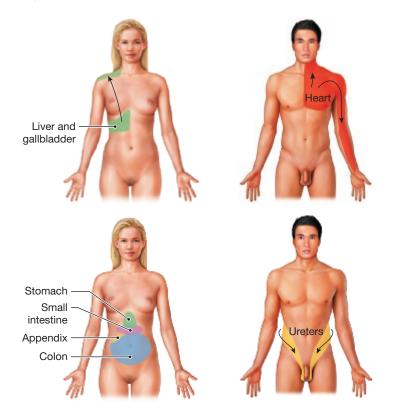

Nociceptors may be sensitive to (1) extremes of temperature, (2) mechanical damage, or (3) dissolved chemicals, such as those released by injured cells. Very strong stimuli by any of these sources may excite a nociceptor. For that reason, people describing very painful sensations—whether caused by heat, a deep cut, or inflammatory chemicals—use a similar descriptive term, such as "burning."

Once pain receptors in a region are stimulated, two types of axons carry the painful sensations. Myelinated fibers carry very localized sensations of **fast pain** (or *prickling pain*). Examples are pain caused by an injection or a deep cut. These sensations reach the CNS very quickly, where they often trigger somatic reflexes. They are also relayed to the primary somatosensory cortex and so receive conscious attention. Slower, unmyelinated fibers carry sensations of **slow pain**, or *burning and aching pain*. Unlike fast pain sensations, slow pain sensations enable you to identify only the general area involved.

Pain sensations from visceral organs are often perceived as originating at the body surface, generally in those regions innervated by the same spinal nerves. The perception of pain coming from parts of the body that are not actually stimulated is called **referred pain**. The precise process responsible for referred pain is not yet clear, but several clinical examples are shown in **Figure 9-2**. Cardiac pain, for example, is often perceived as originating in the skin of the upper chest and left arm.

Pain receptors continue to respond as long as the painful stimulus remains. However, the perception of the pain can decrease over time. This effect is due to the inhibition of centers in the thalamus, reticular formation, lower brainstem, and spinal cord.

Figure 9-2 Referred Pain. Pain sensations from visceral organs are often perceived as arising from areas distant from the actual origin (arrows). This occurs because the body surface is innervated by the same spinal nerves. Each region of perceived pain is labeled according to the organ at which the pain originates.

Temperature

Temperature receptors, or **thermoreceptors**, are free nerve endings located in the dermis, in skeletal muscles, in the liver, and in the hypothalamus. Cold receptors are three or four times more common than warm receptors. There are no known structural differences between warm and cold thermoreceptors.

Temperature sensations are relayed along the same pathways that carry pain sensations. They are sent to the reticular formation, the thalamus, and (to a lesser extent) the primary somatosensory cortex. Thermoreceptors are very active when the temperature is changing, but they quickly adapt to a stable temperature. When you enter an air-conditioned classroom on a hot summer day or a warm lecture hall on a brisk fall evening, the temperature may seem extreme at first. Then you quickly become comfortable as adaptation takes place.

Touch, Pressure, and Position

Mechanoreceptors are sensitive to stimuli such as stretching, compression, or twisting. Distortion of the receptor cell's plasma membrane in response to these stimuli causes mechanically regulated ion channels to open or close. There are three classes of mechanoreceptors: (1) *tactile receptors* (touch), (2) *baroreceptors* (pressure), and (3) *proprioceptors* (position).

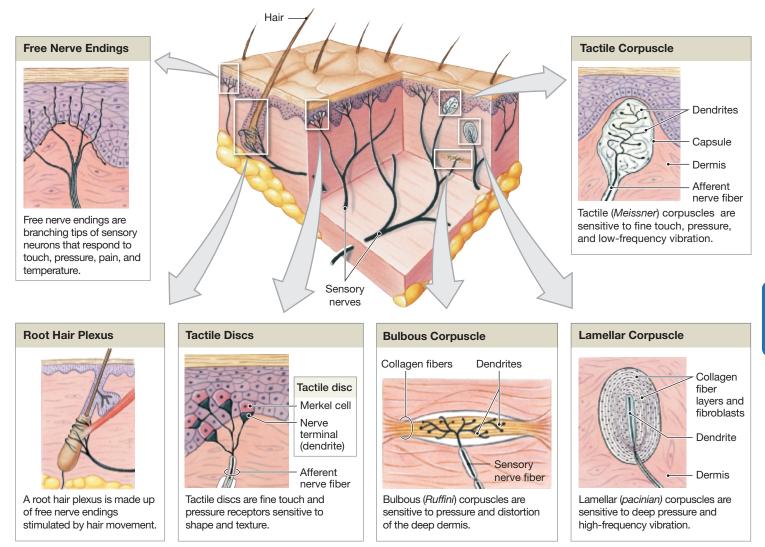

Tactile Receptors

Tactile receptors provide sensations of touch, pressure, and vibration. The distinctions between these sensations are hazy. A touch also represents a pressure, and a vibration is an oscillating touch/pressure stimulus. Fine touch and pressure receptors provide detailed information about a source of stimulation, including its exact location, shape, size, texture, and movement. Crude touch and pressure receptors provide poor localization. They provide little additional information about the stimulus because they have large receptive fields.

Tactile receptors range in complexity from free nerve endings to specialized sensory complexes with accessory cells and supporting structures. **Figure 9-3** shows six types of tactile receptors in the skin:

1. Free nerve endings sensitive to touch and pressure are located between epidermal cells. There appear to be no structural differences between these receptors and the free nerve endings that provide temperature or pain sensations.

Figure 9-3 Tactile Receptors in the Skin.

- 2. Wherever hairs are located, the nerve endings of the **root hair plexus** monitor distortions and movements across the body surface.
- **3. Tactile discs** are fine touch and pressure receptors. Hairless skin contains large sensory epithelial cells (*tactile*, or *Merkel*, *cells*) in its deepest epidermal layer, the stratum basale. The dendrites of a single sensory neuron make close contact with a group of these cells. When compressed, Merkel cells release chemicals that stimulate the neuron.
- **4. Tactile corpuscles**, or *Meissner* (MĪS-ner) *corpuscles*, give us sensations of fine touch and pressure and low-frequency vibration. They are abundant in the eyelids,

lips, fingertips, nipples, and external genitalia. A fibrous capsule surrounds and anchors the corpuscle within the dermis.

5. Lamellar (LAM-eh-lar) corpuscles, or *pacinian* (pa-SIN-ē-an) *corpuscles*, are large receptors sensitive to deep pressure and to pulsing or high-frequency vibrations. A single dendrite lies within concentric layers of collagen fibers separated by interstitial fluid and specialized fibroblasts. These receptors are common in the skin of the fingers, breasts, and external genitalia. They are also present in joint capsules, mesenteries, the pancreas, and the walls of the urethra and urinary bladder.

6. Bulbous corpuscles, or *Ruffini* (roo-FĒ-nē) *corpuscles*, are also sensitive to pressure and distortion of the skin, but they are located in the reticular (deep) layer of the dermis. They contain collagen fibers continuous with those in the surrounding dermis.

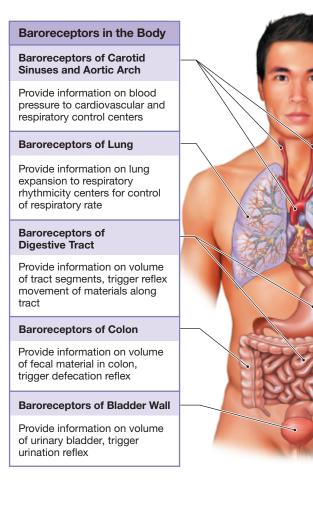

Tactile sensations travel through the posterior column and spinothalamic pathways. Dp. 316 Infection, disease, and damage to sensory neurons or pathways can alter sensitivity to tactile sensations. The locations of tactile responses may have diagnostic significance. For example, sensory loss along the boundary of a dermatome can help identify the affected spinal nerve or nerves. Dp. 311

Baroreceptors

Baroreceptors (bar-ō-rē-SEP-tōrz; *baro-*, pressure) monitor changes in pressure in an organ. They provide information essential to the regulation of autonomic activities.

Figure 9-4 Baroreceptors and the Regulation of Autonomic

Functions. Baroreceptors at several sites provide information essential to the regulation of various autonomic activities, including blood pressure monitoring, respiration, digestion, urination, and defecation.

A baroreceptor consists of free nerve endings that branch within the elastic tissues in the wall of an organ that can expand, such as a blood vessel or a portion of the respiratory, digestive, or urinary tract. When the pressure changes, the elastic walls expand or recoil. This movement distorts the dendritic branches and alters the rate of action potential generation. Baroreceptors respond immediately to a change in pressure, but they adapt rapidly, and the output along the afferent fibers gradually returns to normal.

Figure 9-4 shows the locations of some baroreceptors and summarizes their functions in autonomic activities. Baroreceptors monitor blood pressure in the walls of major blood vessels, including the carotid arteries (at the *carotid sinuses*) and the aorta (at the *aortic arch*). The information plays a major role in regulating cardiac function and adjusting blood flow to vital tissues. Baroreceptors in the lungs monitor the degree of lung expansion. This information is relayed to the respiratory rhythmicity centers in the brain, which set the pace of respiration. D p. 308 Baroreceptors in the digestive and

> urinary tracts trigger various visceral reflexes, including actions that move materials along the digestive tract, defecation, and urination.

Proprioceptors

Proprioceptors monitor the position of joints, the tension in tendons and ligaments, and the state of muscular contraction. *Free nerve endings* in joint capsules detect pressure, tension, and movement at the joint. *Golgi tendon organs* lie between a skeletal muscle and its tendon and monitor the strain on a tendon during muscle contraction. *Muscle spindles* monitor the length of a skeletal muscle and trigger stretch reflexes. \bigcirc p. 314

Proprioceptors do not adapt to constant stimulation. Each receptor continuously sends information to the CNS. Most of this information is processed subconsciously. Only a small proportion of it reaches your conscious awareness. Your sense of body position results from the integration of information from these three types of proprioceptors and from the receptors of the internal ear.

Chemical Detection

Specialized nerve cells called **chemoreceptors** can detect small changes in the concentration of specific chemicals or compounds. They respond only to water-soluble and lipid-soluble substances that are dissolved

in body fluids (interstitial fluid, blood plasma, and CSF). Adaptation usually takes place over a few seconds following stimulation. Except for the special senses of taste and smell, there are no well-defined chemosensory pathways in the brain or spinal cord. The chemoreceptors of the general senses send their information to brainstem centers that deal with the autonomic control of respiratory and cardiovascular functions.

The locations of important chemoreceptors are shown in **Figure 9-5**. Neurons within the respiratory centers of the brain respond to the concentrations of hydrogen ions (pH) and carbon dioxide molecules in the cerebrospinal fluid. Chemoreceptors are also found in the **carotid bodies**, near the origin of the internal carotid arteries on each side of the neck, and in the **aortic bodies**, between the major branches of the aortic arch. These receptors monitor the pH, carbon dioxide, and oxygen levels in arterial blood. The afferent fibers leaving the carotid and aortic bodies reach the respiratory centers by traveling within cranial nerves IX (glossopharyngeal) and X (vagus).

CHECKPOINT

- **4.** List the four types of general sensory receptors, and identify the nature of the stimulus that excites each type.
- 5. Identify the three classes of mechanoreceptors.
- **6.** What would happen if information from proprioceptors in your legs was blocked from reaching the CNS?

See the blue Answers tab at the back of the book.

Build Your Knowledge

Recall that there are separate pathways in the spinal cord that carry sensory information (as you saw in **Chapter 8: The Nervous System**). Examples of sensory pathways and the sensations they deliver to the brain include:

- the posterior column pathway (highly localized fine touch, pressure, vibration, and proprioception);
- the spinothalamic pathway (poorly localized touch, pressure, pain, and temperature);
- and the spinocerebellar pathway (proprioceptive information concerning the positions of muscles, bones, and joints). ⊃ p. 316

9-3 Olfaction, the sense of smell, involves olfactory receptors responding to chemical stimuli

Learning Outcome Describe the sensory organs of smell, and discuss the processes involved in olfaction.

The sense of smell, or *olfaction*, is provided by paired **olfactory organs**. These organs are located in the nasal cavity on either side of the nasal septum (Figure 9-6a). Each olfactory organ

Figure 9-5 Locations and Functions of Chemoreceptors. Chemoreceptors are located in the CNS (on the ventrolateral surfaces of the medulla oblongata) and in the aortic and carotid bodies. These receptors are involved in the autonomic regulation of respiratory and cardiovascular function.

consists of an **olfactory epithelium** containing **olfactory receptor cells**, supporting cells, and regenerative *basal cells* (stem cells) (**Figure 9-6b**). The underlying *lamina propria* consists of areolar tissue with large **olfactory glands**. ⊃ p. 140 Their secretions absorb water and form thick, pigmented mucus. The mucus is produced in a continuous stream that passes across the surface of the olfactory organs. It prevents the buildup of potentially dangerous or overpowering stimuli. It also keeps the area moist and free from dust or other debris.

When you inhale through your nose, the air swirls within the nasal cavity. A normal, relaxed inhalation carries a small sample (about 2 percent) of the inhaled air to the olfactory organs. If you sniff repeatedly, you increase the flow of air across the olfactory epithelium, intensifying the stimulation of the receptors. However, only the molecules of compounds that can diffuse into the overlying mucus can stimulate the olfactory receptors. Such compounds are "volatile" to some degree; that is, they evaporate easily in air. We don't respond to all airborne chemicals. For example, gases such as oxygen and carbon dioxide, and the poisonous gas, carbon monoxide, are odorless. The olfactory receptor cells are highly modified neurons. The exposed dendritic bulb of each receptor cell provides a base for up to 20 cilia-shaped dendrites that extend into the surrounding mucus. Olfactory reception takes place as dissolved chemicals interact with receptors, called *odorant-binding proteins*, on the surfaces of the dendrites.

Odorants are chemicals that stimulate olfactory receptors. The binding of an odorant changes the permeability of the receptor plasma membrane, producing action potentials. This information is relayed to the central nervous system. The CNS interprets the smell on the basis of the particular pattern of receptor activity.

Approximately 10–20 million olfactory receptor cells are packed into an area of roughly 5 cm^2 (0.8 in.²). If we take into account the surface area of the exposed dendrites, the actual sensory area approaches that of the entire body surface. Yet our olfactory sensitivities cannot compare with those of dogs, cats, or fishes. A German shepherd sniffing for smuggled drugs or explosives has an olfactory receptor surface 72 times greater than that of the nearby customs inspector!

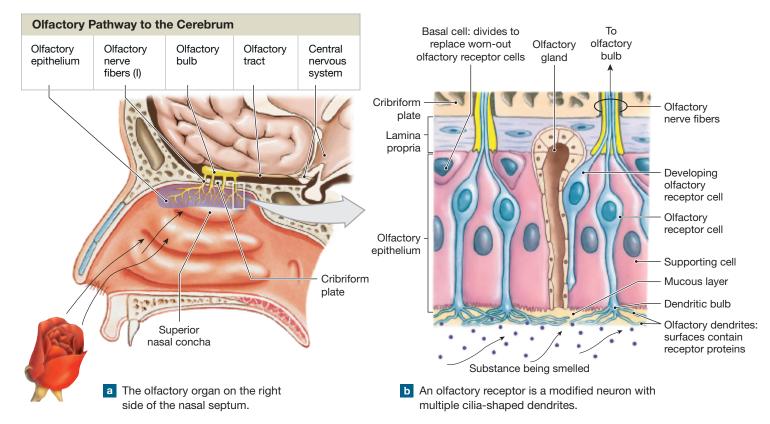

Figure 9-6 The Olfactory Organs.

The Olfactory Pathways

The axons leaving the olfactory epithelium collect into 20 or more bundles that penetrate the cribriform plate of the ethmoid bone to reach the **olfactory bulbs** of the cerebrum. There, the first synapse occurs. These bundles are components of the olfactory cranial nerves (I). Axons leaving each olfactory bulb travel along the olfactory tract to reach the olfactory cortex of the cerebrum, the hypothalamus, and portions of the limbic system.

Olfactory stimuli are the only type of sensory information that reaches the cerebral cortex directly. All other sensations first synapse in processing centers in the thalamus before being relayed. Certain smells can trigger profound emotional and behavioral responses, as well as memories, because of the parallel distribution of olfactory information to the limbic system and hypothalamus. The perfume industry understands the practical implications of these connections and works to develop odors that trigger sexual responses.

Figure 9-7 Taste Buds and Gustatory Epithelial Cells.

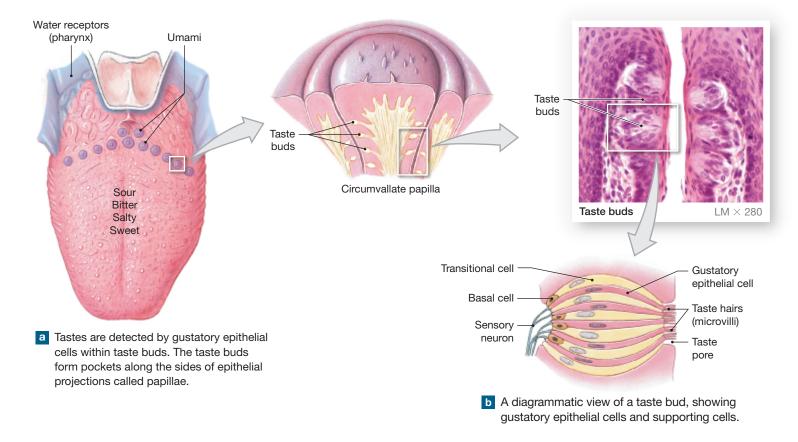

7. Define olfaction.

8. How does repeated sniffing help to identify faint odors? See the blue Answers tab at the back of the book.

9-4 Gustation, the sense of taste, involves taste receptors responding to chemical stimuli

Learning Outcome Describe the sensory organs of taste, and discuss the processes involved in gustation.

Gustation, or taste, provides information about the foods and liquids we eat and drink. **Taste receptors**, or *gustatory* (GUS-ta-tor- \bar{e}) *epithelial cells*, are distributed over the surface of the tongue and adjacent portions of the pharynx and larynx (**Figure 9-7**). The most important taste receptors are on the tongue. By the time we reach adulthood, those on the pharynx and larynx have become less important.

Taste receptors and supporting epithelial cells form sensory structures called **taste buds**. The taste buds are well protected from the mechanical stress due to chewing. They lie along the sides of epithelial projections called **papillae** (pa-PIL-lē; *papilla*, a nipple-shaped mound). The greatest numbers of taste buds are associated with the large *circumvallate papillae*, which form an inverted V that points toward the base of the tongue.

Each taste bud contains slender sensory receptor cells and basal cells (stem cells). The basal cells continually divide, producing daughter cells that mature in stages—basal, transitional, and mature. The mature cells are called **gustatory epithelial cells** (Figure 9-7b).

Each gustatory epithelial cell extends slender microvilli, sometimes called *taste hairs*, into the surrounding fluids through a narrow opening, the **taste pore**. The process behind gustatory reception seems to parallel that of olfaction. Dissolved chemicals contacting the taste hairs stimulate a change in the membrane potential of the gustatory epithelial cell, which leads to action potentials in the sensory neuron.

You are probably already familiar with the four **primary taste sensations:** sweet, salty, sour, and bitter. There is some evidence for differences in sensitivity to tastes along the long axis of the tongue, with greatest sensitivity to salty–sweet anteriorly and to sour–bitter posteriorly. However, there are no differences in the structure of the taste buds. Also, taste buds in all portions of the tongue provide all four primary taste sensations.

Two additional tastes, *umami* and *water*, have been discovered in humans. **Umami** (oo-MAH-mē) is a pleasant taste corresponding to the flavor of beef broth, chicken broth, and Parmesan cheese. Most people say water has no flavor, yet **water receptors** are present, especially in the pharynx. Their sensory output is processed in the hypothalamus and affects several systems involved in water balance and the regulation of blood volume.

The threshold for receptor stimulation varies for each of the primary taste sensations. Also, the taste receptors respond most readily to unpleasant rather than pleasant stimuli. For example, we are much more sensitive to acids, which taste sour, than to either sweet or salty chemicals. We are even more sensitive to bitter compounds than to acids. This sensitivity has survival value, because acids can damage the mucous membranes of the mouth and pharynx, and many biological toxins have an extremely bitter taste.

The Taste Pathways

Taste buds are monitored by cranial nerves VII (facial), IX (glossopharyngeal), and X (vagus). The sensory afferent fibers of these cranial nerves synapse within a nucleus in the medulla oblongata. There the neurons join axons that carry sensory information on touch, pressure, and proprioception. After another synapse in the thalamus, the information is then carried to the gustatory cortex. \bigcirc p. 301

A conscious perception of taste is produced as the information received from the taste buds is combined with other sensory data. Information about the texture of food, along with tasterelated sensations such as "peppery" or "spicy hot," is provided by sensory afferents in cranial nerve V (trigeminal). Olfactory information also plays an overwhelming role in taste perception.

The combination of taste and smell is what provides the *flavor*, or distinctive quality of a particular food and drink. You are several thousand times more sensitive to "tastes" when your olfactory organs are fully functional. By contrast, if you have a cold and a stuffy nose, airborne molecules cannot reach your olfactory receptors. Meals taste dull and unappealing, even though your taste buds are responding normally.

CHECKPOINT

- 9. Define gustation.
- **10.** If you completely dry the surface of your tongue and then place salt or sugar crystals on it, you cannot taste them. Why not?
- See the blue Answers tab at the back of the book.

9-5 Internal eye structures contribute to vision, while accessory eye structures provide protection

Learning Outcome Identify the internal and accessory structures of the eye, and explain their functions.

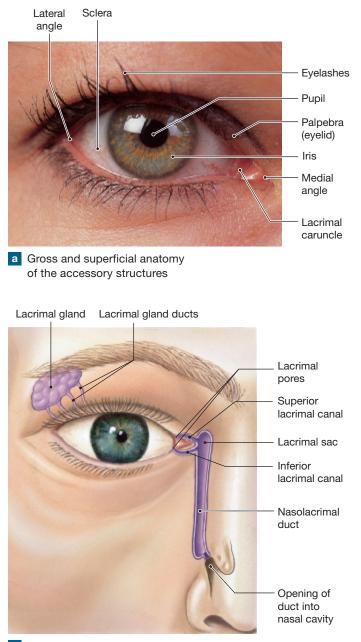

We rely more on vision than on any other special sense. Our eyes contain our visual receptors. Eyes are elaborate structures that enable us to detect not only light but also detailed images. We begin our discussion of these complex organs by considering the *accessory structures* that provide protection, lubrication, and support for our eyes.

The Accessory Structures of the Eye

The accessory structures of the eye include

- 1. the eyelids and associated exocrine glands;
- **2.** the superficial epithelium of the eye (**Figure 9-8a**);
- **3.** structures associated with the production, secretion, and removal of tears (**Figure 9-8b**); and
- 4. the extrinsic eye muscles (Figure 9-9).

b The organization of the lacrimal apparatus

The **eyelids**, or **palpebrae** (pal-PĒ-brē), are a continuation of the skin. Their continual blinking lubricates the surface of the eye. Similar to windshield wipers, they also remove dust and debris. The eyelids can also close firmly to protect the delicate surface of the eye. The upper and lower eyelids are connected at the medial angle (medial canthus) and the lateral angle (lateral canthus) (Figure 9-8a). The eyelashes are very strong hairs that help prevent foreign matter (including insects) from reaching the surface of the eye.

Several types of exocrine glands protect the eye and its accessory structures. Large sebaceous glands are associated with the evelashes, as they are with other hairs and hair follicles. $\supset p$. 162 Along the inner margins of the eyelids, modified sebaceous glands (tarsal glands) secrete a lipid-rich substance that keeps the evelids from sticking together. At the medial angle is a soft mass of tissue called the lacrimal caruncle (KAR-ung-kul). It contains glands that produce thick secretions that contribute to the gritty deposits occasionally found after a night's sleep. These various glands sometimes become infected by bacteria. An infection in a sebaceous gland of one of the eyelashes, in a tarsal gland, or in one of the sweat glands between the eyelash follicles produces a painful localized swelling known as a **sty**.

The inner surfaces of the eyelids and the outer, white surface of the eye are covered by a thin, transparent mucous membrane called the conjunctiva (kon-junk-TĪ-vuh) (Figure 9-10). The conjunctiva extends to the edges of the **cornea** (KOR-ne-uh), a transparent part of the outer fibrous layer of the eye. The cornea of is covered by a delicate corneal epithelium, which is continuous with the conjunctiva. The conjunctiva contains many free nerve endings and is very sensitive. The painful condition of conjunctivitis, or pinkeye, results from damage to and irritation of the conjunctival surface. Its most obvious sign, redness, is due to the dilation of the blood vessels beneath the conjunctival epithelium.

A constant flow of tears keeps the surface of the eyeball moist and clean. Tears reduce friction, remove debris, prevent bacterial infection, and provide nutrients and oxygen to the conjunctival epithelium. The lacrimal apparatus produces, distributes, and removes tears (Figure 9-8b). Superior and lateral to the eyeball is the **lacrimal gland**, or *tear gland*. It has a dozen or more ducts that empty into the pocket between the eyelid and the eye. About the size of an almond, this gland nestles within a depression in the frontal bone, just inside the orbit. The lacrimal gland normally provides the key ingredients and most of the volume of the tears. Its watery, slightly alkaline secretions also contain lysozyme, an enzyme that attacks bacteria. The mixture of secretions from the lacrimal glands, accessory glands, and tarsal glands forms a superficial "oil slick" that assists in lubrication and slows evaporation.

Blinking sweeps tears across the surface of the eye to the medial angle. Two small pores direct the tears into the lacrimal canals, passageways that end at the lacrimal sac (Figure 9-8b). From this sac, the nasolacrimal duct carries the tears to the nasal cavity.

Six **extrinsic eye muscles**, or *oculomotor* (ok-ū-lō-MŌ-ter) muscles, originate on the surface of the orbit and control the position of the eye (Figure 9-9 and Table 9-1). These muscles are the inferior rectus, medial rectus, superior rectus, lateral rectus, inferior oblique, and superior oblique.

Figure 9-9 The Extrinsic Eye Muscles.

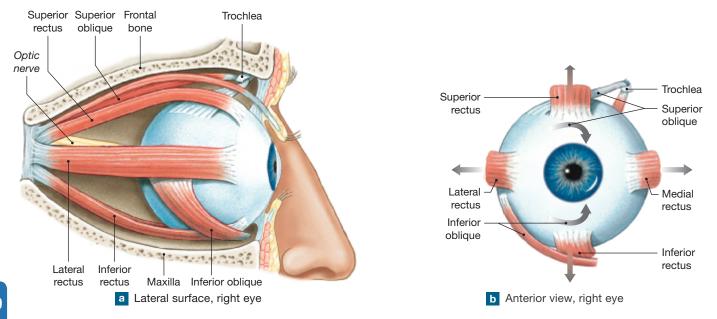

Table 9-1 The Extrinsic Eye Muscles (see Figure 9-9)

Muscle	Origin	Insertion	Action	Innervation
Inferior rectus	Sphenoid bone around optic canal	Inferior, medial surface of eyeball	Eye looks down	Oculomotor nerve (III)
Medial rectus	Sphenoid bone around optic canal	Medial surface of eyeball	Eye looks medially	Oculomotor nerve (III)
Superior rectus	Sphenoid bone around optic canal	Superior surface of eyeball	Eye looks up	Oculomotor nerve (III)
Lateral rectus	Sphenoid bone around optic canal	Lateral surface of eyeball	Eye looks laterally	Abducens nerve (VI)
Inferior oblique	Maxillary bone at anterior portion of orbit	Inferior, lateral surface of eyeball	Eye rolls, looks up and laterally	Oculomotor nerve (III)
Superior oblique	Sphenoid bone around optic canal	Superior, lateral surface of eyeball	Eye rolls, looks down and laterally	Trochlear nerve (IV)

Build Your Knowledge

Recall that a skeletal muscle begins at an origin, ends at an insertion, and contracts to produce a specific action (as you saw in **Chapter 7: The Muscular System**). Generally, a muscle's origin remains stationary and the insertion moves. **D p. 246**

The Eye

The eyes are sophisticated visual instruments. They are more versatile and adaptable than the most expensive cameras, yet compact and durable. Each eye is roughly spherical, has a diameter of nearly 2.5 cm (1 in.), and weighs around 8 g (0.28 oz). The eyeball shares space within the orbit with the extrinsic eye muscles, the lacrimal gland, and the various cranial nerves and blood vessels that service the eye and adjacent areas of the orbit and face. A mass of *orbital fat* cushions and insulates the eye (**Figure 9-10c**).

The eyeball is hollow and filled with fluid. Its interior can be divided into two cavities, anterior and posterior (Figure 9-10b). The smaller **anterior cavity** is subdivided into the *anterior chamber* and the *posterior chamber* (Figure 9-10c). A clear, watery fluid called the *aqueous humor* fills the anterior cavity. The large **posterior cavity**, or *vitreous chamber*, contains a gelatinous substance called the *vitreous body*. The fluid part of this body is *vitreous humor*. The vitreous body and the aqueous humor help to stabilize the shape of the eye.

The wall of the eye contains three distinct layers, formerly called *tunics*. There is an outer *fibrous layer*, an intermediate *vascular layer*, and a deep *inner layer (retina)* (Figure 9-10b).

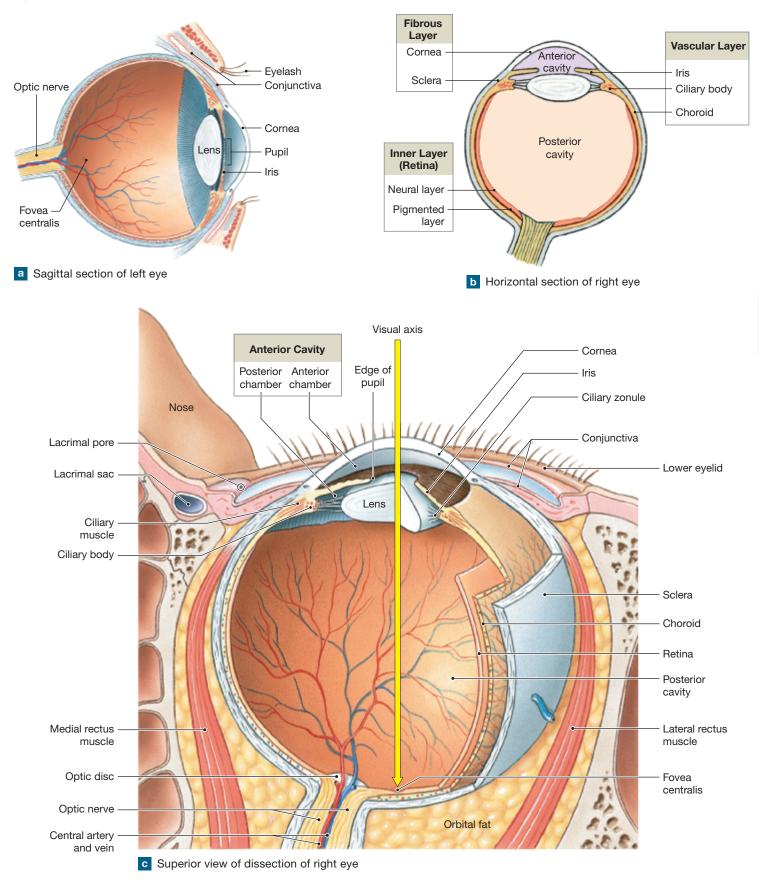

Figure 9-10 The Sectional Anatomy of the Eye.

The Fibrous Layer

The **fibrous layer**, the outermost layer of the eye, consists of the *sclera* (SKLER-uh) and the *cornea*. The fibrous layer (1) provides mechanical support and some degree of physical protection; (2) serves as an attachment site for the extrinsic eye muscles; and (3) assists in the focusing process. The **sclera**, or "white of the eye," is a layer of dense fibrous connective tissue containing both collagen and elastic fibers (**Figure 9-10c**). It is thickest over the posterior surface of the eye and thinnest over the anterior surface. The six extrinsic eye muscles insert on the sclera.

The surface of the sclera contains small blood vessels and nerves that penetrate the sclera to reach internal structures. On the anterior surface of the eye, however, these blood vessels lie under the conjunctiva. The white color of the collagen fibers is visible because this network of capillaries does not carry enough blood to lend an obvious color to the sclera.

The transparent cornea is continuous with the sclera. Unlike the sclera, the collagen fibers of the cornea are organized into a series of layers that does not interfere with the passage of light. The cornea has no blood vessels. Its epithelial cells obtain their oxygen and nutrients from the tears that flow across their surfaces. The cornea has a very restricted ability to repair itself, so corneal injuries must be treated immediately to prevent serious vision losses. Restoring vision after corneal scarring usually requires replacing the cornea through a *corneal transplant*. Such transplants can be performed between unrelated individuals because there are no blood vessels to carry white blood cells, which attack foreign tissues, into the area.

The Vascular Layer

The **vascular layer** contains numerous blood vessels, lymphatic vessels, and the *intrinsic eye muscles*. This middle layer (1) provides a route for blood vessels and lymphatic vessels that supply tissues of the eye; (2) regulates the amount of light entering the eye; (3) secretes and reabsorbs the *aqueous humor* that circulates within the chambers of the eye; and (4) controls the shape of the lens, an essential part of the focusing process.

The vascular layer includes the *iris*, the *ciliary body*, and the *choroid* (Figure 9-10b). The **iris** is visible through the transparent cornea. The iris contains blood vessels, pigment cells, loose connective tissue, and two layers of intrinsic smooth muscle fibers. When these *pupillary muscles* contract, they change the diameter of the central opening, or **pupil**, of the iris. There are two types of pupillary muscles: radial-oriented *dilators* and concentric-oriented *constrictors*. The autonomic nervous system controls both muscle groups. For example, sympathetic activation in response to dim light causes the pupils to dilate, or enlarge. Parasympathetic activation in response to bright light causes the pupils to constrict. \bigcirc p. 325

How is eye color determined? Our genes influence the number of melanocytes on the anterior surface and interior of the iris, as well as the presence of melanin granules in the pigmented epithelium on the posterior surface of the iris. (This pigmented epithelium is part of the inner layer, or retina.) When the iris contains few melanocytes, light passes through the iris and bounces off the pigmented epithelium. The eye then appears blue. The irises of green, brown, and black eyes have increasing numbers of melanocytes. The eyes of people with albinism appear very pale gray or blue gray.

Along its outer edge, the iris attaches to the anterior portion of the **ciliary body**. The ciliary body begins deep to the junction between the cornea and sclera. It extends to the scalloped border that also marks the anterior edge of the thick, neural part of the inner layer (**Figure 9-10c**). Most of the ciliary body consists of the *ciliary muscle*, a ring of smooth muscle that projects into the interior of the eye. Posterior to the iris, the surface of the ciliary body is thrown into folds called *ciliary processes*. The **ciliary zonule** (*suspensory ligament*) is the ring of fibers that attaches the lens to the ciliary processes. The connective tissue fibers hold the lens in place posterior to the iris and centered on the pupil. As a result, light passing through the pupil passes through the center of the lens along the *visual axis*.

The choroid is a vascular layer that separates the fibrous and inner layers posterior to the ciliary body (Figure 9-10c). The choroid contains a capillary network that delivers oxygen and nutrients to the inner layer.

The Inner Layer

The **inner layer**, or **retina**, is the innermost layer of the eye. It consists of a thin, outer layer called the *pigmented layer* and a thick, inner layer called the *neural layer* (**Figure 9-10b**). The pigmented layer absorbs light that passes through the neural layer, preventing light from bouncing back and producing visual "echoes." The neural layer contains

- 1. the photoreceptors that respond to light,
- **2.** supporting cells and neurons that perform preliminary processing and integration of visual information, and
- **3.** blood vessels supplying tissues that line the posterior cavity.

The two layers of the retina are normally very close together but not tightly interconnected. The pigmented layer continues over the ciliary body and iris. The neural layer

9

extends anteriorly only up to the ciliary body, forming a cup that establishes the posterior and lateral boundaries of the posterior cavity.

ORGANIZATION OF THE RETINA. The neural layer of the retina contains several layers of cells (**Figure 9-11a**). The outermost

cells, closest to the wall of the pigmented layer of the retina, are the **photoreceptors**, the cells that detect light. The eye has two main types of photoreceptors: rods and cones.

Rods do not discriminate among colors of light. These very light-sensitive receptors enable us to see in dimly lit rooms, at twilight, or in pale moonlight.

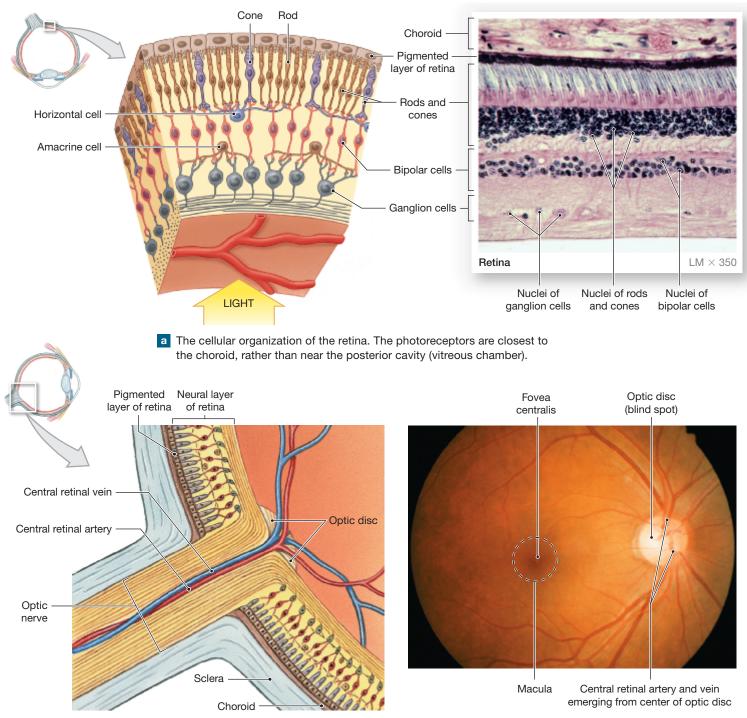

Figure 9-11 Retinal Organization.

b The optic disc in diagrammatic sagittal section.

• A photograph of the retina as seen through the pupil.

Cones give us color vision. We have three types of cones. Each type contains a different visual pigment: red, green, and blue. The stimulation of various combinations of these cone types provides the perception of different colors. Cones give us sharper, clearer images than rods do, but they require brighter light. When you watch a sunset, you can notice your vision shifting from cone-based vision (a clear image in full color) to rod-based vision (a less distinct image in black and white).

A third type of photoreceptor is the *intrinsically photosensitive retinal ganglion cell* (ipRGC). These non-image-forming cells respond to different levels of brightness. They influence the body's 24-hour circadian rhythm (biological clock).

Rods and cones are not evenly distributed across the retina. If you think of the retina as a cup, approximately 125 million rods are found on the sides, and roughly 6 million cones dominate the bottom. Most of these cones are concentrated in the area where the visual image arrives after passing through the cornea and lens. This area, known as the **macula** (MAK-ū-luh; spot), has no rods (**Figure 9-11c**). The very highest concentration of cones is found in the center of the macula in an area called the **fovea** (FŌ-vē-uh; shallow depression) **centralis**. The fovea centralis is the center of color vision and the site of sharpest vision. When you look directly at an object, its image falls on this portion of the retina. An imaginary line drawn from the center of that object through the center of the lens to the fovea centralis establishes the **visual axis** of the eye (**Figure 9-10c**).

You probably already know something about the way this distribution of cones affects our vision. During the day, when there is enough light to stimulate the cones, you see a very good image. But in very dim light cones cannot function. That is why you can't see a dim star if you stare directly at it. But if you look a little to one side rather than directly at the star, you can see it quite clearly. Shifting your gaze moves the image of the star from the fovea centralis, where it does not provide enough light to stimulate the cones, to the sides of the retina, where it stimulates the more sensitive rods.

Rods and cones synapse with roughly 6 million **bipolar cells** (**Figure 9-11a**). Bipolar cells in turn synapse within the layer of **ganglion cells** adjacent to the posterior cavity. The axons of the ganglion cells deliver the sensory information to the brain.

Horizontal cells and *amacrine* (AM-a-krin) *cells* can regulate communication between photoreceptors and ganglion cells, adjusting the sensitivity of the retina. The effect is comparable to adjusting the contrast on a television. These cells play an important role in the eye's adjustment to dim or brightly lit environments.

THE OPTIC DISC. Axons from an estimated 1 million ganglion cells converge on the **optic disc**, a circular region just medial to the fovea centralis. The optic disc is the origin of the optic

nerve (II) (Figure 9-11b). From this point, the axons turn, penetrate the wall of the eye, and proceed toward the diencephalon. Blood vessels that supply the retina pass through the center of the optic nerve and emerge on the surface of the optic disc (Figure 9-11b,c). The optic disc has no photoreceptors or other retinal structures. This area is commonly called the **blind spot** because light striking it goes unnoticed.

Why don't you see a blank spot in your field of vision? The reason is because involuntary eye movements keep the visual image moving and allow your brain to fill in the missing information. Try the simple activity in **Figure 9-12** to prove that a blind spot really exists in your field of vision.

The Chambers of the Eye

The ciliary body and lens divide the interior of the eye into the small anterior cavity and the larger posterior cavity, or vitreous chamber (**Figure 9-13**). Recall that the anterior cavity is further subdivided into the **anterior chamber**, which extends from the cornea to the iris, and the **posterior chamber**, between the iris and the ciliary body and lens.

Aqueous humor fills both chambers. This fluid circulates within the anterior cavity, passing from the posterior to the anterior chamber through the pupil. Aqueous humor also circulates within the posterior cavity, but most of this cavity is filled with a clear gelatinous substance known as the **vitreous body**. The vitreous body helps maintain the shape of the eye. It also holds the retina against the choroid.

AQUEOUS HUMOR. Aqueous humor is secreted into the posterior chamber by epithelial cells of the ciliary processes (**Figure 9-13**). Pressure exerted by this fluid helps maintain

Figure 9-12 A Demonstration of the Presence of a Blind Spot. Close your left eye and stare at the plus sign with your right eye, keeping the plus sign in the center of your field of vision. Begin with the page a few inches away from your eye, and gradually increase the distance. The dot will disappear when its image falls on the blind spot, at your optic disc. To check the blind spot in your left eye, close your right eye, and repeat the sequence while you stare at the dot.

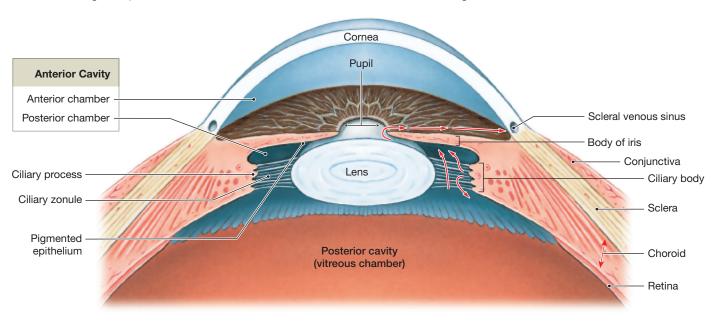

Figure 9-13 The Circulation of Aqueous Humor. Aqueous humor, which is secreted at the ciliary body, circulates through the posterior and anterior chambers before it is reabsorbed through the scleral venous sinus.

the shape of the eye. Circulation of aqueous humor transports nutrients and wastes. In the anterior chamber near the edge of the iris, the aqueous humor enters the **scleral venous sinus** (*canal of Schlemm*). This passageway empties into veins in the sclera and returns the aqueous humor to the venous system.

Interference with the normal circulation and reabsorption of aqueous humor leads to greater pressure inside the eye. If this condition, called **glaucoma**, is left untreated, it can eventually produce blindness by distorting the retina and the optic disc.

The Lens

The **lens** lies posterior to the cornea and is held in place by the ciliary zonule that originates on the ciliary body of the choroid. The primary function of the lens is to focus the visual image on the photoreceptors. The lens does so by changing its shape.

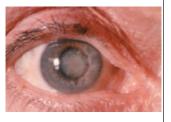

THE STRUCTURE OF THE LENS. The transparent lens consists of concentric layers of cells wrapped in a dense fibrous capsule. The cells making up the interior of the lens lack organelles and are filled with transparent proteins. The capsule contains many elastic fibers that, in the absence of any outside force, contract and make the lens spherical. However, tension in the fibers of the ciliary zonule can overpower their contraction and pull the lens into a flattened oval.

CLINICAL NOTE

Cataracts

The transparency of the lens depends on the transparent proteins maintaining a precise combination of structural and biochemical characteristics. When that balance is disturbed, the lens loses its transparency, a condition known as a **cataract**. Cataracts can result from drug reactions, injuries, or ultraviolet radiation from sunlight or other sources. **Senile cataracts**, however, are a natural consequence of aging and the most common form. Over time, the lens becomes less elastic, takes on a yellowish hue, and eventually begins to lose its transparency. As the lens becomes opaque, or "cloudy," the individual needs brighter and brighter

reading light, and visual clarity fades. If the lens becomes completely opaque, the person will be functionally blind, even though the photoreceptors are normal. Surgical treatment involves removing the lens and replacing it with an artificial substitute.

LIGHT REFRACTION AND ACCOMMODATION. The eye is often compared to a camera. To provide useful information, the lens of the eye, like a camera lens, must focus the arriving image. To say that an image is "in focus" means that the rays of light arriving from an object strike the sensitive surface of the

retina (or the semiconductor device that records light electronically in a digital camera) so as to form a sharp miniature image of the original. If the rays are not perfectly focused, the image will be blurry. Focusing normally occurs in two steps, as light passes first through the cornea and then the lens.

Light is **refracted**, or bent, when it passes from one medium to a medium with a different density. In the human eye, the greatest amount of refraction (bending) occurs when light passes from the air into the cornea, which has a density close to that of water. Then as the light enters the relatively dense lens, the lens provides the extra refraction needed to focus the light rays from an object toward a specific **focal point**—the point at which the light rays converge (**Figure 9-14a**). The distance between the center of the lens and its focal point is the **focal distance** of the lens. Two factors determine the focal distance:

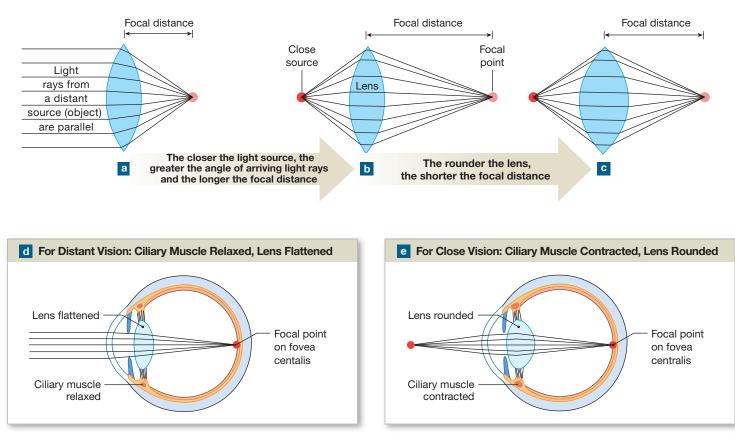

- The distance of the object from the lens. The closer an object is to the lens, the greater the focal distance (Figure 9-14a,b).
- **2.** *The shape of the lens.* The rounder the lens, the more refraction occurs. A round lens has a shorter focal distance than a flatter one (Figure 9-14b,c).

In the eye, the lens changes shape to keep the focal distance constant so the image remains focused on the retina. **Accommodation** is this process of focusing an image on the retina by changing the shape of the lens (**Figure 9-14d,e**). During accommodation, the lens becomes rounder to focus the image of a nearby object on the retina. The lens becomes flatter to focus the image of a distant object on the retina.

How does the lens change shape? The lens is held in place by the ciliary zonule that originates at the ciliary body. Smooth muscle fibers in the ciliary body encircle the lens and act like sphincter muscles. When you view a distant object, the ciliary muscle relaxes, the ciliary zonule pulls at the circumference of the lens, and the lens becomes flatter (Figure 9-14d). As you view a nearby object, the ciliary muscle contracts, and the ciliary body moves toward the lens (Figure 9-14e). This movement reduces the tension in the ciliary zonule, allowing the elastic capsule to pull the lens into a more rounded shape with greater refractive (bending) power.

IMAGE FORMATION. The image of an object reaching the retina is a miniature image of the original, but it is upside down and backward. The brain compensates for both aspects of image reversal without our conscious awareness. The reversal takes

Figure 9-14 Focal Point, Focal Distance, and Visual Accommodation. A lens refracts light toward a specific focal point. The distance from the center of the lens to that point is the focal distance of the lens.

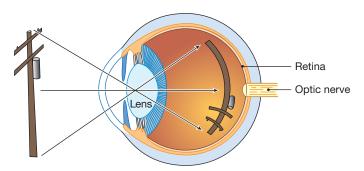

place because an object we see is really a complex light source having a large number of individual points of light. Light from each point is focused on the retina.

Figure 9-15a is a sagittal section through an eye that is looking at a telephone pole. It shows why an image formed on the retina is upside down. Light from the top of the pole is focused on the lower surface of the retina, and light from the bottom of the pole is focused on the upper surface of the retina.

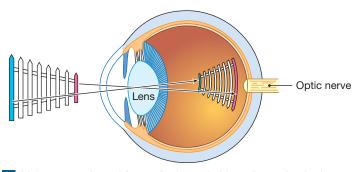

Figure 9-15b is a horizontal section through an eye that is looking at a picket fence. It shows why an image formed on the retina is backward. Light from the left side of the fence falls on the right side of the retina, and light from the right side of the fence falls of the fence falls on the left side of the retina.

If the light passing through the cornea and lens is not refracted properly, the visual image will be distorted. In the condition called **astigmatism**, the degree of curvature in the cornea or lens varies. Minor astigmatism is very common. The image distortion may be so minimal that people are unaware of the condition. Several other visual abnormalities are described in **Spotlight Figure 9-16**.

Figure 9-15 Image Formation. (Note that these illustrations are not drawn to scale. In reality the fovea centralis occupies a small area of the retina, and the projected images are very tiny. Here the crossover of light rays is shown in the lens, but it actually occurs very close to the fovea centralis.)

a Light rays projected from a vertical object show why the image arrives upside down. (Note that the image is also reversed.)

b Light rays projected from a horizontal object show why the image arrives with a left and right reversal. The image also arrives upside down. (As noted in the text, these representations are not drawn to scale.)

CHECKPOINT

- **11.** What superficial accessory structure of the eye would be the first to be affected by inadequate tear production?
- **12.** When the lens is more rounded, are you looking at an object that is close to you or far from you?
- **13.** As Malia enters a dimly lit room, most of the available light becomes focused on the fovea centralis of her eye. Will she be able to see very clearly?

See the blue Answers tab at the back of the book.

9-6 Photoreceptors respond to light and change it into electrical signals essential to visual physiology

Learning Outcome Explain how we form visual images and distinguish colors, and discuss how the central nervous system processes visual information.

The rods and cones of the retina are called *photoreceptors* because they detect *photons*, basic units of visible light. Light is a form of radiant energy that travels in waves with a characteristic wavelength (distance between wave peaks). Our eyes are sensitive to wavelengths that make up the spectrum of **visible light** (700–400 nm). Remember this spectrum, as seen in a rainbow, by the acronym ROY G. BIV (*Red, Orange, Yellow, Green, Blue, I*ndigo, *V*iolet). Color depends on the wavelength of the light. Photons of red light have the longest wavelength and carry the least energy. Photons from the violet portion of the spectrum have the shortest wavelength and carry the most energy.

Rods and Cones

Rods provide the CNS with information about the presence or absence of photons, without regard to wavelength. For this reason, they do not discriminate among colors of light. They are very sensitive, however, and enable us to see in dim conditions.

Cones provide information about the wavelength of photons. Because cones are less sensitive than rods, they function only in relatively bright light. We have three types of cones: *blue cones*, *green cones*, and *red cones*. Each type contains pigments sensitive to blue, green, or red wavelengths of light. Their stimulation in various combinations accounts for our perception of colors.

Persons unable to distinguish certain colors have a form of **color blindness**. The standard tests for color vision involve picking numbers or letters out of a complex image, such as the one in **Figure 9-17**. Color blindness occurs when one or more classes of cones are absent or nonfunctional. Red-green color

Go to Mastering A&P > Study Area > Spotlight Figure Videos

A camera focuses an image by moving the lens toward or away from the film or semiconductor device. This method cannot work in our eyes, because the distance from the lens to the macula cannot change. We focus images on the retina by changing the shape of the lens to keep the focal distance constant, a process called **accommodation**.

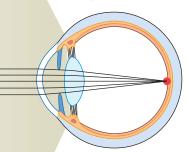

Emmetropia

(normal vision)

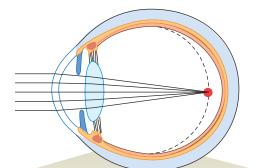

In the healthy eye, when the ciliary muscle is relaxed and the lens is flattened, a distant image will be focused on the retina's surface. This condition is called **emmetropia** (*emmetro*-, proper + *opia*, vision).

The eye has a fixed focal distance and focuses by varying the shape of the lens.

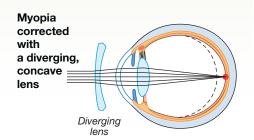

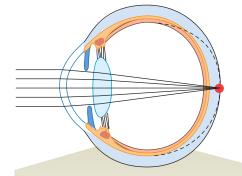

A camera lens has a fixed size and shape and focuses by varying the distance to the film or semiconductor device.

Myopia (nearsightedness)

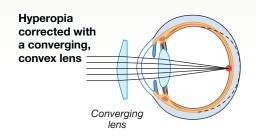

If the eyeball is too deep or the resting curvature of the lens is too great, the image of a distant object is projected in front of the retina. The person will see distant objects as blurry and out of focus. Vision at close range will be normal because the lens is able to round as needed to focus the image on the retina.

Hyperopia (farsightedness)

If the eyeball is too shallow or the lens is too flat, hyperopia results. The ciliary muscle must contract to focus even a distant object on the retina. And at close range the lens cannot provide enough refraction to focus an image on the retina. Older people become farsighted as their lenses lose elasticity, a form of hyperopia called **presbyopia** (presbys, old man).

Surgical Correction

Variable success at correcting myopia and hyperopia has been achieved by surgery that reshapes the cornea. In

photorefractive keratectomy (PRK)

a computer-guided laser shapes the cornea to exact specifications. The entire procedure can be done in less than a minute. A variation on PRK is called *LASIK (Laser-Assisted in-Situ Keratomileusis*). In this procedure the interior layers of the cornea are reshaped and then re-covered by the flap of original outer corneal epithelium. Roughly 70 percent of LASIK patients achieve normal vision, and LASIK has become the most common form of refractive surgery.

Even after surgery, many patients still need reading glasses, and both immediate and long-term visual problems can occur.

Figure 9-17 A Standard Test for Color Vision. Individuals who lack one or more populations of cones are unable to distinguish the patterned image (the number 12).

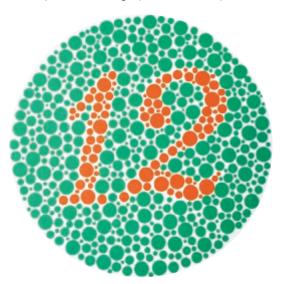

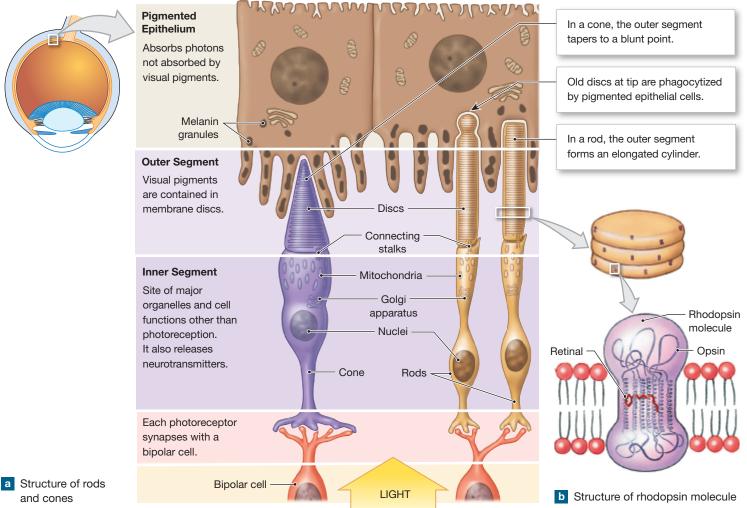

Figure 9-18 The Structure of Rods and Cones.

blindness is the most common kind. In this condition, the red cones are missing and the individual cannot distinguish red light from green light. Ten percent of all males have some color blindness, but the incidence among females is only around 0.67 percent. Total color blindness is extremely rare. Only 1 person in 300,000 has no cone pigments of any kind.

Photoreceptor Structure

The structure of rods and cones is compared in Figure 9-18a. The *outer segment* of a photoreceptor contains hundreds to thousands of flattened membranous discs. The names rod and cone refer to the outer segment's shape. The inner segment of a photoreceptor contains typical cellular organelles and forms synapses with other cells. In the dark, each photoreceptor continually releases neurotransmitters. The arrival of a photon starts a chain of events that alters the membrane potential of the photoreceptor and changes the rate at which it releases **g** neurotransmitter.

and cones

CLINICAL NOTE

Visual Acuity

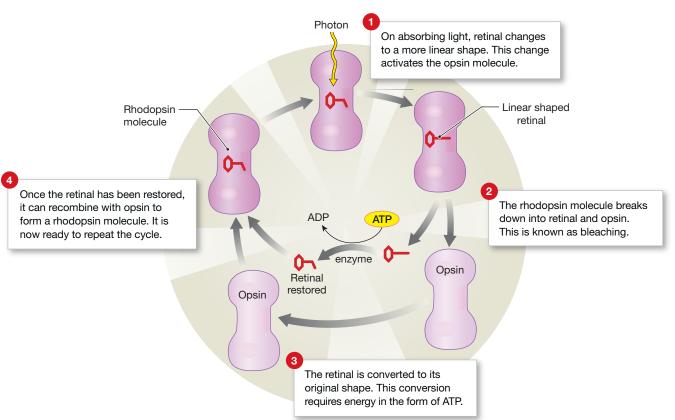

How well you see, or **visual acuity**, is rated on the basis of the sight of a "normal" person. A person whose vision is rated 20/20 can see details at a distance of 20 feet as clearly as a "normal"

individual would. Vision rated 20/15 is better than average, for at 20 feet the person is able to see details that would be clear to a "normal" eye only at a distance of 15 feet. Conversely, a person with 20/30 vision must be 20 feet from an object to discern details that a person with "normal" vision could make out at a distance of 30 feet.

The discs of the outer segment in both rods and cones contain special organic compounds called **visual pigments**. The visual pigments are derived from the compound **rhodopsin** (rō-DOP-sin). Rhodopsin consists of a protein, **opsin**, bound to the pigment **retinal** (RET-i-nal) (**Figure 9-18b**). Retinal is synthesized from **vitamin A**. Retinal is identical

Figure 9-19 Bleaching and Regeneration of Visual Pigments.

in both rods and cones, but a different form of opsin is found in the rods and in each of the three types of cones (red, blue, and green).

Photoreception

The process of *photoreception* is the detection of light. The absorption of photons by visual pigments is the first key step. Photoreception begins when a photon strikes a rhodopsin molecule in the outer segment of a photoreceptor. When the photon is absorbed, a change in the shape of the retinal component activates opsin. Opsin activation starts a chain of enzyme-driven events that alters the rate of neurotransmitter release. This change is the signal that light has struck a photoreceptor at that particular location on the retina.

Shortly after the retinal changes shape, the rhodopsin molecule begins to break down into retinal and opsin, a process known as **bleaching** (Figure 9-19). The retinal must be converted back to its former shape before it can recombine with opsin. This conversion uses energy in the form of ATP, and it takes time. Bleaching contributes to the lingering visual impression that you have after a camera's flash. After an intense

CLINICAL NOTE

Night Blindness

The visual pigments of the photoreceptors are synthesized from vitamin A. The body contains vitamin A reserves for several months, and a significant amount is stored in the cells of the pigmented part of the retina. If dietary sources are inadequate, these reserves are gradually exhausted, and the amount of visual pigment in the photoreceptors begins to decline. Daylight vision is affected. However, in daytime, the light is usually bright enough to stimulate any remaining visual pigments in the cones. As a result,

the problem first becomes apparent at night, when the dim light cannot activate the rods. This condition, known as **night blindness**, can be treated by administering vitamin A. The body can convert the carotene pigments in many vegetables to vitamin A. Carrots are a particularly good source of carotene, which explains the old saying that carrots are good for your eyesight.

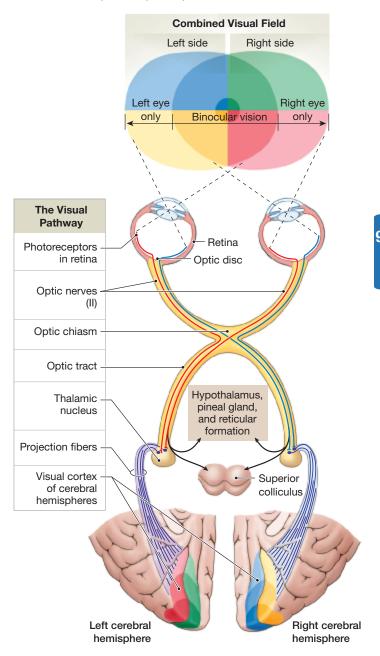

exposure to light, a photoreceptor cannot respond to further stimulation until its rhodopsin molecules have been regenerated. As a result, a "ghost" image remains on the retina.

The Visual Pathways

The visual pathways begin at the photoreceptors and end at the visual cortex of the cerebral hemispheres. In other sensory pathways we have examined, at most one synapse lies between a receptor and a sensory neuron that delivers information to the CNS. In the visual pathways, the message must cross two synapses (photoreceptor to bipolar cell, and bipolar cell to ganglion cell). Only then does it move toward the brain. Axons from all the ganglion cells converge on the optic disc, penetrate the wall of the eye, and proceed toward the diencephalon as the optic nerve (II).

The two optic nerves, one from each eye, meet at the optic chiasm (Figure 9-20). From that point, approximately half of the fibers of each optic nerve proceed within the optic tracts toward the thalamic nucleus on the same side of the brain. The other half cross over to reach the thalamic nucleus on the opposite side. These thalamic nuclei act as switching and processing centers. They relay visual information to reflex centers in the brainstem as well as to the cerebral cortex. The visual information received by the *superior colliculi* (midbrain nuclei in the brainstem) controls constriction or dilation of the pupils and reflexes that control eye movement. \bigcirc p. 307

Figure 9-20 The Visual Pathways. At the optic chiasm, a partial crossover of nerve fibers occurs. As a result, each hemisphere receives visual information from the lateral half of the retina on that side and from the medial half of the retina on the opposite side. Visual association areas in the cerebrum integrate this information to develop a composite picture of the entire visual field.

The sensation of vision arises from the integration of information arriving at the visual cortex of the cerebrum. The visual cortex of each occipital lobe contains a sensory map of the entire field of vision. As with the primary somatosensory cortex, the map does not faithfully duplicate the relative areas within the sensory field. For example, the area assigned to the fovea centralis covers about 35 times the surface it would cover if the map were proportionally accurate. Many centers in the brainstem receive visual information from the thalamic nuclei or over collaterals from the optic tracts. For example, some collaterals bypass the thalamic nuclei and synapse in the hypothalamus. Visual inputs there and at the pineal gland establish a daily pattern of visceral activity that is tied to the day–night cycle. This *circadian* (*circa*, about + *dies*, day) *rhythm* affects your metabolic rate, endocrine function, blood pressure, digestive activities, sleep-wake cycle, and other processes.

The term *blindness* implies a total absence of vision due to damage to the eyes or to the optic pathways. Common causes of blindness include diabetes mellitus, cataracts, glaucoma, corneal scarring, retinal detachment, accidental injuries, and hereditary factors that are as yet poorly understood.

CHECKPOINT

14. If you had been born without cone cells in your eyes, would you still be able to see? Explain.

15. How could a diet deficient in vitamin A affect vision? See the blue Answers tab at the back of the book.

9-7 Equilibrium sensations originate within the internal ear, while hearing involves the detection and interpretation of sound waves

Learning Outcome Describe the parts of the external, middle, and internal ear, and the receptors they contain, and discuss the processes involved in the senses of equilibrium and hearing.

The *internal ear*, a receptor complex located in the temporal bone of the skull, provides us with the special senses of equilibrium and hearing. ⊃ p. 187 *Equilibrium* informs us of the position of the body in space by monitoring gravity, linear acceleration, and rotation. *Hearing* enables us to detect and interpret sound waves.

The basic receptor process for these senses is the same. The receptors—*hair cells*—are mechanoreceptors. The complex structure of the internal ear and the different arrangements of accessory structures permit hair cells to respond to different stimuli and to provide the input for both senses.

Anatomy of the Ear

The ear is divided into three anatomical regions: the external ear, the middle ear, and the internal ear (**Figure 9-21**). The *external ear* is the visible portion of the ear. It collects and directs sound waves toward the *middle ear*, a chamber located

in a thickened portion of the temporal bone. Structures of the middle ear collect and amplify sound waves and transmit them to an appropriate portion of the internal ear. The *internal ear* contains the sensory organs for both hearing and equilibrium.

The External Ear

The **external ear** includes the fleshy and cartilaginous **auricle**, or *pinna*, which surrounds a passageway called the **external acoustic meatus**, or *auditory canal*. The auricle protects the opening of the canal and provides directional sensitivity. Sounds coming from behind the head are blocked by the auricle, but sounds coming from the side or front are collected and channeled into the external auditory meatus. (When you "cup" your ear with your hand to hear a faint sound more clearly, you are exaggerating this effect.)

Ceruminous (se-ROO-mi-nus) **glands** along the external acoustic meatus secrete a waxy material called *cerumen*. It helps prevent the entry of foreign objects and insects. The canal is also lined with many small, outwardly projecting hairs. They trap debris and provide tactile sensations through their root hair plexuses. Dp. 339 The waxy cerumen also slows the growth of microorganisms and reduces the likelihood of infection.

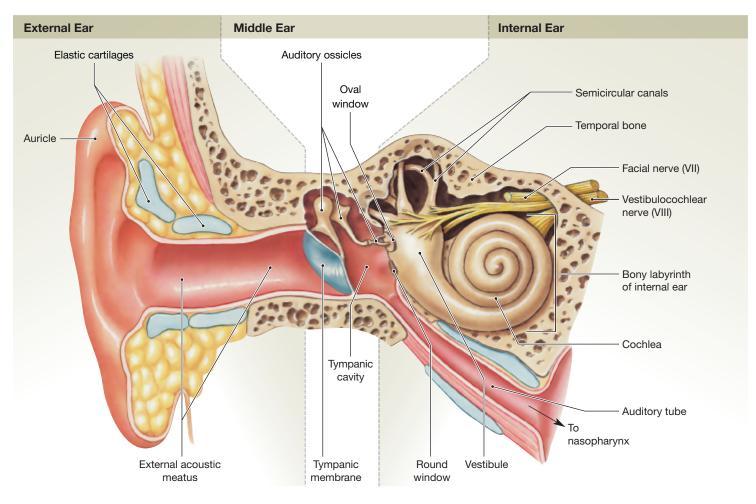

The external acoustic meatus ends at the **tympanic membrane** (*tympanon*, drum) or *eardrum*. This thin, semitransparent sheet separates the external ear from the middle ear (**Figure 9-21**).

The Middle Ear

The **middle ear**, or *tympanic cavity*, is an air-filled chamber separated from the external acoustic meatus by the tympanic membrane. The middle ear communicates with the superior portion of the pharynx, a region known as the *nasopharynx*, and with *air cells* in the mastoid process of the temporal bone.

The connection with the nasopharynx is the **auditory tube**, also called the *pharyngotympanic tube* or the *Eustachian tube* (Figure 9-21). The auditory tube enables the equalization of pressure on either side of the eardrum. Unfortunately, it can also allow microorganisms to travel from the nasopharynx into the middle ear, leading to an unpleasant middle ear infection known as *otitis media*.

THE AUDITORY OSSICLES. The middle ear contains three tiny ear bones, collectively called **auditory ossicles**. These ear bones connect the tympanic membrane with the receptor complex of the internal ear (**Figure 9-22**). The three auditory ossicles are the malleus, the incus, and the stapes. The **malleus** (*malleus*, hammer) attaches at three points to the interior surface of the tympanic membrane. The middle Figure 9-21 The Anatomy of the Ear. The boundaries separating the three regions of the ear (external, middle, and internal) are roughly marked by the dashed lines.

bone—the **incus** (*incus*, anvil)—attaches the malleus to the inner bone, the **stapes** (*stapes*, stirrup). The base of the stapes almost completely fills the oval window. The *oval window* is a small, membrane-covered opening in the temporal bone that surrounds the internal ear.

Vibration of the tympanic membrane converts arriving sound energy into mechanical movements of the auditory ossicles. The ossicles act as levers that collect the force applied to the tympanic membrane and focus it on the oval window. Because the tympanic membrane is larger and heavier than the delicate membrane of the oval window, the amount of movement is markedly increased.

This amplification in movement enables us to hear very faint sounds. It can also be a problem, however, when we are exposed to very loud noises. In the middle ear, two small muscles protect the eardrum and ossicles from violent movements under noisy conditions. The *tensor tympani* (TEN-sor tim-PAN-ē) *muscle* pulls on the malleus. This action increases the stiffness of the tympanic membrane and reduces the amount of possible movement. The *stapedius* (sta-P \bar{E} -d \bar{e} -us) *muscle* pulls on the stapes, reducing its movement at the oval window.

The Internal Ear

Receptors within the **internal ear** (Figures 9-21 and 9-23) give us our senses of equilibrium and hearing. These receptors are protected by the **bony labyrinth**, whose outer walls are fused with the surrounding temporal bone. The bony labyrinth surrounds and protects the **membranous labyrinth** (*labyrinthos*, network of canals), a collection of tubes and chambers that follow the contours of the bony labyrinth. These tubes and chambers are filled with a fluid called **endolymph** (EN-dōlimf). The receptors lie within the membranous labyrinth. Between the bony and membranous labyrinths flows another fluid, the **perilymph** (PER-i-limf) (Figure 9-23a).

Figure 9-22 The Middle Ear.

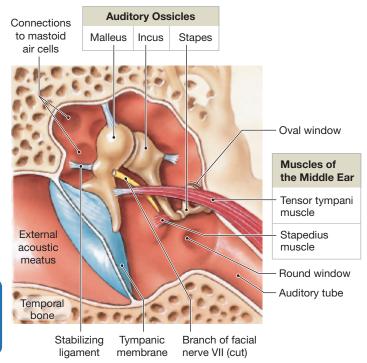

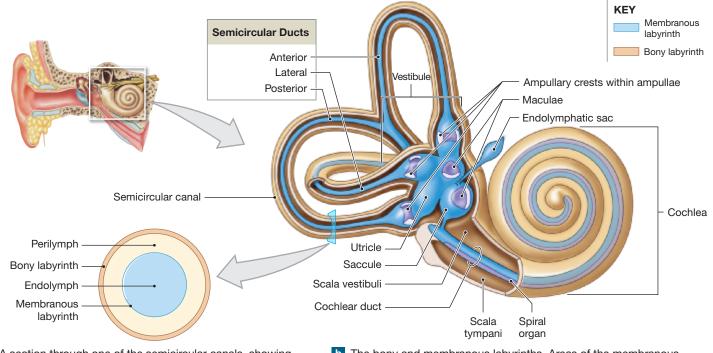

Figure 9-23 The Internal Ear.

The bony labyrinth has three major parts (Figure 9-23b):

- Vestibule. The vestibule (VES-ti-būl) includes a pair of membranous sacs, the saccule (SAK-ūl) and the utricle (Ū-tri-kul). Receptors in these sacs provide sensations of gravity and linear acceleration.
- 2. Semicircular canals. The semicircular canals enclose slender semicircular ducts. Receptors in the semicircular ducts are stimulated by rotation of the head. The combination of vestibule and semicircular canals is called the **vestibular complex** because the fluid-filled chambers within the vestibule are continuous with those of the semicircular canals.
- **3.** *Cochlea.* The bony, spiral-shaped **cochlea** (KOK-lē-uh; *cochlea*, snail shell) contains the **cochlear duct** of the membranous labyrinth. Receptors in the cochlear duct provide the sense of hearing. The duct is sandwiched between a pair of perilymph-filled chambers. The entire complex spirals around a central bony hub, much like a snail shell.

The walls of the bony labyrinth are dense bone everywhere except at two small areas near the base of the cochlea. The

round window is an opening in the bone of the cochlea. A thin membrane spans the opening and separates perilymph in the cochlea from the air-filled middle ear. The membrane spanning the **oval window** is firmly attached to the base of the stapes. Recall that when a sound vibrates the tympanic membrane, the movements are conducted over the malleus and incus to the stapes and oval window. Movement of the stapes ultimately leads to events that stimulate receptors in the cochlear duct, and we hear the sound.

RECEPTOR FUNCTION IN THE INTERNAL EAR. The receptors of the internal ear are called **hair cells**. A representative hair cell is shown in **Figure 9-24c**. Regardless of location, hair cells are always surrounded by supporting cells and monitored by the dendrites of sensory neurons. Each hair cell communicates with a sensory neuron by continually releasing small quantities of neurotransmitter. The free surface of a hair cell supports 80–100 long microvilli called *stereocilia*. Hair cells do not actively move these stereocilia.

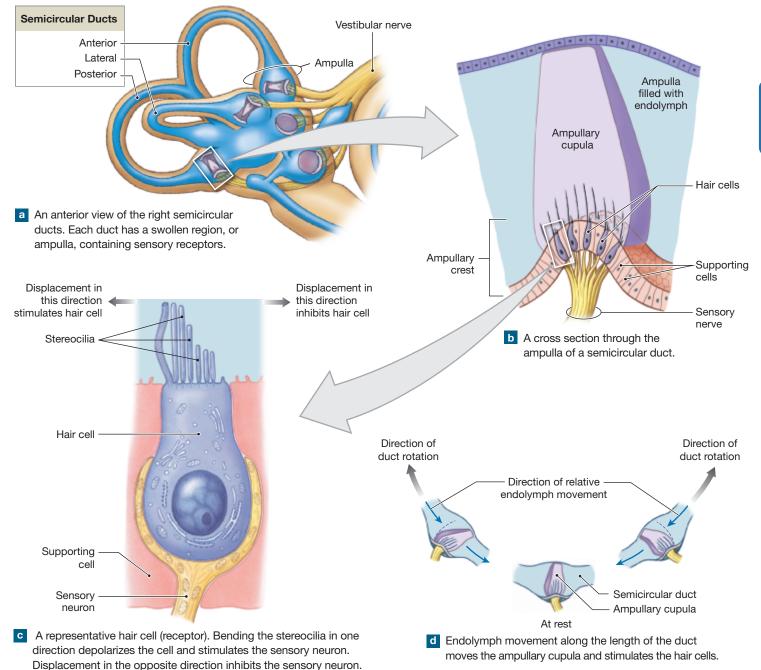

Figure 9-24 The Semicircular Ducts.

Instead, when some external force causes the stereocilia to bend, their movement distorts the cell surface and alters its rate of neurotransmitter release. Displacement of the stereocilia in one direction stimulates the hair cells and increases neurotransmitter release. Displacement in the opposite direction inhibits the hair cells and decreases neurotransmitter release.

Equilibrium

There are two aspects of equilibrium:

- **1. dynamic equilibrium**, which aids us in maintaining our balance when the head and body are moved suddenly, and
- **2. static equilibrium**, which maintains our posture and stability when the body is motionless.

Hair cells of the vestibular complex provide all equilibrium sensations. The semicircular ducts monitor dynamic equilibrium. They provide information about rotational movements of the head. For example, when you turn your head to the left, receptors in the semicircular ducts tell you how rapid the movement is and in which direction.

The saccule and the utricle monitor static equilibrium. They provide information about the position of your head with respect to gravity. If you stand with your head tilted to one side, receptors in the saccule and utricle will report the angle involved and whether your head is tilting forward or backward. These receptors are also stimulated by sudden changes in velocity. For example, when your car accelerates, these receptors give you the sensation of increasing speed.

The Semicircular Ducts: Rotational Motion

Sensory receptors in the semicircular ducts respond to rotational movements of the head. These hair cells are active during a movement but are quiet when the body is motionless. The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle (**Figure 9-23a**). Each semicircular duct contains an **ampulla**, a swollen region that contains the sensory receptors (**Figure 9-24a**). Hair cells attached to the wall of the ampulla form a raised structure known as the **ampullary crest** (**Figure 9-24b**). The stereocilia of the hair cells are embedded in a gelatinous structure called the **ampullary cupula** (KŪ-pū-luh), which nearly fills the ampulla. When the head rotates in the plane of the semicircular duct, movement of the endolymph pushes against this structure and stimulates the hair cells (**Figure 9-24d**). Each semicircular duct responds to one of three possible rotational movements. To distort the cupula and stimulate the receptors, endolymph must flow along the axis of the duct. Such flow takes place only when there is rotation in that plane. A horizontal rotation, as in shaking the head "no," stimulates the hair cells of the lateral semicircular duct. Nodding "yes" excites receptors of the anterior duct, and tilting the head from side to side activates receptors in the posterior duct. The three planes monitored by the semicircular ducts correspond to the three dimensions in the world around us. The ducts provide accurate information about even the most complex movements.

The Vestibule: Gravity and Linear Acceleration

Receptors in the utricle and saccule respond to gravity and linear acceleration. By responding to gravity, they provide information concerning up and down. Utricle receptors are sensitive to horizontal acceleration. Saccule receptors are sensitive to vertical acceleration. The hair cells of the utricle and saccule are clustered in oval maculae (MAK-ū-lē; singular macula, spot) (Figure 9-25a). The hair cell processes in the maculae are embedded in a gelatinous otolithic membrane whose surface contains a thin layer of densely packed calcium carbonate crystals. These calcium carbonate crystals are called otoliths (oto-, ear + lithos, a stone) (Figure 9-25b). When the head is in the normal, upright position, the macula of utricle is oriented horizontally and, the macula of saccule, vertically. When the head tilts, the pull of gravity on the otoliths shifts their weight to the side, distorting the sensory hairs. The change in receptor activity tells the CNS that the head is no longer level (Figure 9-25c).

Otoliths are relatively dense and heavy, and they are connected to the rest of the body only by the sensory processes of the macular hair cells. So whenever the rest of the body makes a sudden movement, the otolith crystals lag behind. For example, you know immediately when an elevator starts downward, because the otoliths within the saccules are displaced upward and bend the stereocilia of the receptor cells. Once they catch up and the elevator has reached a constant speed, you are no longer aware of any movement until the elevator brakes to a halt. As your body slows down, the otoliths of the saccules bend the sensory hairs downward and we "feel" the force of gravity increase.

A similar process accounts for our perception of linear acceleration in a car that speeds up suddenly. The utricle otoliths lag behind, bending the sensory hairs and changing the activity in the sensory neurons. A comparable movement of the otoliths takes place when you raise your chin and gravity

Gravity

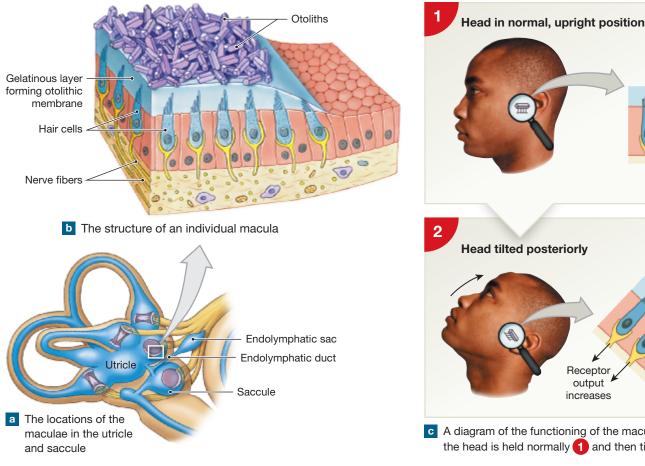

Figure 9-25 The Utricle and Saccule.

pulls the otoliths backward. On the basis of visual information, the brain decides whether the arriving sensations indicate acceleration or a change in head position.

Pathways for Equilibrium Sensations

Sensory neurons monitor hair cells of the vestibule and of the semicircular ducts (Figure 9-24c). The fibers of these neurons form the vestibular nerve, a division of the vestibulocochlear cranial nerve (VIII). These fibers synapse on neurons in the vestibular nuclei located at the boundary between the pons and the medulla oblongata. The two vestibular nuclei (1) integrate sensory information arriving from each side of the head; (2) relay information to the cerebellum; (3) relay information to the cerebral cortex, providing a conscious sense of position and movement; and (4) send commands to motor nuclei in the brainstem and in the spinal cord. These reflexive motor commands are distributed to the motor nuclei for cranial nerves involved with eye, head, and neck movements (III, IV, VI, and XI). Descending instructions along the vestibulospinal tracts of the spinal cord adjust peripheral muscle tone to complement the reflexive movements of the head or neck.

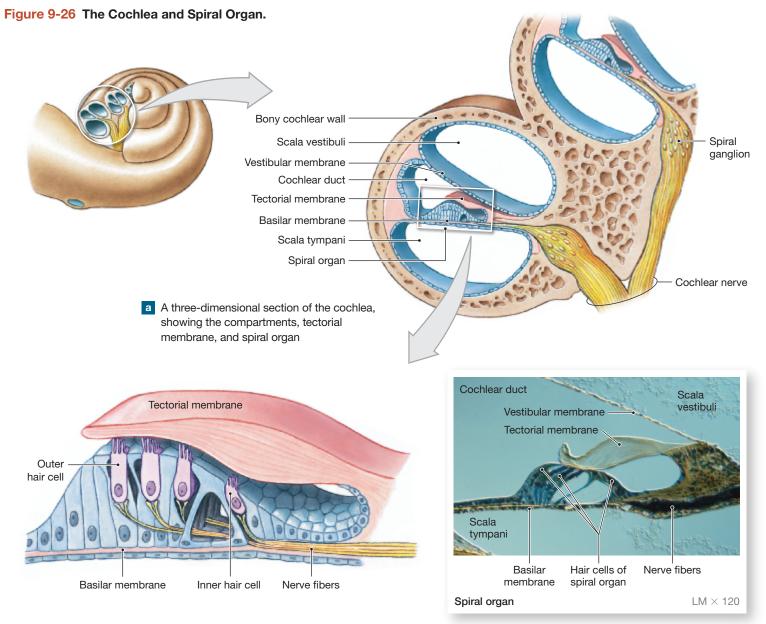

Hearing

The receptors of the cochlear duct provide us with a sense of hearing. They enable us to detect the quietest whisper, yet they remain functional in a noisy room. The receptors responsible for auditory sensations are hair cells similar to those of the vestibular complex. However, their placement within the cochlear duct and the organization of the surrounding accessory structures shield them from stimuli other than sound.

In conveying vibrations from the tympanic membrane to the oval window, the auditory ossicles convert sound energy (pressure waves) in air to pressure pulses in the perilymph of the cochlea. These pressure pulses stimulate hair cells along the cochlear spiral. The frequency (pitch) of the perceived sound is determined by which part of the cochlear duct is stimulated. The intensity (volume) of the perceived sound is determined by how many hair cells at that location are stimulated.

The Cochlear Duct

In sectional view, the cochlear duct, or **scala media**, lies between a pair of perilymph-filled chambers or *scalae*: the **scala vestibuli** (SKĀ-luh ves-TIB-yū-lē), or *vestibular duct*, and the **scala tympani** (SKĀ-luh TIM-pa-nē), or *tympanic duct* (**Figure 9-26a**). The bony labyrinth encases the outer surfaces of these ducts everywhere except at the oval window (the base of the scala vestibuli) and the round window (the base of the scala tympani). Because these two scalae, or ducts, are interconnected at the tip of the cochlear spiral, they really form one long and continuous perilymph-filled chamber. **THE SPIRAL ORGAN.** The hair cells of the cochlear duct are located in the **spiral organ** (*organ of Corti*) (Figure 9-26b). This sensory structure sits on the **basilar membrane**, a membrane that separates the cochlear duct from the underlying scala tympani. The hair cells are arranged in a series of longitudinal rows, with their stereocilia in contact with the overlying **tectorial membrane** (tek-TOR-ē-al; *tectum*, roof). This membrane is firmly attached to the inner wall of the cochlear duct. When a portion of the basilar membrane bounces up and down (in response to pressure waves in the perilymph), the stereocilia of the hair cells are pressed up against the tectorial membrane and distorted.

Diagrammatic and sectional views of the receptor hair cell complex of the spiral organ

The Hearing Process

Hearing is the perception of sound, but what is sound? It consists of waves of pressure conducted through a medium such as air or water. In air, each pressure wave consists of a region where air molecules are crowded together and adjacent regions where they are farther apart. Physicists use the term **cycles** rather than waves, and the number of cycles per second (cps)—or **hertz (Hz)**—represents the **frequency** of the sound.

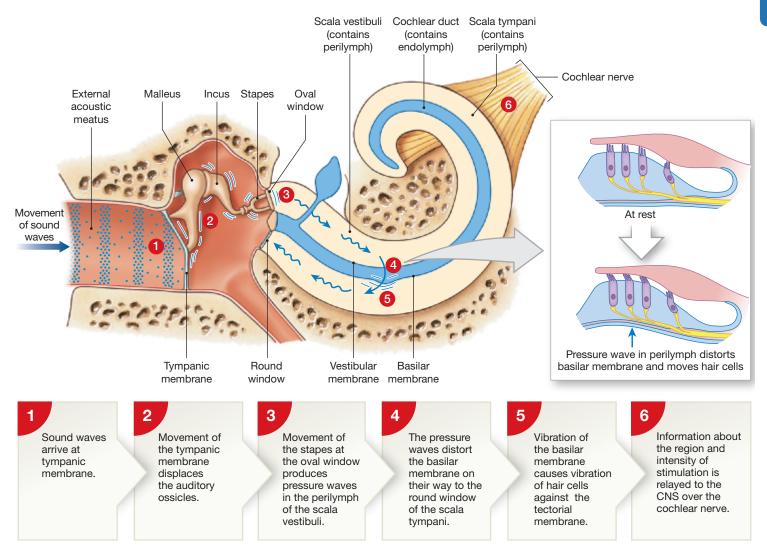

What we perceive as the **pitch** of a sound (how high or low it is) is our sensory response to its frequency. A sound of high frequency (high pitch) might have a frequency of 15,000 Hz or more. A sound of low frequency (low pitch) could have a frequency of 100 Hz or less.

The amount of energy, or power, of a sound determines its *intensity*, or volume (loudness). Intensity is reported in **decibels** (DES-i-belz). Some examples of different sounds and their intensities include a soft whisper (30 decibels), a refrigerator (50 decibels), a gas lawnmower (90 decibels), a chain saw (100 decibels), and a jet plane (140 decibels).

Hearing can be divided into six basic steps, diagrammed in **Figure 9-27**.

- **1** Sound waves arrive at the tympanic membrane. They enter the external acoustic meatus and travel toward the tympanic membrane. Sound waves approaching the side of the head have direct access to the tympanic membrane on that side. Sounds arriving from another direction must bend around corners or pass through the auricle or other body tissues.
- 2 Movement of the tympanic membrane causes displacement of the auditory ossicles. The tympanic membrane provides the surface for sound collection. It vibrates to sound waves with frequencies between

Figure 9-27 Sound and Hearing. Steps in the reception of sound and the process of hearing.

approximately 20 and 20,000 Hz. When the tympanic membrane vibrates, so do the malleus, incus, and stapes.

3 The movement of the stapes at the oval window establishes pressure waves in the perilymph of the scala vestibuli. When the stapes moves, it applies pressure to the perilymph of the scala vestibuli. Because the rest of the cochlea is sheathed in bone, pressure applied at the oval window can be relieved only at the round window. When the stapes moves inward, the membrane spanning the round window bulges outward. As the stapes moves in and out, vibrating at the frequency of the sound at the tympanic membrane, it creates pressure waves within the perilymph.

The pressure waves distort the basilar membrane on their way to the round window of the scala tympani. These pressure waves cause movement in the basilar membrane. The basilar membrane does not have the same structure throughout its length. Near the oval window, it is narrow and stiff. At its terminal end, it is wider and more flexible. As a result, the location of maximum stimulation varies with the frequency of the sound. High-frequency sounds vibrate the basilar membrane near the oval window. The lower the frequency of the sound, the farther from the oval window is the area of maximum distortion. The actual *range* of movement at a given location depends on the amount of force applied by the stapes. The louder the sound, the more the basilar membrane moves.

5 Vibration of the basilar membrane causes hair cells to vibrate against the tectorial membrane. The vibration of the affected region of the basilar membrane pushes hair cells against the tectorial membrane. The displacement of the hair cells results in the release of neurotransmitters and the stimulation of sensory neurons. The hair cells are arranged in several rows. A very soft sound may stimulate only a few hair cells in a portion of one row. As the volume of a sound increases, not only do these hair cells become more active, but additional hair cells—at first in the same row and then in adjacent rows—are stimulated as well. In this way, the number of hair cells responding in a given region of the spiral organ provides information on the intensity of the sound.

⁶ Information about the region and intensity of stimulation is relayed to the CNS over the cochlear nerve, a division of cranial nerve VIII. The cell bodies of the sensory neurons that monitor the cochlear hair cells are located in the *spiral ganglion* at the center of the bony cochlea (**Figure 9-26a**). Their afferent fibers (axons) form the **cochlear nerve**, a division of the vestibulocochlear nerve (VIII). It carries information to the cochlear nuclei of the medulla oblongata for distribution to other centers in the brain.

Auditory Pathways

At the medulla oblongata, fibers from the sensory neurons synapse at the cochlear nucleus on that side (**Figure 9-28**). From there, information ascends to both *inferior colliculi* of the midbrain. This midbrain processing center coordinates a number of responses to acoustic stimuli, including auditory reflexes involving skeletal muscles of the head, face, and trunk. For example, these reflexes automatically turn your head and your eyes toward the source of a sudden loud noise.

CLINICAL NOTE

Hearing Deficits

Probably more than 6 million people in the United States alone have at least a partial hearing deficit. **Conductive deafness** results from conditions in the external or middle ear that block the normal transfer of vibrations from the tympanic membrane

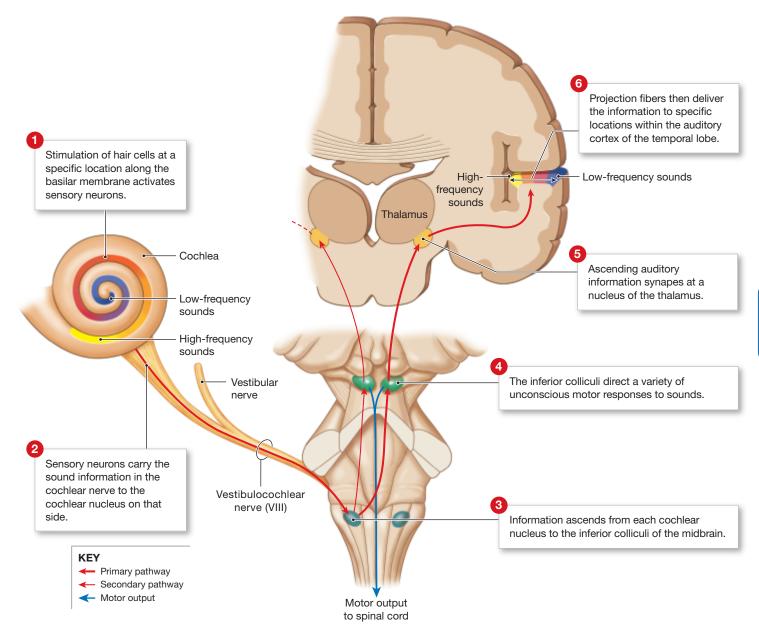

to the oval window. An external acoustic meatus plugged by built-up wax or trapped water may cause a temporary hearing loss. Scarring or perforation of the tympanic membrane and immobilization of one or more of the auditory ossicles are more serious causes of conductive deafness.

In **nerve deafness**, the problem lies within the cochlea or somewhere along the auditory pathway. The vibrations are reaching the oval window and entering the perilymph, but the receptors either cannot respond or their response cannot reach its CNS destinations. Very loud (high-intensity) sounds, for example, can produce nerve deafness by breaking stereocilia off the surfaces of the hair cells. (The reflex contraction of the tensor tympani and stapedius muscles in response to a dangerously loud noise occurs in less than 0.1 second, but this may not be fast enough.) Drugs such as the aminoglycoside antibiotics (*neomycin* or *gentamicin*) may diffuse into the endolymph and kill hair cells. Hair cells and sensory nerves can also be damaged by bacterial infection. For this reason, potential side effects of drug treatment must be balanced against the severity of infection.

Many treatment options are available for conductive deafness. Treatment options for nerve deafness are relatively limited. Early diagnosis improves the chances for successful treatment because many of these problems become progressively worse.

Figure 9-28 Pathways for Auditory Sensations.

Before reaching the cerebral cortex and your conscious awareness, ascending auditory sensations synapse in the thalamus. Thalamic fibers then deliver the information to the auditory cortex of the temporal lobe. In effect, the auditory cortex contains a map of the spiral organ. High-frequency sounds activate one portion of the cortex, and low-frequency

Most of the auditory information from one cochlea is projected to the auditory complex of the cerebral hemisphere on the opposite side of the brain. However, each auditory cortex also receives information from the cochlea on that side. These interconnections enable you to localize left/right sounds.

sounds affect another.

An individual whose auditory cortex is damaged will respond to sounds and have normal acoustic reflexes, but will find it difficult or impossible to interpret the sounds and recognize a pattern in them. Damage to the adjacent association area does not affect the ability to detect tones and patterns but produces an inability to comprehend their meaning.

Auditory Sensitivity

Our hearing abilities are remarkable, but it is difficult to assess the absolute sensitivity of the system. The range from the softest audible sound to the loudest tolerable blast represents a trillionfold increase in power. The receptor process is so sensitive that if we were to remove the stapes, we could, in theory, hear air molecules bouncing off the oval window. We never utilize our full auditory potential, because body movements and our internal organs produce squeaks, groans, thumps, and other sounds that are tuned out by adaptation. When other environmental noises fade away, the level of adaptation drops and the system becomes increasingly sensitive. If we relax in a quiet room, our heartbeat seems to get louder and louder as the auditory system adjusts to the lower level of background noise.

CHECKPOINT

- **16.** If the round window were not able to bulge out with increased pressure in the perilymph, how would sound perception be affected?
- **17.** How would the loss of stereocilia from the hair cells of the spiral organ affect hearing?

See the blue Answers tab at the back of the book.

9-8 Aging is accompanied by a noticeable decline in the special senses

Learning Outcome Describe the effects of aging on smell, taste, vision, equilibrium, and hearing.

The general lack of replacement of neurons leads to an inevitable decline in sensory function with age. Increases in stimulus strength can compensate for part of this functional decline, but the loss of axons that conduct sensory action potentials cannot be compensated for so easily. Next we consider the toll aging takes on various special senses.

Smell and Aging

Unlike populations of other neurons, the population of olfactory receptor cells is regularly replaced by the division of stem cells in the olfactory epithelium. Despite this process, the total number of receptors declines with age, and the remaining receptors become less sensitive. As a result, elderly individuals have difficulty detecting odors in low concentrations. This drop in the number of receptors explains a grandmother's tendency to use too much perfume and why a grandfather's aftershave lotion seems so overpowering. They must use more to be able to smell it.

Taste and Aging

Tasting ability declines with age due to the thinning of mucous membranes and a reduction in the number and sensitivity of taste buds. We begin life with more than 10,000 taste buds, but that number begins declining dramatically by age 50. In addition, aging individuals also experience a decline in the number of olfactory receptor cells. As a result, many elderly people find their food bland and unappetizing. Children, however, find the same food too spicy.

Vision and Aging

Various disorders of vision are associated with normal aging. The most common ones involve the lens and the neural part of the retina. With age, the lens loses its elasticity and stiffens. As a result, seeing close-up objects becomes more difficult, and older individuals become farsighted—a condition called *presbyopia*. D p. 354 For example, the inner limit of clear vision, known as the *near point of vision*, changes from 7–9 cm (2.8–3.5 in.) in children to 15–20 cm (5.9–7.9 in.) in young adults, and typically reaches 83 cm (32.7 in.) by age 60. As noted earlier, advancing age is the most common cause of the loss of transparency in the lens known as *senile cataracts*. D p. 351 In addition, a gradual loss of rods takes place with age. This loss explains why individuals over age 60 need almost twice as much light for reading than individuals at age 40.

The leading cause of blindness in persons over 50 is *macular degeneration*. This condition involves the growth and proliferation of blood vessels in the retina. Blood leaking from these abnormal vessels causes retinal scarring and a loss of photoreceptors. The vascular proliferation begins in the macula, the area of the retina correlated with the clearest vision. As the cones there deteriorate, color vision and the center of the visual field are affected.

Equilibrium and Aging

Problems with equilibrium, or balance, increase with age. An important health concern for people over the age of 60 is falling. Falls cause more than 95 percent of hip fractures. Complications following a hip fracture can be disastrous. It is estimated that 20 percent of hip fracture patients die within a year of their injury. Good balance relies on sensory input from the vestibular complex (vestibule and semicircular canals) and visual and proprioceptive receptors. From about age 55, there is a decrease in the number of nerve cells in the vestibular complex. Damage to the vestibular complex by any cause may lead to dizziness and balance problems. However, problems in balance due to the gradual, age-related loss of vestibular nerve cells are not accompanied by dizziness.

Hearing and Aging

Hearing is generally affected less by aging than are the other senses. However, it becomes more difficult to hear high-pitched sounds because the tympanic membrane loses some of its elasticity. The progressive loss of hearing that occurs with aging is called *presbycusis* (prez-bē-KŪ-sis; *presbys*, old man + *akousis*, hearing).

CHECKPOINT

- **18.** How can a given food be both too spicy for a child and too bland for an elderly individual?
- **19.** Explain why we have an increasingly difficult time seeing close-up objects as we age.

See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

analgesic: A drug that relieves pain without eliminating sensitivity to other stimuli, such as touch or pressure.

anesthesia: A total or partial loss of sensation.

Ménière's disease: A condition in which high fluid pressures rupture the walls of the membranous labyrinth, resulting in acute vertigo (an inappropriate sense of motion) and inappropriate auditory sensations.

nystagmus: Abnormal eye movements that may appear after the brainstem or internal ear is damaged.

ophthalmology (of-thal-MOL-o-j**ē**)**:** The study of the eye and its diseases.

retinitis pigmentosa: A group of inherited retinopathies (see the next term) characterized by the progressive deterioration of photoreceptors, eventually resulting in blindness.

retinopathy (ret-i-NOP-ah-thē): A disease or disorder of the retina.

scotomas (skō-TŌ-muhz**):** Abnormal blind spots in the field of vision (that is, those not caused by the optic disc).

Snellen chart: A printed chart of block letters in graduated type sizes used to measure visual acuity.

strabismus: Deviations in the alignment of the eyes to each other. One or both eyes are turned inward or outward.

synesthesia: Abnormal condition in which sensory nerve messages connect to the wrong centers of the brain. For example, touching an object may produce the perception of a sound, while hearing a tone may produce the visualization of a color.

Chapter Review

Summary Outline

9-1 Sensory receptors connect our internal and external environments with the nervous system *p. 336*

- 1. The **general senses** are temperature, pain, touch, pressure, vibration, and proprioception. The receptors for these sensations are distributed throughout the body. Receptors for the **special senses** (smell, taste, vision, balance, and hearing) are located in specialized areas or in sense organs.
- 2. A *sensory receptor* is a specialized cell that, when stimulated, sends a sensation to the CNS. The simplest receptors are **free nerve endings**. The most complex have specialized accessory structures that isolate the receptors from all but a specific type of stimulus.
- **3.** Each receptor cell monitors a specific *receptive field*. (*Figure 9-1*)

- **4.** Sensory information is relayed in the form of action potentials in a sensory (afferent) fiber. In general, the larger the stimulus, the greater is the frequency of action potentials. The CNS interprets the nature of the arriving sensory information on the basis of the area of the brain stimulated.
- **5. Adaptation**—a reduction in sensitivity in the presence of a constant stimulus—involves changes in receptor sensitivity or inhibition along sensory pathways.

9-2 General sensory receptors are classified by the type of stimulus that excites them *p. 337*

6. Nociceptors respond to a variety of stimuli usually associated with tissue damage. The two types of painful sensations are **fast pain**, or *prickling pain*, and **slow pain**, or *burning and aching pain*.

- **7.** The perception of pain in parts of the body that are not actually stimulated is called **referred pain**. (*Figure 9-2*)
- 8. Thermoreceptors respond to changes in temperature.
- 9. Mechanoreceptors respond to physical distortion of, contact with, or pressure on their plasma membranes.
 Tactile receptors respond to touch, pressure, and vibration.
 Baroreceptors respond to pressure changes in the walls of blood vessels, the digestive and urinary tracts, and the lungs.
 Proprioceptors respond to positions of joints and muscles.
- **10. Fine touch and pressure receptors** provide detailed information about a source of stimulation; **crude touch and pressure receptors** are poorly localized. Important tactile receptors include the *root hair plexus, tactile discs, tactile (Meissner) corpuscles, lamellar (pacinian) corpuscles,* and *bulbous (Ruffini) corpuscles. (Figure 9-3)*
- **11.** Baroreceptors in the walls of major arteries and veins respond to changes in blood pressure, and those along the digestive tract help coordinate reflex activities of digestion. *(Figure 9-4)*
- **12.** Proprioceptors monitor the position of joints, tension in tendons and ligaments, and the state of muscular contraction. Proprioceptors include Golgi tendon organs and muscle spindles.
- **13.** In general, **chemoreceptors** respond to water-soluble and lipid-soluble substances dissolved in the surrounding fluid. They monitor the chemical composition of body fluids. *(Figure 9-5)*

9-3 Olfaction, the sense of smell, involves olfactory receptors responding to chemical stimuli *p. 341*

- **14.** The **olfactory organs** consist of an **olfactory epithelium** containing **olfactory receptor cells** (neurons sensitive to chemicals dissolved in the overlying mucus), supporting cells, and *basal cells* (stem cells). Their surfaces are coated with the secretions of the **olfactory glands**. (*Figure 9-6*)
- **15.** The olfactory receptors are modified neurons.
- **16.** The olfactory system has extensive limbic and hypothalamic connections.

9-4 Gustation, the sense of taste, involves taste receptors responding to chemical stimuli *p. 343*

- **17. Taste receptors** are clustered in **taste buds**. Each taste bud contains **gustatory epithelial cells**, which extend *taste hairs* through a narrow **taste pore**. (*Figure 9-7*)
- **18.** Taste buds are associated with **papillae**, epithelial projections on the superior surface of the tongue. (*Figure 9-7*)
- **19.** The **primary taste sensations** are sweet, salty, sour, and bitter. Receptors for umami and water are also present. *(Figure 9-7)*
- **20.** The taste buds are monitored by cranial nerves that synapse within a nucleus of the medulla oblongata.

9-5 Internal eye structures contribute to vision, while accessory eye structures provide protection *p. 344*

- **21.** The **accessory structures** of the eye include the eyelids and associated exocrine glands, the superficial epithelium of the eye, structures associated with the production and removal of tears, and the extrinsic eye muscles.
- **22.** An epithelium called the **conjunctiva** covers most of the exposed surface of the eye except the transparent **cornea**.
- **23.** The secretions of the **lacrimal gland** bathe the conjunctiva and contain *lysozyme* (an enzyme that attacks bacteria). Tears reach the nasal cavity after passing through the **lacrimal canals**, the **lacrimal sac**, and the **nasolacrimal duct**. (*Figure 9-8*)
- **24.** Six **extrinsic eye muscles** control external eye movements: the **inferior** and **superior rectus**, the **lateral** and **medial rectus**, and the **superior** and **inferior obliques**. (*Figure 9-9*; *Table 9.1*)
- **25.** The eye has three layers: an outer fibrous layer, a vascular layer, and a deeper inner layer. Most of the ocular surface is covered by the **sclera** (a dense fibrous connective tissue), which is continuous with the cornea, both of which are part of the **fibrous layer**. (*Figure 9-10*)
- **26.** The **vascular layer** includes the **iris**, the **ciliary body**, and the **choroid**. The iris forms the boundary between the eye's anterior and posterior chambers. The iris regulates the amount of light entering the eye. The ciliary body contains the *ciliary muscle* and the *ciliary processes*, which attach to the **ciliary zonule** (*suspensory ligament*) of the **lens**. (*Figure 9-10*)
- 27. The inner layer, or retina, consists of an outer *pigmented layer* and an inner *neural layer*. The neural layer contains the two types of image-forming **photoreceptors**, the **rods** and **cones**, and associated neurons. (*Figures 9-10, 9-11*)
- **28.** Cones are densely clustered in the **fovea centralis** (the site of sharpest vision), at the center of the **macula**. (*Figure 9-11*)
- **29.** From the photoreceptors, the information is relayed to **bipolar cells**, then to **ganglion cells**, and to the brain by the optic nerve. Horizontal cells and amacrine cells modify the signals passed between other retinal components. (*Figure 9-11*)
- **30.** The ciliary body and lens divide the interior of the eye into a large **posterior cavity** and a smaller **anterior cavity**. The anterior cavity is subdivided into the **anterior chamber**, which extends from the cornea to the iris, and a **posterior chamber** between the iris and the ciliary body and lens. The posterior cavity contains the gelatinous *vitreous body*, which helps stabilize the shape of the eye and supports the retina. (*Figure 9-13*)
- **31. Aqueous humor** circulates within the eye and re-enters the circulation after diffusing through the walls of the anterior chamber and into veins of the sclera through the **scleral venous sinus** (canal of Schlemm). *(Figure 9-13)*

32. The lens, held in place by the ciliary zonule, focuses a visual image on the retinal receptors. Light is refracted (bent) when it passes through the cornea and lens. During **accommodation**, the shape of the lens changes to focus an image on the retina. (*Figures 9-14, 9-15, Spotlight Figure 9-16*)

9-6 Photoreceptors respond to light and change it into electrical signals essential to visual physiology *p. 353*

- **33.** Light is radiated in waves with a characteristic wavelength. A *photon* is a single energy packet of visible light. Rods respond to almost any photon, regardless of its energy content (wavelength). Cones have characteristic ranges of wavelength sensitivity and provide color vision. **Color blindness** is the inability to detect certain colors. *(Figures 9-17, 9-18)*
- 34. Each photoreceptor contains an outer segment with membranous discs containing visual pigments. Light is absorbed by the visual pigments, which are derivatives of rhodopsin (opsin plus the pigment retinal, which is synthesized from vitamin A). A photoreceptor responds to light by changing its rate of neurotransmitter release and thereby altering the activity of a bipolar cell. (Figures 9-18, 9-19)
- **35.** Visual information is relayed from photoreceptors to bipolar cells to ganglion cells within the retina. The axons of ganglion cells converge at the optic disc and leave the eye as the optic nerve. A partial crossover occurs at the optic chiasm before the information reaches a nucleus in the thalamus on each side of the brain. From these nuclei, visual information is relayed to the visual cortex of the occipital lobe, which contains a sensory map of the field of vision. (*Figure 9-20*)

9-7 Equilibrium sensations originate within the internal ear, while hearing involves the detection and interpretation of sound waves *p. 358*

- **36.** The senses of equilibrium (**dynamic equilibrium** and **static equilibrium**) and hearing are provided by the receptors of the **internal ear**. Its chambers and canals contain the fluid **endolymph**. The **bony labyrinth** surrounds and protects the **membranous labyrinth**, and the space between them contains the fluid **perilymph**. The bony labyrinth consists of the **vestibule**, the **semicircular canals** (receptors in the vestibule and semicircular canals provide the sense of equilibrium), and the **cochlea** (where receptors provide the sense of hearing). The structures and air spaces of the **external ear** and **middle ear** help capture and transmit sound to the cochlea. (*Figures 9-21, 9-22, 9-23*)
- **37.** The external ear includes the **auricle** (*pinna*), which surrounds the entrance to the **external acoustic meatus**, which ends at the **tympanic membrane** (*eardrum*). (*Figures 9-21, 9-22*)
- **38.** The middle ear is connected to the nasopharynx by the **auditory tube** (*pharyngotympanic tube* or *Eustachian*

tube). The middle ear encloses and protects the **auditory ossicles**. (*Figures 9-21, 9-22*)

- **39.** The vestibule includes a pair of membranous sacs, the **saccule** and **utricle**, whose receptors provide sensations of gravity and linear acceleration (static equilibrium). The semicircular canals contain the **semicircular ducts**, whose receptors provide sensations of rotation (dynamic equilibrium). The cochlea contains the **cochlear duct**, an elongated portion of the membranous labyrinth, whose receptors provide the sense of hearing. (*Figure 9-23*)
- **40.** The basic receptors of the internal ear are **hair cells**, whose surfaces support *stereocilia*. Hair cells provide information about the direction and strength of mechanical stimuli. (*Figure 9-24c*)
- **41.** The **anterior**, **posterior**, and **lateral semicircular ducts** are attached to the utricle. Each semicircular duct contains a sensory organ, the **ampullary crest**. The stereocilia of its hair cells contact the **ampullary cupula**, a gelatinous mass that is distorted when endolymph flows along the axis of the duct. (*Figures 9-23, 9-24a,b,d*)
- **42.** In the saccule and utricle, hair cells cluster within **maculae**, where their stereocilia contact a gelatinous otolithic membrane covered by **otoliths** (calcium carbonate crystals). When the head tilts, the otoliths shift, and the resulting distortion in the sensory hairs signals the CNS. (*Figure 9-25*)
- **43.** The vestibular receptors activate sensory neurons whose axons form the **vestibular nerve**, a division of the vestibulocochlear nerve (VIII).
- **44.** The **cochlear duct** lies between the **scala vestibuli** (*vestibular duct*) and the **scala tympani** (*tympanic duct*). The hair cells lie within the **spiral organ** (*organ of Corti*). (*Figure 9-26*)
- **45.** Sound waves travel toward the tympanic membrane, which vibrates; the auditory ossicles amplify and conduct the vibrations to the internal ear. Movement at the oval window applies pressure to the perilymph of the scala vestibuli. (*Figures 9-26, 9-27*)
- **46.** Pressure waves distort the **basilar membrane** and push the hair cells of the spiral organ (organ of Corti) against the **tectorial membrane**. (*Figure 9-27*)
- **47.** The cell bodies of sensory neurons are located in the **spiral ganglion** of the cochlea. Afferent fibers of these neurons form the **cochlear nerve**, synapsing at their respective left or right cochlear nucleus. (*Figure 9-28*)

9-8 Aging is accompanied by a noticeable decline in the special senses *p. 368*

48. As part of aging, there are (1) gradual reductions in smell and taste sensitivity, (2) a tendency toward *presbyopia* and cataract formation in the eyes, (3) problems with equilibrium, or balance, that may lead to falling and hip fractures, and (4) a progressive loss of hearing (*presbycusis*).

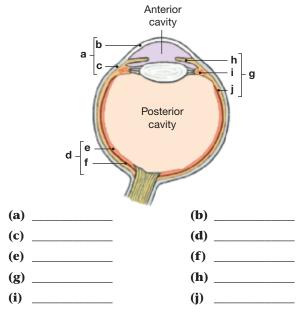

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN B
 a. gravity and acceleration receptors b. pain receptors c. temperature receptors d. sclera and cornea e. rotational movements f. provide information on provide information on
 joint position g. color vision h. site of sharpest vision i. active in dim light j. eardrum k. change in lens shape to focus retinal image l. nearsighted m. farsighted n. sense of smell

15. Identify the structures in the following horizontal section of the right eye.

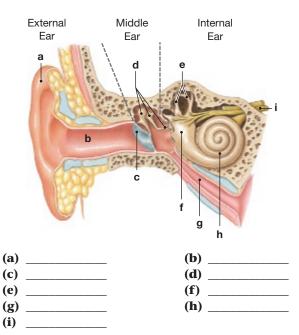

- **16.** In contrast to fast pain, sensations of slow pain
 - (a) are usually relayed by thicker myelinated neurons.
 - (b) are well localized.
 - (c) tend to be aching or burning in nature.
 - (d) include those caused by a deep cut or an injection.

17. Blood pressure is monitored by the _____ in the carotid sinus.

See the blue Answers tab at the back of the book.

- (a) baroreceptors (b) chemoreceptors
- (c) osmoreceptors (d) proprioceptors
- 18. Receptors located in carotid bodies detect changes in (a) blood oxygenation. (b) joint position.
 - (d) skin temperature. (c) pressure in organs.
- 19. The olfactory organ consists of the following except
 - (a) basal cells.
 - (b) olfactory bulb.
 - (c) olfactory receptor cells.
 - (d) supporting cells.
- **20.** Taste buds
 - (a) possess taste pores.
 - (b) form basal cells by continual division of gustatory receptor cells.
 - (c) are absent from circumvallate papillae.
 - (d) relay gustatory information to the brain via cranial nerves V and X.
- 21. Another name for lamellar corpuscles is
 - (a) Meissner corpuscles. (b) Merkel cells.
 - (c) pacinian corpuscles. (d) Ruffini corpuscles.
- 22. A protective mechanism against very loud noises is
 - (a) contraction of the tensor tympani and relaxation of the stapedius.
 - (b) relaxation of the tensor tympani and contraction of the stapedius.
 - (c) contraction of both the tensor tympani and the stapedius.
 - (d) relaxation of both the tensor tympani and the stapedius.
- 23. The optic disc
 - (a) is located lateral to the fovea.
 - (b) is the origin of the optic nerve.
 - (c) has the highest concentration of cones.
 - (d) enables us to see in dim light.
- **24.** Photoreceptors
 - (a) are cells that detect light. (b) are located in the retina.
 - (c) consist of rods and cones. (d) a, b, and c are correct.
- 25. In the ear, the oval window is in direct contact with the
 - (a) incus. (b) malleus.
 - (c) stapes. (d) a, b, and c are correct.
- 26. Infection can spread from the nasopharynx to the middle ear via the
 - (a) auditory tube. (b) mastoid air cells.
 - (c) semicircular canals. (d) tympanic membrane.
- 27. Sensory information from the vestibule and the semicircular ducts is carried by cranial nerve
 - (a) V. (b) VI.
 - (c) VII. (d) VIII.

28. Identify the structures of the external, middle, and internal ear in the following figure.

- 29. In presbycusis, which special sense is progressively lost?(a) Hearing.(b) Smell.
 - (c) Taste. (d) Vision.
- **30.** What three types of mechanoreceptors respond to stretching, compression, twisting, or other distortions of the cell membrane?
- **31.** Identify six types of tactile receptors found in the skin and their sensitivities.
- 32. (a) What structures make up the fibrous layer of the eye?(b) What are the functions of the fibrous layer?
- **33.** Which muscles protect the eardrum and ossicles from violent movements in a noisy environment?
- **34.** What six basic steps are involved in the process of hearing?

Level 2 Reviewing Concepts

- **35.** The CNS interprets sensory information entirely on the basis of the
 - (a) strength of the action potential.
 - (b) number of action potentials.
 - (c) area of brain stimulated.
 - (d) a, b, and c are correct.
- **36.** To visually follow a cat walking to the right, an observer should
 - (a) contract the medial rectus of the left eye and the lateral rectus of the right eye.
 - **(b)** contract the lateral rectus of the left eye and the media rectus of the right eye.
 - (c) contract the medial rectus of both eyes.
 - (d) contract the lateral rectus of both eyes.
- **37.** Distinguish between the general senses and the special senses in the human body.

- **38.** In what form does the CNS receive a stimulus detected by a sensory receptor?
- **39.** Why does the nose run when a person cries?
- **40.** Jane makes an appointment with the optometrist for a vision test. Her test results for visual acuity are reported as 20/15. What does this test result mean? Is a rating of 20/20 better or worse?

Level 3 Critical Thinking and Clinical Applications

- **41.** You are at a park watching some deer 35 feet away from you. Your friend taps you on the shoulder to ask a question. As you turn to look at your friend, who is standing 2 feet away, what changes would your eyes undergo?
- **42.** After attending a Fourth of July fireworks extravaganza, Millie finds it difficult to hear normal conversation, and her ears keep "ringing." What is causing her hearing problems?
- **43.** After riding the express elevator from the twentieth floor to the ground floor, for a few seconds you still feel as if you are descending, even though you have obviously come to a stop. Why?

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

10

- **10-1** Explain the role of intercellular communication in homeostasis, and describe the complementary roles of the endocrine and nervous systems.
- **10-2** Contrast the major structural classes of hormones, and explain the general processes and effects of hormone action on target organs.
- **10-3** Describe the location, hormones, and functions of the pituitary gland.
- **10-4** Describe the location, hormones, and functions of the thyroid gland.
- **10-5** Describe the location, hormones, and functions of the parathyroid glands.
- **10-6** Describe the location, hormones, and functions of the adrenal glands.
- **10-7** Describe the location of the pineal gland, and discuss the functions of the hormone it produces.
- **10-8** Describe the location, hormones, and functions of the pancreas.
- **10-9** Discuss the functions of the hormones produced by the kidneys, heart, thymus, testes, ovaries, and adipose tissue.
- **10-10** Explain how hormones interact to produce coordinated physiological responses, and describe how the endocrine system responds to stress and is affected by aging.
- **10-11** Give examples of interactions between the endocrine system and other body systems presented so far.

An Introduction to the Endocrine System

The human body contains about 30 chemical messengers known as hormones. They regulate activities such as sleep, body temperature, hunger, and stress management. These hormones are products of the endocrine system, which, along with the nervous system, controls and coordinates our body processes. In this chapter we introduce the components and functions of the endocrine system. We also explore the interactions between the nervous and endocrine systems.

Build Your Knowledge

Recall that the endocrine system directs long-term changes in the activities of other organ systems (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). Both the endocrine and nervous systems act to maintain homeostasis as environmental conditions change. The nervous system responds relatively quickly to stimuli. On the other hand, endocrine system responses develop more slowly but last much longer. **> p. 38**

10-1 Homeostasis is preserved through intercellular communication

Learning Outcome: Explain the role of intercellular communication in homeostasis, and describe the complementary roles of the endocrine and nervous systems.

To maintain homeostasis, every cell in the body must communicate with its neighbors and with cells and tissues in distant portions of the body. Most of this communication involves chemical messages. Each cell continually "talks" to its neighbors by releasing chemicals into the extracellular fluid. These chemicals tell cells what their neighbors are doing at any given moment. As a result, tissue function is coordinated at the local level.

Cellular communication also takes place over greater distances. It is coordinated by both the nervous and endocrine systems. The nervous system functions somewhat like a telecommunications company, with a cable network carrying high-speed "messages" from one location to another inside the body. The source and the destination are quite specific, and the effects are short lived. This form of communication is ideal for crisis management. If you are in danger of being hit by a speeding bus, the nervous system can coordinate and direct your leap to safety.

Many life processes, however, require long-term cellular communication. The endocrine system provides this type of regulation, which uses chemical messengers called *hormones* to relay information and instructions between cells. In such communication, hormones are like messages, and the cardiovascular system is e-mail. A hormone released into the bloodstream is distributed throughout the body. Each hormone has **target cells**, specific cells that have the receptors that bind and "read" the hormonal message when it arrives. But hormones are really like e-mail spam—cells throughout the body are exposed to them whether or not they have the necessary receptors. At any moment, each individual cell can respond to only a few of the hormones present. The other hormones are ignored, because the cell lacks the receptors needed to read the messages they contain.

10

A single hormone can alter the metabolic activities of multiple tissues and organs at the same time because target cells can be anywhere in the body. The effects may be slow to appear, but they often persist for days. This persistence makes hormones effective in coordinating cell, tissue, and organ activities on a sustained, long-term basis. For example, circulating hormones keep body water content and levels of electrolytes and organic nutrients within normal limits 24 hours a day throughout our entire lives.

Cells can respond to several different hormones at the same time, as long as they have the proper receptors. The result is a further alteration in cellular operations. Gradual changes in the quantities and identities of circulating hormones can produce complex changes in physical structure and physiological capabilities. Examples are the processes of embryonic and fetal development, growth, and puberty.

Viewed broadly, the differences between the nervous and endocrine systems seem relatively clear. In fact, these broad organizational and functional distinctions are the basis for treating them as two separate systems. Yet when we consider them in detail, we see that the two systems function in parallel ways:

- Both systems rely on the release of chemicals that bind to specific receptors on target cells.
- Both systems share various chemical messengers. For example, norepinephrine and epinephrine are called *hormones* when released into the bloodstream, and *neurotransmitters* when released across synapses.
- Both systems are regulated mainly by negative feedback processes.
- Both systems share a common goal: to maintain homeostasis by coordinating and regulating the activities of other cells, tissues, organs, and systems.

CHECKPOINT

1. List four similarities between the nervous and endocrine systems.

See the blue Answers tab at the back of the book.

10-2 The endocrine system regulates physiological processes through the binding of hormones to receptors

Learning Outcome: Contrast the major structural classes of hormones, and explain the general processes and effects of hormone action on target organs.

The **endocrine system** includes all the endocrine cells and tissues of the body. **Endocrine cells** are glandular secretory cells that release their secretions into the extracellular fluid (as noted in Chapter 4). This feature distinguishes them from exocrine cells, which secrete onto epithelial surfaces. D p. 123 The chemicals released by endocrine cells may affect adjacent cells only—as is the case of *local hormones* such as *prostaglandins*—or they may affect cells throughout the body. We define **hormones** as chemical messengers that are released in one tissue and transported by the bloodstream to target cells in other tissues.

The tissues and organs of the endocrine system, and some of the major hormones they produce, are introduced in **Figure 10-1**. Some of these organs, such as the pituitary gland, have endocrine secretion as a primary function. Others, such as the pancreas, have many other functions besides endocrine secretion. We consider such endocrine organs in more detail in chapters on other systems.

The Structure of Hormones

We can divide hormones into three groups based on their chemical structure:

- 1. Amino acid derivatives. Some hormones are relatively small molecules that are structurally similar to amino acids. (Amino acids, the building blocks of proteins, were introduced in Chapter 2.) ⊃ p. 73 This group includes *epinephrine, norepinephrine*, the *thyroid hormones*, and *melatonin*.
- 2. Peptide hormones. Peptide hormones consist of chains of amino acids. These molecules range from short chain polypeptides, such as *antidiuretic hormone* (ADH) and oxytocin, to small proteins such as growth hormone and prolactin. This is the largest class of hormones. It includes all the hormones secreted by the hypothalamus, pituitary gland, heart, kidneys, thymus, digestive tract, and pancreas.
- 3. Lipid derivatives. There are two classes of lipidbased hormones: steroid hormones and eicosanoids (Ī-kō-sa-noydz). Steroid hormones are lipids that are structurally similar to cholesterol (a lipid introduced in Chapter 2). → p. 72 Steroid hormones are released by the reproductive organs and the adrenal glands. Insoluble in water, steroid hormones are bound to specific transport proteins in blood. Eicosanoids are fatty acid-based compounds derived from the 20-carbon fatty acid *arachidonic* (a-rak-i-DON-ik) *acid*. Eicosanoids coordinate local cellular activities and affect enzymatic processes (such as blood clotting) in extracellular fluids. They include the **prostaglandins**.

Build Your Knowledge

Recall that the major types of lipids are fatty acids, fats, steroids, and phospholipids (as you saw in **Chapter 2: The Chemical Level of Organization**). Fatty acids are long chains of carbon atoms with attached hydrogen atoms and end in a carboxyl group (—COOH). When a fatty acid is in solution, only the carboxyl end dissolves in water. Steroids are large molecules composed of four connected rings of carbon atoms. They differ in the carbon chains that are attached to this basic structure. ⊃ p. 70

Hormone Action

Proteins determine all cellular structures and functions. Structural proteins give a cell its general shape and internal structure, and enzymes direct the cell's metabolism. Hormones alter cellular operations by changing the *types, activities, locations,* or *quantities* of important enzymes and structural proteins in various target cells.

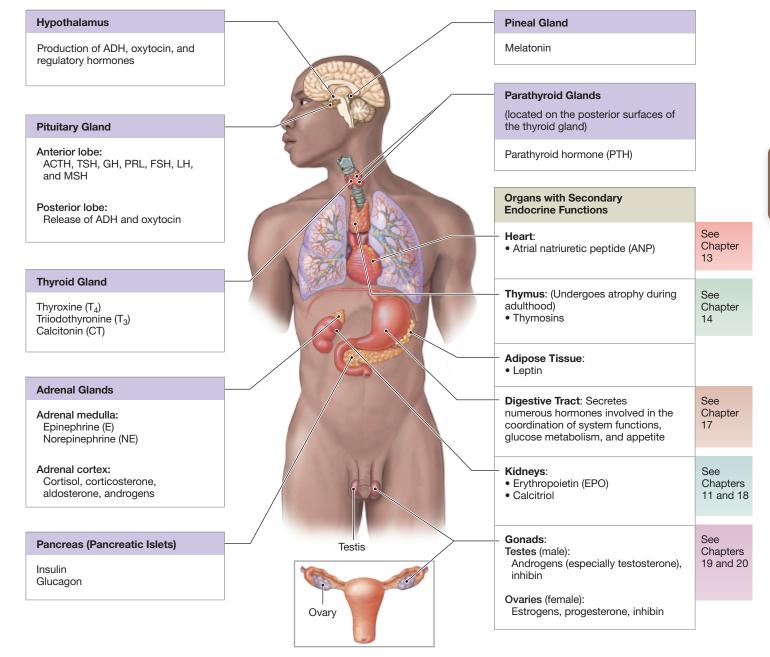

What determines a target cell's sensitivity to a given hormone? The presence or absence of a specific target cell receptor for that hormone is the key to the target cell's sensitivity

Figure 10-1 Organs and Tissues of the Endocrine System.

(Figure 10-2). The way that a hormone alters cellular activities depends on whether its receptors are located on the target cell's plasma membrane or inside the cell (Figure 10-3).

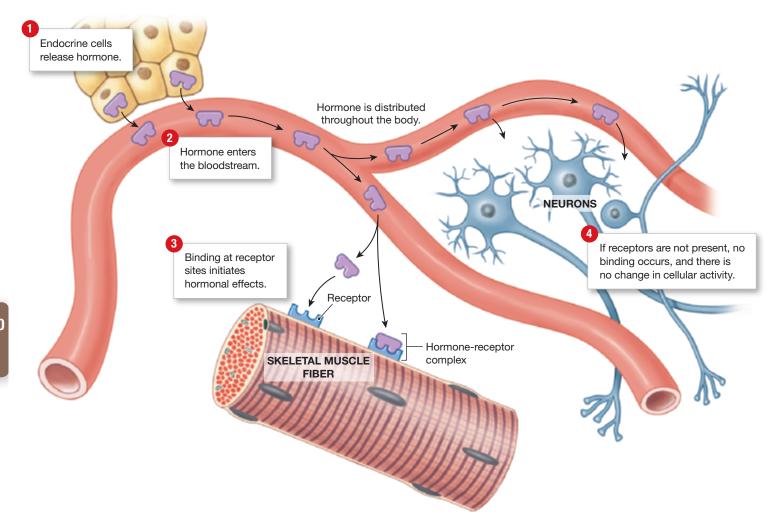

Hormones and Plasma Membrane Receptors

The receptors for epinephrine, norepinephrine, peptide hormones, and eicosanoids are in the plasma membranes of their target cells (**Figure 10-3a**). However, hormones that bind to plasma membrane receptors (also called membrane receptors) cannot directly affect the activities inside the

378 ENDOCRINE SYSTEM

Figure 10-2 The Role of Target Cell Receptors in Hormone Action. For a hormone to affect a target cell, that cell must have receptors that can bind the hormone and initiate a change in cellular activity. The hormone shown here affects skeletal muscle fibers but not neurons, because only the muscle fiber has the appropriate receptors.

target cell. Instead, communication between the hormone and the cell uses both first and second messengers. A **first messenger** is the hormone that binds to a receptor on the plasma membrane surface. A **second messenger** is an intermediary molecule that forms due to a hormone-receptor interaction.

The link between the first messenger and the second messenger usually involves a **G protein**, an enzyme complex coupled to a receptor on the plasma membrane. The G protein is activated when a hormone binds to the receptor at the membrane surface. Its activation gives rise to second messengers in the cell. The second messenger in turn may activate or inhibit enzymes inside the cell, but the net result is a change in the cell's metabolic activities. (Roughly 80 percent of prescription drugs target receptors coupled to G proteins.) When a small number of hormone molecules bind to membrane receptors, thousands of second messengers may be formed in a cell. This process, called *amplification*, magnifies the effect of a hormone on the target cell.

One of the most important second messengers is **cyclic**-**AMP (cAMP) (Figure 10-3a)**. Its formation depends on an activated G protein, which activates an enzyme called **adenylate cyclase**. Adenylate cyclase converts ATP to a ring-shaped molecule of cAMP. Cyclic-AMP then functions as a second messenger, typically by activating a kinase (KĪ-nās). Kinases are enzymes that attach a high-energy phosphate group (PO₄³⁻) to another molecule in a process called *phosphorylation*.

Generally, cAMP activates kinases that phosphorylate proteins. The effect on the target cell depends on the nature of the proteins affected. For example, the phosphorylation of

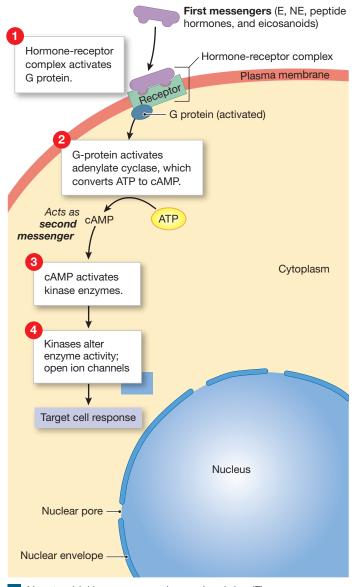

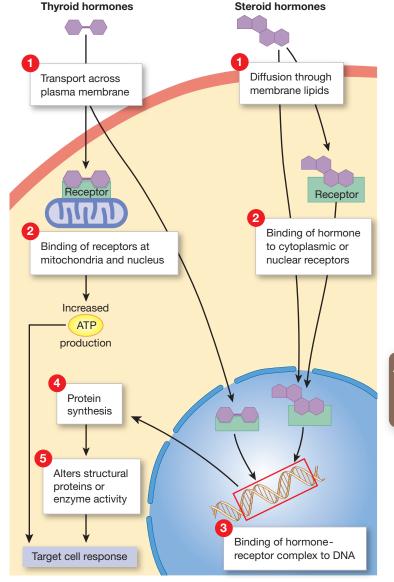

Figure 10-3 Processes of Hormone Action.

a Nonsteroidal hormones, such as epinephrine (E), norepinephrine (NE), peptide hormones, and eicosanoids, bind to membrane receptors and activate G proteins. They exert their effects on target cells through a second messenger, such as cAMP, which alters the activity of enzymes present in the cell.

b Thyroid hormones are transported across the target cell's plasma membrane and either bind to receptors in the nucleus or to receptors on mitochondria. Steroid hormones enter a target cell by diffusion and bind to receptors in the cytoplasm or nucleus. In the nucleus, both steroid and thyroid hormone-receptor complexes directly affect gene activity and protein synthesis. Thyroid hormones also increase the rate of ATP production in the cell.

certain membrane proteins can open ion channels. In the cytoplasm, many enzymes can be activated only by phosphorylation. As a result, a single hormone can have one effect in one target tissue and quite different effects in other target tissues.

The effects of cAMP are usually very short-lived, because another enzyme in the cell, *phosphodiesterase (PDE)*, inactivates

cAMP by converting it to AMP (adenosine monophosphate). In a few instances, the activation of a G protein can *lower* the concentration of cAMP within the cell by stimulating PDE activity. The decline in cAMP has an inhibitory effect on the cell because without phosphorylation, key enzymes remain inactive.

Cyclic-AMP is one of the most common second messengers, but there are many others. Important examples are *calcium ions* and *cyclic-GMP*, a derivative of the high-energy compound *guanosine triphosphate (GTP)*.

Hormones and Intracellular Receptors

Thyroid hormones and steroid hormones cross the plasma membrane before binding to receptors inside the cell (intracellular receptors) (**Figure 10-3b**). Thyroid hormones cross the plasma membrane primarily by a carrier-mediated transport process. Once within the cell, thyroid hormones bind to receptors within the nucleus or on mitochondria. The resulting *hormone-receptor complexes* in the nucleus activate specific genes or change the rate of mRNA transcription. As a result, metabolic activity increases due to changes in the nature or number of enzymes in the cytoplasm. Thyroid hormones bound to mitochondria increase the mitochondrial rates of ATP production.

Steroid hormones diffuse rapidly through the lipid portion of the plasma membrane and bind to intracellular receptors in the cytoplasm or nucleus. The resulting *hormone-receptor complex* then activates or inactivates specific genes. By this process, steroid hormones can alter the rate of DNA transcription in the nucleus. In this way, they change the pattern of protein synthesis and the structure or function of the cell. For example, the sex hormone testosterone stimulates the production of enzymes and proteins in skeletal muscle fibers, increasing muscle size and strength.

The Secretion and Distribution of Hormones

Hormones are released where capillaries are abundant. The hormones quickly enter the bloodstream for distribution throughout the body. Within the blood, hormones may circulate freely or travel bound to special transport proteins. A freely circulating hormone remains functional for less than one hour, and sometimes for as little as two minutes. It is inactivated when (1) it diffuses out of the bloodstream and binds to receptors on target cells, (2) it is absorbed and broken down by certain liver or kidney cells, or (3) it is broken down by enzymes in the plasma or interstitial fluids.

Steroid hormones and thyroid hormones remain in circulation much longer because almost all become attached to special transport proteins. For each hormone, an equilibrium occurs between the bound hormones and the small number remaining in a free state. As the free hormones are removed, they are replaced by the release of bound hormones.

The Control of Endocrine Activity

Endocrine activity—specifically, hormone secretion—is mainly controlled by negative feedback. That is, a stimulus triggers the production of a hormone whose direct or indirect effects reduce the intensity of the stimulus. \bigcirc p. 40

In the simplest case, endocrine activity may be controlled by *humoral* ("liquid") *stimuli*—changes in the composition of the extracellular fluid. For example, when the blood glucose level increases, the pancreas increases its secretion of *insulin*, a hormone that stimulates glucose uptake and use. As the insulin level increases, the glucose level decreases, reducing the stimulation of the insulin-secreting cells. As the glucose level returns to normal, the rate of insulin secretion returns to resting levels.

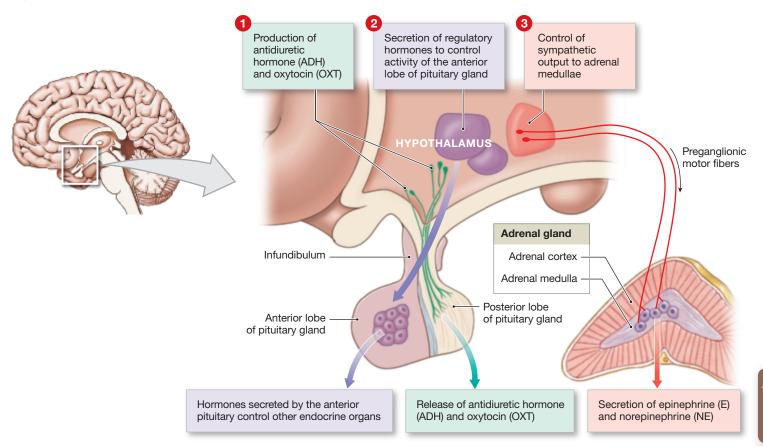

Endocrine activity may also be controlled by *hormonal stimuli*—changes in the levels of circulating hormones. Such control may involve one or more intermediary steps and two or more hormones.

Finally, endocrine control can be triggered by *neural stimuli* that result when a neurotransmitter arrives at a neuroglandular junction. An important example of endocrine activity linked to neural stimuli involves the activity of the hypothalamus.

The hypothalamus provides the highest level of endocrine control. It acts as an important link between the nervous and endocrine systems. Coordinating centers in the hypothalamus regulate the activities of the nervous and endocrine systems in three ways (Figure 10-4):

- The hypothalamus secretes two hormones directly into the general circulation. Neurons in the hypothalamus synthesize two hormones—ADH and oxytocin which are transported along axons to the posterior lobe of the pituitary gland. From there, they are released into the bloodstream for distribution throughout the body. ⊃ p. 306
- The hypothalamus secretes two classes of regulatory hormones. Regulatory hormones are special hormones that control endocrine cells in the anterior lobe of the pituitary gland. Releasing hormones (RH) stimulate the synthesis and secretion of one or more hormones in the anterior lobe. Inhibiting hormones (IH) prevent the synthesis and secretion of pituitary hormones. The hormones released by the anterior lobe of the pituitary gland control other endocrine glands.

Figure 10-4 Hypothalamic Control over Endocrine Function.

3. The hypothalamus controls sympathetic output to the adrenal medullae. The hypothalamus contains autonomic nervous system centers that control the endocrine cells of the adrenal medullae (the interior of the adrenal glands) through sympathetic innervation. ⊃ p. 322 When the sympathetic division is activated, the adrenal medullae release hormones into the bloodstream.

CHECKPOINT

- 2. Define hormone.
- **3.** What primary factor determines each cell's sensitivities to hormones?
- **4.** How would the presence of a molecule that blocks adenylate cyclase affect the activity of a hormone that produces cellular effects through cAMP?
- 5. Why is cAMP described as a second messenger?
- **6.** What are the three types of stimuli that control hormone secretion?

See the blue Answers tab at the back of the book.

10-3 The bilobed pituitary gland is an endocrine organ that releases nine peptide hormones

Learning Outcome: Describe the location, hormones, and functions of the pituitary gland.

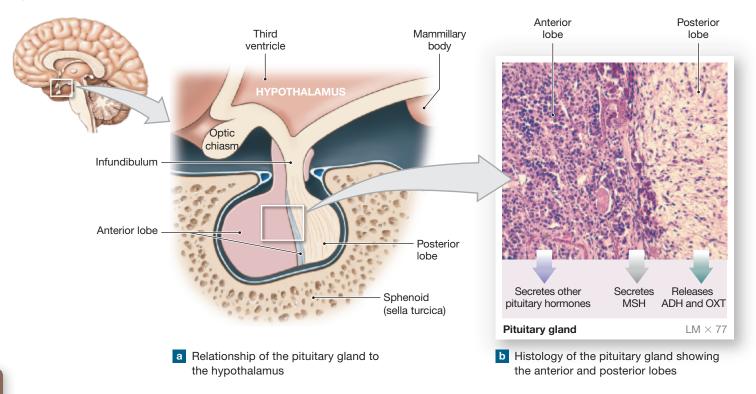

The **pituitary gland**, or **hypophysis** (hī-POF-i-sis), is a small, oval gland nestled within the *sella turcica*, a depression in the sphenoid bone of the skull (**Figure 10-5**). It hangs beneath the hypothalamus, connected by a slender stalk, the **infundibulum** (in-fun-DIB-ū-lum; funnel). The pituitary gland has a complex structure, with distinct anterior and posterior lobes. It secretes nine important peptide hormones. Seven come from the anterior lobe and two from the posterior lobe. All nine bind to membrane receptors. All also use cAMP as a second messenger.

The Anterior Lobe of the Pituitary Gland

The **anterior lobe** of the pituitary gland contains endocrine cells surrounded by an extensive capillary network. The

>

Figure 10-5 The Location and Anatomy of the Pituitary Gland.

hormones secreted by the endocrine cells of the anterior lobe enter the bloodstream through the capillaries. This capillary network is part of the *hypophyseal portal system*.

general circulation. Portal systems are named after their destinations, so this particular network is called the **hypophyseal** (hī-pō-FIZ-ē-al) **portal system**.

The Hypophyseal Portal System

The hypothalamus controls the production of hormones in the anterior lobe of the pituitary gland by secreting regulatory hormones. These hormones are released by hypothalamic neurons near the attachment of the infundibulum. There the hormones enter a network of highly permeable capillaries. Before leaving the hypothalamus, this capillary network unites to form a series of slightly larger vessels that descend to the anterior lobe and then form a second capillary network (Figure 10-6).

The circulatory arrangement illustrated in **Figure 10-6**, in which blood flows from one capillary bed to another, is very unusual. Typically, blood flows from the heart through increasingly smaller arteries to a capillary network and then returns to the heart through increasingly larger veins. Blood vessels that link two capillary networks—including the vessels between the hypothalamus and the anterior lobe—are called *portal vessels*. Here, the portal vessels have the structure of veins, so they are also called *portal veins*. The entire complex is termed a **portal system**.

Portal systems ensure that all the blood entering the portal vessels reaches certain target cells before returning to the

Hypothalamic Control of the Anterior Lobe

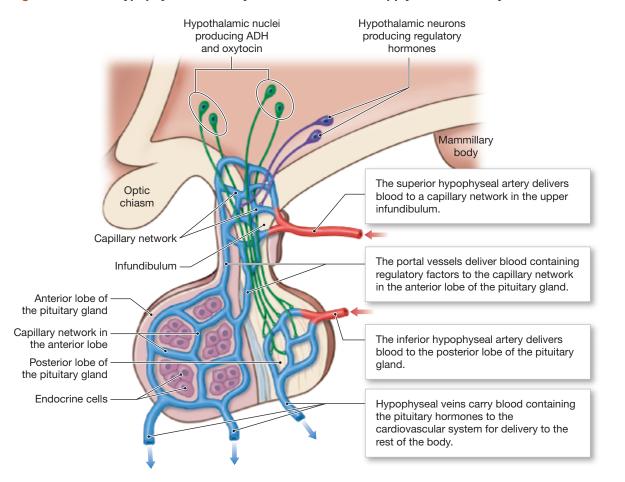

The regulatory hormones released at the hypothalamus travel directly to the anterior lobe by the hypophyseal portal system. An endocrine cell in the anterior lobe of the pituitary may be controlled by releasing hormones (RH), inhibiting hormones (IH), or some combination of the two.

Negative feedback regulates the rate of regulatory hormone secretion by the hypothalamus. The basic regulatory patterns are diagrammed in **Figure 10-7**. We will refer to these patterns in the following description of pituitary hormones. Many of these regulatory hormones are called *tropic hormones* (*tropos*, a turning) because they "turn on" other endocrine glands or support the functions of other organs.

Hormones of the Anterior Lobe

The anterior lobe of the pituitary gland produces seven hormones. The first four described in the following list regulate the production of hormones by other endocrine glands.

1. Thyroid-stimulating hormone (TSH), or *thyrotropin*, targets the thyroid gland and triggers the release of

thyroid hormones. TSH is released in response to *thyro-tropin-releasing hormone (TRH)* from the hypothalamus. As circulating concentrations of thyroid hormones rise, the rates of TRH and TSH production decline (**Figure 10-7a**).

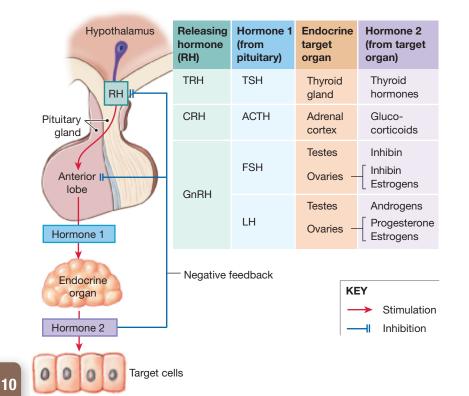

2. Adrenocorticotropic hormone (ACTH), or *corticotropin*, stimulates the release of steroid hormones by the *adrenal cortex*, the outer portion of the adrenal glands. ACTH specifically targets cells producing hormones called *glucocorticoids* (gloo-kō-KOR-ti-koydz), which affect glucose metabolism. ACTH release occurs under the stimulation of *corticotropin-releasing hormone (CRH)* from the hypothalamus. A rise in glucocorticoid levels causes a decline in the production of ACTH and CRH. This type of negative feedback control is similar to that for TSH (Figure 10-7a).

The hormones called **gonadotropins** (gō-nad-ō-TRŌ-pinz) regulate the activities of the male and female *gonads*. (These organs—the testes in males and the ovaries in females— produce reproductive cells as well as hormones.) The production of gonadotropins is stimulated by *gonadotropin-releasing*

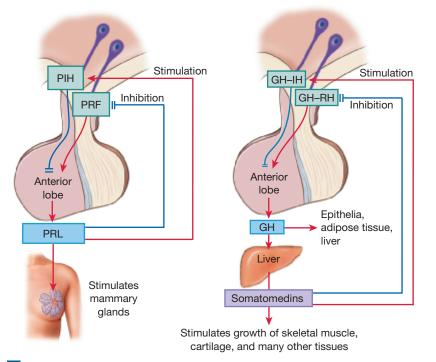

hormone (*GnRH*) from the hypothalamus. An abnormally low production of gonadotropins produces *hypogonadism*. Children with this condition will not undergo sexual maturation. Adults with hypogonadism cannot produce functional sperm (males) or ova (females). The anterior lobe produces two gonadotropins: follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

- **3. Follicle-stimulating hormone (FSH)** promotes ovarian follicle development in females, and, with luteinizing hormone, stimulates the secretion of estrogens by ovarian cells. In males, FSH supports sperm production in the testes. A peptide hormone called *inhibin*, released by the cells of the testes and ovaries, inhibits the release of FSH and GnRH through negative feedback comparable to that for TSH (Figure 10-7a).
- **4.** Luteinizing (LŪ-tē-i-nīz-ing) hormone (LH) induces *ovulation*, the production of reproductive cells in females. It also promotes the secretion by the ovaries of estrogens and *progesterone*, which prepare the body for possible pregnancy. In males, LH is sometimes called *interstitial cell-stimulating hormone (ICSH)* because

Figure 10-7 Negative Feedback Control of Endocrine Secretion.

 a A typical pattern of regulation when multiple endocrine organs are involved. The hypothalamus produces a releasing hormone (RH) to stimulate hormone production by other glands; control occurs by negative feedback.

b Variations on the theme outlined in part (a). Left: The regulation of prolactin (PRL) production by the anterior lobe. In this case, the hypothalamus produces both a releasing factor (PRF) and an inhibiting hormone (PIH); when one is stimulated, the other is inhibited. Right: the regulation of growth hormone (GH) production by the anterior lobe; when GH–RH release is inhibited, GH–IH release is stimulated.

it stimulates the *interstitial endocrine cells* of the testes to produce sex hormones. These male sex hormones are called **androgens** (AN-drō-jenz; *andros*, man). The most important one is *testos-terone*. LH production, like FSH production, is stimulated by GnRH from the hypothalamus. Estrogens, progesterone, and androgens inhibit GnRH production (**Figure 10-7a**).

- **5. Prolactin** (prō-LAK-tin; *pro-*, before + *lac*, milk), or **PRL**, works with other hormones to stimulate mammary gland development. In pregnancy and during the period of nursing following delivery, PRL also stimulates milk production by the mammary glands. Prolactin's effects in human males are poorly understood, but it may help regulate androgen production. The production of PRL is stimulated by prolactin-releasing factor (PRF) from the hypothalamus. Circulating PRL then stimulates prolactin-inhibiting hormone (PIH) from the hypothalamus and also inhibits the secretion of PRE. This regulatory pattern is diagrammed in Figure 10-7b.
- **6. Growth hormone (GH)**, also called *human growth hormone (hGH)* or *somatotropin (soma,* body), stimulates cell growth and division by speeding up the rate of protein synthesis. Skeletal muscle cells and chondrocytes (cartilage cells) are particularly sensitive to GH. Virtually every tissue responds to some degree, however.

GH stimulates growth through two processes indirect and direct. The primary process is indirect, and best understood. Liver cells respond to growth hormone by synthesizing and releasing **somatomedins**, or *insulin-like growth factors (IGFs)*. These peptide hormones bind to receptor sites on a variety of plasma membranes. Somatomedins increase the rates at which amino acids are taken up and combined into new proteins. These effects develop almost immediately after GH is released. They are particularly important after a meal, when blood glucose and amino acid concentrations are high.

The direct actions of GH are more selective. They play a role in mobilizing energy reserves. They tend to occur after blood glucose and amino acid concentrations have returned to normal levels:

• In epithelia and connective tissues, GH stimulates stem cell divisions and the differentiation of daughter cells. (Somatomedins then stimulate the growth of these daughter cells.)

- In adipose tissue, GH stimulates the breakdown of stored fats and the release of fatty acids into the blood. In turn, many tissues stop breaking down glucose and start breaking down fatty acids to generate ATP. This process is termed a *glucose-sparing effect*.
- In the liver, GH stimulates the breakdown of glycogen reserves and the release of glucose into the bloodstream. Because most tissues are now metabolizing fatty acids rather than glucose, the blood glucose level rises higher than normal.

The production of GH is regulated by *growth hormonereleasing hormone* (*GH–RH*) and *growth hormone–inhibiting hormone* (*GH–IH*) from the hypothalamus. Somatomedins stimulate GH–IH and inhibit GH–RH. This regulatory process is summarized in **Figure 10-7b**.

7. Melanocyte-stimulating hormone (MSH) stimulates the melanocytes in the skin to increase their production of melanin. **D** p. 156 MSH is important in the control of skin and hair pigmentation in fishes, amphibians, reptiles, and many mammals other than primates. In humans, MSH is produced locally, within sun-exposed skin. The MSH-producing cells of the pituitary gland in adult humans are virtually nonfunctional, and the circulating blood usually does not contain MSH. However, the human pituitary secretes MSH (1) during fetal development, (2) in very young children, (3) in pregnant women, and (4) in certain diseases. The functions of MSH under these circumstances are not known. The administration of a synthetic form of MSH causes darkening of the skin, so MSH has been suggested as a means of obtaining a "sunless tan."

The Posterior Lobe of the Pituitary Gland

The **posterior lobe** of the pituitary gland contains axons from two different groups of hypothalamic neurons. One group synthesizes antidiuretic hormone (ADH). The other synthesizes oxytocin (OXT). These hormones are transported within axons along the infundibulum to the posterior lobe, as indicated in **Figure 10-6**.

Antidiuretic hormone (ADH), also known as *vasopressin* (*VP*), is released when the body is low on water. Stimuli for its release include a rise in the concentration of solutes in the blood (an increased osmotic concentration) or a fall in blood volume or pressure. Specialized neurons in the hypothalamus, called *osmoreceptors*, detect a rise in osmotic concentration.

The osmoreceptors then stimulate the hypothalamic neurons that release ADH.

Diuresis (dī-ū-RĒ-sis) typically indicates the production of a large volume of urine. The primary function of *anti*diuretic hormone is to decrease the amount of water lost in the urine. With losses minimized, any water absorbed from the digestive tract will be retained, reducing the concentration of solutes. ADH also causes *vasoconstriction*, a constriction of peripheral blood vessels that helps increase blood pressure. Alcohol inhibits ADH release, which explains the increased fluid excretion that follows when someone drinks alcoholic beverages.

In women, **oxytocin** (*okytokos*, swift birth), or **OXT**, stimulates smooth muscle contractions in the wall of the uterus, promoting labor and delivery. Until the final stages of pregnancy, the uterine muscles are insensitive to oxytocin, but they become more sensitive as the time of delivery approaches. The stimulation of uterine muscles by oxytocin helps maintain and complete normal labor and childbirth (discussed in Chapter 20).

Oxytocin also promotes the ejection of milk by the mammary glands. After delivery, oxytocin stimulates the contraction of special contractile cells surrounding the secretory cells and ducts of the mammary glands. In the "milk let-down" reflex, oxytocin is secreted in response to suckling and triggers the release of milk from the breasts.

Oxytocin's functions in sexual activity remain uncertain, but circulating oxytocin levels are known to rise during sexual

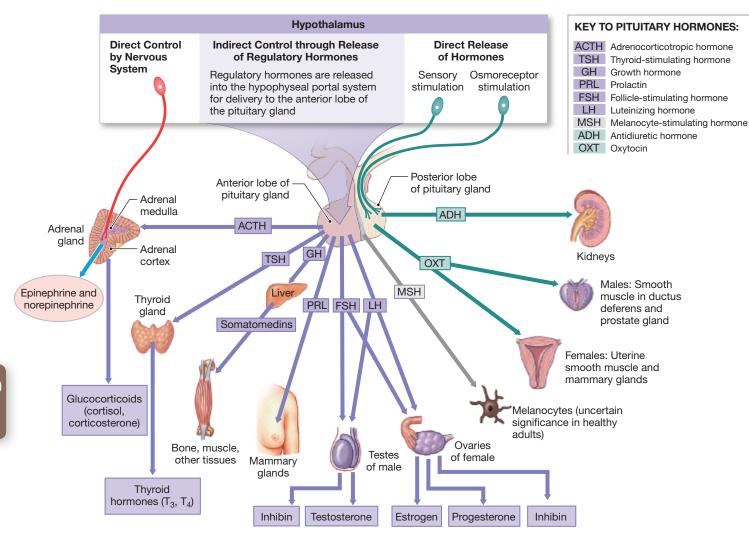

CLINICAL NOTE

Diabetes Insipidus

Diabetes (*diabetes*, to pass through) occurs in several forms. All are characterized by excessive urine production (polyuria). Most forms result from endocrine abnormalities, but diabetes can be caused by physical damage to the kidneys. The two most important forms are diabetes mellitus and diabetes insipidus. (Diabetes mellitus is described on p. 396.)

Diabetes insipidus (*insipidus*, tasteless) develops when the posterior lobe of the pituitary gland no longer releases adequate amounts of ADH or the kidneys fail to respond to ADH. Water conservation at the kidneys is impaired, and excessive amounts of water are lost in the urine. As a result, the individual is constantly thirsty—a condition known as polydipsia (*dipsa*, thirst)— but the body does not retain the fluids consumed. Mild cases may not require treatment, as long as fluid and electrolyte intake keep pace with urinary losses. In severe cases, fluid losses can reach 10 liters per day, and a fatal dehydration will occur unless treatment is provided.

arousal and peak at orgasm in both sexes. In men, oxytocin stimulates smooth muscle contraction in the walls of the sperm duct and prostate gland. These actions may be important in *emission*, the ejection of sperm, prostate secretions, and the secretions of other glands into the male reproductive tract before ejaculation. In women, oxytocin released during intercourse may stimulate smooth muscle contractions in the uterus and vagina that promote the transport of sperm toward the uterine tubes.

Figure 10-8 and **Table 10-1** summarize important information about the hormones of the pituitary gland.

CHECKPOINT

7. If a person were dehydrated, how would the amount of ADH released by the posterior lobe of the pituitary gland change?

- **8.** A blood sample contains elevated levels of somatomedins. Which pituitary hormone would you also expect to be elevated?
- **9.** What effect would elevated circulating levels of cortisol, a hormone from the adrenal cortex, have on the pituitary secretion of ACTH?

• See the blue Answers tab at the back of the book.

10-4 The thyroid gland synthesizes thyroid hormones that affect the rate of metabolism

Learning Outcome: Describe the location, hormones, and functions of the thyroid gland.

The **thyroid gland** lies anterior to the trachea and just inferior to the *thyroid* ("shield-shaped") *cartilage*, which forms most of

Table 10-1 The Pituitary Hormones				
Pituitary Lobe/Hormone	Target	Hormonal Effects		
ANTERIOR LOBE				
Thyroid-stimulating hormone (TSH)	Thyroid gland	Secretion of thyroid hormones		
Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Secretion of glucocorticoids (cortisol, corticosterone)		
Gonadotropins:				
Follicle-stimulating hormone (FSH)	Follicle cells of ovaries	Secretion of estrogen, follicle development		
	Nurse cells of testes	Sperm maturation		
Luteinizing hormone (LH)	Follicle cells of ovaries	Ovulation, formation of corpus luteum, secretion of progesterone		
	Interstitial endocrine cells of testes	Secretion of testosterone		
Prolactin (PRL)	Mammary glands	Production of milk		
Growth hormone (GH)	All cells	Growth, protein synthesis, lipid mobilization and catabolism		
Melanocyte-stimulating hormone (MSH)	Melanocytes of skin	Increased melanin synthesis in epidermis		
POSTERIOR LOBE				
Antidiuretic hormone (ADH)	Kidneys	Reabsorption of water, elevation of blood volume and pressure		
Oxytocin (OXT)	Uterus, mammary glands (females)	Labor contractions, milk ejection		
	Sperm duct and prostate (males)	Contractions of sperm duct and prostate gland		

the anterior surface of the larynx (**Figure 10-9a**). The two lobes of the thyroid gland are united by a slender connection, the *isthmus* (IS-mus). An extensive blood supply gives the thyroid gland a deep red color.

Thyroid Follicles and Thyroid Hormones

The thyroid gland contains numerous **thyroid follicles**, spheres lined by a simple cuboidal epithelium (**Figure 10-9b,c**). The cavity within each follicle contains a viscous *colloid*, a fluid containing large amounts of suspended proteins and thyroid hormones. A network of capillaries surrounds each follicle. They deliver nutrients and regulatory hormones to the glandular cells and pick up their secretory products and metabolic wastes.

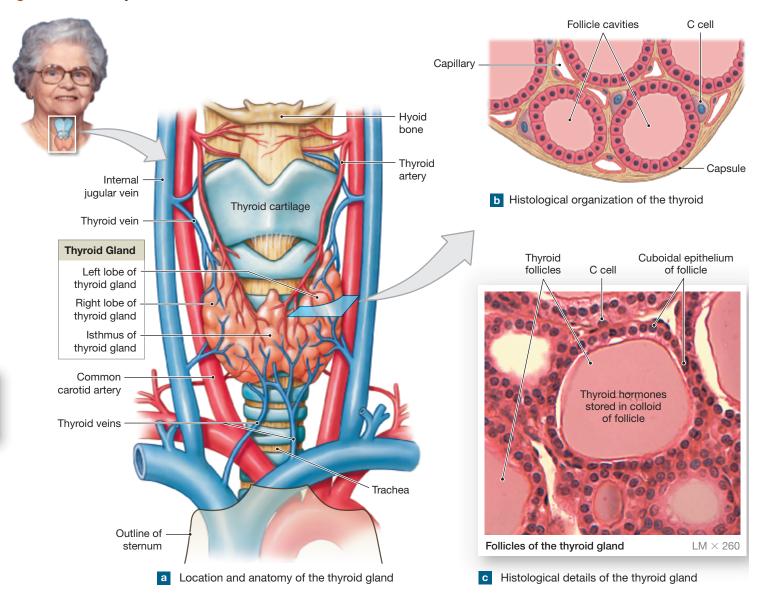

Thyroid hormones are manufactured by the follicular epithelial cells and stored within the follicle cavities. Under TSH stimulation from the anterior lobe of the pituitary gland, the epithelial cells remove hormones from the follicle cavities and release them into the bloodstream. However, almost all the released thyroid hormones are unavailable because they become attached to plasma proteins in the blood. Only the remaining unbound thyroid hormones, a small percentage of the total released, are free to be transported into target cells in body tissues. As the concentration of unbound hormone molecules decreases, the plasma proteins release additional bound hormone. The bound thyroid hormones are a substantial reserve. In fact, the bloodstream normally contains more than a week's supply of thyroid hormones.

The thyroid hormones are derived from molecules of the amino acid tyrosine to which iodine atoms have been attached. The hormone **thyroxine** (thī-ROKS-ēn) contains four atoms of iodine. It is also known as *tetraiodothyronine* (tet-ra-ī-ō-dō-THĪ-rō-nēn), or **T**₄. Thyroxine accounts for roughly 90 percent of all thyroid secretions. **Triiodothyronine**, or **T**₃, is a related, more potent molecule containing three iodine atoms.

Thyroid hormones affect almost every cell in the body. Inside a cell, they bind to receptor sites on mitochondria and in the nucleus (Figure 10-3b). The binding of thyroid hormones to mitochondria increases the rate of ATP production. Thyroid hormone-receptor complexes in the nucleus activate genes coding for the synthesis of enzymes involved in glycolysis and energy production. As a result, rates of metabolism and oxygen consumption increase in the cell. The effect is called the **calorigenic effect** (*calor*, heat) of thyroid hormones because the cell consumes more energy (and energy use is measured in *calories*). When the metabolic rate increases, more heat is generated and body temperature rises. In growing children, thyroid hormones are essential to normal development of the skeletal, muscular, and nervous systems.

Normal production of thyroid hormones establishes the background rates of cellular metabolism. These hormones exert their primary effects on active tissues and organs,

Figure 10-9 The Thyroid Gland.

including skeletal muscles, the liver, the heart, and the kidneys. Overproduction or underproduction of thyroid hormones can, therefore, cause very serious metabolic problems. In many parts of the world, inadequate dietary iodine intake leads to an inability to synthesize thyroid hormones. Under these conditions, TSH stimulation continues, and the thyroid follicles become distended with nonfunctional secretions. The result is an enlarged thyroid gland, or *goiter*. Goiters vary in size, and a large goiter can interfere with breathing and swallowing. This is seldom a problem in the United States where the typical American diet provides roughly three times the minimum daily requirement of iodine. Much of the excess is due to the addition of iodine to table salt (iodized salt), which is consumed in large quantities in processed foods.

The C Cells of the Thyroid Gland and Calcitonin

C cells, or *parafollicular cells*, are endocrine cells sandwiched between the follicle cells and their basement membrane (see Figure 10-9b,c). C cells produce the hormone calcitonin (CT). Calcitonin helps regulate calcium ion concentrations in body fluids.

The control of calcitonin secretion is independent of the hypothalamus or pituitary gland. As **Figure 10-10** shows, C cells release calcitonin when the blood calcium ion (Ca^{2+}) concentration rises above normal. The target organs are the kidneys and the bones. Calcitonin stimulates calcium excretion by the kidneys and prevents the release of calcium

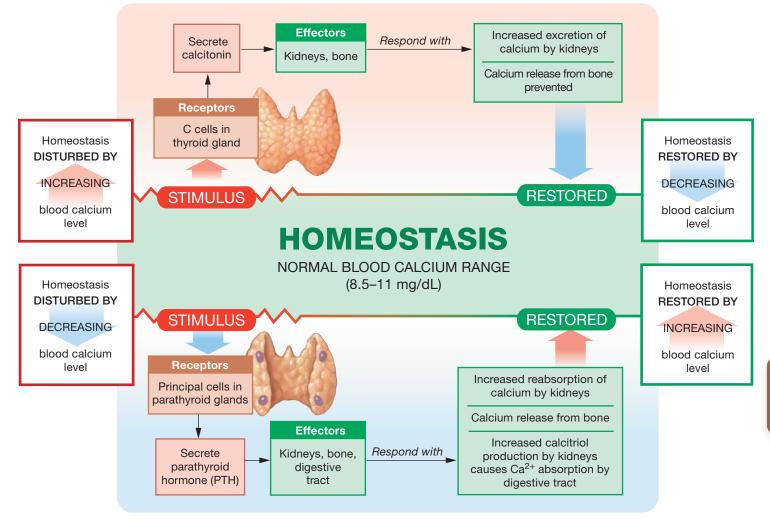

Figure 10-10 The Homeostatic Regulation of the Blood Calcium Ion Concentration.

from bone by inhibiting osteoclast activity (Osteoblasts lack calcitonin receptors). The resulting reduction in the blood calcium level eliminates the stimulus and "turns off" the C cells.

Calcitonin is most important during childhood, when it stimulates active bone growth and calcium deposition in the skeleton. It also acts to reduce the loss of bone mass during prolonged starvation and during late pregnancy, when the maternal skeleton competes with the developing fetus for absorbed calcium ions. The role of calcitonin in healthy nonpregnant adults is unclear, but appears minor.

We have seen the importance of calcium ions in controlling muscle cell and nerve cell activities. \bigcirc pp. 232, 289 Calcium ion concentration also affects the sodium ion permeabilities of excitable membranes. At high calcium levels, sodium permeability decreases, and membranes become less responsive. Such problems are relatively rare, because under normal conditions, calcium levels seldom rise enough to trigger calcitonin secretion. Most homeostatic adjustments prevent lower-than-normal calcium ion concentrations. Low calcium levels are dangerous because sodium ion permeabilities then increase, and muscle cells and neurons become extremely excitable. If calcium levels fall too far, convulsions or muscular spasms can result. Such disastrous events are prevented by the actions of the parathyroid glands.

CHECKPOINT

- **10.** Identify the hormones of the thyroid gland.
- **11.** What signs and symptoms would you expect to see in an individual whose diet lacks iodine?
- **12.** When a person's thyroid gland is removed, signs of decreased thyroid hormone concentration do not appear until about one week later. Why?

See the blue Answers tab at the back of the book.

10-5 The four parathyroid glands, embedded in the posterior surfaces of the thyroid gland, secrete parathyroid hormone to elevate blood calcium levels

Learning Outcome: Describe the location, hormones, and functions of the parathyroid glands.

Two tiny pairs of **parathyroid glands** are embedded in the posterior surfaces of the thyroid gland (**Figure 10-11**). A capsule of connective tissue fibers separates each parathyroid gland from the cells of the thyroid gland. The parathyroid glands have at least two cell populations. The **parathyroid (principal) cells** produce parathyroid hormone. The functions of the other cell type are unknown.

Like the C cells of the thyroid, the principal cells monitor the concentration of circulating calcium ions. When the Ca²⁺ concentration falls below normal, the principal cells secrete **parathyroid hormone (PTH)**, or *parathormone* (Figure 10-10). Parathyroid hormone acts on the same target organs as calcitonin, but it produces the opposite effects. PTH stimulates osteoclasts, inhibits the bone-building functions of osteoblasts, and reduces urinary excretion of calcium ions. PTH also stimulates the kidneys to form and secrete the hormone *calcitriol* (an activated form of vitamin D). Calcitriol promotes the absorption of Ca²⁺ and PO₄³⁻ by the digestive tract.

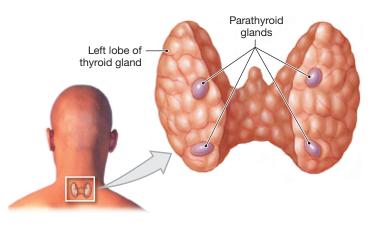

Information concerning the hormones of the thyroid and parathyroid glands is summarized in **Table 10-2**.

CHECKPOINT

- **13.** Identify the hormone secreted by the parathyroid glands.
- **14.** Removal of the parathyroid glands would result in decreased blood concentrations of what important mineral?

See the blue Answers tab at the back of the book.

Figure 10-11 The Parathyroid Glands.

10-6 The adrenal glands, consisting of a cortex and a medulla, cap each kidney and secrete several hormones

Learning Outcome: Describe the location, hormones, and functions of the adrenal glands.

A yellow, pyramid-shaped **adrenal** (ad-RĒ-nal; *ad*-, near + *ren*, kidneys) **gland**, or *suprarenal gland*, sits on the superior border of each kidney (**Figure 10-12a**). Each adrenal gland has two parts with separate functions: an outer *adrenal cortex* and an inner *adrenal medulla* (**Figure 10-12b**).

The Adrenal Cortex

The yellowish color of the **adrenal cortex** is due to stored lipids, especially cholesterol and various fatty acids. The adrenal cortex produces more than two dozen steroid hormones. They are collectively called **corticosteroids**. In the bloodstream, these hormones are bound to transport proteins. Corticosteroids are vital. If the adrenal glands are destroyed or removed, the individual will die unless corticosteroids are administered.

Table 10-2 Hormones of the Thyroid Gland and Parathyroid Glands				
Gland/Cells	Hormone(s)	Targets	Hormonal Effects	
THYROID				
Follicular epitheliu	m Thyroxine (T_4), triiodothyronine (T_3)	Most cells	Increased energy use, oxygen consumption, growth, and development	
C cells	Calcitonin (CT)	Bone, kidneys	Decreased calcium ion concentrations in body fluids (see Figure 10-10)	
PARATHYROIDS				
Principal cells	Parathyroid hormone (PTH)	Bone, kidneys	Increased calcium ion concentrations in body fluids (see Figure 10-10)	

10

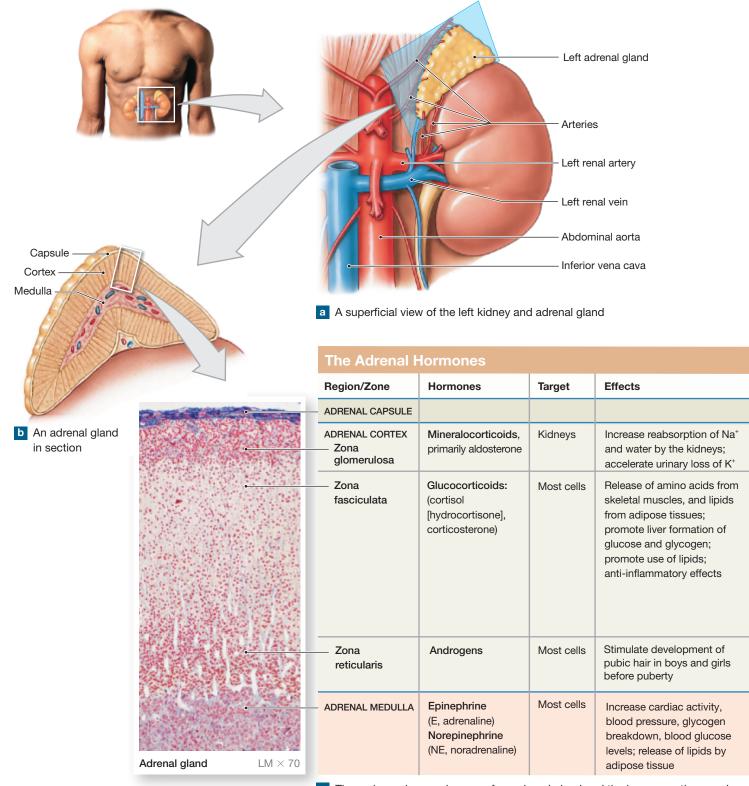

Figure 10-12 The Adrenal Gland and Adrenal Hormones.

c The major regions and zones of an adrenal gland and the hormones they produce

These hormones affect metabolism in many different tissues, so overproduction or underproduction of any of the corticosteroids will have severe consequences.

Each of the three distinct regions or zones of the adrenal cortex synthesizes specific corticosteroids (**Figure 10-12c**). The outer *zona glomerulosa* (glō-mer-ū-LŌ-suh) produces *mineralocorticoids*. The middle *zona fasciculata* (fa-sik-ū-LA-tuh) produces glucocorticoids. The inner *zona reticularis* (re-tik-ū-LAR-is) produces *androgens*.

Mineralocorticoids (MCs)

The **mineralocorticoids (MCs)** affect the electrolyte composition of body fluids. **Aldosterone** (al-DOS-te-rōn) is the principal MC of the adrenal cortex. It stimulates the conservation of sodium ions and the elimination of potassium ions by targeting cells that regulate the ionic composition of excreted fluids.

Specifically, aldosterone causes the retention of sodium by preventing the loss of sodium ions in urine, sweat, saliva, and digestive secretions. The retention of sodium ions is accompanied by a loss of potassium ions. Secondarily, the reabsorption of sodium ions results in the osmotic reabsorption of water at the kidneys, sweat glands, salivary glands, and pancreas. Aldosterone also increases the sensitivity of salt receptors in the tongue, resulting in greater interest in

consuming salty foods. Aldosterone secretion occurs in response to a drop in blood sodium content, blood volume, or blood pressure, or to a rise in blood potassium levels. Aldosterone release also occurs in response to *angiotensin II (angeion*, vessel + *teinein*, to stretch). We will discuss this hormone later in the chapter.

Glucocorticoids (GCs)

The steroid hormones collectively known as **glucocorticoids** (**GCs**) affect glucose metabolism. The three most important glucocorticoids are **cortisol** (KOR-ti-sol; also called *hydrocortisone*), **corticosterone** (kor-ti-KOS-te-rōn), and **cortisone**.

Glucocorticoid secretion takes place under ACTH stimulation and is regulated by negative feedback (Figure 10-7a). Glucocorticoids speed up the rates of glucose synthesis and glycogen formation, especially in the liver. Skeletal muscle and adipose tissues respond by releasing amino acids and fatty acids into the blood, respectively. The liver synthesizes glucose with the amino acids, and other tissues begin to break down fatty acids instead of glucose. This process is another example of a *glucose-sparing effect* that results in an increase in blood glucose levels (p. 385). Glucocorticoids also show *anti-inflammatory* effects. That is, they inhibit the activities of white blood cells and other components of the immune system. "Steroid creams" are often used to control irritating allergic rashes, such as those produced by poison ivy. Injections of glucocorticoids may be used to control more severe allergic reactions. On the negative side, GCs slow wound healing and suppress immune defenses against infectious organisms. For this reason, the topical steroids used to treat superficial rashes should never be applied to open wounds.

Androgens

The adrenal cortex in both sexes produces small quantities of **androgens**, the sex hormones produced in large quantities by the testes in males. Once in the bloodstream, some of the androgens are converted to estrogens, the dominant sex hormones in females. Adrenal androgens stimulate the development of pubic hair in boys and girls before puberty. Adrenal androgens are not important in adult men. In adult women they produce more muscle mass and blood cell formation, and support the sex drive.

The Adrenal Medulla

The **adrenal medulla** is pale gray or pink, due in part to the many blood vessels in the area. It contains large, rounded cells similar to those found in other sympathetic ganglia. These cells are innervated by preganglionic sympathetic fibers. The secretory activities of the adrenal medullae are controlled by the sympathetic division of the ANS. \bigcirc p. 322

The adrenal medulla contains two populations of secretory cells. One produces **epinephrine** (**E**, or *adrenaline*). The other produces **norepinephrine** (**NE**, or *noradrenaline*) (**Figure 10-12c**). These hormones are continuously released at a low rate, but sympathetic stimulation speeds up the rate of discharge dramatically.

Epinephrine makes up 75–80 percent of the secretions from the medulla. The rest is norepinephrine. Receptors for epinephrine and norepinephrine are found on skeletal muscle fibers, adipocytes, liver cells, and cardiac muscle fibers. In skeletal muscles, these hormones trigger a mobilization of glycogen reserves and speed up the breakdown of glucose to provide ATP. This combination results in increased muscular power and endurance. In adipose tissue, stored fats are broken down to fatty acids. In the liver, glycogen molecules are converted to glucose. The fatty acids and glucose are then released into the bloodstream for use by peripheral tissues. The heart responds to adrenal medulla hormones by increasing the rate and force of cardiac contractions. The metabolic changes that follow epinephrine and norepinephrine release peak 30 seconds after adrenal stimulation and linger for several minutes. As a result, the effects produced by stimulation of the adrenal medullae outlast the other signs of sympathetic activation.

CHECKPOINT

- **15.** Identify the two regions of the adrenal gland, and list the hormones secreted by each.
- **16.** What effect would elevated cortisol levels have on blood glucose levels?

See the blue Answers tab at the back of the book.

10-7 The pineal gland, attached to the third ventricle, secretes melatonin

Learning Outcome: Describe the location of the pineal gland, and discuss the functions of the hormone it produces.

The **pineal gland** lies in the posterior portion of the roof of the third ventricle in the brain. $\bigcirc p$. 306 It contains neurons, glial cells, and secretory cells that synthesize the hormone **melatonin** (mel-a-TŌ-nin). Branches of the axons making up the visual pathways enter the pineal gland and affect the rate of melatonin production. The rate is lowest during daylight hours and highest at night.

Several functions have been suggested for melatonin in humans. It may:

- **Inhibit reproductive function.** In some mammals, melatonin slows the maturation of sperm, ova, and reproductive organs. The significance of this effect in humans remains unclear. Circumstantial evidence suggests that melatonin may play a role in the timing of human sexual maturation. For example, melatonin levels in the blood decline at puberty. Also, pineal tumors that eliminate melatonin production cause premature puberty in young children.
- **Protect against damage by free radicals.** Melatonin is a very effective antioxidant. It may protect CNS neurons from *free radicals*, such as nitric oxide (NO) or hydrogen peroxide (H₂O₂), that may form in active neural tissue. (Free radicals are highly reactive atoms or molecules that contain unpaired electrons in their outer electron shell.) ⊃ p. 103
- **Establish day-night cycles of activity.** Because its activity is cyclical, the pineal gland may also be involved in maintaining basic *circadian rhythms*—daily changes in physiological processes that follow a regular day-night pattern. Increased melatonin secretion in darkness has been suggested as a primary cause of *seasonal affective*

CHECKPOINT

- **17.** Increased amounts of light would inhibit the production of which hormone?
- **18.** List three possible functions of melatonin.
- See the blue Answers tab at the back of the book.

disorder (SAD). This condition can develop during the winter in people who live at high latitudes, where sunshine is scarce or lacking. It is characterized by changes in mood, eating habits, and sleeping patterns.

10-8 The endocrine pancreas produces insulin and glucagon, hormones that regulate blood glucose levels

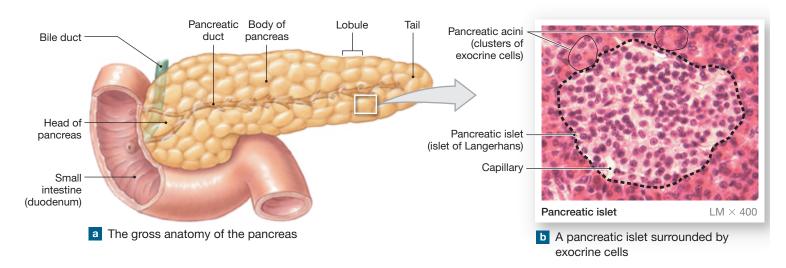

Learning Outcome: Describe the location, hormones, and functions of the pancreas.

The **pancreas** lies in the J-shaped loop between the stomach and proximal portion of the small intestine (Figure 10-13). It is a slender, pale organ with a nodular (lumpy) consistency (Figure 10-13a). It contains both exocrine and endocrine cells. The pancreas is primarily a digestive organ whose exocrine cells make digestive enzymes. (We discuss the **exocrine pancreas** in Chapter 16.)

Cells of the **endocrine pancreas** form clusters known as **pancreatic islets**, or the *islets of Langerhans* (LAN-ger-hanz). The islets are scattered among the exocrine cells (**Figure 10-13b**) and account for only about 1 percent of all pancreatic cells. Each islet contains several cell types. The two most important are alpha and beta cells. **Alpha cells** produce the hormone **glucagon** (GLOO-ka-gon), which raises blood glucose levels. **Beta cells** produce **insulin** (IN-suh-lin), which lowers blood glucose levels. Glucagon and insulin regulate blood glucose levels in much the same way parathyroid hormone and calcitonin control blood calcium levels.

Figure 10-14 diagrams the hormonal regulation of blood glucose levels. Glucose is the preferred energy source for most cells in the body. Under normal conditions, it is the only energy source for neurons. When blood glucose levels rise above normal homeostatic levels, beta cells release insulin. Insulin stimulates the transport of glucose across plasma membranes into target cells. The plasma membranes of almost all cells in the body contain insulin receptors. The only exceptions are (1) neurons and red blood cells, which cannot metabolize nutrients other than glucose; (2) epithelial cells of the kidney tubules, where glucose is reabsorbed; and (3) epithelial cells of the diet.

Figure 10-13 The Endocrine Pancreas.

When glucose is abundant, all cells use it as an energy source rather than amino acids and lipids. The breakdown of glucose molecules generates ATP, which is used to build proteins and to increase energy reserves. Insulin also stimulates amino acid absorption and protein synthesis. This effect helps to maintain glucose levels by preventing the conversion of amino acids to glucose. Insulin also stimulates adipocytes (fat cells) to increase their rates of triglyceride (fat) synthesis and storage. In the liver and in skeletal muscle fibers, insulin also speeds up the formation of glycogen.

In summary, the pancreas secretes insulin when glucose is abundant. Insulin stimulates glucose use to support growth and to establish carbohydrate (glycogen) and lipid (triglyceride) reserves. The increased use of glucose reduces blood glucose levels to within normal limits (**Figure 10-14**).

When glucose concentrations fall below normal homeostatic levels, alpha cells release glucagon to mobilize energy reserves. Skeletal muscles and liver cells break down glycogen into glucose. The glucose molecules are either used for energy (in skeletal muscle fibers) or released into the bloodstream (by liver cells). Adipose tissue breaks down triglycerides (fat) into fatty acids that are released into the bloodstream for use by other tissues. Liver cells take in amino acids from the bloodstream, convert them to glucose, and release the glucose into the bloodstream. As a result, blood glucose concentrations rise toward normal levels (**Figure 10-14**). The interplay between insulin and glucagon both stabilizes blood glucose levels and prevents competition between nervous tissue and other tissues for limited glucose supplies.

Pancreatic alpha and beta cells are sensitive to blood glucose concentrations. For this reason, glucagon and insulin can be secreted without endocrine or nervous system instructions. Yet because the islet cells are very sensitive to variations in blood glucose levels, any hormone that affects blood glucose concentrations will indirectly affect the production of insulin and glucagon. Insulin and glucagon production are also influenced by autonomic activity. Parasympathetic stimulation enhances insulin release. Sympathetic stimulation inhibits insulin release and promotes glucagon release.

Diabetes Mellitus

Whether glucose is absorbed across the digestive tract or manufactured and released by the liver, very little glucose leaves the body intact once it has entered the circulation. Glucose does get filtered out of the blood at the kidneys, but virtually all of it is reabsorbed, so urinary glucose losses are negligible.

Build Your Knowledge

Recall that glucose $(C_6H_{12}O_6)$ is the most important "fuel" in the body (as you saw in **Chapter 2: The Chemical Level of Organization**). Carbohydrates are most important as sources of energy, and our tissues can break down most of them. You learned that the major types of carbohydrates are monosaccharides, disaccharides, and polysaccharides. Glucose and other monosaccharides, and disaccharides (such as sucrose), dissolve readily in water. Polysaccharides are the largest carbohydrate molecules. Glycogen is a polysaccharide composed of interconnected glucose molecules. Like most large polysaccharides, glycogen will not dissolve in water or body fluids. Both liver and muscle cells make and store glycogen. **D pp. 68, 69**

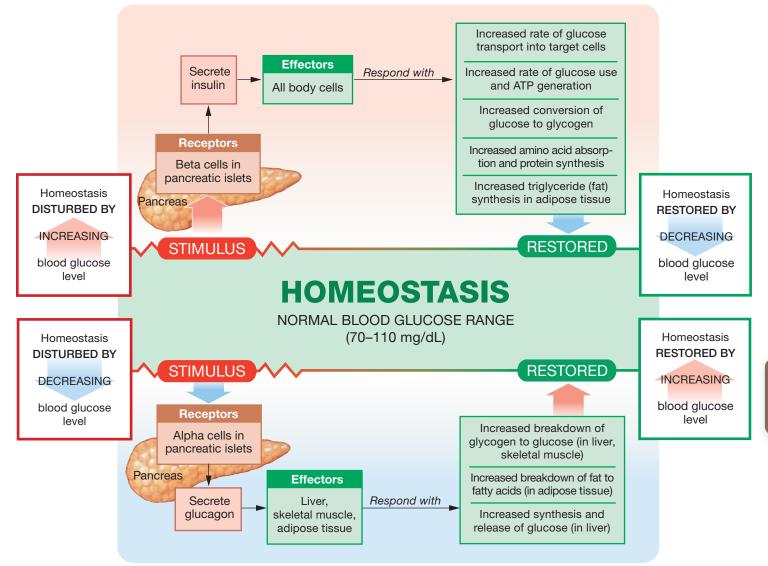

Figure 10-14 The Homeostatic Regulation of the Blood Glucose Concentration.

However, in *diabetes mellitus*, glucose builds up in the blood and urine as a result of faulty glucose metabolism. The two types of diabetes are *Type 1 diabetes* (previously known as juvenile diabetes) and *Type 2 diabetes*. This disorder is discussed in the Clinical Note: Diabetes Mellitus on p. 396.

CHECKPOINT

- **19.** Identify two important types of cells in the pancreatic islets and the hormones produced by each.
- **20.** Which pancreatic hormone causes skeletal muscle and liver cells to convert glucose to glycogen?
- **21.** What effect would increased levels of glucagon have on the amount of glycogen stored in the liver?

See the blue Answers tab at the back of the book.

10-9 Many organs have secondary endocrine functions

Learning Outcome: Discuss the functions of the hormones produced by the kidneys, heart, thymus, testes, ovaries, and adipose tissue.

Many organs that are part of other body systems have secondary endocrine functions. Examples are the intestines (digestive system), the kidneys (urinary system), the heart (cardiovascular system), the thymus (lymphatic system), and the gonads—the testes in males and ovaries in females (reproductive system). We include the endocrine functions of adipose tissue in this section, although all the details have yet to be worked out.

CLINICAL NOTE DIABETES MELLITUS

Untreated diabetes mellitus disrupts metabolic activities throughout the body. Clinical problems arise because the tissues involved are experiencing an energy crisis—in essence, most of the tissues are responding as they would during chronic starvation, breaking down lipids and even proteins because they are unable to absorb glucose from their surroundings. Problems involving abnormal changes in blood vessel structure are particularly dangerous. An estimated 30.3 million people in the United States have some form of diabetes.

Kidney Degeneration

Degenerative changes in the kidneys, a condition called **diabetic nephropathy**, can lead to kidney failure.

Diabetes Mellitus

Diabetes mellitus (mel-Ī-tus; *mellitum*, honey), is characterized by glucose concentrations that are high enough to overwhelm the reabsorption capabilities of the kidneys. (The presence of abnormally high glucose levels in the blood in general is called **hyperglycemia** [hī-per-glī-SĒ-mē-ah].) Glucose appears in the urine (**glycosuria**; glī-kō-SYŪ-rē-a), and urine volume generally becomes excessive (**polyuria**).

subdivided into

Type 1 Diabetes

Type 1 is characterized by inadequate insulin production by the pancreatic beta cells. Persons with Type 1 diabetes require insulin to live and usually require multiple injections daily, or continuous infusion through an insulin pump or other device. This form of diabetes accounts for approximately 5% of cases. It usually develops in children and young adults.

Type 2 Diabetes

Type 2 is the most common form of diabetes mellitus. Most people with this form of diabetes produce normal amounts of insulin, at least initially, but their tissues do not respond properly, a condition known as insulin resistance. Type 2 diabetes is associated with obesity. Weight loss through diet and exercise can be an effective treatment, especially when coupled with oral medicines.

Retinal Damage

The proliferation of capillaries and hemorrhaging at the retina may cause partial or complete blindness. This condition is called **diabetic retinopathy**.

Early Heart Attacks

Degenerative blockages in cardiac circulation can lead to early heart attacks. For a given age group, heart attacks are three to five times more likely in people with diabetes than in nondiabetic people.

Peripheral Nerve Problems

Abnormal blood flow to neural tissues is probably responsible for a variety of neural problems with peripheral nerves, including abnormal autonomic function. These disorders are collectively termed **diabetic neuropathies**.

Peripheral Tissue Damage

Blood flow to the distal portions of the limbs is reduced, and peripheral tissues may suffer as a result. For example, a reduction in blood flow to the feet can lead to tissue death, ulceration, infection, and loss of toes or a major portion of one or both feet.

The Intestines

The intestines process and absorb nutrients. They also release a variety of hormones that coordinate the activities of the digestive system. Local hormones control most digestive processes, but the sympathetic and parasympathetic divisions of the ANS also have an influence. (We describe these hormones in Chapter 16.)

The Kidneys

The kidneys release the steroid hormone *calcitriol*, the peptide hormone *erythropoietin*, and the enzyme *renin*. Calcitriol is important to calcium ion homeostasis. Erythropoietin and renin are involved in the regulation of blood pressure and blood volume.

The kidneys secrete **calcitriol** in response to parathyroid hormone (PTH). Calcitriol synthesis depends on the availability of vitamin D_3 , which may be synthesized in the skin or absorbed from the diet. The liver absorbs vitamin D_3 and converts it to an intermediary product that is released into the circulation and absorbed by the kidneys. Calcitriol stimulates the absorption of calcium and phosphate ions across the intestinal lining of the digestive tract.

Erythropoietin (e-rith-rō-POY-e-tin); *erythros*, red + *poiesis*, making), or **EPO**, is released by the kidneys in response to low oxygen levels in kidney tissues. EPO stimulates the red bone marrow to produce red blood cells. The increase in the number of red blood cells elevates blood volume. Because these cells transport oxygen, this increase improves oxygen delivery to peripheral tissues. (We consider EPO again in Chapter 11.)

Renin (RĒ-nin) is released by specialized kidney cells in response to a decline in blood volume, blood pressure, or both. Once in the bloodstream, renin starts an enzymatic chain reaction, known as the *renin-angiotensin-aldosterone system* (*RAAS*). RAAS leads to the formation of the hormone **angiotensin II**. Angiotensin II stimulates the secretion of aldosterone (by the adrenal cortex) and ADH (by the posterior lobe of the pituitary gland). This combination restricts salt and water loss by the kidneys. Angiotensin II also stimulates thirst and elevates blood pressure. Because renin plays a leading role in the formation of angiotensin II, many physiological and endocrinological references consider renin to be a hormone. (We discuss the *renin-angiotensin-aldosterone system* in Chapters 13 and 18.)

The Heart

The endocrine cells in the heart are cardiac muscle cells in the walls of the *right atrium;* this chamber receives blood from the largest veins. If blood volume becomes too great, these cardiac muscle cells are stretched, stimulating them to release the

hormone **atrial natriuretic peptide (ANP)** (nā-trē-ū-RET-ik; *natrium*, sodium + *ouresis*, making water).

In general, the effects of ANP oppose those of angiotensin II. ANP promotes the loss of sodium ions and water by the kidneys. It also inhibits renin release and ADH and aldosterone secretion. As a result of ANP secretion, both blood volume and pressure decline. (We discuss ANP further when we consider the control of blood pressure and volume in Chapter 13.)

The Thymus

The **thymus** is located in the *mediastinum*, generally just deep to the sternum. In a newborn infant, the thymus is relatively enormous, often extending from the base of the neck to the superior border of the heart. As the child grows, the thymus continues to enlarge slowly, reaching a maximum weight of about 40 g (1.4 oz) just before puberty. After puberty, it gradually diminishes in size. By age 50, the thymus may weigh less than 12 g (0.4 oz).

The thymus produces several hormones that are important in developing and maintaining immune defenses. They are collectively known as **thymosins** (THĪ-mō-sinz). It has been suggested that the gradual decrease in the size and secretory abilities of the thymus may make elderly people more susceptible to disease. (We consider the structure of the thymus and the functions of the thymosins in Chapter 14.)

The Gonads

Information about the reproductive hormones of the testes and ovaries is presented in **Table 10-3**.

The Testes

In males, the **interstitial endocrine cells** of the testes produce the steroid hormones known as androgens. **Testosterone** (tes-TOS-te-rōn) is the most important androgen. It promotes the production of functional sex cells (sperm), maintains the secretory glands of the male reproductive tract, and determines secondary sex characteristics such as the distribution of facial hair and body fat. Testosterone also affects metabolic activities throughout the body. It stimulates protein synthesis and muscle growth, and it produces aggressive behavioral responses. During embryonic development, the production of testosterone affects the development of male reproductive ducts, external genitalia, and CNS structures, including hypothalamic nuclei that will later affect sexual behaviors.

Nurse cells in the testes support the formation of functional sperm. Under FSH stimulation, nurse cells secrete the

Table 10-3	Hormones of the Reproductive System		
Structure/Cells	Hormone	Primary Target	Effects
TESTES			
Interstitial endocrine cells	Androgens	Most cells	Support functional maturation of sperm, protein synthesis in skeletal muscles, male secondary sex characteristics, and associated behaviors
Nurse cells	Inhibin	Anterior lobe of pituitary gland	Inhibits secretion of FSH
OVARIES			
Follicular cells	Estrogens	Most cells	Support follicle maturation, female secondary sex characteristics, and associated behaviors
	Inhibin	Anterior lobe of pituitary gland	Inhibits secretion of FSH
Corpus luteum	Progesterone	Uterus, mammary glands	Prepares uterus for implantation of embryo; prepares mammary glands for secretory activity

hormone **inhibin**. Recall that this hormone inhibits the secretion of FSH by the anterior lobe of the pituitary gland. Throughout adult life, inhibin and FSH interact to maintain sperm production at normal levels.

The Ovaries

In the ovaries, female sex cells (*oocytes*) develop in structures called **ovarian follicles**, under stimulation by FSH. (An oocyte is an immature ovum, or egg cell. Upon fertilization, the oocyte matures to become an *ovum*.) Follicle cells surrounding the oocyte produce **estrogens** (ES-trō-jenz), steroid hormones that support the maturation of the egg cell and stimulate the growth of the lining of the uterus. Under FSH stimulation, follicle cells secrete inhibin, which suppresses FSH release through a negative feedback process similar to that in males.

At ovulation, a mature follicle in an ovary releases an oocyte. The remaining follicle cells then form a **corpus luteum** that releases a mixture of estrogens and **progesterone** (prō-JES-ter-ōn). Progesterone speeds up the movement of fertilized eggs along the uterine tubes and prepares the uterus for the arrival of a developing embryo. In combination with other hormones, it also causes the mammary glands to enlarge.

The production of androgens, estrogens, and progesterone is controlled by regulatory hormones released by the anterior lobe of the pituitary gland. During pregnancy, the placenta functions as an endocrine organ, working with the ovaries and the pituitary gland to promote normal fetal development and delivery.

Adipose Tissue

Recall that adipose tissue is a type of loose connective tissue (introduced in Chapter 4). \bigcirc p. 134 Adipose tissue produces a

peptide hormone called **leptin**, which has several functions. Its best known function is the negative feedback control of appetite. When you eat, adipose tissue absorbs glucose and lipids and synthesizes triglycerides (fats) for storage. At the same time, it releases leptin into the bloodstream. Leptin binds to neurons in the hypothalamus involved with emotion and appetite control. The result is a sense of fullness (satiation) and the suppression of appetite.

Leptin must be present for normal levels of GnRH and gonadotropin synthesis to take place. This explains why (1) thin girls commonly enter puberty relatively late, (2) an increase in body fat content can improve fertility, and (3) women stop menstruating when their body fat content becomes very low.

CHECKPOINT

- **22.** Identify the two hormones secreted by the kidneys, and describe their functions.
- **23.** Describe the action of renin.
- 24. Identify a hormone released by adipose tissue.

See the blue Answers tab at the back of the book.

10-10 Hormones interact to produce coordinated physiological responses

Learning Outcome: Explain how hormones interact to produce coordinated physiological responses, and describe how the endocrine system responds to stress and is affected by aging.

We usually study hormones individually, but the extracellular fluids contain a mixture of hormones. Their concentrations change daily and even hourly. When a cell receives instructions from two different hormones at the same time, four outcomes are possible:

- *Antagonistic effects.* The two hormones may have **antagonistic (opposing) effects**, as is the case for para-thyroid hormone and calcitonin, or insulin and glucagon.
- *Synergistic effects.* The two hormones may have additive effects, in which case the net result is greater than the effect that each would produce acting alone. In some cases, the net result is greater than the *sum* of their individual effects. An example of such a **synergistic** (sin-er-JIS-tik; *syn*, together + *ergon*, work) **effect** is the glucose-sparing action of GH and glucocorticoids. ⊃ pp. 385, 392
- *Permissive effects.* Hormones can have a **permissive effect** on other hormones. In such cases, one hormone must be present if a second hormone is to produce its effects. For example, epinephrine has no apparent effect on energy consumption unless thyroid hormones are also present in normal concentrations.
- **Integrative effects.** Hormones may also produce different but complementary results in a given tissue or organ. These **integrative effects** are important in coordinating the activities of diverse physiological systems. The differing effects of calcitriol and parathyroid hormone on tissues involved in calcium metabolism are an example.

The next few sections focus on how hormones interact to control normal growth, reactions to stress, alterations of behavior, and the effects of aging. More detailed discussions can be found in chapters on cardiovascular function, metabolism, excretion, and reproduction.

Hormones and Growth

Normal growth requires the cooperation of several endocrine organs. Six hormones—GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones—are especially important. Many others also have secondary effects on growth rates and patterns.

- **Growth hormone (GH).** The effects of GH on protein synthesis and cellular growth are most apparent in children. GH supports their muscular and skeletal development. In adults, GH helps to maintain normal blood glucose levels and to mobilize lipid reserves in adipose tissues. GH is not the primary hormone involved, however. An adult with a GH deficiency but normal levels of thyroxine, insulin, and glucocorticoids will have no physiological problems.
- **Thyroid hormones.** Normal growth also requires appropriate levels of thyroid hormones. If these hormones are absent during fetal development or for the first year of life, the nervous system fails to develop normally. Developmental delay results. If thyroxine concentrations decline later in life but before puberty, normal skeletal development does not continue.

CLINICAL NOTE

Hormones and Athletic Performance

The use of hormones to improve athletic performance is banned by the International Olympic Committee, the U.S. Olympic Committee, the National Collegiate Athletic Association, Major League Baseball, and the National Football League. The American Medical Association and the American College of Sports Medicine condemn the practice. A significant number of amateur and professional athletes, however, persist in this dangerous practice. Synthetic forms of testosterone are used most often, but athletes may use any combination of testosterone, growth hormone (GH), erythropoietin (EPO), and a variety of synthetic hormones.

The use of *anabolic steroids* or androgens has become popular with many amateur and professional athletes. The goal of steroid use is to increase muscle mass, endurance, and "competitive spirit." A steroid, such as *androstenedione*, is converted to testosterone in the body. One justification for this steroid use is the unfounded opinion that compounds made in the body are not only safe, but good for you. In reality, the use of natural or synthetic androgens in abnormal amounts carries unacceptable health risks. Androgens produce several complications. These include (1) premature closure of epiphyseal cartilages; (2) liver dysfunctions (such as jaundice and liver tumors); (3) in males, prostate gland enlargement, urinary tract obstructions, testicular atrophy, and infertility; and (4) in females, irregular menstrual periods and changes in body hair distribution. Links to heart attacks, impaired heart function, and strokes have also been suggested. Finally, androgen abuse can cause a generalized depression of the immune system.

Erythropoietin (EPO) is sometimes used by endurance athletes, such as cyclists and marathon runners, to boost the number of oxygen-carrying red blood cells in the bloodstream. This effect increases the oxygen content of the blood, but it also makes the blood more viscous. For this reason, the heart must work harder to push the "thick" blood through the blood vessels. This effort can result in death due to heart failure or stroke in young and otherwise healthy individuals.

The effects of androgens and EPO are reasonably well understood. Drug testing is now widespread in amateur and professional sports, but athletes seeking "an edge" are experimenting with drugs not easily detected by standard tests. The effects of these drugs are difficult to predict. 10

- **Insulin.** Growing cells need adequate supplies of energy and nutrients. Without insulin, the passage of glucose and amino acids across plasma membranes stops or is drastically reduced.
- **Parathyroid hormone (PTH) and calcitriol.** Parathyroid hormone and calcitriol promote the absorption of calcium for building bone. Without adequate levels of both hormones, bones can enlarge but will be poorly mineralized, weak, and flexible. For example, rickets is a condition typically resulting from inadequate production of calcitriol due to vitamin D₃ deficiency in growing children. As a result, the lower limb bones are so weak that they bend under the body's weight. ⊃ p. 178
- **Reproductive hormones.** The presence or absence of sex hormones (androgens in males, estrogens in females) affects the activities of osteoblasts in key locations and the growth of specific cell populations. Androgens and estrogens stimulate cell growth and differentiation in their target tissues, but the targets differ. The differential growth induced by each accounts for gender-related differences in skeletal proportions and secondary sex characteristics.

Hormones and Stress

Any condition—physical or emotional—that threatens homeostasis is a form of **stress**. Stresses may be (1) physical, such as illness or injury; (2) emotional, such as depression or anxiety; (3) environmental, such as extreme heat or cold; or (4) metabolic, such as starvation. Many stresses are opposed by specific homeostatic adjustments. For example, a decline in body temperature leads to shivering or changes in the pattern of blood flow, which can restore normal body temperature.

In addition, the body has a *general* response to stress that can take place while other, more specific, responses are under way. A wide variety of stress-causing factors produce the same basic pattern of hormonal and physiological adjustments. These responses are part of the **general adaptation syndrome (GAS)**, also known as the **stress response**. The GAS has three phases: the *alarm phase*, the *resistance phase*, and the *exhaustion phase*. These phases are described in **Spotlight Figure 10-15**.

Hormones and Behavior

As we have seen, the hypothalamus regulates many endocrine functions. Its neurons also monitor the levels of many circulating hormones. Other portions of the brain that affect how we act, or behave, are also quite sensitive to hormonal stimulation. The clearest demonstrations of the behavioral effects of specific hormones involve individuals whose endocrine glands are oversecreting or undersecreting. But even normal changes in circulating hormone levels can cause behavioral changes. In *precocious* (premature) *puberty*, sex hormones are produced at an inappropriate time, perhaps as early as age five or six. Not only does an affected child begin to develop adult secondary sex characteristics, but the child's behavior also changes. The "nice little kid" disappears, and the child becomes aggressive and assertive due to the effects of sex hormones on CNS function. In normal teenagers, these behaviors are usually attributed to environmental stimuli, such as peer pressure, but here we can see that they have a physiological basis as well. In adults, changes in the mixture of hormones reaching the CNS can affect intellectual capabilities, memory, learning, and emotional states.

Hormones and Aging

The endocrine system undergoes relatively few functional changes with age. The most dramatic exception is the decline in the concentration of reproductive hormones. (We noted the effects of these hormonal changes on the skeletal system in Chapter 6. \supset p. 182 We will continue the discussion in Chapter 20.)

Blood and tissue concentrations of many other hormones, including TSH, thyroid hormones, ADH, PTH, prolactin, and glucocorticoids, do not change with increasing age. Circulating hormone levels may remain within normal limits, but some endocrine tissues become less responsive to stimulation. For example, in elderly individuals, less GH and insulin are secreted after a carbohydrate-rich meal. The reduction in levels of GH and other tropic hormones affects tissues throughout the body. These hormonal effects are associated with the reductions in bone density and muscle mass noted in earlier chapters.

Finally, age-related changes in peripheral tissues may make them less responsive to some hormones. This loss of sensitivity has been documented for glucocorticoids and ADH.

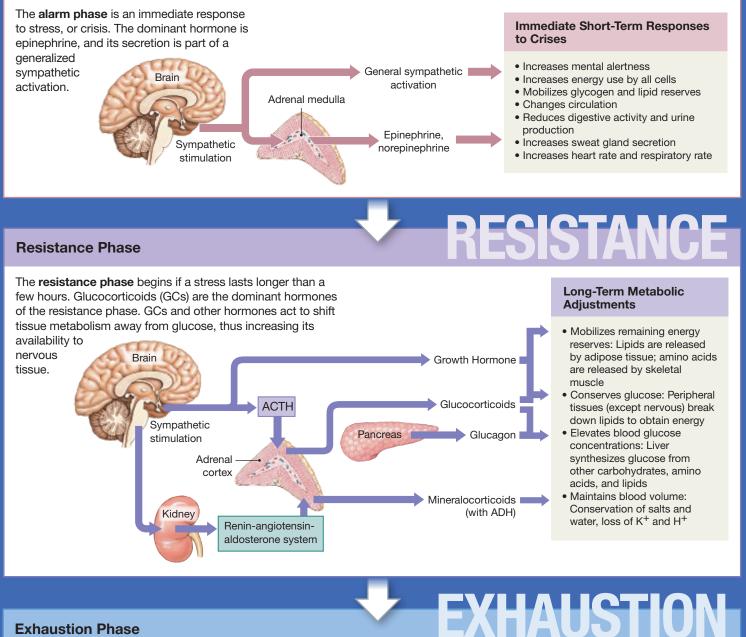

CHECKPOINT

- **25.** Insulin decreases blood glucose levels and glucagon increases blood glucose levels. This is an example of which type of hormonal interaction?
- **26.** The lack of which hormones would inhibit skeletal formation?
- **27.** What are the dominant hormones of the resistance phase of the general adaptation syndrome, and in what ways do they act?
- See the blue Answers tab at the back of the book.

Figure 10-15 SPOTLIGHT THE GENERAL ADAPTATION SYNDROME

Alarm Phase ("Fight or Flight")

ALARM

Exhaustion Phase

The body's lipid reserves are sufficient to maintain the resistance phase for weeks or even months. But when the resistance phase ends, homeostatic regulation breaks down and the exhaustion phase begins. Without immediate corrective actions, the ensuing failure of one or more organ systems will prove fatal.

Collapse of Vital Systems

- · Exhaustion of lipid reserves
- Cumulative structural or functional damage to vital organs
- · Inability to produce glucocorticoids
- Failure of electrolyte balance

ENDOCRINE DISORDERS

Endocrine disorders fall into two basic categories: inadequate hormonal effects and excessive hormonal effects. The observed signs and symptoms may reflect either abnormal hormone production (hyposecretion or hypersecretion) or abnormal target cell sensitivity. Characteristic features of some important endocrine disorders are described in the table below.

CLINICAL NOTE

An Overview of Some Important Endocrine Disorders

Hormone	Results of Underproduction or Tissue Insensitivity	Principal Signs and Symptoms	Results of Overproduction or Tissue Hypersensitivity	Principal Signs and Symptoms	
Growth hormone (GH)	Pituitary growth failure	Delayed growth, abnormal fat distribution, low blood glucose hours after a meal	Gigantism, acromegaly	Excessive growth	
	Congenital hypothyroidism results from thyroid hormone insufficiency during pregnancy.	A goiter, or enlarged thyro gland, can be associated wi thyroid hyposecretion due to iodine insufficiency i adults.	th n	Acromegaly results from the overproduction of growth hormone after puberty, when most of the epiphyseal cartilages have fused. Bone shapes change and cartilaginous areas of the skeleton enlarge. Note the broad facial features and enlarged lower jaw.	
Thyroxine (T ₄), Triiodothyroxine (T ₃)	Congenital hypothyroidism, hypothyroidism, myxedema	Low metabolic rate, low body temperature, impaired physical and mental development	Hyperthyroidism, Graves disease	High metabolic rate and body temperature	
Insulin	Diabetes mellitus (Type 1)	High blood glucose, impaired glucose use, glycosuria	Excess insulin production	Low blood glucose levels, possibly causing coma	
	Addison disease I is caused by hyposecre- tion of corticosteroids, especially glucocorti- coids. Pigment changes result from stimulation of melanocytes by ACTH, which is structurally similar to MSH			Cushing disease is caused by hypersecretion of glucocorticoids. Lipid reserves are mobilized, and adipose tissue accumulates in the cheeks and at the base of the neck.	
Glucocorticoids Example: cortisol	Addison disease	Inability to tolerate stress, mobilize energy reserves, or maintain normal blood glucose levels	Cushing disease	Excessive breakdown of tissue proteins and lipid reserves, impaired glucose metabolism	
Estrogens (females)	Hypogonadism	Sterility, lack of secondary sex characteristics	Precocious puberty	Premature sexual maturation and related behavioral changes	
Androgens (males)	Hypogonadism	Sterility, lack of secondary sex characteristics	Precocious puberty	Premature sexual maturation and related behavioral changes	

10-11 Extensive integration occurs between the endocrine system and other body systems

Learning Outcome: Give examples of interactions between the endocrine system and other body systems presented so far.

The endocrine system provides long-term regulation and adjustments of homeostatic processes that affect many body functions. For all systems, the endocrine system adjusts metabolic rates and use of substrates, such as glucose, triglycerides, and amino acids. It also regulates growth and development. Build Your Knowledge: How the ENDOCRINE SYSTEM integrates with the other body systems presented so far on p. 404 reviews the major functional relationships between it and the integumentary, skeletal, muscular, and nervous systems.

CHECKPOINT

- **28.** Discuss the general role of the endocrine system in the functioning of other body systems.
- **29.** Discuss the functional relationship between the endocrine system and the muscular system.
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

adrenalectomy: Surgical removal of an adrenal gland. **endocrinology** (EN-dō-kri-NOL-ō-jē): The study of hormones, hormone-secreting tissues and glands, and their roles in physiological and disease processes in the body.

Hashimoto's disease: Disorder that affects the thyroid gland, also known as chronic lymphocytic thyroiditis, causing the immune system to attack the thyroid gland. It is the most common cause of hypothyroidism in the United States.

hypocalcemic tetany: Muscle spasms affecting the face and upper extremities; caused by low calcium ion (Ca^{2+}) concentrations in body fluids.

hypophysectomy: Surgical removal of the pituitary gland.

myxedema: In adults, the effects of hyposecretion of thyroid hormones, including subcutaneous swelling, hair loss, dry skin, low body temperature, muscle weakness, and slowed reflexes.

posttraumatic stress disorder (PTSD): A common anxiety disorder that develops after being exposed to a life-threatening situation or terrifying event.

thyroidectomy: Surgical removal of all or part of the thyroid gland.

thyrotoxicosis: A condition caused by the oversecretion of thyroid hormones (*hyperthyroidism*). Signs and symptoms include increases in metabolic rate, blood pressure, and heart rate; excitability and emotional instability; and lowered energy reserves.

Build Your Knowledge

How the ENDOCRINE SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System protects superficial endocrine organs; epidermis synthesizes vitamin D₃ (precursor to calcitriol production)
- The endocrine system secretes sex hormones that stimulate sebaceous gland activity, influence hair growth, fat distribution, and apocrine sweat gland activity; PRL that stimulates development of mammary glands; adrenal hormones that alter dermal blood flow; MSH that stimulates melanocyte activity

Skeletal System

- The Skeletal System protects endocrine organs, especially in brain, chest, and pelvic cavity
- 10
- The endocrine system regulates skeletal growth with several hormones; calcium homeostasis regulated by parathyroid hormone and calcitonin; sex hormones speed growth and closure of epiphyseal cartilages at puberty and help maintain bone mass in adults

Muscular System

- The Muscular System provides protection for some endocrine organs
- The endocrine system secretes hormones that adjust muscle metabolism, energy production, and growth; regulate calcium and phosphate levels in body fluids; speeds skeletal muscle growth

Nervous System

- The Nervous System produces hypothalamic hormones that directly control pituitary secretions and indirectly control secretions of other endocrine organs; controls adrenal medullae; secretes ADH and oxytocin
- The endocrine system secretes several hormones that affect neural metabolism and brain development; hormones that help regulate fluid and electrolyte balance; reproductive hormones that influence CNS development and behaviors

Endocrine System

The endocrine system provides long-term regulation and adjustments of homeostatic processes that affect many body functions. It:

- regulates fluid and electrolyte balance
- regulates cell and tissue metabolism
- regulates growth and development
- regulates reproductive functions
- responds to stressful stimuli through the general adaptation syndrome (GAS)

Chapter Review

Summary Outline

10-1 Homeostasis is preserved through intercellular communication *p. 375*

1. In general, the nervous system performs short-term "crisis management," whereas the endocrine system regulates longer-term, ongoing metabolic processes. Endocrine cells release **hormones**, chemicals that alter the metabolic activities of many different tissues and organs. (*Figure 10-1*)

10-2 The endocrine system regulates physiological processes through the binding of hormones to receptors *p. 376*

- **2.** Hormones can be divided into three groups based on chemical structure: amino acid derivatives, peptide hormones, and lipid derivatives.
- **3.** *Amino acid derivatives* are structurally similar to amino acids; they include *epinephrine, norepinephrine, thyroid hormones, and melatonin.*
- 4. Peptide hormones are chains of amino acids.
- **5.** There are two classes of *lipid derivatives:* **steroid hormones**, lipids that are structurally similar to cholesterol, and **eicosanoids**, fatty acid–based hormones that include **prostaglandins**.
- **6.** Hormones exert their effects by modifying the activities of **target cells** (peripheral cells that are sensitive to that particular hormone). (*Figure 10-2*)
- 7. Receptors for amino acid–derived hormones, peptide hormones, and fatty acid–derived hormones are in the plasma membranes of target cells. In this case, the hormone acts as a **first messenger** that causes the formation of a **second messenger** in the cytoplasm. Thyroid and steroid hormones cross the plasma membrane and bind to intracellular receptors in the cytoplasm or nucleus. Thyroid hormones also bind to mitochondria, where they increase the rate of ATP production. (*Figure 10-3*)
- **8.** Hormones may circulate freely or be carried by transport proteins. Free hormones are rapidly removed from the bloodstream.
- **9.** The most direct patterns of endocrine control involve negative feedback to the endocrine cells resulting from changes in the extracellular fluid.
- **10.** The hypothalamus regulates the activities of the nervous and endocrine systems in three ways: (1) It synthesizes and secretes two hormones into the bloodstream at the posterior lobe of the pituitary gland; (2) it secretes **regulatory**

hormones that control the activities of endocrine cells in the anterior lobe of the pituitary gland; and (3) it exerts direct neural control over the endocrine cells of the adrenal medullae. (*Figure 10-4*)

10-3 The bilobed pituitary gland is an endocrine organ that releases nine peptide hormones *p. 381*

- **11.** The **pituitary gland** (*hypophysis*) releases nine important peptide hormones; all bind to membrane receptors, and most use cyclic-AMP as a second messenger. (*Figure 10-5*)
- **12.** Hypothalamic neurons release regulatory factors into the surrounding interstitial fluids, which then enter highly permeable capillaries.
- **13.** The **hypophyseal portal system** ensures that all the blood entering the *portal vessels* will reach target cells in the anterior lobe of the pituitary gland before returning to the general circulation. (*Figure 10-6*)
- **14.** The rate of regulatory hormone secretion by the hypothalamus is regulated through negative feedback. (*Figure 10-7*)
- 15. The seven hormones of the anterior lobe of the pituitary gland are (1) thyroid-stimulating hormone **(TSH)**, which triggers the release of thyroid hormones; (2) adrenocorticotropic hormone (ACTH), which stimulates the release of glucocorticoids by the adrenal gland; (3) follicle-stimulating hormone (FSH), which stimulates estrogen secretion and egg development in females and sperm production in males; (4) luteinizing hormone (LH), which causes ovulation and progesterone production in females and androgen production in males; (5) prolactin (PRL), which stimulates the development of the mammary glands and the production of milk; (6) growth hormone (GH), which stimulates cell growth and replication by triggering the release of somatomedins from liver cells; and (7) melanocyte-stimulating hormone (MSH), which may be secreted during fetal development, early childhood, pregnancy, or certain diseases. MSH stimulates melanocytes to produce melanin.
- **16.** The **posterior lobe** of the pituitary gland contains the axons of hypothalamic neurons that produce **antidiuretic hormone (ADH)** and **oxytocin (OXT)**. ADH decreases the amount of water lost at the kidneys. In females, oxytocin stimulates smooth muscle cells in the uterus and contractile cells in the mammary glands. In males, it stimulates contractions of smooth muscles in the sperm duct and prostate gland. (*Figure 10-8; Table 10-1*)

10-4 The thyroid gland synthesizes thyroid hormones that affect the rate of metabolism *p. 386*

- **17.** The **thyroid gland** lies near the **thyroid cartilage** of the larynx and consists of two lobes. (*Figure 10-9*)
- The thyroid gland contains numerous thyroid follicles. Thyroid follicles release several hormones, including thyroxine (T₄) and triiodothyronine (T₃). (Table 10-2)
- **19.** Thyroid hormones exert a **calorigenic effect**, which enables us to adapt to cold temperatures.
- **20.** The **C cells** of the follicles produce **calcitonin (CT)**, which helps lower calcium ion concentrations in body fluids. (*Figure 10-10, Table 10-2*)
- **10-5** The four parathyroid glands, embedded in the posterior surfaces of the thyroid gland, secrete parathyroid hormone to elevate blood calcium levels *p. 390*
- **21.** Four **parathyroid glands** are embedded in the posterior surfaces of the thyroid gland. The **principal cells** of the parathyroid produce **parathyroid hormone (PTH)** in response to lower than normal concentrations of calcium ions. Principal cells and the C cells of the thyroid gland maintain calcium levels within relatively narrow limits. (*Figures 10-10, 10-11; Table 10-2*)

10-6 The adrenal glands, consisting of a cortex and a medulla, cap each kidney and secrete several hormones *p. 390*

- **22.** A single **adrenal gland**, or *suprarenal gland*, lies along the superior border of each kidney. Each gland, which is surrounded by a fibrous capsule, can be subdivided into the superficial adrenal cortex and the inner adrenal medulla. (*Figure 10-12*)
- 23. The adrenal cortex manufactures steroid hormones called corticosteroids. The cortex produces (1) glucocorticoids—notably, cortisol, corticosterone, and cortisone, which, in response to ACTH, affect glucose metabolism;
 (2) mineralocorticoids—principally aldosterone, which, in response to angiotensin II, restricts sodium and water losses at the kidneys, sweat glands, digestive tract, and salivary glands; and (3) androgens. (*Figure 10-12*)
- **24.** The **adrenal medulla** produces **epinephrine** and **norepinephrine**. (*Figure 10-12*)

10-7 The pineal gland, attached to the third ventricle, secretes melatonin *p. 393*

25. The **pineal gland** synthesizes **melatonin**. Melatonin appears to (1) slow the maturation of sperm, eggs, and reproductive organs; (2) protect neural tissue from free radicals; and (3) establish daily circadian rhythms.

10-8 The endocrine pancreas produces insulin and glucagon, hormones that regulate blood glucose levels *p. 393*

- 26. The pancreas contains both exocrine and endocrine cells. The exocrine pancreas secretes an enzyme-rich fluid that functions in the digestive tract. Cells of the endocrine pancreas form clusters called pancreatic islets (*islets of Langerhans*), containing alpha cells (which produce the hormone glucagon) and beta cells (which produce insulin). (*Figure 10-13*)
- **27.** Insulin lowers blood glucose levels by increasing the rate of glucose uptake and its use. Glucagon raises blood glucose levels by increasing the rates of glycogen breakdown and glucose synthesis in the liver. (*Figure 10-14*)

10-9 Many organs have secondary endocrine functions *p. 395*

- **28.** The intestines release hormones that coordinate digestive activities.
- **29.** Endocrine cells in the kidneys produce two hormones and an enzyme important in calcium metabolism and in the maintenance of blood volume and blood pressure.
- **30. Calcitriol** stimulates calcium and phosphate ion absorption along the digestive tract.
- **31. Erythropoietin (EPO)** stimulates red blood cell production by the red bone marrow.
- **32. Renin** activity leads to the formation of **angiotensin II**, the hormone that stimulates the production of aldosterone in the adrenal cortex.
- **33.** Specialized muscle cells in the heart produce **atrial natriuretic peptide (ANP)** when blood pressure or blood volume becomes excessive.
- **34.** The **thymus** produces several hormones called **thymosins**, which play a role in developing and maintaining normal immune defenses.
- **35.** The **interstitial endocrine cells** of the testes in males produce androgens and **inhibin**. The androgen testosterone is the most important sex hormone in males. (Table 10-3)
- 36. In females, oocytes (immature eggs) develop in ovarian follicles. Follicle cells surrounding the oocytes produce estrogens and inhibin. After ovulation, these cells reorganize into a corpus luteum that releases a mixture of estrogens and progesterone. If pregnancy occurs, the placenta functions as an endocrine organ. (Table 10-3)
- **37.** Adipose tissue secretes **leptin**, which functions in the negative feedback control of appetite.

10-10 Hormones interact to produce coordinated physiological responses *p. 398*

38. The endocrine system functions as an integrated unit, and hormones often interact. These interactions may have (1) **antagonistic** (opposing) effects, (2) **synergistic** (additive) effects,

(3) **permissive** effects, or (4) **integrative** effects, in which hormones produce different but complementary results.

- **39.** Normal growth requires the cooperation of several endocrine organs. Six hormones are especially important: growth hormone, thyroid hormones, insulin, parathyroid hormone, calcitriol, and reproductive hormones.
- **40.** Any condition that threatens homeostasis is a **stress**. Our bodies respond to a variety of stress-causing factors through the general adaptation syndrome (GAS). The GAS is divided into three phases: (1) the **alarm phase**, under the direction of the sympathetic division of the ANS; (2) the resistance phase, dominated by glucocorticoids; and (3) the exhaustion phase, the eventual breakdown of homeostatic regulation and failure of one or more organ systems. (Spotlight Figure 10-15)
- **41.** Many hormones affect the functional state of the nervous system, producing changes in mood, emotional states, and various behaviors.
- **42.** The endocrine system undergoes relatively few functional changes with advancing age. The most dramatic endocrine change is a decline in the concentration of reproductive hormones.

10-11 Extensive integration occurs between the endocrine system and other body systems p. 403

43. The endocrine system affects all organ systems by adjusting metabolic rates and substrate use, and regulating growth and development.

Review Questions

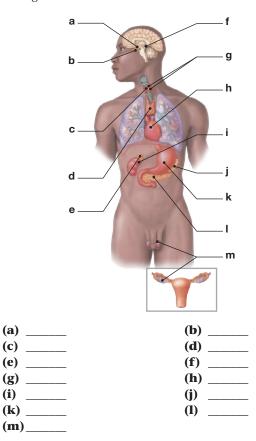

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A	COLUMN B		
1. thyroid gland	a. stimulated by low calcium levels		
2. pineal gland	b. islets of Langerhans		
3. polyuria	c. atrophies by adulthood		
4. parathyroid gland	d. atrial natriuretic peptide		
5. thymus gland	e. stimulates cell growth and protein synthesis		
6. adrenal cortex	f. melatonin		
7. heart	g. hypophysis		
8. endocrine pancreas	h. excessive urine production		
9. gonadotropins	i. calcitonin		
10. hypothalamus	j. secretes regulatory hormones		
11. pituitary gland	k. FSH and LH		
12. growth hormone	 secretes androgens, mineralocorticoids, and glucocorticoids 		

13. Identify the endocrine glands and tissues in the diagram on the right.

See the blue Answers tab at the back of the book.

(**m**)

- **14.** Thyroid hormones are
 - (a) amino acid derivatives.
 - (b) eicosanoids.
 - (c) peptide hormones.
 - (d) steroid hormones.
- 15. The anterior lobe of the pituitary gland does not produce
 - (a) adrenocorticotropic hormone.
 - **(b)** growth hormone.
 - (c) oxytocin.
 - (d) thyroid stimulating hormone.
- **16.** Parathyroid hormone
 - (a) blocks the secretion of calcitriol.
 - (**b**) increases osteoblastic function.
 - (c) promotes urinary excretion of calcium ions.
 - (d) stimulates osteoclastic activity.
- **17.** Aldosterone is produced in the ______ of the adrenal gland.
 - (a) medulla.
 - (**b**) zona fasciculata.
 - (c) zona glomerulosa.
 - (d) zona reticularis.
- 18. Insulin receptors are not found in the plasma membrane of
 - (a) adipocytes.
 - (b) hepatocytes.
 - (c) neurons.

10

- (d) skeletal muscle cells.
- 19. The most abundant secretion from the thyroid gland is
 - (a) triiodothyronine. (b) calcitonin.
 - (c) thyroxine. (d) parathyroid hormone.
- **20.** Reduced fluid losses in the urine due to retention of sodium ions and water is a result of the action of

(b) calcitonin.

- (a) insulin.
- (c) aldosterone. (d) cortisone.
- **21.** Which of the following is not released by the kidneys?
 - (a) angiotensinogen.
 - (b) calcitriol.
 - (c) erythropoietin.
 - (**d**) renin.
- **22.** Which of the following cells secrete insulin?
 - (a) alpha (b) gamma
 - (c) beta (d) delta
- **23.** What are the effects of calcitonin and parathyroid hormone on the blood calcium ion concentration?
- **24.** (a) What three phases of the general adaptation syndrome (GAS) constitute the body's response to stress? (b) What endocrine secretions play dominant roles in each of the first two phases?

Level 2 Reviewing Concepts

25. What is the primary difference in the ways the nervous and endocrine systems communicate with their target cells?

- **26.** How does the interaction of peptide hormones with their receptors differ from the interaction of steroid hormones with their receptors?
- **27.** Is the glucose-sparing effect of growth hormone and glucocorticoids an antagonistic or a synergistic effect? Explain your answer.
- **28.** How would blocking the activity of phosphodiesterase (PDE) affect a cell that responds to hormonal stimulation by the cAMP second messenger system?

Level 3 Critical Thinking and Clinical Applications

- **29.** An infant with congenital hypothyroidism due to an underdeveloped thyroid gland was found to have an elevated level of thyroid-stimulating hormone (TSH). How can this be explained?
- **30.** Janet has been diagnosed with osteoporosis, and her physician requests a blood test. Her blood results indicate excessive levels of calcium, and the physician suspects that Janet suffers from hyperparathyroidism. How can an overactive parathyroid gland cause osteoporosis?

The Cardiovascular System: Blood

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **11-1** Describe the components and major functions of blood, and list the physical characteristics of blood.
- **11-2** Describe the composition and functions of plasma.
- **11-3** List the characteristics and functions of red blood cells, describe the structure and function of hemoglobin, describe how red blood cell components are recycled, and explain erythropoiesis.
- **11-4** Discuss the factors that determine a person's blood type, and explain why blood typing is important.
- **11-5** Categorize the various white blood cells on the basis of their structures and functions, and discuss the factors that regulate their production.
- **11-6** Describe the structure, function, and production of platelets.
- **11-7** Describe the processes that control blood loss after an injury.

Abnormal Hemoglobin, p. 416 Hemolytic Disease of the Newborn, p. 422 Abnormal Hemostasis, p. 429 **Spotlight** The Composition of Whole Blood, p. 412

An Introduction to the Cardiovascular System

Your body is constantly exchanging chemicals with its external environment. The lining of the digestive tract absorbs nutrients, gases move across the thin epithelium of the lungs, and wastes are excreted in the feces and urine. These chemical exchanges rapidly affect every cell, tissue, and organ because of our internal transport network, the **cardiovascular system**.

We can compare the cardiovascular system to the cooling system of a car. Both systems circulate a fluid (blood versus water) with a pump (the heart versus a water pump). Both carry a fluid in flexible tubing (the blood vessels versus radiator hoses). The cardiovascular system is far more complicated, but either system can malfunction due to fluid losses, pump failures, or damaged tubing.

The cardiovascular system is the first organ system to become fully operational. The heart begins beating by the end of the third week of embryonic life. At that time, most other systems have barely begun to develop. Before then, embryos don't need cardiovascular systems because diffusion across their exposed surfaces takes place rapidly enough to meet their demands. When an embryo has reached a few millimeters in length, however, diffusion is too slow for developing tissues. At that stage, the cardiovascular system begins serving as a rapid-transport system for oxygen, nutrients, and waste products. When the heart starts beating, blood begins circulating. The embryo can now make more efficient use of the nutrients from the mother's bloodstream, and the embryo's size doubles in the next week.

We consider the nature of the circulating blood in this chapter. (We discuss the heart in Chapter 12 and the blood vessels in Chapter 13. In Chapter 14, we consider the lymphatic system, a defense system closely connected to the cardiovascular system.)

Recall that blood is a fluid connective tissue (as you saw in **Chapter 4: The Tissue Level of Organization)**. Like all connective tissues, blood has three components: (1) specialized cells, (2) extracellular protein fibers, and (3) a ground substance. The extracellular fibers and ground substance

form the matrix that surrounds the cells. In blood, the ground substance is a fluid. The watery matrix is called plasma. The plasma proteins are dissolved and usually do not form insoluble fibers. \bigcirc **pp. 132, 136**

11-1 Blood has several important functions and unique physical characteristics

Learning Outcome Describe the components and major functions of blood, and list the physical characteristics of blood.

The circulating fluid of the body is **blood**, a specialized connective tissue that contains cells suspended in a fluid matrix. D p. 136 Blood has five major functions:

1. Transporting dissolved gases, nutrients, hormones, and metabolic wastes. Blood carries oxygen from the lungs to the body's tissues, and carbon dioxide from these tissues to the lungs. Blood distributes nutrients absorbed by the digestive tract or released from storage in adipose tissue or in the liver. It carries hormones from endocrine glands toward their target cells. It also absorbs and carries the wastes produced by active cells to the kidneys for excretion.

- 2. Regulating the pH and ion composition of interstitial fluids. Diffusion between interstitial fluids and blood eliminates local deficiencies or excesses of ions such as calcium or potassium. Blood also absorbs and neutralizes the acids generated by active tissues, such as lactic acid produced by skeletal muscle.
- **3.** *Restricting fluid losses at injury sites.* Blood contains enzymes and factors that respond to breaks in vessel walls by initiating the process of *blood clotting*. A blood clot acts as a temporary patch that prevents further blood loss.
- **4.** *Defending against toxins and pathogens.* Blood transports *white blood cells*, specialized cells that migrate into body tissues to fight infections or remove debris. Blood also delivers *antibodies*, special proteins that attack invading pathogens or foreign compounds.

5. Stabilizing body temperature. Blood absorbs the heat generated by active skeletal muscles and redistributes it to other tissues. If body temperature is high, blood is directed toward the skin surface, where heat is lost to the environment. If body temperature is too low, warm blood is directed to the brain and other temperature-sensitive organs.

Composition of Blood

Spotlight Figure 11-1 (pp. 412–413) describes the composition of whole blood, which is made up of plasma and formed elements (blood cells and cell fragments). The components of whole blood may be separated, or **fractionated**, for analytical or clinical purposes.

Whole blood from any source-veins, capillaries, or arteries-has the same basic physical characteristics:

- *Temperature*. The temperature of blood is roughly 38°C (100.4°F), slightly above normal body temperature.
- Viscosity. Blood is five times as viscous ("thick") as water. It is five times stickier, more cohesive, and resistant to flow than water. The high viscosity results from interactions among the dissolved proteins, formed elements, and water molecules in plasma.
- **pH.** Blood is slightly alkaline, with a pH between 7.35 and 7.45 (average: 7.4). ⁵ p. 66

Blood Collection and Analysis

Fresh whole blood is usually collected from a superficial vein, such as the median cubital vein on the anterior surface of the elbow. This procedure is called **venipuncture** (VENi-punk-chur; vena, vein + punctura, a piercing). It is a common sampling technique because (1) superficial veins are easy to locate; (2) the walls of veins are thinner than those of arteries of comparable size; and (3) blood pressure in the veins is relatively low, so the puncture wound seals quickly. The most common clinical procedures examine venous blood.

Blood from peripheral capillaries can be obtained by puncturing the tip of a finger, an ear lobe, or (in infants) the great toe or heel of the foot. A small drop of capillary blood can be used to prepare a blood smear, a thin film of blood on a microscope slide. The blood smear is then stained with special dyes to show different types of formed elements.

An arterial puncture, or "arterial stick," may be required for evaluating the efficiency of gas exchange at the lungs. Samples are usually drawn from the radial artery at the wrist or the brachial artery at the elbow.

CHECKPOINT

- **1.** List five major functions of blood.
- 2. What two components make up whole blood?
- 3. Why is venipuncture a common technique for obtaining a blood sample?
- See the blue Answers tab at the back of the book.

11-2 Plasma, the fluid portion of blood, contains significant quantities of plasma proteins

Learning Outcome Describe the composition and functions of plasma.

Plasma and interstitial fluid account for most of the volume of extracellular fluid (ECF) in the body. Plasma makes up about 55 percent of the volume of whole blood. As shown in Spotlight Figure 11-1, the components of plasma include plasma proteins (7%), other solutes (1%), and water (92%).

Plasma Proteins

The proteins in plasma are in solution (dissolved). The three primary types are albumins (al-BŪ-minz), globulins (GLOB-ūlinz), and fibrinogen (fī-BRIN-ō-jen). They make up more than 99 percent of the plasma proteins.

Albumins make up the majority of the plasma proteins. 11 For this reason, their presence is important in maintaining the osmotic pressure of plasma. Globulins are the second most-abundant proteins in plasma. They include antibodies and transport proteins. Antibodies attack foreign proteins and pathogens. Transport proteins bind small ions, hormones, or compounds that might otherwise be lost at the kidneys or that have very low solubility in water. One example is thyroid-binding globulin, which binds and transports thyroid hormones.

Both albumins and globulins can bind to lipids, such as triglycerides, fatty acids, or cholesterol. These lipids are not themselves water soluble, but the protein-lipid combination readily dissolves in plasma. In this way, the cardiovascular system transports insoluble lipids to peripheral tissues. Globulins involved in lipid transport are called lipoproteins (LĪ-pō-prō-tēnz).

Fibrinogen, the third type of plasma protein, functions in blood clotting. Under certain conditions, fibrinogen molecules interact to form large, insoluble strands of **fibrin** (FĪ-brin). These strands form insoluble fibers that provide the basic framework for a blood clot. If steps are not taken to prevent clotting in a blood sample, the conversion of fibrinogen

SPOTLIGHT Figure 11-1 THE COMPOSITION OF WHOLE BLOOD

A Fluid Connective Tissue

Blood is a fluid connective tissue. It consists of a matrix called **plasma** (PLAZ-muh) and formed elements (cells and cell fragments). The term **whole blood** refers to the combination of both plasma and the formed elements. The cardiovascular system of an adult male contains 5–6 liters (5.3–6.4 quarts) of whole blood; that of an adult female contains 4–5 liters (4.2–5.3 quarts). The sex differences in blood volume primarily reflect differences

in average body size.

PLASMA

Plasma, the matrix of blood, makes up about 55 percent of the volume of whole blood. In many respects, the composition of plasma resembles that of interstitial fluid. This similarity exists because water, ions, and small solutes are continuously exchanged between plasma and interstitial fluids across the walls of capillaries. The primary differences between plasma and interstitial fluid involve (1) the levels of oxygen and carbon dioxide (due to the respiratory activities of tissue cells), and (2) the concentrations and types of dissolved proteins (because plasma proteins cannot cross capillary walls).

7%

Plasma **Plasma Proteins** 1% **Other Solutes** 55% (Range 46-63%) 92% Water consists of ÷ Formed Elements **Platelets** <.1% 45% White Blood Cells (Range 37-54%) **Red Blood Cells** <.1% Formed elements are blood cells and cell fragments that are suspended in plasma. These elements account for about 45 percent The hematocrit of the volume of whole blood. Three types of 99.9% (he-MAT-ō-krit) is the formed elements exist: platelets, white blood cells, and red blood cells. Formed elements are percentage of whole produced through the process of hemopoiesis blood volume occupied (hēm-ō-poy-Ē-sis), also called hematopoiesis. by red blood cells. The Two populations of stem cells – myeloid stem normal hematocrit range for adult cells and lymphoid stem cells-are responsible for males is 40 to 54%, and for adult females the production of formed elements. is 37 to 47%. The sex difference primarily reflects the fact that androgens (male hormones) stimulate red blood cell production, whereas estrogens (female

IMFNTS

hormones) do not.

Plasma Proteins

Plasma proteins are in solution (dissolved) rather than forming insoluble fibers like those in other connective tissues, such as loose connective tissue or cartilage. On average, each 100 mL of plasma contains 7.6 g of protein, almost five times the concentration in interstitial fluid. The large size and globular shapes of most blood proteins prevent them from crossing capillary walls, so they remain trapped within the bloodstream. The liver synthesizes and releases more than 90% of the plasma proteins. These include all albumins, fibrinogen, and most globulins.

Albumins

(al-BŪ-minz) make up roughly 60% of the plasma proteins. As the most abundant plasma proteins, they are major contributors to the osmotic pressure of plasma.

Globulins

(GLOB-ū-linz) account for approximately 35% of the proteins in plasma. Important plasma globulins include antibodies and transport globulins. Antibodies, also called immunoglobulins (i-mū-nō-GLOB-ū-linz), attack foreign proteins and pathogens. Transport globulins bind small ions, hormones, and other compounds.

Electrolytes:

Normal extracellular ion composition is essential for vital cellular activities. The major plasma electrolytes are Na⁺, K⁺, Ca²⁺, Mg²⁺, Cl⁻, HCO3⁻, HPO4⁻, and SO₄2-.

Fibrinogen

(fī-BRIN-ō-jen) functions in clotting, and normally accounts for roughly 4% of plasma proteins. Under certain conditions, fibrinogen molecules interact, forming large, insoluble strands of fibrin (FI-brin) that form the basic framework for a blood clot.

> Plasma also contains enzymes and hormones whose concentrations vary widely.

Organic Wastes:

Waste products are carried to sites of breakdown or excretion. Examples of organic wastes include urea, uric acid. creatinine. bilirubin. and ammonium ions.

Other Solutes

Other solutes are generally present in concentrations similar to those in the interstitial fluids. However, because blood is a transport medium there may be differences in nutrient and waste product concentrations between arterial blood and venous blood.

Nutrients: Organic nutrients are used for ATP production, growth, and maintenance of cells. This category includes lipids (fatty acids, cholesterol, glycerides), carbohydrates (primarily glucose), amino acids, and vitamins.

Organic

Platelets

Platelets are small, membrane-bound cell fragments that contain enzymes and other substances important to clotting.

White Blood Cells

White blood cells (WBCs), or leukocytes (LOO-kō-sīts; leukos, white + -cyte, cell), participate in the body's defense processes. There are five classes of leukocytes, each with slightly different functions that will be explored later in the chapter.

Eosinophils

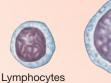

Neutrophils

Monocytes

Red blood cells (RBCs), or erythrocytes (e-RITH-ro-sits; erythros, red + -cyte, cell), are the most abundant blood cells. These specialized cells are essential for the transport of oxygen in the blood.

(a soluble protein) to fibrin (an insoluble protein) will take place. This conversion removes the clotting proteins, leaving a fluid known as **serum**.

The liver synthesizes more than 90 percent of the plasma proteins, including all albumins and fibrinogen and most globulins. For this reason, liver disorders can alter the composition and functional properties of the blood. For example, some forms of liver disease can lead to uncontrolled bleeding due to the inadequate synthesis of fibrinogen and other plasma proteins involved in clotting.

CHECKPOINT

- 4. List the three major types of plasma proteins.
- **5.** What would be the effects of a decrease in the amount of plasma proteins?

See the blue Answers tab at the back of the book.

11-3 Red blood cells, formed by erythropoiesis, contain hemoglobin that can be recycled

Learning Outcome List the characteristics and functions of red blood cells, describe the structure and function of hemoglobin, describe how red blood cell components are recycled, and explain erythropoiesis.

Red blood cells (RBCs), or **erythrocytes**, account for 99.9 percent of the formed elements. RBCs give whole blood its deep red color because they contain the red pigment *hemoglobin*, which binds and transports oxygen and carbon dioxide.

Abundance of Red Blood Cells

Roughly one-third of all cells in the human body are RBCs. A standard blood test reports the number of RBCs per microliter (μ L) of whole blood as the *red blood cell count*. In adult males, 1 microliter, or 1 cubic millimeter (mm³), of whole blood contains roughly 5.4 million RBCs. In adult females, 1 microliter contains about 4.8 million. A single drop of whole blood contains some 260 million RBCs. The blood of an average adult has 25 trillion RBCs.

The *hematocrit* (*hemato*, blood and *krino*, separate) is the percentage of whole blood volume occupied by red blood cells (**Spotlight Figure 11-1**). The hematocrit is measured after a sample of blood has been spun in a centrifuge to make all the formed elements come out of suspension. After centrifugation, three layers can be seen: (1) plasma, forming the top layer, (2) a very thin, off-white *buffy coat* middle layer composed of white blood cells and platelets, and (3) a thick bottom layer of packed

red blood cells. The hematocrit is calculated by comparing the height of the RBC layer to the height of the whole blood sample. The hematocrit closely approximates the volume of the formed elements because whole blood contains roughly 1000 red blood cells for each white blood cell.

Many conditions can affect the hematocrit. The hematocrit increases, for example, during dehydration (when plasma volume is reduced) or after *erythropoietin* (*EPO*) stimulation. **Dp**. 397 The hematocrit decreases as a result of internal bleeding or problems with RBC formation. So, the hematocrit alone does not provide specific diagnostic information. However, a change in hematocrit is an indication that more specific tests are needed.

Structure of RBCs

Red blood cells are specialized to transport oxygen and carbon dioxide within the bloodstream. As **Figure 11-2** shows, each RBC is a biconcave disc with a thin central region and a thick outer margin. This unusual shape gives each RBC a relatively large surface area to volume ratio, which increases the rate of diffusion between the cytoplasm and the surrounding plasma. A flexible cell membrane enables RBCs to bend and squeeze through narrow capillaries.

A red blood cell is very different from the "typical cell" we discussed in Chapter 3. During their formation, RBCs lose most of their organelles, including nuclei, ribosomes, and mitochondria. They retain only the cytoskeleton. Without a nucleus or ribosomes, circulating RBCs can neither divide nor synthesize structural proteins or enzymes. As a result, the RBCs cannot make repairs, so their life span is relatively short—only about 120 days.

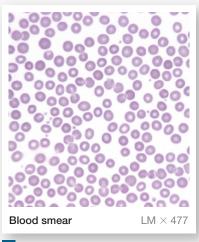

With few organelles and no way to synthesize proteins, their energy demands are low. Without mitochondria, RBCs obtain the energy they need through anaerobic metabolism, relying on glucose absorbed from the surrounding plasma. This characteristic makes RBCs relatively inefficient in terms of energy use. However, it ensures that absorbed oxygen will be carried to peripheral tissues, not "stolen" by mitochondria in the cytoplasm.

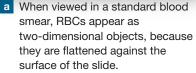

Hemoglobin Structure and Function

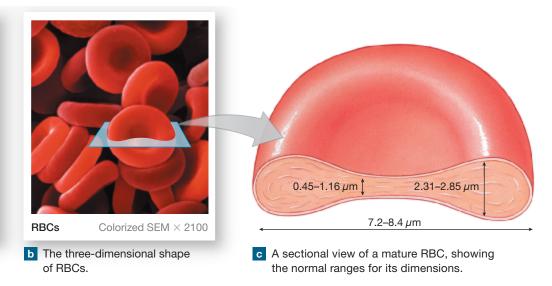

A mature red blood cell consists of a cell membrane enclosing a mass of transport proteins. Molecules of **hemoglobin** (HĒ-mō-glō-bin) **(Hb; Hgb)** account for over 95 percent of an RBC's intracellular proteins. Hemoglobin is responsible for the cell's ability to transport oxygen and carbon dioxide.

Hemoglobin molecules have a complex quaternary structure. A hemoglobin molecule consists of four globular protein subunits, arranged in two pairs. The members of each pair are

Figure 11-2 The Anatomy of Red Blood Cells.

composed of slightly different polypeptide chains. \bigcirc p. 74 Each of the four globular subunits includes a single molecule of an organic pigment called **heme**. A heme molecule holds an iron ion in such a way that it can interact with an oxygen molecule (O₂). The iron–oxygen interaction is very weak, and the two can easily separate. RBCs containing hemoglobin with bound oxygen give blood a bright red color. When oxygen is not bound to hemoglobin, the RBCs give blood a dark red, almost burgundy, color.

The amount of oxygen bound in each RBC depends on the conditions in the surrounding plasma. When oxygen is abundant in the plasma, hemoglobin molecules gain oxygen until all their heme molecules are occupied. As plasma oxygen levels decline, plasma carbon dioxide levels are usually rising. Under these conditions, heme molecules release their oxygen, and the globin portions of each hemoglobin molecule begins to bind carbon dioxide molecules in a process that is just as reversible as the binding of oxygen to heme.

As red blood cells circulate, they are exposed to varying concentrations of oxygen and carbon dioxide. At the lungs, diffusion brings oxygen into the plasma and removes carbon dioxide. The hemoglobin molecules in RBCs respond by absorbing oxygen and releasing carbon dioxide. In peripheral tissues, active cells consume oxygen and produce carbon dioxide. As blood flows through these areas, the situation is reversed. Oxygen diffuses out of the plasma, and carbon dioxide diffuses in. Under these conditions, hemoglobin releases its bound oxygen and binds carbon dioxide. Normal activity levels can be sustained only when tissue oxygen levels are kept within normal limits. The blood of a person who has a low hematocrit, or whose RBCs have a reduced hemoglobin content, has a reduced oxygen-carrying capacity. This condition is called **anemia**. Symptoms of anemia include premature muscle fatigue, weakness, and a general lack of energy.

RBC Life Span and Circulation

RBCs are exposed to severe physical stresses. A single roundtrip from the heart, through the peripheral tissues, and back to the heart takes less than a minute. In that time, an RBC is forced along vessels where it bounces off the walls, collides with other red blood cells, and is squeezed through tiny capillaries. With all this wear and tear and no capacity for repair, either its plasma membrane ruptures or some other damage occurs.

Phagocytes of the spleen, liver, or red bone marrow detect the damage and engulf the RBC. The elimination of RBCs usually goes unnoticed because new ones enter the circulation at a comparable rate. About 1 percent of the circulating RBCs are replaced each day, and approximately 3 million new RBCs enter the circulation each second!

Hemoglobin Recycling

Most of the components of red blood cells are recycled, including their hemoglobin. Macrophages (phagocytic

Build Your Knowledge

Recall that phagocytosis is a process in which solid, extracellular materials are packaged into a vesicle for transport into a cell (as you saw in **Chapter 3: Cell Structure and Function**). Phagocytosis is also called "cell eating." Large particles are brought into the cell as cytoplasmic extensions (pseudopodia) surround and engulf the particle and move it into the cell. Phagocytes are cells that perform phagocytosis. They engulf substances such as bacteria, viruses, cellular debris, and other foreign material. **`p. 98**

cells) in the spleen, liver, and red bone marrow play a role in recycling these components. These phagocytes engulf RBCs and also detect and remove hemoglobin molecules from red blood cells that rupture, or **hemolyze** (HĒ-mō-līz). Hemo-globin remains intact only inside an RBC. If the hemoglobin released by *hemolysis* is not phagocytized, it will not be recycled. Instead, this hemoglobin breaks down in the blood. The individual polypeptide chains are then filtered from the blood by the kidneys and lost in the urine. Fortunately, only about 10 percent of RBCs undergo *hemolysis* in the blood-stream. When large numbers of RBCs do break down in the blood called **hemoglobinuria**.

The recycling of hemoglobin and turnover of red blood cells is shown in **Figure 11-3**. Once a macrophage has engulfed and broken down an RBC, each part of a hemoglobin molecule has a different fate:

- 1. The four globular proteins of each hemoglobin molecule are broken apart into their component amino acids. These amino acids are either metabolized by the cell or released into the bloodstream for use by other cells.
- 2. Iron is extracted from heme molecules. It may be stored in the macrophage or released into the bloodstream, where it binds to **transferrin** (trans-FER-in), a plasma transport protein. Red blood cells developing in the red bone marrow use amino acids and transferrins from the bloodstream to synthesize new hemoglobin molecules. Excess transferrins are removed in the liver and spleen, where the iron is stored in special proteiniron complexes.
- **3.** *After being stripped of its iron, each heme molecule is converted to biliverdin* (bil-ih-VER-din). Biliverdin is an organic compound with a green color. (Bad bruises commonly appear greenish because biliverdin forms in the blood-filled tissues.) Biliverdin is then converted to **bilirubin** (bil-ih-RŪ-bin), an orange-yellow pigment, and released into the bloodstream. Liver cells absorb the bilirubin and normally release it into the small intestine within the bile. Bilirubin reaching the large intestine is converted to related pigment molecules, called *urobilins* (ūr-ō-BĪ-lins) and *stercobilins* (ster-kō-BĪ-lins). Some are absorbed into the bloodstream and excreted into urine. These bilirubin-derived pigments produce the yellow color of urine and the brown color of feces.

If the bile ducts are blocked (by gallstones, for example) or the liver cannot absorb or excrete bilirubin, its levels rise in the bloodstream. Bilirubin then diffuses into peripheral tissues, producing a combination of signs (yellow skin and eyes) called **jaundice** (JAWN-dis).

CLINICAL NOTE

Abnormal Hemoglobin

Abnormal hemoglobin characterizes several inherited disorders. Two of the best known are *thalassemia* and *sickle cell disease (SCD)*.

The various forms of **thalassemia** (thal-ah-SĒ-mē-uh) result from an inability to produce adequate amounts of the globular proteins that make up hemoglobin. This slows the rate of RBC production. The reduced oxygen-carrying capacity of the blood leads to problems in growth and development. Individuals with severe thalassemia need frequent *transfusions*—the administration of blood components—to maintain adequate numbers of RBCs.

Sickle cell disease (SCD) results from a mutation affecting the amino acid sequence of one of the two types of globular

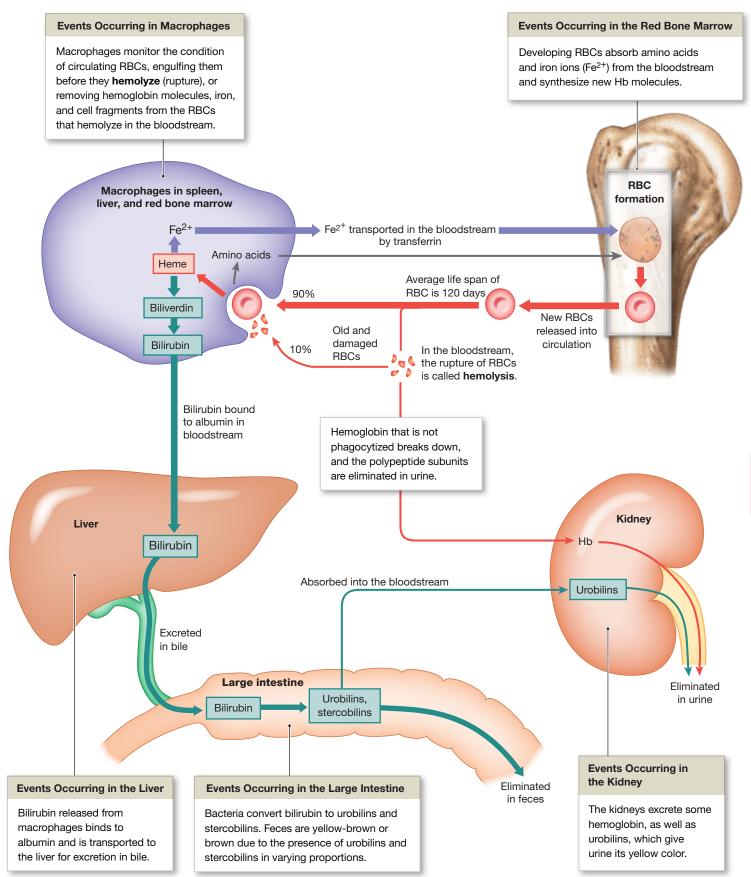

proteins of the hemoglobin molecule. When blood contains an abundance of oxygen, the hemoglobin molecules and the RBCs that carry them

appear normal. But when the defective hemoglobin gives up enough of its bound oxygen, nearby hemoglobin molecules interact and the cells become stiff and curved. This "sickling" makes the cells more fragile and easily damaged. RBCs can also become stuck in capillaries as sickling occurs. This blocks blood flow, and nearby tissues become oxygen starved.

Sickling in Red Blood Cells

Figure 11-3 Recycling of Hemoglobin.

The recycling of the components of an individual red blood cell following hemolysis or phagocytosis is a remarkably efficient process. For example, roughly 26 mg of iron are incorporated into hemoglobin molecules each day, but a dietary iron supply of 1–2 mg can keep pace with the incidental losses in the feces and urine.

Sex and Iron Reserves

Any impairment in iron uptake or metabolism can cause serious clinical problems because RBC formation will be affected. Women are especially dependent on a normal dietary supply of iron because their iron reserves are smaller than those of men. The body of a normal man contains around 3.5 g of iron (in the ionic form Fe^{2+}). Of that amount, 2.5 g is bound to the hemoglobin of circulating red blood cells. The rest is stored in the liver and red bone marrow. In women, total body iron content averages 2.4 g, with roughly 1.9 g in red blood cells. Thus, a woman's iron reserves are only 0.5 g, half that of a typical man. If dietary supplies of iron are inadequate, hemoglobin production slows, and symptoms of *iron deficiency anemia* appear.

The buildup of too much iron in the liver and in cardiac muscle tissue can also cause problems. Excessive iron in cardiac muscle cells has been linked to heart disease.

11 RBC Formation

Embryonic blood cells appear in the bloodstream during the third week of development. These cells divide repeatedly, rapidly increasing in number. The vessels of the embryonic *yolk sac* are the primary sites of blood formation for the first eight weeks of development. As other organ systems appear, some of the embryonic blood cells move out of the bloodstream and into the liver, spleen, thymus, and bone marrow. These embryonic cells differentiate into stem cells that divide to produce blood cells.

From the second to fifth months of development, the liver and spleen are the primary sites of hemopoiesis (blood cell formation and differentiation). As the skeleton enlarges, the bone marrow becomes increasingly important. In adults, red bone marrow is the only site of red blood cell production, as well as the primary site of white blood cell formation.

Red blood cell formation, or **erythropoiesis** (e-rithrō-poy-Ē-sis), takes place only in *red bone marrow*, or **myeloid tissue** (MĪ-e-loyd; *myelos*, marrow). This tissue is located in the vertebrae, sternum, ribs, scapulae, pelvis, and proximal limb bones. Other marrow areas contain a fatty tissue known as *yellow bone marrow*. Under extreme stimulation, such as a severe and sustained blood loss, areas of yellow marrow can convert to red marrow. This change increases the rate of RBC formation.

Stages in RBC Maturation

Red blood cells mature in a series of stages. Blood specialists, known as **hematologists** (hē-ma-TOL-o-jists), have named key stages. Like all formed elements, RBCs result from the divisions of **hemocytoblasts**, or **hematopoietic stem cells** (**HSCs**), in red bone marrow (Figure 11-4). In giving rise to the cells that ultimately become RBCs, the hemocytoblasts produce **myeloid stem cells**. Some of these cells develop through a series of stages to become mature erythrocytes (see left side of Figure 11-4).

Erythroblasts are very immature red blood cells that are actively synthesizing hemoglobin. After roughly four days of differentiation, each erythroblast sheds its nucleus and becomes a **reticulocyte** (re-TIK-ū-lō-sīt). After two or three more days in the red bone marrow synthesizing proteins, reticulocytes enter the bloodstream. At this time they can still be detected in a blood smear with stains that only combine with RNA. Normally, reticulocytes account for about 0.8 percent of the circulating erythrocytes. After 24 hours in circulation, the reticulocytes complete their maturation and resemble other mature RBCs.

The Regulation of Erythropoiesis

For erythropoiesis to proceed normally, the red bone marrow must have adequate supplies of amino acids, iron, and vitamins (including B_{12} , B_6 , and folic acid) for protein synthesis. We obtain **vitamin** B_{12} from dairy products and meat, but its absorption requires *intrinsic factor* produced in the stomach. Without vitamin B_{12} from the diet, normal stem cell divisions cannot take place, and *pernicious anemia* results.

Erythropoiesis is stimulated directly by the hormone erythropoietin and indirectly by several hormones, including thyroxine, androgens, and growth hormone. **Erythropoietin (EPO)**, also called *erythropoiesis-stimulating hormone*, is formed by the kidneys and liver. It appears in the plasma when peripheral tissues, especially the kidneys, are exposed to low oxygen concentrations (**Figure 11-5**). A low oxygen level in tissues is called **hypoxia** (hī-POKS-ē-uh; *hypo-*, below + *oxy-*, presence of oxygen). EPO is released (1) during anemia,

Figure 11-4 The Origins and Differentiation of Red Blood Cells, Platelets, and White Blood Cells.

Hemocytoblast divisions give rise to myeloid stem cells or lymphoid stem cells. Lymphoid stem cells produce the various lymphocytes. Myeloid stem cells produce progenitor cells that divide to produce the other classes of formed elements. The targets of erythropoietin (EPO) and colony-stimulating factors (CSFs) are also indicated.

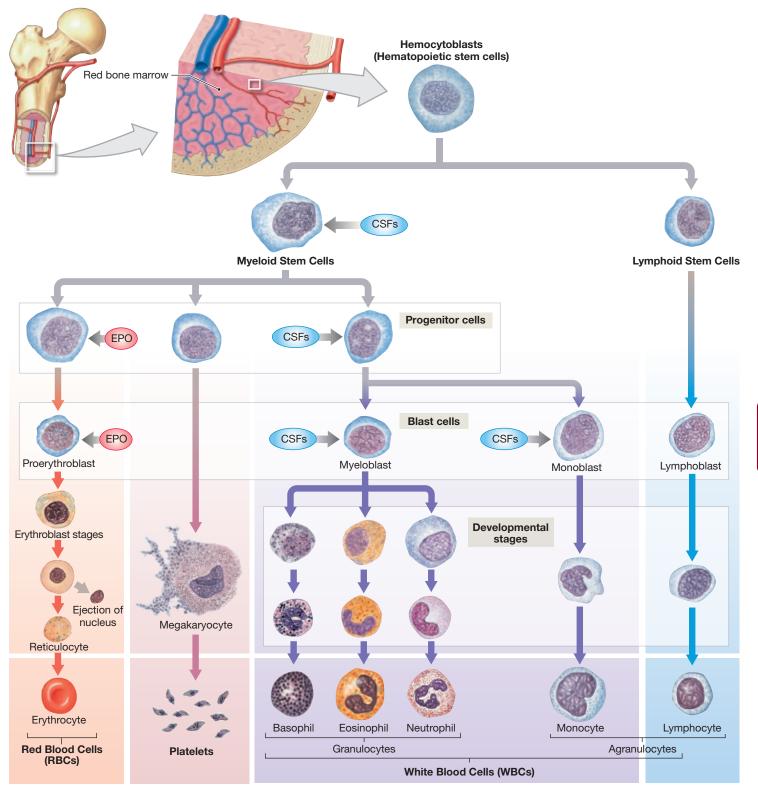

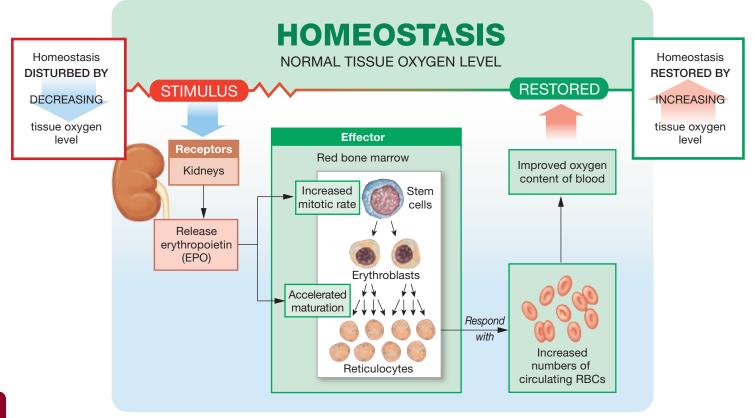

Figure 11-5 The Role of EPO in the Stimulation of Erythropoiesis. Tissues (especially the kidneys) deprived of oxygen release erythropoietin (EPO). EPO accelerates the division of stem cells and the maturation of erythroblasts. More red blood cells then enter the circulation, improving the delivery of oxygen to peripheral tissues.

11

(2) when blood flow to the kidneys declines, (3) when the oxygen content of air in the lungs declines (due to disease or high altitude), and (4) when the respiratory surfaces of the lungs are damaged. Once in the bloodstream, EPO travels to red bone marrow, where it stimulates stem cells and developing RBCs.

Erythropoietin has two major effects: (1) It stimulates increased cell division rates in erythroblasts and in the stem cells that produce erythroblasts; and (2) it speeds up the maturation of red blood cells, primarily by increasing the rate of hemoglobin synthesis. Under maximum EPO stimulation, red bone marrow can increase the rate of RBC formation tenfold, to around 30 million cells per second.

This ability is important to a person recovering from a severe blood loss. However, if EPO is administered to a healthy person, the hematocrit may rise to 65 or more. The resulting increase in blood viscosity increases the workload on the heart, which can lead to sudden death from heart failure. Similar risks result from *blood doping*, in which athletes reinfuse packed RBCs removed at an earlier date. Their goal is to improve oxygen delivery to muscles, thereby enhancing performance.

CHECKPOINT

- **6**. Describe hemoglobin.
- **7.** How would a person's hematocrit change after a significant blood loss?
- **8.** In what way would a disease that causes liver damage affect the level of bilirubin in the blood?
- **9.** Keith develops a blockage in his renal arteries that restricts blood flow to his kidneys. What effect will this have on his hematocrit?

See the blue Answers tab at the back of the book.

11-4 The ABO blood types and Rh system are based on antigen–antibody responses

Learning Outcome Discuss the factors that determine a person's blood type, and explain why blood typing is important.

Antigens are substances (most often proteins) that can trigger a protective defense process called an *immune response*. The plasma membranes of all your cells contain surface antigens, substances that your immune defenses recognize as "normal." In other words, your immune system ignores these substances rather than attacking them as "foreign."

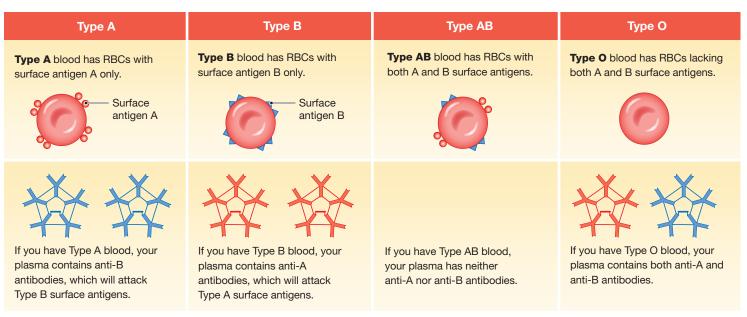

The presence or absence of specific surface antigens in RBC membranes determines your **blood type**. Your genetic makeup determines which antigens occur on your RBCs. Red blood cells have at least 50 kinds of surface antigens, but three are of particular importance: **A**, **B**, and **Rh** (or **D**).

Based on RBC surface antigens, there are four blood types (Figure 11-6a). Type A blood has antigen A only, type B has antigen B only, type AB has both A and B, and type O has neither

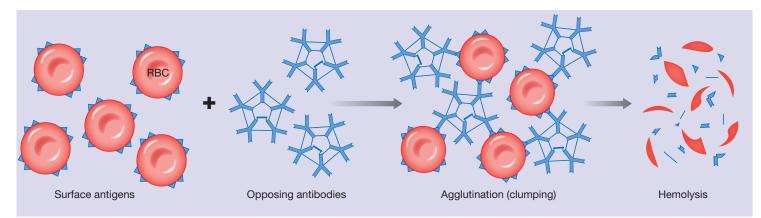

A nor B. Individuals with these blood types are not evenly distributed throughout the world. The average percentages for various populations in the United States are given in Table 11-1.

The term **Rh positive** (Rh⁺) indicates the presence of the Rh antigen on the surface of RBCs. The term **Rh negative** (Rh⁻) indicates the absence of this antigen. When an individual's complete blood type is recorded, the term *Rh* is usually omitted. The data are reported as O negative (O⁻), A positive (A⁺), and so on. In the general U.S. population, blood types are distributed approximately as follows: O⁺, 38 percent; A⁺, 34 percent; B⁺, 9 percent; O⁻, 7 percent; A⁻, 6 percent; AB⁺, 3 percent; B⁻, 2 percent; and AB⁻, 1 percent.

Figure 11-6 Blood Types and Cross-Reactions.

a Blood type depends on the presence of surface antigens (agglutinogens) on RBC surfaces. The plasma contains antibodies (agglutinins) that will react with foreign surface antigens.

b In a cross-reaction, antibodies react with their target antigens causing agglutination and hemolysis of the affected RBCs. In this example, anti-B antibodies encounter B surface antigens, which cause the RBCs bearing the B surface antigens to clump together and break up.

Cross-Reactions in Transfusions

As we noted previously, your immune system ignores the surface antigens—also called *agglutinogens* (a-glū-TIN-ō-jenz)—on your own RBCs. However, your plasma contains antibodies, or *agglutinins* (a-GLŪ-ti-ninz), that will attack surface antigens on RBCs of a different blood type (**Figure 11-6a**). That is, the plasma of individuals with type A blood contains circulating anti-B antibodies, which will attack type B surface antigens. The plasma of type B individuals contains anti-A antibodies, which will attack type A surface antigens. Similarly, type AB individuals lack antibodies against either A or B surface antigens. The plasma of type O individuals has both anti-A and anti-B antibodies.

A transfusion is the process of transferring whole blood or plasma from one person to another. The presence of plasma antibodies is why the blood types of donor and recipient are identified before a transfusion. If an individual receives blood of a different blood type, antibodies in the recipient's plasma meet their specific antigen on the donated RBCs, and a cross-reaction occurs (Figure 11-6b). Initially the binding of antigens and antibodies causes the foreign RBCs to clump together—a process called **agglutination** (a-gloo-ti-NĀ-shun). Then the RBCs may break up, or *hemolyze*. Clumps and fragments of RBCs under attack from antibodies form drifting masses that can plug small blood vessels in the kidneys, lungs, heart, or brain, damaging or destroying tissues. Such cross-reactions, or transfusion reactions, can be avoided by ensuring that the blood types of donor and recipient are compatible.

In practice, the surface antigens on the donor's cells are more important in determining compatibility than are the antibodies in the donor's plasma. Unless large volumes of whole blood or plasma are transferred, cross-reactions between the donor's plasma and the recipient's blood cells will fail to produce significant agglutination. Packed RBCs, with a minimal amount of plasma, are commonly transfused. Even when whole blood is transfused, the plasma is diluted through mixing with the recipient's relatively large plasma volume.

Unlike the case for type A and type B individuals, the plasma of an Rh-negative individual does not normally contain anti-Rh antibodies. These antibodies are present only if the individual has been *sensitized* by previous exposure to Rh-positive

CLINICAL NOTE

Hemolytic Disease of the Newborn

Genes from both parents determine the surface antigens on a person's RBCs. For this reason, a child's blood type can differ from that of either parent. During pregnancy, when fetal and maternal circulatory systems are closely intertwined, the mother's antibodies may cross the placenta, attack-ing and destroying fetal RBCs. The resulting condition is called **hemolytic disease of the newborn (HDN)**. Some forms are quite dangerous and others so mild as to remain undetected.

The sensitization that causes HDN usually takes place during delivery. Bleeding at

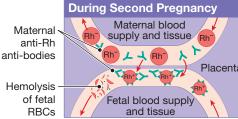

the placenta and uterus exposes an Rh-negative mother to an Rh-positive fetus's Rh antigens. This event can trigger the production of anti-Rh antibodies in the mother. The first Rh-positive infant is not affected because these antibodies are not produced in large amounts until after delivery. However, a sensitized Rh-negative mother will produce mas-

Second Pregnancy Maternal blood supply and tissue Placenta Placenta Maternal blood supply and tissue Placenta Supply and tissue Supp

the mother's anti-Rh antibody production. This is done by administering such antibodies (under the name RhoGAM) to the mother in weeks 26–28 of pregnancy and during and

after delivery. These antibodies destroy any fetal RBCs that cross the placenta before they can stimulate a maternal immune response.

11

RBCs. Such exposure can occur accidentally, during a transfusion. It can also occur in a normal pregnancy when an Rh-negative mother carries an Rh-positive fetus.

Testing for Blood Compatibility

Testing for blood compatibility normally involves two steps: (1) a determination of blood type, and (2) a *cross-match test*. The standard test for blood type categorizes a blood sample on the basis of the three RBC surface antigens most likely to produce dangerous cross-reactions (**Figure 11-7**). The test involves mixing drops of blood with solutions containing anti-A, anti-B, and anti-Rh antibodies and noting any cross-reactions.

For example, if the RBCs clump together when exposed to anti-A and anti-B, the individual has type AB blood. If no reactions take place, the person must be type O. The presence or absence of the Rh antigen is also noted, and the individual is classified as Rh-positive or Rh-negative. In the most common type—type O-positive (O^+)—the RBCs lack surface antigens A and B, but they do have the Rh antigen. Standard blood typing of both donor and recipient can be completed in a matter of minutes.

In an emergency (such as a severe gunshot wound), a patient may require 5 *liters* or more of blood. In such cases, type O blood can be safely administered to a victim of any blood type because type O RBCs lack A and B surface antigens.

Figure 11-7 Blood Type Testing. Test results for blood samples from four individuals. Drops of blood are mixed with solutions containing antibodies to the surface antigens A, B, and Rh (D). Clumping occurs when the sample contains the corresponding surface antigen(s). The blood types of the individuals are shown at right.

Anti-A	Anti-B	Anti-Rh	Blood type
Clumping	No clumping	Clumping	A+
No clumping	Clumping	Clumping	B+
Clumping	Clumping	Clumping	AB+
No clumping	No clumping	No clumping	0-

Type O (especially O⁻) individuals are sometimes called *universal donors* because their blood cells are unlikely to produce severe cross-reactions in a recipient. Type AB individuals were once called *universal recipients* because they lack anti-A or anti-B antibodies, which would attack donated RBCs. This term is no longer used largely because reliable blood supplies and quick compatibility testing typically allow type AB blood to be given to type AB recipients.

Still, cross-reactions can occur, even to type O⁻ blood, because at least 48 other possible antigens are present. Whenever time and facilities permit, further testing is done to ensure complete compatibility. **Cross-match testing** involves exposing the donor's RBCs to a sample of the recipient's plasma under controlled conditions. Another way to avoid compatibility problems is to replace lost blood with synthetic blood substitutes, which do not contain surface antigens that can trigger a cross-reaction.

Because blood groups are inherited, blood tests are also used as paternity tests and in crime detection. Results from such tests can only prove that a particular person is *not* a certain child's father or is *not* guilty of a specific crime. It is impossible, for example, for an adult with type AB blood to be the parent of an infant with type O blood.

CHECKPOINT

- **10.** Which blood type(s) can be safely transfused into a person with type AB blood?
- **11.** Why can't a person with type A blood safely receive blood from a person with type B blood?

See the blue Answers tab at the back of the book.

11-5 The various types of white blood cells contribute to the body's defenses

Learning Outcome Categorize the various white blood cells on the basis of their structures and functions, and discuss the factors that regulate their production.

White blood cells, also known as WBCs or leukocytes, can be distinguished from RBCs by their larger size and the presence of a nucleus and other organelles. WBCs also lack hemoglobin. They help defend the body against invasion by pathogens. WBCs also remove toxins, wastes, and abnormal or damaged cells.

Traditionally, WBCs have been divided into two groups based on their appearance after staining: (1) *granulocytes* (with abundant stained "granules") and (2) *agranulocytes* (with few, if any, stained granules). This scheme is convenient but

somewhat misleading. In reality, the granules in granulocytes are secretory vesicles and lysosomes. The agranulocytes also contain vesicles and lysosomes, but they are quite small and difficult to see with a light microscope.

Typical WBCs in the circulating blood are shown in **Figure 11-8**. *Neutrophils, eosinophils,* and *basophils* are granulocytes. *Monocytes* and *lymphocytes* are agranulocytes.

A typical microliter of blood contains 5000–10,000 WBCs, compared with 4.2 to 6.3 million RBCs. Most of the WBCs in the body are located in connective tissue proper or in organs of the lymphatic system. Circulating WBCs are only a small fraction of the total WBC population.

WBC Circulation and Movement

Unlike RBCs, WBCs circulate for only a short portion of their life span. White blood cells migrate through the loose and dense connective tissues of the body. They use the bloodstream to travel from one organ to another and for rapid transportation to areas of invasion or injury. WBCs can detect the chemical signs of damage to surrounding tissues. When problems are detected, they leave the bloodstream and enter the damaged area.

Circulating WBCs have four characteristics:

- 1. All are capable of amoeboid movement. Amoeboid movement is a gliding motion due to the flow of cytoplasm into slender cellular processes extended in the direction of movement. This mobility allows WBCs to move along the walls of blood vessels and through surrounding tissues.
- All can migrate out of the bloodstream. WBCs can enter surrounding tissue by squeezing between adjacent epithelial cells in the capillary wall. This process is called emigration, or diapedesis (dī-a-pe-DĒ-sis).

- **3.** *All are attracted to specific chemical stimuli.* This characteristic, called **positive chemotaxis** (kē-mō-TAK-sis), guides WBCs to invading pathogens, damaged tissues, and other active WBCs.
- 4. Neutrophils, eosinophils, and monocytes are capable of phagocytosis. These cells can engulf pathogens, cell debris, or other materials. Neutrophils and eosinophils are sometimes called *microphages* to distinguish them from the larger macrophages in connective tissues. Macrophages are monocytes that have moved out of the bloodstream and become actively phagocytic. ⊃ p. 98

Types of WBCs

Neutrophils, eosinophils, basophils, and monocytes are part of the body's *nonspecific defenses*. A variety of stimuli activate such defenses, which do not discriminate between one type of threat and another.

Build Your Knowledge

Recall that one function of connective tissue is defense of the body (as you saw in **Chapter 4: The Tissue Level of Organization**). Connective tissue proper contains fixed (resident) and free (migrating) macrophages, or "big eater," phagocytic cells. In addition to the free macrophages, other phagocytic and antibodyproducing white blood cells move through connective tissue proper. Their numbers increase if the tissue is damaged, as does the production of antibodies. Antibodies are proteins that destroy invading microorganisms or foreign substances. **`pp. 132–133**

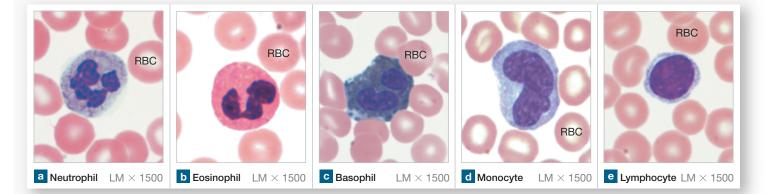

Figure 11-8 White Blood Cells.

11

Lymphocytes, in contrast, are responsible for specific defenses, which mount a counterattack against specific types of invading pathogens or foreign proteins. We discuss specific and nonspecific defenses in Chapter 14.

Neutrophils

Fifty to 70 percent of the circulating white blood cells are neutrophils (NOO-tro-filz). This name reflects the fact that their granules are chemically neutral and thus are difficult to stain with either acidic or basic dyes. A mature neutrophil has a very dense, contorted nucleus with two to five lobes resembling beads on a string (Figure 11-8a).

Neutrophils are usually the first WBCs to arrive at an injury site. They are very active phagocytes, specializing in attacking and digesting bacteria. Most neutrophils have a short life span. They survive in the bloodstream for only about 10 hours. When actively engulfing debris or pathogens, they may last 30 minutes or less. A neutrophil dies after engulfing one to two dozen bacteria, but its breakdown releases chemicals that attract other neutrophils to the site. A mixture of dead neutrophils, cellular debris, and other waste products forms the pus of infected wounds.

Eosinophils

Eosinophils (ē-ō-SIN-ō-filz) have granules that stain darkly with eosin, a red dye. They usually represent 2-4 percent of circulating WBCs. They are similar in size to neutrophils. Their deep red granules and a two-lobed nucleus make them easy to identify (Figure 11-8b). Eosinophils attack objects that are coated with antibodies. They will engulf antibody-marked bacteria, protozoa, or cellular debris, but their primary mode of attack is the exocytosis of toxic compounds. These compounds include nitric oxide and cytotoxic enzymes. These cells increase dramatically in number during a parasitic infection or an allergic reaction. Eosinophils are also attracted to sites of injury, where they release enzymes that reduce inflammation produced by mast cells and neutrophils. In this way, they help to control the spread of inflammation to nearby tissues.

Basophils

Basophils (BĀ-sō-filz) have numerous granules that stain darkly with basic dyes. In a standard blood smear, the granules are a deep purple or blue (Figure 11-8c). These cells are somewhat smaller than neutrophils or eosinophils and are relatively rare. They account for less than 1 percent of the circulating WBC population. Basophils migrate to sites of injury and cross the capillary wall into damaged tissues, where they discharge their granules into the interstitial fluids. The granules contain the chemicals heparin, which prevents blood clotting, and *histamine*, which dilates blood vessels. These chemicals enhance the local inflammation initiated by mast cells. **D** p. 144 Other chemicals released by stimulated basophils attract eosinophils and other basophils to the area.

Monocytes

Monocytes (MON-ō-sīts) are nearly twice the size of a typical erythrocyte. The nucleus is large and commonly oval or shaped like a kidney bean (Figure 11-8d). Monocytes normally account for 2-8 percent of circulating WBCs. They remain in circulation for only about 24 hours before entering peripheral tissues to become tissue macrophages. These migrating monocytes are called *free macrophages* to distinguish them from the immobile *fixed macrophages* in many connective tissues. **D** p. 133 They are aggressive phagocytes, often attempting to engulf items as large as or larger than themselves. Active monocytes release chemicals that attract and stimulate neutrophils, additional monocytes, and other phagocytes, and also draw fibroblasts to the region. The fibroblasts then begin to produce scar tissue, which walls off the injured area.

Lymphocytes

Typical lymphocytes (LIM-fō-sīts) are slightly larger than RBCs and contain a relatively large nucleus surrounded by a thin 11 halo of cytoplasm (Figure 11-8e). Lymphocytes account for 20-40 percent of the WBC population in blood. Lymphocytes migrate continuously from the bloodstream, through peripheral tissues, and back to the bloodstream. Circulating lymphocytes represent a very small fraction of the entire WBC population. At any moment, most lymphocytes are in connective tissues and in organs of the lymphatic system. They protect the body and its tissues, but they do not rely on phagocytosis. Some kinds of lymphocytes directly attack foreign cells and abnormal body cells. Others secrete antibodies into the circulation. The antibodies can attack foreign cells or proteins in distant parts of the body.

The Differential Count and Changes in WBC Abundance

A variety of disorders, including infections, inflammation, and allergic reactions, cause characteristic changes in the circulating populations of WBCs. By examining a stained blood smear, we can obtain a differential count of the WBC population. The values reported indicate the number of each type of cell in a sample of 100 WBCs.

Table 11-	Table 11-2 Formed Elements of the Blood					
	Cell	Abundance (Average number per µL)	Functions	Remarks		
0	RED BLOOD CELLS	5.2 million (range: 4.4–6.3 million)	Transport oxygen from lungs to tissues, and carbon dioxide from tissues to lungs	Remain in bloodstream; 120-day life expectancy; amino acids and iron recycled; produced in red bone marrow		
	WHITE BLOOD CELLS	7000 (range: 5000-10,000)				
C	Neutrophils	4150 (range: 1800–7300) Differential count: 50–70%	Phagocytic: Engulf pathogens or debris in tissues, release cytotoxic enzymes and chemicals	Move into tissues after several hours; survive minutes to days, depending on tissue activity; produced in red bone marrow		
	Eosinophils	165 (range: 0–700) Differential count: 2–4%	Phagocytic: Engulf antibody-labeled materials, release cytotoxic enzymes, reduce inflammation; increase in number during allergic and para- sitic situations	Move into tissues after several hours; survive minutes to days, depending on tissue activity; produced in red bone marrow		
	Basophils	44 (range: 0–150) Differential count: <1%	Enter damaged tissues and release histamine and other chemicals that promote inflammation	Survival time unknown; assist mast cells of tissues in producing inflammation; produced in red bone marrow		
	Monocytes	456 (range: 200–950) Differential count: 2–8%	Enter tissues to become macrophages; engulf pathogens or debris	Move into tissues after 1–2 days; survive months or longer; primarily produced in red bone marrow		
	Lymphocytes	2185 (range: 1500–4000) Differential count: 20–40%	Cells of lymphatic system, providing defense against specific pathogens or toxins	Survive months to decades; circulate from blood to tissues and back; produced in red bone marrow and lymphatic tissues		
	PLATELETS	350,000 (range: 150,000–500,000)	Hemostasis: Clump together and stick to vessel wall (platelet phase); activate intrinsic pathway of coagulation phase	Remain in bloodstream or in vascular organs (such as the spleen); remain intact for 7–12 days; produced by megakaryo- cytes in red bone marrow		

The normal range of abundance for each WBC type is shown in **Table 11-2**. The term **leukopenia** (loo-kō-PĒ-nēuh; *penia*, poverty) indicates reduced numbers of WBCs. **Leukocytosis** (loo-kō-sī-TŌ-sis) refers to excessive numbers of WBCs. A modest leukocytosis is normal during an infection. Extreme leukocytosis (WBC counts of 100,000/ μ L or more) generally indicates some form of **leukemia** (loo-KĒ-mē-uh), a cancer of blood-forming tissues. Only some of the many types of leukemia are characterized by leukocytosis. Other indications are the presence of abnormal or immature WBCs.

WBC Formation

Stem cells that produce WBCs originate in the red bone marrow, from the division of hemocytoblasts. Hemocytoblasts produce (1) lymphoid stem cells, which give rise to lymphocytes; and (2) myeloid stem cells, which give rise to all the other types of formed elements (**Figure 11-4**, p. 419). Granulocytes (basophils, eosinophils, and neutrophils) complete their development in myeloid (red bone marrow) tissue. Monocytes begin their differentiation in red bone marrow, enter the bloodstream, and complete development when they become free macrophages in peripheral tissues. Each of these cell types goes through a characteristic series of developmental stages.

The process of lymphocyte production is called **lymphocytopoiesis**. Many of the lymphoid stem cells responsible for the production of lymphocytes migrate from the red bone marrow to peripheral **lymphatic tissues**, including the thymus, spleen, and lymph nodes. As a result, lymphocytes are produced in these organs as well as in the red bone marrow.

Various hormones are involved in the regulation of white blood cell populations. Hormones called *colony-stimulating factors* (*CSFs*) regulate WBCs other than lymphocytes. Four CSFs have been identified. Each targets single stem cell lines or groups of stem cell lines (**Figure 11-4**, p. 419). Before a person reaches maturity, hormones from the thymus gland (thymosins) promote the differentiation of one type of lymphocyte, the *T cells*. In adults, the production of lymphocytes is regulated by exposure to antigens such as foreign proteins, cells, and toxins. When antigens appear, lymphocyte production escalates. (We describe the control processes in Chapter 14.)

CHECKPOINT

- 12. Identify the five types of white blood cells.
- **13.** Which type of white blood cell would you expect to find in the greatest numbers in an infected cut?
- **14.** Which type of cell would you expect to find in elevated numbers in a person producing large amounts of circulating antibodies to combat a virus?
- 15. How do basophils respond to an injury?
- See the blue Answers tab at the back of the book.

11-6 Platelets, disc-shaped structures formed from megakaryocytes, function in the clotting process

Learning Outcome Describe the structure, function, and production of platelets.

Platelets (PLĀT-lets) are among the formed elements. In nonmammalian vertebrates, platelets are nucleated cells called **thrombocytes** (THROM-bō-sīts; *thrombos*, clot). In humans these formed elements are cell fragments rather than individual cells. For this reason, the term *platelet* is preferred when referring to our blood.

Red bone marrow contains enormous cells with large nuclei called **megakaryocytes** (meg-a-KAR- \bar{e} - \bar{o} -s \bar{i} ts; *megas*, big + *karyon*, nucleus + -cyte, cell) (Figure 11-4). Megakary-ocytes continuously shed cytoplasm in small membrane-enclosed packets. These packets are the platelets that enter the bloodstream. Platelets initiate the clotting process and help close injured blood vessels. They play a major part in a vascular *clotting system*, detailed in the next section.

Platelets are continuously replaced. Each platelet circulates for 9–12 days before being removed by phagocytes. Each microliter of circulating blood contains 150,000-500,000 platelets. The average concentration is $350,000/\mu$ L. About one-third of the platelets in the body are in the spleen and

other blood-rich organs, rather than in the bloodstream. These reserves are mobilized during severe bleeding.

An abnormally low platelet count $(80,000/\mu L \text{ or less})$ is known as *thrombocytopenia* (throm-bō-sī-tō-PĒ-nē-uh). This condition usually results from excessive platelet destruction or inadequate platelet production. Clinical signs include bleeding along the digestive tract, within the skin, and occasionally inside the CNS. In *thrombocytosis* (throm-bō-sī-TŌ-sis), platelet counts can exceed 1,000,000/ μ L. Thrombocytosis usually results from accelerated platelet formation in response to infection, inflammation, or cancer.

CHECKPOINT

- **16.** Explain the difference between platelets and thrombocytes.
- **17.** List the primary functions of platelets.
- See the blue Answers tab at the back of the book.

11-7 Hemostasis involves vascular spasm, platelet plug formation, and blood coagulation

Learning Outcome Describe the processes that control blood loss after an injury.

Hemostasis (*haima*, blood + *stasis*, halt), the stopping of bleeding, halts the loss of blood through the walls of damaged vessels. At the same time, it establishes a framework for tissue repairs.

11

Phases of Hemostasis

Hemostasis has three overlapping phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase*. In reality, hemostasis is a complex cascade, or chain reaction. Many things happen at once, and all of them interact to some degree.

The Vascular Phase. The walls of blood vessels contain smooth muscle and an inner lining of simple squamous epithelium known as an endothelium (en-dō-THĒ-lē-um). Breaking open the wall of a blood vessel, such as by cutting, triggers a contraction in the smooth muscle fibers in the vessel wall that decreases the vessel's diameter (Figure 11-9 1). This local contraction, called a *vascular spasm*, can slow or even stop the loss of blood through the wall of a small vessel. The vascular spasm lasts about 30 minutes, a period called the vascular phase of hemostasis. The membranes of endothelial cells at the injury site also become "sticky." A tear in a small artery or vein

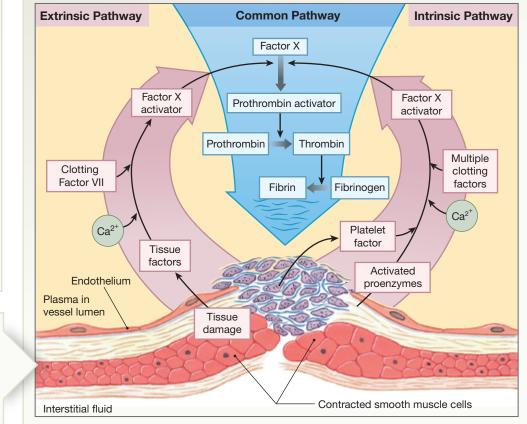

Figure 11-9 The Vascular, Platelet, and Coagulation Phases of Hemostasis.

Vascular Phase Damage to the blood vessel wall triggers a contraction of the smooth muscle fibers in the vessel wall. The damaged endothelial cells become "sticky." Knife blade Image to the blood vessel wall triggers a contraction of the smooth muscle fibers in the vessel wall. The damaged endothelial cells become "sticky." Status Vascular spasm Platelet Phase

Platelets attach to the sticky endothelial cells, to exposed collagen fibers, and to each other, forming a platelet plug.

Coagulation Phase

Coagulation, or blood clotting, involves a complex sequence of steps leading to the conversion of circulating fibrinogen into the insoluble protein fibrin.

may be partially sealed off by the attachment of endothelial cells on either side of the break. In small capillaries, the cells may stick together and block the opening completely.

- 2. The Platelet Phase. The platelets begin to attach to the sticky endothelial surfaces and exposed collagen fibers within 15 seconds of the injury (Figure 11-9 (2)). These attachments mark the start of the platelet phase of hemostasis. Platelets also stick to one another and form a mass called a *platelet plug*. The plug may close the break in the vessel wall, if the damage is not severe or occurs in a small blood vessel.
- The Coagulation Phase. The coagulation phase does not start until 30 seconds or more after the vessel has been damaged (Figure 11-9 3). Coagulation, or *blood clotting,* involves a complex sequence of steps leading to the conversion of circulating fibrinogen into the insoluble protein fibrin. As the fibrin network grows, blood cells

and additional platelets are trapped within the fibrous tangle, forming a **blood clot** that effectively seals off the damaged portion of the vessel (**Figure 11-10**).

The Clotting Process

Normal blood clotting cannot occur unless the plasma contains the necessary **clotting factors**, which include calcium ions and 11 different plasma proteins. Many of these proteins are *proenzymes* (inactive enzymes). When converted to active enzymes, they direct essential reactions in the clotting response. The liver synthesizes most of the circulating clotting proteins.

During the coagulation phase, the clotting proteins interact in sequence. One protein is converted into an enzyme that activates a second protein and so on, in a chain reaction, or *cascade*. A blood clot forms as a result of the cascades of the *extrinsic, intrinsic,* and *common pathways* (Figure 11-9 3).

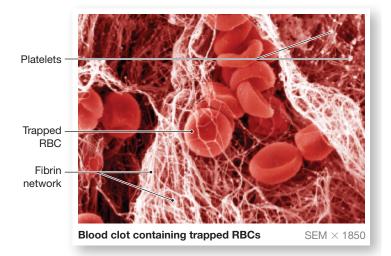

Figure 11-10 The Structure of a Blood Clot.

The extrinsic pathway begins outside the bloodstream, in the vessel wall. The intrinsic pathway begins in the bloodstream. These two pathways join at the common pathway through the activation of Factor X, a clotting protein produced by the liver.

The Extrinsic, Intrinsic, and Common Pathways

When a blood vessel is damaged, both the extrinsic and intrinsic pathways are activated. Clotting is initiated by the shorter and faster extrinsic pathway. The slower, intrinsic pathway reinforces the initial clot, making it larger and more effective.

The **extrinsic pathway** begins when damaged endothelial cells or peripheral tissues release a glycoprotein called **tissue factor**. The greater the damage, the more tissue factor is released and the faster clotting occurs. Tissue factor then combines with calcium ions and another clotting protein (Factor VII) to form an enzyme that can activate Factor X.

The **intrinsic pathway** begins with the activation of proenzymes exposed to collagen fibers at the injury site. This pathway proceeds with the assistance of a *platelet factor* released by aggregating platelets. Platelets also release a variety of other factors that speed up the reactions of the intrinsic

CLINICAL NOTE

Abnormal Hemostasis

Hemostasis involves a complex chain of events, and any disorder that affects any individual clotting factor can disrupt the entire process. As a result, managing many clinical conditions involves controlling or manipulating the clotting process.

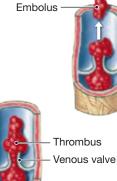

Excessive Coagulation

If the clotting process is not well controlled, clots will form in the circulation rather than at an injury site. These blood clots drift downstream until plasmin digests them or they become lodged in a small blood vessel. A drifting blood clot is a type of **embolus** (EM-bo-lus; *embolos*, plug; *emboli* plural), an abnormal mass within the blood-stream. (Other common emboli are drifting air bubbles and fat

globules.) When an embolus lodges in a blood vessel, it blocks circulation to the area downstream, killing the affected tissues. The resulting condition is called **embolism**.

An embolus in the arterial system can lodge in the capillaries in the brain, causing a tissue-damaging event known as a *stroke*. An embolus in the venous system is likely to lodge in the capillaries in the lung. There it causes a *pulmonary embolism*.

A **thrombus** is a blood clot attached to the inner surface of a vessel wall. It begins to form when platelets stick to the wall of an intact blood vessel. Often the platelets are attracted to roughened areas called *plaques*,

where endothelial and smooth muscle cells contain large quantities of lipids. The blood clot gradu-

ally enlarges, projecting into the vessel's channel (or *lumen*) and reducing its diameter. Eventually the vessel may be completely blocked, or a large chunk of the clot may break off, creating an equally dangerous embolus.

Prevention of these conditions generally includes exercises to increase blood flow and reduce pooling of blood, and pharmacologic or natural "blood thinners."

Inadequate Coagulation

Hemophilia (hē-mō-FĒL-ē-uh) is an inherited disorder characterized by the inadequate production of clotting factors. About 1 person

in 10,000 has hemophilia. Males account for 80–90 percent of those affected. In hemophilia, production of a single clotting factor (most often Factor VIII in the intrinsic clotting pathway) is inadequate. The severity of the condition depends on the degree of underproduction. In severe cases, extensive bleeding accompanies the slightest mechanical stresses and occurs spontaneously at joints and around muscles.

Transfusions of clotting factors can reduce or control the effects of hemophilia. To obtain adequate amounts of clotting factors, however, plasma samples from many individuals must be pooled (combined). This procedure makes treatment very expensive. It also increases the risk of blood-borne infections such as hepatitis or AIDS. Gene-splicing techniques have been used to manufacture Factor VIII. As methods are developed to synthesize other clotting factors, treatment of the various forms of hemophilia will become safer and cheaper. pathway. After a series of linked reactions, activated clotting proteins combine to form an enzyme that can activate Factor X.

The **common pathway** begins when enzymes from either pathway activate Factor X. Factor X then activates a complex called **prothrombin activator**. This complex converts the proenzyme **prothrombin** to the enzyme **thrombin** (THROMbin). Thrombin then completes the clotting process by converting fibrinogen to fibrin.

The thrombin formed in the common pathway also acts to increase the rate of clot formation. Thrombin stimulates the formation of tissue factor and the release of platelet factor by platelets. The presence of these factors further stimulates both the extrinsic and intrinsic pathways. This positive feedback loop accelerates the clotting process, and speed can be very important in reducing blood loss after a severe injury. \supset p. 42

Calcium ions and a single vitamin, **vitamin K**, affect almost every aspect of the clotting process. All three pathways (intrinsic, extrinsic, and common) require the presence of calcium ions, so any disorder that lowers plasma Ca²⁺ concentrations will also impair blood clotting. Adequate amounts of vitamin K must be present for the liver to synthesize four of the clotting factors (including prothrombin). For this reason, a vitamin K deficiency leads to the breakdown of the common pathway, and inactivates the clotting system. We obtain roughly half of our daily requirement of vitamin K from the diet. Bacteria in the large intestine manufacture the other half.

Clot Retraction and Removal

Once the fibrin network has appeared, platelets and red blood cells stick to the fibrin strands. During **clot retraction**, the platelets then contract, pulling the torn edges of the vessel closer together. This process also reduces the size of the damaged area, making it easier for fibroblasts, smooth muscle cells, and endothelial cells in the area to complete repairs.

As the repairs proceed, the clot gradually dissolves in a process called **fibrinolysis** (fī-bri-NOL-i-sis). The process begins when two enzymes activate the proenzyme **plasminogen** (plaz-MIN-ō-jen). These enzymes are thrombin, produced by the common pathway, and **tissue plasminogen activator**, or **t-PA**, released by damaged tissues at the site of the injury. The activation of plasminogen produces the enzyme **plasmin** (PLAZ-min), which begins digesting the fibrin strands and breaking down the clot.

CHECKPOINT

- **18.** A sample of red bone marrow has fewer than normal numbers of megakaryocytes. What body process would you expect to be impaired as a result?
- **19.** Two alternate pathways of interacting clotting proteins lead to coagulation, or blood clotting. How is each pathway initiated?
- **20.** What are the effects of a vitamin K deficiency on blood clotting (coagulation)?
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

blood bank: Place where blood is collected, typed, separated into components, stored, and prepared for transfusion to recipients. **dyscrasia:** An abnormal condition, especially of the blood. **ecchymosis:** Skin discoloration caused by the escape of blood into tissues from ruptured blood vessels.

hematology (HĒM-ah-tol-o-jē): The study of blood and its disorders.

hematuria (hē-ma-TOO-rē-uh): The presence of red blood cells in the urine.

heterologous marrow transplant: The transplantation of bone marrow from one individual to another to replace bone marrow destroyed during cancer therapy.

hypervolemic: Having an excessive blood volume. **hypovolemic:** Having a low blood volume.

normovolemic (nor-mō-vō-LĒ-mik): Having a normal blood volume.

phlebotomy (fle-BOT-o-mē): The process of withdrawing blood from a vein.

polycythemia (po-lē-sī-THĒ-mē-uh): An elevated number of red blood cells in the blood; signs include a high hematocrit and a high hemoglobin concentration.

septicemia: A dangerous condition in which bacteria and bacterial toxins are distributed throughout the body in the bloodstream.

Chapter Review

Summary Outline

An Introduction to the Cardiovascular System p. 410

1. The **cardiovascular system** enables the rapid transport of nutrients, waste products, respiratory gases, and cells within the body.

11-1 Blood has several important functions and unique physical characteristics *p. 410*

- **2. Blood** is a specialized fluid connective tissue. Its functions include (1) transporting dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulating the pH and ion composition of the interstitial fluids; (3) restricting fluid losses at injury sites; (4) defending against pathogens and toxins; and (5) regulating body temperature by absorbing and redistributing heat.
- **3.** Blood contains **plasma** and **formed elements—red blood cells (RBCs), white blood cells (WBCs),** and **platelets.** The plasma and formed elements make up whole blood, which can be **fractionated** for analytical or clinical purposes. The formed elements account for about 45% of the volume of blood. *(Spotlight Figure 11-1)*
- **4. Hemopoiesis,** or **hematopoiesis,** is the process by which all formed elements are produced. *Myeloid stem cells* and *lymphoid stem cells* divide to form all three types of formed elements.

11-2 Plasma, the fluid portion of blood, contains significant quantities of plasma proteins *p. 411*

- **5.** Plasma accounts for about 55 percent of the volume of blood. Roughly 92 percent of plasma is water. (*Spotlight Figure 11-1*)
- **6.** Compared with interstitial fluid, plasma has a higher dissolved oxygen concentration and more dissolved proteins. The three classes of plasma proteins are *albumins*, *globulins*, and *fibrinogen*.
- 7. Albumins constitute about 60 percent of plasma proteins. Globulins make up roughly 35 percent of plasma proteins. They include antibodies (immunoglobulins), which attack foreign proteins and pathogens, and transport proteins, which bind ions, hormones, and other compounds. In the clotting reaction, soluble fibrinogen molecules are converted to insoluble fibrin. The removal of clotting proteins from plasma leaves a fluid called serum.

11-3 Red blood cells, formed by erythropoiesis, contain hemoglobin that can be recycled *p. 414*

8. Red blood cells (**RBCs**), or **erythrocytes**, account for slightly less than half of the blood volume and 99.9 percent

of the formed elements. The **hematocrit** value is the percentage of red blood cells within whole blood. (Spotlight Figure 11-1)

- **9.** RBCs transport oxygen and carbon dioxide within the bloodstream. They are highly specialized cells with a large surface area to volume ratio and a flexible cell membrane. They lack many organelles and usually degenerate after 120 days in the bloodstream. (*Figure 11-2*)
- **10.** Molecules of **hemoglobin (Hb)** account for over 95 percent of RBC proteins. Hemoglobin is a globular protein formed from four subunits. Each subunit contains a single molecule of **heme.** Each heme has an iron atom that can reversibly bind an oxygen molecule. Phagocytes recycle hemoglobin from damaged or dead RBCs. (*Figure 11-4*)
- 11. Erythropoiesis, the formation of RBCs, occurs mainly in the red bone marrow (myeloid tissue) in adults. RBC formation increases under stimulation by erythropoietin (EPO), or erythropoiesis-stimulating hormone. EPO release occurs when peripheral tissues, especially the kidneys, are exposed to low oxygen concentrations. Stages in RBC development include erythroblasts and reticulocytes. (*Figures 11-4, 11-5*)

11-4 The ABO blood types and Rh system are based on antigen–antibody responses *p. 420*

12. Blood type is determined by the presence or absence of three specific **surface antigens** (*agglutinogens*) in the plasma membranes of RBCs: antigens A, B, and Rh (D). Antibodies (*agglutinins*) in the plasma of individuals of some blood types can react with surface antigens on the RBCs of different blood types. Anti-Rh antibodies are synthesized only after an Rh-negative individual becomes sensitized to the Rh surface antigen. (*Figures 11-6, 11-7; Table 11-1*)

11-5 The various types of white blood cells contribute to the body's defenses *p. 423*

- **13. White blood cells (WBCs)**, or **leukocytes**, defend the body against pathogens and remove toxins, wastes, and abnormal or damaged cells.
- 14. White blood cells exhibit amoeboid movement, emigration or diapedesis (the ability to move through vessel walls), and positive chemotaxis (an attraction to specific chemicals). Some WBCs are phagocytic.

- 15. Granulocytes (granular leukocytes) are neutrophils, eosinophils, and basophils. Fifty to 70 percent of circulating WBCs are neutrophils, which are highly mobile phagocytes. The much less common eosinophils are phagocytes attracted to foreign substances that have reacted with circulating antibodies. Their primary mode of attack is the exocytosis of toxic compounds. The relatively rare basophils migrate to damaged tissues and release histamine and heparin, aiding the inflammation response. (Figure 11-8; Table 11-2)
- 16. Agranulocytes (agranular leukocytes) are monocytes and lymphocytes. Monocytes that migrate into peripheral tissues become free macrophages. Most lymphocytes are in the tissues and organs of the lymphatic system, where they function in the body's specific defenses. Different classes of lymphocytes attack foreign cells directly, produce antibodies, and destroy abnormal body cells. (Figure 11-8; Table 11-2)
- 17. Granulocytes and monocytes are produced by myeloid stem cells in the red bone marrow. Lymphoid stem cells responsible for lymphocytopoiesis (production of lymphocytes) also originate in the bone marrow, but many migrate to lymphatic tissues. (Figure 11-4)
- 18. Various hormones are involved in regulating WBC populations. Colony-stimulating factors (CSFs) are hormones that regulate WBC populations other than lymphocytes. (Figure 11-4)

11-6 Platelets, disc-shaped structures formed from megakaryocytes, function in the clotting process p. 427

19. Megakaryocytes in the red bone marrow release packets of cytoplasm (platelets) into the circulating blood. Platelets are essential to the clotting process. (Figure 11-4; Table 11-2)

11-7 Hemostasis involves vascular spasm, platelet plug formation, and blood coagulation p. 427

- 20. Hemostasis prevents the loss of blood through the walls of damaged vessels.
- 21. The initial step of hemostasis, the vascular phase, is a period of local contraction of vessel walls resulting from a vascular spasm at the injury site. The platelet phase follows as platelets stick to damaged surfaces. The third phase of hemostasis is the **coagulation phase**. (Figure 11-9)
- 22. The coagulation phase occurs as factors released by platelets and endothelial cells interact with clotting factors (through either the extrinsic pathway, the intrinsic pathway, or the common pathway) to form a blood clot. (Figures 11-9, 11-10)
- **23.** During **clot retraction**, platelets contract, pulling the torn edges of a damaged blood vessel closer together. During fibrinolysis, the clot gradually dissolves through the action of **plasmin**, the activated form of circulating plasminogen.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A COLUMN B 1. interstitial fluid 2. hemopoiesis **b.** hemocytoblasts c. abundant WBCs **3.** stem cells **4.** hypoxia d. agglutinogens e. neutrophil **5.** surface antigens 6. antibodies f. WBC migration **7.** diapedesis g. extracellular fluid _____ 8. leucopenia

- _____ 9. agranulocyte
- _____ **10.** leukocytosis
- _____ **11.** granulocyte
- **12.** thrombocytopenia **I.** process of blood cell

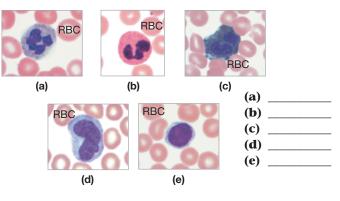

- a. low oxygen concentration

- **h.** monocyte
- i. few WBCs
- **i.** low platelet count
- **k.** agglutinins
- formation

See the blue Answers tab at the back of the book.

(b) pancreas

- **13.** The _____ is the organ that produces most of the plasma proteins in the blood.
 - (a) liver (c) small intestine
 - (d) stomach
- **14.** Erythropoietin is
 - (a) a hormone that stimulates the production of monocytes.
 - (b) a hormone that stimulates the production of red blood cells.
 - (c) a plasma protein that carries triglycerides.
 - (d) a plasma protein that carries steroid hormones.
- **15.** Identify the five types of white blood cells in the following micrographs.

11

- **16.** Unlike adults, the primary sites of hematopoiesis in the fetus between the second and fifth months of development are the (a) liver and spleen. (b) scapulae and pelvis. (c) sternum and ribs. (d) vertebrae. **17.** Binding of oxygen to is the main mechanism by which oxygen is carried in the bloodstream. (a) albumin (**b**) fibrinogen (c) hemoglobin (d) immunoglobulins 18. The main types of proteins found in circulating plasma do not include (a) albumins. (b) antibodies.
- (c) fibrin.
 (d) transport globulins.
 19. When erythrocytes are formed, they lose most of their organelles *except* the
 (a) cytoskeleton.
 (b) mitochondria.
- (c) nuclei. (d) ribosomes.
- **20.** Myeloblasts are the precursors of
- (a) erythrocytes.(b) lymphocytes.(c) monocytes.(d) neutrophils.
- **21.** Universal donors are people with blood type
 - (a) A. (b) B.
 - (c) AB. (d) O.
- **22.** Myeloid stem cells give rise to different types of white blood cells *except*
 - (a) basophils. (b) lymphocytes.
 - (c) monocytes. (d) neutrophils.
- **23.** Name the three major types of plasma proteins and identify their functions.
- **24.** What type(s) of antibodies does the plasma contain for each of the following blood types?
 - **(a)** type A **(b)** type B
 - (c) type AB (d) type O
- **25.** What four characteristics of WBCs are important to their response to tissue invasion or injury?
- **26.** What contribution from the intrinsic and/or extrinsic pathways is necessary for the common pathway to begin?
- **27.** Distinguish between an embolus and a thrombus.

Level 2 Reviewing Concepts

- **28.** To prevent excessive bleeding, hemostasis involves
 - (a) blood coagulation followed by formation of a platelet plug.
 - (b) blood coagulation followed by vascular spasm.
 - (c) formation of a platelet plug followed by vascular spasm.
 - (d) vascular spasm followed by formation of a platelet plug.
- **29.** EPO is released when
 - (a) tissues' levels of oxygen are low.
 - **(b)** tissues are deprived of carbon dioxide.
 - (c) there is a high number of red blood cells in circulation.
 - (d) tissues' levels of oxygen are high.

- **30.** A person with type A blood has
 - (a) anti-A antibodies in the plasma.
 - **(b)** B antigens in the plasma.
 - (c) A antigens on red blood cells.
 - (d) anti-B antibodies on red blood cells.
- **31.** Hemolytic disease of the newborn can result if
 - (a) the mother is Rh-positive and the father is Rh-negative.
 - **(b)** both the father and the mother are Rh-negative.
 - (c) both the father and the mother are Rh-positive.
 - (d) an Rh-negative woman carries an Rh-positive fetus.
- **32.** How is the biconcave structure of a red blood cell related to its function?

Level 3 Critical Thinking and Clinical Applications

- **33.** A 25-year-old man who had lost a significant amount of blood due to a stab wound was rushed to a hospital. After running some tests, his doctor found that the hematocrit of the patient was within the normal range. One day later, after stabilizing his condition and putting him on a continuous intravenous infusion of normal saline, it was noted that his hematocrit had fallen. How could this be explained?
- **34.** Why do many individuals with advanced kidney disease become anemic?
- **35.** In the disease mononucleosis ("mono"), the spleen enlarges because of increased numbers of phagocytes and other cells. Common signs and symptoms of this disease include pale complexion, a tired feeling, and a lack of energy sometimes to the point of not being able to get out of bed. What might cause each of these signs and symptoms?

Hemoglobin: Function and Impact

The Cardiovascular System: The Heart

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **12-1** Describe the anatomy of the heart, including blood supply and pericardium structure, and trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves.
- **12-2** Explain the events of an action potential in cardiac muscle, describe the conducting system of the heart, and identify the electrical events recorded in a normal electrocardiogram.
- **12-3** Explain the events of the cardiac cycle, and relate the heart sounds to specific events in this cycle.
- **12-4** Define cardiac output, describe the factors that influence heart rate and stroke volume, and explain how adjustments in stroke volume and cardiac output are coordinated at different levels of physical activity.

Clinical Notes Heart Valve Disorders, p. 442 Abnormal Conditions Affecting Cardiac Output, p. 453

Spotlight The Heart: Internal Anatomy and Blood Flow, p. 441

The Heart's Role in the Cardiovascular System

Our body cells rely on the surrounding interstitial fluid for oxygen, nutrients, and waste disposal. Conditions in the interstitial fluid are kept stable through continuous exchange between the peripheral tissues and circulating blood. If the blood stops moving, its oxygen and nutrient supplies are quickly exhausted. Its capacity to absorb wastes is soon saturated, and neither hormones nor white blood cells can reach their targets. Thus, all cardiovascular functions ultimately depend on the heart. This muscular organ beats approximately 100,000 times each day. It pumps roughly 8000 liters of blood—enough to fill forty 55-gallon drums, or nearly 8500 quart-sized milk cartons. Despite its impressive workload, the heart is a small organ, about the size of a clenched fist.

Blood flows through a network of blood vessels that extend between the heart and peripheral tissues. Those blood vessels make up two circuits. The **pulmonary circuit** carries blood to and from the gas exchange surfaces of the lungs. The **systemic circuit** transports blood to and from the rest of the body (**Figure 12-1**). Each circuit begins and ends at the heart, and blood travels through them in sequence. Thus, blood returning to the heart from the systemic circuit must complete the pulmonary circuit before re-entering the systemic circuit. **Arteries**, or *efferent* vessels, carry blood away from the heart. **Veins**, or *afferent* vessels, return blood to the heart. **Capillaries** are small, thin-walled vessels between the smallest arteries and the smallest veins. Their thin walls permit the exchange of nutrients, dissolved gases, and wastes between the blood and surrounding tissues.

The heart contains four muscular chambers. Two are associated with each circuit. The **right atrium** (Ā-trē-um; entry chamber; plural, *atria*) receives blood from the systemic circuit, and passes it to the **right ventricle** (VENtri-kl; little belly), which then pumps blood into the pulmonary circuit. The **left atrium** collects blood from the pulmonary circuit, and empties it into the **left ventricle**, which pumps blood into the systemic circuit. When the heart beats, the two atria contract together first, then the ventricles. The two ventricles contract at the same time. They eject equal volumes of blood into the pulmonary and systemic circuits.

We begin this chapter by examining the structural features that enable the heart to perform so reliably. We then consider the physiological processes that regulate the activities of the heart to meet the body's ever-changing needs.

Build Your Knowledge

Recall that the cardiovascular system was our example organ system when we examined the relationships among the various levels of organization of the human body (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). Contractile proteins and their atoms represent the chemical level. Cardiac cells containing those proteins represent the cellular level. Cardiac tissue made up of cardiac cells represent the tissue level. The heart containing cardiac tissue and other tissues represents the organ level. The heart, blood, and blood vessels represent the organ system level. **Dpp. 35, 38**

12-1 The heart is a four-chambered organ, supplied by coronary circulation, that pumps oxygen-poor blood to the lungs and oxygen-rich blood to the rest of the body

Learning Outcome Describe the anatomy of the heart, including blood supply and pericardium structure, and trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves.

The heart is located near the anterior chest wall, directly behind the sternum (Figures 12-2a, 12-3a). It sits in the anterior

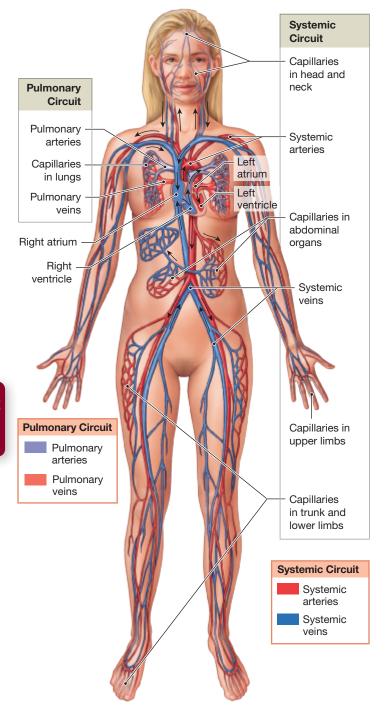

portion of the *mediastinum*, the connective tissue mass between the two pleural cavities (see **Figure 1-10c**, p. 48). The mediastinum also contains the *great vessels* (the largest arteries and veins in the body), thymus, esophagus, and trachea.

The **pericardium** (pehr-ih-KAR-dē-um) surrounds the heart and consists of an outer *fibrous pericardium* and an inner *serous pericardium*. The fibrous pericardium contains a dense network of collagen fibers that stabilize the position of the heart and associated vessels within the mediastinum.

The lining of the pericardium is called the **serous pericardium**. **D p**. 141 This two-layered membrane is

Figure 12-1 An Overview of the Cardiovascular

System. Driven by the pumping of the heart, blood flows through separate pulmonary and systemic circuits. Each circuit begins and ends at the heart and contains arteries, capillaries, and veins.

composed of an outer **parietal layer** and an inner **visceral layer**. The visceral layer of the serous membrane is also known as the *epicardium*. The potential, fluid-filled space between these two serous layers is the **pericardial cavity**. To visualize the relationship between the heart and the pericardial cavity, imagine pushing your fist toward the center of a large balloon (Figure 12-2b). The balloon represents the serous pericardium, and your fist represents the heart. Your wrist, where the balloon folds back on itself, corresponds to the **base** of the heart (Figure 12-2a). The air space inside the balloon corresponds to the pericardial cavity.

The pericardial cavity normally contains a small quantity (15–50 mL, or 0.5–1.7 oz) of *pericardial fluid* secreted by the pericardial (serous) membranes. The fluid acts as a lubricant, reducing friction between the opposing surfaces as the heart beats.

The Surface Anatomy of the Heart

We can use several external features of the heart to identify its four chambers (**Figure 12-3b,c,d**). The two atria have relatively thin muscular walls and are highly expandable. When not filled with blood, the outer portion of each atrium deflates into a lumpy, wrinkled flap. This expandable extension of an atrium is called an **auricle** (AW-ri-kl; *auris*, ear). The **coronary sulcus**, a deep groove, marks the border between the atria and the ventricles. Shallower depressions—the **anterior interventricular sulcus** and **posterior interventricular sulcus**—mark the boundary between the left and right ventricles. Substantial amounts of fat generally lie within these three sulci (SUL-sī). In addition to fat, they also contain the major arteries and veins that carry blood to and from the cardiac muscle.

The great vessels are connected to the superior base of the heart. The inferior, pointed tip of the heart is the **apex** (\bar{A} -peks) (**Figure 12-3a**). A typical heart measures approximately 12.5 cm (5 in.) from the attached base to the apex.

The heart sits at an angle to the longitudinal axis of the body. It is also rotated slightly toward the left, so the anterior surface primarily consists of the right atrium and right ventricle (**Figure 12-3a,b,c**). The wall of the left ventricle forms much of the posterior surface between the base and the apex of the heart (**Figure 12-3d**).

The Heart Wall

The wall of the heart contains three distinct layers: an outer epicardium, a middle myocardium, and an inner endocardium (**Figure 12-4a**). The **epicardium** is the visceral layer that covers the outer surface of the heart. This

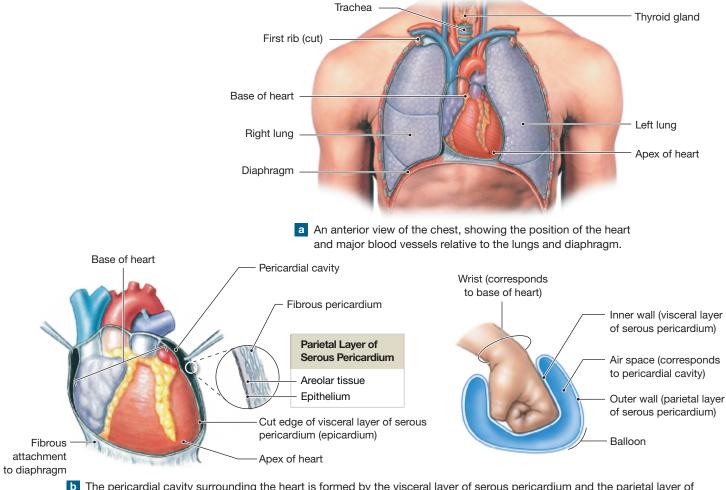

Figure 12-2 The Location of the Heart in the Thoracic Cavity.

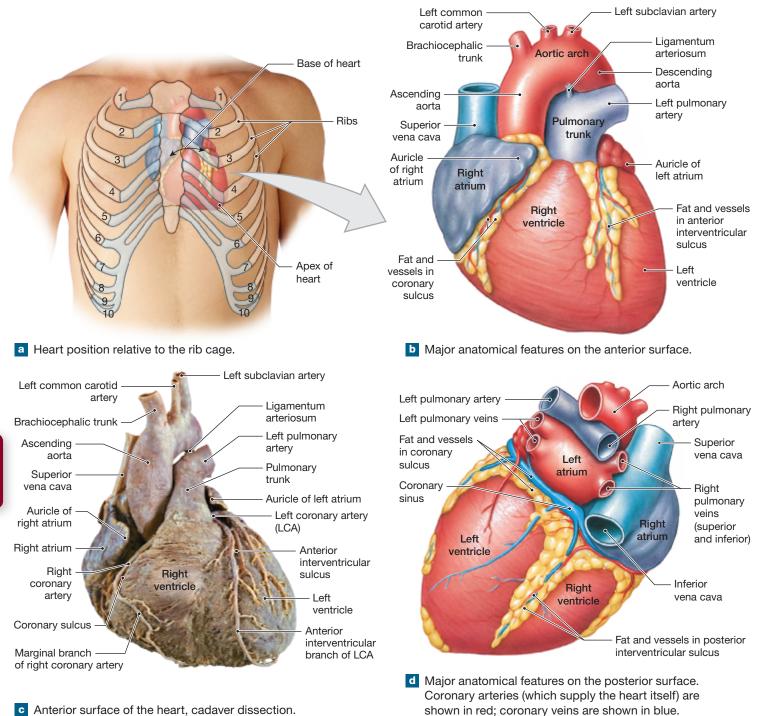

serous membrane consists of an exposed epithelium and an underlying layer of areolar tissue that is attached to the myocardium. The myocardium, or muscular wall of the heart, contains cardiac muscle tissue, blood vessels, and nerves. The cardiac muscle tissue of the myocardium forms bands that wrap around the atria in a figure eight pattern and spiral into the walls of the ventricles (Figure 12-4b). This arrangement results in squeezing and twisting contractions that increase the pumping efficiency of the heart. The heart's inner surfaces, including the heart valves, are covered by the endocardium (en-dō-KAR-dē-um), which is made up of a simple squamous epithelium and underlying areolar tissue. The squamous epithelial lining of the cardiovascular system is called an endothelium. The endothelium of the heart is continuous with the endothelium of the attached great vessels. \bigcirc p. 427

Cardiac Muscle Cells

Typical cardiac muscle cells are shown in **Figure 12-4c,d**. These cells are smaller than skeletal muscle fibers. They contain a single, centrally located nucleus. Like skeletal muscle fibers, each cardiac muscle cell contains myofibrils, and contraction involves the shortening of individual sarcomeres. Cardiac muscle cells are almost totally dependent on aerobic metabolism for the energy needed to continue contracting. Many mitochondria and abundant reserves of myoglobin (to store oxygen) support their energy needs. Energy reserves are stored as glycogen and lipids.

Each cardiac muscle cell is in contact with several others at specialized sites known as **intercalated** (in-TER-ka-lā-ted) **discs**. **>** p. 143 At these sites, the interlocking membranes of adjacent cells are held together by desmosomes and linked by

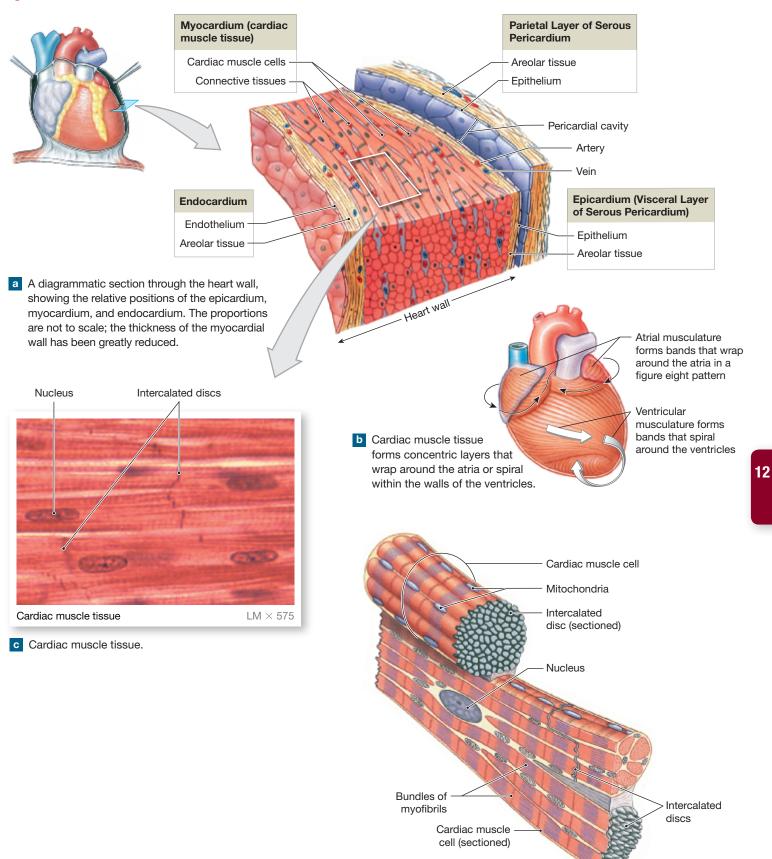

Figure 12-3 The Position and Surface Anatomy of the Heart.

gap junctions. \supset p. 123 The desmosomes help convey the force of contraction from cell to cell, increasing their efficiency as they "pull together" during a contraction. The gap junctions provide for the movement of ions and small molecules, enabling action potentials to travel rapidly from cell to cell.

Connective Tissue in the Heart

The connective tissues of the heart include abundant collagen and elastic fibers that wrap around each cardiac muscle cell and tie together adjacent cells. These fibers (1) provide

d Cardiac muscle cells.

Figure 12-4 The Heart Wall and Cardiac Muscle Tissue.

support for cardiac muscle fibers, blood vessels, and nerves of the myocardium; (2) add strength and prevent overexpansion of the heart; and (3) help the heart return to normal shape after contractions. Connective tissue also forms the *cardiac skeleton* of the heart, discussed in a later section.

Internal Anatomy and Organization

The four chambers of the heart are shown in sectional view in **Spotlight Figure 12-5**. The two atria are separated by the **interatrial septum** (*septum*, wall). The two ventricles are separated by the **interventricular septum**. Both septa are muscular partitions. **Atrioventricular (AV) valves** are folds of fibrous tissue that extend into the openings between the atria and the ventricles. They function as one-way valves, permitting blood to flow only in one direction: from the atria to the ventricles.

The right atrium receives blood from the systemic circuit through two large veins, the superior vena cava (VĒ-na KĀ-vuh; plural, *venae cavae*) and the inferior vena cava and a smaller vein, the coronary sinus (**Spotlight Figure 12-5**). The **superior vena cava** delivers blood from the head, neck, upper limbs, and chest. The **inferior vena cava** carries blood from the rest of the trunk, the viscera, and the lower limbs. The *cardiac veins* draining the myocardium of the heart return deoxygenated blood to the **coronary sinus**. This large, thin-walled vein opens into the right atrium slightly below the connection with the inferior vena cava.

The opening of the coronary sinus lies near the posterior edge of the interatrial septum. From the fifth week of embryonic development until birth an oval opening, the *foramen ovale*, penetrates the interatrial septum. Before birth, the foramen ovale allows blood to flow from the right atrium to the left atrium while the lungs are developing (see **Figure 13-21**, p. 493). At birth, the foramen ovale closes. The opening is permanently sealed off within the first year. A small depression called the *fossa ovalis* remains in the adult heart (**Spotlight Figure 12-5**). Occasionally, the foramen ovale remains open even after birth. Under these conditions, contractions of the left atrium push blood back into the pulmonary circuit. This leads to heart enlargement and eventual heart failure and death if the condition is not surgically corrected.

Blood travels from the right atrium into the right ventricle through a broad opening bounded by three flaps of fibrous tissue. These flaps, or **cusps**, are part of the **tricuspid** (trī-KUSpid; *tri-*, three + *cuspis*, point) **valve**, also known as the *right atrioventricular* (*AV*) *valve* (**Spotlight Figure 12-5**). Each cusp is braced by connective tissue fibers called **chordae tendineae** (KOR-dē TEN-di-nē-ē; "tendinous cords"). These fibers are connected to **papillary** (PAP-i-ler-ē) **muscles**, cone-shaped projections on the inner surface of the ventricle. The contraction of these muscles tenses the chordae tendineae, limiting the movement of the cusps and preventing the backflow of blood into the right atrium. The internal surface of the right and left ventricles have muscular ridges called the *trabeculae carneae* (tra-BEK-ū-lē KAR-nē-ē; *carneus*, fleshy).

Blood leaving the right ventricle flows into the **pulmonary trunk**, the start of the pulmonary circuit. The **pulmonary valve**, or *pulmonary semilunar* (*semi-*, half + *luna*, moon; a crescent, or half-moon, shape) *valve*, guards the entrance to this efferent trunk. Once in the pulmonary trunk, blood flows into the **left** and **right pulmonary arteries**. These vessels branch repeatedly within the lungs before supplying the capillaries where gas exchange occurs. From these respiratory capillaries, oxygenated blood moves into the **left** and **right pulmonary veins**, which deliver it to the left atrium.

The pulmonary trunk is attached to the **aortic arch** by a fibrous band called the *ligamentum arteriosum* (**Spotlight Figure 12-5**). It is all that remains of an important fetal blood vessel that once linked the pulmonary and systemic circuits.

Like the right atrium, the left atrium has an external auricle and a valve, the **mitral** (MĪ-tral; *mitre*, a bishop's hat) **valve**, also called the *left atrioventricular* (AV) valve, or *bicuspid* (bī-KUS-pid) valve. As the name *bicuspid* implies, the left AV valve contains two cusps, rather than three.

The internal organization of the left ventricle resembles that of the right ventricle. A pair of papillary muscles braces the chordae tendineae that insert on the mitral valve. Muscular ridges also line the internal surface of the left ventricle. Blood leaves the left ventricle through the **aortic valve**, or *aortic semilunar valve*, and passes into the **ascending aorta**, the start of the systemic circuit.

Structural Differences between the Left and Right Ventricles

The function of each atrium is to collect blood returning to the heart and deliver that blood to the attached ventricle. With very similar demands, the two atria look almost identical. But the demands on the right and left ventricles are very different, and the two have significant structural differences.

The lungs are close to the heart, and the pulmonary arteries and veins are relatively short and wide. For these reasons, the right ventricle normally does not need to push very hard to propel blood through the pulmonary circuit. The wall of the right ventricle is relatively thin (**Spotlight Figure 12-5**). In sectional view, the right ventricle resembles a pouch attached to the massive wall of the left ventricle. When the right ventricle contracts, it acts like a bellows pump,

SPOTLIGHT Figure 12-5 THE HEART: INTERNAL ANATOMY AND BLOOD FLOW

This diagrammatic frontal section through the heart shows its major landmarks and the path of blood flow (marked by arrows) through the atria, ventricles, and associated blood vessels. Red arrows represent oxygenated blood, and blue arrows represent deoxygenated blood.

As you can see, the right atrium communicates with the right ventricle, and the left atrium with the left ventricle. The atria are separated by the **interatrial septum**. The ventricles are separated by the much thicker **interventricular septum**. Each septum is a muscular partition. The two atrioventricular (AV) valves (tricuspid and mitral) are folds of fibrous tissue that extend into the openings between the atria and ventricles. These valves permit blood to flow in only one direction: from the atria to the ventricles.

Ligamentum arteriosum
Superior vena cava
Ascending aorta

Right pulmonary arteries -

Right Atrium

The right atrium receives deoxygenated blood from the superior vena cava and inferior vena cava. It also receives blood from the cardiac veins through the coronary sinus.

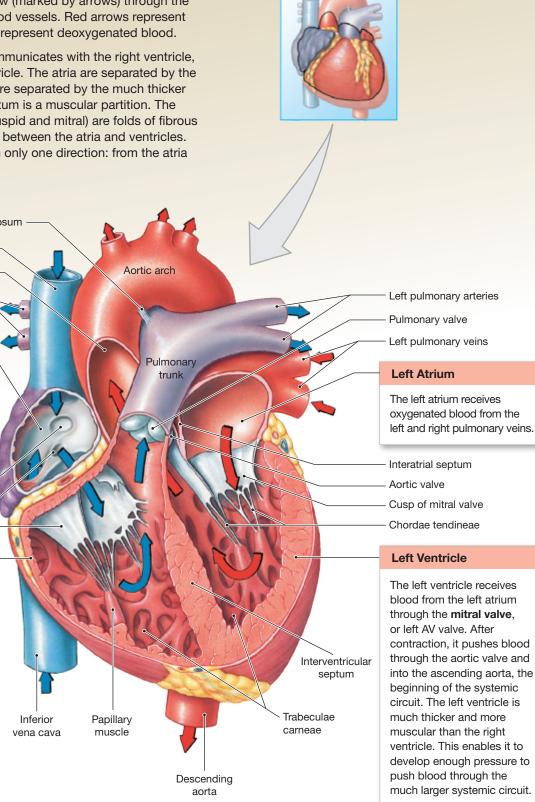

Fossa ovalis -

Opening of coronary sinus

Cusp of tricuspid valve

Right Ventricle

Blood travels from the right atrium into the right ventricle through the **tricuspid valve**, or right AV valve. After the right ventricle contracts, blood is pumped through the pulmonary valve and into the pulmonary trunk, the beginning of the pulmonary circuit. The right ventricle is thin walled since it only needs to push blood through the nearby lungs.

KEY

Oxygenated blood

squeezing the blood against the left ventricle and then out through the pulmonary semilunar valve. This action moves blood very efficiently with minimal effort, but it develops relatively low pressures.

A comparable pumping arrangement would not work well for the left ventricle. Four to six times as much pressure must be exerted to push blood around the systemic circuit as around the pulmonary circuit. The left ventricle has an extremely thick muscular wall and is round in cross section. When this ventricle contracts, it shortens and narrows. That is, (1) the distance between the heart's base and apex decreases, and (2) the diameter of the ventricular chamber decreases. (The effect is similar to simultaneously squeezing and rolling up the end of a toothpaste tube.) More than enough pressure is generated to open the aortic valve and eject blood into the ascending aorta.

As the powerful left ventricle contracts, it also bulges into the right ventricular cavity. This action helps force blood out of the right ventricle. Individuals with severe damage to their right ventricle may survive, because the left ventricle helps push blood through the pulmonary circuit.

The Heart Valves

As we have seen, the heart has two pairs of one-way valves that prevent the backflow of blood as the chambers contract. Let's look at the structure and function of these heart valves.

THE ATRIOVENTRICULAR VALVES. The atrioventricular valves prevent the backflow of blood from the ventricles into the atria. The chordae tendineae and papillary muscles play important roles in the normal function of the AV valves. When the ventricles are relaxed, the chordae tendineae are loose and the AV valve offers no resistance to the flow of blood from atrium to ventricle (Figure 12-6a). When the ventricles contract, blood moving back toward the atrium swings the cusps together, closing the valves (Figure 12-6b). During ventricular contraction, tension in the papillary muscles and chordae tendineae keeps the cusps from swinging into the atrium. This action prevents the backflow, or regurgitation, of blood into the atrium each time the ventricle contracts. A small amount of regurgitation often occurs, even in normal individuals. The swirling blood creates a soft but distinctive sound called a *heart murmur*.

THE SEMILUNAR VALVES. The pulmonary and aortic semilunar valves prevent the backflow of blood from the pulmonary trunk and ascending aorta into the right and left

CLINICAL NOTE

Heart Valve Disorders

Minor abnormalities in valve shape are relatively common. For example, an estimated 10 percent of normal individuals ages 14–30 have some degree of **mitral valve prolapse**. In this condition, the cusps of the mitral valve (the left AV valve) do not close properly. The problem may stem from abnormally long (or short) chordae tendineae or malfunctioning papillary muscles. Because the valve does not work perfectly, some regurgitation takes place when the left ventricle contracts. Most individuals with mitral valve prolapse have no symptoms. They live normal healthy lives unaware of any circulatory malfunction.

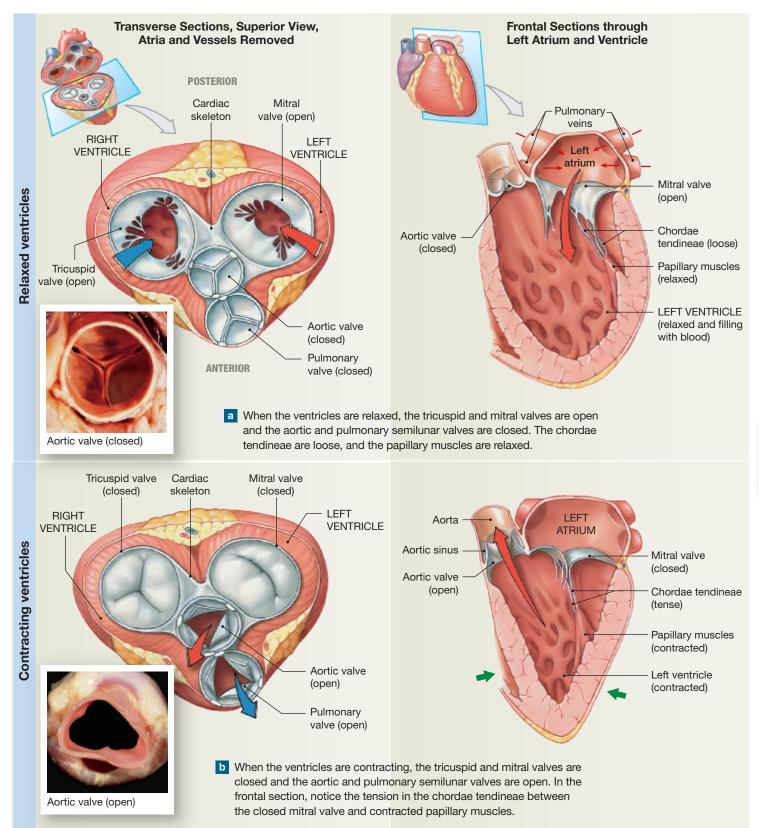

Serious valve problems are very dangerous because they reduce pumping efficiency. If valve function deteriorates such that the heart cannot maintain adequate circulatory flow, symptoms of **valvular heart disease (VHD)** appear. Congenital defects may be responsible, but in many cases the condition develops following *carditis*, an inflammation of the heart. In severe cases, the only option may be to replace the damaged valve with a prosthetic one. One relatively common cause of carditis is **rheumatic** (roo-MA-tik) **fever**, an inflammatory autoimmune response to an infection by streptococcal bacteria. It most often occurs in children.

ventricles, respectively. Unlike the AV valves, the semilunar valves do not require muscular bracing, because the arterial walls do not contract and the relative positions of the cusps are stable. When the semilunar valves close, the three symmetrical cusps in each valve support one another like the legs of a tripod, preventing the movement of blood back into the ventricles (Figure 12-6a).

Saclike expansions of the base of the ascending aorta occur next to each cusp of the aortic semilunar valve. These sacs, called **aortic sinuses**, prevent the cusps from sticking to the wall of the aorta when the valve opens (**Figure 12-6b**). The *right* and *left coronary arteries* originate at the aortic sinuses.

The Cardiac Skeleton of the Heart

The **cardiac skeleton**, or *fibrous skeleton*, of the heart consists of dense bands of tough, elastic connective tissue that encircle the bases of the large blood vessels carrying blood away from the heart (*pulmonary trunk* and *aorta*) and each of the heart valves (**Figure 12-6**). The cardiac skeleton stabilizes the position of the heart valves and also physically isolates the atrial muscle tissue from the ventricular muscle tissue. This isolation is important to normal heart function because it means that the timing of ventricular contraction relative to atrial contraction can be precisely controlled. Figure 12-6 The Valves of the Heart. Red (oxygenated) and blue (deoxygenated) arrows indicate blood flow into and out of a ventricle; thin red arrows, blood flow into an atrium; and green arrows, ventricular contraction.

The Blood Supply to the Heart

The heart works continuously, so cardiac muscle cells require reliable supplies of oxygen and nutrients. The **coronary circulation** supplies blood to the muscle tissue of the heart (Figure 12-7). During maximum exertion the heart's demand for oxygen rises considerably. The blood flow to the heart may then increase up to nine times that of resting levels.

The left and right **coronary arteries** originate at the base of the aorta at the aortic sinuses (Figure 12-7a). Blood pressure here is the highest in the systemic circuit. This high pressure ensures a continuous flow of blood to meet the demands of active cardiac muscle. The right coronary artery supplies blood to the right atrium and to portions of both ventricles. The left coronary artery supplies blood to the left ventricle, left atrium, and interventricular septum.

Each coronary artery gives rise to two branches. The right coronary artery forms the *marginal* and *posterior interventricular* (*descending*) arteries. The left coronary artery forms the *circumflex* and *anterior interventricular* (*descending*) arteries. The anterior interventricular artery supplies small tributaries continuous with those of the posterior artery. Such interconnections between arteries are called **anastomoses** (a-nas-tō-MŌ-sēz; *anastomosis*, outlet). Because the arteries

Figure 12-7 The Coronary Circulation.

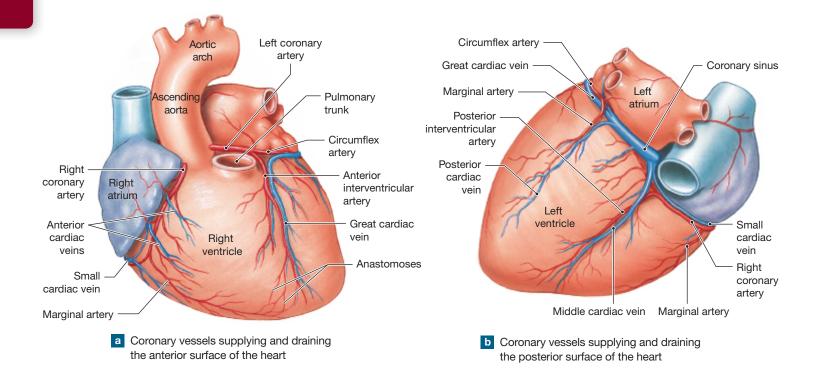

are interconnected in this way, alternate pathways exist for the blood supply to reach cardiac muscle.

The **great** and **middle cardiac veins** carry blood away from the coronary capillaries. They drain into the **coronary sinus**, a large, thin-walled vein in the posterior portion of the coronary sulcus. The coronary sinus opens into the right atrium near the base of the inferior vena cava (**Spotlight Figure 12-5**).

An area of dead tissue caused by an interruption in blood flow is called an **infarct**. In a **myocardial** (mī-ō-KAR-dē-al) **infarction (MI)**, or *heart attack*, the coronary circulation becomes blocked, and cardiac muscle cells die from lack of oxygen. Heart attacks most often result from severe *coronary artery disease*, a condition characterized by the buildup of fatty deposits in the walls of the coronary arteries.

CHECKPOINT

- **1.** Damage to the semilunar valve of the right ventricle would affect blood flow into which vessel?
- **2.** What prevents the AV valves from swinging into the atria?
- **3.** Why is the left ventricle more muscular than the right ventricle?
- See the blue Answers tab at the back of the book.

12-2 Contractile cells and the conducting system produce each heartbeat, and an electrocardiogram records the associated electrical events

Learning Outcome Explain the events of an action potential in cardiac muscle, describe the conducting system of the heart, and identify the electrical events recorded in a normal electrocardiogram.

In a single **heartbeat**, the entire heart—atria and ventricles contracts in a coordinated manner so that blood flows in the correct direction at the proper time. Each time the heart beats, the contractions of individual cardiac muscle cells take place first in the atria and then in the ventricles. Two types of cardiac muscle cells are involved in a normal heartbeat: (1) *Contractile cells* produce the powerful contractions that propel blood, and (2) specialized noncontractile muscle cells of the *conducting system* control and coordinate the activities of the contractile cells.

Contractile Cells

Contractile cells form the bulk of the heart's muscle tissue (about 99 percent of all cardiac muscle cells). In both cardiac contractile cells and skeletal muscle fibers, an action potential leads to the appearance of Ca^{2+} among the myofibrils, and Ca^{2+} binding to troponin on the thin filaments begins a contraction. However, skeletal and cardiac muscle cells differ in the duration of action potentials, the source of Ca^{2+} , and the duration of the resulting contraction.

What happens in cardiac contractile cells? The resting potential of a ventricular contractile cell is about -90 mV. An action potential begins when the plasma membrane of the ventricular cell reaches threshold, usually about -75 mV. The typical stimulus is the excitation of an adjacent contractile cell. Once threshold has been reached, the action potential proceeds in three basic steps (Figure 12-8a):

 Rapid depolarization. At threshold, voltage-gated sodium channels open. The influx of sodium ions rapidly depolarizes the sarcolemma (plasma membrane). The sodium channels close when the membrane potential reaches a value between +20 and +30 mV.

2 *The plateau.* A partial repolarization takes place as some K⁺ leave the cell before most K⁺ channels close. Voltage-gated calcium channels then open and *extracellular* calcium ions enter the cytosol. The calcium channels remain open for a relatively long period—roughly 175 msec (milliseconds). The inflow of positive charges (Ca^{2+}) and reduced outflow of K⁺ delay repolarization, causing the membrane potential to remain near 0 mV for an extended period. This portion of the action potential is called the *plateau*. The extracellular calcium ions initiate contraction, as well as delaying repolarization. Their increased concentration within the cell also triggers the release of Ca^{2+} from reserves in the sarcoplasmic reticulum (SR), which continue the contraction.

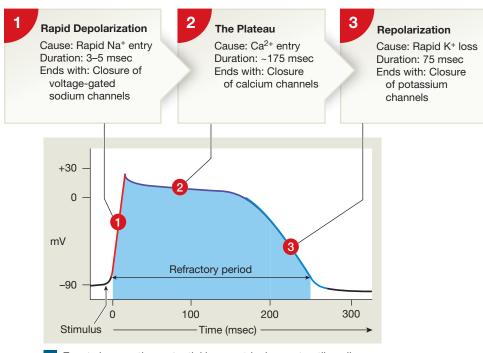

3 **Repolarization.** As the plateau continues, calcium channels begin closing and potassium channels begin opening. As these channels open, potassium ions (K⁺) rush out of the cell. The net result is a rapid repolarization that restores the resting potential.

In contrast, in a skeletal muscle fiber, the 10-msec action potential of a rapid depolarization is immediately followed by a rapid repolarization. This brief action potential ends as the related twitch contraction begins (**Figure 12-8b, top**). The twitch contraction is short and ends as the SR reclaims the Ca^{2+} it released.

In a cardiac contractile cell, the action potential is prolonged because Ca^{2+} continues to enter the cell throughout the plateau (**Figure 12-8b, bottom**). As a result, the period of muscle contraction continues until the plateau ends. As the calcium channels close, the intracellular calcium ions are absorbed by the SR or are pumped out of the cell, and the muscle cell relaxes.

The complete depolarization–repolarization process, or action potential, in a cardiac contractile cell lasts 250–300 msec, some 25–30 times as long as an action potential in a skeletal muscle fiber (**Figure 12-8b**). The membrane cannot respond to further stimulation until it repolarizes, so the refractory period of a cardiac contractile cell membrane is relatively long. For this reason, a normal cardiac contractile cell is limited to a maximum rate of about 200 contractions per minute.

In skeletal muscle fibers, the refractory period ends before the muscle fiber develops peak tension and relaxes. As a result, twitches can build on one another until tension reaches a sustained peak, a state called *tetanus*. ⊃ p. 235 In cardiac contractile cells, the refractory period continues until relaxation is under way. A summation of twitches is therefore not possible. Tetanic contractions cannot take place in a normal cardiac contractile cell, regardless of the frequency and intensity of stimulation. This feature is absolutely vital because a heart in tetany could not pump blood.

a Events in an action potential in a ventricular contractile cell.

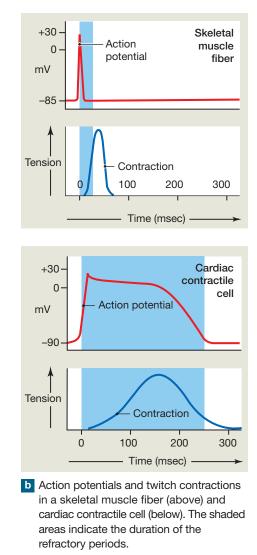

The Conducting System

12

Unlike skeletal muscle, cardiac muscle tissue contracts on its own, without neural or hormonal stimulation. This ability is called *automaticity*, or *autorhythmicity*. It is also characteristic of some types of smooth muscle tissue (discussed in Chapter 7). \bigcirc p. 242

In the heart's normal pattern of activity, contractions follow a precise sequence: The atria contract first, followed by the ventricles. The heart's **conducting system** coordinates cardiac contractions. This system is a network of specialized cardiac muscle cells that initiates and distributes electrical impulses (**Figure 12-9a**). The network is made up of two types of cardiac muscle cells that do not contract, *nodal cells* and *conducting cells*. **Nodal cells** establish the rate of cardiac contraction. They are located at the *sinoatrial* (*SA*) and *atrioventricular* (*AV*) *nodes*. **Conducting cells** interconnect the two nodes and distribute the contractile stimulus throughout the myocardium. In the ventricles, the conducting cells include those in the *AV bundle* and the *bundle branches*, as well as the *Purkinje fibers*.

Nodal cells are unusual because their plasma membranes depolarize spontaneously and generate action potentials at regular intervals. Nodal cells are electrically coupled to one another, to conducting cells, and to normal cardiac muscle cells. As a result, when an action potential is initiated in a

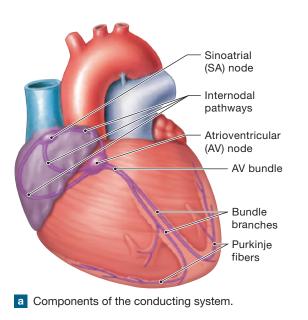

nodal cell, it sweeps through the conducting system. The signal reaches all of the cardiac muscle tissue and causes a coordinated contraction. In this way, nodal cells determine the heart rate.

Not all nodal cells depolarize at the same rate. The normal rate of contraction is established by **pacemaker cells**, the nodal cells that reach threshold first. These pacemaker cells are located in the **sinoatrial** (sī-nō-Ā-trē-al) **node (SA node)**, or *cardiac pacemaker*. It is a tissue mass embedded in the posterior wall of the right atrium near the entrance of the superior vena cava (**Figure 12-9a**). Pacemaker cells depolarize rapidly and spontaneously, generating 70–80 action potentials per minute. This results in a heart rate of 70–80 beats per minute (bpm).

Once the stimulus for a contraction is generated at the SA node, it must be distributed so that (1) the atria contract together, before the ventricles; and (2) the ventricles contract together, in a wave that begins at the apex and spreads toward

Figure 12-9 The Conducting System of the Heart.

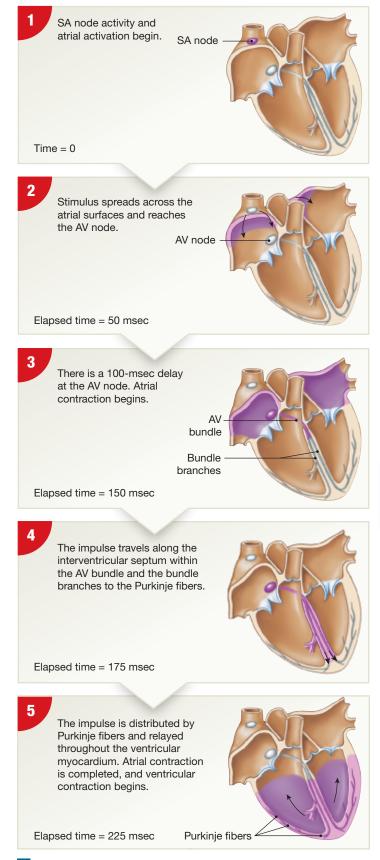

the base. When the ventricles contract in this way, blood is pushed toward the base of the heart into the aorta and pulmonary trunk.

The cells of the SA node are electrically connected to those of the larger **atrioventricular** (ā-trē-ō-ven-TRIK-ū-lar) **node (AV node)** by conducting cells in the atrial walls (**Figure 12-9a**). The AV nodal cells also depolarize spontaneously, but they generate only 40–60 action potentials per minute. Under normal circumstances, before an AV cell depolarizes to threshold spontaneously, it is stimulated by an action potential generated by the SA node. However, if the AV node does not receive this action potential, it will then become the pacemaker of the heart and establish a heart rate of 40–60 beats per minute.

The AV node is located in the floor of the right atrium near the opening of the coronary sinus. From there the action potentials travel to the **AV bundle**, also known as the *bundle of His* (pronounced *hiss*). This bundle of conducting cells extends along the interventricular septum before dividing into **left** and **right bundle branches**. These branches extend to the apex of the heart, turn, and radiate across the inner surfaces of the left and right ventricles. Then specialized **Purkinje** (pur-KIN-jē) **fibers** (*Purkinje cells*) convey the impulses to the contractile cells of the ventricular myocardium.

The path of an impulse from its initiation at the SA node through the heart is shown in Figure 12-9b. Atrial activation begins at the SA node (Figure 12-9b 1). It takes an action potential roughly 50 msec to travel from the SA node to the

b The stimulus for contraction is conducted through the heart in a predictable sequence of events (steps 1–5).

AV node over the conducting pathways. Along the way, the conducting cells pass the contractile stimulus to cardiac muscle cells of the right and left atria. The action potential then spreads across the atrial surfaces through cell-to-cell contact (Figure 12-9b 2). The stimulus affects only the atria because the cardiac skeleton electrically isolates the atria from the ventricles everywhere except at the AV bundle. $\supset p. 442$

At the AV node, the impulse slows down. Another 100 msec pass before it reaches the AV bundle (Figure 12-9b 3). This delay is important because the atria must be contracting, and blood must be moving, before the ventricles are stimulated. Once the impulse enters the AV bundle, it flashes down the interventricular septum, along the bundle branches, and into the ventricular myocardium along the Purkinje fibers (Figure 12-9b 4). Within 75 msec, the stimulus to begin a contraction reaches all of the contractile cells of both ventricles (Figure 12-9b 5).

Abnormal pacemaker function can cause a number of clinical problems. Bradycardia (brād-ē-KAR-dē-uh; bradys, slow) is a condition in which the heart rate is slower than normal (less than 60 bpm). Tachycardia (tak-ē-KAR-dē-uh; tachys, swift) is a faster than normal heart rate (100 bpm or more). In some cases, an abnormal conducting cell or ventricular muscle cell may begin generating action potentials so rapidly that they override those of the SA or AV node. The origin of such abnormal signals is called an **ectopic** 12 (ek-TOP-ik; out of place) pacemaker. The action potentials may completely bypass the conducting system and disrupt the timing of ventricular contractions. Such conditions are commonly diagnosed with the aid of an *electrocardiogram*, which we discuss next.

The Electrocardiogram

The electrical events in the heart are powerful enough to be detected by electrodes placed on the body surface. A recording of these events is an **electrocardiogram** (ē-lek-trō-KARdē-ō- ram), also called an ECG or EKG. Each time the heart beats, a wave of depolarization spreads through the atria, pauses at the AV node, then travels down the interventricular septum to the apex, turns, and spreads through the ventricular myocardium toward the base.

An ECG combines information obtained from electrodes placed at different locations on the body surface. Clinicians can use an ECG to assess the performance of specific nodal, conducting, and contractile components. When a portion of the heart has been damaged by a heart attack, for example, the ECG will reveal an abnormal pattern of impulse conduction.

The appearance of the ECG tracing varies with the placement of the monitoring electrodes, or *leads*. The important features of an electrocardiogram as analyzed with the leads in one of the standard configurations are shown in Figure 12-10:

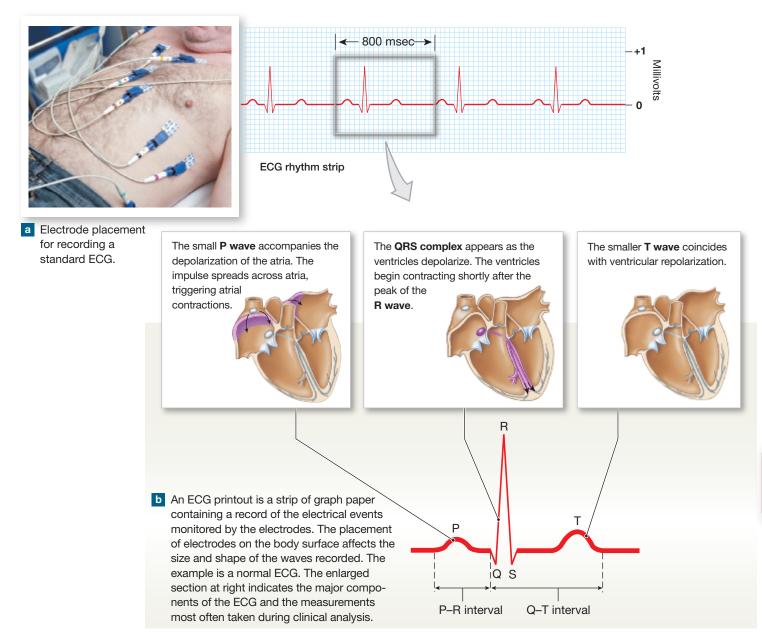

- A small **P** wave accompanies the depolarization of the atria. The atria begin contracting about 25 msec after the start of the P wave.
- A **QRS complex** appears as the ventricles depolarize. This electrical signal is relatively strong because the mass of the ventricular muscle is much larger than that of the atria. The ventricles begin contracting shortly after the peak of the R wave.
- A smaller **T wave** indicates ventricular repolarization. Atrial repolarization is not apparent because it takes place while the ventricles are depolarizing, and the QRS complex masks the electrical events.

Analyzing an ECG involves measuring the size of the voltage changes and determining the temporal (time) relationships of the various components. Attention usually focuses on the amount of depolarization occurring during the P wave and the QRS complex. For example, a smaller than normal electrical signal can mean that the mass of the heart muscle has decreased. In contrast, excessively strong depolarizations can mean that the heart muscle has become enlarged.

The times between waves are reported as segments and intervals. Segments generally extend from the end of one wave to the start of another. Intervals are more variable, but always include at least one entire wave. Commonly used segments and intervals are labeled in Figure 12-10b. The names, however, can be somewhat misleading. For example:

- The P-R interval extends from the start of atrial depolarization to the start of the QRS complex (ventricular depolarization) rather than to R, because in abnormal ECGs the peak at R can be difficult to determine. Extension of the P-R interval to more than 200 msec can indicate damage to the conducting pathways or AV node.
- The **Q-T interval** indicates the time required for the ventricles to undergo a single cycle of depolarization and repolarization. It is usually measured from the end of the P-R interval rather than from the bottom of the Q wave. The Q-T interval can be lengthened by electrolyte disturbances, some medications, conduction problems, coronary ischemia (inadequate blood supply to the heart), or myocardial damage. A congenital heart defect that can cause sudden death without warning may be detectable as a prolonged Q-T interval.

Figure 12-10 An Electrocardiogram.

Electrocardiogram analysis is useful in detecting and diagnosing **cardiac arrhythmias** (ā-RITH-mē-az), abnormal patterns of cardiac activity. Momentary arrhythmias are not inherently dangerous, and about 5 percent of the normal population experiences a few abnormal heartbeats each day. Clinical problems appear when the arrhythmias reduce the heart's pumping efficiency. Serious arrhythmias can indicate damage to the myocardium, injuries to the pacemaker or conduction pathways, exposure to drugs, or variations in the electrolyte composition of the extracellular fluids.

CHECKPOINT

- **4.** How does the fact that cardiac muscle does not undergo tetanus (as skeletal muscle does) affect the functioning of the heart?
- **5.** If the cells of the SA node did not function, how would the heart rate be affected?
- **6.** Why is it important for impulses from the atria to be delayed at the AV node before they pass into the ventricles?
- **7.** What might cause an increase in the size of the QRS complex in an electrocardiogram?

See the blue Answers tab at the back of the book.

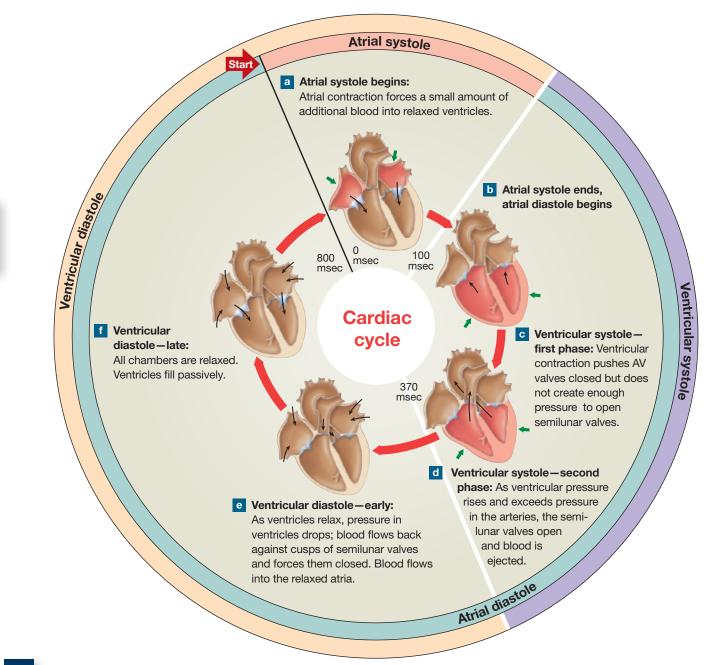

12-3 Events during a complete heartbeat make up a cardiac cycle

Learning Outcome Explain the events of the cardiac cycle, and relate the heart sounds to specific events in this cycle.

A brief resting phase follows each heartbeat. It allows time for the chambers to relax and prepare for the next heartbeat. The period between the start of one heartbeat and the start of the next is a single **cardiac cycle** (**Figure 12-11**). It includes alternating periods of contraction and relaxation. For any one chamber of the heart, the cardiac cycle can be divided into two phases. During contraction, or **systole** (SIS-tō-lē), the chamber squeezes blood into an adjacent chamber or into an arterial trunk. Systole is followed by relaxation, or **diastole** (dī-AS-tō-lē). During diastole, the chamber fills with blood and prepares for the start of the next cardiac cycle.

Fluids move from an area of higher pressure to one of lower pressure. During the cardiac cycle, the pressure within each chamber rises during systole and falls during diastole. An increase in pressure in one chamber causes the blood to flow to another chamber (or vessel) where the pressure is lower. The atrioventricular and semilunar valves ensure that blood flows in one direction only during the cardiac cycle.

Figure 12-11 The Cardiac Cycle. Thin black arrows indicate blood flow, and green arrows indicate contractions. Times noted in the figure are for a heart rate of 75 bpm.

The correct pressure relationships among the heart chambers depend on the careful timing of contractions. The pacemaking and conduction systems normally provide the required interval of time between atrial systole and ventricular systole. If the atria and ventricles were to contract simultaneously, blood could not leave the atria because the AV valves would be closed. In the normal heart, atrial systole and atrial diastole are slightly out of phase with ventricular systole and diastole.

Phases of the Cardiac Cycle

The phases of the cardiac cycle—atrial systole, atrial diastole, ventricular systole, and ventricular diastole—are diagrammed in **Figure 12-11** for a heart rate of 75 bpm. When the cardiac cycle begins, all four chambers are relaxed, the atria are filled with blood, and the ventricles are partially filled with blood.

The cardiac cycle begins with atrial systole. During this phase, the atria contract, completely filling the ventricles with blood (**Figure 12-11a**). Atrial systole lasts 100 msec. As atrial systole ends, atrial diastole and ventricular systole begin (**Figure 12-11b**). As pressures in the ventricles rise above those in the atria, the AV valves swing shut (**Figure 12-11c**). But blood cannot begin moving into the arterial trunks until ventricular pressures exceed the arterial pressures. At this point, the blood pushes open the semilunar valves and flows into the aorta and pulmonary trunk (**Figure 12-11d**). This blood flow continues for the duration of ventricular systole, and lasts approximately 270 msec in a resting adult.

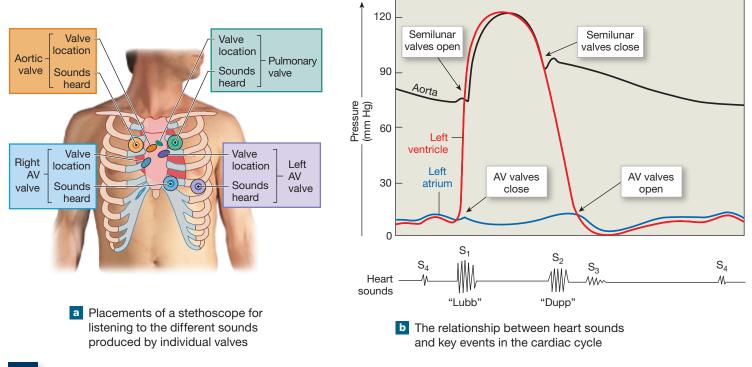

Figure 12-12 Heart Sounds.

The heart then enters ventricular diastole. This phase lasts 530 msec (the 430 msec remaining in this cardiac cycle, plus the first 100 msec of the next when the atria are contracting (**Figure 12-11e**). When ventricular diastole begins, ventricular pressures decline rapidly. As they fall below the pressures of the arterial trunks, the semilunar valves close. Ventricular pressures continue to drop. As they fall below atrial pressures, the AV valves open and blood flows from the atria into the ventricles. Both atria and ventricles are now relaxed in diastole. Blood now flows from the major veins through the relaxed atria and into the ventricles (**Figure 12-11f**).

By the time atrial systole marks the start of another cardiac cycle, the ventricles are roughly 70 percent filled. Atrial systole actually makes a relatively minor contribution to ventricular volume. This fact explains why individuals can survive quite normally when their atria have been so severely damaged that they can no longer function. In contrast, damage to one or both ventricles can leave the heart unable to maintain adequate blood flow. A condition of *heart failure* then exists. In this condition, the heart weakens and peripheral tissues suffer from oxygen and nutrient deprivation.

Heart Sounds

Clinicians use a **stethoscope** to listen for normal and abnormal heart sounds. There are four **heart sounds**, named S_1 through S_4 (**Figure 12-12**). If you listen to your own heart with a stethoscope, you hear the familiar "lubb-dupp" that accompanies each heartbeat. These two sounds (S_1 and S_2)

Go to **Mastering A&P** > Study Area > Menu > MP3 Tutor Session > Cardiovascular Pressure

come from the actions of the heart valves. The first heart sound ("lubb") is produced as the AV valves close and the semilunar valves open. It marks the start of ventricular systole and lasts a little longer than the second sound. The second heart sound, "dupp," occurs at the beginning of ventricular diastole, when the semilunar valves close. Third and fourth heart sounds (S₃ and S_4) may be audible as well, but they are usually very faint. They are seldom detectable in healthy adults. These sounds are associated with atrial contraction and blood flowing into the ventricles rather than with valve action.

CHECKPOINT

- 8. Provide the alternative terms for the contraction and relaxation of heart chambers.
- 9. Is the heart always pumping blood when pressure in the left ventricle is rising? Explain.
- **10.** What events cause the "lubb-dupp" heart sounds as heard with a stethoscope?
- See the blue Answers tab at the back of the book.

12-4 Heart dynamics examines the factors that affect cardiac output

Learning Outcome Define cardiac output, describe the factors that influence heart rate and stroke volume, and explain how adjustments in stroke volume and cardiac output are coordinated at different levels of 12 physical activity.

The term heart dynamics, or cardiodynamics, refers to the movements and forces generated during cardiac contractions. Each time the heart beats, the two ventricles eject equal amounts of blood. Stroke volume (SV) is the amount of blood ejected by a ventricle during a single beat. The stroke volume can vary from beat to beat, so physicians are often more interested in the cardiac output (CO), or the amount of blood pumped by the left ventricle in 1 minute. Cardiac output provides an indication of the blood flow through peripheral tissues. Adequate blood flow is needed to maintain homeostasis.

We can calculate cardiac output by multiplying the heart rate (HR) by the average stroke volume (SV):

СО	=	HR	\times	SV
cardiac output		heart rate		stroke volume
(mL/min)		(beats/min)		(mL/beat)

For example, if the heart rate is 75 beats per minute (bpm) and the average stroke volume is 80 mL per beat, the cardiac output will be:

> $CO = 75 \text{ beats/min} \times 80 \text{ mL/beat}$ $= 6000 \, \text{mL/min} \, (6 \, \text{L/min})$

This value represents a cardiac output that equals the total volume of blood of an average adult every minute. Cardiac output is highly variable, however, because a normal heart can increase both its rate of contraction and its stroke volume. When necessary, stroke volume in a normal heart can almost double. The heart rate can increase by 250 percent. When both increase together, the cardiac output can increase by 500 to 700 percent, or up to 30 liters per minute.

Cardiac output is precisely regulated so that peripheral tissues receive an adequate blood supply under a variety of conditions. The primary factors that regulate cardiac output often affect both heart rate and stroke volume at the same time. These factors include blood volume reflexes, autonomic innervation, and hormones. Secondary factors include various drugs, the concentration of ions in the extracellular fluid, and body temperature (see the Clinical Note "Abnormal Conditions Affecting Cardiac Output").

Blood Volume Reflexes

Cardiac muscle contraction is an active process, but relaxation is entirely passive. The force needed to return cardiac muscle to its precontracted length comes from the blood pouring into the heart, aided by the elasticity of the cardiac skeleton. As a result, there is a direct relationship between the amount of blood entering the heart and the amount of blood ejected during the next contraction.

Two heart reflexes respond to changes in blood volume. One of these occurs in the right atrium and affects heart rate. The other is a ventricular reflex that affects stroke volume.

The **atrial reflex** (*Bainbridge reflex*) adjusts heart rate in response to an increase in the venous return, the flow of venous blood into the heart. Venous return varies in response to alterations in cardiac output, peripheral circulation, and other factors that affect the rate of blood flow through the venae cavae. How does the atrial reflex work? The entry of blood stimulates stretch receptors in the right atrial walls. This triggers a reflexive increase in heart rate through increased sympathetic activity. As a result of sympathetic stimulation, the cells of the SA node depolarize faster and heart rate increases.

The amount of blood pumped out of a ventricle with each heartbeat (the stroke volume) depends not only on venous return but also on the **filling time**—the duration of ventricular diastole, when blood can flow into the ventricles. Filling time depends primarily on the heart rate. The faster the heart rate, the shorter the filling time.

CLINICAL NOTE

Abnormal Conditions Affecting Cardiac Output

The SA node sets the basic rhythm of heart contraction, but various drugs, abnormal variations in extracellular ion concentrations, and changes in body temperature can alter this rhythm. Several drugs, including caffeine and nicotine, have a stimulating effect that causes an increase in heart rate. Caffeine acts directly on the conducting system. It increases the rate of depolarization at the SA node. Nicotine directly stimulates the activity of sympathetic neurons that innervate the heart.

Disorders affecting ion concentrations can affect cardiac output by changing the stroke volume, the heart rate, or both. Changes in extracellular calcium ion concentrations mainly affect the strength and duration of cardiac contractions, and thus stroke volume. If these calcium concentrations are elevated, the condition is called **hypercalcemia**. Cardiac contractile cells become extremely excitable, and their contractions become powerful and prolonged. In extreme cases,

the heart goes into an extended state of contraction that is usually fatal. When calcium levels are abnormally low, the condition is called **hypocalcemia.**

Contractions become very weak and may stop altogether. Abnormal extracellular potassium ion concentrations can change heart rate. They do so by altering the resting membrane potential of nodal cells at the SA node. When potassium concentrations are high in **hyperkalemia**, cardiac contractions become weak and irregular. When the potassium levels are abnormally low

in hypokalemia, heart rate is slowed.

Temperature changes also affect metabolic operations through-

out the body. For example, a lowered body temperature slows the rate of depolarization at the SA node, lowers heart rate, and reduces the strength of cardiac contractions. (In open-heart surgery, the exposed heart may be deliberately chilled until it stops beating.) An elevated body temperature increases heart rate and contractile force—one reason why your heart seems to race and pound when you have a fever.

Over the range of normal activities, the greater the volume of blood entering the ventricles, the more powerful the contraction and the greater the stroke volume. In a resting individual, venous return is relatively low and the walls are not stretched much. As a result, the ventricles develop little power, and stroke volume is low. What happens if venous return suddenly increases (that is, more blood flows into the heart)? The myocardium stretches farther, the ventricles produce greater force upon contraction, and stroke volume increases.

This general rule of "more in = more out" is known as the **Frank-Starling principle**. It is named for the physiologists who first demonstrated the relationship. Its major effect is that the output of blood from the left and right ventricles is balanced under a variety of conditions.

Autonomic Innervation

As we have noted, the pacemaker cells of the SA node establish the basic heart rate. However, the autonomic nervous system (ANS) can modify this heart rate. Both the sympathetic and parasympathetic divisions of the ANS innervate the heart (**Figure 12-13**). Postganglionic sympathetic fibers extend from neuron cell bodies located in the cervical and upper thoracic ganglia. The vagus nerves (X) carry parasympathetic preganglionic fibers to small ganglia near the heart. Both ANS divisions innervate the SA and AV nodes and atrial muscle cells. Both also innervate ventricular muscle cells, but sympathetic fibers far outnumber parasympathetic fibers.

Build Your Knowledge

Recall that the autonomic nervous system (ANS) is an efferent division of the peripheral nervous system (PNS). It carries motor commands from the central nervous system (CNS) to cardiac muscle, smooth muscle, glands, and adipose tissue (as you saw in **Chapter 8: The Nervous System**). The motor commands of the ANS occur outside our conscious awareness. The ANS motor neurons in the CNS are known as preganglionic neurons. Their axons synapse on ganglionic neurons in PNS ganglia. The axons of the ganglionic neurons are called postganglionic fibers. The ANS includes a sympathetic division and a parasympathetic division, which commonly have opposite effects. \supset p. 319

Autonomic Effects on Heart Rate

Autonomic effects on heart rate primarily reflect the responses of the SA node to acetylcholine (ACh) and to norepinephrine (NE). Acetylcholine released by parasympathetic motor neurons lowers the heart rate. Norepinephrine released by sympathetic neurons increases the heart rate. A more sustained rise in heart rate follows the release of epinephrine (E) and norepinephrine by the adrenal medullae during sympathetic activation.

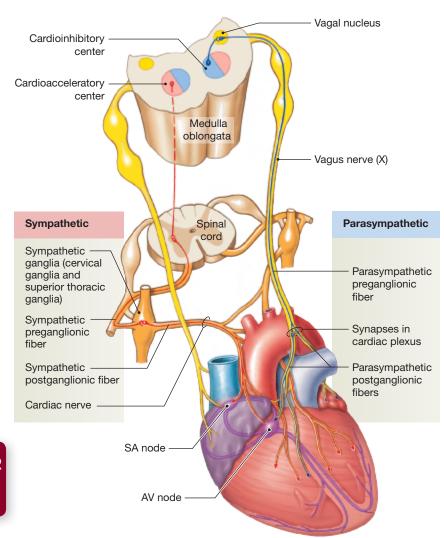

Figure 12-13 Autonomic Innervation of the Heart.

Autonomic Effects on Stroke Volume

The ANS also affects stroke volume by altering *contractility*, the amount of force produced during a contraction. The ANS does so through the release of NE, E, and ACh:

- **NE and E increase contractility.** The sympathetic release of NE at synapses in the myocardium and the release of NE and E by the adrenal medullae stimulate cardiac muscle cell metabolism. This change increases the force of ventricular contraction. The result is an increase in stroke volume.
- ACh decreases contractility. The primary effect of parasympathetic ACh release is inhibition, causing the force of cardiac contractions to decrease. The greatest reduction in contractile force takes place in the atria, because parasympathetic innervation is relatively limited in the ventricles. The result is a decrease in stroke volume.

Both autonomic divisions are normally active at a steady background level, releasing ACh and NE both at the nodes and into the myocardium. Thus, cutting the vagus nerves increases heart rate, and sympathetic blocking agents slow heart rate. Through dual innervation and adjustments in autonomic tone, the ANS can make very delicate adjustments in cardiovascular function.

The Coordination of Autonomic Activity

The *cardiac center* of the medulla oblongata contains the autonomic headquarters for cardiac control. ⊃ p. 308 It includes sympathetic and parasympathetic centers. The **cardioacceleratory center** controls sympathetic motor neurons that increase heart rate. The adjacent **cardioinhibitory center** controls the parasympathetic motor neurons that slow heart rate (**Figure 12-13**). Information about the status of the cardiovascular system arrives at the cardiac center over visceral sensory fibers accompanying the vagus nerves and the sympathetic nerves of the cardiac plexus.

The cardiac center responds to changes in blood pressure and in the arterial concentrations of dissolved oxygen and carbon dioxide. These changes are monitored by baroreceptors and chemoreceptors innervated by the glossopharyngeal (IX) and vagus (X) nerves. A decline in blood pressure or oxygen concentration or an increase in the carbon dioxide level usually means an increased oxygen demand by peripheral tissues. The cardiac center then calls for an increase in cardiac output, and the heart works harder.

In addition to making automatic adjustments in response to sensory information, the cardiac center can be influenced by higher centers, especially centers in the hypothalamus. For this reason, changes in emotional state (such as rage, fear, or arousal) have an immediate effect on heart rate.

Build Your Knowledge

Recall that the medulla oblongata is the region of the brain that is attached to the spinal cord (as you saw in **Chapter 8: The Nervous System).** One of its roles is to relay sensory information to the thalamus and other brainstem centers. It also contains major centers that regulate autonomic function, such as heart rate, blood pressure, respiration, and digestive activities. **D p. 298**

Hormones

Recall that epinephrine and norepinephrine secreted by the adrenal medullae act to increase both heart rate and force of contraction. Thyroid hormones and glucagon also act to increase heart rate and force of contraction. Before synthetic drugs were available, glucagon was widely used to stimulate heart function.

Various drugs that affect the contractility of the heart have been developed for use in cardiac emergencies and to treat heart disease. Drugs that act by increasing the Ca²⁺ concentration within cardiac muscle cells, such as *digitalis* and related drugs, result in an increase in the force of contractions. Many drugs used to treat hypertension (high blood pressure) act to decrease contractility.

CHECKPOINT

- **11.** Define cardiac output.
- **12.** If the cardioinhibitory center of the medulla oblongata were damaged, which division of the autonomic nervous system would be affected, and how would the heart be influenced?
- **13.** What effect would stimulating the acetylcholine receptors of the heart have on cardiac output?
- **14.** What effect does increased venous return have on stroke volume?
- **15.** Why is it a potential problem if the heart beats too rapidly?
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

angina pectoris (an-JĪ-nuh PEK-tor-is): Severe chest pain resulting from temporary ischemia (local loss of blood supply) whenever the heart's workload increases (as during exertion or stress).

balloon angioplasty: A technique for reducing the size of a coronary plaque by compressing it against the arterial walls using a catheter with an inflatable collar.

cardiac tamponade: A condition, resulting from an accumulation of fluid in the pericardial cavity, which restricts movement of the heart and cardiac output.

cardiology (kar-dē-OL-o-jē): The study of the heart, its functions, and its diseases.

coronary arteriography: The production of an x-ray image of coronary circulation after the introduction of a radiopaque dye into one of the coronary arteries through a catheter; the resulting image is a *coronary angiogram*.

coronary artery bypass graft (CABG): The routing of blood around an obstructed coronary artery (or one of its branches) by a vessel transplanted from another site in the body.

coronary thrombosis: The presence of a thrombus (clot) in a coronary artery; may cause circulatory blockage resulting in a heart attack.

defibrillator: A device used to eliminate atrial or ventricular fibrillation (uncoordinated contractions) and restore normal cardiac rhythm.

echocardiography: Ultrasound analysis of the heart and of the blood flow through the great vessels.

heart block: An impairment of conduction in the heart in which damage to conduction pathways (due to mechanical distortion, ischemia, infection, or inflammation) disrupts the heart's normal rhythm.

pericarditis: Inflammation of the pericardium.

Summary Outline

The Heart's Role in the Cardiovascular System p. 435

- 1. The blood vessels of the cardiovascular system can be subdivided into the **pulmonary circuit** (which carries blood to and from the lungs) and the **systemic circuit** (which transports blood to and from the rest of the body). **Arteries** carry blood away from the heart; **veins** return blood to the heart. **Capillaries** are tiny vessels between the smallest arteries and smallest veins. (*Figure 12-1*)
- 2. The heart has four chambers: the **right atrium**, **right ventricle**, **left atrium**, and **left ventricle**.
- **12-1** The heart is a four-chambered organ, supplied by coronary circulation, that pumps oxygen-poor blood to the lungs and oxygen-rich blood to the rest of the body *p. 435*
- 3. The heart is surrounded by the **pericardium**, which is lined by the **serous pericardium**. The **visceral layer of the serous pericardium (epicardium)** covers the heart's outer surface. The **parietal layer of the serous pericardium** lines the inner surface of the *fibrous pericardium*. (*Figure 12-2*)

- **4.** The **coronary sulcus**, a deep groove, marks the boundary between the atria and ventricles. The **anterior** and **posterior interventricular sulci** mark the boundary between the left and right ventricles. (*Figure 12-3*)
- **5.** The bulk of the heart consists of the muscular **myocardium**. The **endocardium** lines the inner surfaces of the heart, and the **epicardium** covers the outer surface. (*Figure 12-4a,b*)
- **6. Cardiac muscle cells** are interconnected by **intercalated discs**, which convey the force of contraction from cell to cell and transmit action potentials. (*Figure 12-4c,d*)
- 7. The atria are separated by the **interatrial septum**, and the ventricles are separated by the **interventricular septum**. The right atrium receives blood from the systemic circuit by two large veins, the **superior vena cava** and **inferior vena cava**. (Spotlight Figure 12-5)
- 8. Blood flows from the right atrium into the right ventricle through the **tricuspid valve** (*right atrioventricular* [AV] *valve*). This opening is bounded by three **cusps** of fibrous tissue braced by the tendinous **chordae tendineae**, which are connected to **papillary muscles**. (*Spotlight Figure 12-5*)
- 9. Blood leaving the right ventricle enters the pulmonary trunk after passing through the pulmonary semilunar valve. The pulmonary trunk divides to form the left and right pulmonary arteries. The left and right pulmonary veins return oxygenated blood to the left atrium. Blood leaving the left atrium flows into the left ventricle through the mitral valve (left atrioventricular [AV] valve or bicuspid valve). Blood leaving the left ventricle passes through the aortic semilunar valve and into the systemic circuit through the aorta. (Spotlight Figure 12-5)
- **10.** Anatomical differences between the ventricles reflect the functional demands on them. The wall of the right ventricle is relatively thin. The left ventricle has a massive muscular wall.
- **11.** Valves normally permit blood flow in only one direction, preventing the **regurgitation** (backflow) of blood. *(Figure 12-6)*
- **12.** The connective tissues of the heart and **cardiac skeleton** support the heart's contractile cells and valves. *(Figure 12-6)*
- 13. The coronary circulation meets the high oxygen and nutrient demands of cardiac muscle cells. The two coronary arteries originate at the base of the aorta. Arterial anastomoses—interconnections between arteries—ensure a constant blood supply. The great and middle cardiac veins carry blood from the coronary capillaries to the coronary sinus. (*Figure 12-7*)

12-2 Contractile cells and the conducting system produce each heartbeat, and an electrocardiogram records the associated electrical events *p. 445*

14. Two general classes of cardiac cells are involved in the normal heartbeat: *contractile cells* and cells of the conducting system.

- **15.** Cardiac contractile cells have a long refractory period, so rapid stimulation produces isolated contractions (twitches) rather than tetanic contractions. (*Figure 12-8*)
- 16. The conducting system includes **nodal cells** and **conducting cells.** The conducting system initiates and distributes electrical impulses within the heart. Nodal cells establish the rate of cardiac contraction. **Pacemaker cells** are nodal cells that reach threshold first. Conducting cells distribute the contractile stimulus to the general myocardium.
- 17. Unlike skeletal muscle, cardiac muscle contracts without neural or hormonal stimulation. Pacemaker cells in the sinoatrial (SA) node (*cardiac pacemaker*) normally establish the rate of contraction. From the SA node, impulses travel to the atrioventricular (AV) node and then to the AV bundle, which divides into bundle branches. From there, Purkinje fibers convey the impulses to the ventricular myocardium. (*Figure 12-9*)
- 18. A recording of electrical activities in the heart is an electrocardiogram (ECG or EKG). Important landmarks of an ECG include the P wave (atrial depolarization), QRS complex (ventricular depolarization), and T wave (ventricular repolarization). (*Figure 12-10*)

12-3 Events during a complete heartbeat make up a cardiac cycle *p. 450*

- **19.** A **cardiac cycle** consists of **systole** (contraction) followed by **diastole** (relaxation). Both ventricles contract at the same time, and they eject equal volumes of blood. (*Figure 12-11*)
- **20.** The closing of the heart valves and the rushing of blood through the heart cause characteristic **heart sounds**. *(Figure 12-12)*

12-4 Heart dynamics examines the factors that affect cardiac output *p. 452*

- **21.** *Heart dynamics,* or *cardiodynamics,* refers to the movements and forces generated during contractions. The amount of blood ejected by a ventricle during a single beat is the **stroke volume (SV)**. The amount of blood pumped by the left ventricle each minute is the **cardiac output (CO)**.
- **22.** The major factors that affect cardiac output are blood volume reflexes, autonomic innervation, and hormones.
- **23.** Blood volume reflexes are stimulated by changes in **venous return**, the amount of blood entering the heart. The **atrial reflex** speeds up the heart rate when entering blood stretches the walls of the right atrium. Ventricular contractions become more powerful and increase stroke volume when the ventricular walls are stretched (the **Frank-Starling principle**).
- **24.** The basic heart rate is established by pacemaker cells, but it can be modified by the ANS. *(Figure 12-13)*
- **25.** Acetylcholine (ACh) released by parasympathetic motor neurons lowers heart rate and stroke volume. Norepinephrine (NE) released by sympathetic neurons increases heart rate and stroke volume.

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A

COLUMN B a. relaxation of heart chambers

- **b.** heart attack
- **c.** cardiac pacemaker
- **d.** tachycardia
- **e.** HR \times SV
- **f.** tricuspid valve
- g. bradycardia
- **h.** mitral valve
- i. interconnections between arteries
- j. visceral pericardium
- **k.** increased venous return
- **1.** contractions of heart
- chambers
- **13.** Identify the superficial structures in the following diagram of the heart.

- 14. Blood in the coronary sinus drains into the
 - (a) left atrium. (**b**) right atrium.
 - (d) right ventricle.
- **15.** Which type of membrane is pericardium an example of?
 - (a) cutaneous
 - (c) mucous
- **16.** The simple squamous epithelium covering the valves of the heart is called
 - (a) epicardium.

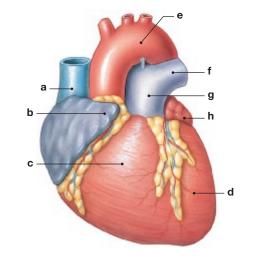

(c) myocardium.

dissolved gases.

(d) endothelium.

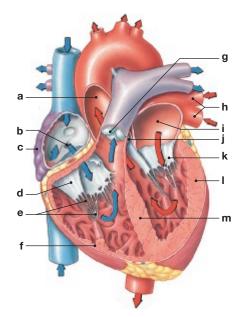

(b) endocardium.

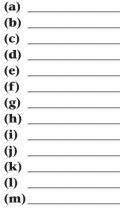

- 17. The cardiac skeleton of the heart
 - (a) consists of hyaline cartilage.
 - (b) is synthesized by osteoblasts.
 - (c) provides attachment for the papillary muscles.
 - (d) isolates the atrial muscle from the ventricular muscle.
- 18. Identify the structures in the following diagram of a sectional view of the heart.

(a)	(b)
(c)	(d)
(e)	(f)

(g) _____ (h) _

12

- (c) left ventricle.
- (b) serous (d) epithelium

- 19. A cardiac impulse travels from the
 - (a) atrioventricular node to the sinoatrial node.
 - (**b**) sinoatrial node to the atrial muscle.
 - (c) atrioventricular bundle to the atrioventricular node.
 - (d) Purkinje fibers to the left bundle branch.
- **20.** On an ECG, a single cycle of ventricular depolarization and repolarization is indicated by the
 - (a) QRS complex. (b) P-R interval.
 - (c) P wave. (d) Q-T interval.
- **21.** The second heart sound occurs due to
 - (a) the sudden flow of blood through semilunar valves.
 - (b) the sudden flow of blood through AV valves.
 - (c) blood rebounding off closed AV valves.
 - (d) blood rebounding off closed semilunar values.
- **22.** Where do the coronary arteries originate? How does the blood pressure in these arteries compare to that of the blood pressure in the rest of the systemic circuit?
- **23.** What are the valves in the heart, and what is the function of each?
- **24.** Trace the normal path of an electrical impulse (action potential) through the conducting system of the heart.
- **25.** (a) What is the cardiac cycle? (b) What phases and events are necessary to complete the cardiac cycle?

Level 2 Reviewing Concepts

- **26.** The muscular wall of the left ventricle is much thicker than the right ventricle because
 - (a) it has to pump a much larger volume of blood out of its chamber.
 - (b) it has to overcome a much greater pressure to eject the blood.
 - (c) the left bundle branch of the conducting system is much bulkier.
 - (d) a, b, and c are correct.
- **27.** The amount of blood forced out of the heart depends on the
 - (a) degree of stretching at the end of ventricular diastole.
 - (b) contractility of the ventricle.
 - (c) amount of pressure required to eject blood.
 - (**d**) a, b, and c are correct.
- **28.** When electrical impulses reach the AV node, there is a delay of 100 milliseconds [0.1sec]. Provide an explanation for this delay.
- **29.** Describe the relationships of the four chambers of the heart to the pulmonary and systemic circuits.
- **30.** What are the sources and clinical significance of the heart sounds?
- **31.** If a decrease in blood pressure is detected by the cardiac center, how will it respond to change the heart's cardiac output?

Level 3 Critical Thinking and Clinical Applications

32. Examination of a 50-year-old man who has a history of breathlessness revealed the presence of a loud systolic murmur and ruptured chordae tendineae of the mitral valve. What could be the cause of the murmur?

- **33.** The following measurements were made on two individuals (the values recorded remained stable for one hour): Person A: heart rate, 75 bpm; stroke volume, 60 mL Person B: heart rate, 90 bpm; stroke volume, 95 mL Which person has the greater venous return? Which person has the longer ventricular filling time?
- **34.** Tarryn suffers from hyperthyroidism, a condition that causes her thyroid gland to produce too much thyroid hormones. Do you expect her blood pressure to be higher or lower than normal? Explain your answer.

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **13-1** Distinguish among the types of blood vessels based on their structure and function.
- **13-2** Explain the processes that regulate blood flow through blood vessels, and discuss the processes that regulate movement of fluids between capillaries and interstitial spaces.
- **13-3** Describe the control processes that regulate blood flow and pressure in tissues, and explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through tissues.
- **13-4** Explain the cardiovascular system's homeostatic response to exercise and hemorrhaging.
- **13-5** Describe the three general functional patterns seen in the pulmonary and systemic circuits.
- **13-6** Identify the major arteries and veins of the pulmonary circuit.
- **13-7** Identify the major arteries and veins of the systemic circuit.
- **13-8** Identify the differences between fetal and adult circulation patterns, and describe the changes in the patterns of blood flow that occur at birth.
- **13-9** Discuss the effects of aging on the cardiovascular system.
- **13-10** Give examples of interactions between the cardiovascular system and other body systems presented so far.

Major Vessels of the Systemic Circuit, pp. 482–483

An Introduction to Blood Vessels and Circulation

We have already examined the composition of blood and the structure and function of the heart, whose pumping action keeps blood in motion (Chapters 11 and 12). Here we consider the vessels that carry blood to peripheral tissues, and the nature of the exchange that takes place between the blood and interstitial fluids.

In this chapter we first examine the structure of arteries, capillaries, and veins. Then we explore their functions, the basic principles of cardiovascular regulation, and the distribution of the body's major blood vessels.

Build Your Knowledge

Recall that the surface of the skin, the epidermis, lacks blood vessels. Its cells depend on the exchange of nutrients, dissolved gases, and wastes with capillaries in the dermis (as you saw in **Chapter 5: The Integumentary System**). Arteries supplying the skin form two networks in the dermis. One is a deep cutaneous plexus, and the other is a superficial subpapillary plexus. Loops of capillaries extending from the subpapillary plexus provide the sites where materials are exchanged with epidermal cells by diffusion. Blood in the capillaries drains into small veins of the subpapillary plexus. These veins then empty into those of the cutaneous plexus. **D p. 159**

13-1 Arteries, arterioles, capillaries, venules, and veins differ in size, structure, and function

Learning Outcome Distinguish among the types of blood vessels based on their structure and function.

Blood circulates throughout the body, moving from the heart through the tissues and back to the heart in blood vessels. Blood leaves the heart by way of the pulmonary trunk, which begins at the right ventricle, and the aorta, which begins at the left ventricle. Each of these vessels has an internal diameter of around 2.5 cm (1 in.). These vessels branch repeatedly, forming the major **arteries** that carry blood to body organs. Within these organs, further branching creates several hundred million tiny arteries, or **arterioles** (ar-TĒR-ē-ōls). The arterioles send blood into more than 10 billion **capillaries**. These capillaries are barely the diameter of a single red blood cell. The capillaries form extensive, branching networks. If all the capillaries in an average adult's body were placed end to end, their combined length would be more than 25,000 miles, enough to circle the planet.

The vital functions of the cardiovascular system take place at the capillary level. *Chemical and gaseous exchange between the blood and interstitial fluid takes place across capillary walls.* Tissue cells rely on capillary diffusion to obtain nutrients and oxygen and to remove metabolic wastes such as carbon dioxide and urea.

Blood flowing out of a capillary network first enters **venules** (VEN-ūls), the smallest vessels of the venous system. These slender vessels merge to form small **veins**. Blood then passes through medium-sized and large veins before reaching the venae cavae (in the systemic circuit) or the pulmonary veins (in the pulmonary circuit) (see **Figure 12-1**, p. 436).

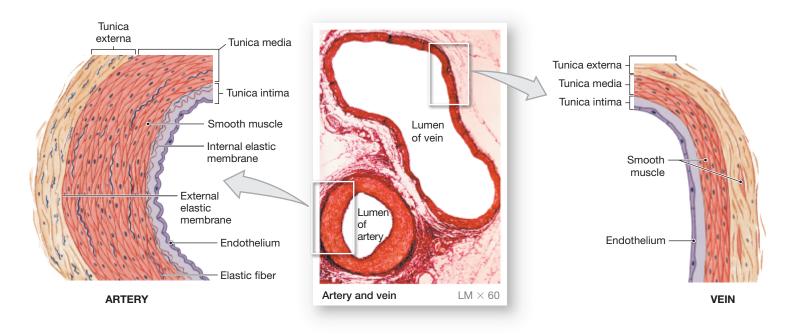

The Structure of Vessel Walls

The walls of arteries and veins are made up of three layers containing different tissues (Figure 13-1):

- 1. The **tunica intima** (IN-ti-muh) is the innermost layer of a blood vessel. It includes an endothelium with its basement membrane and a surrounding layer of connective tissue with elastic fibers.
- 2. The **tunica media** is the middle layer. It contains sheets of smooth muscle within loose connective tissue containing collagen and elastic fibers. Collagen fibers bind the tunica media to the tunica intima and tunica externa. When its smooth muscles contract, vessel diameter decreases. When they relax, vessel diameter increases.

Figure 13-1 A Comparison of a Typical Artery and a Typical Vein. In general, for a vessel of a given

size, an artery has a thicker wall and smaller lumen than a vein.

3. The outer tunica externa (eks-TER-nuh), or tunica adventitia (ad-ven-TISH-uh), forms a sheath of connective tissue around the vessel. Its collagen fibers may intertwine with those of adjacent tissues, stabilizing and anchoring the blood vessel.

Arteries and veins supplying the same region lie side by side (Figure 13-1). Such a sectional view clearly shows the greater wall thickness characteristic of arteries. The thicker tunica media of an artery contains more elastic fibers and smooth muscle cells than does that of a vein. The elastic fibers enable arterial vessels to resist the pressure generated by the heart as it forces blood into the arterial network. The smooth muscle provides a means of actively controlling vessel diameter. Arterial smooth muscle is under the control of the sympathetic division of the autonomic nervous system. When stimulated, these muscles in the vessel wall contract, and the artery constricts in a process called vasoconstriction. When these muscles relax, the diameter of the artery and its central opening, or *lumen*, increase in a process called **vasodilation**.

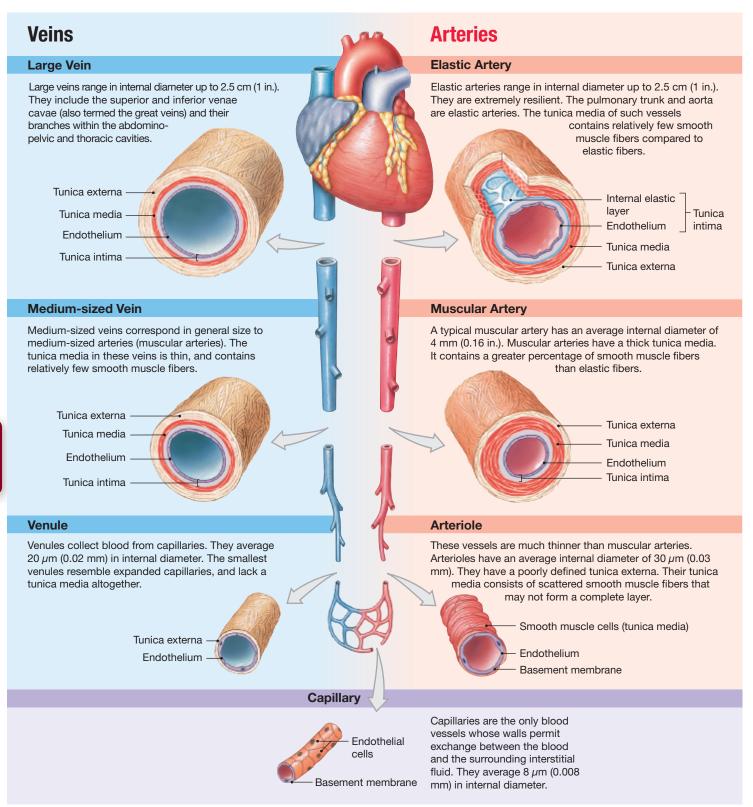

Arteries

On its way from the heart to the capillaries, blood passes through elastic arteries, muscular arteries, and arterioles (Figure 13-2).

Elastic arteries are large, extremely resilient vessels with internal (lumen) diameters up to 2.5 cm (1 in.). The pulmonary trunk and aorta, and their major arterial branches, are elastic 13 arteries. The walls of elastic arteries contain a tunica media dominated by elastic fibers rather than smooth muscle cells. For this reason, elastic arteries are able to absorb the pressure changes of the cardiac cycle. During ventricular systole, blood pressure rises quickly as additional blood is pushed into the systemic circuit. Over this period, the elastic arteries are stretched, and their diameter increases. During ventricular diastole, arterial blood pressure declines, and the elastic fibers recoil to their original dimensions. The net result is that the expansion of the arteries dampens the rise in pressure during ventricular systole, and the arterial recoil slows the decline in pressure during ventricular diastole. If the arteries were solid pipes rather than elastic tubes, pressures would rise much higher during systole. Pressures would also fall much lower during diastole.

Muscular arteries, also known as medium-sized arteries or distribution arteries, distribute blood to skeletal muscles and internal organs. A typical muscular artery has an internal diameter of approximately 4 mm (0.16 in.). The external carotid arteries of the neck are one example. The thick tunica media in a muscular artery contains more smooth muscle cells and fewer elastic fibers than does an elastic artery (Figure 13-2).

Figure 13-2 The Structure of the Various Types of Blood Vessels. The different types of blood vessels have different external and internal (lumen) diameters and wall thicknesses. Note that the wall of a capillary is only one cell thick. This wall consists of an endothelium and a basement membrane.

Arterioles, with an internal diameter of about $30 \,\mu\text{m}$ (0.03 mm), are much smaller than muscular arteries. The tunica media of an arteriole consists of one to two layers of smooth muscle cells. The diameter of the smaller muscular arteries and arterioles changes in response to local conditions, such as low oxygen levels, or to sympathetic or endocrine stimulation. Such changes in diameter alter blood pressure and the rate of flow through dependent tissues.

CLINICAL NOTE

Arteriosclerosis

Arteriosclerosis (ar-tēr-ē-ō-skler-Ō-sis; *skleros*, hard) is a thickening and toughening of arterial walls. Many people know it as "hardening of the arteries." Complications related to it account for about half of all deaths in the United States. The effects of arteriosclerosis are varied. For example, arteriosclerosis of coronary vessels is responsible for *coronary artery disease* (*CAD*). $\stackrel{\frown}{\supset}$ p. 444

Arteriosclerosis of arteries supplying the brain can lead to strokes. Arteriosclerosis takes two major forms:

- 1. Focal calcification is the deposition of calcium salts following the gradual degeneration of smooth muscle in the tunica media. Some focal calcification is part of the aging process. It may also develop in association with *atherosclerosis*.
- Atherosclerosis (ath-er-ō-skler-Ō-sis; athero-, a pasty deposit) is the formation of lipid deposits in the tunica media associated with damage to the endothelial lining. It is the most common form of arteriosclerosis.

Many factors may contribute to the development of atherosclerosis. Lipid levels in the blood are one major factor. Atherosclerosis tends to develop in people whose blood contains elevated levels of lipids, specifically cholesterol. Cholesterol is transported to peripheral tissues in protein–lipid complexes called *lipoproteins*. (We will discuss the various types of lipoproteins in Chapter 17.) When cholesterol-rich lipoproteins remain in circulation for an extended **Capillaries**

When we think of the cardiovascular system, we usually think first of the heart or the great blood vessels attached to it. But the microscopic capillaries that spread throughout most tissues do the real work of the cardiovascular system. The reason is that capillaries are the *only* blood vessels whose walls permit exchange between the blood and the surrounding interstitial fluid. Capillary walls

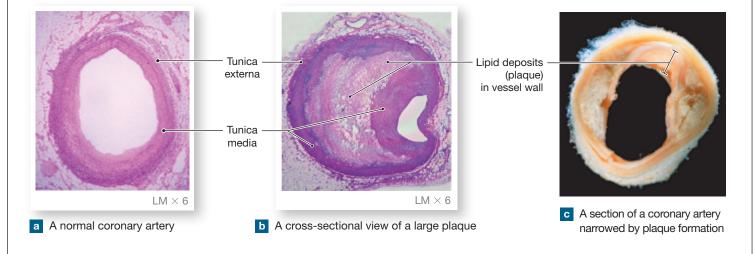

period, circulating monocytes begin removing them from the bloodstream. Eventually the mono-

cytes become filled with lipid droplets. Now called foam cells, they attach themselves to the endothelial lining of blood vessels. These cells then release growth factors that stimulate smooth muscle cells near the tunica intima to divide, thickening the vessel wall.

Other monocytes then invade the area, migrating between the endothelial cells. As these changes take place, the monocytes, smooth muscle fibers, and endothelial cells begin phagocytizing lipids as well. The result is an atherosclerotic **plaque**, a fatty mass of tissue that projects into the lumen of the vessel. At this point, the plaque has a relatively simple structure, and evidence suggests that the process can be reversed with appropriate dietary adjustments.

If the conditions persist, the endothelial cells become swollen with lipids, and gaps appear in the endothelial lining. Platelets now begin sticking to the exposed collagen fibers. This platelet adhesion and aggregation lead to the formation of a localized blood clot that further restricts arterial blood flow. The structure of the plaque is now relatively complex. Plaque growth can be halted, but the structural changes are permanent. A typical plaque is shown in **b** and **c**. A normal artery appears in **a**.

Elderly individuals, especially elderly men, are most likely to develop atherosclerotic plaques. In addition to age, sex, and high blood cholesterol levels, other important risk factors include high blood pressure, cigarette smoking, diabetes mellitus, obesity, and stress.

are relatively thin, so diffusion distances are short, and exchange can take place quickly. In addition, the small diameter of capillaries slows blood flow, allowing time for the diffusion or active transport of materials across capillary walls.

A typical capillary consists of a single layer of endothelial cells inside a basement membrane (**Figure 13-2**). There is no tunica externa and no tunica media. The average internal diameter of a capillary is 8 μ m (0.008 mm), very close to that of a red blood cell. In most regions of the body, the endothelium forms a complete lining. Most substances enter or leave the capillary by diffusing across endothelial cells or through gaps between them. Water, small solutes, and lipid-soluble materials can easily diffuse into the surrounding interstitial fluid. In a few areas (notably, the choroid plexus of the brain, the hypothalamus, and filtration sites in the kidneys), small pores in the endothelial cells also permit the passage of relatively large molecules, including proteins.

Capillaries do not function as individual units. Instead, they function as part of an interconnected network called a **capillary bed** (**Figure 13-3**). A single arteriole usually gives rise to dozens of capillaries. In turn, capillaries collect into several *venules*, the smallest venous vessels. A **precapillary sphincter**, a band of smooth muscle, guards the entrance to each capillary. Contraction of the smooth muscle fibers narrows the diameter of the capillary's entrance and reduces the flow of blood. The relaxation of the sphincter dilates the opening, allowing blood to enter the capillary more rapidly.

Blood usually flows from arterioles to venules at a constant rate, but the blood flow within any single capillary can be quite variable. Each precapillary sphincter undergoes cycles of activity, alternately contracting and relaxing perhaps a dozen times each minute. As a result of this cyclical change—called **vasomotion** (*vaso-*, vessel)—blood flow within any given capillary is intermittent rather than a steady and constant stream. The net effect is that blood may reach the venules by one route now and by a quite different route later.

This process is controlled at the tissue level, as smooth muscle fibers respond to local changes in the concentrations of chemicals and dissolved gases in the interstitial fluid. For example, when dissolved oxygen levels decline within a tissue, the capillary sphincters relax, and blood flow to the area increases. Such control at the tissue level is called *autoregulation*.

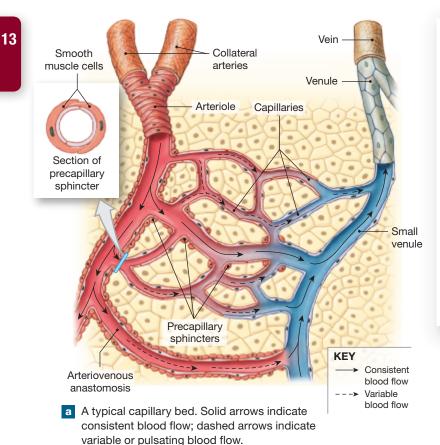

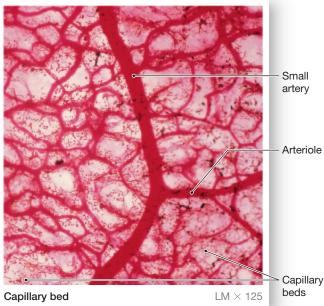

Figure 13-3 The Organization of a Capillary Bed.

b A micrograph of a number of capillary beds.

Sometimes alternate routes for blood flow are formed by an **anastomosis** (a-nas-tō-MŌ-sis; "outlet"; plural, *anastomoses*), the joining of blood vessels. Under certain conditions, blood completely bypasses a capillary bed through an **arteriovenous** (**ar-tēr-ē-ō-VĒ-nus**) **anastomosis**, a vessel that connects an arteriole to a venule (Figure 13-3a). In other cases, a single capillary bed is supplied by an **arterial anastomosis**, in which multiple arteries fuse before giving rise to arterioles. An arterial anastomosis serves as an insurance policy for capillary beds. If one artery is compressed or blocked, the others can continue to deliver blood to the capillary bed, and dependent tissues will not be damaged. Arterial anastomoses are found in the brain, in the coronary circulation, and in many other sites as well. \mathfrak{O} p. 444

Veins

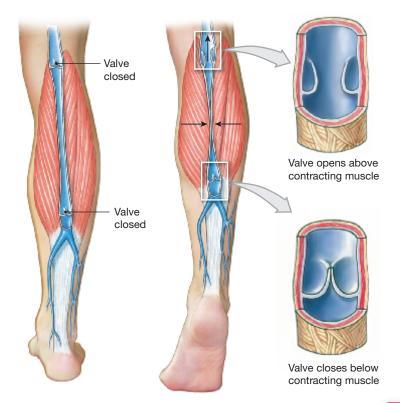

Veins collect blood from all tissues and organs and return it to the heart. Veins are classified on the basis of their internal diameters. **Venules** are the thinnest. An average venule has an internal diameter of 20 μ m (0.02 mm). Those smaller than 50 μ m (0.05 mm) lack a tunica media, and resemble expanded capillaries (Figure 13-2).

Medium-sized veins are comparable in size to muscular arteries. They range from 2 to 9 mm (0.08 to 0.35 in.) in internal diameter. Their tunica media contains several smooth muscle layers. The relatively thick tunica externa has longitudinal bundles of elastic and collagen fibers.

Large veins include the two venae cavae and their tributaries in the abdominopelvic and thoracic cavities. In these veins, the thin tunica media is surrounded by a thick tunica externa made of a mixture of elastic and collagen fibers.

Veins have relatively thin walls because the blood pressure inside them is low. The blood pressure in venules and mediumsized veins is so low that it cannot overcome the force of gravity. In the limbs, medium-sized veins contain valves, folds of tunica intima that project from the vessel wall. They function like the valves in the heart, preventing the backflow of blood (Figure 13-4). As long as the valves work normally, any body movement that compresses a vein will push blood toward the heart, improving venous return. \supset p. 452 If the walls of the veins near the valves weaken or become stretched and distorted, the valves may not work properly. Blood then pools in the veins, and the vessels become distended. The effects range from mild discomfort and a cosmetic problem, as in superficial varicose veins in the thighs and legs, to painful distortion of adjacent tissues, as in hemorrhoids, swollen veins in the lining of the anal canal.

Figure 13-4 The Function of Valves in the Venous System. Valves in the walls of medium-sized veins prevent the backflow of blood. The compression of veins by the contraction of adjacent skeletal muscles helps maintain venous blood flow.

CHECKPOINT

- **1.** List the five general classes of blood vessels.
- **2.** A cross section of tissue shows several small, thinwalled vessels with very little smooth muscle tissue in the tunica media. Which type of vessels are these?
- **3.** What effect would relaxation of precapillary sphincters have on blood flow through a tissue?
- **4.** Why are valves found in veins, but not in arteries? See the blue Answers tab at the back of the book.

13-2 Pressure and resistance determine blood flow and affect rates of capillary exchange

Learning Outcome Explain the processes that regulate blood flow through blood vessels, and discuss the processes that regulate movement of fluids between capillaries and interstitial spaces.

The primary function of the parts of the cardiovascular system (the blood, heart, and blood vessels) is to maintain an adequate blood flow through the capillaries in the tissues and organs of the body. Under normal circumstances, blood flow equals cardiac output. When cardiac output goes up, so does blood flow through capillary beds. When cardiac output declines, blood flow is reduced. But the flow of blood through capillaries also depends on two additional factors-pressure and resistance—as we discuss next.

Factors Affecting Blood Flow

To keep blood moving in the body, the heart must generate enough pressure to overcome the resistance to blood flow in the pulmonary and systemic circuits. Pressure and resistance both affect blood flow to the tissues, but they have opposing effects. In general terms, blood flow and pressure are directly related. That is, when pressure increases, flow increases. Blood flow and resistance are inversely related. So, when resistance increases, flow decreases.

Pressure

Liquids, including blood, cannot be compressed. For this reason, a force exerted against a liquid generates a fluid pressure, or hydrostatic pressure, that is conducted in all directions. If pressures differ from one place to another, a liquid will flow from an area of higher pressure toward an area of lower pressure. The flow rate is directly proportional to the pressure difference. The greater the difference in pressure, the faster the flow.

However, the absolute pressure is less important than the **13** *pressure gradient*—the difference in pressure from one end of the vessel to the other. The largest pressure gradient is found in the systemic circuit between the base of the aorta (where blood leaves the left ventricle) and the entrance to the right atrium (where blood returns to the heart). This pressure difference, called the *circulatory pressure*, averages about 100 mm Hg (millimeters of mercury, a standard unit of pressure). This relatively high circulatory pressure serves primarily to force blood through the arterioles and into the capillaries.

We can divide circulatory pressure into three components: (1) arterial pressure (routinely measured on a person's arm and commonly referred to as **blood pressure**); (2) *capillary pressure;* and (3) venous pressure. Shortly we will discuss each component of circulatory pressure.

Resistance

Resistance is any force that opposes movement. In the cardiovascular system, resistance opposes the movement of blood. For blood to flow, the circulatory pressure must be great enough to overcome the total peripheral resistance, the resistance of the entire cardiovascular system. The steepest decline in pressure within the cardiovascular system—about 65 mm Hg—occurs in the arterial network because of the high resistance of the arterioles. The resistance of the arterial system is termed **peripheral resistance**. Sources of peripheral resistance include vascular resistance, viscosity, and turbulence.

VASCULAR RESISTANCE. Vascular resistance is the resistance of the blood vessels to blood flow. It is the largest component of peripheral resistance. The most important factor in vascular resistance is friction between the blood and the vessel walls. The amount of friction depends on the length and diameter of the vessel. Friction increases with increasing vessel length, because longer vessels have a larger surface area in contact with the blood. Friction also increases with decreasing vessel diameter. For this reason, in small-diameter vessels, nearly all the blood is slowed down by friction with the vessel walls. Vessel length cannot ordinarily be changed, so vascular resistance is controlled by changing the diameter of blood vessels. Such changes take place through the contraction or relaxation of smooth muscle in the vessel walls.

Most of the vascular resistance occurs in arterioles, which are extremely muscular. The walls of an arteriole with a $30-\mu m$ internal diameter, for example, can have a $20-\mu$ m-thick layer of smooth muscle. Local, neural, and hormonal stimuli that stimulate or inhibit contractions of this smooth muscle tissue can adjust the diameters of these vessels. A small change in diameter can produce a very large change in resistance.

VISCOSITY. Viscosity is the resistance to flow caused by interactions among molecules and suspended materials in a liquid. Liquids of low viscosity, such as water, flow at low pressures. Thick, syrupy liquids such as molasses flow only under higher pressures. Whole blood has a viscosity about five times that of water. \bigcirc p. 411 This viscosity is due to its plasma proteins and blood cells.

Under normal conditions, the viscosity of blood remains stable. But disorders that affect the hematocrit or the plasma protein content can change blood viscosity and increase or decrease peripheral resistance. For example, in anemia, the hematocrit is reduced due to inadequate production of hemoglobin, RBCs, or both. As a result, both the oxygen-carrying capacity and the viscosity of the blood are reduced. A reduction in blood viscosity can also result from protein deficiency diseases, in which the liver cannot synthesize normal amounts of plasma proteins.

TURBULENCE. Blood usually flows through a vessel smoothly. The slowest flow is near the walls, and the fastest flow is at the center of the vessel. High flow rates, irregular surfaces due

to injury or disease processes, or sudden changes in vessel diameter upset this smooth flow, creating eddies and swirls. This result, called **turbulence**, increases resistance and slows blood flow.

Turbulence normally occurs when blood flows between the heart's chambers and from the heart into the aorta and pulmonary trunk. In addition to increasing resistance, this turbulence generates the third and fourth heart sounds often heard through a stethoscope. Turbulent blood flow across damaged or misaligned heart valves produces the sound of heart murmurs. $\bigcirc p. 442$

The Interplay between Pressure and Resistance

Neural and hormonal control processes regulate blood pressure, keeping it relatively stable. Adjustments in the peripheral resistance of vessels supplying specific organs allow the rate of blood flow to be precisely controlled. An example is the increase in blood flow to skeletal muscles during exercise (discussed in Chapter 7). \supset p. 267 That increase results from a drop in the peripheral resistance of the arteries supplying active muscles. Of the three sources of resistance, only vascular resistance can be adjusted by the nervous or endocrine systems to regulate blood flow. Viscosity and turbulence, which also affect peripheral resistance, are normally constant.

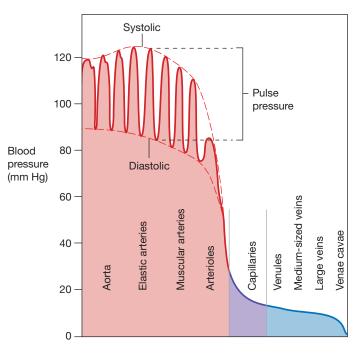

Cardiovascular Pressures within the **Systemic Circuit**

Pressure varies along the path of blood flow within the systemic circuit. Systemic pressures are highest in the aorta, peaking at around 120 mm Hg, and lowest at the venae cavae, averaging about 2 mm Hg (Figure 13-5). Next we consider pressures in the arterial network. We then examine how pressure in the capillaries drives the exchange of substances between the bloodstream and body tissues before we consider pressures in the venous system.

Blood Pressure (Arterial Pressure)

The pressure in large and small arteries fluctuates, rising during ventricular systole and falling during ventricular diastole (Figure 13-5). Systolic pressure is the peak blood pressure measured during ventricular systole. Diastolic pressure is the minimum blood pressure at the end of ventricular diastole. In recording blood pressure, we separate systolic and diastolic pressures by a slash mark, as in "120/80" (read as "one twenty over eighty"). A pulse is a rhythmic pressure oscillation that accompanies each heartbeat. The difference

Figure 13-5 Pressures within the Systemic Circuit. Notice the general reduction of circulatory pressure within the systemic circuit and the elimination of the pulse pressure in the arterioles.

between the systolic and diastolic pressures is the **pulse** pressure (pulsus, stroke).

Pulse pressure lessens as the distance from the heart increases. As noted earlier, the average pressure declines due to 13 friction between the blood and the vessel walls. The pulse pressure fades because arteries are elastic tubes rather than solid pipes. Much as a balloon's walls expand when air enters, the elasticity of the arteries allows them to expand with blood during systole. When diastole begins and blood pressures fall, the arteries recoil to their original dimensions. This arterial recoil

Build Your Knowledge

Recall that diffusion is a passive transport process (as you saw in Chapter 3: Cell Structure and Function). Passive transport processes move ions or molecules across the plasma membrane without any energy being expended by the cell. Osmosis is a special term for the diffusion of water across a selectively permeable membrane that separates two solutions of differing solute concentrations. During osmosis, water moves into the solution with the higher solute concentration. **Dpp. 91, 93**

adds an extra push to the flow of blood because the aortic semilunar valve prevents blood from returning to the heart. The magnitude of this effect, called *elastic rebound*, is greatest near the heart and drops in succeeding arterial sections.

By the time blood reaches a precapillary sphincter, no pressure oscillations remain. The blood pressure is about 35 mm Hg (Figure 13-5). Along the length of a typical capillary, blood pressure gradually falls from about 35 mm Hg to roughly 18 mm Hg, the pressure at the start of the venous system.

Capillary Pressures and Capillary Exchange

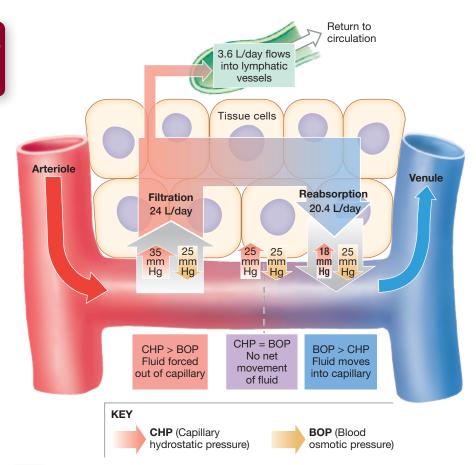

The pressure of blood within a capillary bed is called **capillary pressure**. Blood pushes against capillary walls, just as it does in arteries. But unlike other blood vessel walls, capillary walls are quite permeable to small ions, nutrients, organic wastes, dissolved gases, and water. These materials exit, but most are reabsorbed by the capillaries. The remainder, about 3.6 liters

(0.95 gallons) of water and solutes, flows through peripheral tissues each day. It then enters the **lymphatic vessels** of the lymphatic system, which empty into the bloodstream (**Figure 13-6**).

This continuous movement and exchange of water and solutes out of the capillaries, through the body tissues, and then back into the bloodstream has four important functions:

- **1.** *Communication.* It maintains constant communication between blood plasma and interstitial fluid. Together, they account for most of the volume of extracellular fluid (ECF) in the body.
- **2.** *Distribution.* It speeds the distribution of nutrients, hormones, and dissolved gases throughout tissues.
- **3.** *Transport.* It assists in the transport of insoluble lipids and tissue proteins that cannot enter the bloodstream by crossing capillary walls.
- **4.** *Defense.* It flushes bacterial toxins and other chemical stimuli to lymphatic tissues and organs responsible for providing immunity to disease.

Figure 13-6 Forces Acting across Capillary Walls. At the arterial end of the capillary, capillary hydrostatic pressure (CHP) is greater than blood osmotic pressure (BOP), so fluid moves out of the capillary (filtration). Near the venule, CHP is lower than BOP, so fluid moves into the capillary (reabsorption).

Capillary exchange between the plasma and interstitial fluid plays a key role in homeostasis. The most important processes that move materials across capillary walls are diffusion, filtration, and reabsorption.

Diffusion is the net movement of ions or molecules from an area where their concentration is higher to an area where their concentration is lower. Solute molecules tend to diffuse across the capillary endothelium, driven by their individual concentration gradients. Water-soluble materials—including ions and small organic molecules such as glucose, amino acids, or urea—diffuse through small spaces between adjacent endothelial cells. (Larger water-soluble molecules, such as plasma proteins, cannot normally leave the bloodstream.) Lipid-soluble materialsincluding steroids, fatty acids, and dissolved gases-diffuse across the endothelium, passing through the membrane lipids.

Filtration is the removal of solutes as a solution flows across a porous membrane. Solutes too large to pass through the pores are filtered out of the solution. The driving force of filtration is hydrostatic pressure. As we saw earlier, it pushes water from an area of higher pressure to an area of lower pressure. Water molecules

CLINICAL NOTE

Capillary Dynamics and Blood Volume and Pressure

What happens at the capillary level to a bleeding accident victim? Or to a dehydrated person lost in the desert? In both cases, the decrease in blood volume causes a drop in blood pressure. In the second case, however, the loss in blood volume is also accompanied by a rise in blood osmotic pressure, because as water is lost, the blood becomes more concentrated. In both cases, a net movement of water from the interstitial fluid to the bloodstream takes place, and blood volume increases. This process is known as a recall of fluids.

The opposite situation is edema (e-DĒ-muh), an abnormal accumulation of interstitial fluid in the tissues. Localized edema often occurs around a bruise, for example. Damage to capillaries at the injury site allows plasma proteins to leak into the interstitial fluid, which decreases the osmotic pressure of the blood and elevates that of the tissues. More water then moves into the tissue, resulting in edema. In the U.S. population, serious cases of edema most often result from an increase in pressure in the arterial system, the venous system, or both. This condition often occurs during congestive heart failure (CHF).

Heart failure occurs when cardiac output cannot meet the circulatory demands of the body. In congestive heart failure, the left ventricle can no longer keep up with the right ventricle. Blood flow backs up (becomes congested) in the pulmonary circuit. This situation makes the right ventricle work harder, further elevating pulmonary arterial pressures and forcing blood through the lungs and into the weakened left ventricle. The increased blood pressure in the pulmonary vessels leads to pulmonary edema, a buildup of fluids in the lungs.

move when driven by either hydrostatic (fluid) pressure or osmotic pressure. **D** p. 94

In capillary filtration, water and small solutes are forced across a capillary wall, leaving larger solutes and suspended proteins in the bloodstream (Figure 13-6). At a capillary, the hydrostatic pressure, or capillary hydrostatic pressure (CHP), is greatest at the arterial end (35 mm Hg) and least at the venous end (18 mm Hg). As a result, filtration is greatest at the start of a capillary, where the CHP is highest, and declines along the length of the capillary as CHP falls.

Reabsorption takes place as the result of osmosis. Osmosis refers to the diffusion of water across a selectively permeable membrane. When such a membrane separates two solutions of differing solute concentrations, water moves into the solution with the higher solute concentration. The force of this water movement is called osmotic pressure. Because blood contains more dissolved proteins than does interstitial fluid, its osmotic pressure is higher, and water tends to move from the

interstitial fluid into the blood. **D** p. 94 The osmotic pressure of blood (25 mm Hg) is constant along the length of the capillaries. Thus, capillary hydrostatic pressure (CHP) tends to push water out of the capillary, and blood osmotic pressure (BOP) tends to reabsorb water, or pull it back in (Figure 13-6).

Venous Pressure

Pressure at the start of the venous system (18 mm Hg) is only about one-fifth of the pressure at the start of the arterial system (100 mm Hg) (Figure 13-5). Yet the blood must still travel through a vascular network that is just as complex as the arterial system before returning to the heart. However, venous pressures are low, but the veins offer little resistance. For this reason, once blood enters the venous system, pressure declines very slowly.

As blood travels through the venous system toward the heart, the veins become larger, resistance drops further, and the flow rate increases. Pressures at the entrance to the right atrium fluctuate, but average about 2 mm Hg. This means that the driving force pushing blood through the venous system is a mere 16 mm Hg (18 mm Hg in the venules -2 mm Hg in the venae cavae = 16 mm Hg). In comparison, a pressure of 65 mm Hg acts along the arterial system (100 mm Hg at the aorta -35 mm Hg at the capillaries = 65 mm Hg).

When you are lying down, a pressure gradient of 16 mm Hg is sufficient to maintain venous flow. But when you are standing, 13 venous blood in regions below the heart must overcome gravity as it ascends within the inferior vena cava. Two factors help overcome gravity and propel venous blood toward the heart:

- 1. Muscular compression. The contractions of skeletal muscles near a vein compress it, helping push blood toward the heart. The valves in medium-sized veins ensure that blood flow occurs in one direction only (Figure 13-4, p. 465).
- 2. The respiratory pump. As you inhale, your thoracic cavity expands, reducing pressures within the pleural cavities. This drop in pressure draws air into the lungs. At the same time, it also pulls blood into the inferior vena cava and right atrium from smaller veins in the abdominal cavity and lower body, increasing venous return. During exhalation, the increased pressure that forces air out of the lungs compresses the venae cavae, pushing blood into the right atrium.

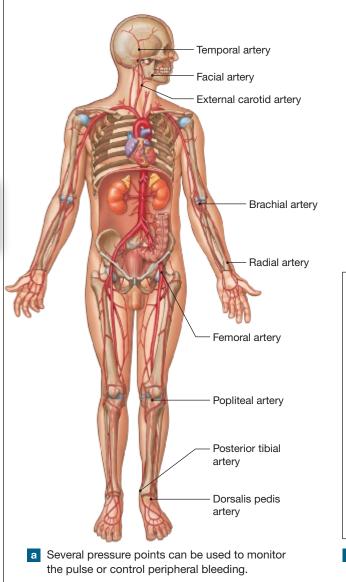

During exercise, both factors work together to increase venous return and push cardiac output to maximal levels. However, when a person stands at attention, with knees locked and leg muscles immobile, these factors are impaired.

CLINICAL NOTE

Checking the Pulse and Blood Pressure

You can feel a pulse within any large or medium-sized artery. The usual procedure involves using your fingertips to compress an artery against a relatively solid mass, preferably a bone. When the vessel is compressed, the pulse is felt as a pressure against the fingertips.

The locations used to check the pulse are shown in **a**. The inside of the wrist is often used because the *radial artery* can easily be pressed against the distal portion of the radius. Other accessible arteries include the *temporal, facial, external carotid, brachial, femoral, popliteal, posterior tibial,* and *dorsalis pedis arteries*. Firm pressure exerted on an artery near the base of a limb can reduce or eliminate arterial bleeding in more distal portions of the limb. These sites are called *pressure points*.

Blood pressure is measured using a *sphygmomanometer* (sfig-mō-ma-NOM-e-ter;

sphygmos, pulse + manometer, device for measuring pressure), as shown in **b**. A clinician places the inflatable cuff around the arm such that inflation of the cuff squeezes the brachial artery. The clinician places a stethoscope over the artery distal to the cuff and then inflates the cuff. A tube connects the cuff to a pressure gauge that measures the pressure inside the cuff in millimeters of mercury (mm Hg). Inflation continues until cuff pressure is roughly 30 mm Hg above the pressure sufficient to collapse the brachial artery, stop the flow of blood, and eliminate the sound of the pulse.

The clinician then slowly lets air out of the cuff. When the pressure in the cuff falls below systolic pressure, blood can again enter the artery. At first, blood enters only at peak systolic pressures, and the sound of blood pulsing through the artery becomes audible through the stethoscope. As the pressure falls further, the sound changes because the vessel is remaining open for longer and longer periods. When the cuff pressure falls below diastolic pressure, blood flow becomes continuous, and the sound of the pulse becomes muffled or disappears completely.

The pressure at which the pulse can first be heard corresponds to the peak systolic pressure. When the pulse fades, the pressure has reached diastolic levels. The distinctive sounds heard during this test are called sounds of Korotkoff (sometimes spelled *Korotkov* or *Korotkow*). When the blood pressure is recorded, systolic and diastolic pressures are usually separated by a slash, as in "120/80" ("one twenty over eighty") or "110/75." A reading of 120/80 corresponds to a pulse pressure of 40 (mm Hg).

b A sphygmomanometer and a stethoscope are used to check an individual's blood pressure.

The reduction in venous return leads to a fall in cardiac output. The blood supply to the brain is in turn reduced, sometimes enough to cause *fainting*, a temporary loss of consciousness. The person then collapses, but once the body is horizontal, both venous return and cardiac output return to normal.

CHECKPOINT

- 5. Identify the factors that contribute to total peripheral resistance.
- 6. In a healthy person, where is blood pressure greater: at the aorta or at the inferior vena cava? Explain.
- 7. While standing in the hot sun, Sally begins to feel light-headed and then faints. Explain what happened.

See the blue Answers tab at the back of the book.

13-3 Cardiovascular regulation involves autoregulation, neural processes, and endocrine responses

Learning Outcome Describe the control processes that regulate blood flow and pressure in tissues, and explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through tissues.

Homeostatic processes regulate cardiovascular activity to ensure that tissue blood flow, also called tissue perfusion, meets the demand for oxygen and nutrients. The factors that affect tissue blood flow are (1) cardiac output, (2) peripheral resistance, and (3) blood pressure. We discussed cardiac output in Chapter 12. Dp. 452 We considered peripheral resistance and pressure earlier in this chapter.

Most cells are relatively close to capillaries. When a group of cells becomes active, the circulation to that region must increase to deliver the oxygen and nutrients they need and to carry away the waste products and carbon dioxide they generate. The goal of cardiovascular regulation is to ensure that these blood flow changes take place (1) at an appropriate time, (2) in the right area, and (3) without drastically altering blood pressure and blood flow to vital organs.

The processes involved in regulating cardiovascular function include the following:

• Autoregulation. Changes in tissue conditions act directly on precapillary sphincters to alter peripheral resistance, producing local changes in the pattern of blood flow within capillary beds. Autoregulation causes immediate, localized homeostatic adjustments. If autoregulation fails to normalize tissue conditions, then neural and endocrine processes are activated.

- *Neural processes.* The nervous system responds to changes in arterial pressure or blood gas levels sensed at specific sites. When those changes take place, the autonomic nervous system adjusts cardiac output and peripheral resistance to maintain adequate blood flow.
- Endocrine processes. The endocrine system releases hormones that enhance short-term adjustments and direct long-term changes in cardiovascular performance.

Short-term responses adjust cardiac output and peripheral resistance to stabilize blood pressure and blood flow to tissues. Long-term adjustments involve alterations in blood volume that affect cardiac output and the transport of oxygen and carbon dioxide to and from active tissues.

The regulatory relationships that compensate for a reduction in blood pressure and blood flow are diagrammed in Figure 13-7.

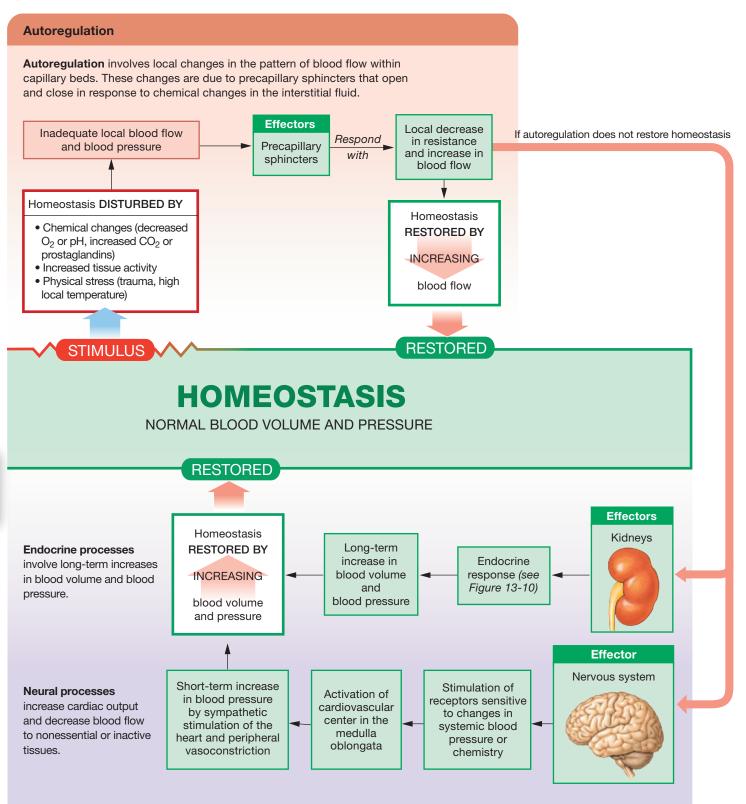

Autoregulation of Blood Flow within Tissues

Under normal resting conditions, cardiac output remains stable. Peripheral resistance within individual tissues is adjusted by precapillary sphincters to control local blood flow.

The smooth muscles of precapillary sphincters respond automatically to certain changes in the local environment. Such changes may take place in oxygen and carbon dioxide levels or the presence of specific chemicals. For example, 13 when oxygen is abundant, the smooth muscle cells in the sphincters contract and slow the flow of blood. As the cells take up and use O₂, tissue oxygen supplies dwindle, carbon dioxide levels rise, and pH falls. These chemical changes signal the smooth muscle cells in the precapillary sphincters to relax, and blood flow increases. Similarly, changes involving other chemicals can trigger the relaxation of precapillary sphincters, increasing blood flow. These triggers include the presence of histamine at an injury site during inflammation, and the release of nitric oxide (NO) by capillary endothelial cells stimulated by high shear forces along the capillary walls.

Factors that promote the dilation of precapillary sphincters are called vasodilators. Those that stimulate the constriction of precapillary sphincters are called vasoconstrictors. Together, such factors control blood flow in a single capillary bed. In high concentrations, these factors also affect arterioles, increasing or decreasing blood flow to all the capillary beds in a given region. Such an event often triggers a neural response, because significant changes in blood flow to one region of the body immediately affect circulation to other regions.

Figure 13-7 Short-Term and Long-Term Cardiovascular Responses.

Neural and Hormonal Processes

Neural Control of Blood Pressure and Blood Flow

The nervous system adjusts cardiac output and peripheral resistance to maintain adequate blood flow to vital tissues and organs. The *cardiovascular center* of the medulla oblongata is responsible for these regulatory activities. Dp. 308 This center includes the *cardiac center* and the *vasomotor center*. The cardiac center has a *cardioacceleratory center*, which increases cardiac output through sympathetic innervation (as noted in Chapter 12). The cardiac center also has a *cardioinhibitory center*, which reduces cardiac output through parasympathetic innervation. Dp. 454

The vasomotor center of the medulla oblongata primarily controls the diameters of arterioles through sympathetic innervation. Inhibition of the vasomotor center leads to vasodilation (dilation of arterioles), reducing peripheral resistance. Stimulation of the vasomotor center causes vasoconstriction (constriction of peripheral arterioles). Very strong stimulation causes **venoconstriction** (constriction of peripheral veins). Both types of constriction increase peripheral resistance.

The *cardiovascular center* detects changes in tissue demand by monitoring arterial blood, especially blood pressure, pH, and dissolved gas concentrations. *Baroreceptor reflexes* respond to changes in blood pressure. *Chemoreceptor reflexes* respond to changes in chemical composition. Negative feedback regulates these reflexes: The stimulation of a receptor by an abnormal condition leads to a response that counteracts the stimulus and restores normal conditions.

Baroreceptor Reflexes

Baroreceptors monitor the degree of stretch in the walls of expandable organs. \bigcirc p. 340 The baroreceptors involved in cardiovascular regulation are found in the walls of (1) the **carotid sinuses**, expanded chambers near the bases of the *internal carotid arteries* of the neck (Figure 13-15a, p. 485); (2) the **aortic arch** (Figure 13-14, p. 484); and (3) the right atrium. These receptors initiate **baroreceptor reflexes** (*baro-*, pressure), autonomic reflexes that adjust cardiac output and peripheral resistance to maintain normal arterial pressures.

Aortic baroreceptors monitor blood pressure within the aortic arch. Any changes trigger the *aortic reflex*, which adjusts blood pressure to maintain adequate blood flow through the systemic circuit. Carotid sinus baroreceptors trigger reflexes that maintain adequate blood flow to the brain. These receptors are extremely sensitive because blood flow to the brain must remain constant. The baroreceptor reflexes triggered by changes in blood pressure at the carotid sinuses and aortic arch are diagrammed in **Figure 13-8**.

When blood pressure rises, the increased output from the baroreceptors alters activity in the cardiovascular center of the medulla oblongata. More specifically, this change inhibits the cardioacceleratory center, stimulates the cardioinhibitory center, and inhibits the vasomotor center (**Figure 13-8**). Two effects result:

- **1.** *A decrease in cardiac output.* Under the command of the cardioinhibitory center, the vagus nerves release ace-tylcholine (ACh) at the sinoatrial node (SA). This parasympathetic stimulation reduces the rate and force of cardiac contractions.
- **2.** *Widespread peripheral vasodilation.* The inhibition of the vasomotor center leads to dilation of peripheral arterioles throughout the body.

This combination of reduced cardiac output and decreased peripheral resistance then lowers blood pressure.

When blood pressure falls below normal, baroreceptor output is reduced (**Figure 13-8**). This change has two major effects that work together to raise blood pressure:

- 1. An increase in cardiac output. Reduced baroreceptor activity stimulates the cardioacceleratory center, inhibits the cardioinhibitory center, and stimulates the vasomotor center. The cardioacceleratory center stimulates sympathetic neurons to the sinoatrial (SA) node, atrioventricular (AV) node, and general myocardium. This sympathetic stimulation increases heart rate and stroke volume. As a result, cardiac output increases immediately.
- **2.** *A widespread peripheral vasoconstriction.* Vasomotor activity, also carried by sympathetic motor neurons, produces rapid vasoconstriction. This change increases peripheral resistance.

These adjustments—increased cardiac output and increased peripheral resistance—work together to elevate blood pressure.

Atrial baroreceptors monitor blood pressure at the end of the systemic circuit—at the venae cavae and the right atrium. The *atrial reflex* is a response to the stretching of the wall of the right atrium. \bigcirc p. 452 Normally, the heart pumps blood into the aorta at the same rate at which it arrives at the right atrium. A rise in blood pressure at the atrium means that blood is arriving at the heart faster than it is being pumped out. The atrial baroreceptors correct the situation by stimulating the cardioacceleratory center, increasing cardiac output until the backlog of venous blood is removed. Atrial pressure then returns to normal.

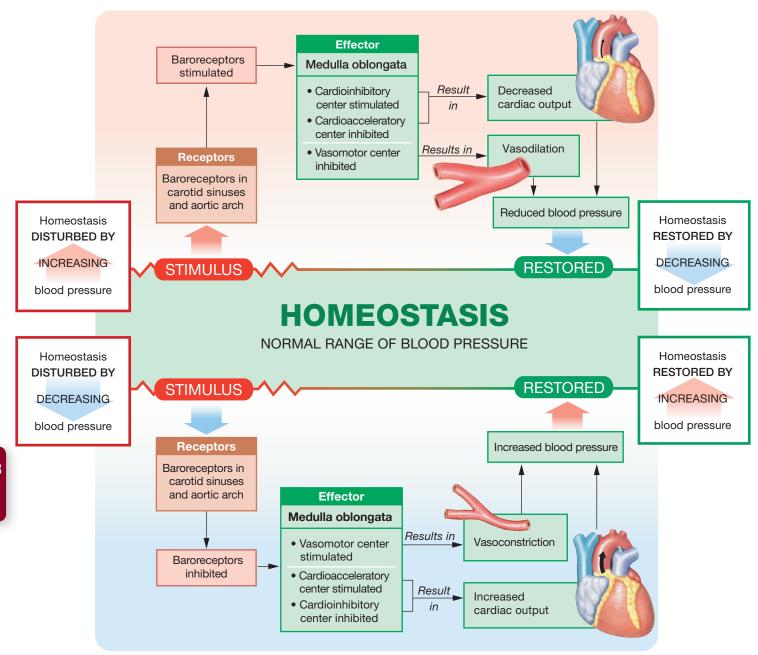

Figure 13-8 The Baroreceptor Reflexes of the Carotid Sinuses and Aortic Arch.

Chemoreceptor Reflexes

The **chemoreceptor reflexes** respond to changes in carbon dioxide, oxygen, or pH levels in blood and cerebrospinal fluid (**Figure 13-9**). The chemoreceptors involved are sensory neurons. They are found in the **carotid bodies** (located in the neck near the carotid sinuses) and in the **aortic bodies** (near the arch of the aorta). \supset p. 341 These receptors monitor the chemical composition of the arterial

blood. Other chemoreceptors on the surface of the medulla oblongata monitor the composition of the cerebrospinal fluid (CSF).

Chemoreceptors are activated by a decrease in pH or in plasma O_2 , or by an increase in CO_2 . Any of these changes leads to a stimulation of the cardioacceleratory and vasomotor centers. This elevates arterial pressure and increases blood flow through peripheral tissues. Chemoreceptor output also affects the respiratory centers in the medulla oblongata.

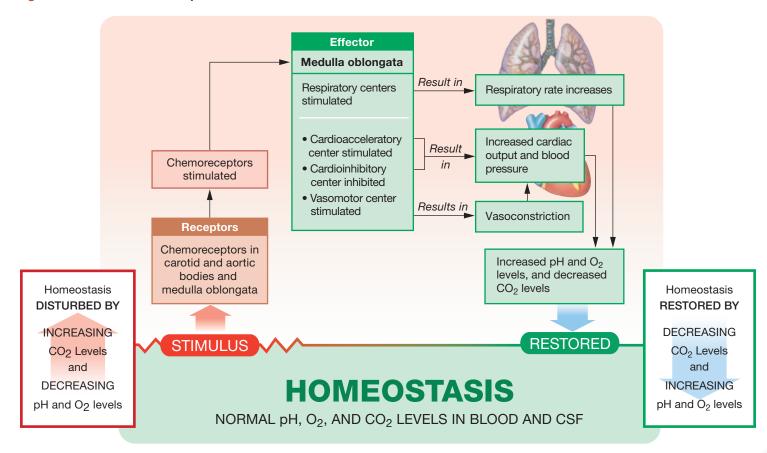

Figure 13-9 The Chemoreceptor Reflexes.

As a result, a rise in blood flow and blood pressure is associated with an elevated respiratory rate. The coordination of cardiovascular and respiratory activity is vital, because accelerating tissue blood flow is useful only if the blood contains adequate oxygen. In addition, an increase in the respiratory rate speeds up venous return through the action of the respiratory pump. \Box p. 469

Hormones and Cardiovascular Regulation

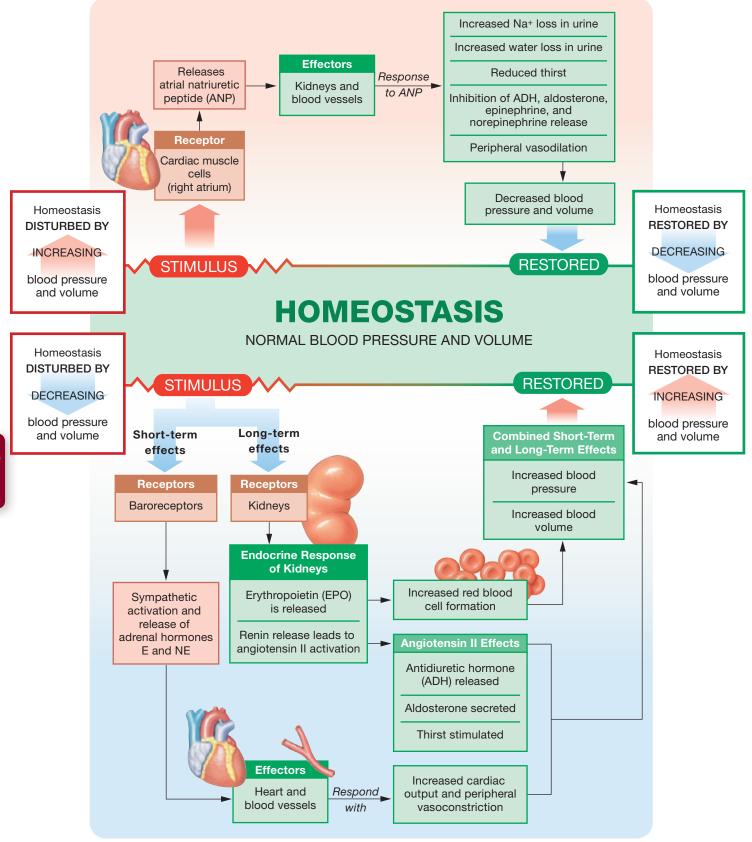

The endocrine system regulates cardiovascular performance in both the short term and long term. In the short term, epinephrine (E) and norepinephrine (NE) from the adrenal medullae stimulate cardiac output and peripheral vasoconstriction. Long-term cardiovascular regulation involves other hormones. These are antidiuretic hormone (ADH), angiotensin II, erythropoietin (EPO), and atrial natriuretic peptide (ANP) (introduced in Chapter 10). \bigcirc pp. 385, 397 Their roles in the regulation of blood pressure and blood volume are diagrammed in Figure 13-10.

Antidiuretic Hormone

Antidiuretic hormone (ADH) is released at the posterior lobe of the pituitary gland. This happens in response to a decrease in blood volume, an increase in the osmotic concentration of the plasma, or the presence of angiotensin II (Figure 13-10). The immediate result is peripheral vasoconstriction that elevates blood pressure. ADH also has a water-conserving effect on the kidneys, thereby preventing a reduction in blood volume.

Angiotensin II

Angiotensin II is formed in the blood following the release of the enzyme renin by specialized kidney cells in response to a fall in blood pressure (**Figure 13-10**). Renin starts an enzymatic chain reaction that ultimately converts an inactive plasma protein, *angiotensinogen*, to the hormone angiotensin II. Angiotensin II stimulates cardiac output and triggers arteriole constriction, which in turn elevates systemic blood pressure almost immediately. This hormone also stimulates the pituitary gland to secrete ADH, and the adrenal cortex to secrete aldosterone.

ADH and aldosterone have complementary effects. ADH stimulates water conservation at the kidneys. Aldosterone stimulates sodium ion retention and potassium ion loss by the kidneys. In addition, angiotensin II stimulates thirst. The presence of ADH and aldosterone ensures that the additional water consumed will be retained, increasing blood volume.

Erythropoietin

The kidneys release erythropoietin (EPO) when blood pressure falls or when the oxygen content of the blood becomes abnormally low (**Figure 13-10**). EPO stimulates red blood cell production. The result is increased blood volume and improved oxygen-carrying capacity of the blood.

Atrial Natriuretic Peptide

In contrast to the three hormones just described, atrial natriuretic peptide (ANP) release is stimulated by *increased* blood pressure (**Figure 13-10**). The cardiac muscle cells in the wall of the right atrium produce ANP when they are stretched by excessive venous return. ANP reduces blood volume and blood pressure by (1) increasing the loss of sodium ions by the kidneys; (2) promoting water losses by increasing the volume of urine; (3) reducing thirst; (4) blocking the release of ADH, aldosterone, E, and NE; and (5) stimulating peripheral vasodilation. As blood volume and blood pressure decrease, the stresses on the atrial walls are removed. ANP production then ceases.

CHECKPOINT

- **8.** Describe the actions of vasodilators and vasoconstrictors.
- **9.** How would applying slight pressure to the common carotid artery affect your heart rate?
- **10.** What effect would the vasoconstriction of the renal artery have on blood pressure and blood volume?

See the blue Answers tab at the back of the book.

13-4 The cardiovascular system adapts to physiological stress

Learning Outcome Explain the cardiovascular system's homeostatic response to exercise and hemorrhaging.

In our day-to-day lives, the components of the cardiovascular system—the blood, heart, and blood vessels—work together in an integrated way. In this section we will see how this adaptable system maintains homeostasis in response to two

common stresses: exercise and blood loss. We will also look at the physiological processes involved in shock, an important cardiovascular disorder.

Exercise and the Cardiovascular System

At rest, cardiac output averages about 5.8 liters per minute. During exercise, both cardiac output and the pattern of blood distribution change dramatically. As exercise begins, several interrelated changes take place:

- *Extensive vasodilation occurs* as the rate of oxygen consumption in skeletal muscles increases. Peripheral resistance drops, blood flow through the capillaries increases, and blood enters the venous system at a faster rate.
- *Venous return increases* as skeletal muscle contractions squeeze blood along the peripheral veins. A faster breathing rate also pulls blood into the venae cavae by the respiratory pump.
- *Cardiac output rises* in response to (1) the rise in venous return (the Frank–Starling principle) and (2) atrial stretching (the atrial reflex). ⊃ pp. 452–453 The increased cardiac output keeps pace with the greater demand. Arterial pressures are maintained despite the drop in peripheral resistance.

CLINICAL NOTE

Exercise, Cardiovascular Fitness, and Health

Cardiovascular performance improves significantly with training. Trained athletes have larger hearts and stroke volumes than do nonathletes. These functional changes are important. Recall that cardiac output is equal to stroke volume times heart rate. So, for a given cardiac output, a person with a larger stroke volume has a lower heart rate. A professional athlete at rest can maintain normal blood flow to peripheral tissues at a heart rate as low as 32 bpm (beats per minute), compared with about 80 bpm for a nonathlete. And, when necessary, the athlete's cardiac output can increase to levels 50 percent higher than those of nonathletes.

If you are not a trained athlete, regular exercise still has several beneficial effects. Even a modest exercise routine (jog-

ging 5 miles per week, for example) can lower total blood cholesterol levels. High cholesterol is one of the major risk factors for atherosclerosis, which leads to cardiovascular disease and strokes. In addition, a healthy lifestyle—regular exercise, a balanced diet, weight control, and no smoking reduces stress, lowers blood pressure, and slows plaque formation. Large-scale statistical studies indicate that regular moderate exercise can cut the incidence of heart attacks almost in half.

This regulation by venous feedback gradually increases cardiac output to about double resting levels. The increase supports faster blood flow to skeletal muscles, cardiac muscle, and the skin. Over this range, which is typical of light exercise, the pattern of blood distribution remains relatively unchanged.

At higher levels of exertion, other physiological adjustments take place as the cardiac and vasomotor centers activate the sympathetic nervous system. Cardiac output increases toward maximal levels (up to 20–25 liters per minute), blood pressure increases, and the pattern of blood distribution shifts. Blood flow to "nonessential" organs (such as those of the digestive system) becomes severely restricted. This shift helps to increase blood flow to active skeletal muscles. When you exercise at maximal levels, your blood essentially races among your skeletal muscles, lungs, and heart. Blood flow to most tissues is diminished, but that to the skin increases further, because body temperature continues to climb. Only the blood supply to the brain is unaffected.

The Cardiovascular Response to Hemorrhage

What happens when we bleed? Recall the local cardiovascular reaction to a break in the wall of a blood vessel discussed in Chapter 11. \bigcirc p. 427 When the clotting response fails to

prevent a significant blood loss and blood pressure falls, the entire cardiovascular system begins making adjustments. The immediate, short-term goal is to maintain adequate blood pressure and peripheral blood flow. The long-term goal is to restore normal blood volume (lower half of **Figure 13-10**).

The Short-Term Elevation of Blood Pressure

Short-term responses appear almost as soon as blood pressure starts to decline. For example, the carotid and aortic reflexes increase cardiac output and cause peripheral vasoconstriction. When you donate blood at a blood bank, the amount collected is usually 500 mL, roughly 10 percent of your total blood volume. Such a loss initially causes a drop in cardiac output. However, the vasomotor center quickly improves venous return and restores cardiac output to normal levels by mobilizing a large *venous reservoir* of slowly moving blood from the digestive organs that drains into the liver, through venoconstriction (see **Figure 13-20** on p. 491). This venous compensation can restore normal arterial pressures and peripheral blood flow after losses of 15–20 percent of total blood volume.

With a more substantial blood loss, cardiac output is maintained by increasing the heart rate, often to 180–200 bpm. Sympathetic activation assists by constricting the muscular arteries and arterioles, which elevates blood pressure.

CLINICAL NOTE

Shock

Shock is an acute circulatory crisis marked by low blood pressure, or **hypotension**, and low peripheral blood flow. Severe and potentially fatal effects develop as vital tissues become starved for oxygen and nutrients. Common causes of shock are (1) a decrease in cardiac output after hemorrhage or other fluid losses, (2) damage to the heart, (3) external pressure on the heart, or (4) extensive peripheral vasodilation.

One important form of shock, called **circulatory shock**, is caused by a decrease in total blood volume of about 30 percent. All such cases share six basic signs or symptoms:

- **1.** *Hypotension.* Systolic pressures are below 90 mm Hg.
- **2.** *Pale, cool, and moist ("clammy") skin.* The skin is pale and cool because of peripheral vasoconstriction. The moisture reflects sympathetic activation of the sweat glands.
- **3.** *Confusion and disorientation.* A decrease in blood pressure at the brain brings about these effects.
- 4. An increase in heart rate with a rapid, weak pulse.
- **5.** *Cessation of urination.* The reduced blood flow to the kidneys slows or stops urine production.

6. A decrease in blood pH (acidosis). Increased acidity is due to the lactate and hydrogen ions generated in oxygen-deprived tissues.

When blood volume declines by more than 35 percent, homeostatic processes become unable to cope with the situation. A vicious cycle begins. Low blood pressure and low venous return lead to decreased cardiac output and myocardial damage, further reducing cardiac output. When the mean arterial pressure falls to about 50 mm Hg, carotid sinus baroreceptors trigger a massive activation of sympathetic vasoconstrictors. The resulting vasoconstriction reduces blood flow to peripheral tissues in order to maintain adequate blood flow to the brain. Immediate treatment is needed to prevent fatal consequences. It must concentrate on (1) preventing further fluid losses and (2) increasing blood volume through transfusions.

Several other forms of shock also exist. In *cardiogenic shock* and *obstructive shock*, the heart is unable to maintain normal cardiac output. *Septic shock, toxic shock syndrome,* and *anaphylactic shock* result from a widespread, uncontrolled vasodilation. All share similar effects and consequences with circulatory shock.

Sympathetic activation also causes the adrenal medullae to secrete E and NE. At the same time, the posterior lobe of the pituitary gland releases ADH, and the fall in blood pressure in the kidneys causes the release of renin. This enzyme, in turn, activates angiotensin II. Both E and NE increase cardiac output. In combination with ADH and angiotensin II, they cause a powerful vasoconstriction that raises blood pressure and improves peripheral blood flow.

The Long-Term Restoration of Blood Volume

After serious hemorrhaging, several days may pass before blood volume returns to normal. When short-term responses are unable to maintain normal cardiac output and blood pressure, the decline in capillary blood pressure triggers a *recall of fluids* from the interstitial spaces. D p. 469 Over this period, ADH and aldosterone promote fluid retention and reabsorption at the kidneys, preventing further reductions in blood volume. Thirst increases, and additional water is absorbed across the digestive tract. This intake of fluid increases blood volume and ultimately replaces the interstitial fluids "borrowed" at the capillaries. Erythropoietin targets the red bone marrow, stimulating red blood cells to mature. These cells increase blood volume and improve oxygen delivery to peripheral tissues.

CHECKPOINT

- 11. Why does blood pressure increase during exercise?
- **12.** Name the immediate and long-term problems related to the cardiovascular response to hemorrhaging.
- **13.** Explain the role of aldosterone and ADH in long-term restoration of blood volume.

See the blue Answers tab at the back of the book.

13-5 The pulmonary and systemic circuits of the cardiovascular system exhibit three general functional patterns

Learning Outcome Describe the three general functional patterns seen in the pulmonary and systemic circuits.

Recall that the cardiovascular system is divided into the **pulmonary circuit** and the **systemic circuit**. \bigcirc p. 435 The pulmonary circuit is made up of arteries and veins that transport blood between the heart and the lungs. This circuit begins at the right ventricle and ends at the left atrium. The systemic circuit is made up of arteries that transport oxygenated blood and nutrients to all other organs and tissues, and veins that return deoxygenated blood to the heart. This circuit begins at the left ventricle and ends at the right atrium.

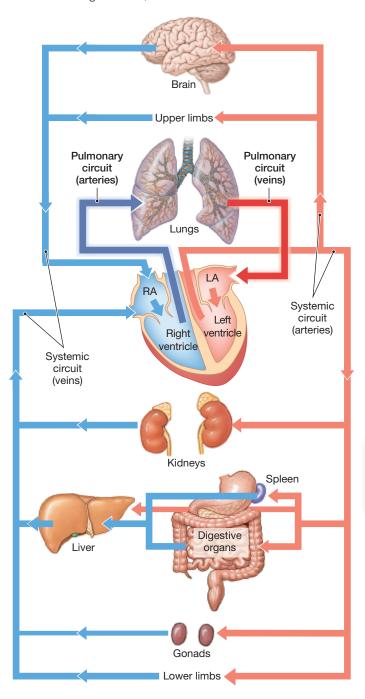

Figure 13-11 summarizes the main distribution routes within the pulmonary and systemic circuits.

We will examine the vessels of these two circuits in the following pages. Three general functional patterns of blood vessels are worth noting:

1. The distribution of arteries and veins on the left and right sides of the body is usually identical—except near the heart, where large vessels connect to the atria or ventricles.

For example, the distribution of the *left* and *right subcla*vian, axillary, brachial, and radial arteries parallels the *left* and *right subclavian*, axillary, brachial, and radial veins.

- 2. A single vessel may have several name changes as it crosses specific anatomical boundaries. For example, the *external iliac artery* becomes the *femoral artery* as it leaves the trunk and enters the thigh.
- **3.** Tissues and organs are usually serviced by several arteries and veins. Often, anastomoses between adjacent arteries or veins reduce the impact of a temporary or even permanent *occlusion* (blockage) of a single blood vessel.

CHECKPOINT

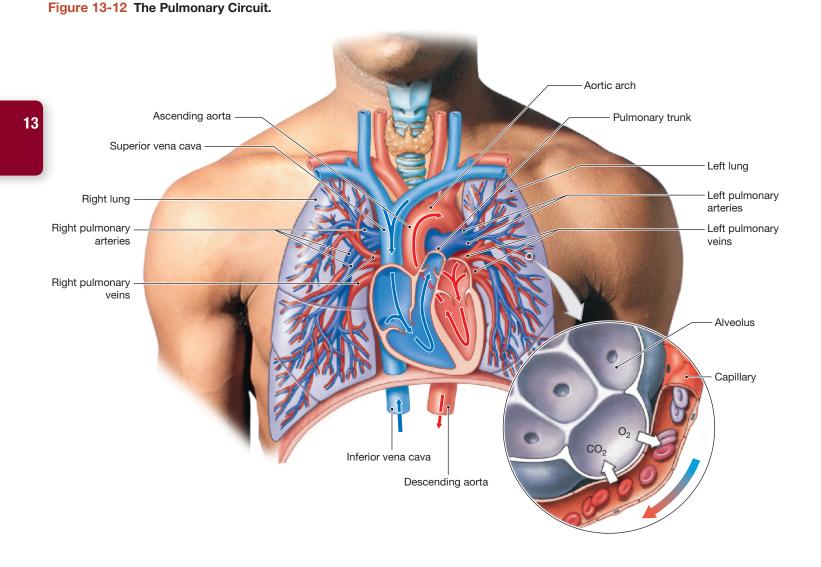

- 14. Identify the two circuits of the cardiovascular system.
- **15.** Identify the three general functional patterns of the body's blood vessels.
- See the blue Answers tab at the back of the book.

13-6 In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs in veins

Learning Outcome Identify the major arteries and veins of the pulmonary circuit.

Blood entering the right atrium has just returned from peripheral capillary beds. There it released oxygen and absorbed carbon dioxide. After traveling through the right atrium and right ventricle, blood enters the **pulmonary trunk** (*pulmo-,* lung), the start of the pulmonary circuit (**Figure 13-12**). (By convention, several large arteries are called *trunks*.) At the lungs, oxygen is replenished, and carbon dioxide is released. The oxygenated blood returns to the heart for distribution by the systemic circuit.

The pulmonary circuit is quite short, compared with the systemic circuit. The base of the pulmonary trunk and the lungs are only about 15 cm (6 in.) apart.

The arteries of the pulmonary circuit differ from those of the systemic circuit in that they carry deoxygenated blood. (For this reason, color-coded diagrams usually show the pulmonary arteries in blue, the same color as systemic veins.) As the pulmonary trunk curves over the superior border of the heart, it gives rise to the left and right pulmonary arteries. These large arteries enter the lungs and then branch repeatedly, giving rise to smaller and smaller arteries.

The smallest branches, the *pulmonary arterioles*, provide blood to capillary networks that surround small air pockets, or **alveoli** (al-VĒ-ō-lī; *alveolus*, sac). The walls of alveoli are thin enough for gas exchange to take place between the capillary blood and inhaled air.

As oxygenated blood leaves the *alveolar capillaries*, it enters venules, which in turn unite to form larger vessels leading to the **pulmonary veins**. These four veins (two from each lung) empty into the left atrium, completing the pulmonary circuit.

CHECKPOINT

- 16. Name the blood vessels that enter and exit the lungs, and note whether they contain primarily oxygenated or deoxygenated blood.
- **17.** Trace the path of a drop of blood through the lungs, beginning at the right ventricle and ending at the left atrium.

See the blue Answers tab at the back of the book.

13-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues other than the lungs' exchange surfaces, and returns deoxygenated blood to the right atrium

Learning Outcome Identify the major arteries and veins of the systemic circuit.

The systemic circuit supplies the capillary beds in all parts of the body not serviced by the pulmonary circuit. This circuit begins at the left ventricle and ends at the right atrium. At any moment, the systemic circuit contains about 84 percent of total blood volume. Spotlight Figure 13-13 provides an overview of the arterial and venous systems of the systemic circuit.

Systemic Arteries

Spotlight Figure 13-13a shows the locations of the major systemic arteries.

The Ascending Aorta

The first systemic vessel and largest artery is the aorta. The ascending aorta begins at the aortic semilunar valve of the left ventricle. The *left* and *right coronary arteries* originate near its base (see Figure 12-7, p. 444). The aortic arch curves across the superior surface of the heart, connecting the ascending aorta with the descending aorta (Figure 13-14).

Arteries of the Aortic Arch

Three elastic arteries—the brachiocephalic (brā-kē-ō-se-FAL-ik) trunk, the left common carotid, and the left subclavian (sub-CLĀ-vē-an)—originate along the aortic arch. They deliver blood to the head, neck, shoulders, and upper limbs (Figures 13-14 and 13-15). The brachiocephalic trunk ascends for a short distance before branching to form the **right common carotid** artery and the right subclavian artery. Note that we have only one brachiocephalic trunk, and that the left common carotid and left subclavian arteries arise separately from the aortic arch. In terms of their peripheral distribution, however, the vessels on the left side are mirror images of those on the right side. Because most of the major arteries are paired, with one artery of each pair on either side of the body, the descriptions that follow will not use the terms right and left.

THE SUBCLAVIAN ARTERIES. The subclavian arteries supply blood to the arms, chest wall, shoulders, back, and central 13 nervous system. Before a subclavian artery leaves the thoracic cavity, it gives rise to three arteries (Figure 13-14). An internal thoracic artery supplies the pericardium and anterior wall of the chest. A vertebral artery supplies the brain and spinal cord. The thyrocervical trunk supplies muscles and other tissues of the neck, shoulder, and upper back.

After passing the first rib, the subclavian gets a new name: the axillary artery (Figure 13-14). This artery crosses the axilla (armpit) to enter the arm, where its name changes again, becoming the brachial artery. The brachial artery provides blood to the arm before branching to create the radial artery and ulnar artery of the forearm. These arteries connect at the palm to form anastomoses-the superficial and deep palmar arches. The digital arteries originate from these anastomoses.

THE CAROTID ARTERY AND THE BLOOD SUPPLY TO THE BRAIN.

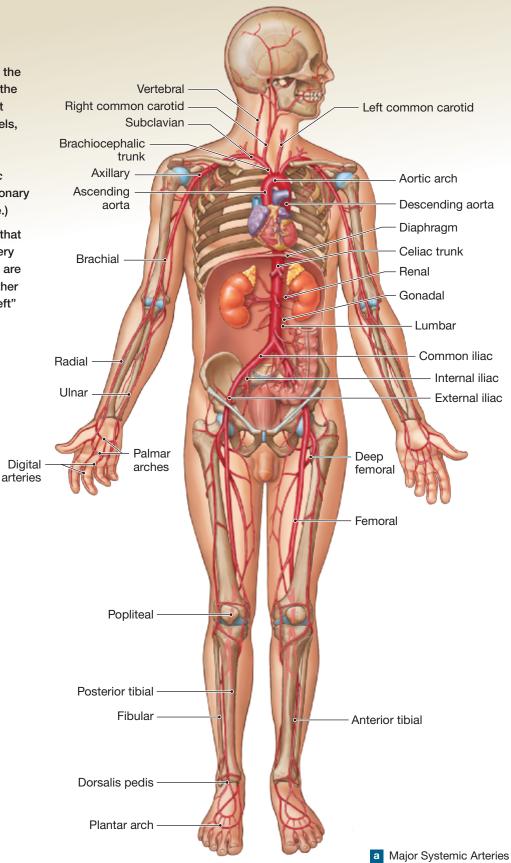

The common carotid arteries ascend deep in the tissues of the neck. Each common carotid artery divides into an external carotid and an internal carotid artery (Figure 13-15a). The external carotid artery can usually be located by pressing gently along either side of the windpipe (trachea) until a strong pulse is felt. The external carotid arteries supply blood

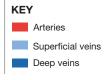

SPOTLIGHT Figure 13-13 MAJOR VESSELS OF THE SYSTEMIC CIRCUIT

Systemic Arteries

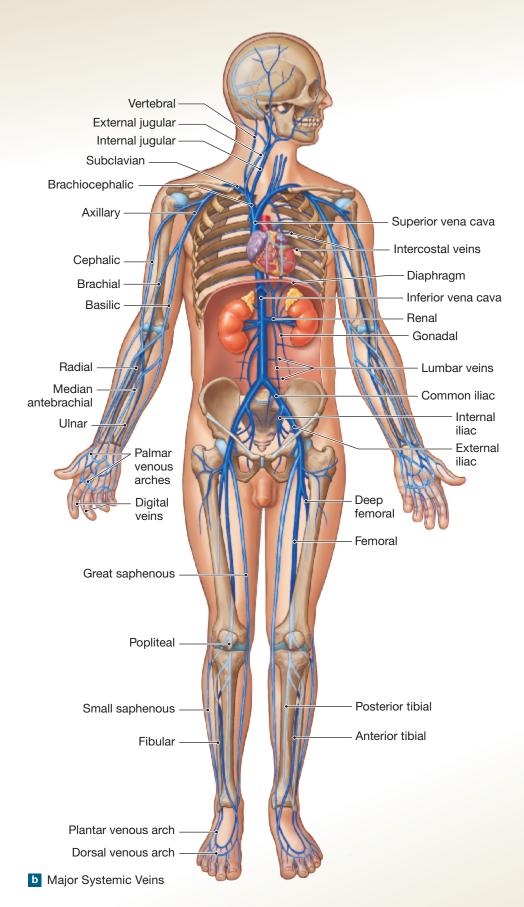

This figure is an overview of the major systemic arteries. Note that all arteries of the systemic circuit originate from the aorta, the large elastic artery extending from the left ventricle of the heart. When naming vessels, several large arteries are called *trunks*. Systemic arterial trunks include the *thyrocervical, brachiocephalic,* and *celiac trunks*. (The *pulmonary trunk* of the pulmonary circuit in Figure 13-12 is another example.)

To reduce clutter here, and in the figures that follow, "artery" will not be repeated in every label. Because most of the major arteries are paired, with one artery of each pair on either side of the body, the terms "right" and "left" will appear in figure labels only when the arteries on both sides are labeled.

>

Systemic Veins

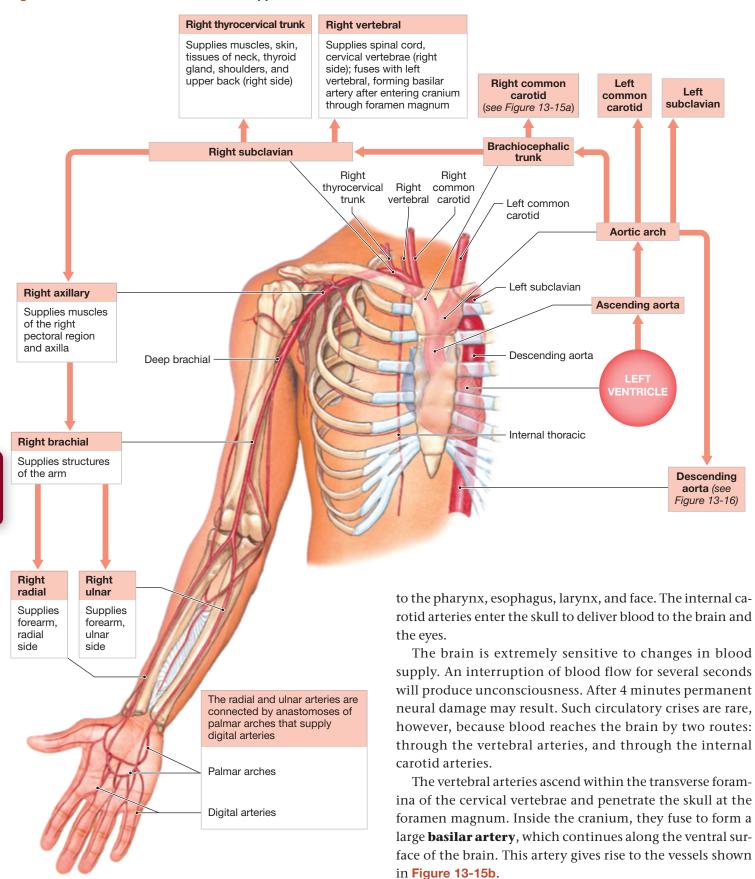

This figure is an overview of the major systemic veins. Note that veins of the systemic circuit merge into two large veins: the superior vena cava, which collects systemic blood from the head, chest, and upper limbs, and the inferior vena cava, which collects systemic blood from all structures inferior to the diaphragm.

To reduce clutter here, and in the figures that follow, "vein" will not be repeated in every label. The same name often applies to both the artery and the vein servicing a particular structure or region. Additionally, "right" and "left" will appear in figure labels only when the veins on both sides are shown.

One significant difference between the systemic arteries and veins is the distribution of major veins in the neck and limbs. Arteries in these areas are located deep beneath the skin, protected by bones and surrounding soft tissues. In contrast, the neck and limbs usually have two sets of peripheral veins, one superficial and the other deep. This dual venous drainage is important for controlling body temperature. In hot weather, venous blood flows through superficial veins, where heat can easily be lost. In cold weather, blood is routed to the deep veins to minimize heat loss.

484 CARDIOVASCULAR SYSTEM

Figure 13-14 Arteries of the Chest and Upper Limb.

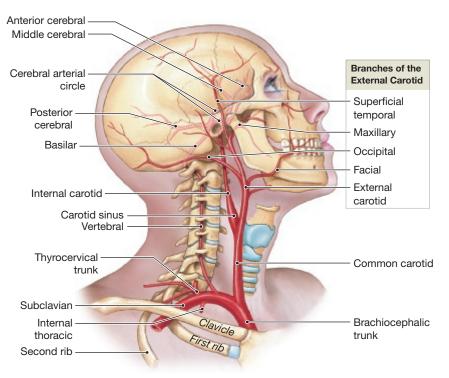

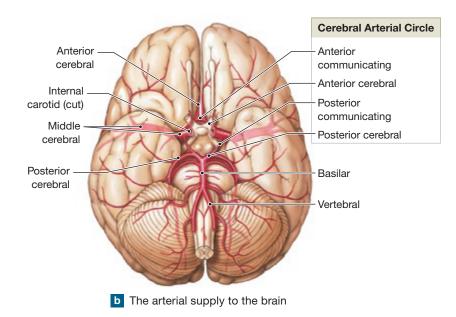

Figure 13-15 Arteries of the Neck, Head, and Brain.

a The general circulation pattern of arteries supplying the neck and superficial structures of the head

The internal carotid arteries normally supply the arteries of the anterior half of the cerebrum. The rest of the brain receives blood from the vertebral arteries. But this pattern of blood flow can easily change, because the internal carotids and the basilar artery are interconnected. They form a ring-shaped anastomosis in the cerebral arterial circle, or circle of Willis, which encircles the infundibulum (stalk) of the pituitary gland. With this arrangement, the brain can receive blood from either the carotid or the vertebral arteries. For this reason, the chances of a serious interruption of blood flow are reduced.

The Descending Aorta

The descending aorta is continuous with the aortic arch. The diaphragm divides the descending aorta into a superior thoracic aorta and an inferior abdominal aorta (Figure 13-16). The thoracic aorta travels within the mediastinum, providing blood to the intercostal arteries, which carry blood to the vertebral column area and the body wall. The thoracic aorta also gives rise to arteries that supply tissues of the lungs not involved in gas exchange, the esophagus, pericardium, and other mediastinal structures. Near the diaphragm, the phrenic (FREN-ik) arteries deliver blood to the muscular diaphragm, which separates the thoracic and abdominopelvic cavities.

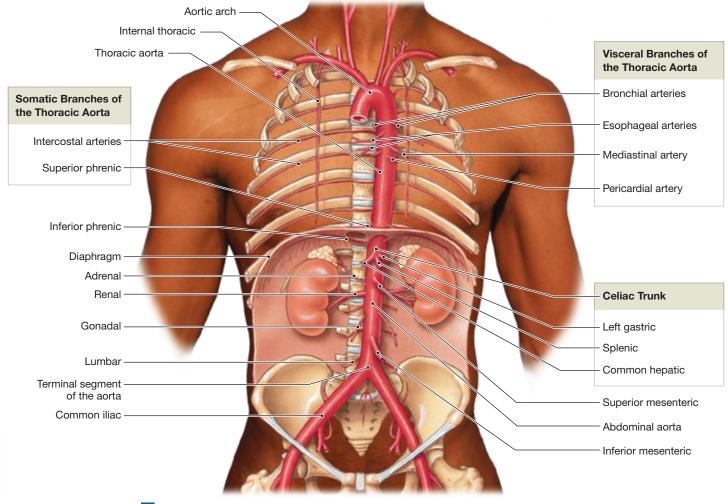

The abdominal aorta delivers blood to all the abdominopelvic organs and structures (Figure 13-16). The celiac (SĒ-lē-ak) trunk, superior mesenteric (mez-en-TER-ik) artery, and inferior mesenteric 13 artery arise on the anterior surface of the abdominal aorta. These three vessels provide blood to the digestive organs. The celiac trunk divides into three branches that deliver blood to the liver, gallbladder, stomach, and spleen. The liver is supplied by a branch of the common hepatic, called the hepatic artery proper. The superior mesenteric artery supplies the pancreas, small intestine, and most of the large intestine. The inferior mesenteric delivers blood to the last portion of the large intestine and rectum.

Paired gonadal (gō-NAD-al) arteries originate between the superior and inferior mesenteric arteries. In males they are called *testicular arteries*. In females, they are ovarian arteries. The adrenal arteries and renal arteries arise along the lateral

surface of the abdominal aorta and travel behind the peritoneal lining to the adrenal glands and kidneys. Small lumbar arteries begin on the posterior surface of the aorta and supply the spinal cord and the abdominal wall.

Near the level of vertebra L₄, the abdominal aorta divides to form a pair of muscular arteries. These common

Figure 13-16 Major Arteries of the Trunk.

a A diagrammatic view, with most of the thoracic and abdominal organs removed

iliac (IL-ē-ak) **arteries** carry blood to the pelvis and lower limbs (**Spotlight Figure 13-13a**). As it travels along the inner surface of the ilium, each common iliac artery divides to form an **internal iliac artery**, which supplies smaller arteries of the pelvis, and an **external iliac artery**, which enters the lower limb.

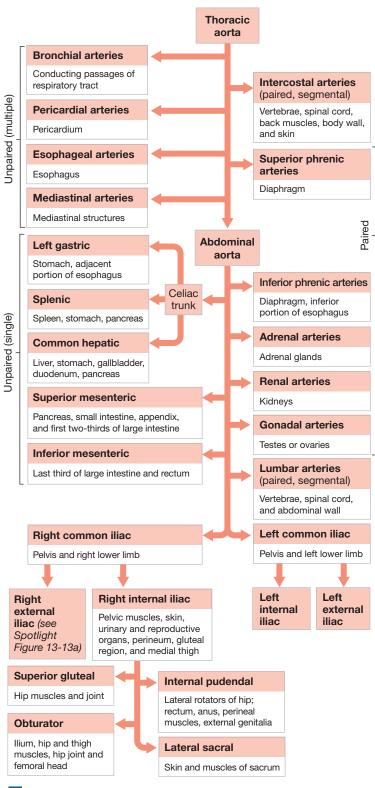

Once in the thigh, the external iliac artery branches, forming the **femoral artery** and the **deep femoral artery**. When it reaches the back of the knee, the femoral artery becomes the **popliteal artery**, which almost immediately branches to form the **anterior tibial**, **posterior tibial**, and **fibular arteries**.

At the ankle, the anterior tibial artery becomes the *dorsalis pedis artery*, and the posterior tibial artery divides in two. These three arteries are connected by two anastomoses.

The arrangement produces a *dorsal arch* on the top of the foot and a *plantar arch* on the bottom.

Systemic Veins

Blood from each of the body's tissues and organs returns to the heart by means of a venous network that drains into the right atrium through the superior and inferior venae cavae. **Spotlight Figure 13-13b** illustrates the major vessels of the venous system. Complementary arteries and veins often run side by side. In many cases they even have comparable names. For example, the axillary arteries run alongside the axillary veins. In addition, arteries and veins often travel along with peripheral nerves that have the same names and innervate the same structures. Figure 13-16 Major Arteries of the Trunk. (continued)

The Superior Vena Cava

The superior vena cava (SVC) receives blood from two regions: the head and neck (Figure 13-17), and the upper limbs, shoulders, and chest (Figure 13-18).

VENOUS RETURN FROM THE HEAD AND NECK. Small veins in the neural tissue of the brain empty into a network of thinwalled channels called the **dural sinuses**. **D** p. 292 The largest, the superior sagittal sinus, is located within the fold of dura mater lying between the cerebral hemispheres. Most of the blood leaving the brain passes through one of the dural sinuses and leaves the skull in one of the internal jugular veins. These veins descend parallel to the common carotid artery in the neck.

The more superficial external jugular veins collect blood from the superficial structures of the head and neck. These veins travel just beneath the skin, and a *jugular venous pulse (JVP*) can sometimes be detected at the base of the neck. Vertebral veins drain the cervical spinal cord and the posterior surface of the skull, descending within the transverse foramina of the cervical vertebrae alongside the vertebral arteries.

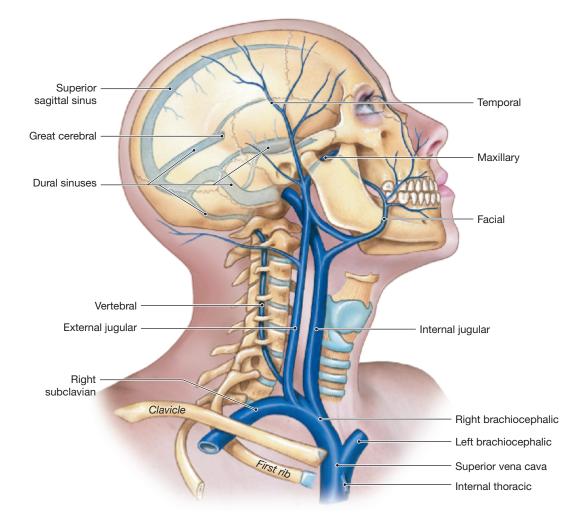

VENOUS RETURN FROM THE UPPER LIMBS AND CHEST. The

major veins of the upper body are illustrated in Figure 13-18. A flowchart indicating the venous tributaries of the superior vena cava is provided in Figure 13-19, p. 490. A venous 13 network in the palms collects blood from the digital veins. These vessels drain into the **cephalic vein** and the **basilic** vein. The superficial median cubital vein passes from the cephalic vein, medially and at an oblique angle, to connect to the basilic vein. (Venous blood samples are typically collected from the median cubital vein.) The deeper veins of the forearm are a radial vein and an ulnar vein. These veins fuse to form the brachial vein. As the brachial vein continues toward the trunk, it joins the basilic vein before entering the axilla as the axillary vein. The cephalic vein drains into the axillary vein at the shoulder.

The axillary vein then continues into the trunk. At the level of the first rib it becomes the **subclavian vein**. After traveling a short distance inside the thoracic cavity, the subclavian meets and merges with the external and internal jugular veins of that side. This fusion creates the large **brachiocephalic** vein, also known as the innominate vein. Near the heart, the two brachiocephalic veins (one from each side of the body) combine to create the superior vena cava. The SVC receives blood from the thoracic body wall through the azygos (AZ-īgos) **vein** before arriving at the right atrium.

Figure 13-17 Major Veins of the Head and Neck. Veins draining the brain and the superficial and

deep portions of the head and neck.

The Inferior Vena Cava

The **inferior vena cava (IVC)** collects most of the venous blood from organs inferior to the diaphragm. (A small amount reaches the superior vena cava through the azygos vein.) A flowchart of the tributaries of the IVC is provided in **Figure 13-19**. The veins of the abdomen are illustrated in **Figure 13-18**. Refer to **Spotlight Figure 13-13b** to see the veins of the lower limbs.

Blood leaving the capillaries in the sole of each foot collects into a network of *plantar veins*, which supply the *plantar venous arch*. The plantar network provides blood to the deep veins of the leg. They are the **anterior tibial vein**, the **posterior tibial vein**, and the **fibular vein**. A *dorsal venous arch* drains blood from capillaries on the superior surface of the foot. This arch is drained by two superficial veins, the **great saphenous vein** (sa-FĒ-nus; *saphenes*, prominent) and the **small saphenous vein**. (Surgeons often use segments of the great saphenous vein, the largest superficial vein, as a bypass vessel during *coronary bypass surgery*.) The plantar arch and the dorsal arch interconnect extensively, so blood flow can easily shift from superficial veins to deep veins.

Behind the knee, the small saphenous, tibial, and fibular veins unite to form the **popliteal vein**. When the popliteal vein reaches the femur, it becomes the **femoral vein**. Before penetrating the abdominal wall, the great saphenous and **deep femoral veins** join the femoral vein. The femoral vein penetrates the body wall and emerges into the pelvic cavity as the **external iliac vein**. As the external iliac travels across the inner surface of the ilium, it is joined by the **internal iliac vein**, which drains the pelvic organs. The resulting **common iliac vein** then meets its counterpart from the opposite side to form the IVC.

Like the aorta, the IVC lies posterior to the abdominopelvic cavity. As it ascends to the heart, it collects blood from several lumbar veins. In addition, the IVC receives blood from the *gonadal, renal, adrenal, phrenic,* and *hepatic veins* before reaching the right atrium (Figure 13-18).

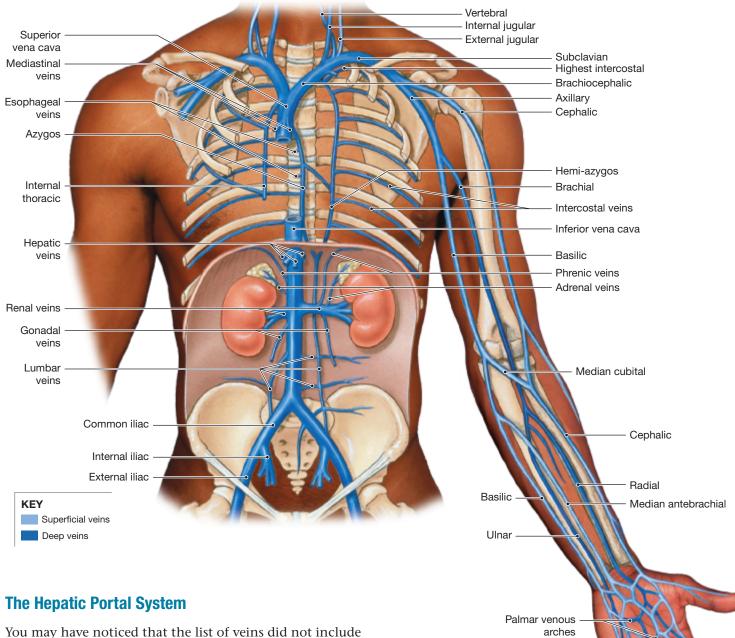

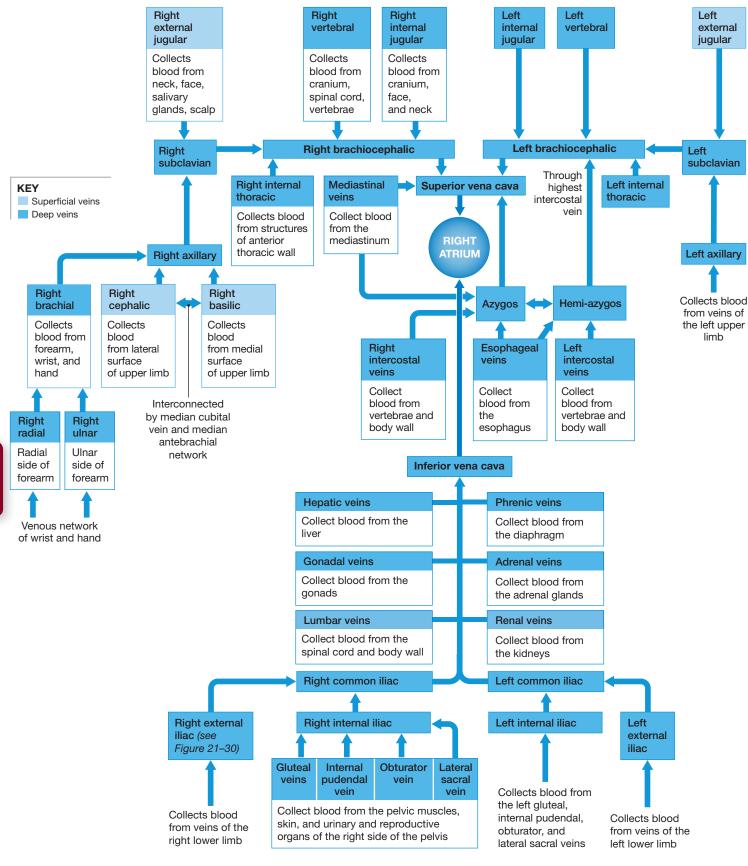

Figure 13-18 The Venous Drainage of the Abdomen and Chest.

You may have noticed that the list of veins did not include any names that refer to digestive organs other than the liver. Instead of traveling directly to the inferior vena cava, blood leaving the capillaries supplied by the celiac, superior, and inferior mesenteric arteries flows to the liver through the **hepatic portal system** (*porta*, a gate). A blood vessel connecting two capillary beds is called a *portal vessel*, and the network formed is called a *portal system*.

Blood in the hepatic portal vessels is quite different in composition from blood in other systemic veins. That is because it contains substances absorbed by the digestive tract. They include high concentrations of glucose and amino acids, various wastes, and an occasional toxin. The blood within a portal system does not immediately mix with blood in the general circulation because the portal system connects one capillary bed to another. The hepatic portal system delivers blood containing these compounds directly to the liver for storage, metabolic conversion, or excretion. In the process, the liver regulates the concentrations of nutrients in the circulating blood.

Digital veins

Figure 13-19 A Flowchart of the Tributaries of the Superior and Inferior Venae Cavae.

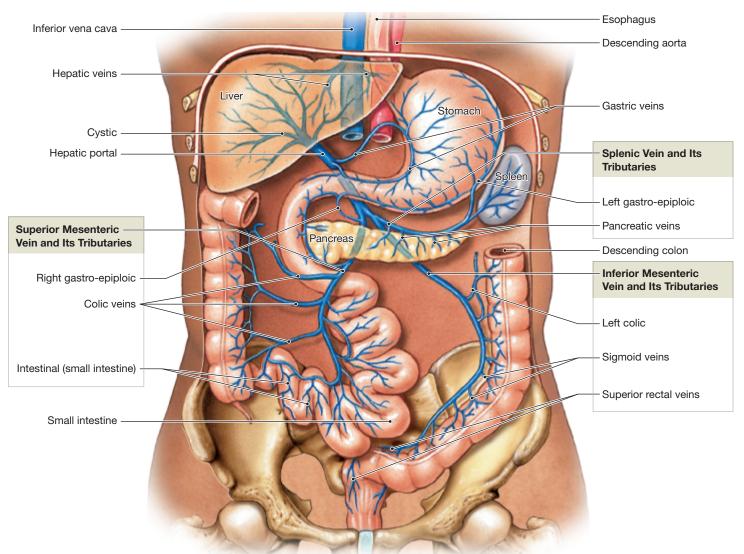

Figure 13-20 The Hepatic Portal System.

Figure 13-20 shows the anatomy of the hepatic portal system. The system begins in the capillaries of the digestive organs. Blood from capillaries along the lower portion of the large intestine enters the inferior mesenteric vein. On their way toward the liver, veins from the spleen, the lateral border of the stomach, and the pancreas fuse with the inferior mesenteric, forming the splenic vein. The superior mesenteric **vein** also drains the lateral border of the stomach, through the right gastro-epiploic vein. In addition, the superior mesenteric collects blood from the entire small intestine and two-thirds of the large intestine. The hepatic portal vein forms through the fusion of the superior mesenteric and splenic veins. Of the two, the superior mesenteric normally contributes the greater volume of blood and most of the nutrients. As it proceeds, the hepatic portal vein receives blood from the gastric veins, which drain the medial border of the stomach, and the cystic vein from the gallbladder. The hepatic portal system ends where the hepatic portal vein empties into the liver capillaries.

Build Your Knowledge

Recall that the hypothalamus controls the production of hormones in the anterior lobe of the pituitary gland by secreting regulatory hormones (as you saw in **Chapter 10: The Endocrine System**). These hormones first enter a capillary network near the attachment between the hypothalamus and infundibulum. The capillaries unite to form slightly larger vessels called portal vessels that descend to the anterior lobe and then form another capillary network. Together, these portal vessels and two capillary networks make up the hypophyseal portal system. Portal systems ensure that all the blood entering the portal vessels reaches certain target cells before returning to the general circulation. Portal systems are named after their destinations. **D p. 382**

After passing through the liver capillaries, blood collects in the hepatic veins, which empty into the inferior vena cava. Because blood goes to the liver before returning to the heart, the composition of the blood in the systemic circulation remains relatively stable, regardless of the digestive activities under way.

CHECKPOINT

- **18.** A blockage of which branch of the aortic arch would interfere with blood flow to the left arm?
- 19. Why would compression of the common carotid arteries cause a person to lose consciousness?
- 20. Grace is in an automobile accident, and her celiac trunk is ruptured. Which organs will be affected most directly by this injury?
- **21.** Describe the general distribution of major arteries and veins in the neck and limbs. What functional advantage does this distribution provide?

See the blue Answers tab at the back of the book.

13-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials until birth

Learning Outcome Identify the differences between fetal and adult 13 circulation patterns, and describe the changes in the patterns of blood flow that occur at birth.

The fetal and adult cardiovascular systems have important differences because of their different sources of respiratory and nutritional support. The embryonic lungs are collapsed and nonfunctional. The embryonic digestive tract has nothing to digest. All of the embryo's nutritional and respiratory needs are provided by diffusion across the *placenta*, a structure within the uterine wall where the maternal and fetal circulatory systems are in close contact.

Placental Blood Supply

Circulation in a full-term (9-month-old) fetus is diagrammed in Figure 13-21a. The fetus's deoxygenated blood flows to the placenta through a pair of **umbilical arteries**. They arise from the fetus's internal iliac arteries before entering the umbilical cord. At the placenta, fetal blood gives up CO₂ and wastes and picks up oxygen and nutrients. Oxygenated blood returns from the placenta in a single umbilical vein before reaching the developing liver. Some of the blood flows through capillary networks within the liver. The **ductus venosus** collects blood from the veins of the liver and from the umbilical vein, and empties into the inferior vena cava. When the placental connection is broken at birth, blood flow through the umbilical vessels ceases. They soon degenerate.

Fetal Circulation in the Heart and Great Vessels

One of the most interesting aspects of circulatory development reflects the differences between an embryo or fetus and an infant. Throughout embryonic and fetal stages, the lungs are collapsed. Yet right after delivery, the newborn infant must extract oxygen from inhaled air rather than across the placenta.

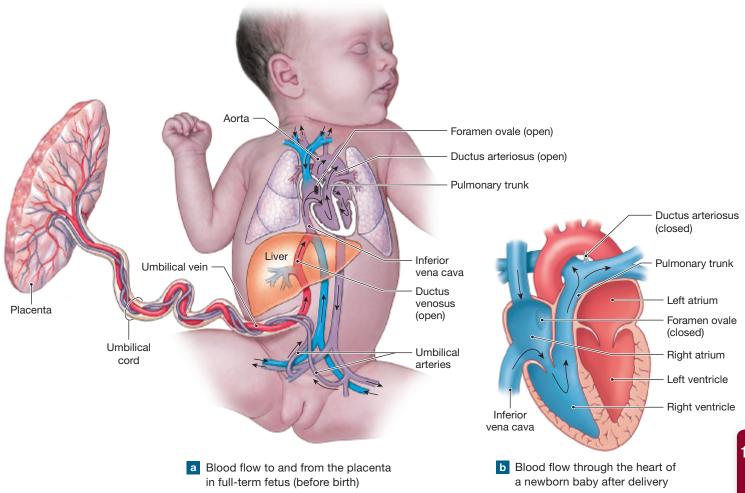

The interatrial and interventricular septa of the heart develop early in the fetus, but the interatrial partition remains functionally incomplete until birth. The foramen ovale, or interatrial opening, is associated with a long flap that acts as a valve. Blood can flow freely from the right atrium to the left atrium, but any backflow closes the valve and isolates the two chambers. For this reason, blood entering the heart at the right atrium can bypass the pulmonary circuit. A second short-circuit exists between the pulmonary and aortic trunks. This connection, the **ductus arteriosus**, consists of a short, muscular vessel.

With the lungs collapsed, their capillaries are compressed and little blood flows through the lungs. During diastole, blood enters the right atrium and flows into the right ventricle, but it also passes into the left atrium through the foramen ovale. About 25 percent of the blood arriving at the right atrium bypasses the pulmonary circuit in this way. In addition, over 90 percent of the blood leaving the right ventricle passes through the ductus arteriosus and enters the systemic circuit rather than continuing to the lungs.

Circulatory Changes at Birth

At birth, dramatic changes take place. When an infant takes its first breath, the lungs expand, and so do the pulmonary vessels. Within a few seconds, the smooth muscles in the ductus arteriosus contract, isolating the pulmonary and aortic trunks. Blood begins flowing through the pulmonary circuit. As pressures rise in the left atrium, the valvular flap closes the foramen ovale (Figure 13-21b). In adults, the interatrial septum bears a shallow depression, the fossa ovalis, that marks the site of the foramen ovale (see Spotlight Figure 12-5, p. 441). The remnants of the ductus arteriosus persist as a fibrous cord, the ligamentum arteriosum.

Figure 13-21 Fetal Circulation.

If the proper cardiovascular changes do not take place at birth or shortly afterward, problems eventually develop. They do so because the heart has to work too hard to provide adequate amounts of oxygenated blood to the systemic circuit. Treatment may involve surgery to close the foramen ovale, the ductus arteriosus, or both. Other congenital heart defects result from abnormal cardiac development or inappropriate connections between the heart and major arteries and veins.

CHECKPOINT

- **22.** Name the three vessels that carry blood to and from the placenta.
- **23.** A blood sample taken from the umbilical cord contains high levels of oxygen and nutrients, and low levels of carbon dioxide and waste products. Is this sample from an umbilical artery or from the umbilical vein? Explain.

24. Name the structures in the fetal circulation that stop functioning at birth. What becomes of these structures?See the blue Answers tab at the back of the book.

13-9 Aging affects the blood, heart, and blood vessels

Learning Outcome Discuss the effects of aging on the cardiovascular system.

The capabilities of the cardiovascular system gradually decline with age. Major changes affect all parts of the cardiovascular system: blood, heart, and vessels.

Age-related changes in blood may include (1) a decreased hematocrit; (2) constriction or blockage of peripheral veins by a stationary blood clot called a *thrombus*, which can become detached, pass through the heart, and become wedged in a small artery (commonly in the lungs) causing *pulmonary embolism;* and (3) the pooling of blood in the veins of the legs because valves are not working effectively.

Age-related changes in the heart include (1) a reduction in maximum cardiac output, (2) changes in the activities of the nodal and conducting cells, (3) a reduction in the elasticity of the cardiac (fibrous) skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) replacement of damaged cardiac muscle cells by scar tissue.

Age-related changes in blood vessels are often linked to arteriosclerosis, a thickening and toughening of arterial walls. For example, (1) the inelastic walls of arteries become less tolerant of sudden pressure increases, which can lead to a bulge in a weakened arterial wall, or *aneurysm* (AN-ū-rizm). Its rupture may (depending on the vessel) cause a stroke, myocardial infarction, or massive blood loss. Also, (2) calcium salts can be deposited on weakened vascular walls, increasing the risk of a stroke or myocardial infarction. (3) Lipid deposits in the tunica media can form atherosclerotic plaques, and (4) thrombi can form at atherosclerotic plaques.

CHECKPOINT

- **25.** Identify components of the cardiovascular system that are affected by age.
- **26.** Define thrombus.
- **27.** Define aneurysm.

See the blue Answers tab at the back of the book.

13-10 The cardiovascular system is both structurally and functionally linked to all other systems

Learning Outcome Give examples of interactions between the cardiovascular system and other body systems.

The section of the chapter on the distribution of blood vessels demonstrated the structural connections between the cardiovascular system and other organ systems. Functionally, the cardiovascular system provides other body systems with oxygen, hormones, nutrients, and white blood cells. It also removes carbon dioxide and metabolic wastes. In addition, circulating blood transfers heat to body tissues.

Build Your Knowledge: How the CARDIOVASCULAR SYSTEM integrates with the other body systems presented so far on p. 495 reviews the major functional relationships between it and the integumentary, skeletal, muscular, nervous, and endocrine systems.

CHECKPOINT

- **28.** Describe what the cardiovascular system provides for all other body systems.
- **29.** What is the relationship between the skeletal system and the cardiovascular system?
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

angiogram: An x-ray of a blood vessel that becomes visible due to a prior injection of dye into the subject's bloodstream.

deep vein thrombosis (DVT): A blood clot in a major vein, usually in the legs. They often occur after extended periods of inactivity, such as long airplane flights. The clot can break free and travel to the lungs as an embolus, where it can cause respiratory distress or respiratory failure.

hypertension: Abnormally high blood pressure; usually defined in adults as blood pressure higher than 140/90.

hypervolemic (hī-per-vō-LĒ-mik): Having an excessive blood volume.

hypovolemic (hī-pō-vō-LĒ-mik): Having a low blood volume.

normotensive: Having normal blood pressure.

orthostatic hypotension: Low blood pressure upon standing, often accompanied by dizziness or fainting; results from a failure of the regulatory processes that increase blood pressure to maintain adequate blood flow to the brain.

phlebitis: Inflammation of a vein.

Raynaud's phenomenon: A condition resulting in the discoloration of the fingers and/or toes when a person is subjected to changes in temperature or to emotional stress.

syncope (SING-kuh-pē): A temporary loss of consciousness due to a sudden drop in blood pressure; fainting.

Build Your Knowledge

How the CARDIOVASCULAR SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System has mast cells that trigger localized changes in blood flow and capillary permeability
- The cardiovascular system delivers immune system cells to injury sites; clotting response seals breaks in skin surface; carries away toxins from sites of infection; provides heat

Skeletal System

- The Skeletal System provides calcium needed for normal cardiac muscle contraction; protects blood cells developing in red bone marrow
- The cardiovascular system transports calcium and phosphate for bone deposition; delivers EPO to red bone marrow, parathyroid hormone and calcitonin to osteoblasts and osteoclasts

Muscular System

- The Muscular System assists venous circulation through skeletal muscle contractions; protects superficial blood vessels, especially in neck and limbs
- The cardiovascular system delivers oxygen and nutrients, removes carbon dioxide, lactate, and heat during skeletal muscle activity

Nervous System

- The Nervous System controls patterns of circulation in peripheral tissues; modifies heart rate and regulates blood pressure; releases antidiuretic hormone (ADH)
- The cardiovascular system has capillaries whose endothelial cells maintain the blood brain barrier; help generate CSF

Endocrine System

- The Endocrine System produces erythropoietin (EPO), which regulates production of RBCs; several hormones increase blood pressure; epinephrine stimulates cardiac muscle, increasing heart rate and force of contraction
- The cardiovascular system distributes hormones throughout the body; the heart secretes atrial natriuretic peptide (ANP)

Cardiovascular System

The cardiovascular system has blood vessels that provide extensive anatomical connections between it and all the other organ systems. It:

- transports dissolved gases, nutrients, hormones, and metabolic wastes
- regulates pH and ion composition of interstitial fluid
- restricts fluid losses at injury sites
- defends against toxins and pathogens
- stabilizes body temperature

Chapter Review

Summary Outline

- **13-1** Arteries, arterioles, capillaries, venules, and veins differ in size, structure, and function *ρ. 460*
- 1. Blood flows through a network of arteries, capillaries, and veins. All chemical and gaseous exchange between the blood and interstitial fluid takes place across **capillary** walls.
- 2. Arteries and veins form an internal distribution system, using blood propelled by the heart. Arteries branch repeatedly, decreasing in size until they become **arterioles;** from the arterioles, blood enters the capillary networks. Blood flowing from the capillaries enters small venules before entering larger veins.
- **3.** The walls of arteries and veins contain three layers: the **tunica intima**, **tunica media**, and outermost **tunica externa**. (*Figure 13-1*)
- 4. The walls of arteries are usually thicker than the walls of veins. The arterial system includes the large elastic arteries, medium-sized muscular arteries, and smaller arterioles. As blood proceeds toward the capillaries, the number of vessels increases, but the diameter of the individual vessels decreases and the walls become thinner. (*Figure 13-2*)
- **5.** Capillaries are the only blood vessels whose walls permit exchange between blood and interstitial fluid.
- 6. Capillaries form interconnected networks called **capillary beds**. A **precapillary sphincter** (a band of smooth muscle) adjusts blood flow into each capillary. Blood flow in a capillary changes as **vasomotion** occurs. (*Figure 13-3*)
- 7. Venules collect blood from capillaries and merge into **medium-sized veins** and then **large veins**. The arterial system is a high-pressure system; blood pressure in veins is much lower. **Valves** in veins prevent backflow of blood. *(Figure 13-4)*

13-2 Pressure and resistance determine blood flow and affect rates of capillary exchange *p. 465*

- **8.** Blood flows from an area of higher pressure to an area of lower pressure. Its flow rate is proportional to the pressure difference (pressure gradient).
- **9.** For circulation to take place, *circulatory pressure* (the pressure gradient across the systemic circuit) must be greater than *total peripheral resistance* (the resistance of the entire cardiovascular system). For blood to flow into peripheral capillaries, **blood pressure** (arterial pressure) must be greater than the **peripheral resistance** (the resistance of

the arterial system). Neural and hormonal control processes regulate blood pressure.

- **10.** Sources of peripheral resistance include **vascular resistance**, **viscosity**, and **turbulence**.
- 11. High arterial pressures overcome peripheral resistance and maintain blood flow through peripheral tissues. Capillary pressures are normally low, and small changes in capillary pressure determine the rate of fluid movement into or out of the bloodstream. Venous pressure, normally low, determines venous return and affects cardiac output and peripheral blood flow.
- **12.** Arterial pressure rises in ventricular systole and falls in ventricular diastole. The difference between the **systolic** and **diastolic pressures** is **pulse pressure**. (*Figure 13-5*)
- **13.** At the capillaries, solute molecules diffuse across the capillary lining, and water-soluble materials diffuse through small spaces between endothelial cells. Water moves when driven by either capillary hydrostatic pressure (CHP) or blood osmotic pressure (BOP). The direction of water movement is determined by the balance between these two opposing pressures. (*Figure 13-6*)
- 14. Valves, muscular compression, and the respiratory pump help the relatively low venous pressures propel blood toward the heart. (*Figure 13-4*)

13-3 Cardiovascular regulation involves autoregulation, neural processes, and endocrine responses *p. 471*

- **15.** Homeostatic processes ensure that tissue blood flow (*tissue perfusion*) delivers adequate oxygen and nutrients.
- **16.** Blood flow varies with cardiac output, peripheral resistance, and blood pressure.
- **17.** Autoregulation, neural processes, and endocrine processes influence the coordinated regulation of cardio-vascular function. Autoregulation involves local factors changing the pattern of blood flow within capillary beds in response to chemical changes in interstitial fluids. Neural processes respond to changes in arterial pressure or blood gas levels. Hormones can assist in both short-term adjustments (changes in cardiac output and peripheral resistance) and long-term adjustments (changes in blood volume that affect cardiac output and gas transport). (*Figure 13-7*)
- **18.** Peripheral resistance is adjusted at the tissues by the dilation or constriction of precapillary sphincters.

- **19. Baroreceptor reflexes** respond to the degree of stretch of expandable organs. Baroreceptors are located in the **carotid sinuses**, **aortic arch**, and the right atrium. (*Figure 13-8*)
- **20.** Chemoreceptor reflexes respond to changes in oxygen, carbon dioxide, or pH levels in blood and cerebrospinal fluid. Sympathetic activation leads to stimulation of the *cardioacceleratory* and *vasomotor centers;* parasympathetic activation stimulates the *cardioinhibitory center.* (*Figure 13-9*)
- **21.** Short-term endocrine regulation of cardiac output and peripheral resistance is achieved by epinephrine and norepinephrine from the adrenal medullae. Hormones involved in long-term regulation of blood pressure and volume are antidiuretic hormone (ADH), angiotensin II, erythropoietin (EPO), and atrial natriuretic peptide (ANP). *(Figure 13-10)*
- **22.** ANP release is stimulated by an increase in blood pressure. ANP encourages sodium loss and fluid loss, reduces blood pressure, inhibits thirst, and lowers peripheral resistance. (*Figure 13-10*)

13-4 The cardiovascular system adapts to physiological stress *p. 477*

- **23.** During exercise, blood flow to skeletal muscles increases at the expense of circulation to "nonessential" organs, and cardiac output rises. Cardiovascular performance improves with training. Athletes have larger stroke volumes, lower resting heart rates, and greater cardiac reserves than do nonathletes.
- **24.** Blood loss causes an increase in cardiac output, peripheral vasoconstriction, and the secretion of hormones that promote fluid retention and red blood cell production.

13-5 The pulmonary and systemic circuits of the cardiovascular system exhibit three general functional patterns *p. 479*

- **25.** The peripheral distributions of arteries and veins are generally identical on both sides of the body, except near the heart. (*Figure 13-11*)
- **13-6** In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs in veins *p. 480*
- 26. The **pulmonary circuit** includes the **pulmonary trunk**, the **left** and **right pulmonary arteries**, and the **pulmonary veins**, which empty into the left atrium. *(Figures 13-11, 13-12)*

13-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues other than the lungs' exchange surfaces, and returns deoxygenated blood to the right atrium *p. 481*

27. In the **systemic circuit**, the **ascending aorta** gives rise to the coronary circulation. The **aortic arch** communicates with the **descending aorta**. (*Spotlight Figure 13-13a; Figures 13-14 to 13-16*)

- **28.** Arteries in the neck and limbs are deep beneath the skin. In contrast, two sets of peripheral veins usually occur in those sites, one superficial and one deep. This dual-venous drainage is important for controlling body temperature. (*Spotlight Figure 13-13b*)
- **29.** The **superior vena cava (SVC)** receives blood from the head, neck, chest, shoulders, and arms. (*Spotlight Figure 13-13b; Figures 13-17 to 13-19*)
- **30.** The **inferior vena cava (IVC)** collects most of the venous blood from organs inferior to the diaphragm. (*Figure 13-19*)
- **31.** The **hepatic portal system** directs blood from the other digestive organs to the liver before the blood returns to the heart. (*Figure 13-20*)

13-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials until birth *p. 492*

- **32.** The placenta receives deoxygenated blood from a pair of **umbilical arteries.** Oxygenated blood returns to the fetus through the single **umbilical vein**, which delivers it to the **ductus venosus** in the liver. (*Figure 13-21a*)
- **33.** Prior to birth, blood bypasses the pulmonary circuit by flowing (1) from the right atrium into the left atrium through the **foramen ovale**, and (2) from the pulmonary trunk into the aortic arch through the **ductus arteriosus**. (*Figure 13-21b*)

13-9 Aging affects the blood, heart, and blood vessels *p. 493*

- **34.** Age-related changes in the blood can include (1) a decreased hematocrit, (2) constriction or blockage of peripheral veins by a *thrombus* (stationary blood clot), and (3) pooling of blood in veins of the legs because the valves are not working effectively.
- **35.** Age-related changes in the heart include (1) a reduction in maximum cardiac output, (2) changes in the activities of the nodal and conducting cells, (3) a reduction in the elasticity of the cardiac skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) replacement of damaged cardiac muscle cells by scar tissue.
- **36.** Age-related changes in blood vessels, often related to arteriosclerosis, include (1) a weakening in the walls of arteries, potentially leading to the formation of an *aneurysm;* (2) the deposition of calcium salts on weakened vascular walls, increasing the risk of stroke or myocardial infarction; (3) lipid deposits in the tunica media forming atherosclerotic plaques; and (4) the formation of thrombi at atherosclerotic plaques.

13-10 The cardiovascular system is both structurally and functionally linked to all other systems *p. 494*

37. The cardiovascular system has blood vessels that deliver oxygen, nutrients, and hormones to all body systems and carry away carbon dioxide and wastes.

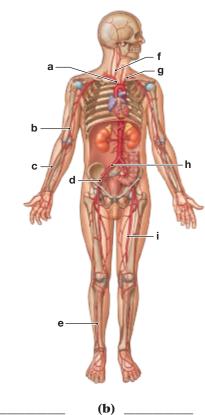

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A	COLUMN B
1. diastolic pressure	a. smallest arterial vessels
2. arterioles	b. drains the liver
3. hepatic vein	c. largest superficial vein in body
4. renal vein	d. aortic and carotid sinuses
5. aorta	e. minimum blood pressure
6. precapillary sphincter	f. blood supply to leg
7. medulla oblongata	g. blood supply to pelvis
8. internal iliac artery	h. peak blood pressure
9. external iliac artery	i. vasomotion
10. baroreceptors	j. largest artery in body
11. systolic pressure	k. drains the kidney
12. saphenous vein	l. contains vasomotor center

13. Identify the major arteries in the following diagram.

- (a) _____ (b) ____ (c) ____ (d) ____
- (e) _____ (f) _____
- (g) _____ (h) ____

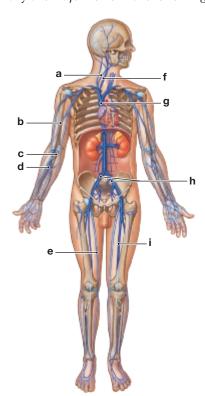

(i) _____

- **14.** The aorta is an example of(a) an arteriole.
 - (c) a muscular artery. (d) a capillary.
- **15.** The axillary artery is a direct continuation of the(a) radial artery.(b) brachial artery.
 - (c) subclavian artery. (d) ulnar artery.
- **16.** Veins that drain blood toward the hepatic portal vein include the following *except* the
 - (a) gastric veins. (b) hepatic veins.
 - (c) splenic vein. (d) superior mesenteric vein.

(b) an elastic artery.

- **17.** Production of red blood cells is stimulated by
 - (a) aldosterone. (b) atrial natriuretic peptide.
 - (c) erythropoietin. (d) renin.
- **18.** To maintain homeostasis, a decrease in blood pressure may lead to
 - (a) a drop in heart rate.
 - (b) the inhibition of the cardioinhibitory center.
 - (c) reduced cardiac contractility.
 - (d) widespread peripheral vasodilation.
- **19.** In response to angiotensin II, antidiuretic hormone is released from the
 - (a) carotid sinus. (b) kidney.
 - (c) pituitary gland. (d) right atrium.
- **20.** The circulatory pressure is higher in ______ than in
 - (a) muscular arteries; elastic arteries
 - (b) arterioles; muscular arteries
 - (c) capillaries; venules
 - (d) venae cavae; large veins

- **21.** Blood flows most readily in the systemic circulation in the presence of
 - (a) high circulatory pressure and high peripheral resistance.
 - **(b)** high circulatory pressure and low peripheral resistance.
 - (c) low circulatory pressure and high peripheral resistance.
 - (d) low circulatory pressure and low peripheral resistance.
- 22. The two factors that assist the relatively low venous pressures in propelling blood toward the heart are(a) ventricular systole and valve closure.
 - (b) gravity and vasomotion.
 - (c) muscular compression and the respiratory pump.
 - (d) atrial and ventricular contractions.
- **23.** Identify the major veins in the following diagram.

(a)	(b)
(c)	(d)
(e)	(f)
(g)	(h)

- (i)
- **24.** Arteries of the pulmonary circuit differ from those of the systemic circuit in that they carry
 - (a) oxygen and nutrients.
 - **(b)** deoxygenated blood.
 - (c) oxygenated blood.
 - (d) oxygen, carbon dioxide, and nutrients.
- **25.** The two arteries formed by the division of the brachiocephalic trunk are the
 - (a) aorta and internal carotid.
 - **(b)** axillary and brachial.
 - (c) external and internal carotid.
 - (d) common carotid and subclavian.
- **26.** The unpaired arteries supplying blood to the visceral organs include the
 - (a) adrenal, renal, and lumbar arteries.

- (b) iliac, gonadal, and femoral arteries.
- (c) celiac trunk and superior and inferior mesenteric arteries.
- (d) a, b, and c are correct.
- **27.** The artery used to measure blood pressure using a
 - sphygmomanometer is the **(a)** brachial artery.
 - (b) external carotid artery.
 - (d) femoral artery.
- **28.** Total peripheral resistance is determined by
 - (a) the vessel length and vessel diameter.
 - (**b**) blood viscosity.

(c) phrenic vein.

(c) radial artery.

- (c) blood turbulence.
- (d) each of the options listed above.
- **29.** Blood from the pelvic muscles, reproductive organs, and bladder is collected by the
 - (a) common iliac vein.
 - (b) axillary vein.
 (d) internal iliac vein.
- 30. (a) What are the primary forces that cause fluid to move out of a capillary and into the interstitial fluid at its arterial end?(b) What are the primary forces that cause fluid to move into a capillary from the interstitial fluid at its venous end?
- **31.** What two effects result when the baroreceptor response to elevated blood pressure (BP) is triggered?
- **32.** How might the respiratory system be influenced if chemoreceptors detect decreased blood pH levels?
- 33. What cardiovascular changes occur at birth?
- **34.** What age-related changes take place in the blood, heart, and blood vessels?

Level 2 Reviewing Concepts

35. When standing in an upright position, the flow of blood in the inferior vena cava toward the heart is aided by the

13

- (a) valves found in medium-sized veins.
- **(b)** contraction of skeletal muscles near the veins.
- (c) expansion of the thoracic cavity during inspiration.
- (d) a, b, and c are correct.
- **36.** Increased CO₂ levels in tissues would promote
 - (a) contraction of precapillary sphincters.
 - (b) an increase in the pH of the blood.
 - (c) relaxation of precapillary sphincters.
 - (d) a decrease of blood flow to tissues.
- **37.** When ANP is released by the right atrium, it will
 - (a) stimulate vasodilation.
 - (b) reduce thirst.
 - (c) block the release of ADH and aldosterone.
 - (d) a, b, and c are correct.
- **38.** How can auto regulation match blood flow to tissue oxygen demand?
- **39.** Why do capillaries permit the diffusion of materials, whereas arteries and veins do not?
- **40.** Why is the blood composition in the hepatic portal vein different from other systemic veins?
- **41.** An accident victim displays the following signs and symptoms: hypotension; pale, cool, moist skin; confusion; and disorientation. Identify her condition, and explain why each of these signs and symptoms occurs. If you took her pulse, what would you find?

Level 3 Critical Thinking and Clinical Applications

- **42.** Systemic inflammatory response syndrome (SIRS) is characterized, among other things, by tachycardia (HR>100 bpm) and low blood pressure due to increased inflammatory chemicals in circulating blood. Why does blood pressure fall, and why does tissue hypoxia (low oxygen) often develop despite the patient having an increased heart rate? What might be used to treat hemodynamic instability of SIRS?
- **43.** Vegans may develop anemia if they do not supplement vitamin B12 (needed for red blood cell production) in their diets. Would a vitamin B12 deficiency put them at risk of developing hypertension or hypotension? Explain your answer.
- **44.** An arterial anastomosis is found around the elbow joint. What is the functional significance?

13

The Lymphatic System and Immunity

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **14-1** Distinguish between innate (nonspecific) defenses and adaptive (specific) defenses.
- **14-2** Identify the major components of the lymphatic system, and explain the functions of each.
- **14-3** List the body's innate (nonspecific) defenses and explain how each functions.
- **14-4** Define adaptive (specific) defenses, identify the forms and properties of immunity, and distinguish between cell-mediated immunity and antibody-mediated (humoral) immunity.
- **14-5** Discuss the different types of T cells and their roles in the adaptive immune response.
- **14-6** Discuss the processes of B cell sensitization, activation, and differentiation, describe the structure and function of antibodies, and explain the primary and secondary immune responses to antigen exposure.
- **14-7** List and explain examples of immune disorders and allergies, and discuss the effects of stress on immune function.
- **14-8** Describe the effects of aging on the lymphatic system and the immune response.
- **14-9** Give examples of interactions between the lymphatic system and other body systems presented so far.

Spotlight Origin and Distribution of Lymphocytes, p. 507

An Introduction to the Lymphatic System and Immunity

We do not live in a completely safe world. The external environment contains a variety of physical hazards—poisonous chemicals, extreme heat, radiation, heavy and/or sharp objects, to name but a few. They can inflict a broad range of injuries, including bumps, cuts, broken bones, and burns. The world is also full of many types of microorganisms that, if allowed to enter into the body, cause some of the most important human diseases. Still other internal processes, such as cancer, can pose extreme, even lethal, danger to the human body.

Many different organs and systems work together to keep us alive and healthy. In this ongoing struggle to maintain health, the *lymphatic system* plays a central role. In this chapter we discuss the components of the lymphatic system and their interactions.

Build Your Knowledge

Recall that the lymphatic system defends against infection and disease and returns tissue fluids to the bloodstream (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). The tissue (interstitial) fluid that is transported by lymphatic vessels is called lymph. Recall also that lymph is a fluid connective tissue. Along the way to the cardiovascular system, lymph is monitored for signs of injury and infection. This recirculation of fluid is essential for homeostasis. **> pp. 38, 132, 468**

14–1 Anatomical barriers and defense processes make up nonspecific defense, and lymphocytes provide specific defense

Learning Outcome Distinguish between innate (nonspecific) defenses and adaptive (specific) defenses.

Our world contains a wide range of viruses, bacteria, fungi, and parasites that cause diseases in humans. Disease-causing organisms are called **pathogens** (*pathos*, disease + *-gen*, to produce). Each pathogen has a different mode of life and interacts with the body in a characteristic way. For example, most of the time viruses exist within cells, which they often eventually destroy. (Viruses lack a cellular structure. They consist only of nucleic acid and protein. They can replicate themselves only within a living cell.) Many bacteria multiply in the interstitial fluids. Some of the largest parasites, such as roundworms, burrow through internal organs. And as if that were not enough, we are constantly at risk from renegade cells that have the potential to produce lethal cancers. \supset p. 114

The **lymphatic system** includes the cells, tissues, and organs responsible for defending the body. The primary cells of the lymphatic system are *lymphocytes*. \bigcirc p. 425.

Immunity is the ability to resist infection and disease. The body's defensive reaction to infectious agents and abnormal substances is known as the **immune response**. We have two types of immunity: (1) *innate (nonspecific) immunity,* and (2) *adaptive (specific) immunity.*

The body has several anatomical barriers and defense processes that either prevent or slow the entry of infectious organisms, or attack them if they do succeed in gaining entry. These defenses are called *innate* because we are born with them and *nonspecific* because they do not distinguish one potential threat from another.

In contrast, lymphocytes respond to *specific* threats. If a bacterial pathogen invades peripheral tissues, lymphocytes organize a defense against that particular type of bacterium. More importantly, this type of defense protects against further attacks by the same type of pathogen. For this reason, we say that lymphocytes provide *adaptive (specific) defenses*.

All the cells and tissues involved in producing immunity are part of an *immune system*. The immune system is a *functional system* and includes parts of the integumentary, skeletal, lymphatic, cardiovascular, respiratory, and digestive systems.

Next we examine the organization of the lymphatic system. Then we will consider the body's nonspecific defenses. Finally, we will see how the lymphatic system interacts with cells and tissues of other systems to defend the body against infection and disease.

CHECKPOINT

- 1. Define pathogen.
- **2.** Explain the difference between innate (nonspecific) defenses and adaptive (specific) defenses.
- See the blue Answers tab at the back of the book.

14-2 Lymphatic vessels, lymphocytes, lymphoid tissues, and lymphoid organs function in body defenses

Learning Outcome Identify the major components of the lymphatic system, and explain the functions of each.

The lymphatic system is one of our least familiar organ systems. It includes four components:

- 1. *Vessels*. A network of **lymphatic vessels**, often called **lymphatics**, begins in peripheral tissues and connects to veins.
- **2.** *Fluid*. A fluid called **lymph** flows through the lymphatic vessels. Lymph resembles plasma but contains a much lower concentration of proteins.
- **3.** *Lymphocytes*. Lymphocytes are specialized white blood cells with an array of specific functions in defending the body.
- 4. Lymphoid tissues and organs.

Lymphoid tissues are collections of loose connective tissue and lymphocytes in structures called *lymphoid nodules*. The tonsils are an example. **Lymphoid organs** are more complex structures that contain large numbers of lymphocytes and are connected to lymphatic vessels. Examples include the lymph nodes, spleen, and thymus.

Primary lymphoid tissues and organs are sites where lymphocytes are formed and mature. They include the red bone marrow and the thymus gland. Recall that red bone marrow is also where other defense cells, the monocytes and macrophages, are formed.

Secondary lymphoid tissues and organs are sites where lymphocytes are activated and cloned (produced in large numbers of identical copies). These tissues and organs include the appendix, spleen, lymph nodes, tonsils, and MALT. **Figure 14-1** provides an overview of the primary vessels, tissues, and organs of the lymphatic system.

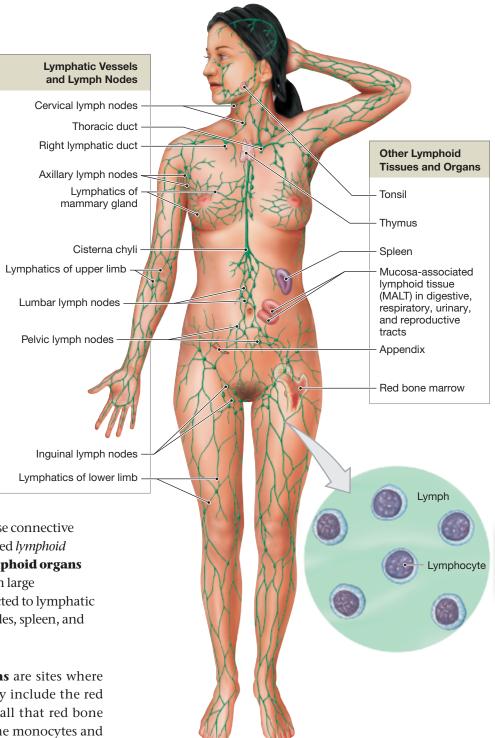

Figure 14-1 The Components of the Lymphatic System.

Functions of the Lymphatic System

The lymphatic system has three major functions:

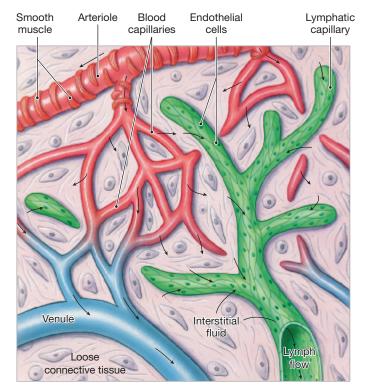

- **Production, maintenance, and distribution of lymphocytes.** Lymphocytes are produced in red bone marrow and the thymus. They are stored within lymphoid organs, such as the spleen. Lymphocytes respond to the presence of (1) invading pathogens, such as bacteria or viruses; (2) abnormal body cells, such as virus-infected cells or cancer cells; and (3) foreign proteins, such as the toxins produced by some bacteria. Lymphocytes work to eliminate these threats or render them harmless. They do so through a combination of physical and chemical actions.
- *Return of fluid and solutes from peripheral tissues to the blood.* The return of tissue fluids through the lymphatic system maintains normal blood volume and eliminates local variations in the composition of the interstitial fluid. The volume of flow is considerable roughly 3.6 liters (0.95 gal) per day. A break in a major lymphatic vessel can cause a rapid and potentially fatal decline in blood volume.
- Distribution of hormones, nutrients, and waste products from their tissues of origin to the general circulation. Substances unable to enter the bloodstream directly may do so by way of lymphatic vessels. For example, lipids absorbed by the digestive tract do not usually enter the bloodstream through capillaries. Instead, they reach the bloodstream only after they have traveled along lymphatic vessels. (We describe this process in Chapter 16).

Lymphatic Vessels

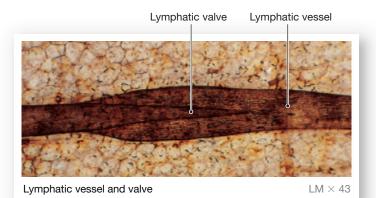

Lymphatic vessels, or lymphatics, carry lymph from peripheral tissues to the venous system. Lymphatic capillaries are the smallest lymphatic vessels. They begin as blind pockets in peripheral tissues (Figure 14-2a). Lymphatic capillaries are lined by an endothelium (simple squamous epithelium) with a basement membrane that is incomplete or absent. The endothelial cells are not bound tightly, but they do overlap. The region of overlap acts as a one-way valve. It permits fluids and solutes (including those as large as proteins), along with viruses, bacteria, and cell debris, to enter, but it prevents them from returning to the intercellular spaces.

From lymphatic capillaries, lymph flows into larger lymphatic vessels that lead toward the trunk of the body. The walls of these lymphatics contain layers comparable to those of veins. Like veins, such lymphatic vessels contain valves (**Figure 14-2b**). Pressures within the lymphatic system are

Figure 14-2 Lymphatic Capillaries.

a The interwoven network formed by blood capillaries and lymphatic capillaries. Arrows indicate the movement of fluid out of blood capillaries and the net flow of interstitial fluid and lymph.

b Like valves in veins, each lymphatic valve permits movement of fluid in only one direction.

extremely low, so the valves are essential to maintaining normal lymph flow. Contractions of skeletal muscles surrounding the lymphatic vessels aid the flow of lymph.

The lymphatic vessels ultimately empty into two large collecting structures called lymphatic ducts (**Figure 14-3**). The **thoracic duct** collects lymph from the lower abdomen, pelvis, and lower limbs, and from the left half of the head, neck, and chest. It empties its collected lymph into the venous system near the junction of the left internal jugular vein and the left

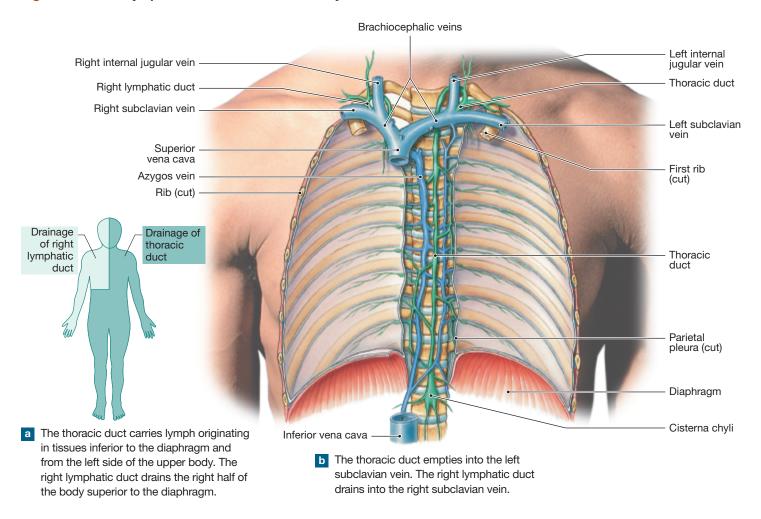

Figure 14-3 The Lymphatic Ducts and the Venous System.

subclavian vein. The base of the thoracic duct is an expanded, saclike chamber called the **cisterna chyli** ($K\overline{I}$ - $l\overline{i}$; *chylos*, juice). The smaller **right lymphatic duct** ends at a comparable location on the right side. It delivers lymph from the right side of the body above the diaphragm. It empties into the right subclavian vein.

Blockage of lymphatic drainage from a limb produces **lymphedema** (limf-e-DĒ-muh). In this condition, interstitial fluids accumulate and the limb gradually becomes swollen and grossly distended.

Lymphocytes

Lymphocytes account for 20–40 percent of circulating white blood cells. \bigcirc p. 425 But circulating lymphocytes make up only a small fraction of the total lymphocyte population. Most of the approximately 1 trillion (10¹²) lymphocytes—with a combined weight of over a kilogram (2.2 lb)—are found within

lymphoid organs or other tissues. The bloodstream serves as a rapid transport system for lymphocytes moving from one site to another.

Types of Circulating Lymphocytes

Three classes of lymphocytes circulate in the blood: *T cells, B cells,* and *NK cells.* Each has distinctive functions.

T CELLS. Most of the circulating lymphocytes (approximately 80 percent) are **T** (thymus-dependent) cells. *Cytotoxic T cells* directly attack foreign cells or virus-infected body cells. These lymphocytes are the primary providers of *cell-mediated immunity*, or *cellular immunity*. *Helper T cells* stimulate the activities of both T cells and B cells. *Regulatory T cells* moderate the immune response by inhibiting both T cells and B cells. *Memory T cells* respond to abnormal or foreign substances they have already encountered or targeted.

B CELLS. B (bone marrow-derived) cells make up 10–15 percent of circulating lymphocytes. Under proper stimulation, B cells differentiate into **plasma cells** that secrete **antibodies**. These antibodies are soluble proteins, also called **immunoglobulins**. ⊃ p. 413 B cells are said to be responsible for *antibody-mediated immunity*. Because antibodies occur in body fluids, antibody-mediated immunity is also known as *humoral* ("liquid") *immunity*. Antibodies bind to specific chemical targets called **antigens**. Most antigens are usually, parts or products of pathogens or abnormal cells, or other foreign compounds. Formation of an antigen–antibody complex starts a chain of events leading to the destruction of the target pathogen, cell, or compound.

NK CELLS. The remaining 5–10 percent of circulating lymphocytes are **NK** (**n**atural **k**iller) **cells**. NK cells provide innate (nonspecific) immunity. These lymphocytes attack foreign cells, normal cells infected with viruses, and cancer cells that appear in normal tissues. Their continual monitoring of peripheral tissues is known as *immune surveillance*.

The Origin and Circulation of Lymphocytes

Lymphocytes in the blood, bone marrow, spleen, thymus, and peripheral lymphatic tissues are visitors, not residents. All types of lymphocytes move throughout the body. They wander through tissues and then enter a blood vessel or lymphatic vessel for transport to another site. In general, lymphocytes have relatively long life spans. Roughly 80 percent survive for four years. Some last 20 years or more. Throughout your life, you maintain normal lymphocyte populations through the divisions of stem cells in your red bone marrow and lymphoid tissues.

Lymphocyte production and development is called **lymphocytopoiesis** (lim-fō-SĪ-tō-poy-Ē-sis). It involves the red bone marrow, thymus, and peripheral lymphoid tissues (**Spotlight Figure 14-4**). As B cells and T cells develop and mature, they gain the ability to respond to the presence of a specific antigen. NK cells gain the ability to respond to a variety of abnormal antigens, allowing them to recognize abnormal cells.

Hemocytoblasts (hematopoietic stem cells) in red bone marrow produce lymphoid stem cells with two different fates. One group remains in the red bone marrow and generates B cells and functional NK cells. The second group of lymphoid stem cells migrates to the thymus. Under the influence of thymic hormones (collectively known as *thymosins*), these cells divide repeatedly to produce large numbers of T cells. These T cells undergo a selection process to ensure that they will not react to the body's own healthy cells and cellular products. (B cells also undergo a selection process in the red bone marrow with the same results.) As they mature, all three types of lymphocytes enter the bloodstream and migrate to peripheral tissues, including lymphoid tissues and organs, such as the spleen.

The T cells and B cells that migrate from their sites of origin retain the ability to divide and produce daughter cells of the same type. A dividing B cell, for example, produces other B cells, not T cells or NK cells. As we will see, the ability of a specific type of lymphocyte to increase in number is important to the success of the immune response.

Lymphoid Tissues

Lymphoid tissues are loose connective tissues dominated by lymphocytes. In a **lymphoid nodule**, the lymphocytes are densely packed in an area of areolar tissue. In many areas, they form large clusters. Each nodule often contains a pale central region, called a *germinal center*, which contains dividing lymphocytes. A single nodule averages about a millimeter in diameter. Its boundaries are not distinct, because no fibrous capsule surrounds it. As a result, nodule size can increase or decrease, depending on the number of lymphocytes present.

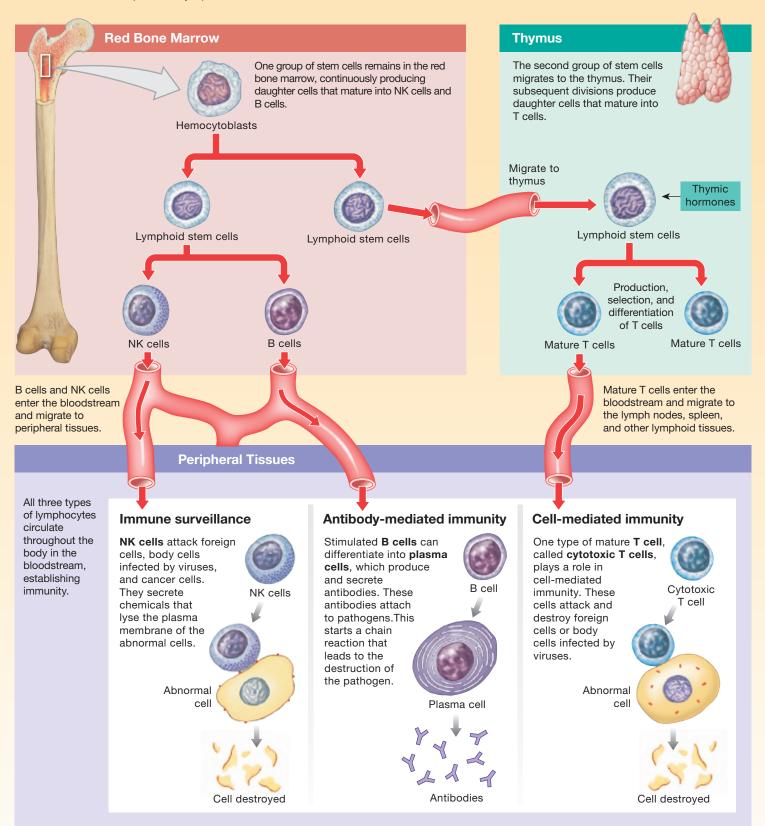

The digestive, respiratory, urinary, and reproductive tracts are open to the external environment. For this reason, they provide a route of entry into the body for potentially harmful organisms and toxins. The epithelia of these systems are protected by a collection of lymphoid tissues called the **mucosaassociated lymphoid tissue (MALT)**.

MALT associated with the digestive tract plays a particularly important role in defending the body because our food usually contains foreign proteins and often bacteria as well. For example, the **tonsils** are large clusters of lymphoid nodules in the walls of the pharynx. They guard the entrance to the digestive and respiratory tracts (**Figure 14-5**). Five tonsils are usually present: a single *pharyngeal tonsil*, or *adenoid*; a pair of *palatine tonsils*; and a pair of *lingual tonsils*. Aggregates of lymphoid nodules, called *Peyer patches*, also lie beneath the epithelial lining of the small intestine. Another example of MALT is the *appendix*, or *vermiform* ("worm-shaped") *appendix*. The appendix is a blind pouch located near the junction of the small and large intestines. Its walls contain a mass of fused lymphoid nodules.

The lymphocytes in a lymphoid nodule are not always able to destroy bacterial or viral invaders. If pathogens do become established in a lymphoid nodule, an inflammatory response to the infection develops. You are probably familiar with two examples. *Tonsillitis* is the inflammation of one of the tonsils (usually the pharyngeal tonsil). *Appendicitis* is the inflammation of the lymphoid nodules in the appendix.

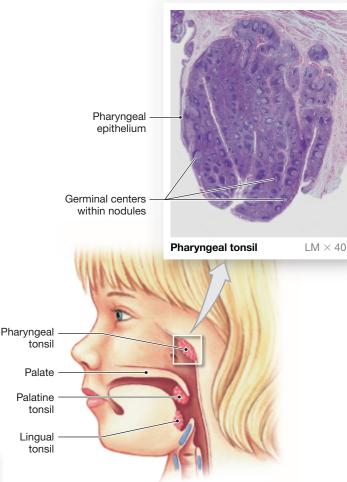

SPOTLIGHT Figure 14-4 ORIGIN AND DISTRIBUTION OF LYMPHOCYTES

Lymphocyte formation, or **lymphocytopoiesis**, involves the red bone marrow, thymus, and peripheral lymphoid tissues. Of the three, the red bone marrow plays the primary role in the maintenance of normal lymphocyte populations. Hemocytoblasts in the red bone marrow produce lymphoid stem cells with two distinct fates.

508 LYMPHATIC SYSTEM

Figure 14-5 The Tonsils. The tonsils are large clusters of lymphoid nodules in the wall of the pharynx. A single pharyngeal tonsil (the adenoid) lies above the paired palatine and lingual tonsils. Each tonsil contains many germinal centers where lymphocytes divide.

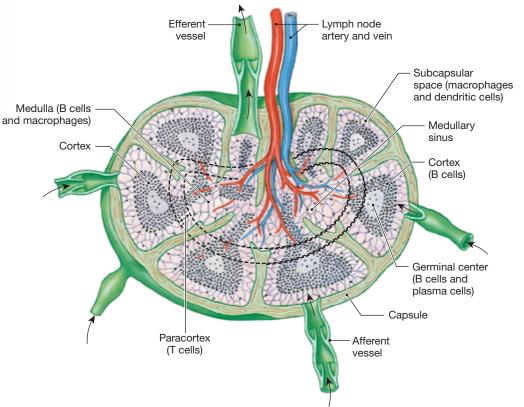

Two sets of lymphatic vessels connect to each lymph node (Figure 14-6). *Afferent lymphatics* bring lymph to the lymph node from peripheral tissues. *Efferent lymphatics* carry the lymph toward the venous system. A lymph node works like a kitchen water filter. It purifies lymph before it reaches the veins. Within the lymph node, the lymph flows through the subscapular space, cortex, paracortex, and medullary sinuses. As it passes, at least 99 percent of the antigens present in the arriving lymph are removed by fixed macrophages and branched *dendritic cells*. (We consider their roles in a later section.) As the antigens are removed and processed, T cells and B cells in the lymph node are stimulated, initiating an immune response.

The Thymus

The **thymus** is the site of T cell production and maturation. This pink gland lies in the mediastinum posterior to the sternum (**Figure 14-7a**). The thymus reaches its greatest size (relative to body size) in the first year or two after birth. It grows to its maximum absolute size during puberty, when it weighs between 30 and 40 g (1.06 to 1.41 oz). Then the thymus gradually decreases in size.

Figure 14-6 The Structure of a Lymph Node. The arrows indicate the direction of lymph flow. Mature B cells and T cells located in different regions of the cortex, paracortex, and medulla remove antigens from the lymph and initiate immune responses.

Lymphoid Organs

Lymphoid organs are separated from surrounding tissues by a fibrous connective tissue capsule. Important lymphoid organs include the *lymph nodes*, the *thymus*, and the *spleen*.

Lymph Nodes

14

Lymph nodes are small, oval lymphoid organs covered by a fibrous capsule. They range in diameter from 1–25 mm (up to 1 in.). The greatest number of lymph nodes is located in the neck, armpits, and groin, where they defend us against bacteria and other invaders. **Figure 14-1** shows the general pattern of lymph node distribution in the body.

Septa

I eft

lobe

14

Figure 14-7 The Thymus.

CLINICAL NOTE

"Swollen Glands"

Lymph nodes are often called *lymph glands.* "Swollen glands" usually accompany tissue inflammation or infection. Chronic or excessive enlargement of lymph nodes is a sign called *lymph-adenopathy* (lim-fad-e-NOP-a-thē). It may occur in response to bacterial or viral infections, endocrine disorders, or cancer.

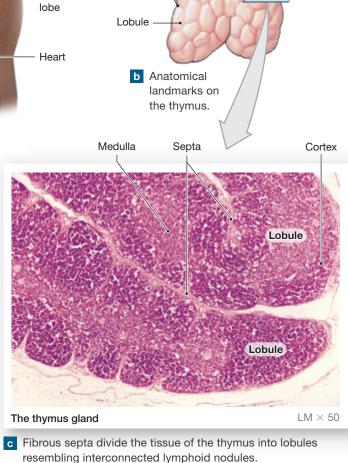

Lymphatic capillaries offer little resistance to the entry or passage of cancer cells. For this reason, cancer cells often spread along the lymphatics and become trapped in lymph nodes. An

analysis of swollen lymph nodes can provide details on the nature and distribution of cancer cells. Such information aids in choosing appropriate therapies.

Lymphomas are cancers arising from lymphocytes or lymphoid stem cells. They are an important group of cancers of the lymphatic system.

The thymus has two lobes. Each is divided into *lobules* by fibrous partitions, or *septa* (singular, *septum;* a wall) (Figure 14-7b). Each lobule consists of an outer cortex and a paler, central *medulla* (Figure 14-7c). The cortex contains clusters of lymphocytes surrounded by other cells that secrete the hormones collectively known as thymosins. Thymosins stimulate lymphocyte stem-cell divisions and T cell maturation. After the T cells migrate into the medulla, they leave the thymus in one of the blood vessels in that region.

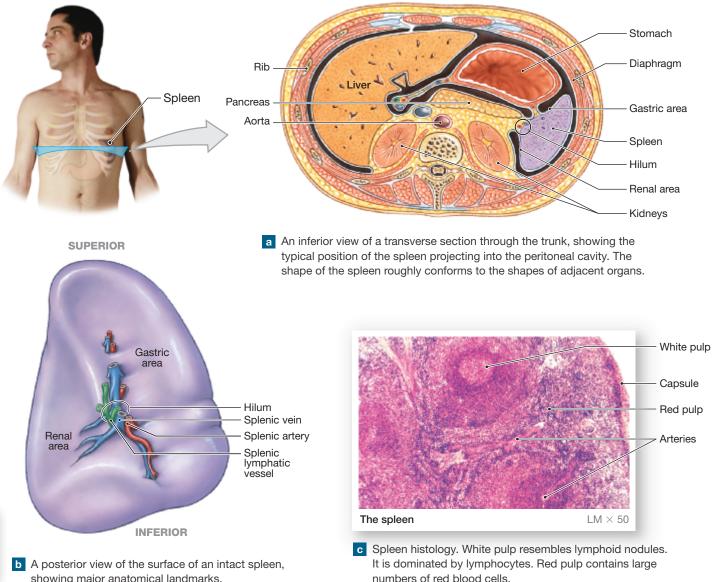

The Spleen

The adult **spleen** contains the largest collection of lymphoid tissue in the body. It is about 12 cm (5 in.) long and can weigh about 160 g (5.6 oz). Its major function parallels that of the lymph nodes, except that it filters blood instead of lymph. The spleen removes abnormal blood cells and components. It also initiates the responses of B cells and T cells to antigens in the circulating blood. In addition, the spleen stores iron from recycled red blood cells. \bigcirc p. 417

The spleen lies between the stomach, the left kidney, and the muscular diaphragm. It is attached to the lateral border of the stomach by a broad band of mesentery (Figure 14-8a). Splenic blood vessels (the *splenic artery* and *splenic vein*) and lymphatic vessels connect with the spleen at the *hilum*, a groove

Figure 14-8 The Spleen.

showing major anatomical landmarks.

bling lymphoid nodules (Figure 14-8c).

at the border between the gastric and renal areas (Figure 14-8b).

In gross dissection, the spleen normally has a deep red color

because of the blood it contains. The cellular components of

the spleen are arranged into areas of *red pulp*, which contain

large numbers of red blood cells, and areas of white pulp resem-

After the splenic artery enters the spleen, it branches out-

ward toward the capsule into many smaller arteries that are surrounded by white pulp. Capillaries then discharge the

blood into a network of reticular fibers that makes up the red pulp. Blood from the red pulp enters venous sinusoids (small and the splenic vein. As blood passes through the spleen, macrophages identify and engulf any damaged or infected cells. The presence of lymphocytes nearby ensures that any microorganisms or other abnormal antigens stimulate an immune response.

Roles of the Lymphatic System in Body Defenses

The human body has multiple body defenses. Together, they provide resistance-the natural or acquired ability to maintain immunity. We can sort body defenses into two general categories:

Go to Mastering A&P > Study Area > Menu > Chapter Quizzes > Section 6-2

14

CLINICAL NOTE

Injury to the Spleen

An impact to the left side of the abdomen can distort or damage the spleen. Such injuries are known risks of contact sports, such as football or hockey, and other athletic activities, such as skiing or sledding. Even a seemingly minor blow to the side may rupture the capsule. The result can be serious internal bleeding and eventual circulatory shock. The spleen can also be damaged by infection, inflammation, or invasion by cancer cells.

Depending on the degree of injury, treatment options for a ruptured spleen may range from immediate surgery to allowing time for healing with a period of hospital rest and, if required, blood transfusions. The spleen is very difficult to repair surgically because it is relatively fragile. (Sutures usually tear out before they have been tensed enough to stop the bleeding.) However, surgery for a ruptured spleen can involve stitches (closing the wound with sutures), removing a portion of it, or complete removal. The removal of the spleen is called a *splenectomy* (sple-NEK-to-mē). A person without a spleen survives without difficulty but has a greater risk of bacterial infections than do individuals with a functional spleen.

- 1. Innate (nonspecific) immunity does not distinguish between one threat and another. The response is the same regardless of the type of invader. These innate defenses are present at birth. They include *physical barriers, phagocytic cells, immune surveillance, interferons, complement, inflammation,* and *fever.* We discuss all of these defenses shortly. They provide the body with a defensive capability known as **nonspecific resistance**.
- 2. Adaptive (specific) immunity protects against particular threats. For example, an adaptive defense may fight infection by one type of bacterium, but ignore other bacteria and all viruses. Many specific defenses develop after birth as a result of exposure to environmental hazards or infectious agents. Adaptive defenses depend on the activities of specific lymphocytes. B cells and T cells are part of our adaptive defenses, which provide protection known as **specific resistance**.

Innate and adaptive defenses work together. Both are necessary to provide adequate resistance to infection and disease.

CHECKPOINT

- **3.** List the components of the lymphatic system.
- **4.** How would blockage of the thoracic duct affect the flow of lymph?

- **5.** If the thymus gland failed to produce thymic hormones, which population of lymphocytes would be affected?
- **6.** Why do lymph nodes enlarge during some infections? See the blue Answers tab at the back of the book.

14-3 Innate (nonspecific) defenses respond in a characteristic way regardless of the potential threat

Learning Outcome List the body's innate (nonspecific) defenses and explain how each functions.

Innate (nonspecific) defenses deny the entry, or limit the spread within the body, of microorganisms or other environmental hazards. Seven major categories of nonspecific defenses are summarized in **Figure 14-9**.

Physical Barriers

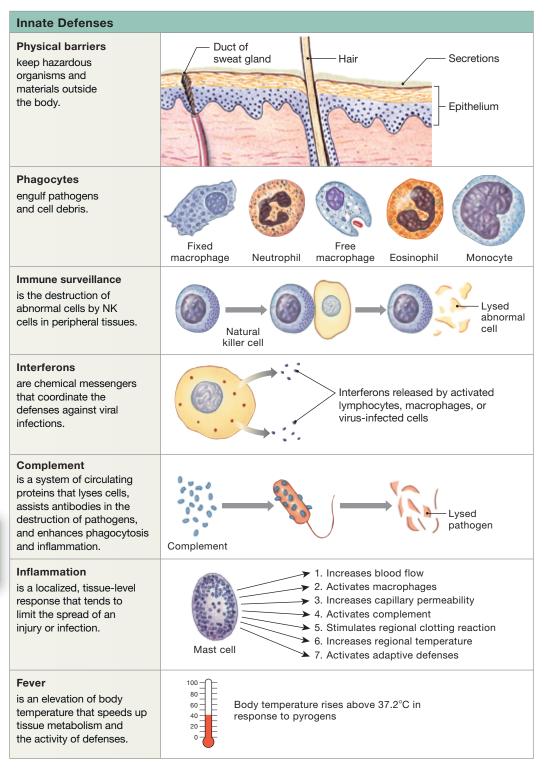

Physical barriers keep hazardous organisms and materials outside the body. To cause trouble, an antigenic substance or a pathogen must enter body tissues. In other words, it must cross an epithelium—either at the skin or across a mucous membrane. The epithelial covering of the skin has a keratin coating, multiple layers of cells, and a network of desmosomes that locks adjacent cells together. pp. 123, 154 These barriers provide very effective protection for underlying tissues.

In addition, specialized accessory structures and secretions protect most epithelia. The hairs on most areas of your body provide some protection against mechanical abrasion, especially on the scalp. They often prevent hazardous materials or insects from contacting the skin's surface. The epidermal surface also receives the secretions of sebaceous glands and sweat glands. These secretions flush the surface, washing away microorganisms and chemical agents. The secretions also contain microbe-killing chemicals, destructive enzymes (*lysozymes*), and antibodies.

The epithelia lining the digestive, respiratory, urinary, and reproductive tracts are more delicate, but they are equally well defended. Mucus bathes most surfaces of the digestive tract. The stomach contains a powerful acid that can destroy many potential pathogens. Mucus is swept across the lining of the respiratory tract. Urine flushes the urinary passageways. Glandular secretions flush structures in the reproductive tract. Special enzymes, antibodies, and an acidic pH add to the effectiveness of these secretions.

14

Figure 14-9 The Body's Innate Defenses. Innate (nonspecific) defenses deny pathogens access to the body or destroy them without distinguishing among specific types.

Phagocytes

Recall that **phagocytes** are cells that can surround and engulf solid objects. They serve as janitors and police in peripheral tissues. They remove cellular debris and respond to invasion by foreign compounds or pathogens. Phagocytes represent the "first line of cellular defense," often attacking and removing microorganisms before lymphocytes become aware of their presence. Two general classes of phagocytic cells are found in the body: *microphages* and *macrophages*.

Microphages are the neutrophils and eosinophils that normally circulate in the blood. These phagocytic cells leave the bloodstream and enter peripheral tissues subjected to injury or infection. Neutrophils are abundant, mobile, and quick to phagocytize cellular debris or invading bacteria. D p. 425 Eosinophils are less abundant. They target foreign compounds or pathogens that have been coated with antibodies.

The body also contains several types of macrophageslarge, actively phagocytic cells derived from circulating monocytes. Almost every tissue in the body shelters resident (fixed) or visiting (free) macrophages. This relatively diffuse collection of phagocytes has been called the monocyte-macrophagesystem, or the reticuloendothelial system. In some organs, fixed macrophages have special names. For example, microglia are macrophages in the central nervous system. Stellate macrophages, or Kupffer (KOOPfer) cells, are found in and around blood channels in the liver.

All phagocytic cells function in much the same way, but their targets may differ from one cell type to another. Mobile

macrophages and microphages also share a number of other functional characteristics in addition to phagocytosis. All can move through capillary walls by squeezing between adjacent endothelial cells, a process known as *emigration*, or *diapedesis* (*dia*, through + *pedesis*, a leaping). They may also be attracted to or repelled by chemicals in the surrounding fluids, a process called **chemotaxis** (*chemo-*, chemistry + *taxis*, arrangement). They are particularly sensitive to chemicals released by other body cells or by pathogens.

Immune Surveillance

Our immune defenses attack and destroy abnormal cells but generally ignore normal cells in the body's tissues. The constant monitoring of normal tissues is called **immune surveillance**. It primarily involves the lymphocytes known as NK (natural killer) cells. The plasma membrane of an abnormal cell generally contains antigens not found on the membranes of normal cells. NK cells recognize an abnormal cell by detecting those antigens. NK cells are much less selective about their targets than other lymphocytes: They respond to a *variety* of abnormal antigens that may appear on a plasma membrane. When encountering such antigens on a bacterium, a cancer cell, or a cell infected with viruses, NK cells secrete proteins called *perforins*. The perforins kill the abnormal cell by creating large pores in its plasma membrane.

NK cells respond much more rapidly than T cells or B cells upon contact with an abnormal cell. Killing the abnormal cells can slow the spread of a bacterial or viral infection. It may also eliminate cancer cells before they spread to other tissues. Unfortunately, some cancer cells avoid detection, a process called *immunological escape*. Once immunological escape has taken place, cancer cells can multiply and spread without interference by NK cells.

Interferons

Interferons (in-ter-FĒR-onz) are small proteins released by activated lymphocytes, macrophages, and tissue cells infected with viruses. Normal cells exposed to interferon molecules respond by producing *antiviral proteins* that interfere with viral replication inside the cell. In addition to slowing the spread of viral infections, interferons stimulate the activities of macrophages and NK cells. Interferons are examples of **cytokines** (SĪ-tō-kīnz), chemical messengers that tissue cells release to coordinate local activities. Most cytokines act only within one tissue. However, those released by cellular defenders also act as hormones and affect the activities of cells and tissues throughout the body. We discuss their role in the regulation of specific defenses later in the chapter.

The Complement System

Plasma contains over 30 special *complement proteins* that form the **complement system**. The term *complement* refers to the fact that this system adds to, or completes, the actions of antibodies and phagocytes. Complement proteins interact with one another in chain reactions similar to those of the clotting system. The reaction begins when a particular complement protein binds either to a pair of antibody molecules already attached to a bacterial cell wall or directly to bacterial cell walls. The bound complement protein then interacts with a series of other complement proteins. Complement activation is known to (1) attract phagocytes, (2) stimulate phagocytosis, (3) destroy plasma membranes, and (4) promote inflammation.

Inflammation

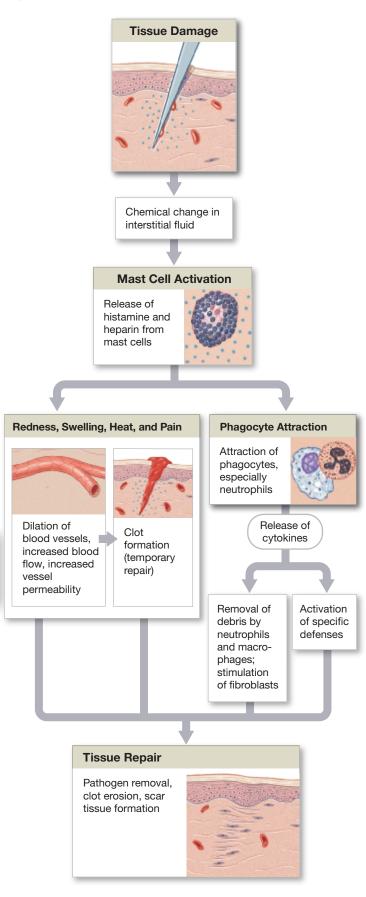

Inflammation, or the *inflammatory response*, is a localized tissue response to injury. ⊃ p. 146 Inflammation produces local swelling, redness, heat, and pain. Any stimulus that kills cells or damages loose connective tissue can produce inflammation. Inflammation has several effects:

- The injury is temporarily repaired, and additional pathogens are prevented from entering the wound.
- The spread of pathogens away from the injury is slowed.
- A wide range of defenses are mobilized to overcome the pathogens and aid permanent repairs. The repair process is called *regeneration*.

Mast cells play a key role in inflammation. (Recall that mast cells are small, motile connective tissue cells. They are often found near blood vessels). ⊃ p. 133 Figure 14-10 summarizes the events of inflammation in the skin. Comparable events occur in almost any tissue subjected to physical damage or to infection.

When stimulated by mechanical stress or chemical changes in the local environment, mast cells release chemicals, including *histamine* and *heparin*, into the interstitial fluid. These chemicals begin the process of inflammation. The histamine makes capillaries more permeable and speeds up blood flow through the area. The combination of abnormal tissue conditions and chemicals released by mast cells stimulates local sensory neurons, producing sensations of pain.

The increased blood flow reddens the area and raises local temperature. These changes increase the rate of enzymatic reactions and speed up the activity of phagocytes. The rise in temperature may also denature foreign proteins or enzymes of invading microorganisms. Figure 14-10 Events in Inflammation.

Increased vessel permeability allows clotting factors and complement proteins to leave the bloodstream and enter the injured area. Clotting does not take place at the actual site of injury, due to the presence of heparin. However, a clot soon forms around the damaged area. The clot both isolates the region and slows the spread of the chemical or pathogen into healthy tissues. Additionally, the release of histamine stimulates other series of events that activate specific defenses and further pave the way for the repair of the injured tissue.

After an injury, tissue conditions generally become more abnormal before they begin to improve. The tissue destruction that takes place after cells have been injured or destroyed is called **necrosis** (ne-KRŌ-sis). This process begins several hours after the original injury and is due to lysosomal enzymes. Lysosomes break down by autolysis, releasing digestive enzymes that first destroy the injured cells and then attack surrounding tissues. \Box p. 102

As local inflammation continues, debris and dead and dying cells collect at the injury site. They form a thick fluid mixture known as **pus**. A buildup of pus in an enclosed tissue space is called an **abscess**.

Fever

Fever is a body temperature greater than $37.2^{\circ}C$ (99°F). Recall from Chapter 8 that the hypothalamus contains a temperature-regulating center and acts as the body's thermostat. \bigcirc p. 306 Circulating proteins called **pyrogens** (PĪ-rō-jenz; *pyr*, fire + *-gen*, to produce) can reset this thermostat and raise body temperature. Pathogens, bacterial toxins, and antigen–antibody complexes may act as pyrogens or stimulate the release of pyrogens by macrophages.

Within limits, a fever may be beneficial. High body temperatures may inhibit some bacteria and viruses. The most likely beneficial effect is an increase in the rate of metabolism. Cells can move faster (enhancing phagocytosis), and enzy-matic reactions proceed more quickly. However, high fevers (over 40°C, or 104°F) can damage many physiological systems. Such high fevers can cause CNS problems, including nausea, disorientation, hallucinations, or convulsions.

CHECKPOINT

- 7. List the body's innate (nonspecific) defenses.
- **8.** What types of cells would be affected by a decrease in the number of monocyte-forming cells in red bone marrow?
- **9.** A rise in the level of interferon in the body indicates what kind of infection?
- **10.** What effects do pyrogens have in the body?

See the blue Answers tab at the back of the book.

14-4 Adaptive (specific) defenses respond to specific threats and are either cell mediated or antibody mediated

Learning Outcome Define adaptive (specific) defenses, identify the forms and properties of immunity, and distinguish between cell-mediated immunity and antibody-mediated (humoral) immunity.

The coordinated activities of T cells and B cells provide adaptive (specific) defenses. These cells respond to the presence of *specific* antigens.

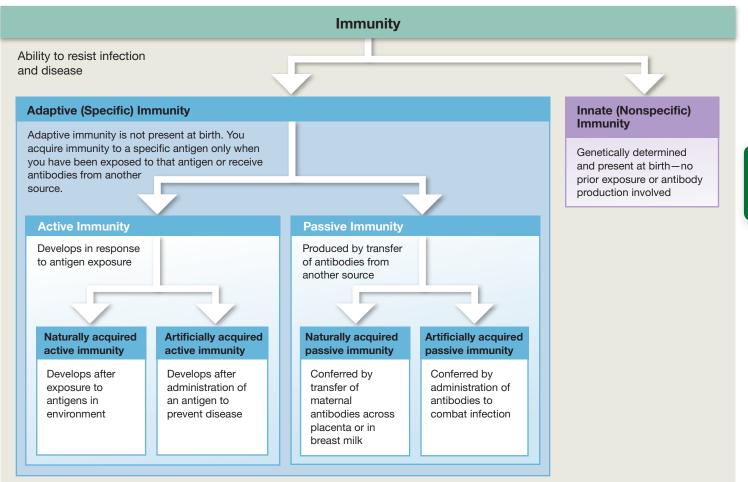

- *T cells* provide a defense against abnormal cells and pathogens inside living cells. This process is called **cell-mediated immunity**, or *cellular immunity*.
- *B cells* provide a defense against antigens and pathogens in body fluids. This process is called **antibody-mediated immunity**, or *humoral immunity*.

Both kinds of immunity are important because they come into play under different circumstances. Activated T cells do not respond to antigens in solution. Antibodies (produced by activated B cells) cannot cross plasma membranes to enter cells. Regardless of whether T cells or B cells are involved, we can categorize immunity into several forms according to when and how it arises in the body (Figure 14-11).

Forms of Immunity

As you have seen, we can classify immunity as either innate or adaptive (Figure 14-11). Innate (nonspecific) immunity is genetically determined and present at birth. It includes the nonspecific defenses previously discussed. Adaptive (specific) immunity is not present at birth. Instead, it develops only when you have been exposed to a specific antigen. Adaptive immunity can be active or passive. These forms of immunity can be either naturally acquired or artificially acquired.

Figure 14-11 Forms of Immunity.

Active immunity develops after exposure to an antigen. It is a result of the immune response. The immune system is capable of defending against an enormous number of antigens. However, the appropriate defenses are mobilized only after you encounter a particular antigen. In active immunity, the body responds to an antigen by making its own antibody. Active immunity may develop either as a result of natural exposure to an antigen in the environment (naturally acquired active immunity), or from deliberate exposure to an antigen (artificially induced active immunity).

- *Naturally acquired active immunity* is not functional at birth. It normally begins to develop after birth. It continues to build as you encounter "new" pathogens or other antigens. This process might be likened to the development of a child's vocabulary: The child begins with a few basic common words and learns new ones as needed.
- Artificially acquired active immunity stimulates the body to produce antibodies under controlled conditions so that you will be able to overcome natural exposure to the same pathogen in the future. This is the basic principle behind immunization, or vaccination, to prevent disease. A **vaccine** is a preparation designed to induce an immune response. It contains either a dead or an inactive pathogen, or antigens derived from that pathogen. (Vaccines are given orally or by intramuscular or subcutaneous injection.)

Passive immunity is produced by transferring antibodies to a person from some other source.

- 14
- In *naturally acquired passive immunity*, a baby receives antibodies from the mother, either before birth (across the placenta) or in early infancy (through breast milk).
 - In *artificially acquired passive immunity,* a person receives antibodies to fight infection or prevent disease after exposure to the pathogen. For example, a person recently bitten by a rabid animal receives an injection of antibodies that attack the rabies virus.

Properties of Adaptive Immunity

Adaptive immunity has four general properties, or characteristics:

1. *Specificity*. A specific defense is activated by a specific antigen. The immune response targets that particular antigen and no others. **Specificity** occurs because the plasma membrane of each T cell and B cell has receptors

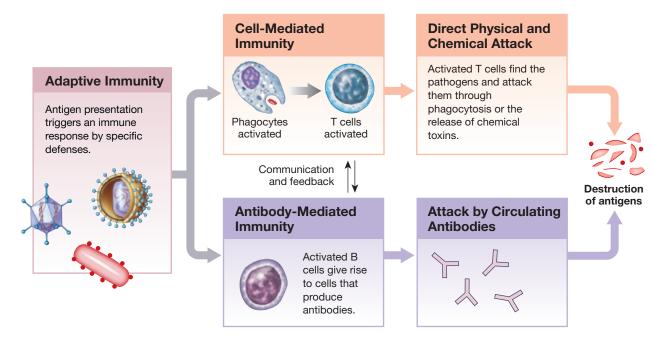

that will bind only one specific antigen, ignoring all other antigens. Either lymphocyte will inactivate or destroy only that specific antigen, without affecting other antigens or normal tissues.

- 2. Versatility. Millions of antigens in the environment can pose a threat to our health. In the course of a normal lifetime, you only encounter a fraction of that number—perhaps tens of thousands of antigens. Your immune system cannot anticipate which antigens it will encounter. It must be ready to confront *any* antigen at *any* time. The immune system gets its **versatility** by producing millions of different lymphocyte populations, each with different antigen receptors, as well as through variability in the structure of synthesized antibodies. In this way, the immune system becomes ready to produce appropriate and specific responses to each antigen when exposure occurs.
- **3.** *Memory.* The immune system "remembers" antigens that it encounters. As a result of immunological **memory**, the immune response to a second exposure to an antigen is stronger and lasts longer than the response to the first exposure. During that first response to an antigen, lymphocytes sensitive to its presence divide repeatedly. Two kinds of cells are produced: some that attack the antigen, and others that remain inactive unless they meet the same antigen at a later date. This inactive group is made up of **memory cells** that enable your immune system to "remember" an antigen it has previously encountered, and launch a faster, stronger, and longer-lasting response if such an antigen ever appears again.
- **4.** *Tolerance. The immune system does not respond to all antigens.* The immune response targets foreign cells and compounds, but it generally ignores normal tissues and their antigens. **Tolerance** is said to exist when the immune system does not respond to such normal antigens, called *self-antigens*. We have tolerance because any B cells or T cells undergoing differentiation (in the red bone marrow and thymus, respectively) are destroyed if they react to normal body antigens. As a result, normal B cells and T cells will ignore self-antigens, but will attack foreign antigens, or *nonself-antigens*.

An Overview of Adaptive Immunity

The purpose of adaptive immunity (defense against specific antigens) is to inactivate or destroy pathogens, abnormal

Figure 14-12 An Overview of Adaptive Immunity.

cells, and foreign molecules (such as toxins). **Figure 14-12** presents an overview of adaptive immunity. When an antigen triggers an adaptive immune response, it usually activates both T cells and B cells. T cells are generally activated first, but only after phagocytes have been exposed to the antigen. Once activated, the T cells attack the antigen and stimulate the activation of B cells. The activated B cells mature into cells that produce antibodies. These antibodies in the bloodstream then bind to and attack the antigen.

Build Your Knowledge

Recall that the plasma membrane of a cell contains lipids, proteins, and carbohydrates (as you saw in **Chapter 3: Cell Structure and Function**). Membrane proteins may function as receptors, channels, carriers, enzymes, anchors, and identifiers. Identifiers, or recognition proteins, identify a cell as self or nonself, normal or abnormal, to the immune system. Carbohydrates form complex molecules with lipids or proteins on the outer surface of a plasma membrane. The carbohydrate portion of molecules such as glycoproteins acts as a receptor for extracellular compounds, such as antigens. ⊃ **p. 90**

CHECKPOINT

- **11.** Explain the difference between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.
- **12.** Identify the two forms of active immunity and the two forms of passive immunity.
- **13.** List the four general properties of adaptive immunity.
- See the blue Answers tab at the back of the book.

14-5 T cells play a role in starting and controlling adaptive immunity

Learning Outcome Discuss the different types of T cells and their roles in adaptive immunity.

Before an adaptive immune response can begin, T cells must be activated by exposure to an antigen. This activation seldom results from direct interaction between the T cell and the antigen. T cells only recognize antigens when they are processed and "properly" presented.

Antigen Presentation

T cells are activated by antigens bound to glycoprotein receptors in the plasma membrane of other cells. **D** p. 91 This process is called **antigen presentation**. The structure of these antigen-binding receptors is genetically determined and differs among individuals. The membrane receptors are called

major histocompatibility complex (MHC) proteins and are grouped into two classes. An antigen bound to a Class I MHC protein acts like a red flag that in effect tells the immune system "Hey, I'm an abnormal cell—kill me!" An antigen bound to a Class II MHC protein tells the immune system "Hey, this antigen is dangerous—get rid of it!"

Class I MHC proteins are in the plasma membranes of all nucleated cells. These MHC proteins bind and display small peptide molecules (chains of amino acids) that are continuously produced in the cell and exported to the plasma membrane. If the cell is healthy and the peptides are normal (self), T cells ignore them. If the cell contains abnormal (nonself), viral, or bacterial peptides, their appearance in the plasma membrane will activate T cells, leading to destruction of the abnormal cell. The recognition of nonself peptides in transplanted tissue is the primary reason why donated organs are commonly rejected by the recipient. In the case of viruses or bacteria, T cells can be activated by contact with viral or bacterial antigens bound to Class I MHC proteins on the surface of infected cells. The activation of T cells by these antigens results in the destruction of the infected cells.

Class II MHC proteins are found in the membranes of lymphocytes and *antigen-presenting cells* (*APCs*). APCs are specialized for activating T cells to attack foreign cells (including bacteria) and foreign proteins. Among the **antigen-presenting cells** are all the phagocytic cells of the monocyte-macrophage group, including (1) free and fixed macrophages in connective tissues, (2) the stellate macrophages in the liver, and (3) microglia in the CNS. D pp. 133, 279 APCs also include the **dendritic cells** in the skin, tissues lining the respiratory and intestinal tracts, lymph nodes, and spleen.

Phagocytic APCs engulf and break down pathogens or foreign antigens. Fragments of the foreign antigens are then bound to Class II MHC proteins and displayed on their cell surfaces. T cells that are exposed to such an antigen become activated, initiating an immune response.

Dendritic cells act as guard cells in peripheral tissues where infections typically occur. Unlike macrophages, which do not migrate far from an infection site, dendritic cells carry their foreign antigens bound to Class II MHC proteins to lymphocyte-packed lymph nodes. In this way, dendritic cells link the innate (nonspecific) defenses with the adaptive (specific) defenses.

T Cell Activation

How do T cells recognize antigens? Inactive T cells have receptors that can bind either Class I or Class II MHC proteins. The receptors also have binding sites for a specific target antigen. If the MHC protein contains the specific antigen that the T cell is programmed to detect, binding takes place. This process is called **antigen recognition**, because the T cell recognizes that it has found an appropriate target.

Whether a T cell responds to Class I or Class II MHC proteins depends on a type of protein in the T cell's own plasma membrane. The membrane proteins are members of a large group of proteins known as **CD (cluster of differentiation) markers**. Two CD markers important in our discussion are CD8 and CD4. CD8 T cells respond to antigens on Class I MHC proteins. CD4 T cells respond to antigens on Class II MHC proteins.

In order for activation to take place, a T cell must bind to the stimulating cell at a second site. This binding occurs between other membrane proteins, each specific to their cell type (APC or T cell). This *costimulation* confirms that antigen recognition has occurred. It prevents the T cell from mistakenly attacking normal (self) tissues. Costimulation determines whether a T cell will become activated.

Upon activation, T cells divide and differentiate into cells with specific functions in the immune response. The four major cell types are *cytotoxic T cells, helper T cells, memory T cells,* and *regulatory T cells.*

Cytotoxic T Cells

Cytotoxic T (T_c) cells, or *killer T cells*, are responsible for cell-mediated immunity. They are CD8 cells and are activated by exposure to antigens bound to Class I MHC proteins (**Figure 14-13**). The activated cells undergo cell divisions that produce more active cytotoxic cells and memory T_c cells. The activated cytotoxic T cells track down and attack the body cells infected by viruses, bacteria, fungi, protozoa, or foreign transplanted tissues that contain the target antigen.

A cytotoxic T cell may destroy its target in several ways (Figure 14-13):

- By releasing *perforin*, which ruptures the target cell's plasma membrane. ⊃ p. 513
- By secreting *cytokines* that activate genes in the target cell's nucleus that tell the cell to die. This process of genetically programmed cell death is called *apoptosis*. ⊃ p. 112
- By secreting a poisonous *lymphotoxin* (lim-fō-TOK-sin), which kills the target cell by disrupting its metabolism.

Helper T Cells

Helper T (T_H) cells have CD4 markers and are activated by exposure to antigens bound to Class II MHC proteins on antigen-presenting cells. Upon activation, they divide to

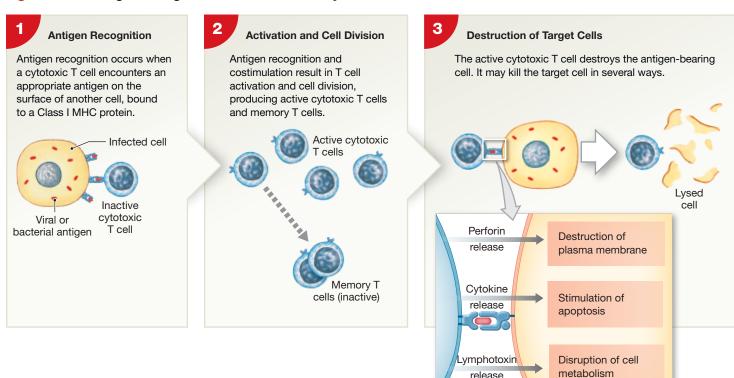

Figure 14-13 Antigen Recognition and Activation of Cytotoxic T Cells.

produce both active helper T and memory T_H cells. Activated **helper T cells** secrete various cytokines that coordinate specific and nonspecific defenses and stimulate both cell-mediated immunity and antibody-mediated immunity. We will learn more about the functions of activated helper T cells in the upcoming section on B cell activation.

Memory T Cells

As previously noted, some of the cells produced following the activation of cytotoxic T cells and helper T cells develop into **memory T cells**. Memory T_C and T_H cells remain "in reserve." If the same antigen appears a second time, these cells will immediately differentiate into cytotoxic T cells and helper T cells, enhancing the speed and effectiveness of the immune response.

Regulatory T Cells

Regulatory T cells have CD8 markers and are activated by exposure to antigens bound to Class I MHC proteins. Activated regulatory T cells moderate the responses of other T cells and of B cells by secreting cytokines called *suppression factors*. Suppression does not take place immediately, because regulatory T cells are activated more slowly than other types of T cells. As a result, regulatory T cells act *after* the initial immune response. In effect, these cells "put on the brakes," limiting the degree of the immune response from a single stimulus.

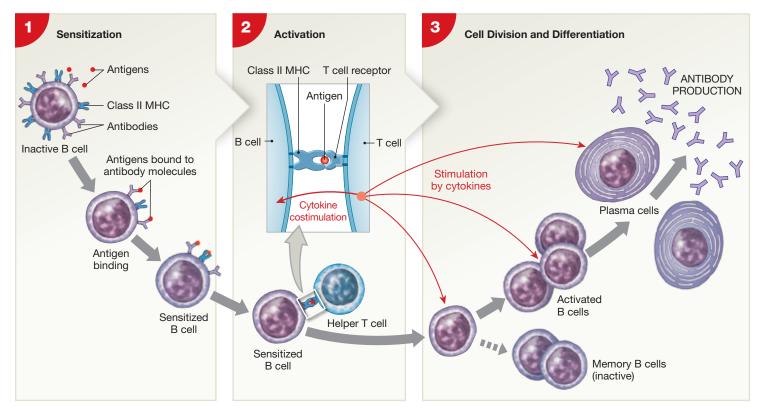

CHECKPOINT

- 14. Identify the four types of T cells.
- **15.** How can an abnormal peptide within the cytoplasm of a cell start an adaptive immune response?
- **16.** A decrease in the number of cytotoxic T cells would affect which type of immunity?
- **17.** Where are Class I MHC proteins and Class II MHC proteins found?
- See the blue Answers tab at the back of the book.

14-6 B cells respond to antigens by producing specific antibodies

Learning Outcome Discuss the processes of B cell sensitization, activation, and differentiation, describe the structure and function of antibodies, and explain the primary and secondary immune responses to antigen exposure.

B cells are responsible for launching a chemical attack on antigens in body fluids. They do so by producing specific antibodies that target specific antigens. B cells do not immediately produce antibodies in response to antigen exposure. They must first undergo sensitization, activation, division, and differentiation into antibody-producing cells (Figure 14-14). **Figure 14-14 The B Cell Response to Antigen Exposure.** A B cell is sensitized by exposure to antigens. Once antigens are bound to antibodies in the B cell plasma membrane, the B cell displays those antigens on Class II MHC proteins in its plasma membrane. Activated helper T cells encountering the antigens release cytokines that costimulate the sensitized B cell and trigger its activation. The activated B cell then divides, producing memory B cells and plasma cells that secrete antibodies.

Build Your Knowledge

Recall that the plasma proteins in blood include albumins, globulins, and fibrinogen (as you saw in **Chapter 11: The Cardiovascular System: Blood**). Globulins make up about one-third of the plasma proteins. They include antibodies, also called immunoglobulins, and transport proteins. ⊃ **p. 413**

B Cell Sensitization and Activation

The body has millions of populations of B cells. Each B cell carries its own particular antibody molecules in its plasma membrane. If corresponding antigens appear in the interstitial fluid, they interact with these antibodies. When antigenantibody binding takes place, the B cell prepares for activation by a process called **sensitization**. During sensitization,

antigens enter the B cell by endocytosis. They then become displayed on the surface of the B cell, bound to Class II MHC proteins.

The sensitized B cell is now "on standby." It does not become activated until it receives an "OK" from a helper T cell that has become activated to the same antigen. Similar to costimulation in T cells, the need for an activated helper T cell acts like a "safety," thus preventing inappropriate B cell activation.

The activated helper T cell then attaches to the MHC protein–antigen complex of the sensitized B cell, and secretes cytokines. The cytokines have several effects, including promoting B cell activation, stimulating B cell division, and accelerating B cell development into plasma cells.

As **Figure 14-14** shows, the activated B cell divides repeatedly, producing daughter cells that differentiate into **plasma cells** and **memory B cells**. The plasma cells synthesize and secrete large quantities of antibodies with the same target as the antibodies on the surface of the sensitized B cell. Memory B cells, like memory T cells, remain in reserve to respond to future exposures to the same antigen. At that time, they respond by differentiating into antibody-secreting plasma cells.

Antibody Structure

An antibody molecule has a Y-shape. It consists of two parallel pairs of polypeptide chains: one pair of long *heavy chains* and one pair of shorter *light chains* (Figure 14-15a). Each chain contains *constant* and *variable segments*. The constant segments of the heavy chains form the base of the antibody molecule. B cells produce only five types of constant segments. (These are the basis of the antibody classification scheme described in the following section.)

The specificity of an antibody molecule depends on the structure of the variable segments of the light and heavy chains. The free tips of the two variable segments form the **antigen binding sites** of the antibody molecule. Small differences in the amino acid sequence of the variable segments affect the precise shape of the antigen binding sites. The different shapes of these sites account for the specific differences among the antibodies produced by different B cells. It has been estimated that the approximately 10 trillion B cells of a normal adult can produce 100 million different antibodies.

When an antibody molecule binds to its specific antigen, an **antigen-antibody complex** is formed. Antibodies do not bind to the entire antigen as a whole. Instead, they bind to certain portions of its exposed surface, regions called *antigenic determinant sites*, or *epitopes* (Figure 14-15b). The specificity of that binding depends on the threedimensional "fit" between the variable segments of the

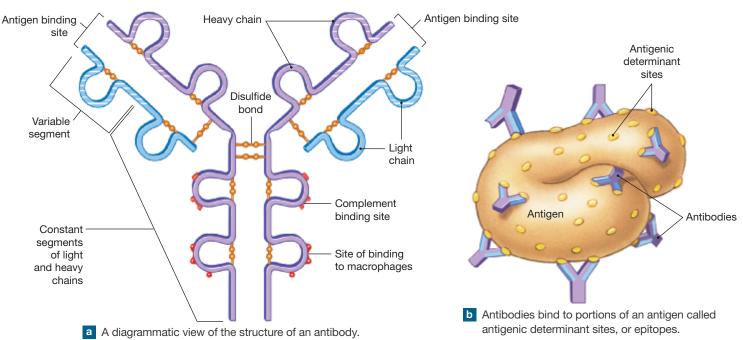

Figure 14-15 Antibody Structure.

antibody molecule and the corresponding sites of the antigen. A *complete antigen* has at least two antigenic determinant sites, one for each arm of the antibody molecule. Exposure to a complete antigen can lead to B cell sensitization and an immune response. Most environmental antigens have multiple antigenic determinant sites. Entire microorganisms may have thousands.

There are five classes of antibodies, or **immunoglobulins** (**Igs**): *IgG*, *IgM*, *IgA*, *IgE*, and *IgD* (**Table 14-1**). Immunoglobulin G, or IgG, is the largest and most diverse class. IgG antibodies are responsible for resistance against many viruses, bacteria, and bacterial toxins. They can also cross the placenta and provide passive immunity to the fetus. Circulating IgM antibodies attack bacteria and also are responsible for the cross-reactions between incompatible blood types. \bigcirc p. 422 IgA is present in exocrine secretions, such as mucus, tears, and saliva, and attacks pathogens before they can cross epithelial surfaces and enter the body. IgE that has bound to antigens stimulates basophils and mast cells to release chemicals that stimulate inflammation. IgD is attached to B cells and can be involved in their sensitization.

Antibody Function

The function of antibodies is to eliminate antigens. The formation of an antigen–antibody complex may cause the elimination of antigens in several ways:

522 LYMPHATIC SYSTEM

Tabl	e 14-1	Classes of Antibodies		
Class	Function		Remarks	
lgG	•	le for defense against many viruses, nd bacterial toxins	Largest class (80%) of antibodies, with several subtypes; also cross the placenta and provide passive immunity to fetus; anti-Rh antibodies produced by Rh-negative mothers are IgG antibodies that can cross the placenta and attack fetal Rh-positive red blood cells, producing <i>hemolytic disease of the newborn</i> \supset p. 422	
lgM	reactions b	anti-B forms responsible for cross- between incompatible blood types; s attack bacteria insensitive to IgG	First antibody type secreted following initial exposure to antigen; levels decline as IgG production accelerates	
lgA	Attacks pathogens before they enter the body tissues		Found in glandular secretions (mucus, tears, and saliva)	
lgE			Bound to surfaces of mast cells and basophils and stimulates release of histamine and other inflammatory chemicals; also important in allergic response	
lgD	Binds antig	gens in the extracellular fluid to B cells	Binding can play a role in sensitization of B cells	

- **1.** *Neutralization.* Antibodies can bind to viruses or bacterial toxins, making them incapable of attaching to a cell. This process is called **neutralization**.
- 2. Precipitation and Agglutination. When a large number of antigens are close together, one antibody molecule can bind to antigenic sites on two different antigens. In this way, antibodies can link antigens together and create large complexes. When the antigen is a soluble molecule (such as a bacterial toxin), the complex may then be too large to stay in solution. The complex settles out of body fluids in a process called **precipitation**. When the target antigen is on the surface of a cell, the formation of large complexes is called **agglutination**. The clumping of red blood cells that takes place when incompatible blood types are mixed is an agglutination reaction. ⊃ p. 421
- **3.** *Activation of complement.* Upon binding to an antigen, portions of the antibody molecule change shape, exposing areas of the constant segments that bind complement proteins (Figure 14-15a). The bound complement molecules then activate the complement system, destroying the antigen.
 - **4.** *Attraction of phagocytes.* Antigens covered with antibodies attract eosinophils, neutrophils, and macrophages. These cells engulf pathogens and destroy cells with foreign or abnormal plasma membranes.
 - **5.** *Enhancement of phagocytosis*. A coating of antibodies and complement proteins makes some pathogens with a slick plasma membrane or capsule easier to engulf. The effect is known as *opsonization*.
 - **6.** *Stimulation of inflammation.* Antibodies may promote inflammation by stimulating basophils and mast cells. This action can help mobilize nonspecific defenses and slow the spread of the infection to other tissues.

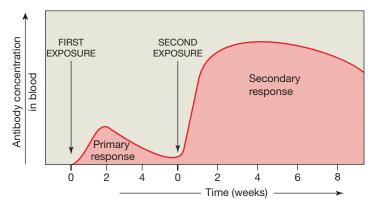

Primary and Secondary Responses to Antigen Exposure

The initial immune response to an antigen is called the **primary response**. When the antigen appears a second time, it triggers a more extensive **secondary response**. The secondary response reflects the presence of large numbers of memory cells that are already "primed" for the arrival of the antigen.

The primary response takes time to develop because the antigen must activate the appropriate B cells, and the B cells must then respond by differentiating into plasma cells (Figure 14-16). As plasma cells begin secreting antibodies, the concentration of circulating antibodies undergoes a gradual, sustained rise. The antibody levels in the blood do not peak until one to two weeks after the initial exposure. IgM molecules are the first to appear in the bloodstream,

Figure 14-16 The Primary and Secondary Immune

Responses. The primary response takes about two weeks to develop peak antibody levels, and antibody concentrations do not remain elevated. In the secondary response, antibody concentrations increase very rapidly to levels much higher than those of the primary response. They also remain elevated for an extended period.

followed by a slow rise in IgG. If the person is no longer exposed to the antigen, the antibody concentrations then decline.

Memory B cells do not differentiate into plasma cells unless they are exposed to the same antigen a second time. If and when that exposure occurs, memory B cells respond right away—faster than the B cells stimulated during the initial exposure. This response is much faster and stronger than the primary response because the numerous memory cells are activated by relatively low levels of antigen. In addition, these cells give rise to plasma cells that secrete massive quantities of antibodies. This antibody secretion is the secondary response to antigen exposure.

The secondary response produces an immediate rise in IgG concentrations to levels many times higher than those of the primary response. The secondary response appears even if the second exposure takes place years after the first. This is possible because memory cells may survive for 20 years or more.

The relatively slow primary response is much less effective at preventing disease than the more rapid and intense secondary response. Immunization is effective because it stimulates the production of memory B cells under controlled conditions. It is the secondary response that prevents disease.

Summary of the Immune Response

We have now examined the basic cellular and chemical interactions that follow the appearance of a foreign antigen in the body. **Table 14-2** reviews the cells that take part in tissue defenses. **Figure 14-17** provides an integrated view of the relationship between innate (nonspecific) immunity and adaptive (specific) immunity.

CLINICAL NOTE

AIDS

Acquired immune deficiency syndrome (AIDS), or late-stage HIV disease, is caused by the human immunodeficiency virus (HIV). HIV is a *retrovirus*, which carries its genetic information in RNA rather than DNA. The virus enters human leukocytes by receptor-mediated endocytosis. D p. 97 Specifically, the virus binds to CD4, a membrane protein characteristic of helper T cells. HIV also infects several types of antigen-presenting cells, including those of the monocyte-macrophage line. It is the infection of helper T cells that leads to clinical problems.

Cells infected with HIV ultimately die from the infection. The gradual destruction of helper T cells impairs the immune response, because these cells play a central role in coordinating cell-mediated and antibody-mediated responses to antigens. To make matters worse, regulatory T cells are relatively unaffected by the virus. Over time the excess of suppressing factors "turns off" the normal adaptive immune response. Circulating antibody levels decline and cell-mediated immunity is reduced. The body is left without defenses against a wide variety of microbial invaders. Microorganisms that ordinarily are harmless can now initiate lethal *opportunistic infections*. The risk of cancer increases because immune surveillance is depressed.

HIV infection takes place through intimate contact with the body fluids of infected persons. The major routes of transmission involve contact with blood, semen, or vaginal secretions, but all body fluids may contain the virus. Most people with AIDS became infected through sexual contact with an HIV-infected person (who may not necessarily show clinical signs of AIDS). The next largest group of infected individuals is intravenous drug users who shared contaminated needles. Relatively few people have become infected with HIV after receiving a transfusion of contaminated blood or blood products. Finally, an

AIDS continues to be a public health problem of massive proportions. Current statistics from the Centers for Disease Control and Prevention (CDC) show that more than 1.2 million people in the United States are infected with HIV. Moreover, nearly 1 in 7 people are not aware that they are infected.

The best defense against AIDS is to abstain from sexual contact or the sharing of needles. All forms of sexual intercourse carry the risk of viral transmission. The use of natural latex (rubber) condoms and synthetic (polyurethane) condoms provides protection from HIV and other viral sexually transmitted diseases (STDs). (Natural lambskin condoms are effective in preventing pregnancy, but they do not block the passage of viruses.)

Clinical signs of AIDS may not appear for five to ten years or more after infection. When they do appear, signs are often mild, consisting of swollen lymph nodes and chronic, but nonfatal, infections. So far as is known, however, AIDS is almost always fatal. Most people infected with the virus eventually die of complications of the disease. (A handful of infected individuals have been able to tolerate the virus without apparent illness for many years.)

Despite intensive efforts, a vaccine has yet to be developed that prevents HIV infection in an uninfected person exposed to the virus. The survival rate for AIDS patients has been steadily increasing. This is because new antiretroviral drugs and drug combinations that slow the progression of the disease are available, and improved antibiotic therapies help combat secondary infections. This combination is extending the life span of patients while the search for more effective treatment continues.

Table 14-2	Cells That Pa	articipate in Tissue Defenses	
Cell		Functions	
Neutrophils		Phagocytosis; stimulation of inflammation	
Eosinophils		Phagocytosis of antigen-antibody complexes; suppression of inflammation; participation in allergic response	
Mast cells and basophils		Stimulation and coordination of inflammation by release of histamine, heparin, prostaglandins	
ANTIGEN-PRESEN	ITING CELLS		
Macrophages (free and fixed macrophages, stellate macrophages, and microglia)		Phagocytosis; antigen processing; antigen presentation with Class II MHC proteins; secretion of cytokines, especially interleukins and interferons	
Dendritic cells		Phagocytosis and pinocytosis; antigen processing; antigen presentation with Class II MHC proteins	
LYMPHOCYTES			
NK cells		Destruction of plasma membranes containing abnormal antigens	
Cytotoxic T cells (T _c)		Lysis of plasma membranes containing antigens bound to Class I MHC proteins; secretion of perforin, lymphotoxin, and other cytokines	
Helper T cells (T _H)		Secretion of cytokines that stimulate cell-mediated and antibody-mediated immunity; activation of sensitized B cells; enhance nonspecific defenses by attracting macrophages to affected areas	
B cells		Differentiation into plasma cells, which secrete antibodies and provide antibody-mediated immunity	
Regulatory T cells		Secretion of suppression factors that inhibit the immune response	
Memory cells (T _C , T _H , B)		Produced during the activation of T cells and B cells; remain in tissues awaiting reappearance of antigens	

Hormones of the Immune System

The body's specific and nonspecific defenses are coordinated by physical interaction and by the release of chemical messengers. An example of physical interaction is the display of antigens by antigen-presenting macrophages. An example of chemical messenger release is the secretion of cytokines by activated helper T cells and other cells involved in the immune response.

14

Cytokines of the immune response are often classified according to their sources: *lymphokines*, secreted by lymphocytes, and *monokines*, released by active macrophages and other antigen-presenting cells. (These terms are misleading, however, because lymphocytes and macrophages may secrete the same chemical messenger. Cells involved with specific defenses and tissue repair may do the same.) Common groups of cytokines include *interleukins*, *interferons*, *tumor necrosis factors*, *phagocyte regulators*, and *colonystimulating factors*.

Interleukins (IL) may be the most diverse and important chemical messengers in the immune system. Nearly 20 types of interleukins have been identified. Lymphocytes and macrophages are the primary sources of interleukins. Other cells, such as endothelial cells, fibroblasts, and astrocytes, produce certain interleukins, such as IL-1. Interleukins have widespread effects that include increasing T cell sensitivity to antigens presented by APCs; stimulating B cell activity and antibody production; and enhancing nonspecific defenses, such as inflammation or fever. Some interleukins help suppress immune function and shorten the duration of an immune response.

Interferons make the cell synthesizing them and its neighbors resistant to viral infection, thereby slowing the spread of the virus. In addition to their antiviral activity, interferons attract and stimulate NK cells and macrophages. Interferons are used to treat some cancers.

Tumor necrosis factors (TNFs) slow tumor growth and kill sensitive tumor cells. In addition, TNFs stimulate the production of neutrophils, eosinophils, and basophils; promote eosinophil activity; cause fever; and increase T cell sensitivity to interleukins.

Phagocytic regulators include several cytokines that coordinate the specific and nonspecific defenses by adjusting the activities of phagocytic cells. These cytokines include factors that attract free macrophages and microphages and prevent their premature departure from the site of an injury.

Colony-stimulating factors (CSFs) are produced by a wide variety of cells. These cells include active T cells, cells of the monocyte–macrophage group, endothelial cells, and fibroblasts. CSFs stimulate the production of blood cells in the red bone marrow and of lymphocytes in lymphoid tissues and organs. \bigcirc p. 419

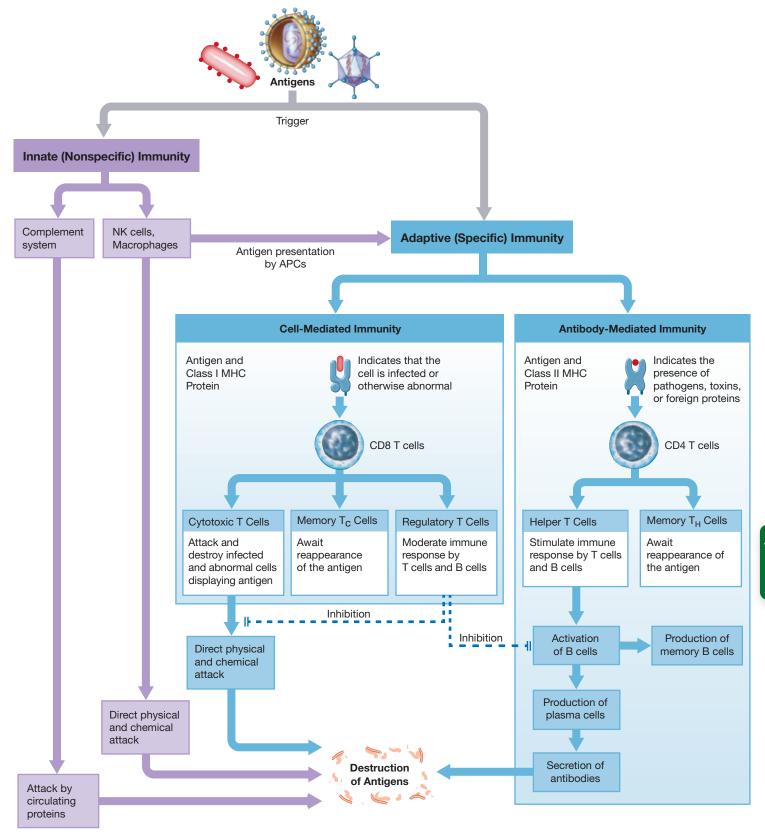

Figure 14-17 An Integrated Summary of the Immune Response.

CHECKPOINT

18. Define sensitization.

- **19.** Describe the structure of an antibody.
- **20.** A sample of lymph contains an elevated number of plasma cells. Would you expect the number of antibodies in the blood to be increasing or decreasing? Why?
- **21.** Would the primary response or the secondary response be more affected by a lack of memory B cells for a particular antigen?

See the blue Answers tab at the back of the book.

14-7 Abnormal immune responses result in immune disorders

Learning Outcome List and explain examples of immune disorders and allergies, and discuss the effects of stress on immune function.

Immunological competence is the ability to produce a normal immune response after exposure to an antigen. We have already discussed the events in the normal immune response, and its relationship to nonspecific defenses. But what happens when the immune response does not respond as it should?

There are many opportunities for things to go wrong because the immune response is so complex. A variety of clinical conditions result from disorders of immune function. General classes of such disorders include *autoimmune disorders, immunodeficiency diseases,* and *allergies.* Autoimmune disorders and immunodeficiency diseases are relatively rare conditions—clear evidence of the effectiveness of the immune system's control processes. Allergies are far more common (and usually far less dangerous).

Autoimmune Disorders

Autoimmune disorders develop when the immune response mistakenly targets normal body cells and tissues. The immune system usually recognizes but ignores antigens normally found in the body—self-antigens. When the recognition system malfunctions, however, activated B cells make antibodies against normal body cells and tissues. These "misguided" antibodies are called **autoantibodies**. The resulting condition depends on which antigen is attacked. For example, *rheumatoid arthritis* occurs when autoantibodies attack connective tissues around the joints. Type 1 diabetes is caused by autoantibodies that attack cells in the pancreatic islets. ⊃ p. 396

Many autoimmune disorders appear to be cases of mistaken identity. For example, proteins associated with the measles, Epstein-Barr, influenza, and other viruses contain amino acid sequences resembling those of myelin proteins. As a result, antibodies that target these viruses may also attack myelin sheaths. This type of mistake accounts for the neurological complications that sometimes follow a vaccination or viral infection. It also may be responsible for *multiple sclerosis*, a demyelination disorder that may affect the optic nerve, brain, and/or spinal cord. D p. 281

For unknown reasons, the risk of autoimmune problems increases for people with unusual types of MHC proteins. At least 50 clinical conditions have been linked to specific variations in MHC structure. Examples include psoriasis, rheumatoid arthritis, myasthenia gravis, narcolepsy, Graves disease, Addison disease, pernicious anemia, systemic lupus erythematosus, and chronic hepatitis.

Immunodeficiency Diseases

In an **immunodeficiency disease**, either the immune system fails to develop normally or the immune response is blocked in some way. Individuals born with **severe combined immunodeficiency disease (SCID)** fail to develop either cell- or antibody-mediated immunity. They cannot produce an immune response, so even a mild infection can prove fatal. Total isolation offers protection at great cost, with severe restrictions on lifestyle. Bone marrow transplants and gene-splicing techniques have been used to treat some types of SCID.

AIDS is an immunodeficiency disease (p. 523) that results from a viral infection that targets helper T cells. As the number of helper T cells declines, the normal adaptive immune response breaks down.

Allergies

Allergies are inappropriate or excessive immune responses to antigens. The sudden increase in cellular activity or antibody levels can have several unpleasant side effects. For example, neutrophils or cytotoxic T cells may destroy normal cells while attacking the antigen. Or the antigen–antibody complex may trigger a massive inflammatory response. Antigens that set off allergic reactions are often called **allergens**.

Four categories of allergies are recognized: *immediate hypersensitivity* (*Type I*), *cytotoxic reactions* (*Type II*), *immune complex disorders* (*Type III*), and *delayed hypersensitivity* (*Type IV*). Immediate hypersensitivity is probably the most common type. (We focus on it on p. 527.) The cross-reactions that take place after a transfusion of an incompatible blood type are an example of Type II (cytotoxic) reactions. \bigcirc p. 422 Type III allergies result if phagocytes are not able to rapidly remove circulating antigenantibody complexes. The presence of these complexes leads to inflammation and tissue damage, especially within blood vessels and the kidneys. Type IV (delayed) hypersensitivity is an inflammatory response that occurs two to three days after exposure to an antigen. An example is the itchy rash that may follow contact with poison ivy or poison oak.

Immediate hypersensitivity is a rapid and especially strong response to an antigen. One common form, *allergic rhinitis,* includes hay fever and environmental allergies. This form may affect 15 percent of the U.S. population. Sensitization to an allergen during the initial exposure leads to the production of large quantities of IgE antibodies. Due to the lag time needed to activate B cells, produce plasma cells, and make antibodies, the first exposure to an allergen does not produce an allergic reaction. Instead, it sets the stage for the next encounter. After sensitization, the IgE antibodies become attached to the plasma membranes of basophils and mast cells throughout the body. When later exposed to the same allergen, these cells are stimulated to release histamine, heparin, several cytokines, prostaglandins, and other chemicals into the surrounding tissues. As a result, the affected tissues suddenly become inflamed.

The severity of an immediate hypersensitivity allergic reaction depends on the person's sensitivity and the location involved. If allergen exposure takes place at the body surface, the response may be restricted to that area. If the allergen enters the bloodstream, the response could be lethal.

CLINICAL NOTE

Stress and the Immune Response

One of the first cytokines produced as part of the immune response is *interleukin-1 (IL-1)*. It promotes inflammation, but it also stimulates production of adrenocorticotropic hormone (ACTH) by the anterior lobe of the pituitary gland. This hormone in turn leads to the secretion of glucocorticoids by the adrenal cortex. \bigcirc p. 392 The anti-inflammatory effects of the glucocorticoids may help control the extent of the immune response. In the short term, such suppression is not dangerous.

Chronic stress, however, depresses the immune system and can be a serious threat to health. The long-term secretion of glucocorticoids, as in the resistance phase of the *stress response*, can inhibit the immune response and lower a person's resistance to disease. \bigcirc p. 401 How does this happen? Glucocorticoids alter the effectiveness of innate and adaptive defenses. Their effects are numerous. They include depressing inflammation, reducing phagocyte numbers and activity, and inhibiting interleukin production, which depresses the response of lymphocytes.

In another Type I allergy called **anaphylaxis** (an-a-fi-LAK-sis; *ana-*, again + *phylaxis*, protection), a circulating allergen affects mast cells throughout the body. A wide range of signs and symptoms can develop within minutes. Changes in capillary permeability produce swelling and edema in the dermis, and raised welts, or *hives*, appear on the skin. Smooth muscles along the respiratory passageways contract, and the narrowed passages make breathing extremely difficult. In severe cases, an extensive peripheral vasodilation takes place. It produces a drop in blood pressure that can lead to a circulatory collapse. This response is **anaphylactic shock**. \bigcirc p. 478 The prompt administration of drugs that block the action of histamine, known as **antihistamines** (an-tē-HIS-ta-mēnz), can prevent many of the signs and symptoms of immediate hypersensitivity.

CHECKPOINT

- **22.** Under what circumstances is an autoimmune disorder produced?
- **23.** How does increased stress reduce the effectiveness of the immune response?
- See the blue Answers tab at the back of the book.

14-8 The immune response diminishes as we age

Learning Outcome Describe the effects of aging on the lymphatic system and the immune response.

As we age, the immune system becomes less effective at fighting disease. T cells become less responsive to antigens, so fewer cytotoxic T cells respond to an infection. This effect may, at least in part, be due to the gradual shrinkage of the thymus and reduced levels of thymic hormones. With fewer helper T cells as well, B cells are less responsive. As a result, antibody levels rise more slowly after antigen exposure. The net result is an increased susceptibility to viral and bacterial infections. For this reason, vaccinations for acute viral diseases, such as the flu (influenza) and pneumococcal pneumonia, are strongly recommended for elderly individuals.

The increased incidence of cancer in elderly people reflects the fact that immune surveillance declines. As a result, tumor cells are not removed as effectively.

CHECKPOINT

- **24.** Why are elderly people more susceptible to viral and bacterial infections?
- **25.** What may account for the increased incidence of cancer among elderly people?
- See the blue Answers tab at the back of the book.

CLINICAL NOTE

Manipulating the Immune Response

An understanding of the immune system and genetic engineering are producing a variety of new therapies. One such therapy involves *monoclonal* (mo-nō-KLŌ-nal) *antibodies* (*MABs*), identical antibodies produced in large quantities in the laboratory by a *clone*, or population of genetically identical cells. One use of MABs is to give passive immunity to patients with a variety of diseases. Other uses include designing MABS that bind to specific antigens on cancer cells to mark them and stimulate an immune response, or attaching chemotherapy drugs to such MABs for delivery to cancer cells.

Genetic engineering can also promote active immunity. One approach uses gene-splicing techniques. The genes that code for an antigenic protein of a viral or bacterial pathogen are identified, isolated, and inserted into a harmless bacterium that can be grown in the laboratory. As a result, a clone will produce large quantities of pure antigen that can be used to stimulate a primary immune response. Vaccines against hepatitis were developed in this way. A similar strategy may someday be successful in developing vaccines for malaria or AIDS.

14-9 For all body systems, the lymphatic system provides defenses against infection and returns tissue fluid to the circulation

Learning Outcome Give examples of interactions between the lymphatic system and other body systems presented so far.

Build Your Knowledge: How the LYMPHATIC SYSTEM integrates with the other body systems presented so far on p. 529 reviews the major functional relationships between it and the integumentary, skeletal, muscular, nervous, endocrine, and cardiovascular systems. Intense research now focuses on two sets of particularly close relationships. One is between cells involved in the immune response and the endocrine system, and the other is between those cells and the nervous system.

In the first case, thymic hormones and cytokines stimulate TRH production by the hypothalamus, leading to the release of TSH by the pituitary gland. As a result, thyroid hormone levels increase and stimulate cell and tissue metabolism when an immune response is under way.

In the second case, the nervous system can also adjust the sensitivity of the immune response. For example, the PNS innervates dendritic cells in the lymph nodes, spleen, skin, and other antigen-presenting cells. The nerve endings release neurotransmitters that heighten local immune responses. For this reason, some skin conditions, such as *psoriasis*, worsen when a person is under stress. It is also known that a sudden decline in the immune response can take place after even a brief period of emotional distress.

CHECKPOINT

- **26.** Identify the role of the lymphatic system for all body systems.
- **27.** How does the cardiovascular system aid the body's nonspecific and specific defenses?
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

allograft: Transplant between compatible recipient and donor of the same species.

autograft: A transplant of tissue that is taken from the same person.

bone marrow transplantation: The infusion of bone marrow from a compatible donor after the destruction of the host's marrow by radiation or chemotherapy; a treatment option for acute, late-stage lymphoma.

graft-versus-host disease (GVH): A condition that results when T cells in donor tissues, such as bone marrow, attack the tissues of the recipient.

immunology: The study of the structure and function of the immune system.

immunosuppression: A reduction in the sensitivity of the immune system.

lymphomas: Cancers consisting of abnormal lymphocytes or lymphoid stem cells; examples include *Hodgkin's lymphoma* and *non-Hodgkin lymphoma*.

mononucleosis: A condition resulting from chronic infection by the *Epstein-Barr virus (EBV)*; signs and symptoms include enlargement of the spleen, fever, sore throat, widespread swelling of lymph nodes, increased numbers of circulating lymphocytes, and the presence of circulating antibodies to the virus.

splenomegaly (splen-ō-MEG-a-lē): Enlargement of the spleen. **systemic lupus erythematosus (LOO-pus e-rith-ē-ma-TŌ-sus) (SLE):** An autoimmune disorder resulting from a breakdown in the antigen recognition process, leading to the production of antibodies that destroy healthy cells and tissues.

tonsillectomy: The removal of an inflamed tonsil.

tonsillitis: Inflammation of one or more tonsils, typically in response to an infection; signs and symptoms include a sore throat, high fever, and leukocytosis (an elevated white blood cell count).

xenograft: A transplant that is made between two different species.

Build Your Knowledge

How the LYMPHATIC SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System provides physical barriers to pathogen entry; dendritic cells in epidermis and macrophages in dermis resist infection and present antigens to trigger the immune response; mast cells trigger inflammation, mobilize cells of lymphatic system
- The lymphatic system provides IgA antibodies for secretion onto integumentary surfaces

Skeletal System

- The Skeletal System supports the production of lymphocytes and other cells involved in the immune response in red bone marrow
- The lymphatic system assists in repair of bone after injuries; osteoclasts differentiate from monocyte-macrophage cell line

Muscular System

- The Muscular System protects superficial lymph nodes and the lymphatic vessels in the abdominopelvic cavity; muscle contractions help propel lymph along lymphatic vessels
- The lymphatic system assists in repair after injuries

Lymphatic System

The lymphatic system provides adaptive (specific) defenses against infection for all body systems. It:

- produces, maintains, and distributes lymphocytes
- returns fluid and solutes from peripheral tissues to the blood
- distributes hormones, nutrients, and waste products from their tissues of origin to the general circulation

Nervous System

- The Nervous System has antigen-presenting microglia that stimulate adaptive defenses; glial cells secrete cytokines; innervation stimulates antigen-presenting cells
- The lymphatic system produces cytokines that affect production of CRH and TRH by the hypothalamus

Endocrine System

- The Endocrine System produces glucocorticoids that have anti-inflammatory effects; thymosins that stimulate development and maturation of lymphocytes; many hormones that affect immune function
- The lymphatic system secretes thymosins from thymus gland; cytokines affect cells throughout the body

Cardiovascular System

- The Cardiovascular System distributes WBCs; carries antibodies that attack pathogens; clotting response helps restrict spread of pathogens; granulocytes and lymphocytes produced in red bone marrow
 - The lymphatic system fights infections of cardiovascular organs; returns tissue fluid to circulation

Chapter Review

Summary Outline

14

- **14-1** Anatomical barriers and defense processes make up nonspecific defense, and lymphocytes provide specific defense *p. 502*
- The cells (*lymphocytes*), tissues, and organs of the lymphatic system play a central role in the body's defenses against a variety of **pathogens**, or disease-causing organisms.
- **2. Immunity** is the ability to resist infection and disease. The body's defensive reaction to infectious agents and abnormal substances is called the **immune response**.

14-2 Lymphatic vessels, lymphocytes, lymphoid tissues, and lymphoid organs function in body defenses p. 503

- 3. The lymphatic system includes a network of **lymphatic** vessels called **lymphatics**. They carry **lymph**, a fluid similar to plasma but with a lower concentration of proteins. **Primary lymphoid tissues and organs** are sites where lymphocytes are formed and mature. **Secondary lymphoid tissues and organs** are sites where lymphocytes are activated and cloned. A series of **lymphoid tissues** and **lymphoid organs** is connected to the lymphatic vessels. (*Figure 14-1*)
- **4.** The lymphatic system produces, maintains, and distributes lymphocytes (cells that attack invading organisms, abnormal cells, and foreign proteins). The system also helps maintain blood volume and eliminate local variations in the composition of the interstitial fluid.
- **5.** Lymph flows along a network of lymphatics that originates in the **lymphatic capillaries**. The lymphatic vessels empty into the **thoracic duct** and the **right lymphatic duct**. (*Figures 14-1 to 14-3*)
- 6. The three classes of lymphocytes are **T cells** (thymusdependent), **B cells** (bone marrow-derived), and **natural killer** (NK) cells.
- **7.** *Cytotoxic T cells* attack foreign cells or body cells infected by viruses; they provide *cell-mediated immunity. Helper T cells* stimulate T cells and B cells. *Regulatory T cells* moderate the specific defense response.
- 8. B cells can differentiate into **plasma cells**, which produce and secrete antibodies that react with specific chemical targets, or **antigens**. Antibodies in body fluids are also called **immunoglobulins**. B cells are responsible for *antibody-mediated immunity*, or *humoral immunity*.

- **9.** NK cells attack foreign cells, normal cells infected with viruses, and cancer cells. They provide a monitoring service called *immune surveillance*.
- **10.** Lymphocytes continuously migrate in and out of the blood through the lymphoid tissues and organs. **Lymphopoiesis** (lymphocyte production and development) involves the red bone marrow, thymus, and peripheral lymphoid tissues. (*Spotlight Figure 14-4*)
- 11. Lymphoid tissues are loose connective tissues dominated by lymphocytes. Mucosa-associated lymphoid tissue (MALT) protects the epithelia of the digestive, respiratory, urinary, and reproductive tracts. Tonsils are clusters of lymphoid nodules (lymphoid tissue with densely packed lymphocytes) in the pharynx wall. (*Figure 14-5*)
- **12.** Important lymphoid organs include the *lymph nodes*, the *thymus*, and the *spleen*. Lymphoid tissues and organs occur in areas especially vulnerable to invasion by pathogens.
- **13. Lymph nodes** are encapsulated masses of lymphoid tissue containing lymphocytes. Lymph nodes monitor and filter the lymph before it drains into the venous system, removing antigens and initiating immune responses. (*Figure 14-6*)
- **14.** The **thymus** lies behind the sternum. T cells mature in the thymus. (*Figure 14-7*)
- **15.** The adult **spleen** contains the largest mass of lymphoid tissue in the body. *Red pulp* contains large numbers of red blood cells, and *white pulp* resembles lymphoid nodules. The spleen removes antigens and damaged blood cells from the circulation, initiates immune responses, and stores iron from recycled red blood cells. (*Figure 14-8*)
- 16. The lymphatic system is a major component of the body's defenses, which are classified as either (1) innate (nonspecific) immunity, which protects without distinguishing one threat from another, and (2) adaptive (specific) immunity, which protects against particular threats only.

14-3 Innate (nonspecific) defenses respond in a characteristic way regardless of the potential threat *p. 511*

- **17.** Innate (nonspecific) defenses prevent the approach, deny the entrance, or limit the spread of living or nonliving hazards. (*Figure 14-9*)
- **18.** Physical barriers include the skin, mucous membranes, hair, epithelia, and various secretions of the integumentary and digestive systems.

- **19. Phagocytes** include **microphages** (neutrophils and eosinophils) and **macrophages** (cells of the *monocyte-macrophage system*).
- **20.** Phagocytes move between cells by *emigration*, or *diapedesis*, and they show *chemotaxis* (sensitivity and orientation to chemical stimuli).
- **21. Immune surveillance** involves constant monitoring of normal tissues by NK cells sensitive to abnormal antigens on the surfaces of otherwise normal cells. NK cells kill both virus-infected cells and cancer cells displaying tumor-specific surface antigens.
- **22. Interferons**—small proteins released by virus-infected cells—trigger the production of antiviral proteins that interfere with viral replication inside other cells. Interferons are **cytokines**, chemical messengers released by tissue cells to coordinate local activities.
- **23.** At least 30 *complement proteins* make up the **complement system.** These proteins interact with each other in chain reactions to destroy target cell membranes, stimulate inflammation, attract phagocytes, and enhance phagocytosis.
- **24. Inflammation** represents a coordinated nonspecific response to tissue injury. *(Figure 14-10)*
- 25. A fever (body temperature greater than 37.2°C, or 99°F) can inhibit pathogens and speed up metabolic processes.Pyrogens can reset the body's thermostat and raise temperature.

14-4 Adaptive (specific) defenses respond to specific threats and are either cell mediated or antibody mediated *p. 515*

- **26.** Adaptive (specific) defenses are provided by T cells and B cells. T cells provide cell-mediated immunity; B cells provide antibody-mediated immunity.
- 27. Forms of immunity include innate (nonspecific) immunity (genetically determined and present at birth) or adaptive (specific) immunity (produced by prior exposure to an antigen or antibody production). The two forms of adaptive immunity are active immunity (develops following exposure to an antigen) and passive immunity (produced by the transfer of antibodies from another source). (Figure 14-11)
- **28.** Adaptive immunity has four general properties: **specificity** (receptors on T cell and B cell membranes bind only to specific antigens); **versatility** (the immune system responds to any of the antigens it encounters); **memory** (memory cells enable the immune system to "remember" previously encountered antigens); and **tolerance** (the ability of the immune system to ignore some antigens, such as those of normal body cells).
- **29.** The purpose of the **adaptive immune response** is to inactivate or destroy specific pathogens, abnormal cells,

and foreign molecules. It is triggered by the presence of an antigen and includes cell-mediated and antibody-mediated defenses. (*Figure 14-12*)

14-5 T cells play a role in starting and controlling adaptive immunity *p. 517*

- **30. Antigen presentation** takes place when an antigen-MHC protein combination appears in a plasma membrane of a nucleated body cell or **antigen-presenting cell (APC)**. Foreign antigens must usually be processed by macrophages or dendritic cells (APCs) and incorporated into their plasma membranes bound to *MHC proteins* before they can activate T cells.
- **31.** T cells respond to antigens bound to Class I and Class II MHC proteins in a process called **antigen recognition**. Activated T cells may differentiate into *cytotoxic T cells, memory T cells, suppressor T cells,* or *helper T cells.*
- **32.** Cell-mediated immunity results from the activation of **CD8** T cells by antigens bound to Class I MHCs. The activated T cells divide to generate **cytotoxic** (or *killer*) **T cells** and **memory T cells**. Activated memory T cells remain in reserve to respond to future exposures to the specific antigen involved. (*Figure 14-13*)
- **33. Regulatory T cells** are also CD8 T cells. They act to depress the responses of B cells and other T cells.
- **34.** T cells with **CD4** markers respond to antigens presented by Class II MHC proteins. Activated **helper T cells** secrete cytokines that help coordinate specific and nonspecific defenses, and regulate cell-mediated and antibody-mediated immunity.

14-6 B cells respond to antigens by producing specific antibodies *p. 519*

- **35.** B cells are responsible for antibody-mediated immunity. They must undergo sensitization by a specific antigen before they become activated by helper T cells sensitive to the same antigen.
- **36.** An activated B cell divides and produces plasma cells and **memory B cells**. Plasma cells produce antibodies. *(Figure 14-14)*
- **37.** An antibody molecule consists of two parallel pairs of polypeptide chains containing *fixed segments* and *variable segments*. (*Figure 14-15*)
- **38.** The binding of an antibody molecule and an antigen forms an **antigen-antibody complex**. Antibodies bind to specific *antigenic determinant sites*.
- 39. Five classes of antibodies exist in body fluids: (1) immuno-globulin G (IgG), responsible for resistance against many viruses, bacteria, and bacterial toxins; (2) IgM, the first antibody class secreted in response to an antigen; (3) IgA, found in glandular secretions; (4) IgE, which stimulates the release of chemicals that accelerate local inflammation; and (5) IgD, found on the surfaces of B cells. (*Table 14-1*)

- **40.** Antibodies can eliminate antigens through **neutraliza-tion, precipitation, agglutination,** activation of complement, attraction of phagocytes, enhancement of phagocytosis, and stimulation of inflammation.
- 41. The antibodies produced by plasma cells upon first exposure to an antigen are the agents of the **primary response**. Maximum antibody levels appear during the **secondary response**, which follows later exposure to the same antigen. (*Figure 14-16*)
- **42.** Cytokines are chemical messengers coordinated by the immune system. **Interleukins** increase T cell sensitivity to antigens; stimulate B cell activity, plasma cell formation, and antibody production; and enhance nonspecific defenses.
- **43.** Interferons slow the spread of a virus by making the infected cell's neighbors resistant to viral infections.
- **44. Tumor necrosis factors (TNFs)** slow tumor growth and kill tumor cells.
- **45.** Several **phagocytic regulators** adjust the activities of phagocytic cells to coordinate specific and nonspecific defenses.
- **46.** The body's *innate (nonspecific) immunity* and *adaptive (specific) immunity* cooperate to eliminate foreign antigens. *(Table 14-2; Figure 14-17)*

14-7 Abnormal immune responses result in immune disorders *p. 526*

- **47. Autoimmune disorders** develop when the immune response mistakenly targets normal body cells and tissues.
- **48.** In an **immunodeficiency disease**, the immune system does not develop normally or the immune response is blocked.
- **49.** *Allergies* are inappropriate or excessive immune responses to **allergens** (antigens that trigger allergic reactions). The four types of allergies are *immediate hypersensitivity* (*Type I*), *cytotoxic reactions* (*Type II*), *immune complex disorders* (*Type III*), and *delayed hypersensitivity* (*Type IV*).
- **14-8** The immune response diminishes as we age *p. 527*
- **50.** As individuals age, the immune system becomes less effective at combating disease.

14-9 For all body systems, the lymphatic system provides defenses against infection and returns tissue fluid to the circulation *p. 528*

51. The lymphatic system has extensive interactions with the nervous and endocrine systems.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

14

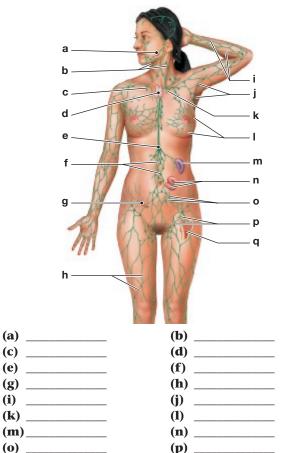

COLUMN A

COLUMN B

1. humoral immunity **a.** exposure to antigen 2. lymphoma **b.** induce fever 3. complement system c. consists of circulating proteins 4. microphages **d.** CNS macrophages 5. macrophages e. monocytes 6. microglia genetically programmed cell death f. 7. interferon transfers of antibodies g. 8. pyrogens h. neutrophils, eosinophils **9.** innate immunity secretion of antibodies i. _____ **10.** active immunity i. present at birth ____ **11.** passive immunity k. cytokine 12. apoptosis **1.** lymphatic system cancer

See the blue Answers tab at the back of the book.

13. Identify the structures of the lymphatic system in the following diagram.

(0) _____

(a) cisterna chyli.

- (q) _____
- 14. The thoracic duct begins at the
 - (b) right lymphatic duct.
 - (c) spleen. (d) thymus.
- 15. Inflammatory events include the following except
 - (a) attraction of phagocytes.
 - (b) increased vascular permeability.
 - (c) release of histamine and heparin.
 - (d) vasoconstriction in the first 72 hours.
- **16.** Which of the following are examples of antigen-presenting cells?
 - (a) dendritic cells in the skin
 - (b) microglia in the central nervous system
 - (c) macrophages in connective tissues
 - (d) all of the above
- **17.** Cytotoxic T cells are
 - (a) activated by exposure to antigens bound to Class I MHC proteins.
 - (b) responsible for antibody-mediated immunity.
 - (c) the precursors of plasma cells.
 - (d) a, b, and c are correct.
- 18. Which type of cell links the innate (nonspecific) defenses and the adaptive (specific) defenses?
 - (a) helper T cell (b) cytotoxic T cell
 - (c) dendritic cell (d) B cell

- 19. The site of T cell production and maturation is the (a) lymph nodes. (b) tonsils.
 - (c) thymus. (d) bone marrow.
- **20.** Red blood cells that are damaged or defective are removed from the circulation by the
 - (a) thymus. (b) lymph nodes. (c) spleen.
 - (d) tonsils.
- 21. Mucosa-associated lymphoid tissue is found in the following sites except the
 - (a) gastrointestinal tract. (b) heart.
 - (c) reproductive tract. (d) respiratory tree.
- 22. Perforins are destructive proteins associated with the activity of
 - (a) T cells. (b) B cells.
 - (c) macrophages. (d) plasma cells.
- **23.** The antigen binding sites of an antibody are formed by the
 - (a) constant segments of heavy chains.
 - (b) constant segments of heavy and light chains.
 - (c) variable segments of light chains.
 - (d) variable segments of heavy and light chains.
- 24. The class of antibodies that can cross the placenta to give passive immunity to the fetus is
 - (a) IgA. **(b)** IgD.
 - (c) IgG. (d) IgM.
- **25.** Anaphylaxis is an example of _____ hypersensitivity.
 - (a) Type I (b) Type II
 - (c) Type III (d) Type IV
- 26. Which two large collecting vessels are responsible for returning lymph to the veins of the cardiovascular system? What areas of the body does each serve?

(h) B cells

- **27.** Give a function for each of the following:
 - (a) cytotoxic T cells (b) helper T cells
 - (c) regulatory T cells (d) plasma cells
 - (e) NK cells (f) interferons
 - (g) T cells
 - (i) interleukins

Level 2 Reviewing Concepts

- **28.** Innate immunity is provided by the following *except*
 - (a) antibodies. (b) the complement system.
 - (c) interferons. (d) skin.
- 29. The protection received by vaccinating a child against measles is an example of
 - (a) artificially induced active immunity.
 - (b) artificially induced passive immunity.
 - (c) naturally acquired active immunity.
 - (d) naturally induced passive immunity.
- 30. List and explain the four general properties of adaptive immunity.
- **31.** In what ways can the formation of an antibody–antigen complex cause elimination of an antigen?
- 32. What is meant by immunological escape of cancer cells?

14

Level 3 Critical Thinking and Clinical Applications

- **33.** A 50-year-old woman visited her physician as she was worried that the lump in her right breast might be cancerous. After examining her breasts, the physician also checked if there were any lumps in her armpits. Why did he do this?
- **34.** Daniel, who usually suffers from seasonal hay fever, has had a runny nose and a sore throat since the last couple of days. Although he took some antihistamines, it did not alleviate his symptoms, and he wonders if he has contracted the common cold. By checking Daniel's blood antibody levels, how will his physician be able to decide if Daniel has an allergic reaction or a cold?

 Differences Between Innate and Adaptive Immunity

The Respiratory System

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **15-1** Describe the primary functions of the respiratory system, and explain how the respiratory exchange surfaces are protected from debris, pathogens, and other hazards.
- **15-2** Identify the structures that conduct air to the lungs, and describe their functions.
- **15-3** Describe the functional anatomy of alveoli, and the superficial anatomy of the lungs.
- **15-4** Define and compare the processes of external respiration and internal respiration.
- **15-5** Describe the physical principles governing the movement of air into and out of the lungs, and the actions of the respiratory muscles.
- **15-6** Describe the physical principles governing the diffusion of gases into and out of the blood.
- **15-7** Describe how oxygen and carbon dioxide are transported in the blood.
- **15-8** List the factors that influence the rate of respiration, and describe the reflexes that regulate respiration.
- **15-9** Describe the changes in the respiratory system that occur with aging.
- **15-10** Give examples of interactions between the respiratory system and other body systems presented so far.

An Introduction to the Respiratory System

When we think of the respiratory system, we generally think of breathing—the movement of air into and out of the lungs. However, an efficient respiratory system must do more than move air. Cells need energy for maintenance, growth, defense, and reproduction. Our cells obtain that energy through an aerobic process that requires oxygen and produces carbon dioxide. \bigcirc p. 103 The respiratory system provides the body's cells with a way to obtain oxygen and get rid of carbon dioxide. An exchange of these gases takes place within the lungs at air-filled pockets called **alveoli** (al-VĒ-ō-lī; singular, *alveolus*). The gas-exchange surfaces of the alveoli are relatively delicate. These surfaces must be very thin for rapid diffusion to take place between the air and the blood. The cardiovascular system links your interstitial fluids and the exchange surfaces of your lungs. Circulating blood carries oxygen from the lungs to peripheral tissues. Your blood also accepts and transports the carbon dioxide generated by those tissues and delivers it to the lungs.

We begin our discussion of the respiratory system by following air as it travels from outside the body to the alveoli of the lungs. Next we consider the mechanics of breathing—how the actions of respiratory muscles bring air into the lungs. Then we examine the physiology of respiration. This topic includes the process of breathing and the processes of gas exchange and gas transport, both between the air and blood and between the blood and tissues.

Build Your Knowledge

Recall that the respiratory system delivers air to sites in the lungs where gas exchange takes place between air and the bloodstream (as you saw in **Chapter 1: An Introduction**

to Anatomy and Physiology). This system also produces sound for communication. **> p. 38**

15-1 The respiratory system, composed of air-conducting and respiratory portions, has several basic functions

Learning Outcome Describe the primary functions of the respiratory system, and explain how the respiratory exchange surfaces are protected from debris, pathogens, and other hazards.

15 The **respiratory system** consists of structures involved in physically moving air into and out of the lungs and in gas exchange.

Functions of the Respiratory System

The respiratory system has five basic functions:

- **1.** Providing a large area for gas exchange between air and circulating blood.
- **2.** Moving air along the respiratory passageways to and from the gas-exchange surfaces of the lungs.
- **3.** Protecting the respiratory surfaces from dehydration, temperature changes, and invading pathogens.

- **4.** Producing sounds for speaking, singing, and other forms of communication.
- **5.** Aiding the sense of smell by the olfactory receptors in the nasal cavity.

Structures of the Respiratory System

On the basis of its anatomical structures, we can divide the respiratory system into upper and lower systems. The **upper respiratory system** consists of the nose, nasal cavity, paranasal sinuses, and pharynx (throat). These structures are the first to filter, warm, and humidify incoming air, protecting the more delicate surfaces of the lower respiratory system. The **lower respiratory system** includes the larynx (voice box); trachea (windpipe); bronchi; and lungs, which contain the bronchioles (air-conducting passageways) and the alveoli (gas-exchange surfaces) (**Figure 15-1**).

The term **respiratory tract** refers to the passageways that carry air to and from the exchange surfaces of the lungs. In functional terms, we can divide the respiratory tract into an upper *conducting portion* and a lower *respiratory portion*. The conducting portion begins at the entrance to the nasal cavity and continues through the pharynx, larynx, trachea, bronchi,

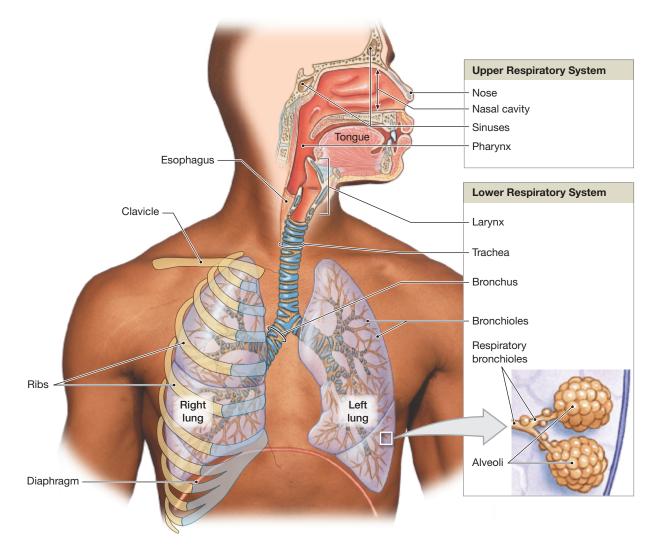

Figure 15-1 The Structures of the Respiratory System.

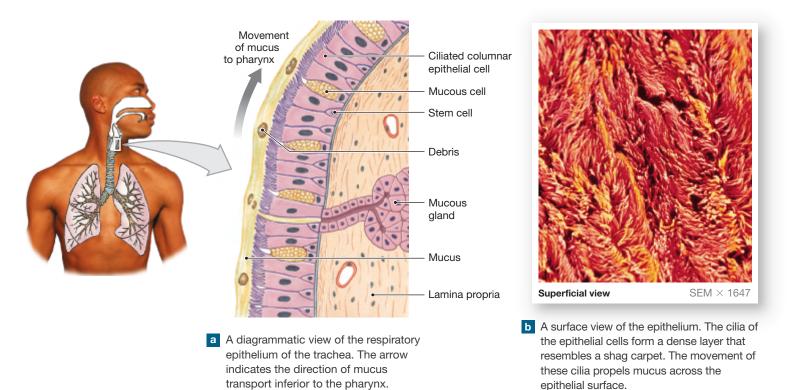

and the larger bronchioles. The respiratory portion includes the respiratory bronchioles (the smallest and thinnest bronchioles) and the alveoli within the lungs.

In addition to delivering air to the lungs, the conducting passageways filter, warm, and humidify the air. In this way they protect the alveoli from debris, pathogens, and environmental extremes. By the time inhaled air reaches the alveoli, most foreign particles and pathogens have been removed. Also, the humidity and temperature are within acceptable limits. This "conditioning process" is due to the respiratory mucosa.

The respiratory mucosa (mū-KŌ-suh) lines the conducting portion of the respiratory tract. Recall that a mucosa is a mucous membrane, one of four types of membranes introduced in Chapter 4. It consists of an epithelium and an underlying layer of areolar tissue. $\supset p$. 140 The respiratory epithelium of the respiratory mucosa is a ciliated columnar epithelium containing many *mucous cells*. The **lamina propria** (LAM-inuh PRO-pre-uh) is the underlying areolar layer that supports the epithelium. It contains mucous glands that secrete onto the epithelial surface (Figure 15-2).

The exchange surfaces of the respiratory system can be severely damaged if inhaled air is contaminated with debris or pathogens. The ciliated epithelium and the mucous cells and mucous glands that produce mucus prevent such damage. The mucus bathes the exposed surfaces of the respiratory tract from the nasal cavity to the bronchi. Cilia sweep that mucus and any trapped debris or microorganisms toward the pharynx. This process is often called the *mucociliary escalator*. The debris and microorganisms can then be swallowed and destroyed by the acids and enzymes of the stomach.

Figure 15-2 The Respiratory Mucosa.

CHECKPOINT

- **1.** Identify the five functions of the respiratory system.
- **2.** List the two anatomical subdivisions of the respiratory system.
- **3.** What membrane lines the conducting portion of the respiratory tract?
- See the blue Answers tab at the back of the book.

15-2 The nose, pharynx, larynx, trachea, bronchi, and larger bronchioles conduct air into the lungs

Learning Outcome Identify the structures that conduct air to the lungs, and describe their functions.

The conducting portion of the respiratory tract begins at the entrance to the nasal cavity. It then continues through the pharynx, larynx, trachea, bronchi, and the larger bronchioles.

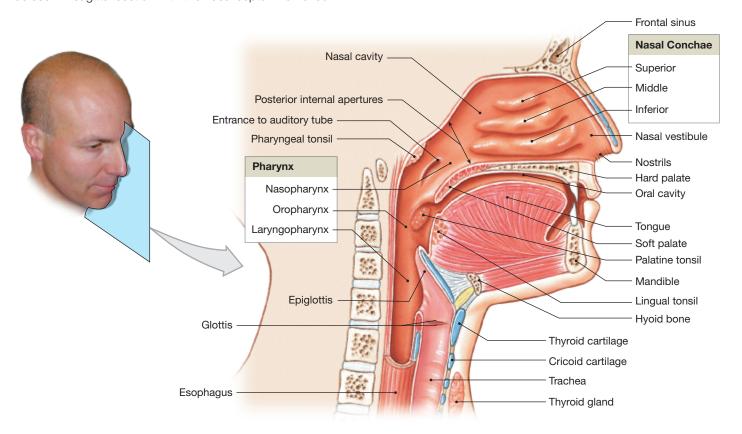

The Nose

Air normally enters the respiratory system through the paired **nostrils**, or **nares** (NĀ-rēz). They open into the **nasal cavity** (Figure 15-3). The **nasal vestibule** (VES-ti-būl) is the

space enclosed by the flexible tissues of the nose. Coarse hairs from the epithelium of the vestibule extend across the nostrils. These hairs guard the nasal cavity from large airborne particles such as sand, dust, and even insects.

The maxillary, nasal, frontal, ethmoid, and sphenoid bones form the lateral and superior walls of the nasal cavity. The *nasal septum* divides the nasal cavity into left and right sides. The anterior portion of the nasal septum is formed of hyaline cartilage. Its bony posterior includes portions of the vomer and the ethmoid bone (see **Figure 6-11a**, p. 188). A bony **hard palate**, formed by the palatine and maxillary bones, forms the floor of the nasal cavity and separates the oral and nasal cavities (**Figure 15-3**). A fleshy **soft palate** extends behind the hard palate and underlies the **nasopharynx** (nā-zō-FAR-ingks), or upper part of the throat. The nasal cavity opens into the nasopharynx at the **posterior internal apertures**, or *choanae* (kō-AN-ē).

The superior, middle, and inferior *nasal conchae* project toward the nasal septum from the lateral walls of the nasal cavity (**Figure 15-3**). Air flowing from the nasal vestibule to the posterior internal apertures tends to flow in narrow grooves between adjacent conchae. As the air eddies and swirls like water flowing over rapids, small airborne particles stick to the mucus that coats the lining of the nasal cavity. In addition to promoting filtration, the turbulent flow allows extra time for warming and humidifying the incoming air. Figure 15-3 The Nose, Nasal Cavity, and Pharynx. The structures of the nasal cavity and pharynx, as seen in sagittal section with the nasal septum removed.

As noted earlier, the nasal cavity is flushed by mucus produced by the *respiratory mucosa*. The respiratory surfaces of the nasal cavity are also cleared by mucus produced in the *paranasal sinuses* (sinuses of the frontal, sphenoid, ethmoid, and paired maxillary and palatine bones) (see **Figure 6-13**, p. 191), and by tears flowing through the nasolacrimal duct (see **Figure 9-8b**, p. 345). Exposure to noxious vapors, large quantities of dust and debris, allergens, or pathogens usually causes mucus production to increase rapidly. As a result, a "runny nose" develops.

The Pharynx

The **pharynx** (FAR-ingks), or throat, is a chamber shared by the digestive and respiratory systems. It extends between the posterior internal apertures and the entrances to the larynx and esophagus. It has three subdivisions: the nasopharynx, the oropharynx, and the laryngopharynx (**Figure 15-3**).

The **nasopharynx** is connected to the nasal cavity by the posterior internal apertures and extends to the posterior edge of the soft palate. The nasopharynx is lined by a typical ciliated

CLINICAL NOTE

Cystic Fibrosis

Cystic fibrosis (CF) is an inherited disease that affects the respiratory, digestive, and reproductive systems. The lungs and pancreas are commonly affected. A defective gene causes problems with the glands that produce mucus and sweat. Interference with the transport of water and salt causes cells to absorb too much water and salt, which leads to thick and sticky secretions. Such secretions by the mucous cells in the respiratory mucosa of affected individuals cannot be transported by the cilia of the respiratory tract. Mucus then blocks the smaller respiratory passageways, making breathing difficult. This inactivation of the normal respiratory defenses leads to frequent bacterial infections. Modern technology and treatment methods have improved survival of many individuals with CF into their 30s and 40s. Death usually results from a massive bacterial infection of the lungs and associated heart failure.

CF is the most common lethal inherited disease affecting individuals of northern European descent. It occurs in 1 in 3200 Caucasian births. It is less frequent in people of southern European ancestry, in the Ashkenazic Jewish population, and in African Americans. respiratory epithelium. The nasopharynx also contains the *pharyngeal tonsil* on its posterior wall and entrances to the *auditory tubes*.

The **oropharynx** extends between the soft palate and the base of the tongue at the level of the hyoid bone. The palatine tonsils lie in the lateral walls of the oropharynx. The narrow **laryngopharynx** (la-rin-gō-FAR-ingks) extends between the level of the hyoid bone and the entrance to the esophagus. Materials entering the digestive tract pass through both the oropharynx and laryngopharynx. Both are lined by a stratified squamous epithelium that can resist abrasion, chemical attack, and invasion by pathogens.

The Larynx

Inhaled air leaves the pharynx and enters the larynx through a narrow opening of the glottis (**Figure 15-3**). The glottis is the vocal apparatus, or "voice box" of the larynx. The **larynx** (LAR-ingks) is a cartilaginous tube that surrounds and protects the glottis. It consists of nine cartilages stabilized by ligaments, skeletal muscles, or both. The three largest cartilages are the *epiglottis, thyroid cartilage*, and *cricoid cartilage* (**Figure 15-4a,b**).

The **epiglottis** (ep-i-GLOT-is) is shaped like a shoehorn and projects superior to the glottis, forming a lid over it. During swallowing, the larynx is elevated, and the elastic epiglottis

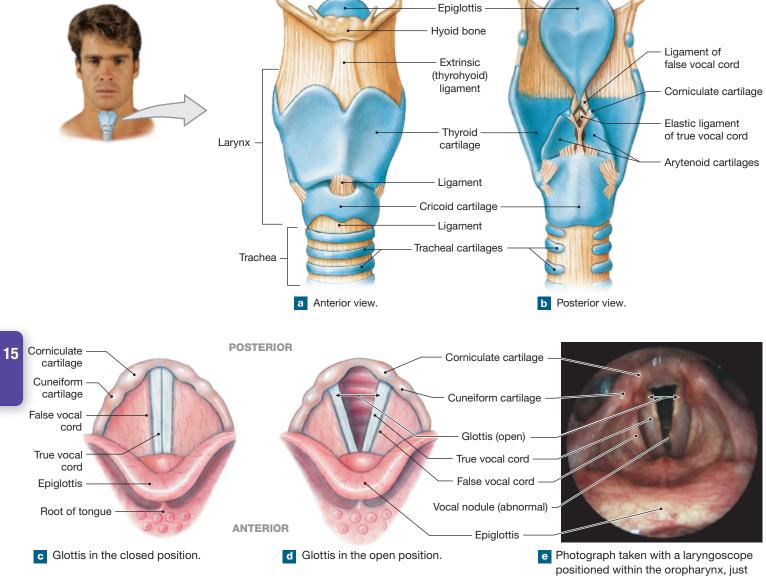

Figure 15-4 The Anatomy of the Larynx and Vocal Cords.

positioned within the oropharynx, just superior to the larynx. Note the abnormal vocal nodule. folds back over the glottis, preventing liquids or solid food from entering the respiratory tract.

The curving thyroid (thyroid; shield-shaped) cartilage forms much of the anterior and lateral surfaces of the larynx. A prominent ridge on the anterior surface of this cartilage forms the "Adam's apple." Inferior to the thyroid cartilage is the cricoid (KRI-koyd; ring-shaped) cartilage, which provides posterior support to the larynx. The thyroid and cricoid cartilages protect the glottis and the entrance to the trachea. Their broad surfaces are sites for the attachment of important laryngeal muscles and ligaments.

The larynx also contains three pairs of smaller cartilages that are supported by the cricoid cartilage. They are the arytenoid, corniculate, and cuneiform cartilages. Between the thyroid cartilage and these smaller cartilages, two pairs of ligaments, enclosed by folds of epithelium, extend across the larynx. The ligaments of the upper pair are known as the false vocal cords. They are relatively inelastic. They help prevent foreign objects from entering the open glottis. They also protect the more delicate, lower pair of folds, the true vocal cords. The true vocal cords contain elastic ligaments that extend between the thyroid cartilage and the arytenoid cartilages (Figure 15-4b). The elastic true vocal cords are involved in the production of sound. The voice box or glottis (GLOT-is) is made up of the true vocal cords and the space between them (Figure 15-4c,d,e).

Food or liquids that touch the vocal cords trigger the *coughing* reflex. In a cough, the glottis is kept closed while the chest and abdominal muscles contract, compressing the lungs. When the glottis is opened suddenly, the resulting blast of air through the trachea ejects material blocking the entrance to the glottis.

The Vocal Cords and Sound Production

How do you produce sounds? Air passing through your open glottis vibrates its vocal cords, producing sound waves. The pitch of the sound, like the pitch of a vibrating harp string, depends on the diameter, length, and tension of the vibrating vocal cords. Short, thin strings vibrate rapidly, producing a high-pitched sound. Long, thick strings vibrate more slowly, producing a low-pitched tone. The diameter and length of the vocal cords are directly related to the size of your larynx. Children have small larynxes with slender, short vocal cords, so their voices tend to be high-pitched. At puberty, the larynx of males enlarges more than that of females. Because the vocal cords of adult males are thicker and longer, they produce lower tones than those of adult females. The amount of tension in the vocal cords is controlled by small, intrinsic skeletal muscles of the larynx. These muscles change the position of the arytenoid cartilages. Increased tension in the vocal cords raises the pitch. Decreased tension lowers the pitch.

The distinctive sound of your voice does not depend solely on the sounds produced by the larynx. Further amplification and resonance take place in the pharynx, the oral cavity, the nasal cavity, and the paranasal sinuses. The final production of distinct words further depends on voluntary movements of the tongue, lips, and cheeks.

The Trachea

The **trachea** (TRĀ-kē-uh), or *windpipe*, is a tough, flexible tube. It is about 2.5 cm (1 in.) in diameter and approximately 11 cm (4.25 in.) long (Figure 15-5a). The trachea begins at the level of the sixth cervical vertebra (C_6) , where it attaches to the cricoid cartilage of the larynx. It ends in the mediastinum, at the level of the fifth thoracic vertebra (T_5) , where it branches to form the right and left primary bronchi.

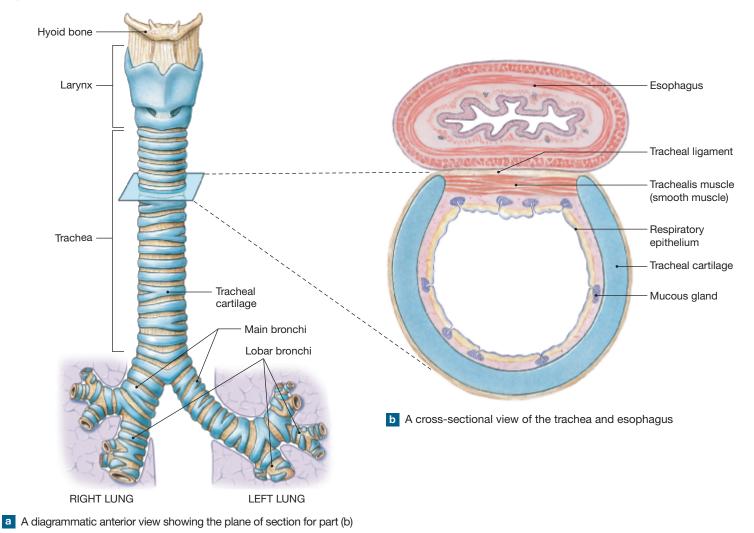

The trachea contains 15-20 tracheal cartilages. They stiffen the tracheal walls and protect the airway. They also prevent the trachea's collapse or overexpansion as pressures change in the respiratory system.

Each tracheal cartilage is C-shaped. The open portion of the "C" faces posteriorly, toward the esophagus (Figure 15-5b). Because the cartilages are not continuous, the posterior tracheal wall can easily distort, allowing large masses of food to pass along the esophagus. The ends of each tracheal cartilage are connected by an elastic ligament and the trachealis muscle, a band of smooth muscle. The diameter of the trachea is adjusted by the contractions of these muscles, which are under autonomic control. Sympathetic stimulation increases the diameter of the trachea, making it easier to move large volumes of air along the respiratory passageways.

The Bronchi

The trachea branches within the mediastinum into the **right** main bronchus and left main bronchus (BRONG-kus; plu- 15 ral, bronchi) (Figure 15-5a). The walls of the main bronchi resemble the wall of the trachea, including a ciliated epithelium and C-shaped cartilaginous rings. The right main bronchus supplies the right lung, and the left supplies the left lung. The right main bronchus is larger in diameter and descends toward the lung at a steeper angle. For these reasons, most foreign objects that enter the trachea find their way into the right main bronchus rather than the left.

The main bronchi and their branches form the bronchial tree. Figure 15-6a shows the branching pattern of the left main bronchus as it enters the lung. (The number of branches has been reduced for clarity.) Each main bronchus gives rise to lobar bronchi, which enter the lobes of that lung. In each lung, the lobar bronchi divide to form 9-10 segmental bronchi. Figure 15-5 The Anatomy of the Trachea.

CLINICAL NOTE

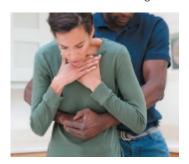

Tracheal Blockage

We sometimes breathe in foreign objects. This process is called *aspiration*. Coughing usually expels objects that become lodged in the larynx or trachea. If the person can speak or make a sound, the airway is still open, and no emergency measures should be taken. If the victim can neither breathe nor speak, an immediate threat to life exists.

In the *Heimlich* (HĪM-lik) *maneuver*, or *abdominal thrust*, a rescuer applies compression to the abdomen just beneath the diaphragm. This action forcefully elevates the diaphragm and may generate enough pressure to remove the blockage. The maneuver must be performed properly to avoid damage to internal organs. Organizations such as the American Red Cross, local fire departments, and other charitable groups periodically hold brief training sessions in the proper performance of the Heimlich maneuver.

If blockage results from a swelling of the epiglottis or tissues surrounding the glottis, a professionally qualified rescuer may insert a curved tube through the pharynx and glottis to permit airflow. This procedure is called *intubation*. If a tracheal blockage

remains, a *tracheostomy* (trā-kē-OS-to-mē; *stoma*, mouth) may be performed. This procedure involves making an incision through the anterior tracheal wall and inserting a tube. The tube bypasses the larynx and permits air to flow directly into the trachea.

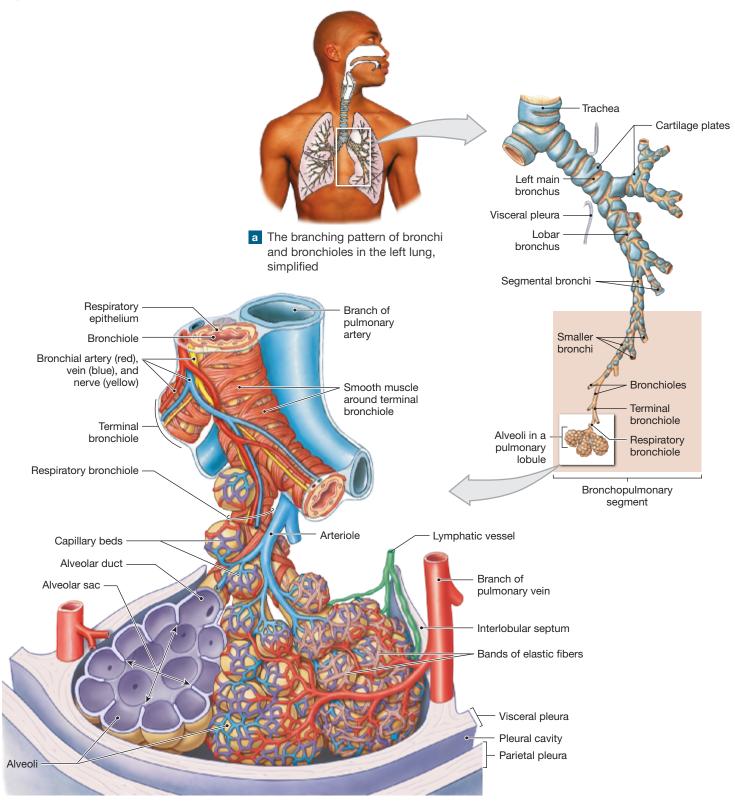

Figure 15-6 Bronchial Branching and a Lobule of the Lung.

b The structure of a single pulmonary lobule, part of a bronchopulmonary segment

Each segmental bronchus supplies air to a specific region of a lung, called a *bronchopulmonary segment*, where it branches repeatedly into smaller bronchi.

The cartilages of the lobar bronchi are relatively massive, but farther along the branches of the bronchial tree the cartilages become smaller and smaller. When the diameter of the passageway has narrowed to about 1 mm (0.04 in.), cartilages disappear completely. This narrow passage is a **bronchiole**.

The walls of bronchioles are dominated by smooth muscle tissue, whose activity is regulated by the autonomic nervous system. Bronchioles are to respiratory system function as arterioles are to cardiovascular system function. Just as changes to the diameter of arterioles regulate blood flow into capillary beds, changes to the diameter of bronchioles control the resistance to airflow and the distribution of air in the lungs. Sympathetic activation leads to a relaxation of smooth muscles in the walls of bronchioles, causing bronchodilation, the enlargement of airway diameter. Parasympathetic stimulation leads to contraction of these smooth muscles and bronchoconstriction, a reduction in the diameter of the airway. Extreme bronchoconstriction can almost completely block the passageways, making breathing difficult or impossible. This can occur during an asthma (AZ-muh) attack or during allergic reactions in response to inflammation of the bronchioles.

15-3 The smallest bronchioles and the alveoli within the lungs make up the respiratory portion of the respiratory tract

Learning Outcome Describe the functional anatomy of alveoli, and the superficial anatomy of the lungs.

The Bronchioles

Bronchioles branch further into the finest conducting passageways, the *terminal bronchioles*. These fine tubes have internal diameters of 0.3–0.5 mm. Each terminal bronchiole supplies air to a lobule of the lung. A **pulmonary lobule** (LOB-ūl) is a segment of lung tissue that is bounded by connective tissue partitions. Branches of the pulmonary arteries, pulmonary veins, and respiratory passageways supply each lobule (**Figure 15-6b**). Within a lobule, a terminal bronchiole divides to form several *respiratory bronchioles*. These passages are the thinnest branches of the bronchial tree. They deliver air to the gas-exchange surfaces of the lungs.

The Alveolar Ducts and Alveoli

Respiratory bronchioles open into passageways called **alveolar ducts** (Figure 15-7a). The ducts end at **alveolar sacs**, common chambers connected to multiple individual alveoli—the exchange surfaces of the lungs. Each lung contains about 150 million alveoli. They give the lung an open, spongy appearance (Figure 15-7b).

To meet our metabolic needs, the alveolar exchange surfaces of the lungs must be very large, equal to approximately 140 square meters—roughly one-half of a tennis court. The alveolar epithelium consists mainly of a simple squamous epithelium (**Figure 15-7c**). The squamous epithelial cells, called **pneumocytes type I** (*type I alveolar cells*), are unusually thin. Roaming **alveolar macrophages** (*dust cells*) patrol the epithelium. They phagocytize any particles that have reached the alveolar surfaces.

Scattered among the squamous cells are larger **pneumocytes type II**, or *type II alveolar cells*. These cells produce an oily secretion called **surfactant** (sur-FAK-tant). They secrete surfactant onto the alveolar surfaces, where it forms a superficial coating over a thin layer of water.

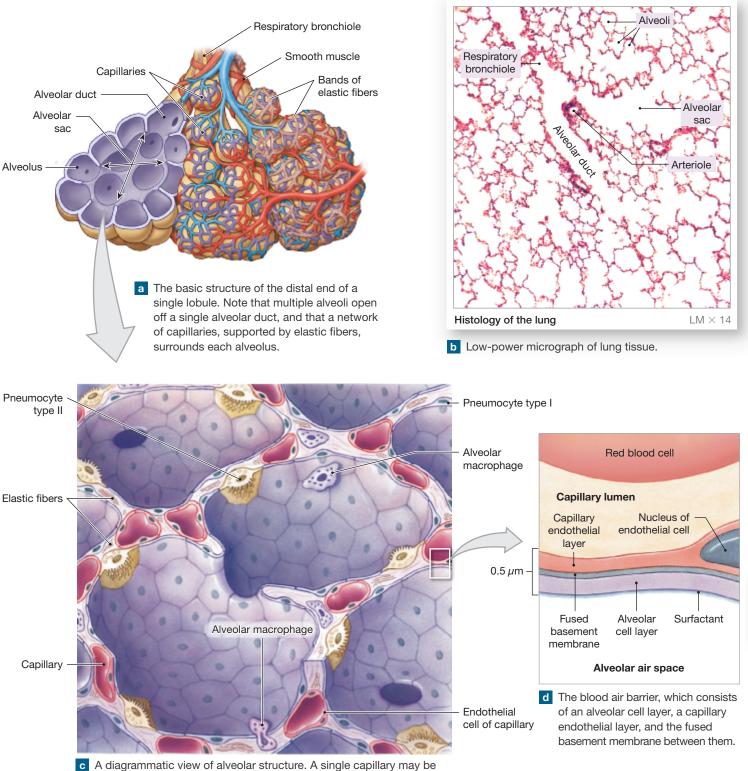

Surfactant plays a key role in keeping the alveoli open. It reduces surface tension in the liquid coating the alveolar surfaces. Recall from Chapter 2 that surface tension results from the attraction between water molecules at an air-water boundary. \supset p. 61 Without surfactant, the surface tension would collapse the thin alveolar walls. When surfactant levels are inadequate (as a result of injury or genetic abnormalities), each inhalation must be forceful enough to pop open the alveoli. An individual with this condition—called **respiratory distress syndrome**—is soon exhausted by the effort required to keep inflating the deflated lungs.

The Blood Air Barrier

Gas exchange takes place across the **blood air barrier** of the alveoli. The blood air barrier has three layers (Figure 15-7d):

1. *Alveolar cell layer.* Squamous epithelial cells line the alveolus.

A diagrammatic view of alveolar structure. A single capillary may l involved in gas exchange with several alveoli simultaneously.

- **2.** *Capillary endothelial layer*. Endothelial cells line an adjacent capillary.
- **3.** *Fused basement membrane*. Lies between the alveolar and endothelial cells.

At the blood air barrier, only a very short distance separates alveolar air from blood. The total distance can be as little as $0.1 \,\mu$ m, but averages about $0.5 \,\mu$ m. Diffusion across the blood air barrier proceeds very rapidly because the distance is short and because both oxygen and carbon dioxide molecules are small and lipid soluble. The plasma membranes of the epithelial and endothelial cells do not prevent oxygen and carbon dioxide from moving between blood and alveolar air.

The respiratory exchange surfaces receive blood from arteries of the *pulmonary circuit.* \bigcirc p. 480 Recall that the pulmonary arteries carry deoxygenated blood. They enter the lungs and branch, following the bronchi and their branches to the lobules. Each lobule receives an arteriole. A network of capillaries surrounds each alveolus directly beneath the alveolar epithelium. After gas exchange takes place, oxygen-rich blood from the alveolar (pulmonary) capillaries passes through the pulmonary venules. This blood then enters the pulmonary veins, which deliver it to the left atrium.

In addition to taking part in gas exchange, the endothelial cells of the alveolar capillaries are the primary source of *angiotensin-converting enzyme (ACE)*. ACE converts circulating angiotensin I to angiotensin II. Angiotensin II plays an important role in regulating blood volume and blood pressure. \bigcirc p. 475

CLINICAL NOTE

Pneumonia

15

Pneumonia (nū-MŌN-yuh; *pneumon*, lung + *-ia*, condition) is an inflammation of the lungs. It typically results from an infection by bacteria or viruses. As inflammation occurs, fluids leak into the alveoli. The respiratory bronchioles swell, narrowing passageways and restricting the flow of air. Respiratory function deteriorates as a result. When bacteria are involved, they are usually normal residents of the mouth and pharynx that have somehow managed to evade the respiratory defenses. Pneumonia is most serious in infants and young children, and individuals over age 65.

Pneumonia becomes more likely when the respiratory defenses have been compromised by other factors, such as epithelial damage from smoking or the breakdown of the immune system (as in AIDS). For example, the most common pneumonia in individuals with AIDS is caused by the fungus *Pneumocystis carinii*. This fungus is normally found in the alveoli, but in healthy individuals the respiratory defenses prevent invasion and tissue damage.

How do the tissues of conducting passageways of your lungs get the oxygen and nutrients that they themselves need? This nourishment comes from capillaries supplied by the bronchial arteries, which branch from the thoracic aorta. \bigcirc p. 486 The venous blood from these bronchial capillaries then returns to the heart by either the systemic circuit or pulmonary circuit. Most of this venous blood drains into the pulmonary veins, where it dilutes the oxygenated alveolar blood returning to the heart.

Blood pressure in the pulmonary circuit is usually relatively low. Pulmonary artery systolic pressures are 30 mm Hg or less. With pressures that low, pulmonary arteries can easily become blocked by small blood clots, fat masses, or air bubbles. Any drifting masses in the blood are likely to cause problems almost at once because the lungs receive the entire cardiac output. The blockage of a branch of a pulmonary artery will stop blood flow to a group of lobules or alveoli. This condition is called **pulmonary embolism**.

The Lungs

The two lungs and the branches of the bronchial tree are shown in Figure 15-8. Each of the two lungs has distinct **lobes** that are separated by deep fissures. The right lung has three lobes (superior, middle, and inferior). The left lung has two (superior and inferior). The bluntly rounded apex of each lung extends into the base of the neck above the first rib. The concave base of each lung rests on the superior surface of the diaphragm, the muscular sheet that separates the thoracic and abdominopelvic cavities. The curving costal surface of each lung follows the inner contours of the rib cage. The mediastinal surfaces of both lungs have grooves that mark the passage of large blood vessels and indentations of the pericardium. In anterior view, the medial edge of the right lung forms a vertical line, but the medial margin of the left lung is indented at the cardiac notch. This notch provides space for the pericardial cavity, which sits to the left of the midline of the body.

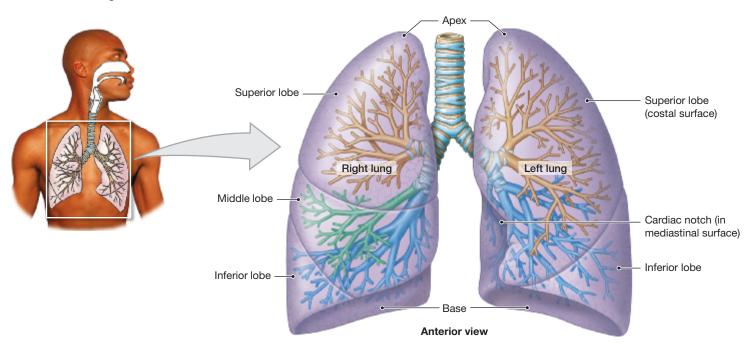

The lungs have a light and spongy consistency because most of the actual volume of each lung consists of air-filled passageways and alveoli. Abundant elastic fibers allow the lungs to tolerate large changes in volume.

The Pleural Cavities

The thoracic cavity has the shape of a broad cone. Its walls are the rib cage. Its floor is the muscular diaphragm. Within the thoracic cavity, each lung is surrounded by a single pleural cavity. Each pleural cavity is lined by a serous membrane called the **pleura** (PLOOR-uh). \supset p. 141 The *parietal pleura* covers

Figure 15-8 The Gross Anatomy of the Lungs. The lobes are shown as though transparent to make the main branching of the bronchial tree visible.

the inner surface of the body wall and extends over the diaphragm and mediastinum. The *visceral pleura* covers the outer surfaces of the lungs, extending into the fissures between the lobes (**Figure 15-9**). The two pleural cavities are separated by the mediastinum.

Each pleural cavity actually represents a potential space rather than an open chamber because the parietal and visceral layers are usually in close contact. Both layers secrete a small amount of *pleural fluid*. This slippery fluid reduces friction between the pleural surfaces as you breathe. Pleural fluid is sometimes obtained for diagnostic purposes using a long needle between the ribs. This procedure is called *thoracentesis* (thōr-a-sen-TĒ-sis; *thorac-*, chest + *kentesis*, puncture). The extracted fluid is examined for bacteria, blood cells, and other abnormal components.

If an injury to the chest wall penetrates the parietal pleura or damages the alveoli, the visceral pleura can allow air into the pleural cavity. This condition, called **pneumothorax** (noo-mō-THOR-aks; *pneuma*, air), breaks the fluid bond between the pleurae and allows the lung's elastic fibers to recoil. The result is a collapsed lung, or **atelectasis** (at-e-LEK-ta-sis; *ateles*, imperfect + *ektasis*, expansion). Treatment involves removing as much of the air as possible before sealing the opening. This procedure restores the pleural fluid bond and reinflates the lung. Lung volume can also be reduced if blood accumulates in the pleural cavity. This condition is called **hemothorax**.

CLINICAL NOTE

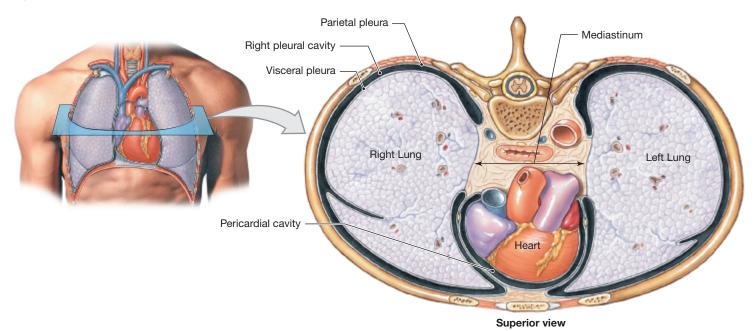

Tuberculosis

Tuberculosis (too-ber-kū-LŌ-sis), or TB, results from a bacterial infection of the lungs, although other organs may be invaded as well. The bacterium, *Mycobacterium tuberculosis*, may colonize respiratory passageways, interstitial spaces, or alveoli, or a combination of all three. Signs and symptoms vary but generally include coughing and chest pain with fever, night sweats, fatigue, and weight loss.

Tuberculosis is a major worldwide health problem. In 1900, TB, then known as "consumption," was a leading cause of death. Today, it remains among the most common and serious infectious diseases. An estimated one-fourth of the world's population is infected with TB. According to the World Health Organization, in 2016, 10.4 million people were diagnosed with TB and 1.7 million died from the disease. Unlike other deadly infectious diseases, such as AIDS, TB is transmitted through casual contact. By coughing, sneezing, or speaking, an infected individual can send the bacterium into the air in tiny droplets that can be inhaled by other people.

Treatment for TB is complex, because the bacteria are slow growing and can spread to many different tissues, such as the bones, lymphatic system, and meninges. The bacteria can develop resistance to standard antibiotics and require prolonged treatment. As a result, several antibiotic drugs are administered over a period of six to nine months. It is important that individuals take their TB drugs during their full treatment period. Stopping too soon can allow the bacteria still alive to become resistant to two or more antibiotics, making the TB more difficult to treat.

15-4 External respiration and internal respiration allow gas exchange within the body

Learning Outcome Define and compare the processes of external respiration and internal respiration.

15

The general term *respiration* includes two integrated processes: *external respiration* and *internal respiration*. **External respiration** includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. Its purpose, and the primary function of the respiratory system, is to meet the respiratory demands of cells under various conditions. **Internal respiration** is the absorption of oxygen and the release of carbon dioxide by those cells. (We discuss the cellular pathways involving oxygen use and carbon dioxide release in Chapter 17.)

External respiration has three steps:

1. *Pulmonary ventilation,* or breathing, is the physical movement of air into and out of the lungs.

- **2.** *Gas diffusion* takes place at two sites. One is across the respiratory membrane between alveolar air spaces and alveolar capillaries. The other is across capillary walls between blood and other tissues.
- **3.** *Transport of oxygen and carbon dioxide* takes place between the alveolar capillaries and the capillary beds in other tissues. The bloodstream carries out this step.

Abnormalities in any of these processes will ultimately affect the gas concentrations in the interstitial fluids. As a result, cellular activities will be impacted. If oxygen concentrations decline, the affected tissues will be starved for oxygen. **Hypoxia** (hī-POK-sē-uh), or low tissue oxygen levels, results. It places severe limits on the metabolic activities of the affected area. If the supply of oxygen gets cut off completely,

Build Your Knowledge

Recall that mitochondria produce about 95 percent of the energy a cell needs to stay alive (as you saw in **Chapter 3: Cell Structure and Function**). The key reactions in mitochondrial activity consume oxygen and generate carbon dioxide. The process of mitochondrial energy production is known as aerobic (*aero*-, air + *bios*, life) metabolism, or *cellular respiration*. This type of respiration differs from both external respiration and internal respiration. \bigcirc **p. 103** **anoxia** (an-OK-sē-uh), or lack of oxygen, results. Anoxia kills cells very quickly. Much of the damage from strokes and heart attacks results from localized anoxia.

CHECKPOINT

- **11.** Define external respiration and internal respiration.
- **12.** Name the integrated steps involved in external respiration.

See the blue Answers tab at the back of the book.

15-5 Pulmonary ventilation—the exchange of air between the atmosphere and the lungs—involves pressure changes and muscle movement

Learning Outcome Describe the physical principles governing the movement of air into and out of the lungs, and the actions of the respiratory muscles.

Pulmonary ventilation is the physical movement of air into and out of the respiratory tract. Its primary function is to maintain adequate **alveolar ventilation**, the movement of air into and out of the alveoli. Alveolar ventilation prevents the buildup of carbon dioxide in the alveoli. It also ensures a continuous supply of oxygen for absorption by the bloodstream.

Pressure and Airflow to the Lungs

As we know from television weather reports, air will flow from an area of higher pressure to an area of lower pressure. This difference between the high and low pressures is called a *pressure gradient*. Pressure gradients apply both to the movement of atmospheric winds and to the movement of air into and out of the lungs (pulmonary ventilation). In a closed, flexible container (such as a lung), the pressure on a gas (such as air) can be changed by increasing or decreasing the container's volume: As the volume of the container (the lungs) increases, the pressure of the gas (air) decreases. As volume decreases, pressure increases.

The volume of the lungs depends on the volume of the thoracic cavity. As we have seen, only a thin film of pleural fluid separates the parietal and pleural membranes. The two membranes can slide across each other, but they are held together by that fluid film. You can see the same principle when you set a wet glass on a smooth surface. You can slide the glass easily, but when you try to lift it, you feel considerable resistance from this fluid bond. A comparable bond exists between the parietal pleura and the visceral pleura covering the lungs. Due to this bond, the surface of each lung sticks to the inner wall of the chest and to the superior surface of the diaphragm. Thus, any expansion or contraction of the thoracic cavity directly affects the volume of the lungs.

Changes in the volume of the thoracic cavity result from movements of the diaphragm and rib cage, as shown in **Spotlight Figure 15-10**:

- **Diaphragm**. The diaphragm forms the floor of the thoracic cavity. When relaxed, the diaphragm is dome shaped. It projects upward into the thoracic cavity, compressing the lungs. When the diaphragm contracts, it flattens, increasing the volume of the thoracic cavity and expanding the lungs. When the diaphragm relaxes, it returns to its original position, which decreases the volume of the thoracic cavity.
- *Rib cage*. Elevating the rib cage increases the volume of the thoracic cavity, because of the way the ribs and the vertebrae articulate. Lowering the rib cage decreases the volume of the thoracic cavity. The external intercostal muscles and accessory muscles (such as the sternocleidomastoid) elevate the rib cage. The internal intercostal muscles and other accessory muscles (such as the rectus abdominis and other abdominal muscles) lower the rib cage.

At the start of a breath, pressures inside and outside the lungs are the same. There is no movement of air (**Spotlight Figure 15-10a**). When the diaphragm contracts and the movement of respiratory muscles enlarges the thoracic cavity, the lungs expand. As a result, the pressure inside the lungs decreases. Air now enters the respiratory passageways because the pressure inside the lungs (P_{inside}) is lower than the atmospheric pressure outside ($P_{outside}$) (**Spotlight Figure 15-10b**).

During exhalation, downward movement of the rib cage and upward movement of the diaphragm reverse the process and reduce the volume of the lungs. Pressure inside the lungs now exceeds atmospheric pressure. As a result, air moves out of the lungs (**Spotlight Figure 15-10c**).

Compliance

The **compliance** of the lungs is the ease with which the lungs stretch and expand. The greater the compliance, the easier it is to fill and empty the lungs. The lower the compliance, the greater is the force required to fill and empty the lungs.

Various disorders affect compliance. For example, compliance increases with the loss of supporting connective tissues due to alveolar damage, as in *emphysema* (see p. 561). Compliance decreases if surfactant production is too low to prevent the alveoli from collapsing on exhalation, as in *respiratory*

SPOTLIGHT Figure 15-10 PULMONARY VENTILATION Figure 15-10

Go to Mastering A&P > Study Area > Spotlight > **Figure Videos**

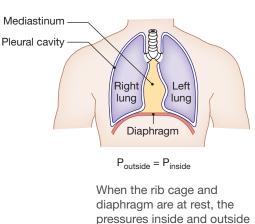

Pulmonary ventilation, or breathing, is the movement of air into and out of the respiratory system. It occurs by changing the volume of the lungs. Changes in lung volume take place through the contraction of skeletal muscles. The most important respiratory muscles are the diaphragm and the external intercostal muscles.

a AT REST

As the diaphragm is depressed or the rib cage (ribs and sternum) is elevated, the volume of the thoracic cavity increases and air moves into the lungs. The outward movement of the ribs as they are elevated resembles the outward swing of a raised bucket handle.

the lungs are equal, and no

air movement occurs.

Thoracic cavity volume increases $P_{outside} > P_{inside}$

• EXHALATION

When the rib cage returns to its original position and the diaphragm relaxes, the volume of the thoracic cavity decreases. Pressure within the lungs increases, and air moves out.

Thoracic cavity volume decreases Poutside < Pinside

distress syndrome (see p. 544). Compliance is also decreased when movements of the rib cage are limited by arthritis or other skeletal disorders that affect the joints of the ribs or spinal column.

When you are at rest, the muscular activity involved in pulmonary ventilation accounts for 3–5 percent of your resting energy demand. If compliance is reduced, the energy demand increases dramatically. You can become exhausted simply trying to continue breathing.

Modes of Breathing

We use our respiratory muscles in various combinations, depending on the volume of air that must be moved into and out of the system. Respiratory movements are classified as quiet breathing or forced breathing.

In **quiet breathing,** inhalation involves muscular contractions, but exhalation is passive. Inhalation involves the contraction of the **primary respiratory muscles**—the diaphragm and the external intercostal muscles. Diaphragm contraction normally accounts for around 75 percent of the air movement in normal quiet breathing. The external intercostal muscles account for the remaining 25 percent. These percentages can change, however. For example, pregnant women increasingly rely on movements of the rib cage as the uterus expands and forces abdominal organs against the diaphragm.

In **forced breathing**, both inhalation and exhalation are active and involve the *accessory respiratory muscles* (Spotlight Figure 15-10b,c). During exhalation, the internal intercostal muscles and abdominal muscles are active.

Lung Volumes and Capacities

A single breath, or **respiratory cycle**, consists of an inhalation, or *inspiration*, and an exhalation, or *expiration*. The **respiratory rate** is the number of breaths per minute. In normal adults at rest, this rate ranges from 12 to 18 breaths per minute. Children breathe more rapidly. For example, children one to five years of age normally take about 20 to 30 breaths per minute.

We exchange only a small proportion of the air in our lungs during a single quiet respiratory cycle. This amount of air is called the *tidal volume*. It can be increased by inhaling more vigorously and exhaling more completely.

We can divide the total volume of the lungs into a series of *volumes* and *capacities* (each the sum of various volumes) as shown in **Figure 15-11**:

• The **tidal volume (TV)** is the amount of air you move into or out of your lungs during a single respiratory cycle. It averages about 500 mL in both males and females.

- The **expiratory reserve volume (ERV)** is the amount of air that you can voluntarily expel at the end of a normal, quiet respiratory cycle. With the maximum use of accessory muscles, males can expel about 1000 mL of air. Female ERV averages 700 mL.
- The **inspiratory reserve volume (IRV)** is the amount of air that you can take in over and above the tidal volume. Because the lungs of males are larger than those of females, the IRV of males averages 3300 mL versus 1900 mL in females.
- The **vital capacity** is the sum of the tidal volume, the expiratory reserve volume, and the inspiratory reserve volume. It is the maximum amount of air that you can move into and out of your respiratory system in a single respiratory cycle.
- The **residual volume** is the amount of air that remains in your lungs even after a maximal exhalation. It is typically about 1200 mL in males and 1100 mL in females. Most of this residual volume exists because the lungs are held against the thoracic wall, preventing their elastic fibers from contracting further.
- The **minimal volume** is the amount of air that would remain in your lungs if they were allowed to collapse. The minimal volume ranges from 30 to 120 mL. However, even at minimal volume, some air remains in the lungs, because the surfactant coating the alveolar surfaces prevents their collapse.

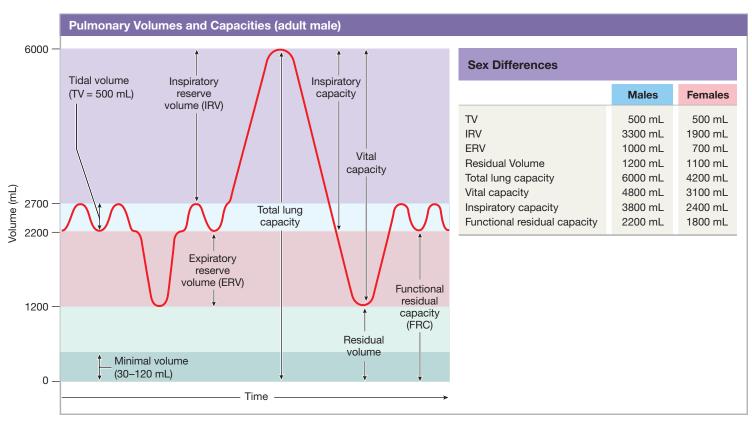

Not all of the inhaled air reaches the alveolar exchange surfaces within the lungs. A typical inhalation brings about 500 mL of air into the respiratory system. The first 350 mL travels along the conducting passageways and enters the alveolar spaces, but the last 150 mL never gets farther than the conducting passageways and does not take part in gas exchange with the blood. The total volume of these passageways (150 mL) is known as the *anatomic dead space* of the lungs.

CHECKPOINT

- **13.** Define compliance and identify some factors that affect it.
- **14.** What is tidal volume?
- **15.** Mark breaks a rib that punctures the chest wall on his left side. What do you expect will happen to his left lung as a result?
- **16.** In pneumonia, fluid accumulates in the alveoli of the lungs. How would this accumulation affect vital capacity?

See the blue Answers tab at the back of the book.

Figure 15-11 Pulmonary Volumes and Capacities. The red line indicates the volume of air within the lungs during breathing.

15-6 Gas exchange depends on the partial pressures of gases and the diffusion of molecules

Learning Outcome Describe the physical principles governing the diffusion of gases into and out of the blood.

During pulmonary ventilation, the alveoli are supplied with oxygen, and carbon dioxide is removed from the bloodstream. The actual process of gas exchange with the external environment takes place between the blood and alveolar air across the respiratory membrane. This process depends on (1) the partial pressures of the gases involved and (2) the diffusion of molecules between a gas and a liquid. $\bigcirc p. 92$

Mixed Gases and Partial Pressures

15

The air we breathe is a mixture of gases. Nitrogen molecules (N_2) are the most abundant. They account for about 78.6 percent of atmospheric gas molecules. Oxygen molecules (O_2) are the second most abundant. These molecules make up roughly 20.9 percent of air. Most of the remaining 0.5 percent consists

of water molecules. Carbon dioxide (CO_2) contributes a mere 0.04 percent.

Atmospheric pressure at sea level is approximately 760 mm Hg. Each of the gases in air contributes to the total atmospheric pressure in proportion to its relative abundance. The pressure contributed by a single gas is the **partial pressure** of that gas, abbreviated as P. All the partial pressures added together equal the total pressure exerted by the gas mixture. For the atmosphere, this relationship can be summarized as:

$$P_{N_2} + P_{O_2} + P_{H_2O} + P_{CO_2} = 760 \text{ mm Hg}$$

We can easily calculate the partial pressure of each gas because we know the individual percentages of each gas in air. For example, the partial pressure of oxygen P_{o_2} is 20.9 percent of 760 mm Hg, or approximately 159 mm Hg. The partial pressures of other atmospheric gases are listed in **Table 15-1**.

These values are important because the partial pressure of each gas determines its rate of diffusion between alveolar air and the bloodstream. Note that the partial pressure of oxygen determines how much oxygen enters solution, but it has no effect on the diffusion rates of nitrogen or carbon dioxide.

Table 15-1	Partial Pressures (mm Hg) and Normal Gas Concentrations (%) in Air			
Source of Sample	Nitrogen (N ₂)	Oxygen (O ₂)	Carbon Dioxide (CO ₂)	Water Vapor (H ₂ O)
Inhaled Air (Dry)	597 (78.6%)	159 (20.9%)	0.3 (0.04%)	3.7 (0.5%)
Alveolar Air (Satura	tted) 573 (75.4%)	100 (13.2%)	40 (5.2%)	47 (6.2%)
Exhaled Air (Satura	ted) 569 (74.8%)	116 (15.3%)	28 (3.7%)	47 (6.2%)

Alveolar Air versus Atmospheric Air

As soon as air enters the respiratory tract, its characteristics begin to change. For example, in passing through the nasal cavity, the inhaled air becomes warmer and more humid (the amount of water vapor increases). On reaching the alveoli, the incoming air mixes with air that remained in the alveoli after the previous respiratory cycle. The resulting alveolar gas mixture, thus, contains more carbon dioxide and less oxygen than does atmospheric air.

As noted earlier, the last 150 mL of inhaled air (about 30 percent of the tidal volume) never gets farther than the conducting passageways, the anatomic dead space of the lungs. During the next exhalation, the departing alveolar air mixes with air in the dead space to produce yet another mixture that differs from both atmospheric and alveolar samples. The differences in composition between atmospheric (inhaled) and alveolar air are also given in Table 15-1.

CLINICAL NOTE

8

Decompression Sickness

Decompression sickness is a painful condition that develops when a person is exposed to a sudden drop in atmospheric pressure. Nitrogen is the gas responsible for the problems experienced, due to its high partial pressure in air. When the pressure drops, nitrogen comes out of solution and forms bubbles, just as bubbles form when a can of soda is opened. The bubbles may form in joint cavities, in the bloodstream, and in the cerebrospinal fluid. Individuals with decompression sickness typically curl up because of the pain in affected joints. This response accounts for the condition's common name: *the bends*. Decompression

sickness most often affects scuba divers who return to the surface too quickly after breathing air under greater than normal pressures while submerged. It can also develop in airline passengers subjected to sudden losses of cabin pressure.

Partial Pressures in the Pulmonary and Systemic Circuits

Figure 15-12 shows the partial pressures of oxygen and carbon dioxide in the pulmonary and systemic circuits. The deoxygenated blood delivered by the pulmonary arteries has a lower P_{o_2} and a higher P_{co_2} than does alveolar air (**Figure 15-12a**). Diffusion between the alveolar air and the pulmonary (alveolar) capillaries then raises the P_{o_2} of the blood and lowers its P_{co_2} . By the time the blood enters the pulmonary venules, it has reached equilibrium with the alveolar air. Blood departs the alveoli with a P_{o_2} of about 100 mm Hg and a P_{co_2} of roughly 40 mm Hg.

As this blood enters pulmonary veins, it mixes with blood that flowed through capillaries around the conducting passageways. The blood leaving the conducting passageways carries relatively little oxygen. As a result, the partial pressure of oxygen in the mix of blood in the pulmonary veins drops to 95 mm Hg. This is the P_{o_2} in the blood that enters the systemic circuit.

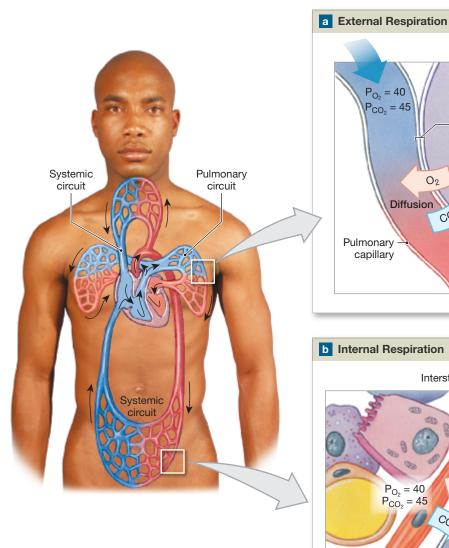

Normal interstitial fluid has a P_{o_2} of 40 mm Hg and a P_{co_2} of 45 mm Hg. As a result, oxygen diffuses out of the capillaries, and carbon dioxide diffuses in, until the capillary partial pressures are the same as those in the adjacent tissues (Figure 15-12b). When the blood returns to the alveolar capillaries, external respiration will replace the oxygen released into the tissues, and the excess CO₂ will be lost.

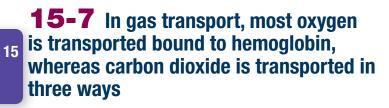

15

CHECKPOINT

- **17.** True or false: Each gas in a mixture of gases exerts a partial pressure equal to its relative abundance.
- **18.** What happens to air as it passes through the nasal cavity?
- **19.** Compare the oxygen and carbon dioxide content of alveolar air and atmospheric air.
- See the blue Answers tab at the back of the book.

Figure 15-12 An Overview of Respiratory Processes and Partial Pressures in Respiration.

Learning Outcome Describe how oxygen and carbon dioxide are transported in the blood.

Oxygen and carbon dioxide have limited solubilities (ability to dissolve) in blood plasma. These limits are a problem because peripheral tissues need more oxygen and generate more carbon dioxide than the plasma alone can absorb and transport. Red blood cells (RBCs) solve this problem. They take up dissolved oxygen and carbon dioxide molecules from plasma and bind them (in the case of oxygen) or use them to manufacture soluble compounds (in the case of carbon

dioxide). These reactions remove dissolved gases from the blood plasma. As a result, these gases continue to diffuse into the blood and never reach equilibrium.

capillary

The important thing about these reactions is that they are both temporary and completely reversible. When plasma oxygen or carbon dioxide concentrations are high, RBCs remove the excess molecules. When plasma concentrations are falling, RBCs release their stored reserves.

Build Your Knowledge

Recall that many important biological reactions are freely reversible (as you saw in **Chapter 2: The Chemical Level of Organization**). A reversible reaction consists of two reactions, synthesis and decomposition, that take place at the same time. At equilibrium, the rates of the two reactions are in balance. As a result, as fast as a molecule is synthesized, another one like it undergoes decomposition. This equilibrium is upset if the concentrations of one or more molecules are changed. When this change takes place, the equilibrium of the reversible reaction will shift so that either more synthesis or more decomposition will occur. **D p. 63**

Oxygen Transport

Only about 1.5 percent of the oxygen in arterial blood consists of oxygen molecules in solution. The rest of the oxygen molecules are bound to *hemoglobin (Hb) molecules*. Recall that the hemoglobin molecule is made up of four globular protein subunits. Each subunit contains a heme unit with a central iron ion. \bigcirc p. 414 Each iron ion binds one oxygen molecule. Thus, a hemoglobin molecule can bind four oxygen molecules. This binding takes place through a reversible reaction that can be summarized as:

$Hb + O_2 \Longrightarrow HbO_2$

The amount of oxygen bound (or released) by hemoglobin depends primarily on the P_{o_2} of its surroundings. The lower the oxygen content of a tissue, the more oxygen is released by hemoglobin molecules passing through local capillaries. For example, inactive tissues have little demand for oxygen, and the local P_{o_2} is about 40 mm Hg. Under these conditions, the passing hemoglobin collectively releases about 25 percent of its stored oxygen. In contrast, if the local P_{o_2} of active tissues declines to 15–20 mm Hg (about one-half of the P_{o_2} of normal tissue), the passing hemoglobin then collectively releases up to 80 percent of its stored oxygen. In practical terms, this means that active tissues will receive roughly three times as much oxygen as will inactive tissues.

The amount of oxygen released by hemoglobin is also influenced by pH and temperature. Active tissues generate acids that lower the pH of the interstitial fluids. When the pH

CLINICAL NOTE

Carbon Monoxide Poisoning

Murder victims who die in cars inside a locked garage are common in mystery stories. In real life, entire families are killed each winter by leaky furnaces or space heaters. The cause of death is carbon monoxide poisoning. The exhaust of automobiles and other petroleum-burning engines, of oil lamps, and of fuelfired space heaters contains the odorless gas, carbon monoxide (CO). CO competes with O₂ molecules for the binding sites on heme units. Unfortunately, the carbon monoxide usually wins. Even at very low partial pressures, it has a much stronger affinity (attraction) for hemoglobin than does oxygen. The attachment of a CO molecule essentially makes that heme unit unavailable for respiratory purposes. If CO molecules make up just 0.1 percent of inhaled air, enough hemoglobin will be affected that survival is impossible without medical assistance. Treatment includes (1) preventing further CO exposure; (2) administering pure oxygen, because at sufficiently high partial pressures the O2 molecules "bump" the CO from the hemoglobin; and, if necessary, (3) transfusing compatible red blood cells.

decreases, hemoglobin molecules release their bound oxygen molecules more readily. Hemoglobin also releases more oxygen when body temperature rises.

All three factors (P_{o_2} , pH, and temperature) are important during maximal exertion. When a skeletal muscle works hard, its temperature rises and the local pH and P_{o_2} decline. The combination makes the hemoglobin entering the area release much more oxygen for use by active muscle fibers. Without this automatic adjustment, tissue P_{o_2} would fall to very low levels almost immediately, and the exertion would end.

Carbon Dioxide Transport

Carbon dioxide is generated by aerobic metabolism in peripheral tissues. Carbon dioxide travels in the bloodstream in three different ways. After entering the blood, a CO_2 molecule either (1) dissolves in the plasma, (2) binds to hemoglobin within red blood cells, or (3) is converted to a bicarbonate ion (HCO₃⁻) (**Figure 15-13**). All three processes are completely reversible, allowing carbon dioxide to be picked up from body tissues and delivered to the alveoli.

Transport in Plasma

Plasma becomes saturated with carbon dioxide quite rapidly. As a result, only about 7 percent of the carbon dioxide

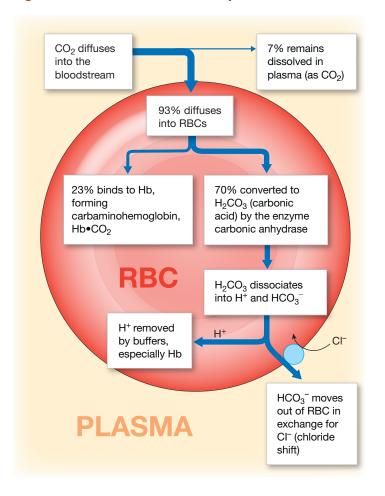

Figure 15-13 Carbon Dioxide Transport in Blood.

absorbed by peripheral capillaries is transported as dissolved gas molecules. The rest diffuses into red blood cells (RBCs).

Hemoglobin Binding

15 Once in red blood cells, some of the carbon dioxide molecules are bound to the protein "globin" portions of hemoglobin molecules, forming **carbaminohemoglobin** (kar-bām-inō-hē-mō-GLŌ-bin). Such binding does not interfere with the binding of oxygen to heme units. For this reason, hemoglobin can transport both oxygen and carbon dioxide at the same time. Normally, about 23 percent of the carbon dioxide entering the blood in peripheral tissues is transported as carbaminohemoglobin.

Carbonic Acid Formation and Dissociation

Roughly 70 percent of the carbon dioxide molecules absorbed by blood are ultimately transported in the plasma as bicarbonate ions (HCO₃⁻). The bicarbonate ions are not formed directly from carbon dioxide. First, carbon dioxide in RBCs is converted to carbonic acid (H_2CO_3) by the enzyme *carbonic anhydrase*. Each carbonic acid molecule immediately dissociates into a hydrogen ion and a bicarbonate ion. The reactions can be summarized as follows:

$$CO_2 + H_2O \xrightarrow{\text{carbonic anhydrase}} H_2CO_3 \xleftarrow{} H^+ + HCO_3^-$$

The reactions take place very rapidly and are completely reversible. Because most of the carbonic acid formed immediately dissociates into hydrogen ions and bicarbonate, we will ignore the intermediary step and summarize the reaction as follows:

$$CO_2 + H_2O \implies H^+ + HCO_3^-$$

In peripheral capillaries, this reaction rapidly ties up large numbers of carbon dioxide molecules. The equilibrium of this reaction shifts toward the right, because carbon dioxide continues to diffuse out of the interstitial fluids and the hydrogen ions and bicarbonate ions are being continuously removed. Where do they go? Most of the hydrogen ions bind to hemoglobin molecules. This binding prevents their release from the RBCs and a lowering of plasma pH. The bicarbonate ions diffuse into the surrounding plasma. The exit of the bicarbonate ions is matched by the entry of chloride ions from the plasma, thus trading one anion for another. This mass movement of chloride ions into RBCs is known as the *chloride shift*.

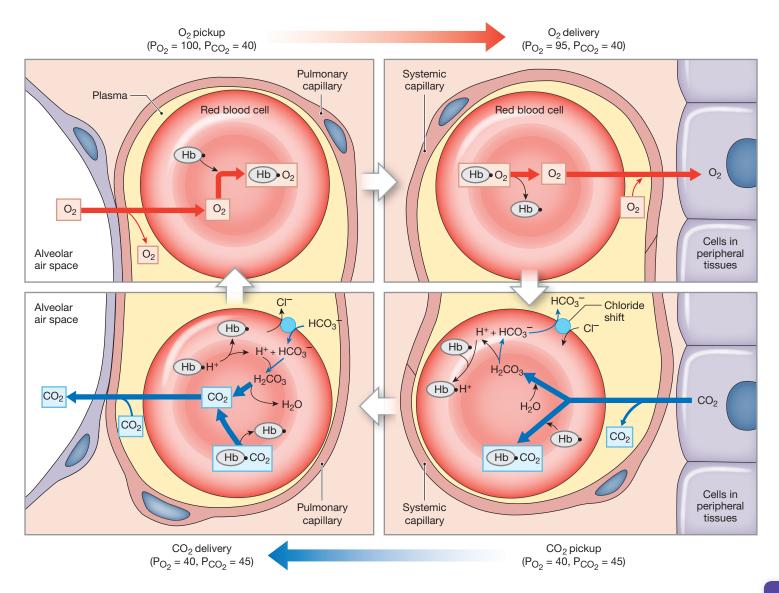

When venous blood reaches the alveoli, carbon dioxide diffuses out of the plasma, and the P_{co_2} declines. Recall that all of the reactions involved in carbon dioxide transport in RBCs are reversible. Thus, when carbon dioxide diffuses out of the red blood cells, the processes shown in Figure 15-13 proceed in the opposite direction. Hydrogen ions separate from the hemoglobin molecules. Bicarbonate ions diffuse out of the plasma and into the cytoplasm of the RBCs. There they are converted to water and CO₂.

Figure 15-14 summarizes the events by which oxygen and carbon dioxide are transported and exchanged between the respiratory and cardiovascular systems.

CHECKPOINT

- **20.** Identify the three ways that carbon dioxide is transported in the bloodstream.
- **21.** As you exercise, hemoglobin releases more oxygen to active skeletal muscles than it does when the muscles are at rest. Why?
- **22.** How would blockage of the trachea affect blood pH?
- See the blue Answers tab at the back of the book.

Figure 15-14 A Summary of Gas Transport and Exchange. Shown here are the events that occur in oxygen pickup from the alveoli and delivery to peripheral tissues and in carbon dioxide pickup from peripheral tissues and delivery to the alveoli.

15-8 Neurons in the medulla oblongata and pons, along with respiratory reflexes, control respiration

Learning Outcome List the factors that influence the rate of respiration, and describe the reflexes that regulate respiration.

Cells continuously absorb oxygen from the interstitial fluids and generate carbon dioxide. Under normal conditions, cellular rates of absorption and generation are matched by the rates of delivery and removal at the capillaries. Moreover, those rates are identical to those of oxygen absorption and carbon dioxide removal at the lungs. If these rates become unbalanced, the activities of the cardiovascular and respiratory systems must be adjusted. Homeostatic processes restore equilibrium. They involve (1) changes in blood flow and oxygen delivery under local control and (2) changes in the depth and rate of respiration under the control of the brain's respiratory centers.

The Local Control of Respiration

Both the rate of oxygen delivery at each tissue and the efficiency of oxygen pickup at the lungs are regulated at the local level. If a peripheral tissue becomes more active, the interstitial P_{o_2} falls and the P_{co_2} rises. These changes increase the difference

between partial pressures in the tissues and arriving blood, so more oxygen is delivered and more carbon dioxide is carried away. In addition, rising P_{co_2} levels cause smooth muscles in the walls of arterioles in the area to relax, increasing blood flow.

Local adjustments in blood flow, or of airflow into alveoli, also make gas transport more efficient. For example, as blood flows to alveolar capillaries, it is directed to pulmonary lobules with a relatively high P_{o_2} . This takes place because precapillary sphincters in alveolar capillary beds constrict when the local P_{o_2} is low. (This response is the opposite of that seen in peripheral tissues. \bigcirc p. 464) Also in the lungs, smooth muscles in the walls of bronchioles are sensitive to the P_{co_2} of the air they contain. When the P_{co_2} increases, the bronchioles dilate, and when the P_{co_2} declines, the bronchioles constrict. As a result, airflow is directed to lobules in which the P_{co_2} is high.

Control by the Respiratory Centers of the Brain

Respiratory control has both involuntary and voluntary components. Your brain's involuntary respiratory centers (in the medulla oblongata and pons) regulate the respiratory muscles and control the frequency (respiratory rate) and the depth of breathing. These centers respond to sensory information arriving from the lungs and other portions of the respiratory tract, as well as from a variety of other sites. The voluntary control of respiration reflects activity in the cerebral cortex that affects the output of the respiratory centers or of motor neurons that control respiratory muscles.

The **respiratory centers** are three pairs of nuclei in the reticular formation of the pons and medulla oblongata. The paired **respiratory rhythmicity centers** of the medulla oblongata play a key role in setting the pace for respiration. Each center can be subdivided into a *dorsal respiratory group* (*DRG*), which contains an *inspiratory center*, and a *ventral respiratory group* (*VRG*), which contains an *expiratory center*. Their output is adjusted by the two pairs of nuclei making up the respiratory centers of the pons. The centers in the pons adjust the respiratory rate and the depth of respiration in response to sensory stimuli, emotional states, or speech patterns.

The Activities of the Respiratory Rhythmicity Centers

Reciprocal inhibition takes place between the neurons involved with inhalation and exhalation. \bigcirc p. 314 When the inspiratory neurons are active, the expiratory neurons are inhibited, and vice versa. The pattern of interaction between these groups differs between quiet breathing and forced breathing.

The DRG's inspiratory center functions in every respiratory cycle. It contains neurons that control inspiratory muscles. These muscles are the external intercostal muscles and the diaphragm. During quiet breathing, the neurons gradually increase stimulation of the inspiratory muscles for two seconds. Then the inspiratory center becomes silent for the next three seconds. During that period of inactivity, the inspiratory muscles relax and passive exhalation takes place. The inspiratory center maintains this basic rhythm even in the absence of sensory or regulatory stimuli.

The VRG functions only during forced breathing. It has an expiratory center that contains neurons that control accessory respiratory muscles involved in active exhalation. Its inspiratory center contains neurons involved in maximal inhalation, such as gasping. The relationships between the inspiratory and expiratory centers during quiet breathing and forced breathing are diagrammed in **Figure 15-15**.

Any factor that alters the metabolic or chemical activities of nervous tissues can affect the performance of these respiratory centers. For example, elevated body temperature or CNS stimulants (such as amphetamines or caffeine) increase the respiratory rate. Conversely, decreased body temperature or CNS depressants (such as barbiturates or opiates) reduce the respiratory rate. Reflexes triggered by physical or chemical stimuli also strongly influence respiratory activities.

The Reflex Control of Respiration

Normal breathing takes place automatically without conscious control (**Spotlight Figure 15-16**). The activities of the respiratory centers are modified by sensory information from mechanoreceptors (such as stretch and pressure receptors) and chemoreceptors. Information from these receptors alters the pattern of respiration. The induced changes are called *respiratory reflexes*.

Mechanoreceptor Reflexes

Mechanoreceptors respond to changes in lung volume or to changes in arterial blood pressure. Several populations of baroreceptors are involved in respiratory function. (See Chapter 9.) D p. 340

The **inflation reflex** prevents the lungs from overexpanding during forced breathing. The mechanoreceptors involved are stretch receptors that are stimulated when the lungs expand. Sensory fibers leaving the lungs reach the respiratory rhythmicity centers through the vagus nerves. As the volume

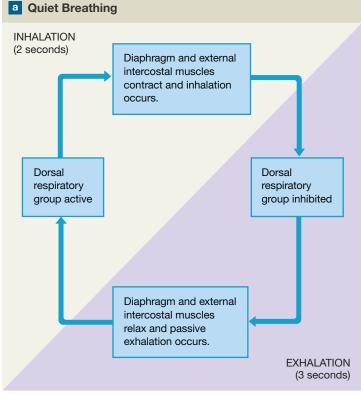

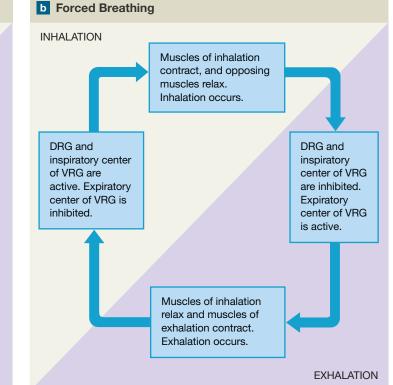

Figure 15-15 Basic Regulatory Patterns of Respiration.

of the lungs increases, the DRG inspiratory center is gradually inhibited, and the VRG expiratory center is stimulated. Thus, inhalation stops as the lungs near maximum volume, and active exhalation then begins.

The deflation reflex normally only functions during forced exhalation. This reflex inhibits the expiratory center and stimulates the inspiratory center when the lungs are deflating. The smaller the volume of the lungs, the greater the inhibition of the expiratory center. Finally, exhalation stops and inhalation begins.

The inflation reflex and the deflation reflex are not involved in normal quiet breathing, but both are important in regulating forced inhalations and exhalations during strenuous exercise. Together, the inflation and deflation reflexes are known as the Hering-Breuer reflexes, after the physiologists who described them in 1865.

Recall that carotid and aortic baroreceptors affect systemic blood pressure (described in Chapter 13. \bigcirc p. 473) The output from these baroreceptors also affects the respiratory centers. When blood pressure falls, the respiratory rate increases. When blood pressure rises, the respiratory rate declines. This adjustment results from the stimulation or inhibition of the respiratory centers by sensory fibers in the glossopharyngeal (IX) and vagus (X) nerves.

Chemoreceptor Reflexes

Chemoreceptors respond to chemical changes in the blood and cerebrospinal fluid. **Dp.** 340 Their stimulation leads to an increase in the depth and rate of respiration. Receptors in the carotid bodies (adjacent to the carotid sinus) and the aortic bodies (near the aortic arch) are sensitive to the pH, P_{co_2} , and P_{o_2} in arterial blood. Receptors in the medulla oblongata respond to the pH and P_{co_2} in cerebrospinal fluid.

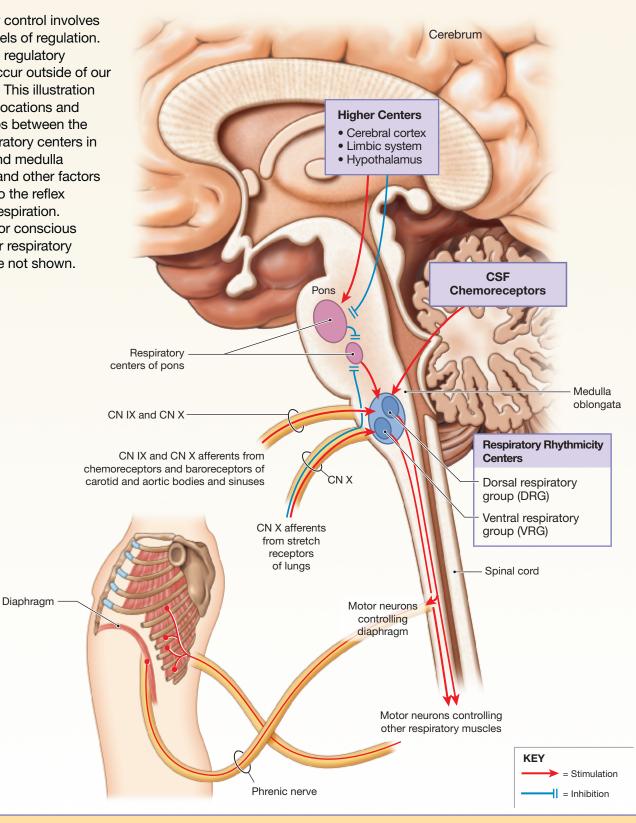

Carbon dioxide levels have a much more powerful effect on respiratory activity than do oxygen levels. The reason is that a 15 relatively small increase in arterial Pco2 stimulates CO2 receptors, but arterial Po, does not usually decline enough to activate oxygen receptors. For this reason, carbon dioxide levels are responsible for regulating respiratory activity under normal conditions. However, when arterial Po, does fall, the two types of receptors work together. Carbon dioxide is generated during oxygen consumption, so when O₂ concentrations are falling rapidly, CO₂ levels are usually increasing. For this reason, you cannot hold your breath "until you turn blue." Once the P_{con} rises to critical levels, you will be forced to take a breath.

The cooperation between the carbon dioxide and oxygen receptors breaks down only under unusual circumstances. For example, you can hold your breath longer than normal by

SPOTLIGHT Figure 15-16 THE CONTROL OF RESPIRATION

Respiratory Centers and Reflex Controls

Respiratory control involves multiple levels of regulation. Most of the regulatory activities occur outside of our awareness. This illustration shows the locations and relationships between the major respiratory centers in the pons and medulla oblongata and other factors important to the reflex control of respiration. Pathways for conscious control over respiratory muscles are not shown.

taking deep, full breaths. However, the practice is very dangerous. The danger lies in the fact that the increased ability is due not to extra oxygen, but to the loss of carbon dioxide. If the P_{co_2} is reduced enough, breath-holding ability may increase to the point that you become unconscious from oxygen starvation in the brain without ever feeling the urge to breathe.

The chemoreceptors monitoring CO_2 levels are also sensitive to pH. Any condition affecting the pH of blood or CSF will affect respiratory performance. For example, the rise in lactate level after exercise is accompanied by a decrease in pH that helps stimulate respiratory activity.

Control by Higher Centers

Higher centers influence respiration through their effects on the respiratory centers of the pons and by the direct control of respiratory muscles. For example, you can voluntarily suppress or exaggerate the contractions of respiratory muscles. This control is necessary during talking or singing. The depth and rate of respiration also change following the activation of centers involved with rage, eating, or sexual arousal. These changes, directed by the limbic system, take place at an involuntary level. **Spotlight Figure 15-16** summarizes the factors involved in the regulation of respiration.

Respiratory Changes at Birth

The respiratory systems of a fetus and a newborn differ in several important ways. Before delivery, pulmonary arterial resistance is high, because the pulmonary vessels are collapsed. The rib cage is compressed, and the lungs and conducting passageways contain only small amounts of fluid and no air.

At birth, the newborn takes a truly heroic first breath through powerful contractions of the diaphragm and the external intercostal muscles. The inhaled air enters the passageways with enough force to overcome surface tension and inflate the bronchial tree and most of the alveoli. The same drop in pressure that pulls air into the lungs pulls blood into the pulmonary circulation. The exhalation that follows fails to empty the lungs completely, because the rib cage does not return to its former, fully compressed state. Cartilages and connective tissues keep the conducting passageways open, and the surfactant covering the alveolar surfaces prevents their collapse. The next breaths complete the inflation of the alveoli.

CLINICAL NOTE

Emphysema and Lung Cancer

Emphysema and lung cancer are two relatively common disorders. Both are often associated with cigarette smoking. **Emphysema** (em-fi-ZĒ-muh) is a chronic, progressive condition. It is characterized by shortness of breath and an inability to tolerate physical exertion. The underlying problem is the destruction of alveolar surfaces and inadequate surface area for gas exchange. In essence, respiratory bronchioles and alveoli no longer function. The alveoli gradually expand, and adjacent alveoli merge to form larger air spaces supported by fibrous tissue without alveolar capillary networks. As connective tissues are eliminated, compliance increases, so air moves into and out of the lungs more easily than before. However, the loss of respiratory surface area restricts oxygen absorption, so the individual becomes short of breath.

Emphysema has been linked to breathing air that contains fine particles or toxic vapors, such as those in cigarette smoke. Genetic factors also predispose individuals to the condition. Some degree of emphysema is a normal consequence of aging. An estimated 66 percent of adult males and 25 percent of adult females have detectable areas of emphysema in their lungs.

Lung cancer, or *bronchopulmonary carcinoma*, is an aggressive class of malignancies originating in the bronchial passageways or alveoli. These cancers affect the epithelial cells that line conducting passageways, mucous glands, or alveoli. Signs and symptoms generally do not appear until tumors restrict airflow or

compress adjacent structures. Chest pain, shortness of breath, a cough or a wheeze, and weight

loss are common. Treatment programs vary with the cellular organization of the tumor and whether metastasis (cancer cell migration) has taken place. Surgery, radiation therapy, or chemotherapy may be involved.

According to the CDC, more people die from lung cancer than any other type of cancer. In 2015, lung cancer affected an estimated 113,535 men and 104,992 women in the United States. It also accounted for 13.5 percent of new cancer cases in both men and women and 25.3 percent of all cancer deaths.

Healthy lung

Smoker's lung

Pathologists sometimes use these physical changes to determine whether a newborn died before delivery or shortly thereafter. Before the first breath, the lungs are completely filled with amniotic fluid, and extracted lungs will sink if placed in water. After an infant's first breath, even the collapsed lungs contain enough air to keep them afloat.

CHECKPOINT

- **23.** Are peripheral chemoreceptors more or less sensitive to levels of carbon dioxide than they are to levels of oxygen? Why?
- **24.** Strenuous exercise stimulates which set of respiratory reflexes?
- **25.** Little Johnny tells his mother he will hold his breath until he turns blue and dies. Should she worry?

See the blue Answers tab at the back of the book.

15-9 Respiratory performance declines with age

Learning Outcome Describe the changes in the respiratory system that occur with aging.

Many factors interact to make the respiratory system less efficient in elderly people. Here are two examples:

1. Chest movements are restricted by several changes. These include arthritic changes in rib joints, decreased flex-ibility at the costal cartilages, and age-related muscular weakness. (These restrictions counterbalance an increase in compliance of the lungs as elastic tissue deteriorates with age.) Together, the stiffening and reduction in chest movement limit pulmonary ventilation and vital capacity. These changes contribute to the decline in exercise performance and capabilities with increasing age.

2. Some degree of emphysema is normal in people over age 50. The extent varies widely with lifetime exposure to cigarette smoke and other respiratory irritants. Studies comparing nonsmokers and people who have smoked for various lengths of time clearly show the negative effects of smoking on respiratory performance.

CHECKPOINT

26. Describe two age-related changes that combine to reduce the efficiency of the respiratory system.

See the blue Answers tab at the back of the book.

15-10 The respiratory system provides oxygen to, and removes carbon dioxide from, other organ systems

Learning Outcome Give examples of interactions between the respiratory system and other body systems presented so far.

Refer to Build Your Knowledge: How the RESPIRATORY SYSTEM integrates with the other body systems presented so far on p. 563. It reviews the major functional relationships between this system and the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, and lymphatic systems. Note that the respiratory system has many structural and functional connections to the cardiovascular system.

CHECKPOINT

- **27.** Identify the key function that the respiratory system provides for all other organ systems presented so far.
- **28.** How does the nervous system support the functions of the respiratory system?
- See the blue Answers tab at the back of the book.

asthma (AZ-muh): An acute respiratory disorder characterized by unusually sensitive, irritated conducting airways.

bronchitis (brong-KĪ-tis): Inflammation of the bronchial lining.

cardiopulmonary resuscitation (CPR): The application of cycles of compression to the rib cage and mouth-to-mouth breathing to restore cardiovascular and respiratory function.

chronic obstructive pulmonary disease (COPD): A general term describing temporary or permanent lung disease of the bronchial tree; characterized by chronic bronchitis and chronic airway obstruction.

dyspnea (DISP-nē-uh): Difficult or labored breathing. **epistaxis** (ep-i-STAK-sis): A nosebleed.

hypercapnia (hī-per-KAP-nē-uh): An abnormally high level of carbon dioxide in the blood.

hypocapnia: An abnormally low level of carbon dioxide in the blood.

influenza: A viral infection of the respiratory tract; "the flu."

pleurisy: Inflammation of the pleurae and secretion of excess amounts of pleural fluid.

sputum: A mixture of saliva and mucus coughed up from the respiratory tract, often as a result of infection.

Build Your Knowledge

How the RESPIRATORY SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System protects portions of upper respiratory tract; hairs guard entry to nostrils
- The respiratory system provides oxygen to tissues and removes carbon dioxide

Endocrine System

- The Endocrine System produces epinephrine and norepinephrine, which stimulate respiratory activity and dilate respiratory passageways
- The respiratory system produces angiotensin-converting enzyme (ACE) from capillaries in the lungs. ACE converts angiotensin I to angiotensin II

Skeletal System

- The Skeletal System protects the lungs with its axial division; movements of the rib cage are important in breathing
- The respiratory system provides oxygen to skeletal structures and disposes of carbon dioxide

Muscular System

- The Muscular System controls the entrances to the respiratory tract; intrinsic laryngeal muscles control airflow through larynx and produce sounds; respiratory muscles change thoracic cavity volume so air moves into and out of lungs
- The respiratory system provides oxygen needed for muscle contractions and disposes of carbon dioxide generated by active muscles

Nervous System

- The Nervous System monitors respiratory volume and blood gas levels; controls pace and depth of respiration
- The respiratory system provides oxygen needed for neural activity and disposes of carbon dioxide

Lymphatic System

- The Lymphatic System protects against infection with tonsils at entrance to respiratory tract; lymph nodes monitor lymph drainage from lungs and provide specific defenses when infection occurs
- The respiratory system has alveolar macrophages that provide nonspecific defenses; mucous membrane lining the upper respiratory system traps pathogens and protects deeper tissues

Cardiovascular System

 The Cardiovascular System circulates the red blood cells that transport oxygen and carbon dioxide between lungs and peripheral tissues

 The respiratory system provides oxygen needed for heart muscle contraction; bicarbonate ions contribute to the buffering capacity of blood; activation of angiotensin II by ACE is important in regulation of blood pressure and blood volume

Respiratory System

The respiratory system provides oxygen and eliminates carbon dioxide for our cells. It:

- provides a large area for gas exchange between air and circulating blood
- moves air to and from the gas-exchange surfaces of the lungs along the respiratory passageways
- protects the respiratory surfaces from dehydration, temperature changes, and defends against invading pathogens
- produces sounds for speaking, singing, and other forms of communication
- aids the sense of smell by the olfactory receptors in the nasal cavity

Chapter Review

Summary Outline

An Introduction to the Respiratory System p. 536

1. To continue functioning, body cells must obtain oxygen and eliminate carbon dioxide. These processes take place in **alveoli**, air-filled pockets in the lungs.

15-1 The respiratory system, composed of air-conducting and respiratory portions, has several basic functions *p. 536*

- 2. The functions of the **respiratory system** include (1) providing an area for gas exchange between air and circulating blood; (2) moving air to and from exchange surfaces; (3) protecting exchange surfaces from dehydration, temperature changes, and pathogens; (4) producing sound for speaking; and (5) aiding the stimulation of olfactory (smell) receptors.
- **3.** The respiratory system includes the **upper respiratory system**, composed of the nose, a nasal cavity, paranasal sinuses, and pharynx, and the **lower respiratory system**, which includes the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs. (*Figure 15-1*)
- **4.** The **respiratory tract** consists of the conducting passageways that carry air to and from the alveoli.
- **5.** The **respiratory mucosa** (respiratory epithelium and underlying areolar tissue) lines the conducting portion of the respiratory tract. (*Figure 15-2*)

15-2 The nose, pharynx, larynx, trachea, bronchi, and larger bronchioles conduct air into the lungs *p. 538*

- **15 6.** Air normally enters the respiratory system through the **nostrils**, which open into the **nasal cavity**. The **nasal vestibule** (entrance) is guarded by hairs that screen out large particles. (*Figure 15-3*)
 - 7. The **hard palate** separates the oral and nasal cavities. The **soft palate** separates the superior nasopharynx from the rest of the pharynx. The **posterior nasal apertures** connect the nasal cavity and nasopharynx. (*Figure 15-3*)
 - **8.** The **pharynx** (throat) is a chamber shared by the digestive and respiratory systems.
 - 9. Inhaled air passes through the glottis on its way to the lungs. The **larynx** surrounds and protects the glottis, or "voicebox." The **epiglottis** projects into the pharynx. The **glottis** includes the **true vocal cords** and the space between them. Exhaled air passing through the

glottis vibrates the true vocal cords and produces sound. *(Figure 15-4)*

- **10.** The wall of the **trachea** ("windpipe") contains C-shaped tracheal cartilages, which protect the airway. The posterior tracheal wall can distort to permit large masses of food to pass along the esophagus. (*Figure 15-5*)
- **11.** The trachea branches within the mediastinum to form the **right** and **left main bronchi**. (*Figure 15-5*)
- **12.** The main bronchi, **lobar bronchi**, and their branches form the *bronchial tree*. As the **segmental bronchi** branch within the lung, the amount of cartilage in their walls decreases, and the amount of smooth muscle increases. (*Figure 15-6a*)

15-3 The smallest bronchioles and the alveoli within the lungs make up the respiratory portion of the respiratory tract *p. 544*

- **13.** Each terminal **bronchiole** delivers air to a single pulmonary **lobule**. Within the lobule, the terminal bronchiole branches into *respiratory bronchioles*. (*Figure 15-6b*)
- **14.** The respiratory bronchioles open into **alveolar ducts**, which end at **alveolar sacs**. Many alveoli are interconnected at each alveolar sac. (*Figure 15-7a,b*)
- 15. The blood air barrier consists of (1) a simple squamous alveolar epithelium, (2) a capillary endothelium, and (3) fused basement membranes. The alveolar squamous cells are also called pneumocytes type I. Pneumocytes type II produce surfactant, an oily secretion that keeps the alveoli from collapsing. Alveolar macrophages engulf foreign particles. (*Figure 15-7c,d*)
- **16.** The **lungs** are made up of five **lobes:** three in the right lung and two in the left lung. *(Figure 15-8)*
- **17.** Each lung is enclosed by a single pleural cavity lined by a **pleura** (serous membrane). (*Figure 15-9*)

15-4 External respiration and internal respiration allow gas exchange within the body *p. 548*

18. Respiration involves two integrated processes: external respiration (the exchange of oxygen and carbon dioxide between interstitial fluid and the external environment) and internal respiration (the exchange of oxygen and carbon dioxide between interstitial fluid and cells). If the oxygen content declines, the affected tissues suffer from hypoxia;

if the oxygen supply is completely shut off, **anoxia** and tissue death result.

19. External respiration includes *pulmonary ventilation*, or breathing (movement of air into and out of the lungs); *gas diffusion* between the alveoli and circulating blood, and between the blood and interstitial fluids; and *transport of oxygen and carbon dioxide* between the alveolar capillaries and capillary beds in other tissues by the bloodstream.

15-5 Pulmonary ventilation—the exchange of air between the atmosphere and the lungs involves pressure changes and muscle movement *p. 549*

- **20.** A single breath, or **respiratory cycle**, consists of an inhalation (*inspiration*) and an exhalation (*expiration*).
- **21.** The difference between the pressure inside the respiratory tract and atmospheric pressure determines the direction of airflow. *(Spotlight Figure 15-10)*
- **22.** The primary respiratory muscles (the diaphragm and the external intercostal muscles) are involved in **quiet breathing**, in which exhalation is passive. Accessory respiratory muscles become active during the active inhalation and exhalation movements of **forced breathing**, in which exhalation is active. (*Spotlight Figure 15-10*)
- **23.** The **vital capacity** includes the **tidal volume** plus the **expiratory reserve volume** and the **inspiratory reserve volume**. The air left in the lungs at the end of maximum expiration is the **residual volume**. (*Figure 15-11*)

15-6 Gas exchange depends on the partial pressures of gases and the diffusion of molecules *p. 552*

- **24.** In a mixed gas, the individual gases exert a pressure proportional to their abundance in the mixture. The pressure contributed by a single gas is its **partial pressure**.
- **25.** Alveolar air and atmospheric air differ in composition. Gas exchange occurs efficiently across the respiratory membrane. (*Figure 15-12; Table 15-1*)

15-7 In gas transport, most oxygen is transported bound to hemoglobin, whereas carbon dioxide is transported in three ways *p. 554*

- **26.** Blood entering peripheral capillaries delivers oxygen and takes up carbon dioxide. The transport of oxygen and carbon dioxide in the blood involves reactions that are completely reversible.
- **27.** Over the range of oxygen pressures normally present in the body, a small change in plasma P_{o_2} will result in a large change in the amount of oxygen bound or released by hemoglobin.

28. Aerobic metabolism in peripheral tissues generates carbon dioxide. Roughly 7 percent of the CO₂ transported in the blood is dissolved in the plasma; another 23 percent is bound as **carbaminohemoglobin** in RBCs; and 70 percent is converted to carbonic acid, which dissociates into a hydrogen ion and a bicarbonate ion. The bicarbonate ion exits the RBC and enters the plasma. (*Figures 15-13, 15-14*)

15-8 Neurons in the medulla oblongata and pons, along with respiratory reflexes, control respiration *p. 557*

- **29.** Large-scale changes in oxygen demand require the integration of cardiovascular and respiratory responses.
- **30.** Arterioles leading to alveolar capillaries constrict when oxygen is low, and bronchioles dilate when carbon dioxide is high.
- **31.** The **respiratory centers** include three pairs of nuclei in the reticular formation of the pons and medulla oblongata. These nuclei regulate the respiratory muscles and control the respiratory rate and the depth of breathing. The paired **respiratory rhythmicity centers** in the medulla oblongata set the basic pace for respiration. Each center has a *dorsal respiratory group* (*DRG*), with an *inspiratory center*, and a *ventral respiratory group* (*VRG*), with an *expiratory center*. (*Figure 15-15, Spotlight Figure 15-16*)
- **32.** The **inflation reflex** prevents overexpansion of the lungs during forced breathing; the **deflation reflex** stimulates inhalation when the lungs are deflating. Chemoreceptor reflexes respond to changes in the pH, P_{o_2} , and P_{co_2} of the blood and cerebrospinal fluid. (Spotlight Figure 15-16)
- **33.** Conscious and unconscious thought processes can affect respiration by affecting the respiratory centers or the motor neurons controlling respiratory muscles.
- **34.** Before delivery, the fetal lungs are fluid filled and collapsed. After the first breath, the alveoli normally remain inflated for the life of the individual.

15-9 Respiratory performance declines with age *p. 562*

35. The respiratory system is generally less efficient in elderly people because (1) movements of the rib cage are restricted by arthritic changes, decreased flexibility of costal cartilages, and age-related muscle weakness, lowering pulmonary ventilation and vital capacity of the lungs; and (2) some degree of emphysema is normal in elderly people.

15-10 The respiratory system provides oxygen to, and removes carbon dioxide from, other organ systems *p. 562*

36. The respiratory system has extensive anatomical and physiological connections to the cardiovascular system.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A

COLUMN B

- **1.** nasopharynx
- **2.** laryngopharynx
- 3. thyroid cartilage
- **4.** septal cells
- 5. dust cells
- 6. parietal pleura
- 7. visceral pleura ____
- 8. hypoxia
- 9. anoxia
- - **10.** collapsed lung
 - **11.** inhalation
- 12. exhalation

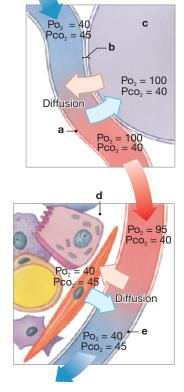

following figure:

(a) _____

- a. atelectasis
- **b.** no O_2 supply to tissues
- c. alveolar macrophages
- **d.** produce oily secretion e. covers inner surface of thoracic body wall
- **f.** low O₂ content in tissue fluids
- g. inferior portion of pharynx
- **h.** inspiration
- superior portion of pharynx i.
- Adam's apple j.
- k. covers outer surface of lungs
- **I.** expiration

Label the pink and light blue arrows in the upper and lower portions of the figure to indicate the directions of the diffusion of oxygen and carbon dioxide.

- 15. Cartilage can be found in the wall of the
 - (a) primary bronchus. (b) terminal bronchiole.
 - (c) respiratory bronchiole. (d) alveolar duct.
- 16. Exhalation can be aided by the contraction of the
 - (a) diaphragm.
 - (**b**) pectoralis minor muscle.
 - (c) rectus abdominis muscle.
 - (d) sternocleidomastoid muscle.
- (b) _____ (c) _____ (**d**) b (e) _____ (f) _____ (g) _____ (h) _____ (i) _____

13. Identify the structures of the respiratory system in the

14. Identify the structures in the following figure:

Level 2 Reviewing Concepts

- **17.** When the diaphragm contracts, it tenses and moves inferiorly, causing
 - (a) an increase in the volume of the thoracic cavity.
 - (b) a decrease in the volume of the thoracic cavity.
 - (c) decreased pressure on the contents of the abdominopelvic cavity.
 - (d) increased pressure in the thoracic cavity.
- **18.** Gas exchange at the blood air barrier is efficient because
 - (a) the differences in partial pressure are substantial.
 - (b) the gases are lipid soluble.
 - (c) the total surface area is large.
 - (d) a, b, and c are correct.
- **19.** What is the functional significance of the decreased amount of cartilage and the increased amount of smooth muscle in the lower respiratory passageways?
- **20.** Why is breathing through the nasal cavity more desirable than breathing through the mouth?
- **21.** Where is the hormone thymosin secreted from? What is its effect?

Level 3 Critical Thinking and Clinical Applications

- **22.** Individuals who are anemic generally do not exhibit an increase in respiratory rate or tidal volume, even though their blood is not carrying enough oxygen. Why?
- **23.** Considering that surfactant is produced in sufficient quantities at around 35 weeks, discuss why premature babies have a higher risk of respiratory distress at birth.

The Digestive System

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

16-1 Identify the organs of the digestive system, list their major functions, and describe the four layers of the wall of the digestive tract.

16

- **16-2** Discuss the anatomy of the oral cavity, and list the functions of its major structures.
- **16-3** Describe the structures and functions of the pharynx and esophagus, and the key events of the swallowing process.
- **16-4** Describe the anatomy of the stomach, including its histology, and discuss its roles in digestion and absorption.
- **16-5** Describe the anatomy of the small intestine, including its histology, and explain the functions and regulation of intestinal secretions.
- **16-6** Describe the structure and functions of the pancreas, liver, and gallbladder, and explain how their activities are regulated.
- **16-7** Describe the structure of the large intestine, including its regional specializations, and list its absorptive functions.
- **16-8** List the nutrients required by the body, describe the chemical digestion of organic nutrients, and discuss the absorption of organic and inorganic nutrients.
- **16-9** Summarize the effects of aging on the digestive system.
- **16-10** Give examples of interactions between the digestive system and other body systems presented so far.

Regulation of Gastric Activity, p. 580 Chemical Events in Digestion, p. 597

An Introduction to the Digestive System

Few people give any serious thought to the digestive system unless it malfunctions. Still, we spend hours filling and emptying it. We often refer to this system in our everyday language. We "have a gut feeling," "want to chew on" something, or find someone's opinions "hard to swallow." When something does go wrong with the digestive system, even something minor, most people seek immediate relief. For this reason, every hour of television programming contains advertisements for toothpaste and mouthwash, dietary supplements, antacids, and laxatives. All living organisms must obtain nutrients from their environment to sustain life. These substances serve as raw materials for synthesizing essential compounds (anabolism). They are also broken down to provide the energy that cells need to continue functioning (catabolism). \bigcirc pp. 61–63, 237–239

In this chapter, we discuss the structure and function of the digestive tract and several digestive glands, notably the liver and pancreas, and the process of digestion.

Build Your Knowledge

Recall that the digestive system processes food and absorbs nutrients (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). Nutrients are the substances from food that are necessary for normal physiological functions. They include carbohydrates, proteins, fats, vitamins, minerals, and water. **Dpp. 39, 64**

16-1 The digestive system the digestive tract and accessory organs—performs various food-processing functions

Learning Outcome Identify the organs of the digestive system, list their major functions, and describe the four layers of the wall of the digestive tract.

In our bodies, the digestive system provides the fuel that keeps all the body's cells functioning. It also provides the building blocks needed for cell growth and repair. The respiratory system works with the cardiovascular system to supply the oxygen needed to "burn" metabolic fuels (catabolism).

The **digestive system** consists of a muscular tube, the **digestive tract**, and various **accessory organs**. The digestive tract is also called the *gastrointestinal (GI) tract* or *alimentary canal*. It begins with the oral cavity (mouth) and continues through the pharynx (throat), esophagus, stomach, small intestine, and large intestine. It ends at the rectum and anus. These subdivisions of the digestive tract have overlapping functions, but each region has certain areas of specialization and shows distinctive histological specializations.

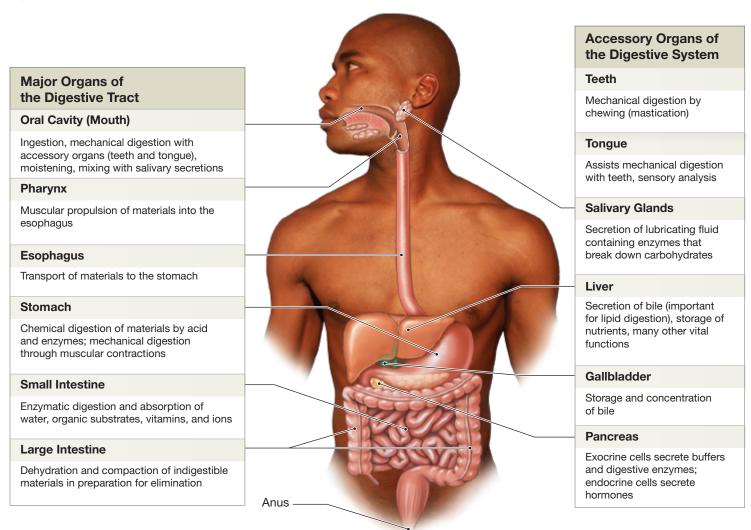

Accessory digestive organs include the teeth, tongue, and glandular organs such as the salivary glands, liver, and pancreas, as well as the gallbladder, which has a storage function. Glandular organ secretions and the gallbladder contents enter ducts that empty into the digestive tract. The major components of the digestive system are shown in **Figure 16-1**.

Functions of the Digestive System

Digestive functions involve six related processes:

- **1. Ingestion** takes place when food and drink enter the oral cavity (mouth) of the digestive tract.
- 2. Mechanical digestion is the crushing and shearing that makes solid foods easier to propel along the digestive tract. It also increases their surface area, making them more susceptible to attack by enzymes. The tongue and the teeth in the oral cavity begin the process. Swirling, mixing, and churning motions of the stomach and intestines provide mechanical digestion after ingestion.
- **3. Chemical digestion** refers to the chemical breakdown of food into small organic molecules that can be absorbed by the digestive epithelium.
- **4. Secretion** is the release of water, acids, enzymes, buffers, and salts by the epithelium of the digestive tract, the glandular organs, and the gallbladder.
- **5. Absorption** is the movement of small organic molecules, electrolytes (inorganic ions), vitamins, and water across the digestive epithelium and into the interstitial fluid of the digestive tract.

Figure 16-1 The Components of the Digestive System.

6. Defecation (def-e-KĀ-shun) is the elimination of wastes from the body. Within the digestive tract, waste products from glandular and secretory organs mix with indigestible materials of the digestive process and gallbladder. These waste products are dehydrated, compacted, and ejected from the digestive tract as *feces*.

The lining of the digestive tract also plays a defensive role. It protects surrounding tissues from (1) the corrosive effects of digestive acids and enzymes, (2) physical stresses, such as abrasion, and (3) bacteria that either are swallowed with food or reside in the digestive tract. The digestive epithelium and its secretions provide a nonspecific defense against these bacteria. When bacteria reach the underlying tissues, macrophages and other cells of the immune system attack them. \bigcirc pp. 511, 517

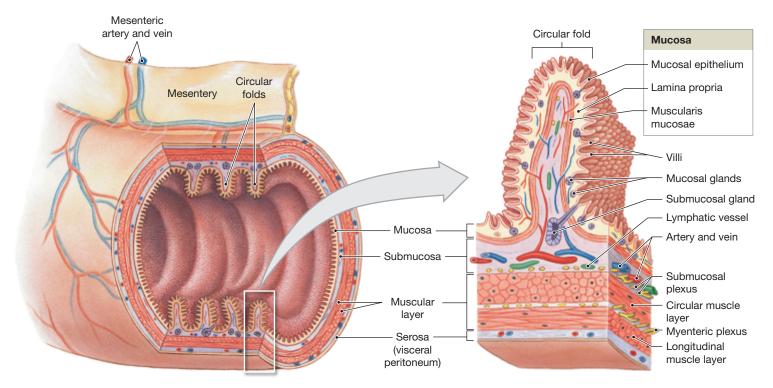

Histological Organization of the Digestive Tract

The digestive tract has four major layers: the *mucosa*, the *submucosa*, the *muscular layer*, and the *serosa* (Figure 16-2).

The Mucosa

The **mucosa**, or inner lining of the digestive tract, is a *mucous membrane*. D p. 140 It consists of an epithelium moistened by glandular secretions, called the mucosal epithelium, and an underlying layer of areolar tissue, the *lamina propria*. Along most of the length of the digestive tract, the mucosa has permanent transverse *circular folds*. The folding increases the surface area available for absorption. In the small intestine, the mucosa forms fingerlike projections, called *villi* (*villus*, shaggy hair), that further increase the area for absorption.

Figure 16-2 The Structure of the Digestive Tract. A diagrammatic view of a representative portion of the digestive tract. The features illustrated are typical of the small intestine. The wall of the digestive tract is made up of four layers: the mucosa, submucosa, muscular layer, and serosa.

The oral cavity, pharynx, esophagus, and anus (where mechanical stresses are most severe) are lined by a stratified squamous epithelium. The remainder of the digestive tract is lined by a simple columnar epithelium, often containing various types of secretory cells. Ducts opening onto the epithelial surfaces carry the secretions of glands located in the lamina propria, in the surrounding submucosa, or within accessory secretory organs.

In most regions of the digestive tract, the outer portion of the mucosa contains a narrow band of smooth muscle and elastic fibers. The circular folds and villi are moved by contractions of this layer, called the *muscularis* (mus-kū-LA-ris) *mucosae* (mū-KŌ-sē) (**Figure 16-2**).

The Submucosa

The **submucosa** is a layer of dense irregular connective tissue that binds the mucosa to the muscular layer. The submucosa contains numerous blood vessels and lymphatic vessels. Along its outer margin, it contains a network of nerve fibers, sensory neurons, and parasympathetic motor neurons. This neural network is the *submucosal plexus*. It is involved in controlling contractions of the smooth muscle in the muscularis mucosae. It is also involved in regulating the secretion of digestive glands.

The Muscular Layer

The **muscular layer** is a band of smooth muscle cells arranged in an inner circular layer and an outer longitudinal layer (**Figure 16-2**). Contractions of these layers agitate and propel materials along the digestive tract. Both actions are controlled primarily by another neural network, the *myenteric plexus* (*mys*, muscle + *enteron*, intestine). It lies between the circular and longitudinal smooth muscle layers. The myenteric and submucosal plexus make up the *enteric nervous system* (*ENS*) \bigcirc p. 274) The myenteric plexus contains parasympathetic ganglia, sensory neurons, interneurons, and sympathetic postganglionic fibers. Parasympathetic stimulation increases muscular tone and activity. Sympathetic stimulation promotes muscular inhibition and relaxation.

The Serosa

The **serosa**, a serous membrane, covers the muscular layer along most portions of the digestive tract enclosed by the peritoneal cavity. This *visceral peritoneum* is continuous with the *parietal peritoneum*, which lines the inner surfaces of the body wall. \bigcirc p. 141 In some areas within the peritoneal cavity, portions of the digestive tract are suspended by **mesenteries** (MEZ-en-ter-ēz). Mesenteries are double sheets of serous membrane composed of the parietal peritoneum and visceral peritoneum. The loose connective tissue sandwiched between the epithelial surfaces of the mesenteries provides a pathway for the blood vessels, nerves, and lymphatic vessels servicing the digestive tract. The mesenteries also stabilize the positions of the attached organs. They prevent the intestines from becoming entangled during digestive movements or sudden changes in body position.

There is no serosa covering the muscular layer of the oral cavity, pharynx, esophagus, and rectum. Instead, the muscular layer is surrounded by dense connective tissue with collagen fibers that firmly attaches these regions of the digestive tract to adjacent structures. This fibrous wrapping is called an *adventitia* (ad-ven-TISH-uh).

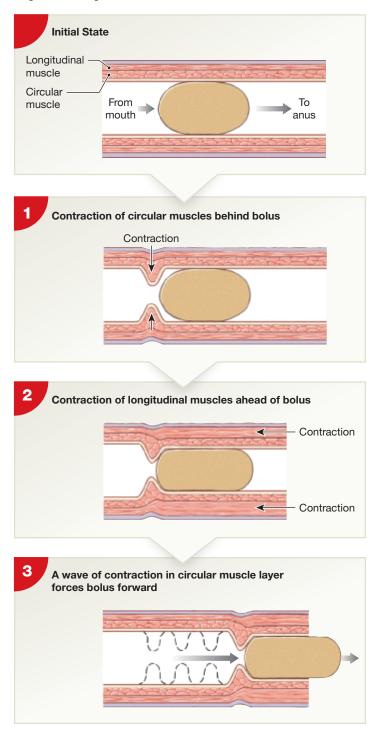

Build Your Knowledge

Recall that smooth muscle is found within almost every organ, forming sheets, bundles, and sheaths around other tissues (as you saw in **Chapter 7: The Muscular System**). Smooth muscle cells are able to contract over a greater range of lengths than skeletal or cardiac muscle. This ability is important in organs that undergo large changes in volume, such as the stomach. In addition, many smooth muscles are not innervated by motor neurons. Instead, they contract either automatically (in response to pacesetter cells) or in response to environmental or hormonal stimulation. ⊃ **pp. 242, 243**

The Movement of Digestive Materials

Recall that the muscular layers of the digestive tract consist of smooth muscle tissue. *Pacesetter cells* in the smooth muscle of the digestive tract trigger waves of contraction, making rhythmic cycles of activity. The coordinated contractions in the walls of the digestive tract play a vital role in two processes: *peristalsis (peri-,* around + *stalsis,* constriction); and *segmentation.* Peristalsis refers to the movement of material along the tract. Segmentation is the mechanical mixing of the material.

The muscular layer propels materials from one part of the digestive tract to another by means of **peristalsis** (per-i-STAL-sis), waves of muscular contractions that move along the digestive tract (**Figure 16-3**). During a peristaltic movement, the circular muscles first contract behind the digestive contents, such as a *bolus* (food mass). Then longitudinal muscles **Figure 16-3 Peristalsis.** Peristalsis propels materials along the length of the digestive tract.

contract, shortening adjacent segments of the tract. A wave of contraction in the circular muscles then forces the materials in the desired direction.

Regions of the small intestine also carry out **segmentation**, movements that churn and break up digestive materials. Over time, this action thoroughly mixes the contents with intestinal secretions. Because segmentation movements do not follow a set pattern, they do not propel materials in any particular direction.

CHECKPOINT

- 1. Identify the organs of the digestive system.
- **2.** List and define the six primary functions of the digestive system.
- **3**. Describe the functions of the mesenteries.
- **4.** Name the layers of the digestive tract from superficial to deep.
- **5.** Which is more efficient in propelling intestinal contents from one place to another—peristalsis or segmentation?

See the blue Answers tab at the back of the book.

16-2 The oral cavity contains the tongue, salivary glands, and teeth, each with specific functions

Learning Outcome Discuss the anatomy of the oral cavity, and list the functions of its major structures.

The **oral cavity** (mouth), or **buccal** (BUK-ul) **cavity**, is the part of the digestive tract that receives food. The oral cavity

is lined by the *oral mucosa*, which has a stratified squamous epithelium. The oral cavity (1) senses and analyzes food before swallowing; (2) mechanically digests food through the actions of the teeth, tongue, and surfaces of the palate; (3) lubricates food by mixing it with mucus and salivary gland secretions; and (4) begins limited chemical digestion of carbohydrates and lipids with salivary enzymes.

The boundaries of the oral cavity are shown in **Figure 16-4**. The mucosae of the *cheeks*, or lateral walls of the oral cavity, are supported by pads of fat and the buccinator muscles. Anteriorly, the mucosa of each cheek is continuous with that of the lips, or **labia** (LĀ-bē-uh; singular, *labium*). The **vestibule** is the space between the cheeks (or lips) and the teeth. The **gingivae** (JIN-ji-vē; singular, *gingiva*), or gums, are pink ridges of oral mucosae that surround the bases of the teeth. They cover the tooth-bearing surfaces of the upper and lower jaws.

The **hard palate** and **soft palate** form the roof for the oral cavity. The tongue dominates its floor. The free anterior portion of the tongue is connected to the oral cavity floor by a thin fold of mucous membrane, the **frenulum** (FREN-yū-lum; *frenum*, bridle) **of tongue**, or *lingual frenulum*. The imaginary dividing line between the oral cavity and the oropharynx extends between the base of the tongue and the dangling *uvula* (Ū-vū-luh). The uvula helps prevent food from entering the pharynx too soon.

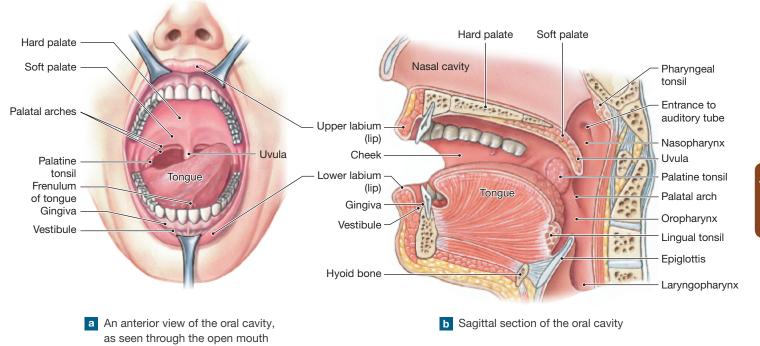

Figure 16-4 The Oral Cavity.

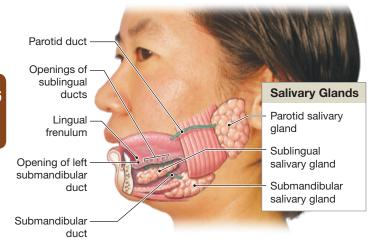

The Tongue

The muscular **tongue** manipulates materials inside the mouth and is occasionally used to bring foods (such as ice cream) into the oral cavity. The primary functions of the tongue are (1) mechanical digestion by compression, abrasion, and distortion; (2) manipulation to assist in chewing and to prepare food for swallowing; and (3) sensory analysis by touch, temperature, and taste receptors. Small glands under the tongue secrete the enzyme *lingual lipase*. This enzyme begins lipid digestion in the oral cavity. Most of the tongue lies within the oral cavity, but the base of the tongue extends into the oropharynx. A pair of prominent lateral swellings at the base of the tongue marks the location of the *lingual tonsils*, clusters of lymphoid nodules that help resist infections. \bigcirc pp. 506, 508

Salivary Glands

Three pairs of salivary glands secrete into the oral cavity (Figure 16-5). On each side, a large **parotid salivary gland** lies under the skin covering the lateral and posterior surface of the mandible. \bigcirc p. 190 The **parotid duct** empties into the vestibule at the level of the second upper molar. The **sublingual salivary glands** are located beneath the mucous membrane of the floor of the mouth. Numerous sublingual ducts open along either side of the lingual frenulum.

Figure 16-5 The Salivary Glands. This lateral view shows the relative positions of the salivary glands and ducts on the left side of the head. For clarity, the left ramus and body of the mandible have been removed.

The **submandibular salivary glands** are in the floor of the mouth along the inner surfaces of the mandible. Their ducts open into the mouth behind the teeth on either side of the lingual frenulum.

These salivary glands produce 1.0–1.5 liters of saliva each day. What makes up saliva? Saliva is 99.4 percent water, plus *mucins* and an assortment of ions, buffers, waste products, metabolites, and enzymes. Mucins are glycoproteins that absorb water and form mucus. Buffers in the saliva keep the pH of your mouth near 7. They prevent the buildup of acids produced by bacteria. At mealtimes, large quantities of saliva lubricate the mouth and dissolve chemicals that stimulate the taste buds. Coating the food with slippery mucus reduces friction and makes swallowing possible.

A continuous background level of secretion flushes and cleans the oral surfaces. Salivary antibodies (IgA) and *lysozyme* help control populations of oral bacteria. A reduction or loss of salivary secretions—caused by radiation, emotional distress, certain drugs, sleep, or other factors—triggers a bacterial population explosion. Recurring infections and the progressive erosion of the teeth and gums result.

Each of the salivary glands produces a slightly different kind of saliva. The parotid glands produce a secretion rich in **salivary amylase**, an enzyme that breaks down starches (complex carbohydrates) into smaller molecules that can be absorbed by the digestive tract. Saliva from the submandibular and sublingual salivary glands contains fewer enzymes but more buffers and mucus.

During eating, all three salivary glands increase their rates of secretion. Salivary production may reach 7 mL (0.24 fl oz) per minute, with about 70 percent of that volume provided by the submandibular glands. The autonomic nervous system normally controls salivary secretion.

Teeth

Movements of the tongue are important in passing food across the opposing surfaces of the **teeth**. These surfaces carry out chewing, or **mastication** (mas-ti-KĀ-shun), of food. Mastication breaks down tough connective tissues in meat and the plant fibers in vegetables. It also helps saturate the food with salivary secretions.

Figure 16-6a shows the parts of a sectioned tooth. The **neck** of the tooth marks the boundary between the **root** and the **crown**. The crown is the exposed portion of the tooth that projects beyond the gums. A layer of **enamel** covers the crown. Enamel contains a crystalline form of calcium phosphate. Enamel is the hardest biologically manufactured substance.

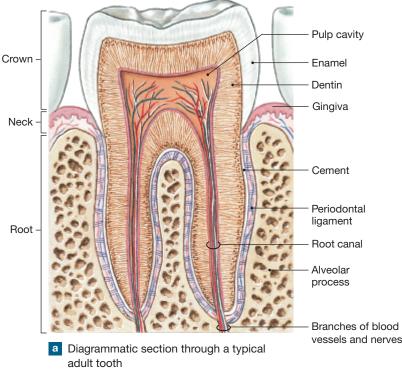

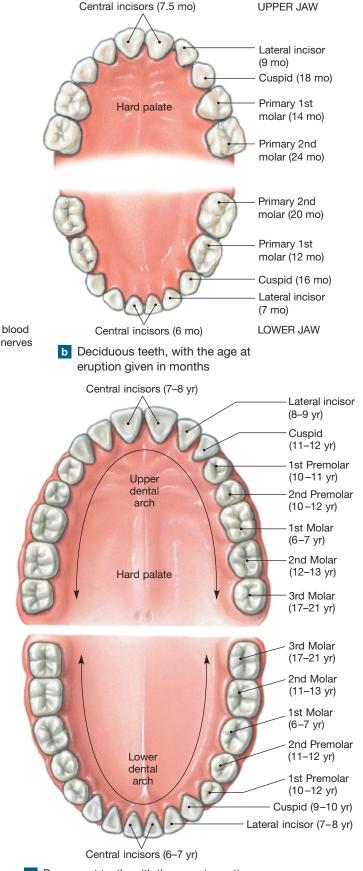

Figure 16-6 Teeth: Structural Components and Dental Succession.

Adequate amounts of calcium, phosphate, and vitamin D_3 during childhood are essential for an enamel coating that is complete and resistant to decay.

Most of each tooth consists of **dentin** (DEN-tin), a mineralized matrix similar to that of bone. Dentin differs from bone in that it does not contain cells. Instead, cytoplasmic processes extend into the dentin from cells within the central **pulp cavity**. The pulp cavity receives blood vessels and nerves through one to four narrow root canals at the root (base) of the tooth. The root of each tooth sits within a bony cavity or socket, called the tooth socket or alveolus (a hollow cavity). Collagen fibers of the periodontal ligament (peri-, around + odonto-, tooth) extend from the dentin of the root to the surrounding bone. A layer of cement (se-MENT) covers the dentin of the root, providing protection and firmly anchoring the periodontal ligament. Cement is similar in structure to bone, but softer. Where the tooth penetrates the gum surface, epithelial cells form tight attachments to the tooth and prevent bacterial access to the easily eroded cement of the root.

Tooth decay generally results from the action of bacteria that live in your mouth. Bacteria on the surfaces of the teeth produce a sticky matrix that traps food particles and creates

Permanent teeth, with the age at eruption given in years

deposits known as *dental plaque*. Over time, this organic matter can calcify and form a hard layer of *tartar*, or *dental calculus*, which can be difficult to remove.

Types of Teeth

A set of permanent teeth is shown in **Figure 16-6c**. Each of the four types of teeth has a specific function. **Incisors** (in-SĪ-zerz) are blade-shaped teeth at the front of the mouth. They are useful for clipping or cutting, as when you nip off the tip of a carrot stick. **Cuspids** (KUS-pidz), or *canines*, are conical, with a sharp ridgeline and a pointed tip. They are used for tearing or slashing. You might weaken a tough piece of celery by the clipping action of the incisors and then take advantage of the shearing action provided by the cuspids. **Bicuspids** (bī-KUS-pidz), or *premolars*, and **molars** have flattened crowns with prominent ridges. They are used for crushing, mashing, and grinding. You might shift a tough nut or piece of meat to the premolars and molars for crushing.

Dental Succession

Two sets of teeth form during development. The first to appear are the **deciduous teeth** (dē-SID-ū-us; *deciduus*, falling off), also known as *primary teeth*, *milk teeth*, or *baby teeth*. Most children have 20 deciduous teeth (**Figure 16-6b**). These teeth are later replaced by the **permanent teeth**, or *permanent dentition* (**Figure 16-6c**), which permit the processing of a wider variety of foods.

As replacement proceeds, the periodontal ligaments and roots of the deciduous teeth erode. The deciduous teeth either fall out or are pushed aside by the **eruption** (emergence) of the permanent teeth. Adult jaws are larger and can accommodate more than 20 teeth. As a person grows up, three additional teeth appear on each side of the upper and lower jaws, bringing the permanent tooth count to 32. The last teeth to appear are the *third molars*, or *wisdom teeth*. Wisdom teeth (or any other teeth) that develop in locations that do not permit their eruption are called *impacted teeth*. Impacted teeth can be surgically removed to prevent abscesses from forming.

CHECKPOINT

- 6. Name the structures associated with the oral cavity.
- 7. The oral cavity is lined by which type of epithelium?
- **8.** The digestion of which nutrient would be affected by damage to the parotid salivary glands?
- **9.** Which type of tooth is most useful for chopping off bits of raw vegetables?
- See the blue Answers tab at the back of the book.

16-3 The pharynx is a passageway between the oral cavity and the esophagus

Learning Outcome Describe the structures and functions of the pharynx and esophagus, and the key events of the swallowing process.

The Pharynx

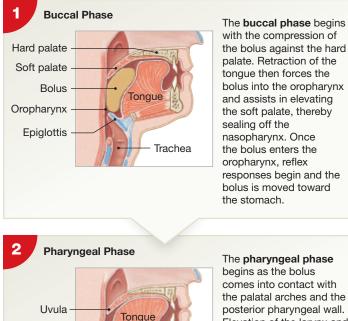

The **pharynx** (FAR-ingks), or throat, serves as a common passageway for solid food, liquids, and air. (The three major subdivisions of the pharynx were discussed in Chapter 15.) **)** p. 539 Food normally passes through the oropharynx and laryngopharynx on its way to the esophagus. Both of these regions of the pharynx have a stratified squamous epithelium similar to that of the oral cavity. The underlying lamina propria contains mucous glands plus the pharyngeal, palatal, and lingual tonsils. The pharyngeal muscles cooperate with muscles of the oral cavity and esophagus to begin the process of swallowing (described shortly). The muscular contractions during swallowing force the food mass into and along the esophagus.

The Esophagus

The **esophagus** (Figure 16-1) is a muscular tube that conveys solid food and liquids to the stomach. It is about 25 cm (10 in.) long and about 2 cm (0.75 in.) in diameter. It begins at the pharynx, runs posterior to the trachea in the neck, and passes through the mediastinum in the thoracic cavity. It then enters the abdominopelvic cavity through the *esophageal hiatus* (hī-Ā-tus; a gap or opening), an opening in the diaphragm. Finally it empties into the stomach. In a *diaphragmatic hernia*, or *hiatal* (hī-Ā-tal) *hernia*, abdominal organs slide up into the thoracic cavity through the esophageal hiatus.

The esophagus is lined with a stratified squamous epithelium that resists abrasion, hot or cold temperatures, and chemical attack. The secretions of esophageal mucous glands lubricate this epithelial surface and prevent materials from sticking to it during swallowing. The upper third of its muscular layer contains skeletal muscle, the lower third contains smooth muscle, and a mixture of each makes up the middle third.

Regions of circular muscle in the superior and inferior ends of the esophagus make up the *upper esophageal sphincter* and the *lower esophageal sphincter*. The lower sphincter is normally in active contraction. This condition prevents the backflow of materials from the stomach into the esophagus. **Figure 16-7 The Swallowing Process.** This sequence, based on a series of x-rays, shows the phases of swallowing and the movement of a bolus from the mouth to the stomach.

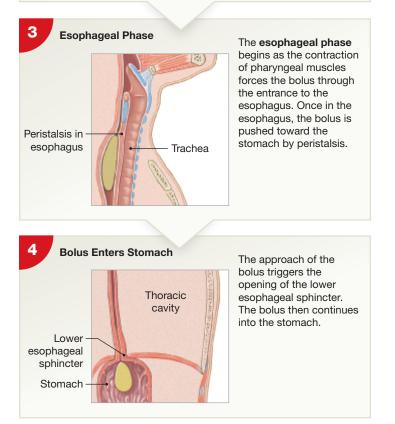

Bolus

Epiglottis

Larynx

comes into contact with the palatal arches and the posterior pharyngeal wall. Elevation of the larynx and folding of the epiglottis direct the bolus past the closed glottis. At the same time, the uvula and soft palate block passage back to the nasopharynx.

Swallowing

Swallowing, or **deglutition** (dē-gloo-TISH-un), is a complex process that can be initiated voluntarily but proceeds automatically once it begins. You take conscious control over swallowing when you eat or drink, but swallowing is also controlled at the subconscious level. Before food can be swallowed, it must have the proper texture and consistency. Once food has been shredded or torn by the teeth, moistened with salivary secretions, and "approved" by the taste receptors, the tongue begins compacting the debris into a small mass, or **bolus**.

We can divide the process of swallowing into three phases. The buccal, pharyngeal, and esophageal phases are detailed in **Figure 16-7**. The buccal phase is the only phase of swallowing that we can consciously control. The involuntary *swallowing reflex* begins when tactile receptors on the palatal arches and uvula are stimulated by the passage of the bolus.

CHECKPOINT

- **10.** Describe the function of the pharynx.
- **11.** What process is occurring when the soft palate and larynx elevate and the glottis closes?
- See the blue Answers tab at the back of the book.

16-4 The J-shaped stomach receives food from the esophagus and aids in chemical and mechanical digestion

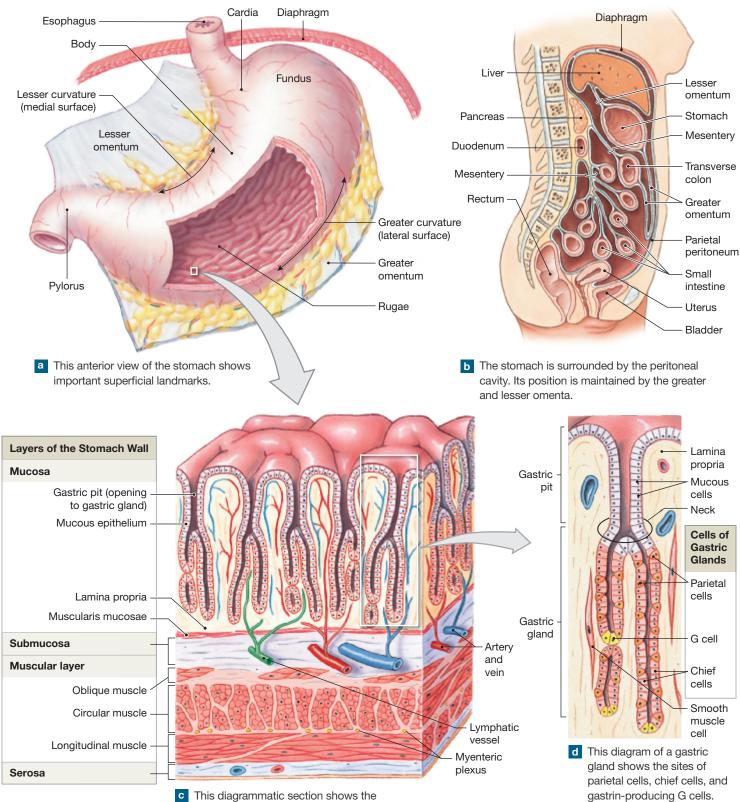

Learning Outcome Describe the anatomy of the stomach, including its histology, and discuss its roles in digestion and absorption.

The **stomach** has four primary functions: (1) storage of ingested food; (2) mechanical digestion of ingested food; (3) disruption of chemical bonds in food through the action of acids and enzymes; and (4) production of *intrinsic factor*, a compound necessary for the absorption of vitamin B_{12} in the small intestine. Ingested substances mix with secretions of the glands of the stomach. The result is a viscous, highly acidic, soupy mixture of partially digested food called **chyme** (KĪM).

The stomach is a muscular, J-shaped organ. It has four main regions (**Figure 16-8a**). The esophagus connects to the smallest region, the **cardia** (KAR-dē-uh). The bulge of the stomach superior to the cardia is the **fundus** (FUN-dus). The large area between the fundus and the curve of the J is the **body**. The **pylorus** (pī-LOR-us; *pyle*, gate + *ouros*, guard) is the distal part of the J. It connects the stomach with the small intestine. A muscular **pyloric sphincter** regulates the flow of chyme between the stomach and small intestine.

16

Figure 16-8 The Anatomy of the Stomach.

organization of the stomach wall.

The stomach's volume increases while you eat and then decreases as chyme enters the small intestine. When the stomach is relaxed (empty), the mucosa has prominent longitudinal folds, called **rugae** (ROO-gē; wrinkles). These temporary features let the gastric (*gaster*, stomach) lumen expand. As the stomach expands, the rugae gradually flatten out until, at maximum distension, they almost disappear. (The world record, set in 2013, for eating hot dogs with buns in ten minutes is 69!) When empty, the stomach resembles a muscular tube with a narrow and constricted lumen. When fully expanded, it can contain 1–1.5 liters of material.

Unlike the two-layered muscular layer of other parts of the digestive tract, that of the stomach contains three layers. It has a longitudinal layer, a circular layer, and an inner *oblique layer*. The extra layer of smooth muscle strengthens the stomach wall and assists in the mixing and churning essential to forming chyme.

The visceral peritoneum covering the outer surface of the stomach is continuous with a pair of mesenteries. The **greater omentum** (ō-MEN-tum; *omentum*, a fatty skin) extends below the *greater curvature* and forms an enormous pouch that hangs over and protects the abdominal viscera (**Figure 16-8b**). The much smaller **lesser omentum** extends from the *lesser curvature* to the liver.

The Gastric Wall

The stomach is lined by a simple columnar epithelium dominated by mucous cells. This *mucous epithelium* secretes an alkaline mucus that covers and protects epithelial cells from acids, enzymes, and abrasive materials. Shallow depressions, called **gastric pits**, open onto the gastric surface (**Figure 16-8c**). The mucous cells at the base, or *neck*, of each gastric pit actively divide and replace superficial cells of the mucous epithelium shed into the chyme. A typical gastric epithelial cell has a life span of three to seven days.

In the fundus and body of the stomach, each gastric pit is connected with **gastric glands** that extend deep into the underlying lamina propria (Figure 16-8d). Gastric glands are dominated by two types of secretory cells: *parietal cells* and *chief cells*. Together, they secrete about 1500 mL of **gastric juice** each day.

Gastric glands within the lower stomach (the *pylorus*) also contain endocrine cells that are involved in regulating gastric activity, as we discuss shortly.

Parietal Cells

Parietal cells secrete intrinsic factor and hydrochloric acid (HCl). **Intrinsic factor** aids the absorption of vitamin B_{12}

across the intestinal lining. (Recall from Chapter 11 that this vitamin is needed for normal erythropoiesis.) D p. 418 Hydrochloric acid lowers the pH of the gastric juice, keeping the stomach contents at a pH of 1.5–2.0. The acidity of gastric juice kills microorganisms, breaks down plant cell walls and connective tissues in meat, and activates enzymes secreted by chief cells.

Chief Cells

Chief cells secrete a protein called **pepsinogen** (pep-SIN-ō-jen) into the stomach lumen. When pepsinogen contacts the hydrochloric acid released by the parietal cells, it is converted to **pepsin**, a *proteolytic* (protein-digesting) *enzyme*. In newborn infants (but not adults), the stomach produces *rennin* and *gastric lipase*. These enzymes are important for the digestion of milk. Rennin coagulates milk proteins, thus slowing their passage through the stomach and allowing more time for its digestion. Gastric lipase begins the digestion of milk fats.

The Regulation of Gastric Activity

The production of acid and enzymes by the stomach mucosa can be (1) controlled by the central nervous system, (2) regulated by reflexes of the enteric nervous system coordinated in the wall of the stomach, and (3) regulated by hormones of the digestive tract. Regulation of gastric secretion proceeds in three overlapping phases. They are named according to the location of the control center: the cephalic phase, the gastric phase, and the intestinal phase (**Spotlight Figure 16-9**).

- Cephalic phase. The cephalic phase of gastric secretion begins when you sense or think of food (1) in Spotlight Figure 16-9). This phase prepares the stomach to receive food. It is directed by different regions of the CNS, including the cerebral cortex and hypothalamus. The neural output proceeds by way of the parasympathetic division of the ANS. The vagus nerves innervate the submucosal plexus of the stomach. Next, postganglionic parasympathetic fibers innervate mucous cells, parietal cells, chief cells, and endocrine cells of the stomach.
- 2. Gastric phase. The gastric phase begins when food arrives in the stomach (2) in Spotlight Figure 16-9). The stimulation of stretch receptors in the stomach wall and of chemoreceptors in the mucosa triggers local reflexes controlled by the submucosal and myenteric plexuses. The myenteric plexus stimulates mixing waves in the muscular layer of the stomach wall. The submucosal plexus stimulates the parietal cells and chief cells. It also

SPOTLIGHT Figure 16-9 REGULATION OF GASTRIC ACTIVITY

Gastric activity is regulated by the central nervous system, by reflexes within the walls of the digestive tract, and by hormones of the digestive tract. Regulation of gastric secretion proceeds in three overlapping phases, named according to the location of the control center.

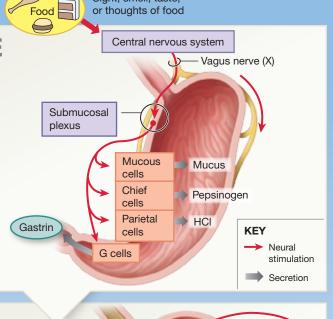

The *duodenum* (doo-ō-DĒ-num) is the portion of the small intestine closest to the stomach. It plays a key role in controlling digestion because it monitors the contents of the chyme that it receives from the stomach. The duodenum adjusts the activities of the stomach and accessory organs to protect lower (distal) portions of the small intestine.

CEPHALIC PHASE

The **cephalic phase** of gastric secretion begins when you see, smell, taste, or think of food. This phase is directed by the parasympathetic division of the autonomic nervous system. It prepares the stomach to receive food. In response to stimulation, the production of gastric juice speeds up, reaching rates of about 500 mL/h, or about 2 cups per hour. This phase generally lasts only minutes.

² GASTRIC PHASE

The **gastric phase** begins when food arrives in the stomach. The stimulation of stretch receptors in the stomach wall and of chemoreceptors in the mucosa triggers local reflexes in the submucosal and myenteric plexuses. This results in mixing waves from the muscular layer, and the secretion of mucus, pepsinogen, and HCl from the cells of the gastric glands.

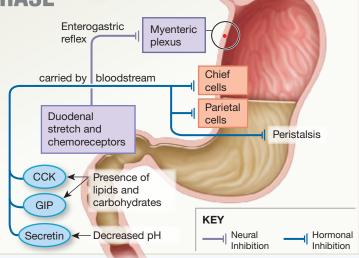

Sight, smell, taste,

Submucosal and Stretch Distension myenteric plexuses receptors Elevated pH -> Chemoreceptors carried by Mucous Mucus bloodstream cells Chief Pepsinogen cells Mixing waves Parietal Gastrin HCI cells KEY Partly G cells Neural digested stimulation peptides Hormonal stimulation

³ INTESTINAL PHASE

The **intestinal phase** of gastric secretion begins when chyme first enters the duodenum of the small intestine. The function of the intestinal phase is to control the rate of gastric emptying to ensure that the secretory, digestive, and absorptive functions of the small intestine can proceed efficiently.

CLINICAL NOTE

Gastritis and Peptic Ulcers

Inflammation of the gastric mucosa is called **gastritis** (gas-TRĪ-tis). It can develop after a person has swallowed drugs, including alcoholic beverages and aspirin. Gastritis is also associated with smoking, severe emotional or physical stress, bacterial infection of the gastric wall, or ingestion of strongly acidic or alkaline chemicals.

Gastritis may lead to ulcer formation. A **peptic ulcer** develops when the digestive acids and enzymes erode the lining of the stomach or proximal portion of the small intestine (duodenum). The terms **gastric ulcer** (in the stomach) or **duodenal ulcer** (in the duodenum of the small intestine) indicate specific locations. Peptic ulcers result from excessive production of acid or inadequate production of the alkaline mucus that protects the epithelium against that acid. It is now known that infection by the bacterium *Helicobacter pylori* is responsible for over 80 percent of peptic ulcers. Treatment for ulcers involves the administration of drugs such as *cimetidine* (*Tagamet*) that inhibit gastric acid production, combined with antibiotics if *Helicobacter pylori* is present.

stimulates **G cells** in gastric glands within the pylorus to release the hormone **gastrin** into the bloodstream. Proteins, alcohol in small doses, and caffeine are potent stimulators of gastric secretion because they excite the chemoreceptors in the gastric lining. Both parietal and chief cells respond to the presence of gastrin by accelerating their secretory activities. The effect on the parietal cells is the most pronounced, and the pH of the gastric juice drops sharply. This phase may continue for several hours while the acids and enzymes process the ingested materials.

During this period, gastrin also stimulates stomach contractions, which mix the ingested materials with the gastric secretions to form chyme. As mixing proceeds, the contractions begin sweeping down the length of the stomach. Each time the pylorus contracts, a small quantity of chyme squirts through the pyloric sphincter into the small intestine.

3. Intestinal phase. The intestinal phase of gastric secretion begins when chyme first enters the duodenum of the small intestine (3) in Spotlight
Figure 16-9). Most of the regulatory controls for this phase (whether neural or endocrine) are inhibitory. By controlling the rate of gastric emptying, they ensure that all functions of the small intestine can proceed efficiently. For example, the movement of chyme

CLINICAL NOTE

Stomach Cancer

Stomach (or *gastric*) **cancer** is one of the most common lethal cancers. The incidence is higher in Japan and Korea, where the typical diet includes large quantities of pickled foods. Because the signs and symptoms can resemble those of gastric ulcers, the condition may not be reported in its early stages. Diagnosis usually involves x-rays of the stomach at various degrees of distension. \supset p. 50

The treatment of stomach cancer involves a *gastrectomy* (gas-TREK-to-mē), the surgical removal of part or all of the stomach. The lack of intrinsic factor (produced by the stomach) can be overcome with high daily doses of vitamin B_{12} .

temporarily reduces the stimulation of stretch receptors in the stomach wall and increases their stimulation in the wall of the small intestine. This produces the *enterogastric reflex*. This reflex temporarily inhibits neural stimulation of gastrin production and gastric motility, and further movement of chyme. At the same time, the entry of chyme stimulates the release of the intestinal hormones *secretin, cholecystokinin (CCK)*, and *gastric inhibitory peptide (GIP)*. The resulting reduced gastric activity gives the small intestine time to adjust to the arriving acids.

Inhibitory reflexes that depress gastric activity are stimulated when the proximal portion of the small intestine becomes too full, too acidic, unduly irritated by chyme, or filled with partially digested proteins, carbohydrates, or fats.

In general, chyme moves into the small intestine at the highest rate when the stomach is greatly distended and the meal contains relatively little protein. A large meal containing small amounts of protein, large amounts of carbohydrates (such as rice or pasta), wine (alcohol), and after-dinner coffee (caffeine) will leave your stomach extremely quickly. Why? This happens because both alcohol and caffeine stimulate gastric secretion and motility.

Digestion in the Stomach

The stomach carries out the preliminary digestion of proteins by pepsin. For a variable period, it allows the digestion of carbohydrates by salivary amylase and of lipids by lingual lipase. These enzymes continue to work until the pH of the stomach contents falls below 4.5. They generally remain active one to two hours after a meal. As the stomach contents become more fluid and the pH approaches 2.0, pepsin activity increases. Protein disassembly begins. Protein digestion is not completed in the stomach, because time is limited and pepsin attacks only certain peptide bonds. However, pepsin typically breaks down complex proteins into smaller peptide and polypeptide chains before chyme enters the small intestine.

Chemical digestion occurs in the stomach, but nutrients are not absorbed there. Why not? There are four reasons: (1) the epithelial cells are covered by a blanket of alkaline mucus and are not directly exposed to chyme, (2) the epithelial cells lack the specialized transport processes found in cells lining the small intestine, (3) the gastric lining is impermeable to water, and (4) digestion has not been completed by the time chyme leaves the stomach. At this stage, most carbohydrates, lipids, and proteins are only partially broken down.

CHECKPOINT

- **12.** Name the four main regions of the stomach.
- **13.** Discuss the significance of the low pH in the stomach.
- **14.** In a person suffering from chronic gastric ulcers, why might the branches of the vagus nerves serving the stomach be cut in an attempt to provide relief?
- See the blue Answers tab at the back of the book.

16-5 The small intestine chemically digests and absorbs nutrients

Learning Outcome Describe the anatomy of the small intestine, including its histology, and explain the functions and regulation of intestinal secretions.

The **small intestine** plays a key role in digesting and absorbing nutrients. Ninety percent of nutrient absorption takes place there. (Most of the rest takes place in the large intestine.)

The small intestine is about 6 m (20 ft) long. Its diameter ranges from 4 cm (1.6 in.) at the stomach to about 2.5 cm (1 in.) at the junction with the large intestine. It has three segments: the *duodenum*, the *jejunum*, and the *ileum* (Figure 16-10a):

1. The **duodenum** (doo-ō-DĒ-num), 25 cm (10 in.) in length, is the segment closest to the stomach. This portion of the small intestine is the "mixing bowl." It receives chyme from the stomach and digestive secretions from the pancreas and liver. From its connection with the stomach, the duodenum curves in a C that encloses the pancreas. Except for its proximal 2.5 cm (1 in.), the duodenum lies outside the peritoneal cavity (**Figure 16-8b**, p. 578). Organs that lie posterior to the peritoneal cavity are called **retroperitoneal** (*retro*, behind).

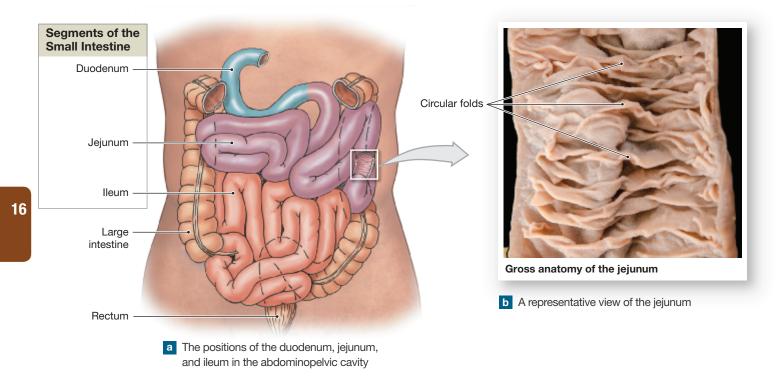

Figure 16-10 The Segments of the Small Intestine.

- An abrupt bend marks the boundary between the duodenum and the jejunum (je-JOO-num). At this site, the small intestine reenters the peritoneal cavity, supported by a sheet of mesentery. The jejunum is about 2.5 meters (8 ft) long. The bulk of chemical digestion and nutrient absorption takes place in the jejunum. One rather drastic approach to weight control involves surgery to remove a significant portion of the jejunum.
- **3.** The **ileum** (IL-ē-um), the final segment of the small intestine, is also the longest. It averages 3.5 m (12 ft) in length. The ileum ends at the *ileocecal valve*. This sphincter controls the flow of material from the ileum into the *cecum*, the first portion of the large intestine.

The small intestine fills much of the peritoneal cavity. Its position is stabilized by a mesentery attached to the dorsal body wall (Figure 16-8b, p. 578). Blood vessels, lymphatic vessels, and nerves run to and from the segments of the small intestine within the connective tissue of the mesentery.

The Intestinal Wall

The intestinal lining bears a series of transverse folds called **circular folds**, or *plicae circulares* (PLĪ-sē sir-kū-LAR-ēz) (**Figure 16-10b**). The circular folds are permanent features. They do not disappear when the small intestine fills.

The mucosa of the small intestine is composed of a multitude of fingerlike projections called **villi** (Figure 16-11b). These structures are covered by a simple columnar epithelium carpeted with microvilli (Figure 16-11c). Because the microvilli project from the epithelium like the bristles on a brush, these cells are said to have a *brush border* (Figure 16-11d).

If the small intestine were a simple tube with smooth walls, it would have a total absorptive area of about 3300 cm² (3.6 ft²). Instead, the mucosa contains roughly 800 circular folds. Each circular fold supports a forest of villi, and each villus is covered by epithelial cells blanketed in microvilli. This arrangement increases the total area for absorption to approximately 2 million cm², or more than 2200 ft².

Each villus contains a network of capillaries that originate in the submucosa (Figure 16-11c). These capillaries carry absorbed nutrients to the hepatic portal circulation for delivery to the liver. D p. 489 In addition to capillaries, each villus contains nerve endings and a lymphatic capillary called a **lacteal** (LAK-tē-ul; *lacteus*, milky). Lacteals transport materials that cannot enter blood capillaries. For example, absorbed fatty acids are carried in protein-lipid packages that are too large to diffuse into the bloodstream. These packets, called *chylomicrons (chylos*, juice), reach the venous circulation by way of the thoracic duct of the lymphatic system. The name *lacteal* refers to the pale, milky appearance of lymph that contains large quantities of lipids.

The most important enzymes introduced into the intestinal lumen come from the exposed microvilli of intestinal cells. Brush border enzymes break down materials that come into contact with the brush border. The epithelial cells then absorb the breakdown products. When these cells are shed, they disintegrate within the lumen, releasing both intracellular and brush border enzymes.

At the bases of the villi are entrances to *intestinal glands* (Figure 16-11b). Stem cells within the bases of the intestinal glands divide continuously to replenish the intestinal epithelium. Other cells secrete a watery *intestinal juice*. In addition to the intestinal glands, the duodenum contains large *duodenal glands*, or *submucosal glands*, which secrete an alkaline mucus that helps buffer the acids in chyme. Intestinal glands also contain endocrine cells that produce intestinal hormones discussed in a later section.

Intestinal Movements

After chyme has entered the duodenum, weak peristaltic contractions move it slowly toward the jejunum. These contractions are local reflexes not under CNS control. Their effects are limited to within a few centimeters of the site of the original stimulus.

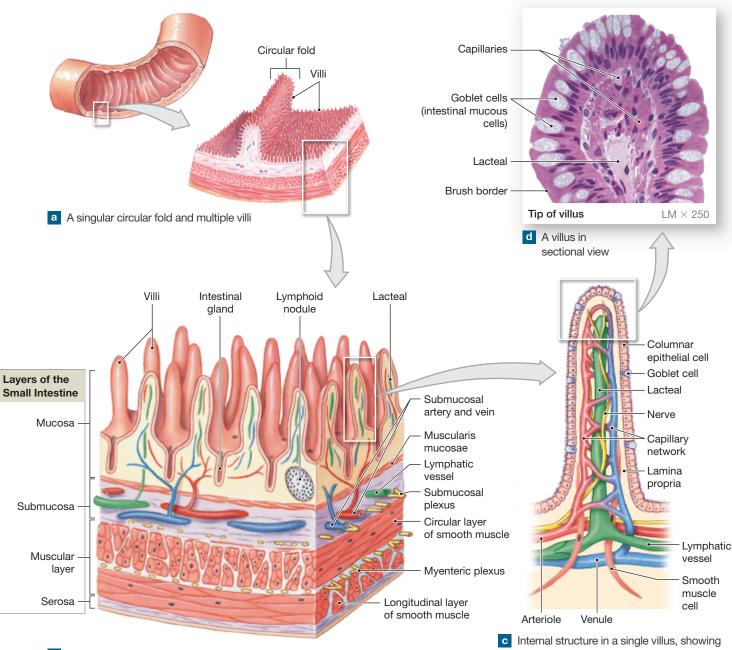

More elaborate reflexes coordinate activities along the entire length of the small intestine. Distension of the stomach initiates the *gastroenteric* (gas-trō-en-TER-ik) *reflex*. This reflex immediately speeds up glandular secretion and peristaltic activity in all intestinal segments. The increased peristalsis moves materials along the length of the small intestine and empties the duodenum.

The *gastroileal* (gas-trō-IL-ē-al) *reflex* is a response to circulating levels of the hormone gastrin. The entry of food into the stomach triggers the release of gastrin, which relaxes the ileocecal valve at the entrance to the large intestine. With the valve relaxed, peristalsis pushes materials from the ileum into the large intestine. On average, it takes about five hours for ingested food to pass from the duodenum to the end of the ileum. So, the first of the materials to enter the duodenum after breakfast may leave the small intestine during lunch.

Intestinal Secretions

Roughly 1.8 liters of watery **intestinal juice** enters the intestinal lumen each day. Intestinal juice moistens the intestinal contents, helps buffer acids, and keeps both the digestive

Figure 16-11 The Intestinal Wall.

b The organization of the intestinal wall

16

enzymes and the products of digestion in solution. Much of this fluid arrives by osmosis, as water flows out of the mucosa. The rest is secreted by intestinal glands stimulated by the activation of touch and stretch receptors in the intestinal walls.

Hormonal and CNS controls are important in regulating the secretions of the digestive tract and accessory organs. The duodenum is the focus of these regulatory processes, because it is the first segment of the intestine to receive chyme. Here the acid content of the chyme must be neutralized and the appropriate enzymes added. The duodenal glands protect the duodenal

epithelium from gastric acids and enzymes. They increase their secretions in response to local reflexes and also to parasympathetic stimulation carried by the vagus nerves.

As a result of parasympathetic stimulation, the duodenal glands begin secreting during the cephalic phase of gastric secretion, long before chyme reaches the pyloric sphincter. Sympathetic stimulation inhibits their activation, leaving the duodenal lining relatively unprepared for the arrival of the acidic chyme. This is probably why duodenal ulcers can be caused by chronic stress or by other factors that promote sympathetic activation.

CLINICAL NOTE

Vomiting

The vomiting reflex occurs in response to chemical or mechanical irritation of the soft palate, pharynx, esophagus, stomach, or proximal portions of the small intestine. The sensations of irritation are relayed to the vomiting center of the medulla oblongata, which coordinates the motor responses. In preparation, the pylorus relaxes, and the contents of the duodenum and proximal ieiunum are discharged into the stomach by strong peristaltic waves that travel toward the stomach rather than toward the ileum. Vomiting, or emesis (EM-e-sis), then takes place as the stomach regurgitates its contents through the esophagus and pharynx. As regurgitation occurs, the uvula and soft palate block the entrance to the nasopharynx. Increased salivary secretion assists in buffering the stomach acids, preventing erosion of the teeth. Such damage is one sign of the eating disorder *bulimia*, in which some people force themselves to vomit in order to lose weight.

Intestinal Hormones

Duodenal endocrine cells produce various peptide hormones that coordinate the secretory activities of the stomach, duodenum, pancreas, and liver. We introduced these hormones in the discussion on the regulation of gastric activity. **Spotlight Figure 16-9** indicates the factors that stimulate their secretion.

Gastrin is secreted by duodenal cells in response to large quantities of incompletely digested proteins. Gastrin promotes increased stomach motility and stimulates the production

of acids and enzymes. (Recall that gastrin is also secreted by endocrine cells in the distal portion of the stomach.)

Secretin (sē-KRĒ-tin) is released when the pH in the duodenum falls as acidic chyme arrives from the stomach. The primary effect of secretin is to increase the secretion of bile by the liver and buffers by the pancreas.

Cholecystokinin (kō-lē-sis-tō-KĪ-nin), or **CCK**, is secreted when chyme arrives in the duodenum, especially when it contains lipids and partially digested proteins. CCK also targets the pancreas and gallbladder. In the pancreas, CCK speeds up the production and secretion of all types of digestive enzymes. At the gallbladder, it causes the ejection of *bile* into the duodenum. The presence of either secretin or CCK in high concentrations also reduces gastric motility and the rates of secretions.

Gastric inhibitory peptide (GIP) is released when fats and carbohydrates (especially glucose) enter the small intestine. GIP inhibits gastric activity and causes the release of insulin from the pancreatic islets.

The functions of the major gastrointestinal hormones are summarized in Table 16-1. Their interactions are diagrammed in Figure 16-12.

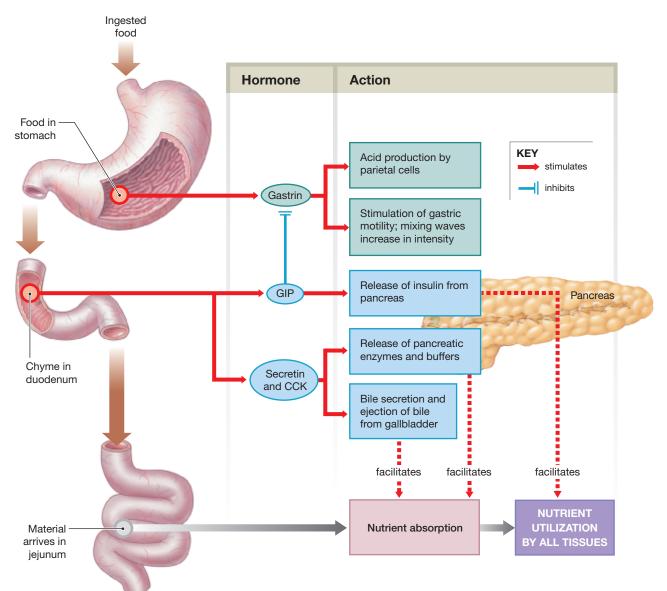

Digestion in the Small Intestine

In the stomach, food becomes saturated with gastric juices and exposed to the digestive effects of a strong acid (HCl) and a proteolytic enzyme (pepsin). Most of the chemical digestive processes are completed in the small intestine, where the final products of digestion—simple sugars, fatty acids, and

Table 16-1	mportant Gastrointestinal Hormones and Their Primary Effects						
Hormone	Stimulus	Origin	Target	Effects			
Gastrin	Vagus nerve stimulation or arrival of food in the stomach	Stomach	Stomach	Stimulates production of acids and enzymes, increases motility			
	Arrival of chyme containing large quantities of undigested proteins	Duodenum	Stomach	Stimulates production of acids and enzymes, increases motility

amino acids—are absorbed, along with most of the water content. However, the small intestine produces only a few of the enzymes needed to break down the complex materials found in the diet. The liver and pancreas contribute most of the enzymes and buffers, as we discuss next.

CHECKPOINT

16

- **15.** Which ring of muscle regulates the flow of chyme from the stomach to the small intestine?
- **16.** Name the three segments of the small intestine from proximal to distal.
- **17.** How is the small intestine adapted for the absorption of nutrients?
- See the blue Answers tab at the back of the book.

16-6 The pancreas, liver, and gallbladder are accessory organs that assist with chemical digestion in the small intestine

Learning Outcome Describe the structure and functions of the pancreas, liver, and gallbladder, and explain how their activities are regulated.

The pancreas provides digestive enzymes, as well as buffers that help neutralize chyme. The liver secretes *bile*, a solution stored in the gallbladder for later discharge into the small intestine. Bile contains buffers and *bile salts*, compounds that aid the digestion and absorption of lipids.

The Pancreas

The **pancreas** lies posterior to the stomach. It extends laterally from the duodenum toward the spleen (**Figure 16-13a**). It is a long, pinkish-gray organ, about 15 cm (6 in.) in length with a weight of around 80 g (3 oz). The surface of the pancreas has a lumpy texture, and its tissue is soft and easily torn. Like the duodenum, the pancreas is retroperitoneal. Only its anterior surface is covered by peritoneum (**Figure 16-8b**).

Histological Organization of the Pancreas

The pancreas has two distinct functions, one endocrine and the other exocrine. Recall from Chapter 10 that the pancreas contains collections of endocrine cells called **pancreatic islets** that secrete the hormones insulin and glucagon. \bigcirc p. 393 However, these cells account for only about 1 percent of the cell population of the pancreas. Exocrine cells and their associated ducts account for the rest. The pancreas is primarily an exocrine organ that produces a mixture of digestive enzymes, water, and buffers called **pancreatic juice**.

The numerous ducts that branch throughout the pancreas end at saclike pouches called **pancreatic acini** (AS-i-nī; singular *acinus*, grape) (**Figure 16-13b**). The *acinar cells* of these pouches secrete digestive enzymes. The epithelial cells that line the ducts secrete buffers and water that neutralize and dilute the acid in the chyme. The smaller ducts converge to form larger ducts that fuse to form the **pancreatic duct**, which carries these secretions to the duodenum. The pancreatic duct penetrates the duodenal wall with the *bile duct* from the liver and gallbladder.

Pancreatic enzymes do most of the digestive work in the small intestine. These digestive enzymes are broadly classified according to their intended targets. **Carbohydrases**

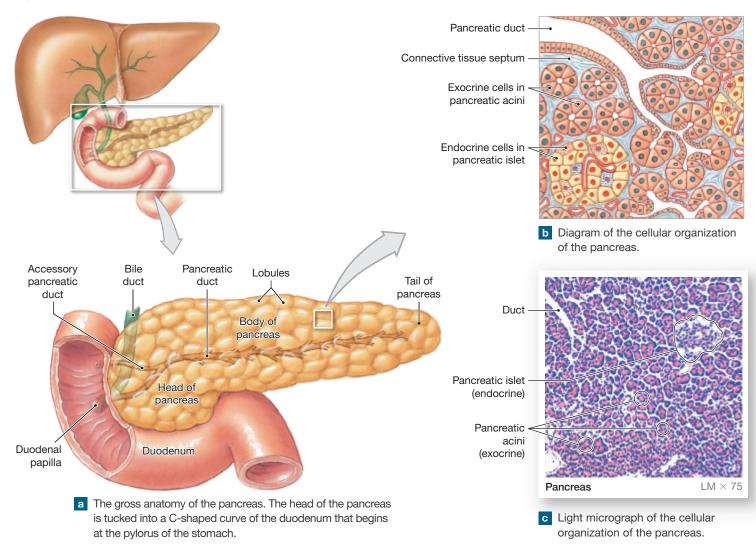

Figure 16-13 The Pancreas.

(kar-bō-HĪ-drā-sez) digest sugars and starches; **lipases** (LĪ-pāsez) break down lipids; **nucleases** break down nucleic acids (RNA and DNA); and **proteases** (prō-tē-ā-sez) (proteolytic enzymes) break proteins apart.

The Control of Pancreatic Secretion

Each day, the pancreas secretes about 1000 mL (1 qt) of pancreatic juice. The secretions are controlled primarily by hormones from the duodenum.

The duodenum releases secretin when acidic chyme arrives from the stomach. This hormone triggers the pancreas to secrete a watery, alkaline fluid with a pH between 7.5 and 8.8. Among its other components, this secretion contains buffers, primarily *sodium bicarbonate*, that increase the pH of the chyme.

Another duodenal hormone, cholecystokinin (CCK), stimulates the production and secretion of pancreatic enzymes. The specific enzymes are **pancreatic amylase**, which (like salivary amylase) breaks down carbohydrates; **pancreatic lipase**; a group of nucleases; and several proteases.

Proteases make up about 70 percent of total pancreatic enzyme production. The most abundant proteases are **trypsin** (TRIP-sin), **chymotrypsin** (kī-mō-TRIP-sin), and **carboxypeptidase** (kar-bok-sē-PEP-ti-dās). Together, they break down complex proteins into a mixture of short peptide chains and amino acids.

Pancreatic enzymes are quite powerful. The pancreatic cells protect themselves by secreting their products as inactive *proenzymes*. They are activated only after they reach the small intestine.

The Liver

The firm, reddish-brown **liver** is the largest visceral organ. It is one of our most versatile organs and the center for metabolic regulation in the body. It weighs about 1.5 kg (3.3 lb) and accounts for roughly 2.5 percent of total body weight. Most of the liver lies in the right hypochondriac and epigastric abdominopelvic regions. \supset p. 45

Anatomy of the Liver

The liver is wrapped in a tough fibrous capsule and covered by a layer of visceral peritoneum. The liver is divided into four unequal lobes: the large **left** and **right lobes** and the smaller **caudate** and **quadrate lobes** (**Figure 16-14**). On the anterior surface, the *falciform ligament* marks the division between the left and right lobes. The thickened posterior margin of the falciform ligament is the *round ligament*, a fibrous remnant of the fetal umbilical vein.

CLINICAL NOTE

Pancreatitis

Pancreatitis (pan-krē-a-TĪ-tis) is an inflammation of the pancreas. It is extremely painful. The factors that may produce it include blocked excretory ducts, bacterial or viral infections, ischemia (blocked circulation), and drug reactions (especially those involving alcohol). These factors provoke a crisis by injuring exocrine cells in at least a portion of the organ. The result is autolysis and the activation of proteolytic enzymes, which then digest surrounding undamaged cells. In most cases, only a portion of the pancreas is affected. The condition usually subsides in a few days. In 10–15 percent of cases, enzymes may ultimately destroy the organ. Its loss results in two disease conditions: *diabetes mellitus* (which requires the administration of insulin) and *nutrient malabsorption* (which requires oral administration of pancreatic enzymes).

Lodged within a recess under the right lobe of the liver is the *gallbladder*. The gallbladder is a muscular sac that stores and concentrates bile before it is ejected into the small intestine. The gallbladder and associated structures will be described in a later section.

We discussed the circulation to the liver in Chapter 13. > pp. 485, 489, 491. Roughly one-third of the blood supply to the liver is arterial blood from the hepatic artery proper (a branch of the common hepatic artery). The rest is venous blood from the hepatic portal vein, which begins in the capillaries of the esophagus, stomach, small intestine, and most of the large intestine. Liver cells, called **hepatocytes** (HEP-ah-tō-sīts), adjust the circulating levels of nutrients by selective absorption and secretion. The blood leaving the liver returns to the systemic circuit through the hepatic veins.

Histological Organization of the Liver

The lobes of the liver are divided by connective tissue into about 100,000 **liver lobules**, the basic functional units of the liver. Each lobule is roughly 1 mm in diameter. The histological organization and structure of a typical liver lobule is shown in **Figure 16-15**.

The hepatocytes in a lobule form a series of irregular plates arranged like the spokes of a wheel. The "plates" are only one cell thick. Exposed hepatocyte surfaces are covered with microvilli. Within a lobule, specialized and highly permeable capillaries, called *sinusoids*, form passageways between the adjacent plates that empty into the *central vein*. Sinusoids permit the free exchange of water and solutes as large as plasma proteins between blood and interstitial fluid. The sinusoidal lining includes **stellate macrophages**, or *Kupffer* (KOOP-fer) *cells*. These cells are part of the monocyte–macrophage system. They engulf pathogens, cell debris, and damaged blood cells.

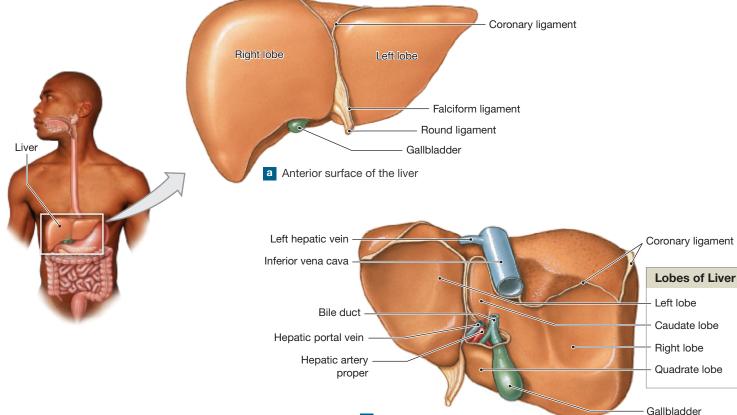

Blood enters the sinusoids from branches of the hepatic portal vein and hepatic artery proper. These two branches, plus a small branch of the bile duct, form a **portal triad**, or *portal area*, at each of the six corners of a lobule (**Figure 16-15a**). As blood flows through the sinusoids, the hepatocytes absorb solutes from the plasma and secrete materials such as plasma proteins. Blood then leaves the sinusoids and enters the **central vein** of the lobule. The central veins of all of the lobules ultimately merge to form the hepatic veins, which empty into the inferior vena cava. Liver diseases (including the various forms of *hepatitis*) and conditions such as alcoholism can lead to degenerative changes in liver tissue and reduction of the blood supply.

The hepatocytes also secrete a fluid called **bile**. Bile is released into a network of narrow channels, called **bile canaliculi**, between adjacent liver cells (**Figure 16-15b**). These canaliculi extend outward from the central vein, carrying bile toward a network of ever-larger bile ducts within the liver until it eventually leaves the liver through the **common hepatic duct** (**Figure 16-16a**). Bile in the common hepatic duct may either flow into the **bile duct**, which empties into the duodenum, or enter the **cystic duct**, which leads to the gallbladder.

Liver Functions

The liver has over 200 known functions. They fall into three general roles: (1) *metabolic regulation*, (2) *hematological regulation*, and (3) *bile production*. In this discussion, we provide an overview.

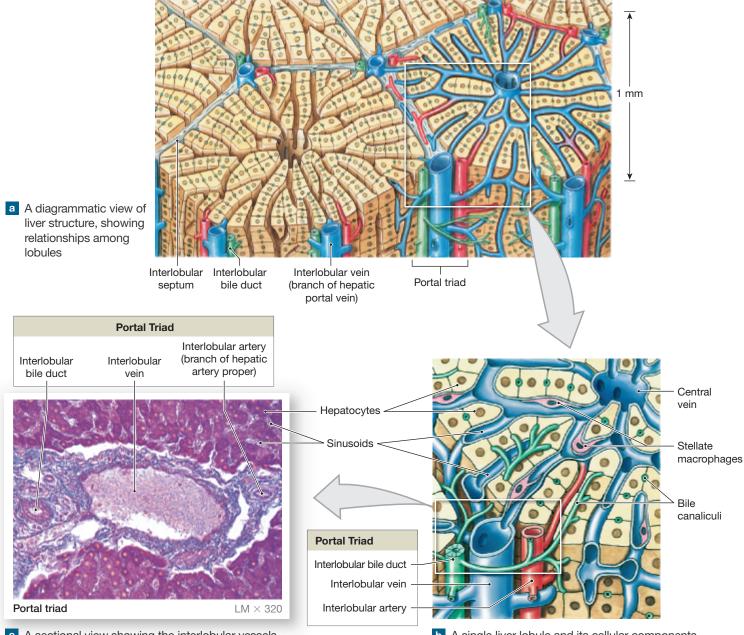

METABOLIC REGULATION. The liver is the primary organ involved in regulating the composition of circulating blood. All blood leaving the absorptive areas of the digestive tract flows through the liver before reaching the general circulation. For this reason, hepatocytes are well positioned to (1) extract absorbed nutrients or toxins from the blood before they reach the rest of the body and (2) monitor and adjust the circulating levels of organic nutrients. The liver removes and stores excess nutrients. It corrects nutrient deficiencies by mobilizing stored reserves or synthesizing necessary compounds. For example, when blood glucose levels rise, the liver removes glucose and synthesizes the storage compound glycogen. When blood glucose levels fall, the liver breaks down stored glycogen

b Posterior surface of the liver

Figure 16-15 Liver Histology.

c A sectional view showing the interlobular vessels and ducts within a portal triad

b A single liver lobule and its cellular components

16

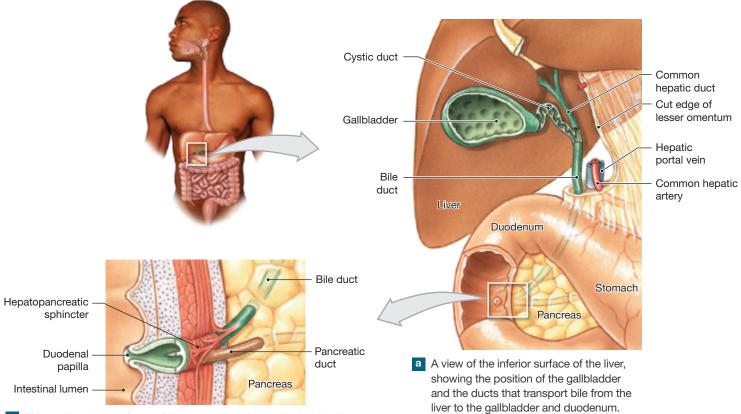

and releases glucose into the circulation. The liver also removes circulating toxins and metabolic wastes for later inactivation or excretion. In addition, it absorbs and stores fat-soluble vitamins (A, D, E, and K).

HEMATOLOGICAL REGULATION. The liver is the largest blood reservoir in the body. It receives about 25 percent of cardiac output. As blood passes through the liver, stellate macrophages remove aged or damaged red blood cells, debris, and patho-

gens. Stellate macrophages are antigen-presenting cells that can stimulate an immune response. \bigcirc p. 518 Hepatocytes also synthesize the plasma proteins. These molecules determine the osmotic concentration of the blood, transport nutrients, and make up the clotting and complement systems. \bigcirc p. 411

THE PRODUCTION AND ROLE OF BILE. Recall that bile is synthesized in the liver and ejected into the lumen of the duodenum. Bile consists mostly of water, ions, *bilirubin* (a pigment

Figure 16-16 The Gallbladder.

b This sectional view of part of the duodenum shows the duodenal papilla opening and location of the hepatopancreatic sphincter.

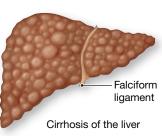

derived from hemoglobin), cholesterol, and an assortment of lipids collectively known as **bile salts**. The water and ions in bile help dilute and buffer acids in chyme as it enters the small intestine. Bile salts are synthesized from cholesterol in the liver. They are required for the normal digestion and absorption of fats.

CLINICAL NOTE

Liver Disease

Any condition that severely damages the liver represents a serious threat to life. The liver has a limited ability to regenerate itself after injury. Even so, liver function does not fully recover unless a normal circulatory pattern is reestablished. Important types of liver disease

include *cirrhosis* (sir-Ō-sis), in which fibrous tissue replaces lobules, and various forms of *hepatitis* (hep-a-TĪ-tis) caused by viral infections. In some cases, liver transplants are used to treat liver failure. Unfortunately, the supply of suitable donor tissue is limited.

Most dietary lipids are not water soluble. Mechanical processing in the stomach creates large droplets containing various lipids. Pancreatic lipase is not lipid soluble and can interact with lipids only at the surface of the droplet. Large droplets have a lower surface area to volume relationship compared to smaller droplets. As a result, larger droplets have more of their lipids isolated and protected from these digestive enzymes. Bile salts break the droplets apart through a process called **emulsification** (ē-mul-si-fi-KĀ-shun). This process creates tiny droplets with a superficial coating of bile salts. The formation of tiny droplets increases the total surface area available for enzymatic attack. In addition, the layer of bile salts aids the interaction between lipids and lipid-digesting enzymes from the pancreas. (We will return to lipid digestion later.)

 Table 16-2 summarizes the liver's major functions.

The Gallbladder

The **gallbladder** is a hollow, pear-shaped organ that stores and concentrates bile prior to its ejection into the small intestine. This muscular sac lies in a recess in the posterior surface of the liver's right lobe (**Figure 16-16a**). The cystic duct extends from

Table 16-2	Major Functions of the Liver			
DIGESTIVE AND METABOLIC FUNCTIONS				
Synthesis and secretion of bile				
Storage of glycogen and lipid reserves				
Maintenance of normal blood levels of glucose, amino acids, and fatty acids

Blood storage (largest blood reservoir in the body)				
Absorption and breakdown of circulating hormones (insulin, epinephrine) and immunoglobulins				
Absorption and inactivation of lipid-soluble drugs				

the gallbladder to the point where it unites with the common hepatic duct to form the bile duct. The bile duct and the pancreatic duct join and share a passageway that enters the duodenum at the *duodenal papilla* (Figure 16-16b). The muscular **hepatopancreatic sphincter** surrounds their shared passageway.

A major function of the gallbladder is *bile storage*. Bile is secreted continuously, roughly 1 liter each day. However, it is released into the duodenum only under the stimulation of the intestinal hormone cholecystokinin (CCK). In its absence, the hepatopancreatic sphincter remains closed, so bile leaving the liver in the common hepatic duct cannot flow through the bile duct and into the duodenum. Instead, it enters the cystic duct and is stored within the expandable gallbladder. Whenever chyme enters the duodenum, CCK is released. Its presence relaxes the hepatopancreatic sphincter and stimulates contractions within the walls of the gallbladder that push bile into the small intestine. The amount of CCK secreted increases if the chyme contains large amounts of fat.

Another function of the gallbladder is *bile modification*. When filled to capacity, the gallbladder contains 40–70 mL of bile. The composition of bile gradually changes as it remains in the gallbladder. Water is absorbed, and the bile salts and other components of bile become increasingly concentrated. If the bile salts become too concentrated, they may precipitate and form *gallstones* that can cause a variety of clinical problems.

CHECKPOINT

- **18.** Does a high-fat meal raise or lower the level of cholecystokinin (CCK) in the blood?
- 19. The digestion of which nutrient would be most impaired by damage to the exocrine pancreas?

See the blue Answers tab at the back of the book.

16-7 The large intestine is divided into three parts with regional specialization

Learning Outcome Describe the structure of the large intestine, including its regional specializations, and list its absorptive functions.

The horseshoe-shaped **large intestine** begins at the end of the ileum and ends at the anus. The large intestine lies inferior to the stomach and liver and almost completely frames the small intestine (**Figure 16-17**). The main functions of the large intestine include (1) reabsorption of water and compaction of the intestinal contents into feces, (2) absorption of important vitamins freed by bacterial action, and (3) storage of fecal material prior to defecation.

The large intestine, also called the *large bowel*, has an average length of about 1.5 m (5 ft) and a width of 7.5 cm (3 in.). It can be divided into three parts: (1) the pouchlike *cecum*, the first portion; (2) the *colon*, the largest portion; and (3) the *rectum*, the last 15 cm (6 in.) of the large intestine and the end of the digestive tract.

The Cecum

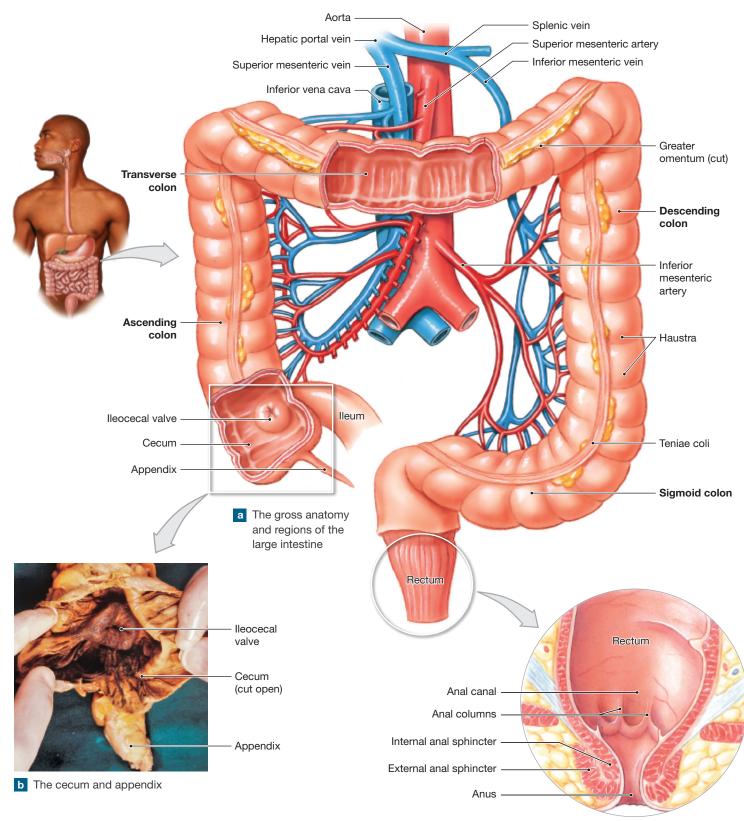

Material arriving from the ileum first enters an expanded pouch, the **cecum** (SĒ-kum). Compaction begins there. A muscular sphincter, the **ileocecal** (il-ē-ō-SĒ-kal) **valve**, guards the connection between the ileum and the cecum.

The slender, hollow **appendix**, or *vermiform* (*vermis*, worm) *appendix*, attaches to the cecum along its posteromedial surface. The appendix is generally about 9 cm (3.5 in.) long, but its size and shape are quite variable. The walls of the appendix are dominated by lymphoid nodules, and it functions primarily as an organ of the lymphatic system. Inflammation of the appendix is known as *appendicitis*.

The Colon

The **colon** has a larger diameter and thinner wall than the small intestine. Major characteristics of the colon are a lack of villi and an abundance of mucous cells. The most striking

Figure 16-17 The Large Intestine.

c The rectum and anus

external feature of the colon is the presence of pouches, or **haustra** (HAWS-truh; singular, *haustrum*). Haustra permit the colon to expand and elongate (**Figure 16-17a**). Three separate longitudinal bands of smooth muscle—the **teniae coli** (TĒ-nē-ē KŌ-lē)— run along the outer surface of the colon just beneath the serosa. Muscle tone within these bands creates the haustra.

The colon can be divided into four segments. The **ascending colon** begins at the ileocecal valve. It ascends along the right side of the peritoneal cavity until it reaches the inferior margin of the liver. It then turns horizontally, becoming the **transverse colon**. The transverse colon continues toward the left side, passing below the stomach and following the curve of the body wall. Near the spleen, it turns inferiorly to form the **descending colon**. The descending colon continues along the left side until it curves and forms the S-shaped **sigmoid** (SIG-moyd; *sigmeidos*, the Greek letter *S*) **colon**. The sigmoid colon empties into the rectum.

The Rectum

The **rectum** (REK-tum) forms the last 15 cm (6 in.) of the digestive tract (**Figure 16-17c**). It is an expandable organ for the temporary storage of feces. The last portion of the rectum, the **anal canal**, contains small longitudinal folds called *anal columns*. The distal margins of these columns are joined by transverse folds that mark the boundary between the columnar epithelium of the rectum and a stratified squamous epithelium like that found in the oral cavity. Very close to the **anus**, which is the exit of the anal canal, the epidermis becomes keratinized and identical to that on the skin surface.

The circular muscle layer of the muscular layer in this region forms the **internal anal sphincter**. The smooth muscle cells of this sphincter are not under voluntary control. The **external anal sphincter**, which encircles the anus, consists of skeletal muscle fibers and is under voluntary control.

The Functions of the Large Intestine

16 The major functions of the large intestine are absorbing a variety of substances and preparing the fecal material for elimination.

Absorption in the Large Intestine

The reabsorption of water is an important function of the large intestine. Roughly 1500 mL of watery material enters the colon each day, but only about 200 mL of feces is ejected. To appreciate how efficient our digestion is, consider the

average composition of feces: 75 percent water, 5 percent bacteria, and the rest a mixture of indigestible materials, small quantities of inorganic matter, and the remains of intestinal epithelial cells.

In addition to reabsorbing water, the large intestine absorbs a variety of other substances. Examples include useful compounds such as bile salts and vitamins, organic waste products such as bilirubin-derived breakdown products, and various toxins generated by bacterial action.

BILE SALTS. Most of the bile salts entering the large intestine are rapidly absorbed in the cecum. They are then transported to the liver for secretion in bile.

VITAMINS. Vitamins are organic molecules related to lipids and carbohydrates that are essential to many metabolic reactions. Many enzymes require the binding of an additional ion or molecule, called a *cofactor*, before substrates can also bind. *Coenzymes* are nonprotein molecules that function as cofactors, and many vitamins are essential coenzymes.

Bacteria residing within the colon generate three vitamins that supplement our diets:

- **Vitamin K**, a fat-soluble vitamin needed by the liver to synthesize four clotting factors, including prothrombin.
- *Biotin,* a water-soluble vitamin important in glucose metabolism.
- **Vitamin B**₅ (pantothenic acid), a water-soluble vitamin required in the manufacture of steroid hormones and some neurotransmitters.

Vitamin K deficiencies lead to impaired blood clotting. Intestinal bacteria produce roughly half of our daily vitamin K requirements. Deficiencies of biotin or vitamin B_5 are extremely rare after infancy because the intestinal bacteria produce enough to make up for any shortage in the diet.

CLINICAL NOTE

Colorectal cancer is relatively common in both men and women. Although colorectal cancer is the third leading cause of cancer-related deaths—an estimated 50,630 colorectal cancer deaths were expected in 2018—the death rate has declined over several decades. The best defense appears to be early detection and prompt treatment. The standard simple screening test involves checking a stool (fecal) sample for blood as part of a routine physical examination.

ORGANIC WASTES. In the large intestine, bacteria convert bilirubin into other products. Some of these are absorbed into the bloodstream and excreted in the urine, producing its yellow color. Others remain in the colon. Upon exposure to oxygen, they are further modified into the pigments that give feces a brown color. (Recall that we discussed the breakdown of heme and its release as bilirubin in the bile in Chapter 11.) \bigcirc p. 416

TOXINS. Bacterial action breaks down peptides that remain in the feces. This action generates (1) ammonia; (2) nitrogencontaining compounds that are responsible for the odor of feces; and (3) hydrogen sulfide (H_2S), a gas that produces a "rotten egg" odor. Much of the ammonia and other toxins cross the epithelium of the colon and are absorbed into the hepatic portal circulation. The liver removes these toxins and processes them into relatively nontoxic compounds that are excreted at the kidneys.

Intestinal enzymes do not alter indigestible carbohydrates. They arrive in the colon intact. These polysaccharide molecules are a nutrient source for resident bacteria. The metabolic activities of these bacteria create intestinal gas, or *flatus*. Meals containing large amounts of indigestible carbohydrates (such as beans) stimulate bacterial gas production.

Movements of the Large Intestine

The gastroileal and gastroenteric reflexes move material into the cecum while you eat. Movement from the cecum to the transverse colon is very slow, allowing hours for the reabsorption of water. Powerful peristaltic contractions called *mass movements* take place a few times a day. They move material from the transverse colon through the rest of the large intestine. The normal stimulus is distension of the stomach and duodenum. The commands are over the intestinal nerve plexuses. The contractions force feces into the rectum and produce the conscious urge to defecate.

Defecation

The rectum is usually empty until a powerful peristaltic contraction forces feces out of the sigmoid colon. Distension of the rectal wall then triggers the **defecation reflex**. This reflex involves two positive feedback loops:

1. In the shorter feedback loop, stretch receptors in the rectal walls stimulate a series of increased local peristaltic contractions in the sigmoid colon and rectum. The contractions move feces toward the anus and increase distension of the rectum. 2. The stretch receptors in the rectal walls also stimulate parasympathetic motor neurons in the sacral spinal cord. These neurons stimulate increased peristalsis (mass movements) in the descending colon and sigmoid colon that push feces toward the rectum, further increasing distension there.

The passage of feces through the anal canal requires relaxation of the internal anal sphincter, but when it relaxes, the external sphincter automatically closes. Thus, the actual release of feces requires conscious effort to open the external sphincter voluntarily. Without the conscious commands, peristaltic contractions cease until additional rectal expansion triggers the defecation reflex again.

CLINICAL NOTE

Diverticulosis

In diverticulosis (d ī-ver-tik-ū-LŌ-sis), pockets called *diverticula* form in the intestinal mucosa, generally in the sigmoid colon. These pockets get forced outward, probably by pressures during defecation. If the pockets push through weak points in the muscular layer, they form chambers that can become infected and inflamed. The inflammation causes pain and occasional bleeding, a condition known as *diverticulitis* (d ī-ver-tik-ū-LĪ-tis). Inflammation of other portions of the colon is called *colitis* (ko-LĪ-tis).

CLINICAL NOTE

Diarrhea and Constipation

Diarrhea (d ī-a-RĒ-uh) exists when an individual has frequent, watery bowel movements. Diarrhea results when the mucosa of the colon cannot maintain normal levels of absorption. Bacterial, viral, or protozoan infection of the colon or small intestine can cause acute bouts of diarrhea lasting several days. Severe diarrhea is life threatening due to cumulative fluid and electrolyte losses.

Constipation is infrequent defecation, generally involving dry, hard feces. Constipation occurs when fecal material moves through the colon so slowly that excessive water reabsorption takes place. Constipation can usually be treated by oral administration of stool softeners such as Colace, laxatives, or *cathartics* (ka-THAR-tiks), which promote defecation. These compounds either promote water movement into the feces, add bulk, or irritate the lining of the colon to stimulate peristalsis.

Irritable bowel syndrome (IBS) is a disorder characterized by diarrhea, constipation, or both.

In addition, other conscious actions can raise intra-abdominal pressures and help to force fecal material out of the rectum. These actions include tensing the abdominal muscles or elevating intra-abdominal pressures by attempting to forcibly exhale with a closed glottis (called the *Valsalva maneuver*). Such pressures also force blood into the network of veins in the lamina propria and submucosa of the anal canal, causing them to stretch. Repeated bouts of straining to force defecation can cause these veins to be permanently distended, producing *hemorrhoids*.

CHECKPOINT

20. Identify the four segments of the colon.

- **21.** What are some structural differences between the large intestine and the small intestine?
- **22.** A narrowing of the ileocecal valve would hamper movement of chyme between what two organs?

See the blue Answers tab at the back of the book.

16-8 Chemical digestion is the alteration of food that allows the absorption and use of nutrients

Learning Outcome List the nutrients required by the body, describe the chemical digestion of organic nutrients, and discuss the absorption of organic and inorganic nutrients.

A balanced diet contains all the ingredients needed to maintain homeostasis. These ingredients include six nutrients: carbohydrates, proteins, lipids, water, minerals, and vitamins. The digestive system handles each one differently. Large organic molecules must be broken down through chemical

Build Your Knowledge

Recall that a decomposition reaction breaks a molecule into smaller fragments (as you saw in **Chapter 2: The Chemical Level of Organization**). Decomposition reactions involving water are important in breaking down complex molecules in the body. Breaking one of the chemical bonds in a complex molecule by adding a water molecule is called hydrolysis. The components of the water molecule (H and OH) are added to the resulting fragments. **D p. 63** digestion before absorption can occur. Water, minerals, and vitamins can be absorbed without preliminary processing, but special transport processes may be involved.

The Processing and Absorption of Nutrients

Food contains large organic molecules. Many of them are insoluble. The digestive system first breaks down the physical structure of the ingested material and then disassembles the component molecules into smaller fragments. This disassembly produces small organic molecules that can be released into the bloodstream. Once absorbed by cells, they are used to generate ATP or to build complex carbohydrates, proteins, and lipids.

Foods are usually complex chains of simpler molecules. In a typical dietary carbohydrate, the basic molecules are simple sugars. In a protein, the building blocks are amino acids, in lipids they are usually fatty acids. and in nucleic acids, they are nucleotides. In a process called *hydrolysis*, digestive enzymes break the chemical bonds between the component molecules of carbohydrates, lipids, proteins, and nucleic acids. \bigcirc pp. 68, 70, 73

Digestive enzymes differ in their targets. Carbohydrases break the bonds between sugars. Lipases separate fatty acids from glycerides. Proteases split the linkages between amino acids. Specific enzymes in each class may be even more selective, breaking bonds between specific molecules. For example, a given carbohydrase might ignore all bonds except those connecting two glucose molecules. The chemical digestion of carbohydrates, lipids, and proteins, and their route to the bloodstream, are shown in **Spotlight Figure 16-18. Table 16-3** reviews the major digestive enzymes and their functions.

Carbohydrate Digestion and Absorption

Carbohydrate digestion begins in the mouth during mastication, through the action of salivary amylase. This enzyme breaks down complex carbohydrates into smaller fragments, producing a mixture primarily composed of disaccharides (two simple sugars) and trisaccharides (three simple sugars). Salivary amylase continues to digest the starches and glycogen in the meal for an hour or two before stomach acids render it inactive. In the duodenum, the action of pancreatic amylase breaks down the remaining complex carbohydrates.

Brush border enzymes on the surfaces of the intestinal microvilli break disaccharides and trisaccharides into monosaccharides (simple sugars). D p. 583 The intestinal epithelium then absorbs the resulting simple sugars through carriermediated transport processes, such as facilitated diffusion or

SPOTLIGHT Figure 16-18 CHEMICAL EVENTS IN DIGESTION

Go to Mastering A&P > Study Area > Spotlight Figure Videos

A typical meal contains carbohydrates, proteins, lipids, water, minerals (electrolytes), and vitamins. The digestive system handles each component differently. Large organic molecules must be chemically broken down before they can be absorbed. Water, minerals, and vitamins can be absorbed without processing, but they may require special transport processes.

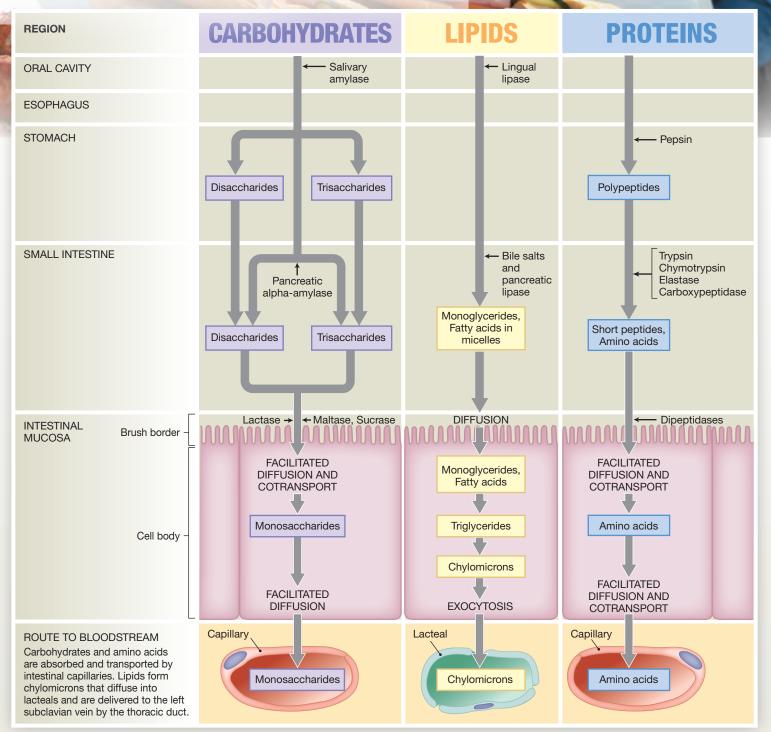

Table 16-3 Digestive Enzymes and Their Functions					
Enzyme		Source	Target	Products	
CARBOHYDRASE	5				
Amylase		Salivary glands, pancreas	Complex carbohydrates	Disaccharides and trisaccharides	
Maltase, sucrase, lactase		Small intestine	Maltose, sucrose, lactose	Monosaccharides

cotransport. \bigcirc p. 95 Glucose uptake, for example, takes place through cotransport with sodium ions. (The sodium ions are then ejected by the sodium–potassium exchange pump.)

Simple sugars entering an intestinal cell diffuse through the cytoplasm and cross the basement membrane by facilitated diffusion to enter the interstitial fluid. They then enter intestinal capillaries for delivery to the hepatic portal vein and liver.

Lipid Digestion and Absorption

Lipid digestion involves lingual lipase from glands of the tongue and pancreatic lipase from the pancreas. Fats, or triglycerides, are the most abundant dietary lipids. (Recall that a triglyceride molecule consists of three fatty acids attached to a single molecule of glycerol. \bigcirc p. 71) Triglycerides and other dietary fats are relatively unaffected by conditions in the stomach and enter the duodenum in the form of large lipid droplets.

CLINICAL NOTE

Lactose Intolerance

Lactose is the primary carbohydrate in milk. The enzyme lactase breaks down lactose. This enzyme performs an essential service throughout infancy and early childhood. If the intestinal mucosa

stops producing lactase, the person becomes *lactose intolerant*. After a meal containing milk or other dairy products, such people can experience lower abdominal pain, gas, diarrhea, and vomiting. Lactaid[®] is one lactase supplement used to treat lactose intolerance.

Recall that bile salts emulsify these drops into tiny droplets that can be more efficiently attacked by pancreatic lipase. This enzyme breaks apart the triglycerides. The resulting mixture of fatty acids and monoglycerides interacts with bile salts to form small lipid-bile salt complexes called micelles (mī-SELZ). When a micelle contacts the intestinal epithelium, the enclosed lipids diffuse across the plasma membrane and enter the cytoplasm. The intestinal cells manufacture new triglycerides from the arriving fatty acids and monoglycerides. They are then coated with proteins. This step creates a soluble complex known as a **chylomicron** (kī-lō-MĪ-kron; *chylos*, juice+*mikros*, small). The chylomicrons are secreted by exocytosis into the interstitial fluids. From there, they enter intestinal lacteals through large gaps between adjacent lacteal endothelial cells. From the lacteals they proceed along lymphatic vessels and through the thoracic duct. They enter the bloodstream at the left subclavian vein.

Protein Digestion and Absorption

Proteins have very complex structures, so protein digestion is both complex and time consuming. Protein digestion first requires disrupting the structure of food so that proteolytic enzymes can attack individual protein molecules. This step involves mechanical processing in the oral cavity, through mastication, and chemical processing in the stomach, through the action of hydrochloric acid.

Exposure of the ingested food to a strongly acid environment breaks down plant cell walls and the connective tissues in animal products. The acid also kills most pathogens. The acidic contents of the stomach provide the proper environment for the activity of pepsin, the proteolytic enzyme secreted by chief cells of the stomach. Pepsin does not complete protein digestion, but it reduces the relatively huge proteins of the chyme into smaller polypeptide fragments.

When chyme enters the duodenum and buffers have increased the pH, pancreatic proteolytic enzymes can begin working. Trypsin, chymotrypsin, and carboxypeptidase each break peptide bonds between different amino acids. These enzymes complete the disassembly of the polypeptide fragments into a mixture of short peptide chains and individual amino acids. *Peptidases* are enzymes on the surfaces of the intestinal microvilli. They complete the process by breaking the peptide chains into individual amino acids.

The intestinal epithelial cells then absorb the amino acids through both facilitated diffusion and cotransport. Carrier proteins at the inner, basal surface of the cells release the absorbed amino acids into the interstitial fluid. Once within the interstitial fluids, most of the amino acids diffuse into intestinal capillaries.

Water and Electrolyte Absorption

Each day, roughly 2000 mL of water enters the digestive tract in food or drink. Salivary, gastric, intestinal, pancreatic, and bile secretions add about 7000 mL. Out of that total of 9000 mL, only about 150 mL is lost in the fecal wastes. This water conservation occurs passively, following osmotic gradients. Recall that in osmosis, water always tends to flow into solutions containing relatively higher concentrations of solutes. \bigcirc p. 93

Intestinal epithelial cells are continually absorbing dissolved nutrients and electrolytes (inorganic ions). These activities gradually lower the solute concentration of the intestinal contents. As the solute concentration decreases, water moves into the surrounding tissues, "following" the solutes and maintaining osmotic equilibrium. The absorption of sodium and chloride ions is the most important factor promoting water movement. Other ions absorbed in smaller quantities are calcium, potassium, magnesium, iodine, bicarbonate, and iron. Calcium absorption takes place under hormonal control, requiring the presence of parathyroid hormone and calcitriol. Regulatory processes governing the absorption or excretion of the other ions are poorly understood.

Absorption of Vitamins

Vitamins are essential organic compounds that are required in very small quantities. \bigcirc p. 594 There are two major groups of vitamins: fat-soluble vitamins and water-soluble vitamins.

The four **fat-soluble vitamins**—vitamins A, D, E, and K enter the duodenum in fat droplets, mixed with dietary lipids. The vitamins remain in association with those lipids when micelles form. The fat-soluble vitamins are then absorbed from the micelles along with the products of lipid digestion. Vitamin K is also produced by the action of resident bacteria in the colon. \bigcirc p. 594

The nine **water-soluble vitamins** include the B vitamins, common in milk and meats, and vitamin C, found in citrus fruits. All but one, vitamin B_{12} , are easily absorbed by the digestive epithelium. Vitamin B_{12} cannot be absorbed by the intestinal mucosa unless it is bound to intrinsic factor, a protein secreted by the parietal cells of the stomach. \bigcirc p. 579 Bacteria in the intestinal tract are an important source of several watersoluble vitamins. (We consider the functions of vitamins and those of minerals as well in Chapter 17.)

CHECKPOINT

- **23.** What component of food would increase the number of chylomicrons in the lacteals?
- **24.** Removal of the stomach would impair the absorption of which vitamin?
- **25.** Why is it that diarrhea is potentially life threatening but constipation is not?
- See the blue Answers tab at the back of the book.

16-9 Many age-related changes affect digestion and absorption

Learning Outcome Summarize the effects of aging on the digestive system.

Normal digestion and absorption take place in elderly individuals. However, many changes in the digestive system parallel age-related changes already described for other systems:

- **The division rate of epithelial stem cells declines.** The digestive epithelium becomes more susceptible to damage by abrasion, acids, or enzymes. For this reason, peptic ulcers become more likely. In the mouth, esophagus, and anus, the stratified epithelium becomes thinner and more fragile.
- *Smooth muscle tone decreases.* General gastrointestinal motility decreases, and peristaltic contractions are weaker. This change slows the rate of intestinal movement and promotes constipation. Sagging and inflammation of the pouches (haustra) in the walls of the colon can occur. Straining to eliminate compacted feces can stress the less resilient walls of blood vessels, producing hemorrhoids. Weakening of muscular sphincters can lead to esophageal reflux and frequent bouts of "heartburn."

- The effects of cumulative damage become apparent. One example is the gradual loss of teeth due to *dental caries* ("cavities") or *gingivitis* (inflammation of the gums). Cumulative damage can involve internal organs as well. Toxins such as alcohol and other injurious chemicals absorbed by the digestive tract are transported to the liver for processing. Liver cells are not immune to these toxic compounds. Chronic exposure can lead to cirrhosis or other liver diseases.
- **Cancer rates increase.** Cancers are most common in organs in which stem cells divide to maintain epithelial cell populations. Rates of colon cancer and stomach cancer rise with age. Oral, esophageal, and pharyngeal cancers are particularly common in older people who smoke.
- **Dehydration is common among the elderly.** One reason is that osmoreceptor sensitivity declines with age.
- Changes in other systems have direct or indirect effects on the digestive system. For example, a reduction in bone mass and calcium in the skeleton is associated with erosion of the tooth sockets and eventual tooth loss. The decline in smell and taste sensitivity with age can lead to dietary changes that affect the entire body.

CHECKPOINT

26. Identify general digestive system changes that occur with aging.

See the blue Answers tab at the back of the book.

16-10 The digestive system is extensively integrated with other body systems

Learning Outcome Give examples of interactions between the digestive system and other body systems presented so far.

The digestive system is functionally linked to all other systems. It has extensive anatomical connections to the nervous, cardiovascular, endocrine, and lymphatic systems. We have also seen that the digestive tract is also an endocrine organ that produces a variety of hormones.

Refer to Build Your Knowledge: How the DIGESTIVE SYSTEM integrates with the other body systems presented so far on p. 601. It reviews the major functional relationships between this system and the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, and respiratory systems. Note that the digestive system has extensive structural and functional connections to the cardiovascular system.

CHECKPOINT

- **27.** Identify the functional relationships between the digestive system and other body systems presented so far.
- **28.** List the digestive system functions that are related to the cardiovascular system.
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

achalasia (ak-a-LĀ-zē-uh): A condition that results when a bolus cannot reach the stomach due to constriction of the lower esophageal sphincter.

cholecystitis (kō-lē-sis-TĪ-tis): Inflammation of the gallbladder due to a blockage of the cystic duct or common bile duct by gallstones.

 $\label{eq:cholelithiasis} {\bf (ko-l\bar{e}-li-TH\bar{l}-a-sis): The presence of gallstones in the gallbladder.}$

colectomy (ko-LEK-to-mē): The removal of all or a portion of the colon.

colonoscope (ko-LON-o-skōp): A long, flexible, tubular fiberoptic instrument for examining the interior of the colon. **colostomy** (ko-LOS-to-mē): The attachment of the cut end of the colon to an opening in the body wall after a colectomy.

esophagitis (ē-sof-a-JĪ-tis): Inflammation of the esophagus. **gastroenteritis** (gas-trō-en-ter-Ī-tis): Inflammation of the lining of the stomach and intestine, characterized by vomiting and diarrhea and resulting from bacterial toxins, viral infections, or various poisons.

gastroenterology (gas-trō-en-ter-OL-o-jē): The study of the digestive system and its diseases and disorders. **inflammatory bowel disease (ulcerative colitis):** A chronic inflammation of the digestive tract, most commonly affecting the colon.

laparoscopy (lap-a-ROS-ko-pē): The use of a flexible fiber-optic instrument introduced through the abdominal wall to permit direct visualization of the viscera, tissue sampling, and limited surgical procedures.

liver biopsy: A sample of liver tissue, generally taken by inserting a long needle through the anterior abdominal wall.

perforated ulcer: A particularly dangerous ulcer in which gastric acids erode through the wall of the digestive tract, allowing its contents to enter the peritoneal cavity.

periodontal disease: A loosening of the teeth within the bony sockets (alveolar sockets) caused by erosion of the periodontal ligaments by acids produced through bacterial action.

 $peritonitis\ (per-i-t\bar{o}-N\bar{I}-tis):$ Inflammation of the peritoneal membrane.

polyps (POL-ips): Small growths with a stalk protruding from a mucous membrane that are usually benign.

Build Your Knowledge

How the DIGESTIVE SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System provides vitamin D_3 needed for the absorption of calcium and phosphorus
- The digestive system provides lipids for storage by adipocytes in hypodermis

Skeletal System

- The Skeletal System (axial division and pelvic girdle) supports and protects parts of digestive tract; teeth are used in mechanical processing of food
- The digestive system absorbs calcium and phosphate ions for use in bone matrix; provides lipids for storage in yellow marrow

Cardiovascular System

- The Cardiovascular System distributes hormones of the digestive tract; carries nutrients, water, and ions from sites of absorption; delivers nutrients and toxins to liver
- The digestive system absorbs fluid to maintain normal blood volume; absorbs vitamin K; liver excretes heme (as bilirubin), synthesizes blood clotting proteins

Respiratory System

- The Respiratory System can assist in defecation by producing increased thoracic and abdominal pressure through contraction of respiratory muscles
- The digestive system produces pressure with digestive organs against the diaphragm that can assist in exhalation and limit inhalation

Muscular System

- The Muscular System protects and supports digestive organs in abdominal cavity; controls entrances and exits of digestive tract
- The digestive system regulates blood glucose and fatty acid levels and metabolizes lactate from active muscles with the liver

Nervous System

- The Nervous System regulates movement and secretion with the ANS; reflexes coordinate passage of materials along the digestive tract; control over skeletal muscles regulates ingestion and defecation; hypothalamic centers control hunger, satiation, and feeding
- The digestive system provides compounds essential for neurotransmitter synthesis

Endocrine System

- The Endocrine System produces epinephrine and norepinephrine that stimulate constriction of sphincters and depress digestive activity; hormones coordinate activity along digestive tract
- The digestive system provides nutrients and substrates to endocrine cells; endocrine cells of pancreas secrete insulin and glucagon; liver produces angiotensinogen

Lymphatic System

• The Lymphatic System defends against infection and toxins absorbed from the digestive tract; lymphatic vessels carry absorbed lipids to the general circulation

> The digestive system secretes acids and enzymes that provide innate (nonspecific) defense against pathogens

Digestive System

The digestive system provides organic substrates, vitamins, ions, and water required by all cells. It:

- ingests solid and liquid materials into the body
- mechanically digests solid materials to ease their movement and chemical breakdown in the digestive tract
- chemically digests food into smaller fragments in the digestive tract
- secretes water, acids, enzymes, and buffers into the digestive tract
- absorbs small organic molecules (organic substrates), mineral ions, vitamins, and water across the digestive epithelium
- eliminates compacted waste products from the body by defecation

Chapter Review

Summary Outline

16-1 The digestive system—the digestive tract and accessory organs—performs various food-processing functions *p. 569*

- 1. The digestive system consists of the muscular **digestive tract** and various **accessory organs**. (*Figure 16-1*)
- **2.** The digestive tract includes the oral cavity, pharynx, esophagus, stomach, small intestine, large intestine, rectum, and anus. Accessory digestive organs include the teeth, tongue, salivary glands, liver, pancreas, and gallbladder. (*Figure 16-1*)
- **3.** Digestive functions include **ingestion**, **mechanical digestion**, **chemical digestion**, **secretion**, **absorption**, and **defecation**.
- **4.** The epithelium and underlying connective tissue, the *lamina propria*, form the **mucosa** (mucous membrane) of the digestive tract. Next, moving deeper, are the **submucosa**, the **muscular layer**, and the *adventitia*, a layer of dense connective tissue. For viscera projecting into the peritoneal cavity, the layer is covered by the **serosa**, a serous membrane. (*Figure 16-2*)
- **5.** Double sheets of peritoneal membrane called **mesenteries** suspend portions of the digestive tract.
- **6.** The neurons that innervate the smooth muscle of the muscular layer are not under voluntary control.
- 7. The muscular layer propels materials through the digestive tract by means of the contractions of **peristalsis**.
 Segmentation movements in areas of the small intestine churn digestive materials. (*Figure 16-3*)

16-2 The oral cavity contains the tongue, salivary glands, and teeth, each with specific functions *p. 573*

8. The functions of the **oral cavity** are (1) sensory analysis of foods; (2) mechanical processing by the teeth, tongue, and palatal surfaces; (3) lubrication of food by mixing with mucus and salivary secretions; and (4) limited digestion of carbohydrates and lipids.

16

- **9.** The oral cavity (mouth), or **buccal cavity**, is lined by oral mucosa. The **hard palate** and **soft palate** form its roof, and the tongue forms its floor. (*Figure 16-4*)
- **10.** The primary functions of the **tongue** include (1) mechanical processing, (2) manipulation to assist in chewing and swallowing, and (3) sensory analysis.
- **11.** The **parotid**, **sublingual**, and **submandibular salivary glands** discharge their secretions into the oral cavity.

Saliva lubricates the mouth, dissolves chemicals, flushes the oral surfaces, and helps control bacteria. (*Figure 16-5*)

- 12. Mastication (chewing) occurs through the contact of the opposing surfaces of the teeth. The periodontal ligament anchors each tooth in a bony socket. Dentin forms the basic structure of a tooth. The crown is coated with enamel, and the root is covered with cement. (*Figure 16-6a*)
- **13.** The 20 primary teeth, or **deciduous teeth**, are replaced by the 32 **permanent teeth** (*secondary dentition*) during development. (*Figure 16-6b,c*)

16-3 The pharynx is a passageway between the oral cavity and the esophagus *p. 576*

- **14.** The **pharynx** (throat) serves as a common passageway for solid food, liquids, and air. Pharyngeal muscle contractions during swallowing propel the food mass along the esophagus and into the stomach.
- **15.** The **esophagus** carries solids and liquids from the pharynx to the stomach through an opening in the diaphragm, the *esophageal hiatus*.
- 16. Deglutition (swallowing) can be divided into buccal, pharyngeal, and esophageal phases. Swallowing begins with the compaction of a bolus and its movement into the pharynx, followed by the elevation of the larynx, folding back of the epiglottis, and closure of the glottis. Peristalsis moves the bolus down the esophagus to the *lower esophageal sphincter. (Figure 16-7)*

16-4 The J-shaped stomach receives food from the esophagus and aids in chemical and mechanical digestion *p. 577*

- **17.** The **stomach** has four major functions: (1) storage of ingested food, (2) mechanical digestion of food, (3) breakage of chemical bonds by acids and enzymes, and (4) production of intrinsic factor. **Chyme** forms in the stomach as gastric and salivary secretions are mixed with food.
- 18. The four regions of the stomach are the cardia, fundus, body, and pylorus. The pyloric sphincter guards the exit out of the stomach. In a relaxed state the stomach lining contains numerous rugae (ridges and folds). (*Figure 16-8*)
- 19. Within the **gastric glands**, **parietal cells** secrete **intrinsic factor** and hydrochloric acid. **Chief cells** secrete **pepsinogen**, which acids in the gastric lumen convert to the enzyme **pepsin**. Gastric gland **G cells** secrete the hormone **gastrin**.

20. Gastric secretion includes (1) the **cephalic phase**, which prepares the stomach to receive ingested materials; (2) the **gastric phase**, which begins with the arrival of food in the stomach; and (3) the **intestinal phase**, which controls the rate of gastric emptying. (*Spotlight Figure 16-9*)

16-5 The small intestine chemically digests and absorbs nutrients *p. 582*

- **21.** The **small intestine** includes the **duodenum**, the **jejunum**, and the **ileum**. A sphincter, the *ileocecal valve*, marks the junction between the small and large intestines. (*Figure 16-10*)
- **22.** The intestinal mucosa has transverse **circular folds** and small projections called intestinal **villi**. Both structures increase the surface area for absorption. Each villus contains a lymphatic capillary called a **lacteal**. (*Figure 16-11*)
- **23.** Some of the smooth muscle cells in the muscular layer of the small intestine contract periodically, without stimulation, to produce brief localized peristaltic contractions that slowly move materials along the tract. More extensive peristaltic activities are coordinated by the *gastroenteric* and the *gastroileal reflexes*.
- **24.** Intestinal glands secrete **intestinal juice**, mucus, and hormones. Intestinal juice moistens the chyme, helps buffer acids, and dissolves digestive enzymes and the products of digestion.
- 25. Intestinal hormones include gastrin, secretin, cholecystokinin (CCK), and gastric inhibitory peptide (GIP). (*Figure 16-12; Table 16-1*)
- **26.** Most of the important digestive and absorptive functions occur in the small intestine. Digestive enzymes and buffers are produced by the pancreas and liver.

16-6 The pancreas, liver, and gallbladder are accessory organs that assist with chemical digestion in the small intestine *p. 586*

- **27.** The **pancreatic duct** penetrates the wall of the duodenum, where it delivers the secretions of the **pancreas**. (*Figure 16-13a*)
- **28.** Exocrine gland ducts branch repeatedly before ending in the **pancreatic acini** (blind pockets). (*Figure 16-13b,c*)
- **29.** The pancreas has both an endocrine function (secreting insulin and glucagon into the blood) and an exocrine function (secreting water, ions, and digestive enzymes into the small intestine). Pancreatic enzymes include **carbohydrases**, **lipases**, **nucleases**, and **proteases**.
- **30.** Pancreatic exocrine cells produce a watery **pancreatic juice** in response to hormonal instructions from the duodenum. When chyme arrives in the small intestine, secretin and CCK are released.
- **31.** The release of secretin triggers the pancreatic production of a fluid containing buffers (primarily sodium bicarbonate) that increases the pH of the chyme. CCK stimulates the

pancreas to produce and secrete **pancreatic amylase**, **pancreatic lipase**, nucleases, and several proteolytic enzymes—notably **trypsin**, **chymotrypsin**, and **carboxypeptidase**.

- **32.** The **liver**, the largest visceral organ in the body, performs over 200 known functions.
- **33.** The liver is made up of four unequally sized lobes: the **left, right, caudate**, and **quadrate lobes**. (*Figure 16-14*)
- **34.** The **liver lobule** is the organ's basic functional unit. Blood is supplied to the lobules by branches of the hepatic artery proper and hepatic portal vein. Within the lobules, blood flows past *hepatocytes* through *sinusoids* to the **central vein. Bile canaliculi** carry bile away from the central vein and toward bile ducts. (*Figure 16-15*)
- **35.** The bile ducts from each lobule unite to form the **common hepatic duct**, which meets the **cystic duct** to form the **common bile duct**, which empties into the duodenum. (*Figure 16-16a*)
- **36.** The liver performs metabolic and hematological regulation, and produces **bile**. (*Table 16-2*)
- **37.** The **gallbladder** stores and concentrates bile for ejection into the duodenum. Stimulation by cholecystokinin (CCK) relaxes the **hepatopancreatic sphincter**, allowing bile to enter the duodenum. (*Figure 16-16b*)

16-7 The large intestine is divided into three parts with regional specialization *p. 592*

- **38.** The main functions of the **large intestine** are to (1) reabsorb water and compact the feces, (2) absorb vitamins made by bacteria, and (3) store feces prior to defecation. The large intestine has three parts: the cecum, the colon, and the rectum. (*Figure 16-17a*)
- **39.** The **cecum** collects and stores material from the ileum and begins the process of compaction. The **appendix** contains lymphoid tissue and is part of the lymphatic system. It is attached to the cecum.
- **40.** The **colon** has a larger diameter and a thinner wall than the small intestine. It bears **haustra** (pouches) and **teniae coli** (three longitudinal bands of muscle).
- **41.** The **rectum** terminates in the **anal canal**, leading to the **anus**. (*Figure 16-17b*)
- **42.** The large intestine reabsorbs water and other substances, such as *vitamins, bile salts, organic wastes,* and *toxins*. Bacteria residing in the large intestine are responsible for intestinal gas, or *flatus*.
- **43.** Distension of the stomach and duodenum stimulates peristalsis, or *mass movements*, of materials from the transverse colon to the rectum. Muscular sphincters control the passage of fecal material to the anus. Distension of the rectal wall triggers the *defecation reflex*. Under normal circumstances, the release of feces cannot occur unless the **external anal sphincter** is voluntarily relaxed.

16-8 Chemical digestion is the alteration of food that allows the absorption and use of nutrients p. 596

- 44. The digestive system first breaks down the physical structure of ingested materials, and then digestive enzymes break the component molecules into smaller fragments through a process called hydrolysis. (Spotlight Figure 16-18; Table 16-3)
- 45. Amylases break down complex carbohydrates into disaccharides and trisaccharides. Enzymes at the epithelial surface break these molecules into monosaccharides that are absorbed by the intestinal epithelium through facilitated diffusion or cotransport. (Spotlight Figure 16-18)
- 46. Triglycerides are emulsified into lipid droplets that interact with bile salts to form micelles. The fatty acids and monoglycerides resulting from the action of pancreatic lipase diffuse from the micelles across the intestinal epithelium. The intestinal cells then synthesize new triglycerides. These are packaged in chylomicrons, which are released into the interstitial fluid for transport to the general circulation by way of the lymphatic system. (Spotlight Figure 16-18)
- 47. Protein digestion involves low pH and the enzyme pepsin in the stomach, and various pancreatic proteases in the small intestine. Peptidases liberate amino acids that are absorbed by the intestinal epithelium and released into the interstitial fluids. (Spotlight Figure 16-18)

- 48. About 2000 mL of water are ingested each day, and digestive secretions provide another 7000 mL. All but about 150 mL of water is reabsorbed through osmosis.
- **49.** Various processes are responsible for the movement of ions (such as sodium, calcium, chloride, and bicarbonate).
- 50. The fat-soluble vitamins are enclosed within fat droplets and are absorbed with the products of lipid digestion. The water-soluble vitamins (except B₁₂) diffuse easily across the digestive epithelium.

16-9 Many age-related changes affect digestion and absorption p. 599

51. Age-related digestive system changes include a thinner and more fragile epithelium due to a reduction in epithelial stem cell divisions, weaker peristaltic contractions as smooth muscle tone decreases, the effects of cumulative damage, increased cancer rates, and increased dehydration.

16-10 The digestive system is extensively integrated with other body systems p. 600

52. The digestive system has extensive structural and functional connections to the nervous, cardiovascular, endocrine, and lymphatic systems.

See the blue Answers tab at the back of the book.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Plac

OLUMN A	COLUMN B
1. pyloric sphincter	a. emulsification of fats
2. liver cells	b. double serous membrane sheet
3. intrinsic factor	c. moves materials along digestive tract
4. mesentery	d. regulates flow of chyme into duodenum
5. chief cells	e. increases muscular activity of digestive tract
6. palate	f. starch digestion
7. parietal cells	g. inhibits muscular activity of digestive tract
8. parasympathetic stimulat	ion h. aids vitamin B_{12} absorption

i. roof of oral cavity

k. produce hydrochloric acid

j. pepsinogen

1. hepatocytes

16

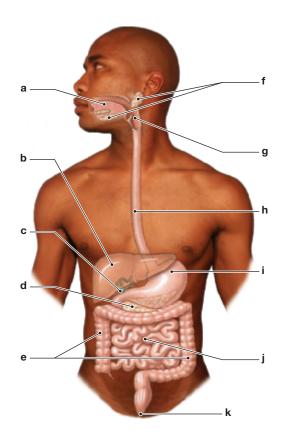

- 10. peristalsis **11.** bile salts
 - **12.** salivary amylase

9. sympathetic stimulation

- 13. The saliva released into the vestibule next to the second
 - upper molar is produced by the
 - (a) parotid gland.
 - (b) submandibular gland.
 - (c) sublingual gland.
 - (d) a, b, and c are correct.

- 14. The activities of the digestive system are regulated by
 - (a) hormonal processes.
 - (b) local processes.
 - (c) neural processes.
 - (d) a, b, and c are correct.

- **15.** The process of swallowing can be divided into
 - (a) cephalic, pharyngeal, and esophageal phases.
 - (b) cephalic, gastric, and intestinal phases.
 - (c) buccal, gastric, and intestinal phases.
 - (d) buccal, pharyngeal, and esophageal phases.
- **16.** The ileum is lined by the
 - (a) simple squamous epithelium.
 - (b) stratified squamous epithelium.
 - (c) simple columnar epithelium.
 - (d) pseudostratified columnar epithelium.
- **17.** Label the digestive system structures in the following figure.

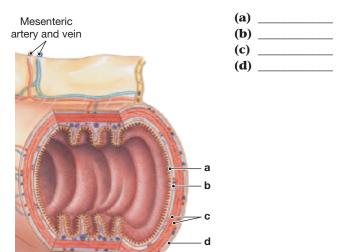

(a)	(b)
(c)	(d)
(e)	(f)
(g)	(h)
(i)	(j)

(k) ____

(c) jejunum.

- 18. The teniae coli are found on the outer surface of the
 - (a) esophagus. (b) stomach.
 - (d) sigmoid colon.
- **19.** The portal area (or portal triad) contains branches from the
 - (a) hepatic artery proper, hepatic vein, and hepatic portal vein.
 - (b) hepatic artery proper, hepatic vein, and bile duct.
 - (c) hepatic artery proper, hepatic portal vein, and bile duct.
 - (d) hepatic vein, hepatic portal vein, and bile duct.

- 20. The pancreas is mainly responsible for the secretion of(a) bile.(b) enzymes and buffers.
 - (c) intrinsic factor. (d) cholecystokinin.
 - tor. (**u**) cholecystokinin.
- **21.** Label the four layers of the digestive tract in the following figure.

- 22. The primary function of bile salts is to
 - (a) break down proteins.
 - (b) emulsify fats.
 - (c) stimulate the enterogastric reflex.
 - (d) deactivate pancreatic enzymes.
- **23.** What is the function of Kupffer cells?
 - (a) remove circulating hormones and antibodies
 - (b) metabolize drugs into less harmful metabolites
 - (c) phagocytize pathogens, cell debris, and old red blood cells
 - (d) remove excess amino acids and triglycerides
- **24.** Absorption of the products of lipid digestion occurs together with absorption of
 - (a) vitamins A, B, and C.
 - **(b)** vitamins A, C, and D.
 - (c) vitamins A, D, and E.
 - (d) vitamins B, C, and E.
- **25.** Which parts of the digestive tract are involved in mechanical digestion?
- **26.** What is the function of the submucosal plexus in the submucosa of the digestive tract?
- **27.** Describe the layers of the digestive tract, proceeding from superficial (the innermost layer nearest the lumen) to deep (the outermost layer).
- **28.** What are the four primary functions of the oral (buccal) cavity?
- **29.** What specific function does each of the four types of teeth perform in the oral cavity?
- **30.** Why is the duodenum referred to as the "mixing bowl"?
- **31.** What are the primary digestive functions of the pancreas, liver, and gallbladder?
- **32.** Describe two ways in which the digestive and respiratory systems interact.
- 33. What six age-related changes occur in the digestive system?

Level 2 Reviewing Concepts

- 34. A reduction or loss of salivary secretions will
 - (a) result in an increase in oral bacteria.
 - (b) have an influence on chemical digestion of food.
 - (c) affect your taste sensation.
 - (d) a, b, and c are correct.
- **35.** In order for feces to pass through the anal canal during defecation, there is a
 - (a) voluntary relaxation of both the internal and external anal sphincters.
 - **(b)** involuntary relaxation of both the internal and external anal sphincters.
 - (c) voluntary relaxation of the internal anal sphincter and involuntary relaxation of the external sphincter.
 - (d) involuntary relaxation of the internal anal sphincter and voluntary relaxation of the external anal sphincter.
- **36.** Chyme containing lots of fats and glucose stimulates the
 - secretion of **(a)** gastrin.
- (**b**) gastric inhibitory peptide.
- (c) secretin. (d) cholecystokinin.
- **37.** Describe how the action and outcome of peristalsis differ from those of segmentation.
- **38.** How does the stomach promote and assist in the digestive process?
- **39.** Describe the events that occur during the three phases of gastric secretion.

Level 3 Critical Thinking and Clinical Applications

- **40.** If your gallbladder is removed, will you still be able to digest and absorb fats?
- **41.** Barb suffers from Crohn's disease, a regional inflammation of the intestine that is thought to have some genetic basis, although the actual cause remains unknown. When the disease flares up, she experiences abdominal pain, weight loss, and anemia. Which part(s) of the intestine is (are) probably involved, and what might be the causes of her signs and symptoms?

Metabolism and Energetics

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

- **17-1** Define metabolism and energetics, and explain why cells need to synthesize new organic molecules.
- **17-2** Describe the basic steps in glycolysis, the citric acid cycle, and the electron transport chain, and summarize the energy yields of glycolysis and cellular respiration.
- **17-3** Describe the pathways involved in lipid metabolism, and summarize the processes of lipid transport and distribution.
- **17-4** Discuss protein metabolism and the use of proteins as an energy source.
- **17-5** Discuss nucleic acid metabolism and the limited use of nucleic acids as an energy source.
- **17-6** Explain what makes up a balanced diet and why such a diet is important.
- **17-7** Define metabolic rate, describe the factors involved in determining an individual's BMR, and discuss the homeostatic processes that maintain a constant body temperature.
- **17-8** Describe the age-related changes in dietary requirements.

Clinical Notes

An Introduction to Nutrition and Metabolism

The amount and type of nutrients you get from meals can vary widely. Your body builds energy reserves when nutrients, such as carbohydrates or lipids, are abundant. It mobilizes them when nutrients are in short supply. The endocrine and nervous systems adjust and coordinate the metabolic activities of the body's tissues. They also control the storage and mobilization of these energy reserves. In this chapter, we consider what happens to nutrients once they are inside the body.

Build Your Knowledge

Recall that foods are usually complex chains of simpler molecules (as you saw in **Chapter 16: The Digestive System**). In a typical dietary carbohydrate, the basic molecules are simple sugars. In a protein, the building blocks are amino acids. In lipids they are usually fatty acids. Digestive enzymes, such as carbohydrases, proteases, and lipases, break the chemical bonds of a complex food molecule in the process of hydrolysis. \bigcirc **p. 596**

17-1 Metabolism refers to all the chemical reactions in the body, and energetics refers to the flow and transformation of energy

Learning Outcome Define metabolism and energetics, and explain why cells need to synthesize new organic molecules.

Cells are chemical factories that break down organic molecules to obtain energy. Our cells then use this energy to generate ATP, the body's most important high-energy compound. Chemical reactions within mitochondria provide most of the energy a typical cell needs. \bigcirc p. 103 To generate energy, cells in the human body must also obtain oxygen and nutrients. Oxygen is absorbed at the lungs. The digestive tract absorbs nutrients. **Nutrients** include essential substances such as water, vitamins, mineral ions, carbohydrates, lipids, and proteins. The cardiovascular system distributes oxygen and nutrients to cells throughout the body.

Mitochondria break down the organic nutrients to provide energy for cell growth, cell division, contraction, secretion, and other functions. Each tissue contains different populations of cells. As a result, the energy and nutrient requirements of any two tissues, such as loose connective tissue and cardiac muscle, can be quite different.

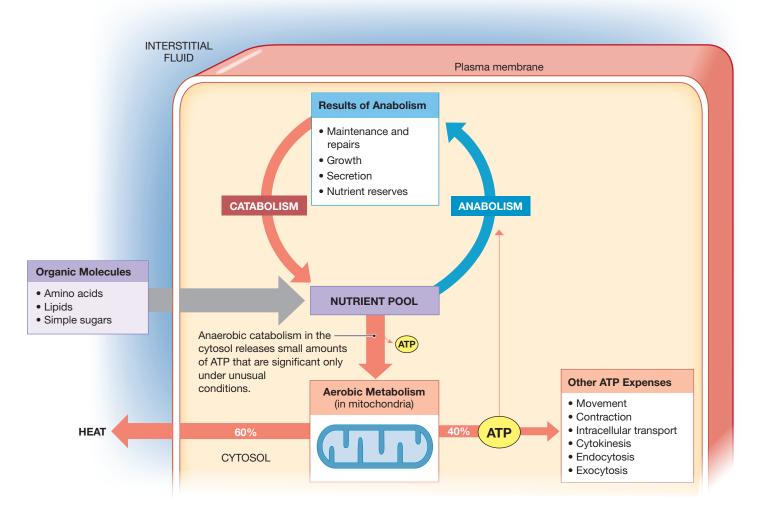

The body's metabolic needs change when cells, tissues, and organs change their levels of activity. Our energy and nutrient requirements can vary from moment to moment (resting versus active), hour to hour (asleep versus awake), and year to year (child versus adult). Understanding energy requirements is part of **energetics**, the study of the flow of energy and its change(s) from one form to another. The term **metabolism** refers to all the chemical reactions in the body. \bigcirc p. 61 *Cellular metabolism* refers to the chemical reactions within cells. It provides the energy needed to maintain homeostasis and to perform essential functions. **Figure 17-1** provides an overview of the processes involved in cellular metabolism. Amino acids, lipids, and simple sugars cross the plasma membrane and join the other nutrients already in the cytosol. All the cell's metabolic operations rely on this *nutrient pool* of organic building blocks.

The breakdown of organic molecules is called **catabolism**. This process releases energy that can be used to synthesize ATP or other high-energy compounds. \bigcirc p. 63 Catabolism proceeds in a series of steps. In general, the first steps take place in the cytosol, where enzymes break down large organic molecules into smaller fragments. Carbohydrates are broken down into short carbon chains. Triglycerides are split into fatty acids and glycerol. Proteins are broken down to individual amino acids.

These preparatory steps produce relatively little ATP. However, further catabolic reactions produce smaller organic molecules that mitochondria can absorb and process. Mitochondrial activity releases significant amounts of energy. As mitochondrial enzymes break the covalent bonds that hold these molecules together, they capture roughly 40 percent of the released energy. The captured energy is used to convert ADP to ATP. \supset p. 78 The rest escapes as heat that warms the interior of the cell and the surrounding tissues.

Anabolism is the synthesis of new organic molecules. It involves the formation of new chemical bonds. ^{(→} p. 63 The ATP produced by mitochondria provides energy to support anabolism and other cell functions. Those functions, such as ciliary or cell movement, contraction, active transport, and cell division, vary from one cell to another. For example,

Figure 17-1 Cellular Metabolism. Cells obtain organic molecules from the interstitial fluid and break them down in mitochondria to produce ATP. Only about 40 percent of the energy released through catabolism is captured in ATP. The rest is lost as heat. The ATP generated by catabolism provides energy for all vital cellular activities, including anabolism.

muscle fibers need ATP to provide energy for contraction, and gland cells need ATP to synthesize and transport their secretions.

Cells synthesize new organic components for four basic reasons:

- **1.** *To carry out structural maintenance and repairs.* Most structures in the cell are temporary, not permanent. Their removal and replacement are part of the process of **metabolic turnover**.
- **2.** *To support growth.* Cells preparing to divide increase in size and synthesize extra proteins and organelles.
- **3.** *To produce secretions.* Secretory cells must synthesize their products and deliver them to the interstitial fluid.
- **4.** *To store nutrient reserves.* Most cells "prepare for a rainy day"— an emergency, extreme activity, or inadequate nutrient supply in the bloodstream. Cells

do so by storing nutrients in a form that can be mobilized as needed. For example, muscle cells store glucose in the form of glycogen, and fat cells (adipocytes) store fatty acids in triglycerides. Liver cells store both glycogen and triglycerides.

The nutrient pool is the source of organic molecules for both catabolism and anabolism (**Figure 17-1**). Cells tend to conserve materials needed to build new compounds and tend to break down the rest. Cells continuously replace membranes, organelles, enzymes, and structural proteins. These anabolic activities require more amino acids than lipids, and few carbohydrates. Energy-releasing catabolic activities, however, tend to process these organic molecules in the reverse order. In general, when a cell with excess carbohydrates, lipids, and amino acids needs energy, it first breaks down carbohydrates. Lipids are the second choice as an energy source. Amino acids are seldom broken down if other energy sources are available.

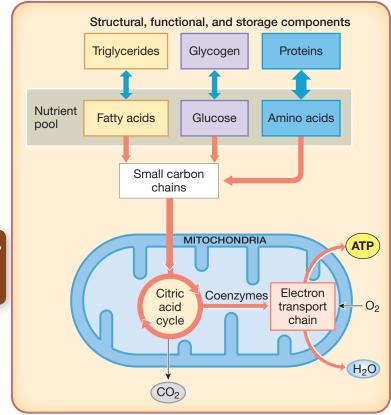

610 DIGESTIVE SYSTEM

Mitochondria provide most of the energy that supports cellular operations. In effect, the cell feeds its mitochondria from its nutrient pool, and in return the cell gets the ATP it needs. However, mitochondria are picky eaters: They will accept only specific organic molecules for processing and energy production. Chemical reactions in the cytosol take available organic nutrients and break them into smaller fragments that the mitochondria can use. The mitochondria then break down the fragments further, generating carbon dioxide, water, and ATP. This mitochondrial activity involves two pathways: the *citric acid cycle* and the *electron transport chain* (Figure 17-2).

CHECKPOINT

- **1.** Define energetics.
- 2. Define metabolism.
- 3. Compare catabolism and anabolism.
- See the blue Answers tab at the back of the book.

Figure 17-2 Nutrient Use in Cellular Metabolism. Cells use molecules in the nutrient pool to build up reserves and to manufacture cellular structures. Catabolism within mitochondria provides the ATP needed to sustain cell functions. Mitochondria absorb small carbon chains produced by the breakdown of fatty acids, glucose, and amino acids from the nutrient pool. The small carbon chains are broken down further by means of the citric acid cycle and the electron transport chain.

Build Your Knowledge

Recall that the cells in your body generate ATP through anaerobic (non-oxygen-requiring) metabolism in the cytosol and through aerobic (oxygen-requiring) metabolism in mitochondria (as you saw in **Chapter 7: The Muscular System**). The anaerobic breakdown of glucose to pyruvate is called glycolysis. This process generates a small amount of ATP and provides pyruvate molecules that enter mitochondria. The complete breakdown of pyruvate through aerobic metabolism generates most of a body cell's ATP. **D p. 238**

17-2 Carbohydrate metabolism involves glycolysis, ATP production, and gluconeogenesis

Learning Outcome Describe the basic steps in glycolysis, the citric acid cycle, and the electron transport chain, and summarize the energy yields of glycolysis and cellular respiration.

Carbohydrates are most familiar to us as sugars and starches. They are important sources of energy. Most cells generate ATP and other high-energy compounds by breaking down carbohydrates, especially glucose. We can summarize the complete reaction sequence as:

$$\begin{array}{ccc} C_{6}H_{12}O_{6} + 6O_{2} & \longrightarrow & 6CO_{2} + 6H_{2}O \\ \\ \text{glucose} & \text{oxygen} & \text{carbon dioxide} & \text{water} \end{array}$$

This overall reaction is called **cellular respiration**. The breakdown of glucose takes place in a series of small steps. Several of these steps release enough energy to support the conversion of ADP to ATP. The complete catabolism of one molecule of glucose provides a typical cell with 30–32 ATP molecules.

Most ATP production occurs inside mitochondria, but the first steps take place in the cytosol. Recall that *glycolysis* breaks down glucose into smaller molecules that mitochondria can absorb and use (see Chapter 7). These reactions are said to be *anaerobic* because glycolysis does not require oxygen. ⊃ p. 237 The subsequent reactions take place within mitochondria. These reactions consume oxygen and are thus *aerobic*. The mitochondrial activity responsible for ATP production is called **aerobic metabolism**. (The terms cellular respiration and aerobic metabolism are often considered interchangeable. However, as we discussed, cellular respiration includes both anaerobic and aerobic reactions.)

Glycolysis

Glycolysis (glī-KOL-i-sis; *glykus*, sweet + *lysis*, a loosening) is the breakdown of glucose to *pyruvic acid*. In this process, a series of enzymatic steps breaks the six-carbon glucose molecule ($C_6H_{12}O_6$) into two three-carbon molecules of pyruvic acid (CH_3 —CO—COOH). At the normal pH inside cells, each pyruvic acid molecule loses a hydrogen ion and exists as the negatively charged ion CH_3 —CO—COO⁻. This ionized form is called **pyruvate**, rather than pyruvic acid.

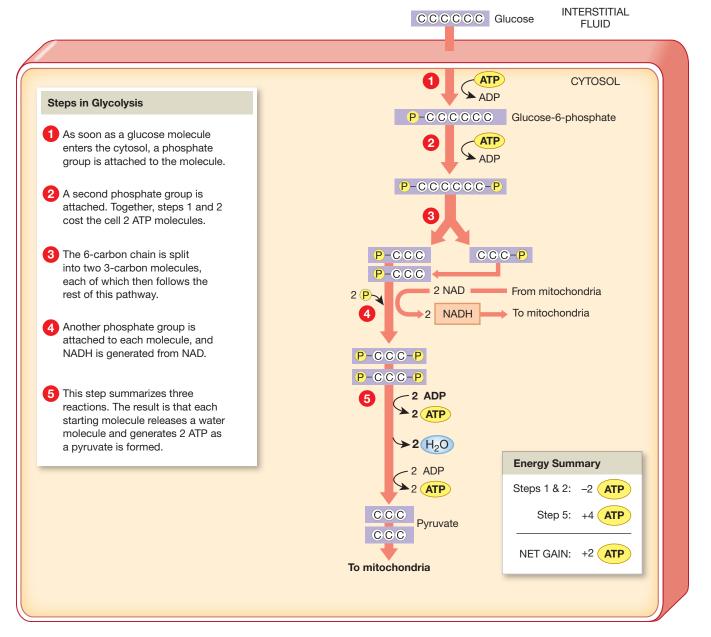

Glycolysis requires (1) glucose molecules; (2) appropriate cytosolic enzymes; (3) ATP and ADP; and (4) **NAD** (**n**icotinamide

adenine dinucleotide), a coenzyme that removes hydrogen atoms. *Coenzymes* are organic molecules, usually derived from vitamins, that must be present for an enzymatic reaction to occur. \bigcirc p. 594 If any of these four participants are missing, glycolysis cannot take place.

The basic steps of glycolysis are summarized in **Figure 17-3**. This reaction sequence yields a net gain of two ATP molecules for each glucose molecule converted to two pyruvate molecules. Two molecules of NADH, another high-energy compound, are also produced.

A few highly specialized cells, such as red blood cells, lack mitochondria and derive all their ATP by glycolysis. Skeletal

Figure 17-3 Glycolysis. Within a cell's cytosol, glycolysis involves a series of enzymatic steps that break down a six-carbon glucose molecule into two three-carbon pyruvate molecules. Each glucose molecule converted to two pyruvate molecules yields a net gain of two ATPs.

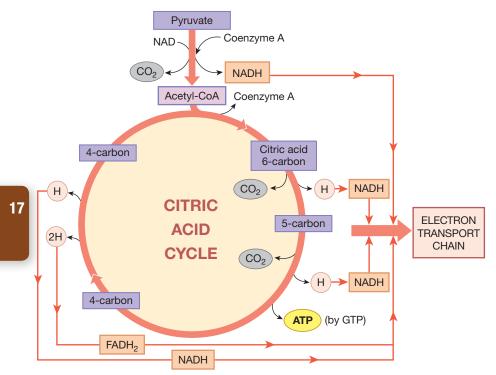

muscle fibers rely on glycolysis for energy production during periods of active contraction. Most cells can survive brief periods of hypoxia (low oxygen levels) by using the small supplies of ATP provided by glycolysis alone. When oxygen is readily available, however, mitochondrial activity provides most of the ATP cells require.

Energy Production Within Mitochondria

Glycolysis yields an immediate net gain of two ATP molecules for the cell. However, a great deal of additional energy is still stored in the chemical bonds of pyruvate. The cell's ability to capture that energy depends on the presence of oxygen. If oxygen supplies are adequate, mitochondria will absorb the pyruvate molecules and break them down completely. The hydrogen atoms of pyruvate are removed by coenzymes and are ultimately the source of most of the cell's energy gain. The carbon and oxygen atoms are removed and released as carbon dioxide.

Recall that a double membrane surrounds each mitochondrion. \bigcirc p. 103 The outer membrane is permeable to ions and small organic molecules such as pyruvate. Such substances easily enter the intermembrane space between the outer and inner membranes. A carrier protein in the inner membrane

Figure 17-4 The Citric Acid Cycle. Within mitochondria, the citric acid cycle breaks down pyruvate molecules produced by glycolysis (and other catabolic pathways). This overview of the citric acid cycle shows the distribution of carbon, hydrogen, and oxygen atoms through one complete turn.

transports the pyruvate from the intermembrane space into the mitochondrial matrix.

Once inside the mitochondrion, each pyruvate molecule takes part in a reaction leading to a sequence of enzymatic reactions called the **citric acid cycle** (Figure 17-4). This reaction sequence is also known as the *tricarboxylic* (trī-kar-bok-SIL-ik) *acid (TCA) cycle*, and the *Krebs cycle*. We use citric acid cycle as the preferred term, because citric acid is the first substrate of the cycle. The role of the citric acid cycle is to remove hydrogen atoms from organic molecules and transfer them to coenzymes.

The Citric Acid Cycle

In the mitochondrion, a pyruvate molecule takes part in a complex reaction involving NAD and another coenzyme called *coenzyme A* (or *CoA*). This reaction yields one molecule each of carbon dioxide, NADH, and **acetyl-CoA** (AS-e-til-K \overline{O} - \overline{a}). Acetyl-CoA consists of a 2-carbon *acetyl group* (CH₃CO) bound to coenzyme A. When the acetyl group is transferred from CoA to a 4-carbon molecule, a 6-carbon molecule called *citric acid* is produced.

As citric acid is produced, CoA is released to bind with another acetyl group. A complete revolution, or turn, of the citric acid cycle removes the two added carbon atoms, regenerating the initial 4-carbon molecule. (This is why this reaction

sequence is called a *cycle*.) The two removed carbon atoms become part of two molecules of carbon dioxide (CO₂), a metabolic waste product. The hydrogen atoms of the acetyl group are removed by coenzymes.

The only immediate energy benefit of one revolution of the citric acid cycle is the formation of a single molecule of *GTP* (guanosine triphosphate). This high-energy compound is readily converted into ATP. The real value of the citric acid cycle can be seen by following the fate of the hydrogen atoms that are removed by the coenzymes NAD and **FAD** (flavine **a**denine **d**inucleotide). The two coenzymes form NADH and FADH₂ and transfer the hydrogen atoms to the *electron transport chain*.

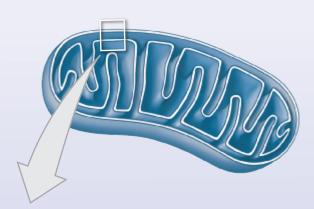

The Electron Transport Chain

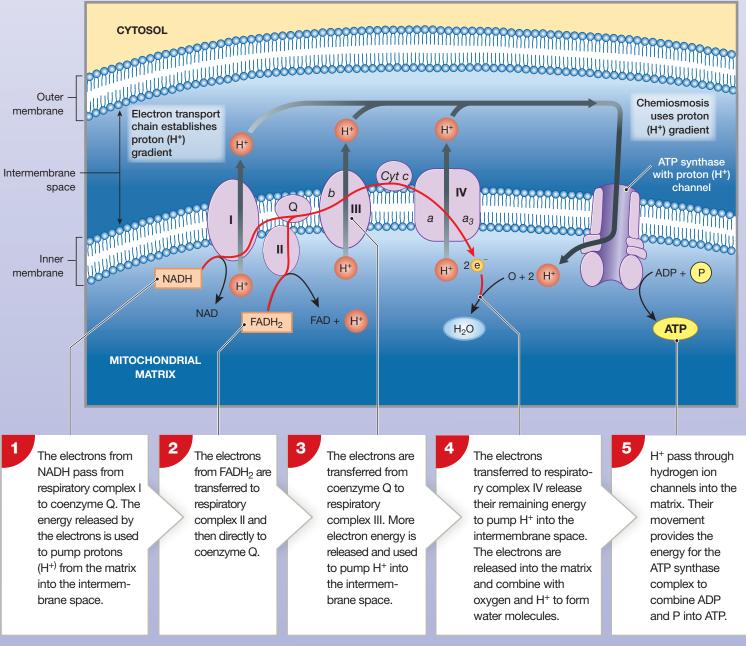

The **electron transport chain (ETC)** is embedded in the inner mitochondrial membrane (**Spotlight Figure 17-5**). The ETC consists of four respiratory protein complexes (I–IV), coenzyme Q, and electron carriers made up

SPOTLIGHT Figure 17-5 ELECTRON TRANSPORT CHAIN AND ATP FORMATION

The final step in aerobic ATP production involves the indirect transfer of energy from the high-energy electrons carried by NADH and FADH₂ to ATP molecules. This energy transfer involves the **electron transport chain** (ETC) and **chemiosmosis** along the inner mitochondrial membrane.

The electron transport chain (ETC) consists of four respiratory complexes (I-IV), coenzyme Q, and cytochrome molecules (b, c, a, and a_3). Except for cytochrome c (Cyt c), these molecules are associated with respiratory complexes III and IV. The hydrogen atoms delivered by NADH and FADH₂ are first split into electrons (e⁻) and protons (H⁺). The high-energy electrons are passed along the respiratory complexes such that their energy is released in a series of small steps. This energy is used to pump H⁺ into the intermembrane space. The result is a proton (H⁺) gradient across the inner membrane. Chemiosmosis uses this proton (H⁺) gradient to generate ATP through ATP synthase. The red line with the arrowhead (\longrightarrow) indicates the paths and destination of the electrons.

of a series of *cytochrome* molecules (b, c, a, and a_3). The cytochromes are proteins, which contain a metal ion, either iron or copper. The ETC does not produce ATP directly. Instead, it creates the conditions necessary for ATP production.

The hydrogen atoms from the citric acid cycle do not enter the ETC intact. Only their high-energy electrons enter the ETC. Their protons are released into the mitochondrial matrix. The electrons that travel along the ETC release energy as they pass from coenzyme Q and along the series of cytochrome molecules.

The red lines in **Spotlight Figure 17-5** show the paths and destinations of electrons. Those from NADH go from respiratory protein complex I to coenzyme Q. The electrons from FADH₂ enter the ETC at respiratory protein complex II and are passed to coenzyme Q. As a result, the electrons carried by NADH enter the ETC at a higher energy level than those carried by FADH₂. The electrons from both paths are passed from coenzyme Q to respiratory protein complex III, which contains cytochrome *b*. From there, the electrons are shuttled by cytochrome *c* to additional cytochromes within respiratory protein complex IV.

The energy released at each of several steps drives proton (H^+) pumps in respiratory protein complexes I, III, and IV. Recall that a hydrogen ion (H^+) consists solely of a proton. $\bigcirc p. 67$ These proton pumps move H^+ from the mitochondrial matrix into the intermembrane space. This pumping creates a steep concentration gradient of protons (H^+) across the inner membrane. The concentration gradient provides the energy to convert ADP to ATP.

Despite the concentration gradient, hydrogen ions cannot diffuse into the matrix because they are not lipid soluble. However, proton (H⁺) channels in the inner membrane permit H⁺ to enter the matrix. These ion channels and attached proteins make up a membrane enzyme called *ATP synthase*. The kinetic energy of the passing hydrogen ions is used to attach a phosphate group to ADP, forming ATP. This overall process is called **chemiosmosis** (kem-ē-oz-MŌ-sis), a term that links the chemical formation of ATP with transport across a membrane. At the end of the ETC, an oxygen atom accepts two electrons from respiratory protein complex IV and combines with two hydrogen ions to form a molecule of water.

The electron transport chain is the most important process for generating ATP. It provides roughly 95 percent of the ATP needed to keep our cells alive. Stopping or slowing the rate of mitochondrial activity will usually kill a cell. For example, if the cell's supply of oxygen is cut off, mitochondrial ATP production will cease because the ETC will be unable to pass along its electrons. With the last reaction in the chain stopped, the entire ETC comes to a halt, like a line of cars at a washed-out bridge. When the ETC stops, NADH and FADH₂ can't drop off their hydrogen atoms, so the citric acid cycle stops as well. The affected cell quickly dies of energy deprivation. If many cells are affected, the individual may die.

Energy Yield of Glycolysis and Cellular Respiration

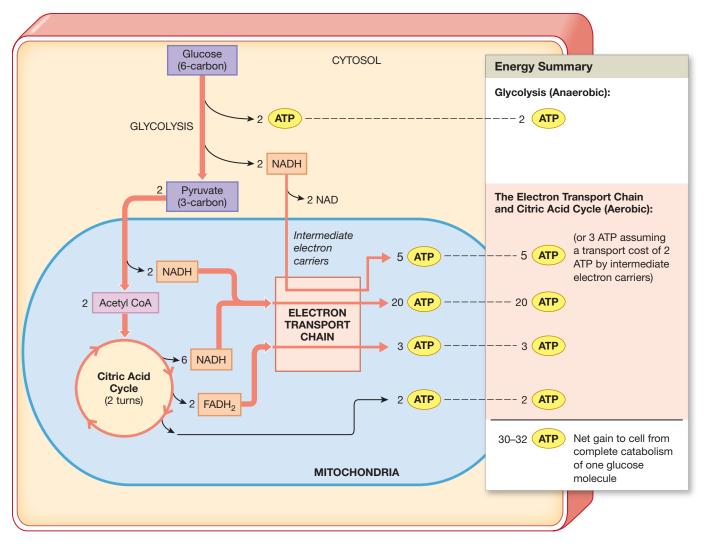

For most cells, the main method of generating ATP is the complete reaction pathway, beginning with glucose and ending with carbon dioxide and water. **Figure 17-6** summarizes the process in terms of energy gained:

- During glycolysis in the cytosol, the cell gains two molecules of ATP and two NADH for each glucose molecule broken down to two pyruvate molecules.
- Inside the mitochondria, the two pyruvate molecules derived from each glucose molecule are fully broken down in the citric acid cycle. Two revolutions of the citric acid cycle, each yielding a molecule of ATP, provide a gain of two additional molecules of ATP. An additional eight NADH and two FADH₂ are also formed.
- For each molecule of glucose broken down, a total of ten NADH and two FADH₂ deliver their high-energy electrons to the electron transport chain in the inner mitochondrial membrane. Overall, each NADH yields 2.5 ATP and each FADH₂ yields 1.5 ATP. So, the ten NADH yield 25 ATP and the two FADH₂ yield 3 ATP, for a total of 28 ATP. Adding the two ATP generated in glycolysis and the two ATP from the citric acid cycle gives a total of 32 molecules of ATP. That total assumes that the cell expends no energy in transporting the hydrogen atoms from the two NADH formed during glycolysis into a mitochondrion. Because the energy requirements of different transport processes vary, it is estimated that up to two ATP are used to transport the two NADH. Subtracting those two ATP then, leaves us a minimal total of 30 ATP.

Summing up, for each glucose molecule processed, a typical cell gains 30–32 molecules of ATP. *All but two of them are produced within mitochondria*.

Gluconeogenesis (Glucose Synthesis)

Some of the steps in the breakdown of glucose, or glycolysis, are not reversible. For this reason, cells cannot generate glucose simply by using the same enzymes and reversing the steps in glycolysis (**Figure 17-7**). Glycolysis and the production of glucose require different sets of regulatory enzymes. As a result, the two processes are independently regulated. **Figure 17-6 A Summary of the Energy Yield of Aerobic Metabolism.** For each glucose molecule broken down by glycolysis, only two molecules of ATP (net) are produced. However, glycolysis, the formation of acetyl-CoA, and the citric acid cycle all yield coenzyme molecules (NADH or FADH₂ molecules). When electrons from these coenzymes pass through the electron transport chain, many additional ATP molecules are produced. The citric acid cycle generates an additional two ATP molecules.

Some three-carbon molecules other than pyruvate can be used to synthesize glucose. For this reason, a cell can create glucose molecules from other carbohydrates, lactate, glycerol, or some amino acid molecules. However, cells cannot use acetyl-CoA to make glucose. This is because the reaction that removes the carbon dioxide molecule (a *decarboxylation*) between pyruvate and acetyl-CoA cannot be reversed.

Gluconeogenesis (gloo-kō-nē-ō-JEN-e-sis; *glykus*, sweet + *neo*-, new + *genesis*, an origin) is the synthesis of glucose from noncarbohydrate precursor molecules, such as lactate (derived from pyruvate when oxygen is less available), glycerol (from lipids), or some amino acids (from proteins). Fatty acids and many amino acids cannot be used for gluconeogenesis because their breakdown produces acetyl-CoA.

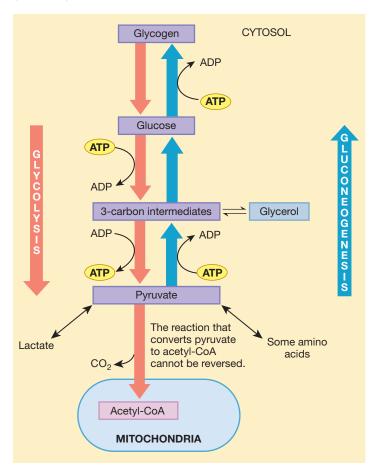

CLINICAL NOTE

kidney damage.

Carbohydrate Loading

Performance in endurance sports improves if muscles have large stores of glycogen. Endurance athletes try to achieve this by eating carbohydrate-rich meals for three days before competing. This practice is called **carbohydrate loading.** Studies in Sweden, Australia, and South Africa have shown that attempts to deplete carbohydrate stores by exercising to exhaustion before carbohydrate loading—a practice called *carbohydrate depletion/loading*—are less effective than three days of rest or minimal exercise during carbohydrate loading. This less intense approach improves mood and reduces the risks of muscle and **Figure 17-7 Carbohydrate Metabolism.** A flowchart of the pathways of glycolysis and gluconeogenesis. Lactate, glycerol, and some amino acids can be converted to glucose in gluconeogenesis.

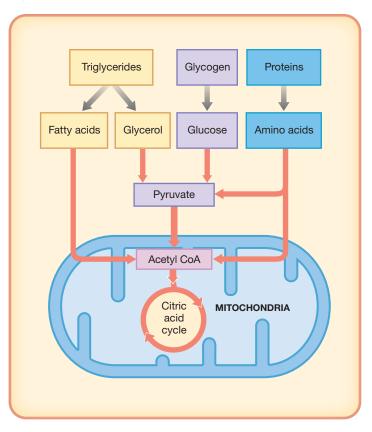

Glucose molecules formed by gluconeogenesis can be used to manufacture other simple sugars, complex carbohydrates, or nucleic acids. In the liver and in skeletal muscle, glucose molecules are stored as **glycogen**. ⊃ p. 69 Glycogen is an important energy reserve that can be broken down when the cell cannot obtain enough glucose from interstitial fluid. Glycogen molecules are large, but glycogen reserves take up very little space because they form compact, insoluble granules.

17

Alternate Catabolic Pathways

Aerobic metabolism is relatively efficient and capable of generating large amounts of ATP. It is the cornerstone of normal cellular metabolism, but it has one obvious limitation—cells must have adequate supplies of both oxygen and glucose. Cells can survive only for brief periods without oxygen. Low glucose concentrations have a much smaller effect on most cells, because cells can break down other nutrients to provide organic

Figure 17-8 Alternate Catabolic Pathways.

molecules for the citric acid cycle (Figure 17-8). Many cells can switch from one nutrient source to another as the need arises. For example, many cells can shift from glucose-based ATP production to lipid-based ATP production when necessary. Recall that skeletal muscles catabolize glucose when actively contracting, but at rest they rely on fatty acids. \bigcirc p. 238

Cells break down proteins for energy only when lipids or carbohydrates are unavailable. This makes sense because the enzymes and organelles that cells need to survive are composed of proteins. Nucleic acids are present only in small amounts, and they are seldom catabolized for energy, even when the cell is dying of acute starvation. This also makes sense, as the DNA in the nucleus determines all the structural and functional characteristics of the cell.

17-3 Lipid metabolism involves lipolysis, beta-oxidation, and the transport and distribution of lipids as lipoproteins and free fatty acids

Learning Outcome Describe the pathways involved in lipid metabolism, and summarize the processes of lipid transport and distribution.

Like carbohydrates, lipid molecules contain carbon, hydrogen, and oxygen, but in different proportions. Triglycerides (fats) are the most abundant lipid in the body, so we will focus on their breakdown and synthesis. \bigcirc p. 71

Lipid Catabolism

During lipid catabolism, or lipolysis (li-POL-i-sis), lipids are broken down into pieces that can be converted to pyruvate or channeled directly into the citric acid cycle (Figure 17-8). A triglyceride is first split into its component parts by hydrolysis, yielding one molecule of glycerol and three fatty acid molecules. Enzymes in the cytosol convert glycerol to pyruvate, which then enters the citric acid cycle. The catabolism of fatty acids involves a different set of enzymes that generate acetyl-CoA directly.

Beta-oxidation is a series of reactions that break the fatty acids down into two-carbon fragments, and generate NADH and FADH₂. This process takes place inside mitochondria, so

the two-carbon fragments can enter the citric acid cycle immediately as acetyl-CoA. (Some of the two-carbon fragments may combine to form ketone bodies, short carbon chains discussed on \bigcirc p. 619.) A cell produces 120 ATP molecules from the breakdown of one 18-carbon fatty acid molecule. This yield is almost 1.3 times the energy obtained from the breakdown of three 6-carbon glucose molecules (90-96 ATP).

Lipids and Energy Production

Lipids are important energy reserves because they can provide large amounts of ATP. Lipids can be stored in compact droplets in the cytosol because they are insoluble in water. However, if the droplets are large, it is difficult for water-soluble enzymes to get at them. For this reason, lipid reserves are more difficult to access than carbohydrate reserves. Also, most lipids are processed inside mitochondria, and mitochondrial activity is limited by the availability of oxygen. The net result is that lipids cannot provide large amounts of ATP quickly.

However, cells with modest energy demands can shift to lipid-based energy production when glucose supplies are limited. Skeletal muscle fibers normally cycle between lipid metabolism and carbohydrate metabolism. At rest (when energy demands are low), these cells break down fatty acids. During activity (when energy demands are high and immediate), skeletal muscle fibers shift to glucose metabolism.

CLINICAL NOTE

Dietary Fats and Cholesterol

Elevated cholesterol levels are associated with the development of coronary artery disease (CAD) \supset p. 444 and atherosclerosis. D p. 463 Nutritionists now recommend limiting cholesterol intake to under 300 mg per day-a 40 percent reduction for the average American adult. Yet cholesterol is important. Consider the following points:

- · Cholesterol has many vital functions in the human body. It is part of all plasma membranes. It waterproofs the epidermis. Cholesterol is also a key constituent of bile, and the precursor of several steroid hormones and one vitamin (D_3) . Because cholesterol is so important, the goal of dietary restrictions is not to eliminate cho-
- lesterol, but to keep cholesterol levels within acceptable limits. • The cholesterol in the diet is not the only source of circulating cholesterol. The human
 - body can manufacture cholesterol from acetyl-CoA obtained during glycolysis or by

the breakdown (beta-oxidation) of other lipids. If the diet contains an abundance of saturated

fats, excess lipids are broken down to acetyl-CoA and used to make cholesterol. People trying to lower blood cholesterol levels by dietary control must also restrict other lipids-especially saturated fats.

- Genetic factors affect each person's cholesterol level. If you reduce your dietary intake of cholesterol, your body will synthesize more to maintain "acceptable" concentrations in the blood. An "acceptable" level depends on your genetic makeup. In virtually all instances, however, dietary restrictions can lower blood cholesterol significantly.
 - Cholesterol levels vary with age and physical condition. In general, as we age, our cholesterol levels gradually rise. Cholesterol levels are considered unhealthy if they are higher than those of 90 percent of the population in a given age group. For males, this level ranges from 185 mg/dL at age 19 to 250 mg/dL at age 70. For females, the comparable levels are 190 mg/dL and 275 mg/dL, respectively. Everyone should be screened for high cholesterol levels as they age.

Lipid Synthesis

Lipogenesis (lip-ō-JEN-e-sis; *lipos*, fat) is the synthesis of lipids. Glycerol is synthesized from an intermediate three-carbon product of glycolysis. The synthesis of most other types of lipids, including steroids and almost all fatty acids, begins with acetyl-CoA. Lipogenesis can use almost any organic molecule because lipids, amino acids, and carbohydrates can be converted to acetyl-CoA.

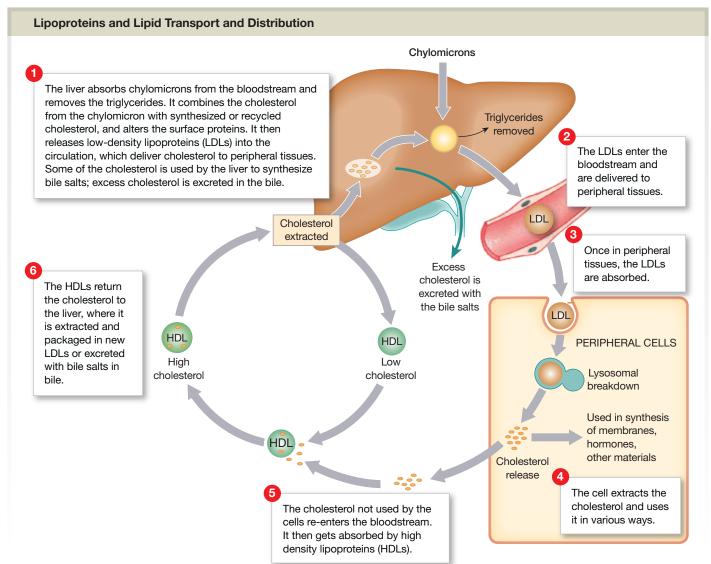

Body cells cannot *build* every fatty acid they can break down. For example, *linoleic acid* and *linolenic acid* are both 18-carbon unsaturated fatty acids synthesized by plants. They cannot be synthesized in the human body. They are called **essential fatty acids** because they must be included in your diet. These fatty acids are also needed to synthesize prostaglandins and phospholipids in plasma membranes throughout the body.

Lipid Transport and Distribution

Like glucose, lipids are needed throughout the body. All cells use lipids to maintain their plasma membranes. Steroid hormones must reach their target cells in many different tissues. Because most lipids are not soluble in water, special means of transport are required to distribute them around the body. Free fatty acids make up a small percentage of the total circulating lipids. Most lipids circulate in the bloodstream as lipoproteins (**Figure 17-9**).

Free fatty acids (FFA) are lipids that can diffuse easily across plasma membranes. A major source of free fatty acids is the breakdown of fat stored in adipose tissue. When released into the blood, the fatty acids bind to albumin, the most abundant plasma protein. Liver cells, cardiac muscle cells, skeletal muscle fibers, and many other body cells can

Figure 17-9 Lipoproteins and Lipid Transport.

metabolize free fatty acids. They are an important energy source during periods of starvation, when glucose supplies are limited.

Lipoproteins are lipid–protein complexes that contain triglycerides and cholesterol. An outer coating of phospholipids and proteins makes the entire complex soluble. The exposed proteins bind to specific membrane receptors. This binding determines which cells absorb the associated lipids.

Lipoproteins are classified by size and by their relative proportions of lipid and protein. One group, the *chylomicrons*, is produced by intestinal epithelial cells from the fats in food. \bigcirc p. 598 They are the largest lipoproteins. About 95 percent of their weight consists of triglycerides. Chylomicrons transport triglycerides absorbed from the intestinal tract to the bloodstream. A capillary wall enzyme breaks down the triglycerides into fatty acids and monoglycerides that are absorbed by skeletal muscle, cardiac muscle, adipose tissue, and the liver.

Two other major groups of lipoproteins are the **low-den**sity lipoproteins (LDLs) and high-density lipoproteins (HDLs). These lipoproteins are formed in the liver and contain few triglycerides. Their main roles are to shuttle cholesterol between the liver and other tissues. LDLs deliver cholesterol to peripheral tissues. It is often called "bad cholesterol" because LDL cholesterol may end up in arterial plaques. HDLs transport excess cholesterol from peripheral tissues to the liver for storage or excretion in the bile. HDL cholesterol is called "good cholesterol" because it is returning from peripheral tissues and does not cause circulatory problems.

CHECKPOINT

- 7. Define lipolysis and beta-oxidation.
- **8.** Why are high-density lipoproteins (HDLs) considered beneficial?

See the blue Answers tab at the back of the book.

17-4 Protein catabolism involves transamination and deamination, and protein synthesis involves amination and transamination

Learning Outcome Discuss protein metabolism and the use of proteins as an energy source.

The body can synthesize at least 100,000 different proteins, each with varied functions and structures. Yet each protein

contains some combination of the same 20 amino acids. Under normal conditions, cellular proteins are continuously recycled in the cytosol. Peptide bonds are broken, and the resulting free amino acids are used in synthesizing new proteins. \bigcirc p. 73

If other energy sources are inadequate, mitochondria can generate ATP by breaking down amino acids in the citric acid cycle. Not all amino acids enter the citric acid cycle at the same point, so the ATP benefits vary. However, the average ATP yield is comparable to that of carbohydrate catabolism.

Amino Acid Catabolism

The first step in amino acid catabolism is the removal of the amino group. This step requires a coenzyme derived from **vitamin B**₆ (*pyridoxine*). The amino group is removed in one of two ways.

Transamination (trans-am-i-NĀ-shun) is a process in which one amino acid is formed from another. The process removes the amino group from an amino acid and attaches it to another small carbon chain, creating a "new" amino acid. In this way, a cell can synthesize many of the amino acids needed for protein synthesis. Cells of the liver, skeletal muscles, heart, lung, kidney, and brain are all particularly active in protein synthesis. These cells perform many transaminations.

Deamination (dē-am-i-NĀ-shun) prepares an amino acid for breakdown in the citric acid cycle. Deamination is the removal of an amino group in a reaction that generates an ammonium ion (NH_4^+) . Ammonium ions are highly toxic, even in low concentrations. Liver cells are the primary sites of deamination. They have enzymes needed to deal with the problem of ammonium ion generation. Liver cells combine carbon dioxide with ammonium ions to produce **urea**, a relatively harmless, water-soluble compound. It is excreted in the urine.

The fate of the carbon chain remaining after deamination in the liver depends on its structure. The carbon chains of some amino acids can be converted to pyruvate and then used in gluconeogenesis. Other carbon chains are converted to acetyl-CoA and broken down in the citric acid cycle. Still others are converted to **ketone bodies**, metabolic acids that are also produced during lipid catabolism. One example of a ketone body generated in the body is *acetone*, a small molecule that can diffuse into the alveoli of the lungs, giving the breath a distinctive "fruity" odor.

Liver cells do not catabolize ketone bodies. Instead, the ketone bodies diffuse from the liver cells and into the

general circulation. Cells in peripheral tissues absorb the ketone bodies and reconvert them into acetyl-CoA for breakdown in the citric acid cycle and the production of ATP. The increased production of ketone bodies during protein and lipid catabolism by the liver results in high ketone body concentrations in body fluids, a condition called **ketosis** (kē-TŌ-sis).

Protein catabolism is not a practical source of quick energy for three reasons:

- **1.** Proteins are more difficult to break apart than are complex carbohydrates or lipids.
- **2.** One of the by-products, ammonium ions, is toxic to cells.
- **3.** Proteins are the most important structural and functional components of any cell. Extensive protein catabolism threatens homeostasis at the cellular and systems levels.

Amino Acids and Protein Synthesis

Your body can synthesize about half of the amino acids needed to build proteins. (The basic process of protein synthesis was detailed in Chapter 3.) \supset pp. 108–111 There are 10 **essential amino acids**, which must come from the diet. Your body cannot synthesize eight of them (*isoleucine, leucine, lysine, threonine, tryptophan, phenylalanine, valine,* and *methionine*). The other two (*arginine* and *histidine*) can be synthesized, but not in amounts that growing children need.

Other amino acids are called **nonessential amino** acids, because the body can make them on demand. Your body cells can readily synthesize the carbon frameworks for them. Then an amino group can be added by transamination or by **amination**—using an ammonium ion as the reactant.

Protein deficiency diseases develop in people who do not consume adequate amounts of all essential amino acids. All amino acids must be available if protein synthesis is to take place. Every transfer RNA molecule must appear at the active ribosome in the proper sequence, bearing its individual amino acid. If that does not happen, the entire process comes to a halt.

Several inherited metabolic disorders result from an inability to produce specific enzymes involved in amino acid metabolism. People with **phenylketonuria** (fen-il-kē-tō-NŪ-rē-uh), or **PKU**, cannot convert the amino acid phenylalanine to the amino acid tyrosine. This reaction is an

essential step in the synthesis of norepinephrine, epinephrine, and melanin. The problem in PKU is a defect in the enzyme phenylalanine hydroxylase. If PKU is not detected in infancy, central nervous system development is inhibited. Severe brain damage results. People with PKU need to follow a diet that limits foods containing phenylalanine. The condition is common enough that a warning is printed on the packaging of products that contain phenylalanine, such as diet drinks.

Figure 17-10 summarizes the major metabolic pathways for lipids, carbohydrates, and proteins. This diagram presents the reactions in a "typical" cell, but no one cell can perform all the anabolic and catabolic operations required by the body as a whole. As cells differentiate during development, each cell type develops its own set of enzymes that determines its metabolic capabilities. With such cellular diversity in the body, homeostasis can be preserved only when the metabolic activities of tissues, organs, and organ systems are coordinated.

CLINICAL NOTE

Ketoacidosis

A ketone body is also called a *keto acid* because it dissociates in solution, releasing a hydrogen ion. The appearance of ketone bodies is a threat to blood plasma pH. During even a brief fasting period, production of ketone bodies increases. During prolonged starvation, ketone levels continue to rise. Eventually, the pH-buffering capacities of the blood are exceeded, and a dangerous drop in pH occurs. This acidification of the blood and body tissues is called **ketoacidosis** (kē-tō-as-i-DŌ-sis). In severe ketoacidosis, pH may fall below 7.05, low enough to disrupt normal tissue activities. Coma, cardiac arrhythmias, and death can result.

In *diabetes mellitus*, most peripheral tissues cannot utilize glucose because of a lack of insulin. \bigcirc p. 396 Under these circumstances, cells survive by catabolizing lipids and proteins. The result is the production of large numbers of ketone bodies. This condition leads to *diabetic ketoacidosis*, the most common and life-threatening form of ketoacidosis.

CHECKPOINT

- **9.** Define transamination and deamination.
- **10.** How would a diet deficient in vitamin B₆ affect protein metabolism?
- See the blue Answers tab at the back of the book.

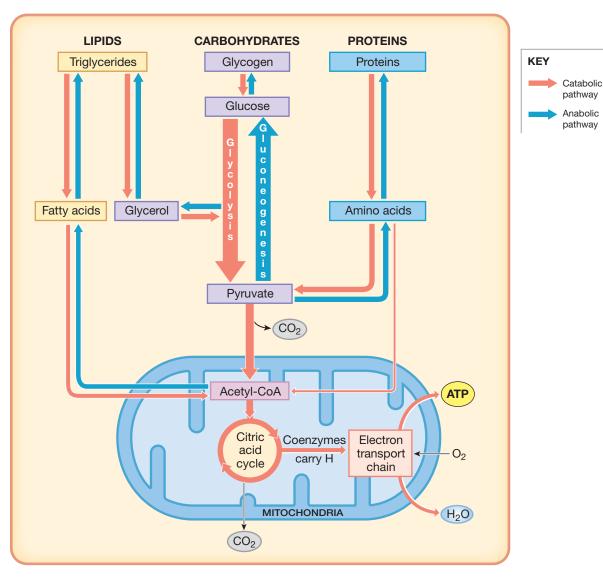

Figure 17-10 A Summary of Catabolic and Anabolic Pathways for Lipids, Carbohydrates, and

Proteins. The major catabolic pathways are in red. The major anabolic pathways are in blue.

17-5 Nucleic acid catabolism involves RNA, but not DNA

Learning Outcome Discuss nucleic acid metabolism and the limited use of nucleic acids as an energy source.

Living cells contain both DNA and RNA. The genetic information contained in nuclear DNA is absolutely essential to the long-term survival of a cell. As a result, DNA is never catabolized for energy, even if the cell is dying of starvation. By contrast, the RNA molecules involved in protein synthesis are broken down and replaced regularly.

RNA Catabolism

In the breakdown of RNA, the molecule is disassembled into individual nucleotides. Most nucleotides are recycled into new nucleic acids, but they can also be broken down to simple sugars and nitrogen bases. When nucleotides are broken down, only the sugars, cytosines, and uracils can enter the citric acid cycle and be used to generate ATP. Adenine and guanine cannot be catabolized. Instead, these nitrogen bases undergo deamination and are excreted as **uric acid**. Like urea, uric acid is a relatively nontoxic waste product, but it is far less soluble than urea. Urea and uric acid are called *nitrogenous wastes*, because they contain nitrogen atoms. An elevated level of uric acid in the blood is called *hyperuricemia* (hī-per-ū-ri-SĒ-mē-uh). Uric acid saturates body fluids. Although symptoms may not appear immediately, uric acid crystals may begin to form. The condition that then develops is called *gout*. Initially, the joints of the limbs are affected, especially the metatarsal-phalangeal joint of the great toe. Most cases of hyperuricemia and gout are linked to problems with the excretion of uric acid by the kidneys.

Nucleic Acid Synthesis

Most cells synthesize RNA, but DNA synthesis takes place only in cells preparing for mitosis (cell division) or meiosis (gamete production). (We described the process of DNA replication in Chapter 3.) \supset p. 112

Messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA) are transcribed by different forms of the enzyme RNA polymerase. Messenger RNA is manufactured when specific genes are activated. A strand of mRNA has a life span measured in minutes or hours. Ribosomal RNA and tRNA are more durable than mRNA. For example, the average strand of rRNA lasts just over five days. However, replacement of rRNA and tRNA involves a considerable amount of synthetic activity.

CHECKPOINT

17

- 11. Why do cells not use DNA as an energy source?
- 12. What are nitrogenous wastes?
- **13.** Elevated levels of uric acid in the blood could indicate an increased catabolic rate for which type of macromolecule?

See the blue Answers tab at the back of the book.

17-6 Adequate nutrition is necessary to prevent deficiency disorders and maintain homeostasis

Learning Outcome Explain what makes up a balanced diet and why such a diet is important.

Homeostasis can be maintained indefinitely only if the digestive tract absorbs fluids, organic substances, minerals, and vitamins at a rate that keeps pace with cellular demands. The absorption of nutrients from food is called **nutrition**.

The body's requirement for each nutrient varies from day to day and from person to person. *Nutritionists* attempt to analyze a diet in terms of its ability to meet the needs of a specific individual. A **balanced diet** contains all the nutrients needed to maintain homeostasis. Such a diet includes essential amino acids and fatty acids, minerals, vitamins, and substrates for generating energy. In addition, the diet must include enough water to replace losses in urine, feces, and evaporation. A balanced diet prevents **malnutrition**, an unhealthy state resulting from the inadequate or excessive absorption of one or more nutrients.

Food Groups and a Balanced Diet

One way of maintaining good health and preventing malnutrition is to consume a diet based on the ChooseMyPlate plan. To remind Americans to eat a healthful diet, the United States Department of Agriculture created a diagram of a place setting at mealtime called MyPlate (Figure 17-11). It shows the proportions of food we should consume from each of the **five basic food groups:** grains (orange), vegetables (green), fruits (red), dairy (blue), and protein (purple). Oils should be used sparingly in addition to the five basic food groups. Table 17-1 summarizes the benefits of these food groups. (Visit www .choosemyplate.gov for more information.)

It is important that you take in nutrients in sufficient *quantity* (to meet your energy needs) and *quality* (including essential amino acids, fatty acids, vitamins, and minerals). The key is to make intelligent choices about what you eat.

Figure 17-11 MyPlate Food Guide. The recommended proportion of each food group at mealtime is indicated by its size on the plate. Foods should be consumed in proportions based on both the food group and the individual's level of activity.

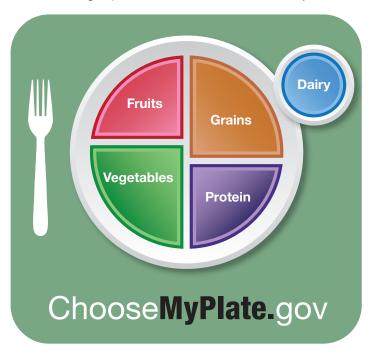

Table 17-1	Basic Food Groups and Their Effects on Health				
Nutrient Group		Provides	Health Effects		
Grains (recommended: at least half of the total eaten should be whole grains)		Carbohydrates; vitamins E, thiamine, niacin, folate; calcium; phosphorus; iron; sodium; dietary fiber	Whole grains prevent rapid rise in blood glucose levels, and consequent rapid rise in insulin levels		
Vegetables (recommended: especially dark-green and orange vegetables)		Carbohydrates; vitamins A, C, E, folate; dietary fiber; potassium	Reduce risk of cardiovascular disease; protect against colon cancer (folate) and prostate cancer (lycopene in tomatoes)		
Fruits (recommended: a variety of fruit each day)		Carbohydrates; vitamins A, C, E, folate; dietary fiber; potassium	Reduce risk of cardiovascular disease; protect against colon cancer (folate)		
Dairy (recommended: low-fat or fat-free milk, yogurt, and cheese)		Complete proteins; fats; carbohydrates; calcium; potassium; magnesium; sodium; phosphorus; vita- mins A, B ₁₂ , pantothenic acid, thiamine, riboflavin	Good source of calcium, which strengthens bones; Whole milk: High in calories, may cause weight gain; saturated fats correlated with heart disease		
Protein (recommended: lean meats, fish, poultry, eggs, dry beans, nuts, legumes)		Complete proteins; fats; calcium; potassium; phosphorus; iron; zinc; vitamins E, thiamine, B ₆	Fish and poultry lower risk of heart disease and colon cancer (compared to red meat). Consumption of up to one egg per day does not appear to increase incidence of heart disease; nuts and legumes improve blood cholesterol ratios, lower risk of heart disease and diabetes		

For example, consider the essential amino acids. You must obtain them from your diet. Some foods in the dairy and protein groups—specifically, beef, fish, poultry, eggs, and milk—provide all the essential amino acids in sufficient quantities. They are said to contain **complete proteins**. Many plants also supply adequate *amounts* of protein, but these are **incomplete proteins** because one or more essential amino acids are lacking. People who follow a vegetarian diet, which is largely restricted to the grains, fruits, and vegetables groups (with or without the dairy group), must include a combination of foods that meets all their amino acid requirements. A vegan diet, which avoids all animal products, can be a problem because vitamin B₁₂ can be obtained only from animal products, or from fortified cereals or tofu.

Table 17.1 Basis Food Groups and Their Effects on Health

Minerals, Vitamins, and Water

Minerals, vitamins, and water are essential components of the diet. The body cannot synthesize minerals. Our cells can generate only a small quantity of water and very few vitamins.

Minerals

Minerals are inorganic ions released through the dissociation of electrolytes, such as sodium chloride. Minerals are important for three reasons:

- **1.** *Ions such as sodium and chloride determine the osmotic concentration of body fluids.* Potassium is important in maintaining the osmotic concentration inside body cells.
- 2. *Ions in various combinations play major roles in important physiological processes.* As we have seen, these processes include the maintenance of membrane

. •

Build Your Knowledge

Recall that inorganic compounds are substances that generally do not contain carbon and hydrogen (as you saw in **Chapter 2: The Chemical Level of Organization**). They include small molecules (such as carbon dioxide and water) and ionic compounds. Inorganic compounds held together by ionic bonds undergo dissociation or ionization in water. In this process, ionic bonds are broken as individual ions interact with the positive or negative ends of polar water molecules. **Dpp. 64–65**

potentials; the construction and maintenance of the skeleton; muscle contraction; the generation of action potentials; the release of neurotransmitters; blood clotting; the transport of respiratory gases; buffer systems; fluid absorption; and waste removal.

3. *Ions are essential cofactors in a variety of enzymatic reactions.* For example, the enzyme that breaks down ATP (ATPase) in a contracting skeletal muscle requires the presence of calcium and magnesium ions. Another type of ATPase required for the conversion of glucose to pyruvate needs both potassium and magnesium ions.

The major minerals and a summary of their functions are presented in **Table 17-2**. Your body contains reserves of several important minerals. However, the reserves are often small. Chronic dietary deficiencies can lead to various clinical problems. On the other hand, a dietary excess of mineral ions can also prove dangerous.

Table 17-2 Minerals and Mineral Reserves

Mineral	Significance	Total Body Content	Primary Route of Excretion	Recommended Daily Allowance (RDA) in mg
BULK MINERALS	Significance		Excretion	
Sodium	Major cation in body fluids; essential for normal membrane function	110 g, primarily in body fluids	Urine, sweat, feces	1500
Potassium	Major cation in cytoplasm; essential for normal membrane function	140 g, primarily in cytoplasm	Urine	4700
Chloride	Major anion in body fluids; functions in forming HCl	89 g, primarily in body fluids	Urine, sweat	2300
Calcium	Essential for normal muscle and neuron function, and normal bone structure	1.36 kg, primarily in skeleton	Urine, feces	1000–1200
Phosphorus	In high-energy compounds, nucleic acids, and bone matrix (as phosphate)	744 g, primarily in skeleton	Urine, feces	700
Magnesium	Cofactor of enzymes, required for normal membrane functions	29 g (skeleton, 17 g; cytoplasm and body fluids, 12 g)	Urine	310–400
TRACE MINERALS				
Iron	Component of hemoglobin, myoglobin, cytochromes	3.9 g (1.6 g stored as ferritin or hemosiderin)	Urine (traces)	8–18
Zinc	Cofactor of enzyme systems, notably car- bonic anhydrase	2 g	Urine, hair (traces)	8–11
Copper	Required as cofactor for hemoglobin syn- thesis	127 mg	Urine, feces (traces)	0.9
Manganese	Cofactor for some enzymes	11 mg	Feces, urine (traces)	1.8–2.3

Vitamins

A **vitamin** (*vita*, life) is an essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. There are two groups: fat-soluble vitamins and water-soluble vitamins.

Fat-Soluble Vitamins. Vitamins A, D, E, and K are **fat-soluble vitamins**. They dissolve in lipids. They are absorbed primarily from the digestive tract along with the lipid contents of micelles.

The term *vitamin* D refers to a group of steroid-like molecules, including vitamin D_3 , or cholecalciferol. \bigcirc p. 72 Unlike the other fat-soluble vitamins, which must be absorbed across the digestive tract, vitamin D_3 can usually be synthesized in adequate amounts by skin exposed to sunlight. Current information about the fat-soluble vitamins is summarized in Table 17-3.

Fat-soluble vitamins normally diffuse into plasma membranes, including the lipid inclusions in the liver and adipose tissue. As a result, your body contains a significant reserve of these vitamins. For this reason, a dietary insufficiency of fat-soluble vitamins rarely causes the signs and symptoms of **hypovitaminosis** (hī-pō-vī-ta-min-Ō-sis), or *vitamin deficiency disease. Too much* of a vitamin can also have harmful effects. **Hypervitaminosis** (hī-per-vī-ta-min-Ō-sis) occurs when dietary intake exceeds the body's ability to store, use, or excrete a particular vitamin. This condition most often involves one of the fat-soluble vitamins.

Water-Soluble Vitamins. Most of the **water-soluble vitamins** are components of coenzymes (**Table 17-4**). For example, NAD is derived from niacin, FAD from vitamin B_2 (riboflavin), and coenzyme A from vitamin B_5 (pantothenic acid). Water-soluble vitamins are rapidly exchanged between the digestive tract and the circulating blood. Excessive amounts are readily excreted in the urine. For this reason, hypervitaminosis involving water-soluble vitamins is relatively uncommon, except among people who take large doses of vitamin supplements.

The bacteria that live in the intestines help prevent deficiency diseases. They produce small amounts of five of the nine water-soluble vitamins, in addition to fat-soluble vitamin K. The intestinal epithelium can easily absorb all the water-soluble vitamins except B_{12} . The B_{12} molecule is large. To be absorbed, it must be bound to intrinsic factor from the gastric mucosa, as we discussed in Chapter 16. \bigcirc p. 579

Water

Daily water requirements average 2500 mL (10 cups), or about 40 mL/kg (0.6 fl oz/lb) body weight. The specific requirement varies with environmental conditions and metabolic activities. For example, exercise increases metabolic energy requirements and accelerates water losses due to evaporation and perspiration. The temperature rise accompanying a fever has a similar

Table 17-3The Fat-Soluble Vitamins

Vitamin	Significance	Sources	Recommended Daily Allowance (RDA) in mg	Effects of Deficiency	Effects of Excess
A	Maintains epithelia; required for synthesis of visual pigments; sup- ports immune system; promotes growth and bone remodeling	Leafy green and yellow vegetables	0.7–0.9	Retarded growth, night blindness, deterioration of epithelial membranes	Liver damage, skin peeling, CNS effects (nausea, anorexia)
D (also known as D ₃)	Required for normal bone growth, intestinal calcium and phosphorus absorption, and retention of these ions at the kidneys	Synthesized in skin exposed to sunlight	0.005–0.015*	Rickets, skeletal dete- rioration	Calcium deposits in many tissues, disrupting functions
E	Prevents breakdown of vitamin A and fatty acids	Meat, milk, vegetables	15	Anemia, other problems suspected	Nausea, stomach cramps, blurred vision, fatigue
K	Essential for liver synthesis of pro- thrombin and other clotting factors	Vegetables; production by intesti- nal bacteria	0.09–0.12	Bleeding disorders	Liver dysfunction, jaundice

effect. For each degree (°C) that temperature rises above normal, daily water loss increases by 200 mL. The advice "Drink plenty of fluids" when you are sick has a solid physiological basis.

You obtain most of your daily water ration by eating or drinking. Food provides roughly 48 percent, and another

40 percent comes from drinking fluids. A small amount of water—called *metabolic water*—is produced in mitochondria by the electron transport chain. \bigcirc p. 613 Metabolic water amounts to roughly 300 mL of water per day (slightly more than 1 cup), about 12 percent of the average daily water requirement.

Table 17-4	The Water-Soluble Vitamins					
Vitamin	Significance	Sources	Recommended Daily Allowance (RDA) in mg	Effects of Deficiency	Effects of Excess	
B ₁ (thiamine)	Coenzyme in many pathways	Milk, meat, bread	1.1–1.2	Muscle weakness, CNS and cardiovascular problems including heart disease; called <i>beriberi</i>	Hypotension	
B ₂ (riboflavin)	Part of FAD	Milk, meat, eggs, cheese	1.1–1.3	Epithelial and mucosal dete- rioration	Itching, tingling	
B ₃ (niacin, nicotinic acid)	Part of NAD	Meat, bread, potatoes	14–16	CNS, GI, epithelial, and mucosal deterioration; called <i>pellagra</i>	Itching, burning; vasodi- lation; death after large dose	
B₅ (pantothenic acid)	Part of coenzyme A	Milk, meat	10	Delayed growth, CNS distur- bances	None reported	
B ₆ (pyridoxine)	Coenzyme in amino acid and lipid metabolism	Meat, whole grains, vegetables, orange juice, cheese and milk	1.3–1.7	Delayed growth, anemia, convulsions, epithelial changes	CNS alterations, per- haps fatal	
B ₇ (biotin)	Coenzyme in many pathways	Eggs, meat, vegetables	0.03	Fatigue, muscular pain, nau- sea, dermatitis	None reported	
B ₉ (folic acid [synthetic], fo- late [natural])	Coenzyme in amino acid and nucleic acid metabolisms	Leafy vegetables, some fruits, liver, cereal and bread	0.2–0.4	Delayed growth, anemia, gastrointestinal disorders, developmental abnormalities	Few noted except at massive doses	
B ₁₂ (cobalamin)	Coenzyme in nucleic acid metabolism	Milk, meat	0.0024	Impaired RBC production, causing <i>pernicious anemia</i>	Polycythemia (elevated hematocrit)	
C (ascorbic acid)	Coenzyme in many pathways	Citrus fruits	75–90; Smokers add 35 mg	Epithelial and mucosal dete- rioration; called scurvy	Kidney stones	

Diet and Disease

Diet has a profound influence on our general health. We have already considered the effects of too many and too few nutrients, above-normal or below-normal concentrations of minerals, and hypervitaminosis and hypovitaminosis. More subtle long-term problems can occur when the diet includes the wrong proportions or combinations of nutrients. The average diet in the United States contains too much sodium and too many calories, and lipids—particularly saturated fats—provide too great a proportion of those calories. Such a diet increases the incidence of obesity, heart disease, atherosclerosis, hypertension, and diabetes in the U.S. population.

CHECKPOINT

- **14.** Identify the two types of vitamins.
- **15.** What is the difference between foods containing complete proteins and those containing incomplete proteins?
- 16. How would a decrease in the amount of bile salts in the bile affect the amount of vitamin A in the body?See the blue Answers tab at the back of the book.

17-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing processes

Learning Outcome Define metabolic rate, describe the factors involved in determining an individual's BMR, and discuss the homeostatic processes that maintain a constant body temperature.

When chemical bonds are broken, energy is released. Inside

cells, some of that energy may be captured as ATP, but much of it is lost to the environment as heat. The unit of energy measurement is the **calorie** (KAL-o-rē) (Cal), the amount of energy required to raise the temperature of 1 g of water 1 degree Celsius. One gram of water is not a very practical measure when you are interested in the metabolic operations that keep a 70-kg human alive, so we use the **kilocalorie (kcal)** (KIL-ō-kal-o-rē), or **Calorie** (abbreviated Cal), also known as the "large calorie," instead. One Calorie is the amount of energy needed to raise the temperature of 1 *kilo*gram of water 1 degree Celsius. Calorie-counting guides for foods list Calories, not calories.

The Energy Content of Food

How do we know how much energy food contains? In cells, organic molecules combine with oxygen and are broken down to carbon dioxide and water. Oxygen is also consumed when something burns, and this process of combustion can be experimentally observed and measured. A known amount of food is sealed inside a chamber, called a **calorimeter** (kalō-RIM-e-ter), which is filled with oxygen and surrounded by a known volume of water. Then the chamber contents are electrically ignited. When the food has completely burned to ash, the number of Calories released can be determined by comparing the water temperatures before and after the test.

Such measurements show that the burning, or catabolism, of lipids releases a considerable amount of energy—roughly 9.46 Calories per gram (Cal/g). In contrast, the catabolism of carbohydrates releases 4.18 Cal/g, and the catabolism of protein releases 4.32 Cal/g. Most foods are mixtures of fats, proteins, and carbohydrates, so the values in a "Calorie counter" vary as a result.

Energy Expenditure: Metabolic Rate

Clinicians can examine your metabolic state and determine how many Calories your body uses. The result can be expressed as Calories per hour, Calories per day, or Calories per unit of body weight per day. What is actually measured is the sum of all the various anabolic and catabolic processes occurring in your body—your **metabolic rate** at that time. Metabolic rate varies with the activity under way. For instance, measurements taken while a person is sprinting are quite different from those taken while a person is sleeping. **Figure 17-12** shows the energy expenditures for various common activities.

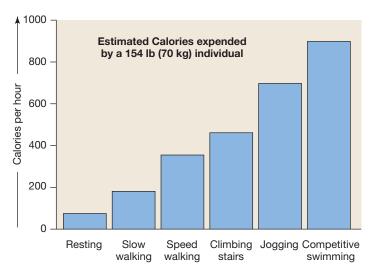

Figure 17-12 Caloric Expenditures for Various Activities.

To reduce such variations, the testing conditions are standardized so as to determine the **basal metabolic rate (BMR)**. Ideally, the BMR reflects the minimum, resting energy expenditures of an awake, alert person. An average individual has a BMR of 70 Cal per hour, or about 1680 Cal per day. Although the test conditions are standardized, other uncontrollable factors influence the BMR. These factors include age, sex, physical condition, body weight, and genetic differences.

Daily energy expenditures for a given individual vary widely with activity. For example, a person leading a sedentary life may have minimal energy demands, but one hour of swimming can increase the daily caloric requirements by 500 Cal or more. If daily energy intake exceeds the body's total energy demands, the excess energy will be stored, primarily as triglycerides in adipose tissue. If daily caloric expenditures exceed dietary intake, the body's energy reserves will decrease, with a corresponding loss in weight. This relationship explains the importance of both Calorie counting and daily exercise in a weight-control program.

Thermoregulation

The BMR (basal metabolic rate) estimates the rate of energy use by the body. Body cells capture only a part of that energy as ATP, and the rest is "lost" as heat. This heat loss serves an important homeostatic purpose. Humans are subject to vast changes in environmental temperatures, but our complex biochemical systems have a major limitation. Our enzymes operate over only a relatively narrow temperature range. Accordingly, our bodies have anatomical and physiological mechanisms that keep body temperatures within acceptable limits, regardless of environmental conditions. This homeostatic process is called **thermoregulation** (*therme*, heat). \supset p. 40 Failure to control body temperature can result in serious physiological effects. For example, a body temperature below 36°C (97°F) or above 40°C (104°F) can cause disorientation. A temperature above 42°C (108°F) can cause convulsions and permanent cell damage.

Processes of Heat Transfer

Heat exchange with the environment involves four basic processes: (1) *radiation*, (2) *conduction*, (3) *convection*, and (4) *evaporation* (Figure 17-13).

1. *Radiation.* Objects warmer than the environment lose heat as infrared radiation. When you feel the sun's heat, you are experiencing radiant heat. Your body loses heat the same way, but in proportionally smaller amounts. More than half of the heat you lose indoors is lost through radiation.

- **2.** *Conduction.* Conduction is the direct transfer of energy through physical contact. When you sit on a cold plastic chair in an air-conditioned room, you are immediately aware of this process. Conduction is generally not an effective way of gaining or losing heat. Its impact depends on the temperature of the object and the amount of skin area it contacts.
- **3.** *Convection.* Convection is heat loss to the cooler air that moves across the surface of your body. As your body loses heat to the air next to your skin, that air warms and rises, moving away from the skin surface. Cooler air replaces it, and as this air in turn warms, the pattern repeats. Convection accounts for about 15 percent of the body's heat loss indoors.
- **4.** *Evaporation.* When water evaporates, it changes from a liquid to a vapor. Evaporation absorbs energy—roughly 580 calories (0.58 Cal) per gram of water evaporated—and cools the surface on which it occurs. The rate of evaporation at your skin is highly variable. Each hour, 20–25 mL of water crosses epithelia and evaporates from the alveolar surfaces of the lungs and the surface of the skin. This *insensible water loss* remains relatively constant. It accounts for roughly 20 percent of your body's average indoor heat loss. The sweat glands are responsible for *sensible perspiration*. They have a tremendous scope of activity, ranging from virtual inactivity to secretory rates of 2–4 liters (or 2–4 kg) per hour. This rate is equivalent to an entire day's resting water loss in under an hour.

Figure 17-13 Processes of Heat Transfer.

To maintain a constant body temperature, an individual must lose heat as fast as it is generated by metabolic operations. Heat loss and heat gain involve the activities of many different systems. The **heat-loss center** and **heat-gain center** of the hypothalamus coordinate those activities. The heat-loss center adjusts activity through the parasympathetic division of the autonomic nervous system, and the heat-gain center directs its responses through the sympathetic division. The overall effect is to control temperature fluctuations by influencing two events: the rate of heat production and the rate of heat loss to the environment. Changes in behavior, such as moving into the shade or sunlight, or adding or removing clothing, may also support these processes.

Promoting Heat Loss. When the temperature at the heat-loss center rises above its set point, three responses occur:

- 1. *The vasomotor center is inhibited.* This response causes peripheral blood vessels to dilate, sending warm blood flowing to the surface of the body. The skin takes on a reddish color and rises in temperature. Heat loss through radiation and convection increases.
- 2. Sweat glands are stimulated to increase their secretions. The perspiration flows across the skin, and heat loss through evaporation speeds up.
- **3.** *The respiratory centers are stimulated.* As a result, the depth of respiration increases. Often, the person begins breathing through the mouth, which enhances heat loss through increased evaporation from the lungs.

The efficiency of heat loss by evaporation varies with environmental conditions, especially the "relative humidity" of the air. At 100 percent humidity, the air is saturated. It is holding as much water vapor as it can at that temperature. Under these conditions, cooling by evaporation is ineffective. This is why humid, tropical conditions can be so uncomfortable—people perspire continuously but remain warm and wet.

Promoting Heat Gain. The function of the heat-gain center of the brain is to prevent **hypothermia** (hī-pō-THER-mē-uh), or below-normal body temperature. When body temperature falls below acceptable levels, the heat-loss center is inhibited

and the heat-gain center is activated. Its activation results in responses that: (1) *conserve body heat*, and (2) *promote heat generation*.

Stimulation of the vasomotor center constricts peripheral blood vessels and decreases blood flow to the skin, reducing losses of heat by radiation, convection, and conduction. The skin cools. With blood flow restricted, the skin may take on a bluish or pale coloration. In addition, blood returning from the limbs is shunted into a network of deep veins that lies beneath an insulating layer of subcutaneous fat. \bigcirc p. 483 (Under warm conditions, blood flows through a superficial venous network, where heat can be lost.)

In addition to conserving heat, the heat-gain center stimulates two processes that generate heat. In *shivering thermogenesis* (ther-mō-JEN-e-sis), muscle tone is gradually increased until stretch receptors stimulate brief, oscillatory contractions of antagonistic skeletal muscles. The resulting shivering stimulates energy consumption by skeletal muscles, and the generated heat warms the deep vessels to which the blood has been diverted. Shivering can increase the rate of heat generation by as much as 400 percent.

Nonshivering thermogenesis involves the release of hormones that increase the metabolic activity of all tissues. The heat-gain center stimulates the adrenal medullae through the sympathetic division of the autonomic nervous system. As a result, epinephrine is released. It increases both the breakdown of glycogen and glycolysis in the liver and in skeletal muscles, and increases the metabolic rate in most tissues. The heat-gain center also stimulates the release of thyroxine by the thyroid gland, increasing the rate of carbohydrate catabolism and the breakdown of all other nutrients. These effects develop gradually over a period of days to weeks.

CHECKPOINT

- **17.** Compare a pregnant woman's BMR (basal metabolic rate) to her BMR when she is not pregnant.
- **18.** Under what conditions would evaporative cooling of the body be ineffective?
- **19.** What effect would vasoconstriction of peripheral blood vessels have on body temperature on a hot day?
- See the blue Answers tab at the back of the book.

17-8 Caloric needs decline with advancing age

Learning Outcome Describe the age-related changes in dietary requirements.

Nutritional requirements do not change drastically with age. However, changes in lifestyle, eating habits, and income can affect nutrition and health. The recommended proportions of calories provided by different foods remain the same at all ages. Proteins should provide 11–12 percent of daily caloric intake, carbohydrates 55–60 percent, and fats less than 30 percent.

Caloric *requirements*, however, do change with aging. For each decade after age 50, caloric requirements decrease by 10 percent. These decreases are associated with reductions in metabolic rates, body mass, activity levels, and exercise tolerance.

With age, several factors combine to produce an increased need for calcium. Some degree of osteoporosis is a normal consequence of aging. A sedentary lifestyle contributes to the problem. The rate of bone loss decreases if calcium levels are kept elevated.

Elderly people are also likely to require supplemental vitamin D_3 if they are to absorb the calcium they need. Many

elderly people spend most of their time indoors and avoid the sun when outdoors. This behavior slows sun damage to their skin, which is thinner than that of younger people. However, it also halts vitamin D_3 production by the skin. \bigcirc p. 157 This vitamin is converted to the hormone calcitriol, which stimulates calcium absorption by the small intestine.

Maintaining a healthy diet becomes more difficult with age due to changes in the senses of smell and taste and in the structure of the digestive system. With age, the number and sensitivity of olfactory and gustatory receptors decrease. **>** p. 368 Food seems less appetizing, so elderly people eat less. The mucosal lining of the digestive tract becomes thinner with age, so nutrient absorption becomes less efficient. Elderly people on fixed budgets may also eat less animal protein, the main source of iron in the diet. Small quantities plus inefficient absorption makes them prone to iron deficiency, which causes anemia.

CHECKPOINT

- **20.** Which changes with aging: nutritional requirements or caloric requirements?
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

anorexia: Persistent loss of appetite.

antipyretic drugs: Drugs administered to control or reduce fever.

eating disorders: Psychological problems that result in inadequate or excessive food consumption. Examples include anorexia nervosa and bulimia.

familial hypercholesterolemia: The most common inherited type of hyperlipidemia (high levels of lipids in the blood). It affects one in every 500 children born, who then present with high LDL levels.

heat exhaustion: A malfunction of thermoregulatory mechanisms caused by excessive fluid loss in perspiration.

heat stroke: A condition in which the thermoregulatory center stops functioning and body temperature rises uncontrollably.

ketonemia (kē-tō-NĒ-mē-uh): Elevated levels of ketone bodies in blood.

ketonuria (kē-tō-NOO-rē-uh): The presence of ketone bodies in urine.

liposuction: The removal of adipose tissue by suction through an inserted tube.

obesity: Body weight more than 20 percent above the ideal weight for a given individual.

pyrexia (pī-REK-sē-uh): A fever; that is, a body temperature greater than 99°F (37.2°C).

Chapter Review

Summary Outline

17-1 Metabolism refers to all the chemical reactions in the body, and energetics refers to the flow and transformation of energy *p. 608*

- **1. Energetics** is the study of the flow of energy and its change(s) from one form to another. Its focus includes understanding a range of energy requirements from cells to the whole body.
- **2.** In general, during *cellular metabolism*, cells break down excess carbohydrates first, then lipids, while conserving amino acids. Only about 40 percent of the energy released through *catabolism* is captured in ATP; the rest is released as heat. (*Figure 17-1*)
- **3.** Cells synthesize new compounds (*anabolism*) to (1) perform structural maintenance and repair, (2) support growth, (3) produce secretions, and (4) build nutrient reserves.
- **4.** Cells "feed" small organic molecules to their mitochondria; in return, the cells get the ATP they need to perform cellular functions. (*Figure 17-2*)

17-2 Carbohydrate metabolism involves glycolysis, ATP production, and gluconeogenesis *p. 610*

- **5.** Most cells generate ATP and other high-energy compounds through the breakdown of carbohydrates.
- **6. Glycolysis** and **aerobic metabolism** provide most of the ATP used by typical cells. In glycolysis, each molecule of glucose yields two molecules of pyruvate and two molecules of ATP. (*Figure 17-3*)
- **7.** In the presence of oxygen, the pyruvate molecules enter the mitochondria, where they are broken down completely in the **citric acid cycle**. The carbon and oxygen atoms are lost as carbon dioxide, and the hydrogen atoms are passed by *coenzymes* to the *electron transport chain. (Figure 17-4)*
- **8. The electron transport chain (ETC)** is embedded in the inner mitochondrial membrane. It is made up of four respiratory protein complexes, coenzyme Q, and *cytochromes* that eventually pass along electrons to oxygen to form water. Energy released by the passage of the electrons is used to pump protons (H⁺) from the matrix to the intermembrane space. *(Spotlight Figure 17-5)*

17

9. ATP is formed through **chemiosmosis**. During this process, H⁺ pass from the intermembrane space to the mitochondrial matrix through H⁺ channels in the inner membrane. Energy from the movement of the H⁺ is used by *ATP synthase* to form ATP from ADP and P. (*Spotlight Figure 17-5*)

- **10.** For each glucose molecule processed through glycolysis, the citric acid cycle, and the ETC, a typical cell gains 30–32 ATP molecules. (*Figure 17-6*)
- **11. Gluconeogenesis**, the synthesis of glucose, enables a cell to manufacture glucose molecules from noncarbohydrate carbon substrates such as pyruvate, lactate, glycerol, or some amino acids. *Glycogen* is an important energy reserve when extracellular glucose is low. (*Figure 17-7*)
- **12.** When supplies of glucose are limited, cells can break down other nutrients to provide molecules for the citric acid cycle. *(Figure 17-8)*

17-3 Lipid metabolism involves lipolysis, beta-oxidation, and the transport and distribution of lipids as lipoproteins and free fatty acids *p. 617*

- **13.** During **lipolysis** (lipid catabolism), lipids are broken down into pieces that can be converted into pyruvate or channeled into the citric acid cycle.
- **14.** Triglycerides, the most abundant lipids in the body, are split into glycerol and fatty acids. Glycerol enters glycolysis pathways, and fatty acids enter mitochondria.
- **15. Beta-oxidation** is the breakdown of fatty acid molecules into two-carbon fragments that can enter the citric acid cycle or be converted to ketone bodies.
- **16.** Lipids cannot provide large amounts of ATP in a short amount of time. However, cells can shift to lipid-based energy production when glucose reserves are limited.
- **17.** In **lipogenesis**, the synthesis of lipids, almost any organic molecule can be used to form glycerol. **Essential fatty acids** cannot be synthesized and must be included in the diet.
- 18. Lipids circulate as free fatty acids (FFA) (fatty acids associated with albumin that can diffuse easily across plasma membranes) or as lipoproteins (lipid-protein complexes that contain triglycerides and cholesterol). Low-density lipoproteins (LDLs) and high-density lipoproteins (HDLs) carry cholesterol between the liver and other tissues. (*Figure 17-9*)

17-4 Protein catabolism involves transamination and deamination, and protein synthesis involves amination and transamination *p. 619*

19. If other energy sources are inadequate, mitochondria can break down amino acids. In the mitochondria, the amino group may be removed by *transamination* or *deamination*.

The resulting carbon skeleton may enter the citric acid cycle to generate ATP or be converted to ketone bodies.

- **20.** Protein catabolism is impractical as a source of quick energy.
- **21.** The body can synthesize roughly half of the amino acids needed to build proteins. The 10 *essential amino acids* must be acquired through the diet.
- **22.** No one body cell can perform all the anabolic and catabolic operations necessary to support human life. Homeostasis can be preserved only when the metabolic activities of different tissues are coordinated. (*Figure 17-10*)

17-5 Nucleic acid catabolism involves RNA, but not DNA *p. 621*

23. DNA in the nucleus is never catabolized for energy. RNA molecules are broken down and replaced regularly; usually they are recycled as new nucleic acids.

17-6 Adequate nutrition is necessary to prevent deficiency disorders and maintain homeostasis *p. 622*

- **24. Nutrition** is the absorption of essential nutrients from food. A *balanced diet* contains all the ingredients needed to maintain homeostasis; it prevents **malnutrition**.
- **25.** The five **basic food groups** are grains, vegetables, fruits, dairy, and protein. These are arranged in a mealtime *plate setting* to reflect a recommended daily food consumption. (*Figure 17-11, Table 17-1*)
- **26. Minerals** act as cofactors in various enzymatic reactions. They also contribute to the osmotic concentration of body fluids, and they play a role in membrane potentials, action potentials, neurotransmitter release, muscle contraction, skeletal construction and maintenance, gas transport, buffer systems, fluid absorption, and waste removal. (*Table 17-2*)
- **27. Vitamins** are coenzymes in vital enzymatic reactions. They are needed in very small amounts. Vitamins A, D, E, and K are **fat-soluble vitamins;** taken in excess, they can lead to **hypervitaminosis. Water-soluble vitamins** are not stored in the body; a lack of adequate dietary supplies can lead to **hypovitaminosis** (*vitamin deficiency disease*). (*Tables 17-3, 17-4*)

- **28.** Daily water requirements average about 40 mL/kg (0.6 fl oz/lb) body weight. Water is obtained from food, drink, and metabolic generation.
- **29.** A balanced diet can improve a person's general health.

17-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing processes *p. 626*

- **30.** The energy content of food is usually expressed as **Calories** per gram (Cal/g). Body cells capture less than half of the energy content of glucose or any other organic nutrient.
- **31.** The catabolism of lipids releases 9.46 Cal/g, about twice the amount released by equivalent weights of carbohydrates or proteins.
- **32.** The total of all the body's anabolic and catabolic processes over a given period of time is an individual's **metabolic rate**. The **basal metabolic rate (BMR)** is the rate of energy utilization at rest. (*Figure 17-12*)
- **33.** The homeostatic regulation of body temperature is **thermoregulation**. Heat exchange with the environment involves four processes: **radiation**, **conduction**, **convection**, and **evaporation**. (*Figure 17-13*)
- **34.** The hypothalamus acts as the body's thermostat, containing the **heat-loss center** and the **heat-gain center**.
- **35.** Responses involved in increasing heat loss include both physiological processes (dilation of superficial blood vessels, increased perspiration, and accelerated respiration) and behavioral adaptations.
- **36.** Body heat may be conserved by reducing blood flow to the skin. Heat can be generated by *shivering thermogenesis* and *nonshivering thermogenesis*.

17-8 Caloric needs decline with advancing age *p. 629*

37. Caloric requirements decrease by 10 percent each decade after age 50. Changes in the senses of smell and taste dull appetite, and changes to the digestive system decrease the efficiency of nutrient absorption from the digestive tract.

Review Questions

Level 1 Reviewing Facts and Terms

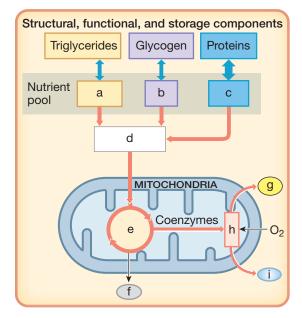

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A

COLUMN B

- **1.** glucose formation a. lipogenesis _____ **2.** lipid catabolism **b.** gluconeogenesis **3.** synthesis of lipids c. essential amino acid **4.** linoleic acid **d.** below-normal body temperature 5. deamination e. unit of energy **6.** phenylalanine f. fat-soluble vitamins **7.** ketoacidosis g. water-soluble vitamins **8.** A, D, E, and K h. lipolysis **9.** B complex and vitamin C **i.** nitrogenous waste **10.** calorie j. essential fatty acid _____ **11.** uric acid **k.** removal of an amino group **12.** hypothermia **1.** decrease in pH 13. In aerobic glucose metabolism, most of the ATP molecules are produced in the (a) cytoplasm. (b) endoplasmic reticulum. (c) mitochondria. (d) nucleus. **14.** During cellular respiration, the complete breakdown of one molecule of glucose leads to the formation of _____ molecule(s) of carbon dioxide. (a) one **(b)** two (c) six (d) 30-32 15. The molecule that cannot be used to synthesize glucose is (a) acetyl-CoA. (b) glycerol. (c) lactate. (d) pyruvate. 16. Essential fatty acids are (a) 15-carbon unsaturated fatty acids. (**b**) produced by the liver. (c) not found in vegetables and seeds. (d) used in the synthesis of prostaglandins. 17. Uric acid is produced in the catabolism of (a) carbohydrates. (b) lipids. (c) nucleotides. (d) proteins.
- 18. Zinc is important for the body because it
 - (a) is the major cation in body fluids.
 - (b) functions as a cofactor of enzyme systems.
 - (c) is needed for oxygen to bind to hemoglobin.
 - (d) helps in maintaining the membrane potential of muscles.

19. Choose from the word bank to label the missing terms in the following diagram of nutrient use in cellular metabolism.

Word Bank: citric acid cycle, amino acids, glucose, electron transport chain, fatty acids, ATP, CO₂, small carbon chains, H_2O .

- (a) _____ (b) _____
- (d) _____ (c) _____ (e) _____
- (f) _____ (g) _____
- (i) _____
- (h) _____

17

- **20.** The type of lipoproteins that transport triglycerides absorbed by the intestinal tract to the bloodstream are called
 - (a) LDLs. (b) chylomicrons.
 - (c) HDLs. (d) ketone bodies.
- **21.** The process in which one amino acid is formed from another is called
 - (a) deamination.
- (b) beta-oxidation.(d) transamination.
- (c) chemiosmosis.22. A complete protein contains
 - (a) the proper balance of amino acids.
 - (b) all the essential amino acids in sufficient quantities.
 - (c) a combination of nutrients selected from the food pyramid.
 - (d) N compounds produced by the body.
- **23.** Adequate amounts of vitamin _____ can be made by exposure of skin to sunlight.
 - **(a)** A
 - **(b)** B₁₂
 - (c) C
 - (**d**) D₃
- **24.** The basal metabolic rate (BMR) represents the
 - (a) maximum energy expenditure when exercising.
 - **(b)** minimum, resting energy expenditure of an awake, alert person.
 - (c) minimum amount of energy expenditure during light exercise.
 - (d) muscular energy expenditure added to the resting energy expenditure.
- **25.** Heat loss from the skin's surface due to formation of water vapor is referred to as
 - (a) conduction. (b) radiation.
 - (c) evaporation. (d) convulsion.
- 26. Define the terms metabolism, anabolism, and catabolism.
- **27.** What is a lipoprotein? What are the major groups of lipoproteins, and how do they differ?
- **28.** Why are vitamins and minerals essential components of the diet?
- **29.** What are the energy yields (in Calories per gram) of the catabolism of carbohydrates, lipids, and proteins?
- **30.** What is the basal metabolic rate (BMR)?
- **31.** What four processes are involved in heat transfer?

Level 2 Reviewing Concepts

- **32.** Loss of heat from the body is not promoted by
 - (a) the stimulation of the respiratory centers.
 - (b) an increased secretion by the sweat glands.
 - (c) elevated levels of thyroxine.
 - (d) inhibiting the vasomotor center.

- **33.** Diabetics are at risk of developing ketoacidosis due to a lack of insulin and the
 - (a) breakdown of lipids and proteins.
 - **(b)** inability to produce tyrosine from phenylalanine.
 - (c) elevated levels of uric acid in the blood.
 - (d) a, b and c are correct.
- **34.** Define glycolysis. What substances are required for this process?
- **35.** What substances enter the citric acid cycle, and what substances leave it? Why is it called a cycle?
- **36.** Why are lipids an important source of energy reserve in the body?
- **37.** How can the MyPlate food guide be used as a tool for developing a healthy lifestyle?
- **38.** How is the brain involved in the regulation of body temperature?
- **39.** Articles in popular media sometimes refer to "good cholesterol" and "bad cholesterol." To what types of cholesterol do these terms refer, and what are their functions?

Level 3 Critical Thinking and Clinical Applications

- **40.** Excessive consumption of vitamin supplements can lead to hypervitaminosis. This usually involves the fat-soluble vitamins rather than water-soluble vitamins. Why is this so?
- **41.** Your friend Christine has been overweight for the past five years, mainly due to a sedentary lifestyle. She recently joined a fitness program and is finding it difficult to keep up with the rigorous activities laid out for her. What advise can you give her about her energy expenditure so that she can lose weight?

Energy Production

The Urinary System

Learning Outcomes

These Learning Outcomes tell you what you should be able to do after completing the chapter. They correspond by number to this chapter's sections.

18

- **18-1** Identify the organs of the urinary system, and describe the functions of the system.
- **18-2** Describe the locations and structures of the kidneys, trace the path of blood flow to, within, and from a kidney, and describe the structure of the nephron.
- **18-3** Discuss the major functions of each portion of the nephron, and outline the processes involved in urine formation.
- **18-4** Describe the factors that influence glomerular filtration pressure and the glomerular filtration rate (GFR).
- **18-5** Describe the structures and functions of the ureters, urinary bladder, and urethra, discuss the control of urination, and describe the urinary reflexes.
- **18-6** Define the terms *fluid balance, electrolyte balance,* and *acid-base balance,* discuss their importance for homeostasis, and describe how water and electrolytes are distributed within the body.
- **18-7** Explain the basic processes involved in maintaining fluid balance and electrolyte balance.
- **18-8** Explain the buffering systems that balance the pH of the intracellular and extracellular fluids, and identify the most common threats to acid-base balance.
- **18-9** Describe the effects of aging on the urinary system.
- **18-10** Give examples of interactions between the urinary system and other body systems presented so far.

Clinical Notes

Kidney Failure, p. 652 Urinary Tract Infections, p. 654 Incontinence, p. 655 Disturbances of Acid-Base Balance, p. 663 **Spotlight** A Summary of Kidney Function, pp. 648–649

An Introduction to the Urinary System

The human body contains trillions of cells bathed in extracellular fluid. In previous chapters we compared these cells to factories that burn nutrients to obtain energy. Imagine what would happen if real factories were as close together as cells in the body. Each factory would generate significant quantities of solid and gaseous wastes. Together they would create serious pollution problems.

We do not have such problems in our bodies as long as the activities of the digestive, cardiovascular, respiratory, and urinary systems are coordinated. The digestive tract absorbs nutrients from food and ejects solid wastes. The liver adjusts the nutrient concentration of the circulating blood. The cardiovascular system delivers these nutrients, plus oxygen from the respiratory system, to peripheral tissues. As blood leaves these tissues, it carries the waste gas carbon dioxide and metabolic waste products to sites of excretion. The carbon dioxide is eliminated at the lungs (as described in Chapter 15). The urinary system removes most of the metabolic wastes.

In this chapter, we consider the organization of the urinary system. We describe how the kidneys remove metabolic wastes from the circulation to produce urine. We also examine the roles of fluid balance, electrolyte balance, and acid-base balance in homeostasis.

Build Your Knowledge

Recall that the urinary system excretes waste products from the blood and controls water balance by regulating the volume of urine produced (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology**). You are already familiar with three examples of waste products—bilirubin-derived pigments, urea, and uric acid—that are excreted by the kidneys. Recall also that the loss of water in urine is important in compensating for high blood pressure and blood volume. \bigcirc **pp. 39, 416, 619, 621**

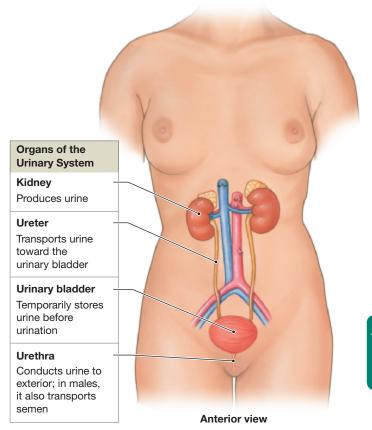

18-1 The urinary system—made up of the kidneys, ureters, urinary bladder, and urethra—has three major functions

Learning Outcome Identify the organs of the urinary system, and describe the functions of the system.

The **urinary system** has three major functions. They are: (1) *excretion*, the removal of metabolic waste products from body fluids; (2) *elimination*, the discharge of these waste products into the environment; and (3) *homeostatic regulation* of the volume and solute concentration of blood.

The organs of the urinary system include the paired kidneys, paired ureters, urinary bladder, and urethra (**Figure 18-1**). The two **kidneys** perform excretory functions. These organs produce **urine**, a fluid containing water, ions, and small soluble compounds. Urine from the kidneys flows along the **urinary tract**, which consists of paired tubes called **ureters** (\bar{u} -R \bar{E} -terz), to the **urinary bladder**, a muscular sac for temporary storage of urine. From the urinary bladder, urine passes through the **urethra** (\bar{u} -R \bar{E} -thra) to the exterior.

The urinary bladder and the urethra eliminate urine in a process called **urination** or **micturition** (mik-chū-RISH-un). The muscular urinary bladder contracts to force urine through the urethra and out of the body.

The urinary system removes metabolic wastes generated by the body's cells (especially the nitrogenous wastes *urea* and *uric acid*). It also has several other essential homeostatic functions that are often overlooked. They include:

- Regulating blood volume and blood pressure, by adjusting how much water is lost in urine, and secreting erythropoietin and renin. D p. 397
- Regulating plasma concentrations of sodium, potassium, chloride, and other ions, by controlling how much is lost in the urine. The kidneys also control the calcium ion level through the synthesis of calcitriol. D p. 397
- *Helping to stabilize blood pH*, by controlling the loss of hydrogen ions (H⁺) and bicarbonate ions (HCO₃⁻) in urine.
- *Conserving valuable nutrients*, such as glucose and amino acids, by preventing their loss in urine.

These activities are carefully regulated to keep the composition of the blood within acceptable limits. A disruption of any of these functions has immediate and potentially fatal consequences.

CHECKPOINT

- 1. Name the three major functions of the urinary system.
- **2.** Identify the organs of the urinary system.
- **3.** Define micturition.
- See the blue Answers tab at the back of the book.

18-2 The kidneys are highly vascular organs containing functional units called nephrons, which perform filtration, reabsorption, and secretion

Learning Outcome Describe the locations and structures of the kidneys, trace the path of blood flow to, within, and from a kidney, and describe the structure of the nephron.

The **kidneys** are located on either side of the vertebral column between the last thoracic (T_{12}) and third lumbar (L_3) vertebrae. The right kidney sits slightly lower than the left kidney (**Figure 18-2a**). The superior surface of each kidney is capped by an adrenal gland. The kidneys and adrenal glands lie

in part (a) shows the kidney's retroperitoneal position.

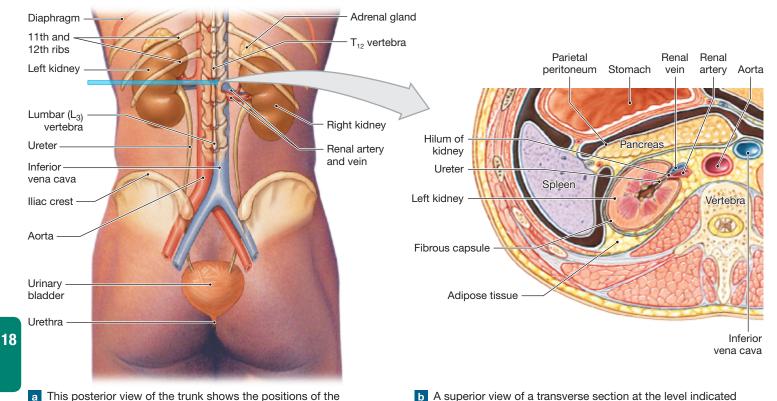

Figure 18-2 The Position of the Kidneys.

a This posterior view of the trunk shows the positions of the kidneys and other organs of the urinary system.

between the muscles of the dorsal body wall and the peritoneal lining (**Figure 18-2b**). This position is called *retroperitoneal* (re-trō-per-i-tō-NĒ-al; *retro*-, behind) because the organs are behind the peritoneum. $\supset p. 582$

The kidneys are held in position within the abdominal cavity by (1) the overlying peritoneum, (2) contact with adjacent organs, and (3) supporting connective tissues. Each kidney is covered by a *fibrous capsule*, surrounded by a cushion of adipose tissue, and anchored to surrounding structures by a dense, fibrous outer layer. Collagen fibers extend from this outer layer to the fibrous capsule. This arrangement of connective tissues helps prevent the jolts and shocks of day-to-day existence from disturbing normal kidney function. Damage to the suspensory fibers of the outer layer may cause the kidney to be displaced and stress attached blood vessels and ureter. This condition is called a *floating kidney*. It is dangerous because the ureters or renal blood vessels may become twisted during movement.

Superficial and Sectional Anatomy of the Kidneys

A typical kidney is reddish-brown. It is about 10 cm (4 in.) long, 5.5 cm (2.2 in.) wide, and 3 cm (1.2 in.) thick in adults. Each kidney weighs about 150 g (5.25 oz). An indentation called the **hilum** is the point of entry for the renal artery and renal nerves. It is also the point of exit for the renal veins and the ureter (**Figure 18-2b**). The **fibrous capsule** covers the surface of the kidney and lines the *renal sinus*, an internal cavity within the kidney. (The adjective *renal* is derived from *ren*, which means "kidney" in Latin.)

The kidney is divided into an outer **renal cortex** and an inner **renal medulla** (Figure 18-3a,b). The renal cortex is in contact with the fibrous capsule. The medulla contains 6 to 18 conical **renal pyramids**. The tip of each pyramid, known as the **renal papilla**, points toward the renal sinus. Bands of the renal cortex, called *renal columns*, extend toward the renal

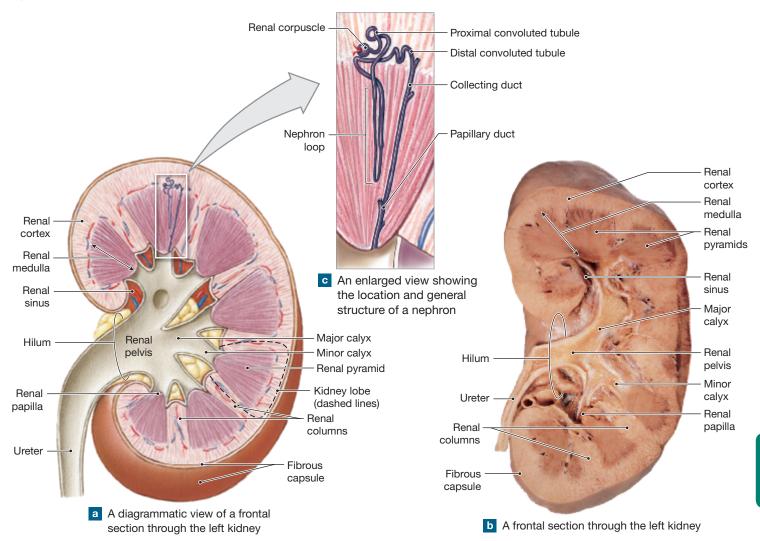

Figure 18-3 The Structure of the Kidney.

sinus between adjacent renal pyramids. A **kidney lobe** consists of a renal pyramid, the overlying layer of renal cortex, and adjacent tissues of the renal columns.

Urine is produced in the kidney lobes. Ducts within each renal papilla discharge urine into a cup-shaped drain, called a **minor calyx** (KĀ-liks; *calyx*, a cup of flowers; plural *calyces*). Four or five minor calyces (KAL-i-sēz) merge to form a **major calyx**. Two or three major calyces combine to form a large, funnel-shaped chamber, the **renal pelvis**. The renal pelvis is connected to the ureter, through which urine drains out of the kidney.

Urine production begins in **nephrons** (NEF-ronz), microscopic tubular structures in the cortex of each kidney lobe (**Figure 18-3c**). Each kidney has roughly 1.25 million nephrons, with a combined length of about 145 kilometers (85 miles).

The Blood Supply to the Kidneys

Because the kidneys function to filter out wastes in the blood and excrete them in the urine, it's not surprising that the kidneys are well supplied with blood. The kidneys receive 20–25 percent of the total cardiac output. In normal, healthy people, about 1200 mL of blood flows through the kidneys each minute—a phenomenal amount of blood for organs with a combined weight of less than 300 g (10.5 oz)!

Kidney blood flow is shown in **Figure 18-4a**. Each kidney receives blood from a **renal artery** that originates from the abdominal aorta. As the renal artery enters the renal sinus, it divides into **segmental arteries** that supply **interlobar arteries** that radiate outward between the renal pyramids. The interlobar arteries supply blood to the **arcuate** (AR-kū-āt) **arteries**, which arch along the boundary between the cortex and medulla. Each arcuate artery gives rise to a number of **cortical radiate arteries**, or *interlobular arteries*, supplying the cortex. **Afferent arterioles** branching from each cortical radiate artery deliver blood to the capillaries supplying individual nephrons (**Figure 18-4b**).

Blood reaches each nephron through an afferent arteriole and leaves in an **efferent arteriole** (Figure 18-4c,d). It then travels to the **peritubular capillaries** surrounding the nephron. The peritubular capillaries provide a route for picking up or delivering substances that are reabsorbed or secreted by different portions of the nephron.

The path of blood from the peritubular capillaries differs depending on the location of the nephron. **Cortical nephrons** lie almost entirely within the renal cortex. **Juxtamedullary** (juks-tuh-MED-ū-lar-ē) **nephrons** (*juxta*, near) extend deep within the renal medulla. In juxtamedullary nephrons, the peritubular capillaries are connected to the **vasa recta** (*rectus*,

18

straight)—long, straight capillaries that parallel the nephron loop deep into the renal medulla (**Figure 18-4d**). As we will see later, the juxtamedullary nephrons enable the kidneys to produce concentrated urine.

Blood from the peritubular capillaries and vasa recta enters a network of venules and small veins that converge on the **cortical radiate veins**, or *interlobular veins*. Blood continues to converge and empty into the **arcuate** and **interlobar veins**. There are no segmental veins, and the interlobar veins drain directly into the **renal vein** (Figure 18-4a).

The Nephron

The nephron is the basic functional unit in the kidney. Each nephron consists of two main parts: (1) a *renal corpuscle*, and (2) a *renal tubule*. A renal tubule is about 50 mm (2 in.) in length. The **renal tubule** is composed of two *convoluted* (coiled or twisted) segments separated by a U-shaped tube (Figure 18-3c). The convoluted segments are in the cortex. The U-shaped tube extends partially or completely into the medulla.

An Overview of the Nephron and Collecting System

A schematic diagram of a representative nephron is shown in **Figure 18-5**. The nephron begins at the **renal corpuscle** (KOR-pus-ul). This spherical structure consists of the *glomerular* (Bowman's) *capsule*, a cup-shaped chamber that contains a capillary network known as the *glomerulus* (glo-MER-ū-lus; *glomus*, a ball). Each renal corpuscle is about 200 µm (0. 2 mm) in diameter.

As previously described, blood arrives at the glomerulus by way of an *afferent arteriole* and departs in an *efferent arteriole*. In the renal corpuscle, blood pressure forces fluid and dissolved solutes out of the glomerular capillaries and into the surrounding *capsular space*. This process is called *filtration*. \bigcirc p. 468 Filtration produces a protein-free solution known as a **filtrate**.

From the renal corpuscle, the filtrate enters the renal tubule. The major segments of the renal tubule are the *proximal convoluted tubule* (PCT), the *nephron loop*, also called the *loop of Henle* (HEN-lē), and the *distal convoluted tubule* (DCT). As the filtrate travels along the renal tubule, it is now called **tubular fluid**, and its composition gradually changes.

Each nephron empties into a *collecting duct*, the start of the **collecting system**. The collecting duct leaves the cortex and descends into the medulla. It carries the tubular fluid from many nephrons toward a *papillary duct* that delivers the fluid, now called *urine*, into the calyces and on to the renal pelvis.

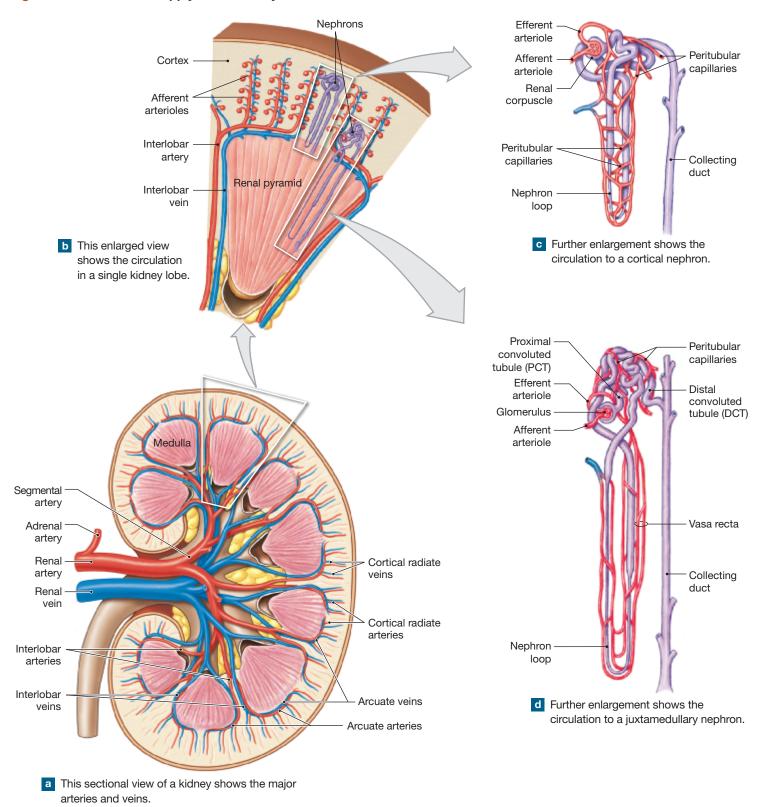

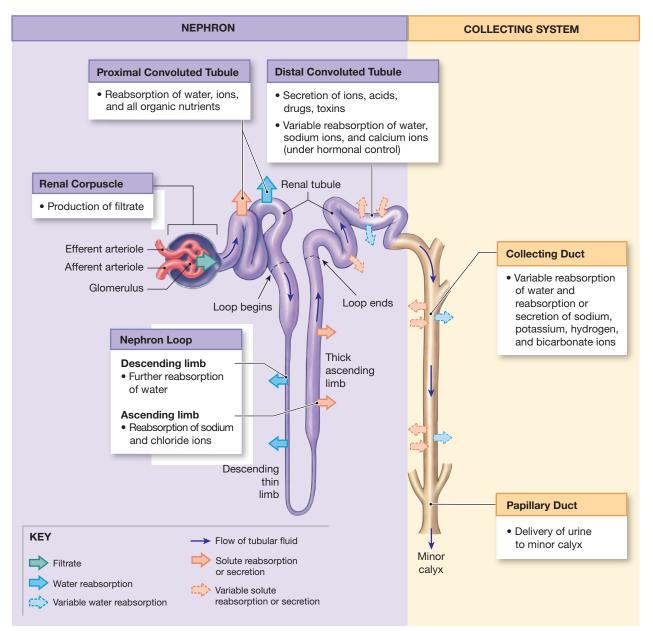

Figure 18-4 The Blood Supply to the Kidneys.

Figure 18-5 A Representative Nephron and the Collecting System. This schematic drawing highlights the major structures and functions of each segment of the nephron (purple) and the collecting system (tan).

Functions of the Nephron

18

Urine has a very different composition from the filtrate produced at the renal corpuscle. Each segment of the nephron has a role in converting filtrate to urine (**Figure 18-5**). The renal corpuscle is the site of filtration. The functional advantage of filtration is that it is a passive process and does not require an expenditure of energy. The disadvantage of filtration is that any filter with pores large enough to permit the passage of organic waste products cannot *prevent* the passage of water, ions, and nutrients such as glucose, fatty acids, and amino acids. These substances, along with most of the water, must be reclaimed or they are lost in the urine. Filtrate leaves the renal corpuscle and enters the renal tubule, which carries out these functions:

- Reabsorbing all the useful organic molecules, or nutrients, from the filtrate.
- Reabsorbing over 90 percent of the water in the filtrate.
- Secreting into the tubular fluid any waste products that were missed by the filtration process.

Additional water and salts will be removed in the collecting system before the urine is released into the minor calyx.

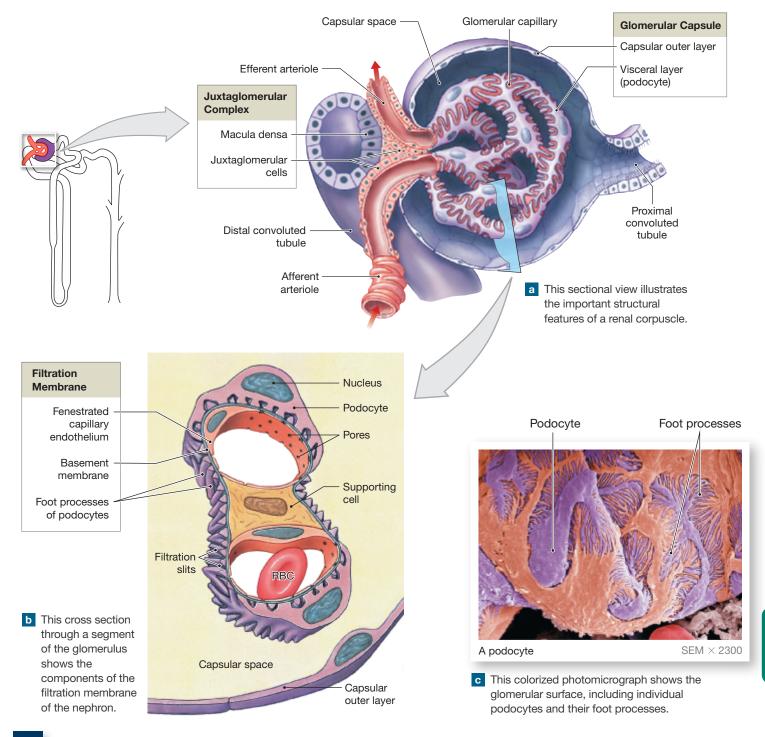

The Renal Corpuscle

A renal corpuscle consists of the capillary network of the **glomerulus** and the **glomerular capsule** (Figure 18-6a). The glomerular capsule forms the outer wall of the renal corpuscle and encloses the glomerular capillaries. The glomerulus projects into the glomerular capsule much as the heart projects into the pericardial cavity. A squamous epithelium makes up

the *capsular outer layer*. It ends at the *visceral layer*, which covers the glomerular capillaries. The two layers are separated by the **capsular space**, which receives the filtrate and empties into the renal tubule.

The visceral layer covering the capillaries consists of cells called **podocytes** (PŌ-dō-sits, *podon*, foot) (**Figure 18-6b,c**). Podocytes have extensions, or "feet"—called **foot processes**, or *pedicels*,—that wrap around individual capillaries. A thick

Figure 18-6 The Renal Corpuscle.

Go to **Mastering A&P** > Study Area > Menu > PAL 3.1 > Anatomical Models > Urinary System

basement membrane separates the endothelial cells of the capillaries from the podocytes. The glomerular capillaries are said to be *fenestrated* (FEN-e-strā-ted; *fenestra*, a window) because their endothelial cells contain pores (Figure 18-6b).

To enter the capsular space, a solute must be small enough to pass through (1) the pores of the fenestrated endothelial cells, (2) the fibers of the basement membrane, and (3) narrow *filtration slits* between the foot processes of the podocytes. Together, the fenestrated endothelium, basement membrane, and foot processes form the **filtration membrane**. The filtration membrane prevents the passage of blood cells and most plasma proteins. It permits the movement of water, metabolic wastes, ions, glucose, fatty acids, amino acids, vitamins, and other solutes into the capsular space. Most of the valuable solutes will be reabsorbed by the proximal convoluted tubule.

The Proximal Convoluted Tubule

The filtrate next moves into the first segment of the renal tubule, the **proximal convoluted tubule (PCT)** (Figure 18-5). The cells lining the PCT reabsorb organic nutrients, plasma proteins, and ions from the tubular fluid and release them into the interstitial fluid, or *peritubular fluid*, surrounding the renal tubule. The reabsorbed substances in the peritubular fluid eventually re-enter the blood. As a result of this transport, the solute concentration of the peritubular fluid increases while that of the tubular fluid decreases. Water then moves out of the tubular fluid by osmosis, reducing the volume of tubular fluid.

The Nephron Loop

The last portion of the PCT bends sharply toward the renal medulla. This turn leads to the **nephron loop**, or *loop of Henle* (Figure 18-5). This loop is composed of a *descending limb* and an *ascending limb*. Fluid in the descending limb flows toward the renal pelvis. Fluid in the ascending limb flows toward the renal cortex.

The ascending limb is not permeable to water and solutes, but it actively transports sodium and chloride ions out of the tubular fluid. As a result, the peritubular fluid of the renal medulla contains an unusually high solute concentration. The descending limb is permeable to water, and as it descends into the renal medulla, water moves out of the tubular fluid by osmosis.

The Distal Convoluted Tubule

The ascending limb of the nephron loop ends where it bends and comes in close contact with the glomerulus and its vessels (**Figure 18-3c**). At this point, the **distal convoluted tubule** (**DCT**) begins. It passes immediately adjacent to the afferent and efferent arterioles (**Figure 18-6a**). The distal convoluted tubule is an important site for three vital processes: (1) the active secretion of ions, acids, drugs, and toxins; (2) the selective reabsorption of sodium ions from the tubular fluid; and (3) the selective reabsorption of water, which assists in concentrating the tubular fluid.

The epithelial cells of the DCT closest to the glomerulus are unusually tall, and their nuclei are clustered together. This region is called the *macula densa* (MAK-ū-la DEN-sa) (**Figure 18-6a**). The cells of the macula densa are closely associated with unusual smooth muscle fibers—the *juxtaglomerular* (*juxta*, near) *cells*—in the wall of the afferent arteriole. Together, the macula densa and juxtaglomerular cells form the **juxtaglomerular complex**, an endocrine structure that secretes the hormone erythropoietin and the enzyme renin. These secretions are involved in the regulation of blood volume and blood pressure (see Chapter 10). \bigcirc p. 397

The Collecting System

The distal convoluted tubule, the last segment of the nephron, opens into the collecting system, which consists of collecting ducts and papillary ducts (**Figure 18-5**). Each **collecting duct** receives tubular fluid from many nephrons. Several collecting ducts merge to form a **papillary duct**, which delivers urine to a minor calyx. The collecting system does more than transport tubular fluid from the nephrons to the renal pelvis. It also adjusts the fluid's composition and determines the final osmotic concentration and volume of the urine. These adjustments include reabsorbing water, and reabsorbing or secreting sodium, potassium, hydrogen, and bicarbonate ions.

 Table 18-1 summarizes the functions of the different regions

 of the nephron and collecting system.

Table 18-1	The Functions of the Nephron and Collecting System in the Kidney			
Region		Primary function		
Renal corpuscle		Filtration of plasma to initiate urine formation		
Proximal convoluted tubule (PCT)		Reabsorption of ions, organic molecules, vitamins, water		
Nephron loop		Descending limb: reabsorption of water from tubular fluid		
		Ascending limb: reabsorption of ions; assists in creating the concentration gradient in the renal medulla, enabling the kidney to produce concentrated urine		
Distal convoluted tubule (DCT)		Reabsorption of water and sodium ions; secretion of acids, ammonia, and drugs		
Collecting duct		Reabsorption of water; reabsorption or secretion of sodium, potassium, bicar- bonate, and hydrogen ions		
Papillary duct		Conduction of urine to minor calyx

18-3 Different portions of the nephron form urine by filtration, reabsorption, and secretion

Learning Outcome Discuss the major functions of each portion of the nephron, and outline the processes involved in urine formation.

The primary purpose of **urine** production is to maintain homeostasis by regulating the volume and composition of the blood. This process involves the excretion of dissolved solutes, especially the following three metabolic waste products:

- **1.** *Urea*. Urea is the most abundant organic waste. Your body generates about 21 g (0.74 oz) of urea each day. Most of it is formed during the breakdown of amino acids.
- 2. Creatinine. Creatinine is generated in skeletal muscle tissue through the breakdown of creatine phosphate. Recall that creatine phosphate is a high-energy compound that plays an important role in muscle contraction. D p. 237 Your body generates roughly 1.8 g (0.06 oz) of creatinine each day.

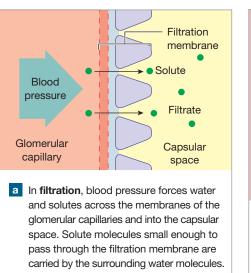

3. *Uric acid.* Uric acid is a product of the breakdown and recycling of RNA molecules. Your body generates about 480 mg (0.017 oz) of uric acid each day.

These wastes are dissolved in the bloodstream. They can be eliminated only when dissolved in urine. For this reason, their removal involves an unavoidable water loss. The kidneys can minimize this water loss by producing urine with an osmotic concentration more than four times that of blood plasma. If the kidneys could not concentrate the filtrate produced by glomerular filtration, water losses would lead to fatal dehydration within hours. The kidneys also ensure that the excreted urine does not contain potentially useful organic substrates present in blood plasma, such as sugars or amino acids.

Nephron Processes

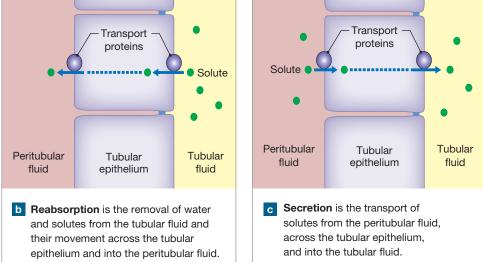

To carry out its functions, the kidneys rely on three distinct physiological processes (**Figure 18-7**). These processes take place in each nephron and include:

- Filtration. In filtration, blood pressure forces water across the filtration membrane in the renal corpuscle (Figure 18-7a). Solute molecules small enough to pass through the membrane are carried by the surrounding water molecules.
- **2.** *Reabsorption.* Reabsorption is the removal of water and solute molecules from the tubular fluid, and their movement across the tubular epithelium and into the peritubular fluid (Figure 18-7b). The reabsorbed substances in the peritubular fluid

>

Figure 18-7 Physiological Processes of the Nephron.

re-enter the circulation at the peritubular capillaries. Reabsorption takes place after the filtrate has left the renal corpuscle. Filtration is based solely on size, but reabsorption is a selective process. It involves simple diffusion or the activity of carrier proteins in the tubular epithelium. Water reabsorption occurs passively through osmosis.

3. *Secretion*. Secretion is the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid (Figure 18-7c). Secretion is necessary because filtration does not force all the dissolved materials out of the blood. Tubular secretion can further lower the plasma concentration of undesirable materials, including many drugs.

Together, these three processes produce a fluid that is very different from other body fluids. **Table 18-2** indicates the efficiency of the renal system by comparing the concentrations of various substances in urine and plasma. The kidneys can continue to work efficiently only so long as filtration, reabsorption, and secretion proceed in proper balance. Any disruption in this balance has immediate and potentially disastrous effects on the composition of the circulating blood. If both kidneys fail to perform their roles, death will occur within a few days unless medical assistance is provided.

As we have seen, all segments of the nephron and collecting system are involved in urine formation. Most regions perform a combination of reabsorption and secretion, but the balance

Table 18-2	Normal Laboratory Values for Solutes in Urine and Plasma					
Component		Urine	Plasma			
IONS (mEq/L)						
Sodium (Na ⁺)		40–220	135–145			
Potassium (K ⁺)	25–100	3.5–5.50				
Chloride (Cl ⁻)	110–250	100–108				
Bicarbonate (HCO3	1–9	20–28				
METABOLITES AND NUTRIENTS (mg/dL)						
Glucose		0.009	70–110			
Lipids		0.002	450–1000			
Amino acids		0.188	40			
Proteins	0.000	6–8 g/dL				
NITROGENOUS WASTES (mg/dL)						
Urea		1800	8–25			
Creatinine		150	0.6–1.5			
Uric acid		40	2–6			
Ammonia		60	<0.1			

between these two processes varies from one region to another. As indicated in **Table 18-1**:

- Filtration occurs exclusively in the renal corpuscle, across the glomerular capillary walls.
- Reabsorption of nutrients occurs primarily at the proximal convoluted tubule.
- Active secretion occurs primarily at the distal convoluted tubule.
- Regulation of the amounts of water, sodium ions, and potassium ions lost in the urine results from interactions between the nephron loop and the collecting system.

Next we will take a closer look at events in each of the segments of the nephron and collecting system.

Filtration at the Glomerulus

Blood pressure at the glomerulus tends to force water and solutes out of the bloodstream and into the capsular space. For filtration to occur, this outward force must exceed any opposing pressures, such as the osmotic pressure of the blood. (We introduced the forces acting across capillary walls in Chapter 13. You may find it helpful to review Figure 13-6.) D p. 468 The net force promoting filtration is called the **filtration pressure**. Filtration pressure at the glomerulus is higher than capillary blood pressure elsewhere in the body because of the slight difference in the diameters of afferent and efferent arterioles (**Figure 18-6a**). The diameter of the efferent arteriole is slightly smaller, so it offers more resistance to blood flow than does the afferent arteriole. As a result, blood "backs up" in the afferent arteriole, increasing the blood pressure in the glomerular capillaries.

Filtration pressure is very low (around 10 mm Hg). Kidney filtration will stop if glomerular blood pressure falls significantly. Minor variations in blood pressure are compensated for by reflexive changes in the diameters of the afferent arterioles, the efferent arterioles, and/or the glomerular capillaries. These changes can take place automatically or in response to sympathetic stimulation. More serious declines in systemic blood pressure can reduce or even stop glomerular filtration. As a result, hemorrhage, shock, or dehydration can cause a dangerous or even fatal reduction in kidney function. The kidneys are more sensitive to blood pressure than are other organs, so it is not surprising to find that they control many of the homeostatic processes responsible for regulating blood pressure and blood volume. We consider one example-the renin-angiotensin-aldosterone system—later in this chapter.

18

The Glomerular Filtration Rate

Filtrate production at the glomerulus is called *glomerular filtration*. The **glomerular filtration rate (GFR)** is the amount of filtrate produced in the kidneys each minute. Each kidney contains about 6 square meters—some 64 square feet—of filtration surface and the GFR averages an astounding *125 mL per minute*. This means that almost 20 percent of the fluid delivered to the kidneys by the renal arteries leaves the bloodstream and enters the capsular spaces. In the course of a single day, the glomeruli generate about 180 liters (48 gal) of filtrate, roughly 70 times the total plasma volume. But as the filtrate passes through the renal tubules, over 99 percent of it is reabsorbed.

Tubular reabsorption is obviously an extremely important process! An inability to reclaim the water entering the filtrate, as in *diabetes insipidus*, can quickly cause death by dehydration. (We discussed this condition, caused by inadequate ADH secretion, in Chapter 10.) \bigcirc p. 385

Glomerular filtration is the vital first step essential to all kidney functions. Without filtration, waste products are not excreted, pH control is jeopardized, and an important process for regulating blood volume is eliminated. Filtration depends on adequate blood flow to the glomerulus and normal filtration pressures. We discuss the regulatory factors involved in maintaining a stable GFR later in the section on the control of kidney function.

Build Your Knowledge

Recall that cells may move lipid-insoluble substances, such as ions and organic substrates, across their plasma membranes with specialized membrane proteins (as you saw in Chapter 3: Cell Structure and Function). This process is called carrier-mediated transport. It may be passive (no ATP required) or active (ATP required). In passive transport, solutes are carried from an area of high concentration to an area of low concentration. Active transport processes may follow or oppose an existing concentration gradient. Recall that the carrier proteins can only bind specific substrates, but may be used over and over again. Many carrier proteins transport one ion or molecule at a time, but some move two solutes at the same time. The two solutes may be moved together in the same direction (into the cell), or in opposite directions (into and out of the cell). **D pp. 91, 95**

Reabsorption and Secretion along the Renal Tubule

Reabsorption and secretion in the kidney involve a combination of diffusion, osmosis, and carrier-mediated transport. Recall that in carrier-mediated transport, a specific substrate binds to a carrier protein that aids its movement across the plasma membrane. \bigcirc p. 95 This movement may or may not require energy from ATP molecules.

Events at the Proximal Convoluted Tubule

The cells of the PCT actively reabsorb organic nutrients, plasma proteins, and ions from the filtrate. The cells then transport them into the peritubular fluid (interstitial fluid) surrounding the renal tubule. Osmotic forces then pull water across the wall of the PCT and into the surrounding peritubular fluid. The reabsorbed materials and water diffuse into peritubular capillaries.

The PCT usually reclaims 60–70 percent of the volume of filtrate produced at the glomerulus, along with virtually all the glucose, amino acids, and other organic nutrients. The PCT also actively reabsorbs ions, including sodium, potassium, calcium, magnesium, bicarbonate, phosphate, and sulfate. The ion pumps involved are individually regulated. They may be influenced by circulating ion or hormone levels. For example, the presence of parathyroid hormone stimulates calcium ion reabsorption. ⊃ p. 390

Reabsorption is the primary function of the PCT. However, a few substances (such as hydrogen ions) can be actively secreted into the tubular fluid. Such active secretion plays an important role in regulating blood pH, a topic we consider in a later section. A few compounds in the tubular fluid, including urea and uric acid, are ignored by the PCT and by other segments of the renal tubule. The concentrations of these waste products gradually rise in the tubular fluid as water and other nutrients are removed.

Events at the Nephron Loop

Approximately 60–70 percent of the volume of the filtrate produced at the glomerulus has been reabsorbed before the tubular fluid reaches the nephron loop. In the process, useful organic molecules and many mineral ions have been reclaimed. The nephron loop reabsorbs more than half of the remaining water, as well as two-thirds of the sodium and chloride ions remaining in the tubular fluid.

18

The descending and ascending limbs of the nephron loop have different permeability characteristics. The *descending thin limb* is permeable to water but not to solutes. For this reason, water can continually flow in or out by osmosis, but solutes cannot cross the tubular epithelium. The ascending limb is impermeable to water. The *ascending thin limb* is permeable to urea. The *thick ascending limb* actively pumps sodium and chloride ions out of the tubular fluid and into the surrounding peritubular fluid of the renal medulla. $\supset p. 640$

Over time, a concentration gradient is created in the medulla. The highest concentration of solutes (roughly four times that of plasma) occurs near the bend in the nephron loop. Because the descending limb is freely permeable to water, water continually flows out of the tubular fluid and into the peritubular fluid by osmosis. From there, the sodium ions, chloride ions, and water diffuse into the peritubular capillaries and vasa recta and back into circulation.

Roughly half the volume of tubular fluid that enters the nephron loop is reabsorbed in the descending limb. Most of the sodium and chloride ions are removed in the thick ascending limb. With the loss of the sodium and chloride ions, the solute concentration of the tubular fluid declines to around one-third that of plasma. However, waste products such as urea now make up a significant percentage of the remaining solutes. In essence, most of the water and solutes have been removed, leaving relatively highly concentrated waste products behind.

Events at the Distal Convoluted Tubule and the Collecting System

By the time the tubular fluid reaches the distal convoluted tubule, roughly 80 percent of the water and 85 percent of the solutes have already been reabsorbed. The DCT is connected to a collecting duct that drains into the renal pelvis.

As the tubular fluid passes through the DCT and collecting duct, final adjustments are made in its composition and concentration. Its composition depends on the types of solutes present. Its concentration also depends on the volume of water in which the solutes are dissolved. The DCT and collecting duct are impermeable to solutes. For this reason, changes in tubular fluid composition take place only through active reabsorption or secretion. The primary function of the DCT is active secretion.

Throughout most of the DCT, the tubular cells actively transport sodium ions out of the tubular fluid in exchange for potassium ions or hydrogen ions. The DCT and collecting **18** ducts contain ion pumps that respond to the hormone aldosterone from the adrenal cortex. Aldosterone secretion occurs in response to lowered sodium ion concentrations or elevated potassium ion concentrations in the blood. The higher the aldosterone level, the more sodium ions are reclaimed, and the more potassium ions are lost.

The amount of water reabsorbed along the DCT and collecting duct is controlled by circulating levels of antidiuretic hormone (ADH). In the absence of ADH, the distal convoluted tubule and collecting duct are impermeable to water. The higher the level of circulating ADH, the greater the water permeability and its reabsorption. The result is a more concentrated urine. Water moves out of the DCT and collecting duct because in each region the tubular fluid contains fewer solutes than the surrounding interstitial fluid. As previously noted, the tubular fluid arriving at the DCT has a solute concentration only about one-third that of the peritubular fluid in the surrounding cortex. That is because the thick ascending limb of the nephron loop has removed most of the sodium and chloride ions.

If the circulating ADH level is low, little water reabsorption will take place at the DCT. Virtually all the water reaching the DCT will be lost in the urine (Figure 18-8a). If the circulating ADH level is high, the DCT and collecting duct will be very permeable to water (Figure 18-8b). In this case, the individual will produce a small quantity of urine with a solute concentration four to five times that of extracellular fluids.

The fluid passing along the collecting duct enters the papillary duct. The papillary duct contains carrier proteins for urea. Urea is transported by facilitated diffusion into the peritubular fluid of the renal medulla. Some of this urea diffuses back into the ascending thin limb. This recycled urea contributes from one-third to one-half of the solutes of the concentration gradient established by the nephron loop.

Normal Urine

The general characteristics of normal urine are listed in Table 18-3. However, the composition of the urine excreted each day depends on the metabolic and hormonal events under way. Because the composition and concentration of the urine vary independently, an individual can produce either a small quantity of concentrated urine or a large quantity of dilute urine and still excrete the same amount of dissolved materials. For this reason, physicians often analyze the urine produced over a 24-hour period rather than testing a single sample. This practice enables them to assess both quantity and composition accurately.

Spotlight Figure 18-9 (pp. 648–649) provides a summary of kidney function. It shows the major steps in the reabsorption of water and the production of concentrated urine.

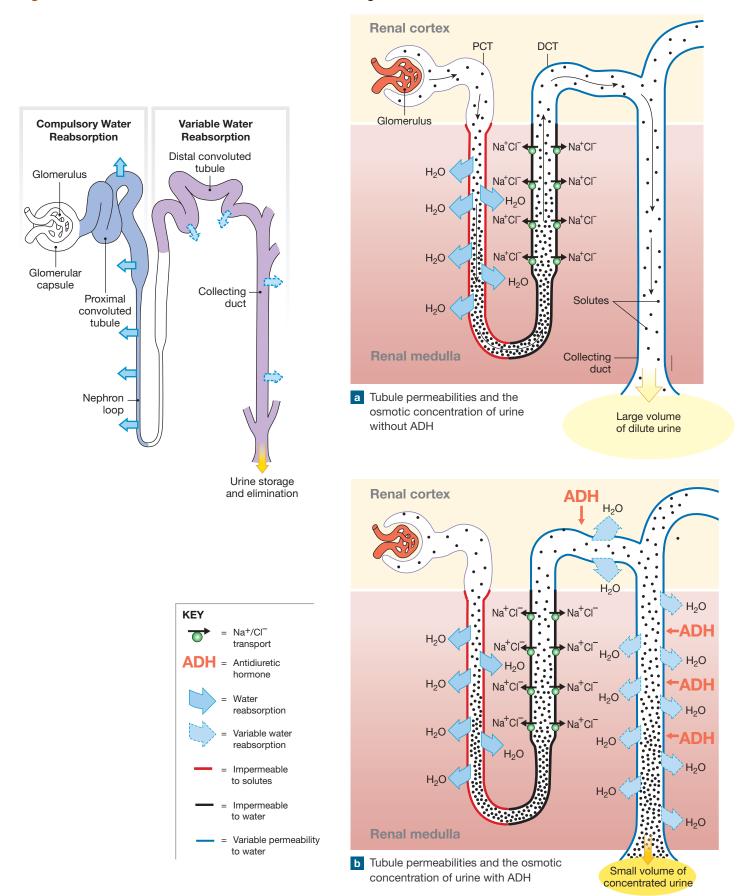

Figure 18-8 The Effects of ADH on the DCT and Collecting Duct.

SPOTLIGHT Figure 18-9 A SUMMARY OF KIDNEY FUNCTION

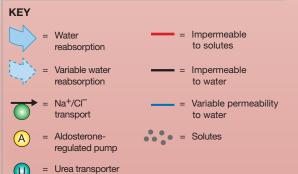

The filtrate produced by the renal corpuscle has the same osmotic concentration as plasma—about 300 mOsm/L. It has the same composition as blood plasma but does not contain plasma proteins.

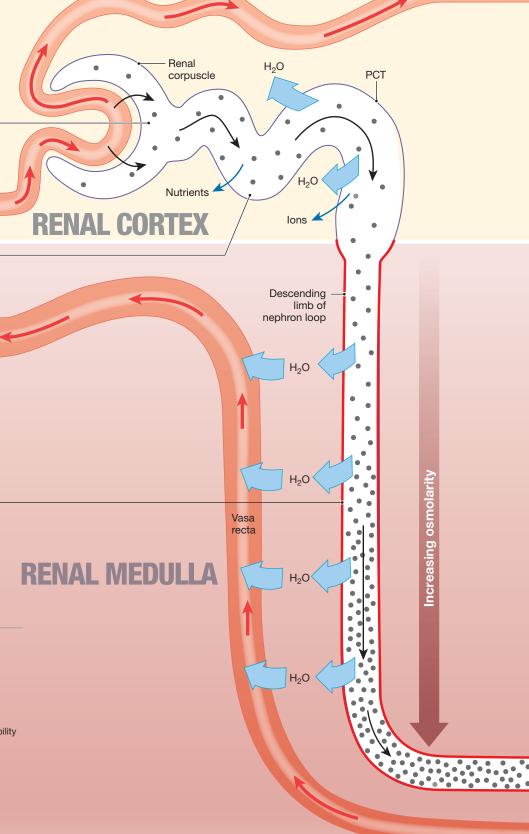

2

In the proximal convoluted tubule (PCT), the active removal of ions and organic nutrients results in a continuous osmotic flow of water out of the tubular fluid. This decreases the volume of filtrate but keeps the solutions inside and outside the tubule isotonic. Between 60 and 70 percent of the filtrate volume is absorbed here.

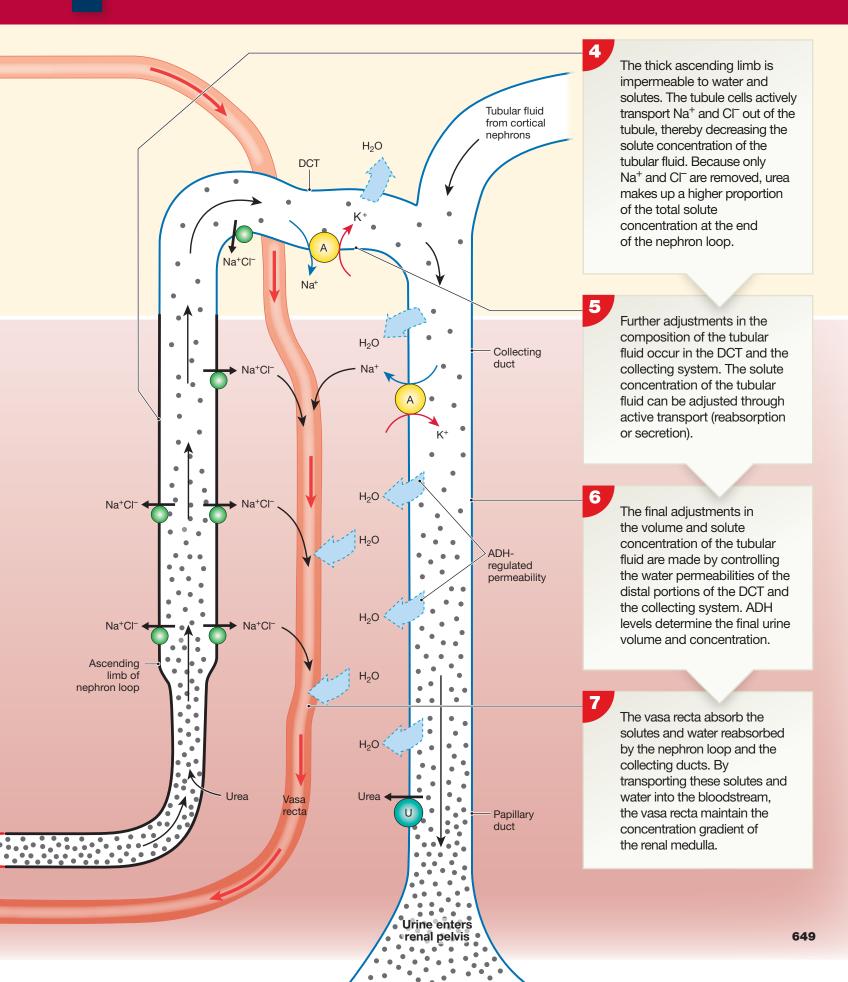

3

In the PCT and descending limb of the nephron loop, water moves into the surrounding peritubular fluid. This compulsory reabsorption of water results in a small volume of highly concentrated tubular fluid.

>

Characteristic	Normal range
рН	4.5-8 (average: 6.0)
Specific gravity (density of urine/ density of pure water)	1.003–1.030
Osmotic concentration (Osmolarity) (number of solute particles per liter; for comparison, fresh water \approx 5 mOsm/L, body fluids \approx 300 mOsm/L, and seawater \approx 1000 mOsm/L)	855–1335 mOsm/L
Water content	93–97%
Volume	700–2000 mL/day
Color	Clear yellow
Odor	Varies with composition
Bacterial content	None (sterile)

CHECKPOINT

18

- **7.** A decrease in blood pressure would have what effect on the GFR?
- **8.** If nephrons lacked a nephron loop, what would be the effect on the volume and solute (osmotic) concentration of the urine produced?
- **9.** What effect would low circulating levels of antidiuretic hormone (ADH) have on urine production?

18-4 Normal kidney function depends on a stable GFR

Learning Outcome Describe the factors that influence glomerular filtration pressure and the glomerular filtration rate (GFR).

Normal kidney function depends on adequate blood flow. Blood flow is needed to maintain filtration pressures and a stable glomerular filtration rate (GFR). Three levels of control regulate GFR: (1) *autoregulation*, or local blood flow regulation; (2) hormonal regulation, started by the kidneys; and (3) autonomic regulation, mostly by the sympathetic division of the autonomic nervous system (ANS).

The Local Regulation of Kidney Function

Autoregulation can compensate for minor variations in blood pressure. Autoregulation takes place through automatic changes in the diameters of afferent arterioles, efferent arterioles, and glomerular capillaries. For example, a reduction in blood flow and in glomerular filtration pressure triggers dilation of the afferent arteriole and glomerular capillaries, and constriction of the efferent arteriole. This combination keeps glomerular blood pressure and blood flow within normal limits in the short term. As a result, glomerular filtration rates remain relatively constant. If blood pressure rises, the afferent arteriole walls are stretched. Smooth muscle cells respond by contracting. The resulting reduction in afferent arteriolar diameter decreases glomerular blood flow and keeps the GFR within normal limits.

The Hormonal Control of Kidney Function

Hormonal processes result in long-term adjustments in blood pressure and blood volume that stabilize the GFR. The major hormones involved in regulating kidney function are angiotensin II, ADH, aldosterone, and atrial natriuretic peptide (ANP). (We have discussed these hormones in earlier chapters, so we provide only a brief overview here.) \bigcirc p. 475 The secretion of angiotensin II, aldosterone, and ADH is integrated by the *renin-angiotensin-aldosterone system*.

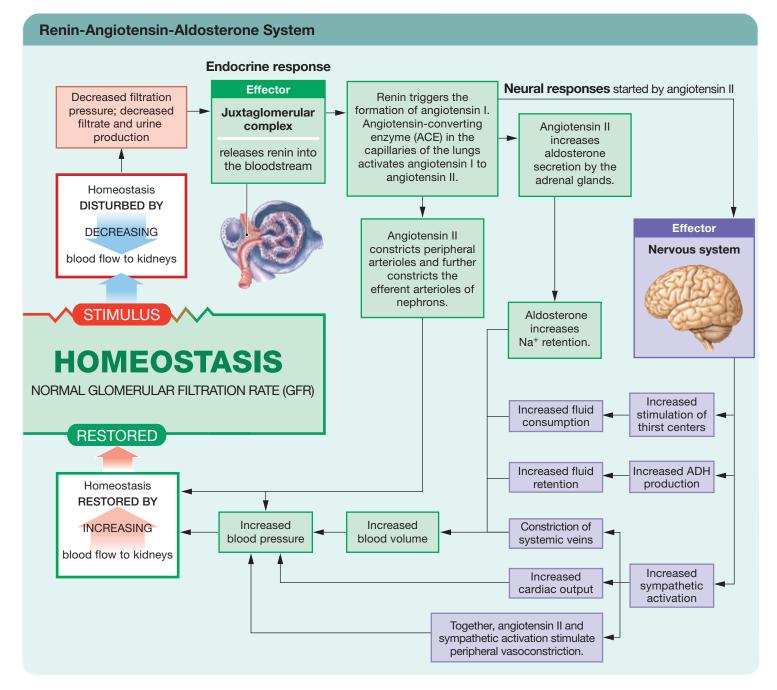

The Renin-Angiotensin-Aldosterone System

Glomerular pressures may remain low because of a decrease in blood volume, a fall in systemic pressures, or a blockage in the renal artery or its tributaries. In response to low glomerular pressures, the juxtaglomerular complex releases the enzyme renin into the circulation. **Renin** converts the inactive *angiotensinogen* to *angiotensin I*. Angiotensin I is then converted to **angiotensin II** by **angiotensin-converting enzyme (ACE)**. This conversion takes place in the lung capillaries. \supset p. 546 A general overview of the response of the renin-angiotensinaldosterone system to a decrease in GFR is diagrammed in **Figure 18-10**. The overall result is increased glomerular pressure.

Angiotensin II acts at peripheral capillary beds, the nephron, adrenal glands, and the CNS. It has these effects:

- *In peripheral capillary beds*, it causes a brief but powerful vasoconstriction. This response raises blood pressure in the renal arteries.
- *At the nephron*, it triggers constriction of the efferent arterioles. This effect raises glomerular pressures and filtration rates.
- At the adrenal gland, it stimulates the secretion of aldosterone by the adrenal cortex and of epinephrine (E) and norepinephrine (NE) by the adrenal medulla. A sudden, dramatic increase in systemic blood pressure results. At the kidneys, aldosterone stimulates sodium reabsorption along the DCT and collecting system.

• *In the CNS*, angiotensin II triggers the release of ADH. This hormone, in turn, stimulates the reabsorption of water and sodium ions. It also induces the sensation of thirst.

Antidiuretic Hormone (ADH)

Antidiuretic hormone has two key effects. (1) It increases the water permeability of the DCT and collecting duct, so that water is reabsorbed from the tubular fluid. (2) It also brings on thirst, leading to the intake of water. ADH release takes place

both under angiotensin II stimulation, and independently, when hypothalamic neurons are stimulated. These neurons respond to a reduction in blood pressure or an increase in the solute concentration of the circulating blood.

Aldosterone

Aldosterone stimulates the reabsorption of sodium ions and the secretion of potassium ions along the DCT and collecting duct. Aldosterone secretion primarily takes place (1) under

CLINICAL NOTE

Kidney Failure

Kidney failure, or renal failure, occurs when the kidneys become unable to perform the excretory functions needed to maintain homeostasis. Renal failure is of two general types. Acute renal failure occurs when filtration slows suddenly or stops. The cause may be exposure to toxic drugs, renal ischemia, urinary obstruction, or trauma. The reduction in kidney function takes place over a few days and may persist for weeks. In chronic renal failure, kidney function deteriorates gradually. Problems build up

over time. This condition generally cannot be reversed. Its progression can only be slowed.

How is chronic kidney failure managed? Management typically involves restricting water, salt, and protein intake. This combination reduces strain on the urinary system by minimizing (1) the volume of urine produced and (2) the amount of nitrogenous wastes. Acidosis-blood plasma pH

below 7.35-is a common problem in patients with kidney failure. It can be countered with infusions of bicarbonate ions. If drugs, infusions, and dietary controls cannot stabilize the composition of the blood, more drastic measures are taken. Examples are dialysis or a kidney transplant.

In hemodialysis, a dialysis machine performs the functions of damaged kidneys. The machine pumps a patient's blood past a semipermeable membrane. lons, nutrients, and organic wastes diffuse through the membrane into a dialysis fluid. The composi-

> tion of the fluid is carefully regulated. The process takes several hours. It must be repeated two or three times each week.

> In a kidney transplant, the kidney from a healthy compatible donor is surgically inserted into the patient's body and connected to the urinary bladder. If the surgery is successful, the transplanted kidney(s) can take over all normal kidney functions.

angiotensin II stimulation and (2) in response to a rise in the potassium ion concentration of the blood. \bigcirc p. 392

Atrial Natriuretic Peptide (ANP)

The actions of ANP oppose those of the renin-angiotensinaldosterone system (see Figure 13-10, \supset p. 476). Overall, ANP lowers blood volume and blood pressure. Atrial cardiac muscle cells release ANP when blood volume and blood pressure are too high. The actions of ANP that affect the kidneys include (1) a decrease in the rate of sodium ion reabsorption in the DCT, leading to increased sodium ion loss in the urine; (2) dilation of glomerular capillaries, which results in increased glomerular filtration and urinary water loss; and (3) inactivation of the renin-angiotensin-aldosterone system by inhibiting secretion of renin, aldosterone, and ADH. The net result is an accelerated loss of sodium ions and an increase in the volume of urine produced. This combination lowers blood volume and blood pressure.

Sympathetic Activation and Kidney Function

18

Most autonomic innervation of the kidneys is through the sympathetic division of the ANS. Sympathetic activity mainly serves to shift blood flow away from the kidneys, which lowers the glomerular filtration rate. Sympathetic activation has both direct and indirect effects on kidney function. The direct effect is a powerful constriction of the afferent arterioles, decreasing the GFR and slowing production of filtrate. Triggered by a sudden crisis, such as an acute reduction in blood pressure or a heart attack, sympathetic activation can override the local regulatory processes that act to stabilize the GFR. As the crisis passes and sympathetic activity decreases, the GFR returns to normal.

When the sympathetic division alters the regional pattern of blood circulation, there are often indirect effects on blood flow to the kidneys. For example, the dilation of superficial vessels in warm weather shifts blood away from the kidneys, and glomerular filtration declines temporarily. The effect becomes especially pronounced during strenuous exercise. As blood flow increases to the skin and skeletal muscles, it decreases to the kidneys. At maximal levels of exertion, renal blood flow may be less than one-quarter of normal resting levels.

Such a reduction can create problems for endurance athletes, such as distance swimmers and marathon runners. Metabolic wastes build up during a long event. Protein is commonly lost in the urine because glomerular cells may be damaged by low oxygen levels (hypoxia). If the damage is substantial, blood appears in the urine. Such problems generally disappear within 48 hours. A small number of runners, however, suffer kidney failure (renal failure) and permanent impairment of kidney function.

CHECKPOINT

- **10.** List the factors that affect the glomerular filtration rate (GFR).
- **11.** What effect would increased aldosterone secretion have on the K⁺ concentration in urine?
- **12.** What is the effect of sympathetic activation on kidney function?

18-5 Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra, aided by urinary reflexes

Learning Outcome Describe the structures and functions of the ureters, urinary bladder, and urethra, discuss the control of urination, and describe the urinary reflexes.

Filtrate modification and urine production end when the fluid enters the renal pelvis. The ureters, urinary bladder, and urethra make up the *urinary tract*. It transports, stores, and eliminates urine (**Figure 18-11**).

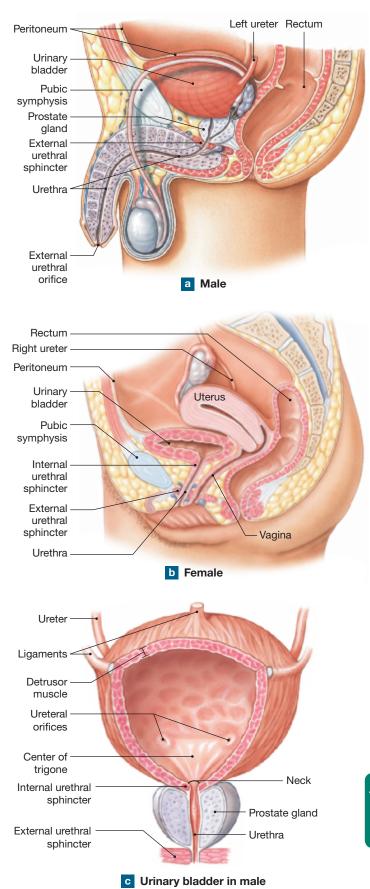

The Ureters

The **ureters** are a pair of muscular tubes that conduct urine from the kidneys to the urinary bladder. This distance is about 30 cm (12 in.) (**Figure 18-1**). Each ureter begins at the funnelshaped renal pelvis. It ends at the posterior wall of the bladder without entering the peritoneal cavity. The **ureteral orifices** within the urinary bladder are slit-like rather than rounded. This shape prevents the backflow of urine into the ureters or kidneys when the urinary bladder contracts.

The wall of each ureter contains three layers. They are an inner transitional epithelium, a middle layer of longitudinal and circular bands of smooth muscle, and an outer connective tissue layer continuous with the renal capsule. About every 30 seconds, a peristaltic contraction begins at the renal pelvis. It sweeps along the ureter, forcing urine toward the urinary bladder.

Solids made of calcium deposits, magnesium salts, or crystals of uric acid may form within the kidney, ureters, or urinary bladder. These solids are called *calculi* (KAL-kū-li), or *kidney stones*. Their presence results in a painful condition known as *nephrolithiasis* (nef-rō-li-THI-uh-sis). Kidney stones not only obstruct the flow of urine but may also reduce or prevent filtration in the affected kidney.

Figure 18-11 Organs for Conducting and Storing Urine.

The Urinary Bladder

The **urinary bladder** is a hollow, muscular organ that stores urine prior to urination. Its size varies depending on how distended it is. A full urinary bladder can contain as much as a liter of urine.

The urinary bladder lies in the pelvic cavity. Only its superior surface is covered by a layer of peritoneum. It is held in position by peritoneal folds (*umbilical ligaments*) that extend to the umbilicus (navel), and by bands of connective tissue attached to the pelvic and pubic bones. In males, the base of the urinary bladder lies between the rectum and the pubic symphysis (**Figure 18-11a**). In females, the urinary bladder sits inferior to the uterus and anterior to the vagina (**Figure 18-11b**).

The *trigone* (TRI-gon) is a triangular area within the urinary bladder. This area is bounded by the ureteral openings and the entrance to the urethra (**Figure 18-11c**). The urethral entrance lies at the apex of this triangle at the most inferior point in the bladder. The area surrounding the urethral entrance is called the *neck* of the urinary bladder. The neck contains a muscular **internal urethral sphincter**. The smooth muscle of this sphincter provides involuntary control over the discharge of urine from the bladder.

A *transitional epithelium* lines the urinary bladder. This stratified epithelium is continuous with the renal pelvis and the ureters. It can tolerate a considerable amount of stretching (as shown in Figure 4-5c). \supset p. 129

The bladder wall consists of inner and outer layers of longitudinal smooth muscle with a circular layer between the two. Together, these layers form the powerful **detrusor** (de-TROO-sor) **muscle** of the bladder. Contraction of this muscle compresses the urinary bladder and expels its contents into the urethra.

The Urethra

The **urethra** extends from the neck of the urinary bladder to the exterior of the body. In males, the urethra extends to the external opening, or **external urethral orifice**, at the tip of the penis. This distance may be 18–20 cm (7–8 in.). In females, the urethra is very short. It extends 2.5–3.0 cm (about 1 in.) from the bladder to the exterior (**Figure 18-11b**). The external urethral orifice is near the anterior wall of the vagina. In both sexes, as the urethra passes through the muscular floor of the pelvic cavity, a circular band of skeletal muscle forms the **external urethral sphincter** (**Figure 18-11**). This sphincter consists of skeletal muscle fibers. Its contractions are under voluntary control.

CLINICAL NOTE

Urinary Tract Infections

Urinary tract infections (UTIs) result when bacteria or yeasts (fungi) colonize the urinary tract. The intestinal bacterium *Escherichia coli* is most commonly involved. Women are particularly susceptible to UTIs because the external urethral orifice is so close to the vagina and anus. Sexual intercourse can push bacteria into the urethra. The urinary bladder can also become infected because the urethra is relatively short.

A UTI may produce no symptoms, but it can be detected by the presence of bacteria and blood cells in urine. If the urethral wall becomes inflamed, the condition is termed *urethritis*. Inflammation of the lining of the bladder is called *cystitis*. Many infections, including sexually transmitted diseases (STDs) such as *gonorrhea*, cause a combination of urethritis and cystitis. These conditions cause painful urination, called *dysuria* (dis-Ū-rē-uh). The urinary bladder also becomes tender and sensitive to pressure. Despite the discomfort of urination, the person feels the urge to urinate frequently. UTIs generally respond to antibiotics, although reinfections can occur.

In untreated cases, the bacteria may proceed along the ureters to the renal pelvis. Inflammation of the walls of the renal pelvis produces *pyelitis* (pi-e-LI-tis). If the bacteria invade the renal cortex and medulla as well, *pyelonephritis* (pi-e-lō-nef-RI-tis) results. Its signs and symptoms include a high fever, intense pain on the affected side, vomiting, diarrhea, and blood cells and pus in the urine.

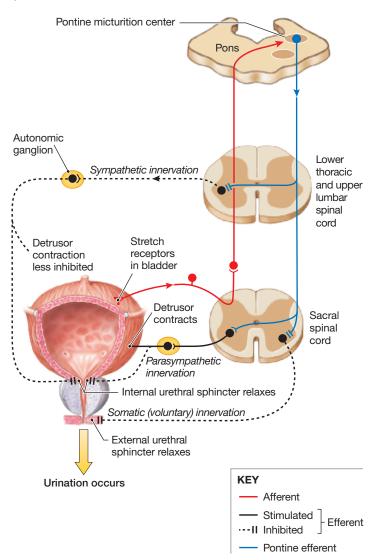

The Control of Urination

As we have seen, urine reaches the urinary bladder by peristaltic contractions of the ureters. The urge to urinate generally appears when your urinary bladder contains about 200 mL of urine. Whether or not we urinate depends on an interplay between spinal reflexes and higher centers in the brain that provide conscious control over urination.

The discharge of urine depends on contraction of the urinary bladder detrusor muscle, along with the opening of the internal and external urethral sphincters. Recall that the detrusor and internal sphincter are composed of smooth muscle and under autonomic (involuntary) control. Sympathetic activity inhibits detrusor contraction and stimulates internal urethral sphincter contraction. Parasympathetic activity stimulates detrusor contraction and inhibits internal urethral sphincter contraction. The external sphincter is composed of skeletal muscle and under somatic (voluntary) control.

Two spinal reflexes control urination (micturition): the **urine storage reflex** and the **urine voiding reflex**.

Urine storage occurs by spinal reflexes and a storage center in the pons. When urine is being stored, afferent (sensory) impulses from stretch receptors in the urinary bladder stimulate sympathetic impulses to the detrusor muscle and internal **Figure 18-12 The Urine Voiding Reflex and Urination.** This diagram illustrates the components of the urine voiding reflex that stimulates smooth muscle contractions in the urinary bladder. Urination occurs after voluntary relaxation of the external urethral sphincter.

urethral sphincter. This sympathetic activity permits filling of the bladder. The *pontine storage center* further inhibits urination by decreasing parasympathetic activity and increasing somatic motor nerve activity at the external urethral sphincter. Urine storage (*continence*) occurs as urine is unable to pass through the urethra.

Urination occurs by spinal reflexes and the *pontine micturition center* (Figure 18-12). The voiding reflex begins when the volume of urine in the bladder reaches 300–400 mL. At such adult threshold volumes, afferent impulses from stretch receptors in the urinary bladder stimulate interneurons that relay sensations to the micturition center in the pons. This center initiates sacral spinal reflexes that increase parasympathetic impulses (increasing bladder contractions) and decrease sympathetic activity

CLINICAL NOTE

Incontinence

Incontinence (in-KON-ti-nens) is the inability to control urination voluntarily. Infants lack voluntary control over urination because the necessary corticospinal connections have yet to be established. For this reason, "toilet training" before age 2 often involves the parent learning to anticipate the timing of the micturition reflex rather than training the child to exert conscious control.

Trauma to the internal or external urethral sphincter can contribute to incontinence in otherwise normal adults. For example, some new mothers develop stress urinary incontinence (SUI) after childbirth. Pressures caused by a cough or sneeze can overwhelm the sphincter muscles, causing urine to leak out. Incontinence may also develop in older people because of a general loss of muscle tone.

Damage to the CNS, the spinal cord, or the nerves to the bladder or external sphincter may also produce incontinence. For example, incontinence often comes with Alzheimer's disease or spinal cord injury. In most cases, the affected person develops an *automatic bladder*. The micturition reflex remains intact, but voluntary control of the external sphincter is lost, so the person cannot prevent the reflexive emptying of the bladder.

Damage to the pelvic nerves can eliminate the micturitionreflex entirely. A catheter must usually be inserted to help discharge the urine.

Build Your Knowledge

Recall that capillaries, unlike other blood vessels, are permeable to small ions, nutrients, organic wastes, dissolved gases, and water (as you saw in **Chapter 13: The Cardiovascular System: Blood** Vessels and Circulation). Two forces, capillary hydrostatic pressure (CHP) and blood osmotic pressure (BOP), are involved in the continual exchange of these materials between the bloodstream and body tissues. At the arterial end of a capillary, CHP is greater than BOP. As a result, fluid is forced out (filtration). Near the venule end of a capillary, BOP is greater than CHP. For this reason, fluid moves into the capillary (reabsorption). Overall, about 3.6 liters (0.95 gal) more fluid leaves the body's capillaries than is absorbed each day. Such capillary exchange plays a key role in homeostasis by maintaining constant communication between blood plasma and interstitial fluid. **pp. 464, 468**

(relaxing the internal urethra sphincter). As a result, the detrusor contracts and the internal urethral sphincter relaxes. There is also a decrease in efferent somatic motor nerve activity, causing the external urethral sphincter to relax. Voiding (urination) occurs as urine passes through the urethra. At the end of normal urination, less than 10 mL of urine remains in the bladder.

CHECKPOINT

- **13.** What is responsible for the movement of urine from the kidneys to the urinary bladder?
- **14.** An obstruction of a ureter by a kidney stone would interfere with the flow of urine between what two structures?
- **15.** Voluntary control of urination depends on your ability to control which muscle?
- See the blue Answers tab at the back of the book.

18-6 Fluid balance, electrolyte balance, and acid-base balance are interrelated and essential to homeostasis

Learning Outcome Define the terms *fluid balance, electrolyte balance,* and *acid-base balance*, discuss their importance for homeostasis, and describe how water and electrolytes are distributed within the body.

Few topics have the wide-ranging clinical importance of fluid, electrolyte, and acid-base balance in the body. *Treatment of any serious illness affecting the nervous, cardiovascular, respiratory, urinary, or digestive system must always include steps to restore normal fluid, electrolyte, and acid-base balance.*

Most of your body weight is water. Water accounts for up to 99 percent of the volume of the fluid outside cells. It is an essential ingredient of cytoplasm. All of a cell's operations rely on water as a diffusion medium for the distribution of gases, nutrients, and waste products. If the water content of the body changes, cellular activities are jeopardized. For example, when water content declines too far, proteins denature, enzymes cease functioning, and cells die. To survive, the body must maintain a normal volume and composition in both the **extracellular fluid** or **ECF** (the interstitial fluid, plasma, and other body fluids) and the **intracellular fluid** or **ICF** (the cytosol).

The concentrations of various ions and the pH (hydrogen ion concentration) of the body's water are as important as their absolute quantities. If concentrations of calcium or potassium ions in the ECF become too high, cardiac arrhythmias develop. Death can result. A pH outside the normal range can lead to a variety of dangerous conditions. Low pH is especially dangerous because hydrogen ions break chemical

18

bonds, change the shapes of complex molecules, disrupt cell membranes, and impair tissue functions.

In this section we consider the dynamics of exchange between the various body fluids, such as blood plasma and interstitial fluid, and between the body and the external environment. Homeostasis of fluid volumes, solute concentrations, and pH involves three interrelated factors:

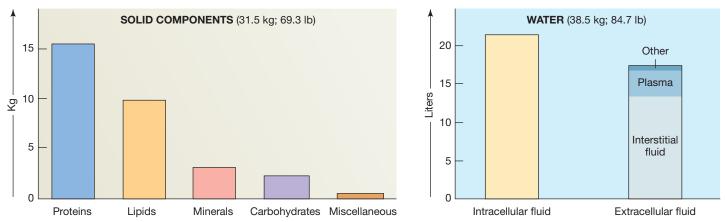

- *Fluid balance*. You are in *fluid balance* when the amount of water you gain each day is equal to the amount you lose. Maintaining normal fluid balance involves regulating the content and distribution of water in the ECF and ICF. Cells and tissues cannot transport water, but they can transport ions. In this way, they create concentration gradients that are then eliminated by osmosis.
- *Electrolyte balance*. Electrolytes are ions released when inorganic compounds dissociate. They are so named because when in solution they can conduct an electrical current. ⊃ p. 67 Each day, your body fluids gain electrolytes from food and drink. Your body fluids also lose electrolytes in urine, sweat, and feces. **Electrolyte balance** exists when there is neither a net gain nor a net loss of any ion in body fluids. Electrolyte balance mainly involves balancing the rates of absorption across the digestive tract with rates of loss at the kidneys.
- Acid-base balance. You are in acid-base balance when the production of hydrogen ions in your body is equal to their loss. When acid-base balance exists, the pH of body fluids remains within normal limits. D p. 66 Preventing a reduction in pH is a primary problem because normal metabolic operations generate a variety of acids. The kidneys and lungs play key roles in maintaining the acidbase balance of body fluids.

The ECF and the ICF

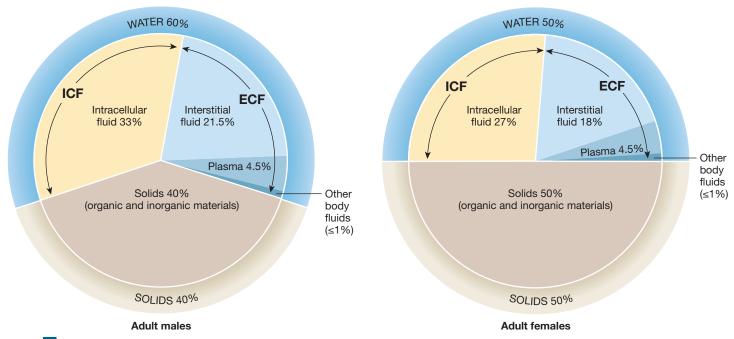

Figure 18-13a presents an overview of the body makeup of a 70-kg (154-lb) person with a minimum of body fat. The distribution is based on overall average values for males and females aged 18–40 years. Water makes up about 60 percent of the total body weight of an adult male, and 50 percent of that of an adult female (**Figure 18-13b**). This difference between the sexes reflects the relatively larger mass of adipose tissue in adult females, and the greater average muscle mass in adult males. (Adipose tissue is only 10 percent water but skeletal muscle is 75 percent water.)

In both sexes, intracellular fluid contains more of the total body water than does extracellular fluid. Exchange between the ICF and ECF takes place across plasma membranes by osmosis, diffusion, and carrier-mediated transport.

a The body composition (by weight, averaged for both sexes) and major body fluid compartments of a 70-kg (154-lb) person. For technical reasons, it is extremely difficult to determine the precise size of any of these compartments; estimates of their relative sizes vary widely.

The largest subdivisions of the ECF are the interstitial fluid of peripheral tissues and the plasma of the circulating blood (Figure 18-13a). Minor components of the ECF include lymph, cerebrospinal fluid (CSF), synovial fluid, serous fluids (pleural, pericardial, and peritoneal fluids), aqueous humor, perilymph, and endolymph. In clinical situations, it is common practice to estimate that two-thirds of the total body water is in the ICF and one-third in the ECF. This ratio underestimates the real volume of the ECF, because it neglects the water in bone, in many dense connective tissues, and in the minor ECF components. However, these fluid volumes are relatively isolated. Exchange with the rest of the ECF occurs more slowly than does exchange between plasma and other interstitial fluids. Exchange among the subdivisions of the ECF takes place mainly across the endothelial lining of capillaries. Fluid may also travel from the interstitial spaces to the plasma through lymphatic vessels that drain into the venous system. $\bigcirc p. 504$ The kinds and amounts of dissolved electrolytes, proteins, nutrients, and waste products within each ECF subdivision or component are not the same. However, these variations are relatively minor compared with the major differences *between* the ECF and the ICF.

The ECF and ICF are called **fluid compartments** because they commonly behave as distinct entities. Cells are able to maintain internal environments with a composition that differs from their surroundings. They can do so because of the presence of a plasma membrane and active transport at the membrane surface. The principal ions in the ECF are sodium, chloride, and bicarbonate. The ICF contains an abundance of potassium, magnesium, and phosphate ions, plus large numbers of negatively charged proteins. **Figure 18-14** compares the ICF with the two main subdivisions of the ECF (plasma and interstitial fluid).

Despite these differences in the concentrations of specific substances, the osmotic concentrations of the ICF and ECF are identical. Osmosis eliminates minor differences in concentration almost at once because most plasma membranes are freely permeable to water. The regulation of water balance and electrolyte balance is tightly intertwined because changes in solute concentrations lead to immediate changes in water distribution.

CHECKPOINT

- **16.** Identify the three interrelated processes essential to stabilizing body fluid volumes.
- **17.** List the components of extracellular fluid (ECF) and intracellular fluid (ICF).

See the blue Answers tab at the back of the book.

18-7 Blood pressure and osmosis are involved in maintaining fluid and electrolyte balance

Learning Outcome Explain the basic processes involved in maintaining fluid balance and electrolyte balance.

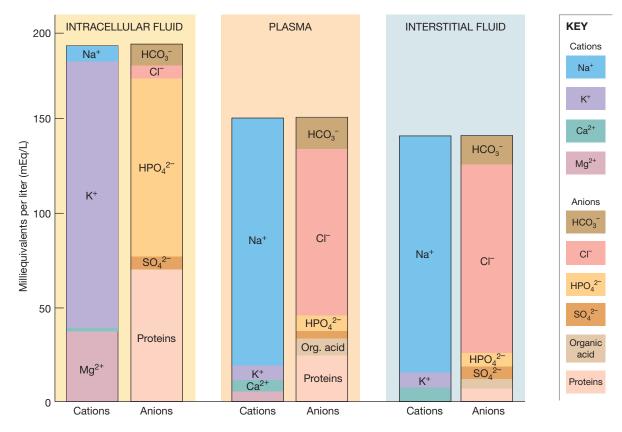

Fluid Balance

Water circulates freely within the ECF compartment. At capillary beds throughout the body, capillary blood pressure forces water out of the plasma and into the interstitial spaces. Some of that water is reabsorbed due to higher blood osmotic pressure along the distal portion of the capillary bed. The rest circulates into lymphatic vessels for transport to the venous circulation (see Figure 13-6, p. 468).

Fluid also moves continuously among the minor components of the ECF:

1. Water moves back and forth across the epithelial surfaces lining the peritoneal, pleural, and pericardial cavities and through the synovial membranes lining

Figure 18-14 Ions in Body Fluids. Notice that each fluid compartment is electrically neutral and the ionic composition is markedly different between the ICF and ECF (plasma and interstitial fluid). (For information concerning the chemical composition of other body fluids, see Appendix.)

joint capsules. The flow rate is significant. For example, roughly 7 liters (1.8 gal) of peritoneal fluid is produced and reabsorbed each day.

2. Water also moves between the blood and the cerebrospinal fluid (CSF), between the aqueous humor and vitreous humor of the eye, and between the perilymph and endolymph of the internal ear. The volumes involved in these water movements are small. We will largely ignore them in the discussion that follows.

Table 18-4 indicates the major factors in fluid balance. You lose about 2500 mL of water each day in urine, feces, and *insensible perspiration*—the gradual movement, or evaporation, of water across the epithelia of the skin and respiratory tract. The losses due to *sensible perspiration*—secretion by the sweat glands—varies with the level of activity. In vigorously exercising individuals, the water losses due to sensible perspiration can be considerable, reaching well over 4 liters an hour. ⊃ p. 163 Water losses are normally balanced by the gain of water through eating (40 percent), drinking (48 percent), and metabolic generation (12 percent). *Metabolic generation* of water occurs primarily as a result of mitochondrial ATP production. ⊃ p. 625

Fluid Shifts

Water movement between the ECF and ICF is called a **fluid shift**. Fluid shifts occur relatively rapidly, reaching equilibrium within a period of minutes to hours. These shifts occur in response to changes in the osmotic concentration, or *osmolarity*, of the extracellular fluid.

• *If the osmotic concentration of the ECF increases, that fluid will become hypertonic with respect to the ICF.* Water will then move from the cells into the ECF until equilibrium is restored.

Table 18-4	Water Balance		
		Daily	nput
Source		(mL)	(%)
Water content of food		1000	40
Water consumed as liquid		1200	48
Metabolic water produced during catabolism		300	12
Total		2500	100
		Daily Output	
		Daily C	Dutput
Method of Elimina	tion	Daily C (mL)	Output (%)
Method of Elimina Urination	tion	-	
		(mL)	. (%)
Urination		(mL) 1200	(%) 48
Urination Evaporation at skin		(mL) 1200 750	(%) 48 30

• *If the osmotic concentration of the ECF decreases, that fluid will become hypotonic with respect to the ICF.* Water will then move from the ECF into the cells, and the ICF volume will increase.

In summary, if the osmolarity of the ECF changes, a fluid shift between the ICF and ECF will tend to oppose the change. The ICF acts as a "water reserve," because the volume of the ICF is much greater than that of the ECF. In effect, instead of a large change in the osmotic concentration of the ECF, smaller changes occur in both the ECF and the ICF.

Electrolyte Balance

As we have noted, you are in electrolyte balance when the rates of gain and loss are equal for each electrolyte in your body. Electrolyte balance is important because:

- A gain or loss of electrolytes can cause a gain or loss in water.
- *The concentrations of individual electrolytes affect a variety of cell functions.* We have described many examples of the effects of ions on cell function in earlier chapters. ⊃ pp. 389, 453

Two cations, Na⁺ and K⁺, deserve attention because (1) they are major contributors to the osmotic concentrations of the ECF and ICF, respectively, and (2) they directly affect the normal functioning of all cells. Sodium is the main cation within the extracellular fluid. More than 90 percent of the osmotic concentration of the ECF results from the presence of sodium salts, mostly sodium chloride (NaCl) and sodium bicarbonate (NaHCO₃). Changes in the osmotic concentration of body fluids usually reflect changes in Na⁺ concentration. Potassium is the main cation in the intracellular fluid. Extracellular potassium concentrations are normally low. In general:

- The most common problems involving electrolyte balance are caused by an imbalance between sodium gains and losses.
- Problems with potassium balance are less common but significantly more dangerous than those related to sodium balance.

Sodium Balance

The amount of sodium in the ECF represents a balance between sodium ion absorption at the digestive tract and sodium ion excretion at the kidneys and other sites. The rate of uptake varies directly with the amount included in the diet. Sodium losses take place mainly by excretion in urine and through perspiration. The kidneys are the most important sites for regulating sodium ion losses. In response to circulating aldosterone, the kidneys reabsorb Na⁺ (which decreases sodium loss). In response to atrial natriuretic peptide (ANP), the kidneys increase the loss of sodium ions. \bigcirc pp. 651–652

Whenever the rate of sodium intake or output changes, a corresponding gain or loss of water tends to keep the Na⁺ concentration constant. For example, eating a heavily salted meal will not raise the sodium ion concentration of body fluids. Why not? As sodium chloride crosses the digestive epithelium, osmosis brings additional water from the digestive tract into the ECF. This is why individuals with high blood pressure are told to restrict their salt intake. When dietary salt is absorbed, "water follows salt," so blood volume—and, thus, blood pressure—increases.

Potassium Balance

Roughly 98 percent of the body's potassium is within the ICF. Cells expend energy to recover potassium ions as they diffuse across their plasma membranes and into the ECF. The K^+ concentration of the ECF is relatively low. It represents a balance between (1) the rate of gain across the digestive epithelium and (2) the rate of loss in urine.

The rate of gain is proportional to the amount of potassium in the diet. The rate of loss is strongly affected by aldosterone. Urinary potassium losses are controlled through adjustments in the rate of active secretion along the distal convoluted tubules of a kidney's nephrons. The ion pumps sensitive to aldosterone reabsorb sodium ions from the tubular fluid in exchange for potassium ions from the peritubular (interstitial) fluid. In other words, K⁺ are secreted into the urine.

High plasma concentrations of potassium ions also stimulate aldosterone secretion directly. When potassium levels rise in the ECF, aldosterone levels increase, and additional potassium ions are lost in the urine. When potassium levels fall in the ECF, aldosterone levels decrease, and potassium ions are conserved.

CHECKPOINT

- **18.** Describe a fluid shift.
- **19.** How would eating a meal high in salt content affect the amount of fluid in the intracellular fluid compartment (ICF)?
- **20.** What effect would being in the desert without water for a day have on the osmotic concentration of your blood plasma?

See the blue Answers tab at the back of the book.

18-8 In acid-base balance, regulation of hydrogen ions in body fluids involves buffer systems and compensation by respiratory and renal processes

Learning Outcome Explain the buffering systems that balance the pH of the intracellular and extracellular fluids, and identify the most common threats to acid-base balance.

The pH of your body fluids represents a balance among the acids and bases in solution. The pH of the ECF normally remains within relatively narrow limits, usually 7.35–7.45. Any deviation from the normal range is extremely dangerous. Changes in hydrogen ion concentrations disrupt the stability of cell membranes, alter protein structure, and change the activities of important enzymes. You could not survive for long with a pH below 6.8 or above 7.7.

Acidosis is the physiological state that exists when blood pH falls below 7.35. Alkalosis exists when the pH exceeds 7.45. These conditions affect virtually all systems. The nervous and cardio-vascular systems are particularly sensitive to pH changes. Severe acidosis (pH below 7.0) can be deadly because (1) CNS function deteriorates, and the person becomes comatose; (2) cardiac contractions grow weak and irregular, and signs of heart failure develop; and (3) peripheral vasodilation produces a dramatic drop in blood pressure, and circulatory collapse can occur.

Acidosis and alkalosis are both dangerous. In practice, problems with acidosis are much more common. The reason is that normal cellular activities generate several acids (including carbonic acid).

Acids in the Body

Carbonic acid (H_2CO_3) is an important acid in body fluids. At the lungs, carbonic acid breaks down into carbon dioxide and water. The carbon dioxide then diffuses into the alveoli. In peripheral tissues, carbon dioxide in solution interacts with water to form carbonic acid. The carbonic acid molecules then dissociate into hydrogen ions and bicarbonate ions (see Chapter 15). $\supset p.556$ The complete reaction sequence is

carbonic anhydrase

$$CO_2 + H_2O \implies H_2CO_3 \implies H^+ + HCO_3^-$$

carbon dioxide water carbonic acid hydrogen ion bicarbonate ion

This reaction occurs spontaneously in body fluids. It takes place much more rapidly in the presence of the enzyme *carbonic anhydrase*. This enzyme is found in many cell types, including red blood cells, liver and kidney cells, and parietal cells of the stomach. The partial pressure of carbon dioxide (P_{co_2}) is the most important factor affecting the pH of in body tissues. Most of the carbon dioxide in solution is converted to carbonic acid, and most of the carbonic acid dissociates into hydrogen ions and bicarbonate ions. For this reason, the partial pressure of carbon dioxide (P_{co_2}) and pH are inversely related, as the seesaw in **Figure 18-15** illustrates. When carbon dioxide concentrations rise, additional hydrogen ions and bicarbonate ions are released, and pH goes down. (Recall that the greater the concentration of hydrogen ions, the lower the pH value.)

At the alveoli, carbon dioxide diffuses into the atmosphere, the number of hydrogen ions and bicarbonate ions drops, and the pH rises. This process effectively removes hydrogen ions from solution. We will consider it in more detail in the next section.

Metabolic acids are generated during normal metabolism. Some come from the catabolism of amino acids, carbohydrates, or lipids. One example is lactic acid, which is associated with the anaerobic metabolism of glucose. Another is ketone bodies from the breakdown of fatty acids. Under normal conditions, metabolic acids are recycled or excreted rapidly. For this reason, significant accumulations do not occur.

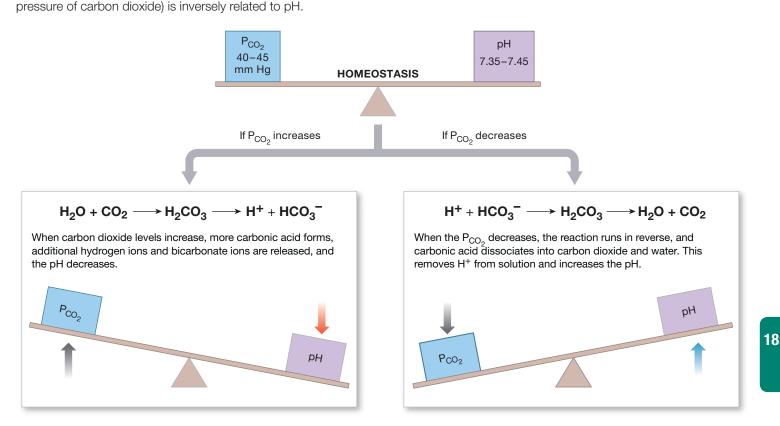

Buffers and Buffer Systems

The acids produced in normal metabolic operations are temporarily neutralized by buffers and buffer systems in body fluids. *Buffers* are dissolved compounds that stabilize the pH of a solution by donating or removing hydrogen ions (H^+). \supset p. 68 Buffers include *weak acids* that can donate H^+ , and *weak bases* that can absorb H^+ . A **buffer system** consists of a combination of a weak acid and its dissociation products: a hydrogen ion and an anion.

The body has three major buffer systems: *protein buffer systems*, the *carbonic acid–bicarbonate buffer system*, and the *phosphate buffer system*. Each has slightly different characteristics and distributions.

Protein buffer systems contribute to the regulation of pH in the ECF and ICF. Protein buffer systems include proteins and free amino acids. The amino acid side groups of proteins and the side group and structural groups of free amino acids respond to changes in pH by accepting or releasing H⁺. If pH climbs, the carboxyl group (—COOH) of the amino acid acts as a weak acid. It dissociates and releases a hydrogen ion. If pH drops, the amino group (—NH₂) can act as a weak base. It can accept an additional hydrogen ion, forming an amino ion (—NH₃⁺).

Figure 18-15 The Basic Relationship between Carbon Dioxide and Plasma pH. The P_{co_2} (partial pressure of asthen dioxide) is inversely related to plan

The plasma proteins and hemoglobin in red blood cells contribute to the buffering capabilities of blood. Interstitial fluids contain extracellular protein fibers and dissolved amino acids that also help regulate pH. In the ICF of active cells, structural and other proteins provide an extensive buffering capability. Protein buffering systems help prevent destructive pH changes when cellular metabolism produces metabolic acids, such as lactic acid.

The **carbonic acid-bicarbonate buffer system** is an important buffer system in the ECF. With the exception of red blood cells, your body cells generate carbon dioxide 24 hours a day. As noted earlier, most of the carbon dioxide is converted to carbonic acid, which then dissociates into a hydrogen ion and a bicarbonate ion. The carbonic acid and its dissociation products make up the carbonic acid-bicarbonate buffer system. The carbonic acid acts as a weak acid. The bicarbonate ion acts as a weak base. The net effect of this buffer system is that $CO_2 + H_2O \Longrightarrow H^+ + HCO_3^-$. If hydrogen ions are removed, they will be replaced through the combining of water with carbon dioxide. If hydrogen ions are added, most will be removed through the formation of carbon dioxide and water.

The primary role of the carbonic acid-bicarbonate buffer system is to prevent pH changes caused by metabolic acids. The hydrogen ions released by the dissociation of these acids combine with bicarbonate ions, producing water and carbon dioxide. The carbon dioxide can then be removed at the lungs. This buffering system can cope with large amounts of acid because body fluids contain an abundance of bicarbonate ions, known as the *bicarbonate reserve*. When hydrogen ions enter the ECF, the bicarbonate ions that combine with them are replaced from the bicarbonate reserve.

The **phosphate buffer system** consists of an anion, *dihydrogen phosphate* ($H_2PO_4^-$), which is a weak acid. This ion and its dissociation products make up the phosphate buffer system:

 $H_2PO_4^- \iff H^+ + HPO_4^{2-}$ dihydrogen phosphate hydrogen ion monohydrogen phosphate

In solution, dihydrogen phosphate $(H_2PO_4^{-})$ reversibly dissociates into a hydrogen ion and monohydrogen phosphate (HPO_4^{2-}) . In the ECF, the phosphate buffer system plays only a supporting role in the regulation of pH. The reason is that the concentration of bicarbonate ions far exceeds that of phosphate ions. However, the phosphate buffer system is quite important in buffering the pH of the ICF. There the concentration of phosphate ions is relatively high.

Maintaining Acid-Base Balance

Buffer systems can tie up excess hydrogen ions (H^+), but they provide only a temporary solution to an acid-base imbalance. The hydrogen ions are only made harmless. They have not been eliminated. For homeostasis to be preserved, the captured H^+ must ultimately be removed from body fluids. The problem is that there is a limited supply of buffer molecules. Once a buffer binds a H^+ , it cannot bind any more H^+ . With the buffer molecules tied up, the capacity of the ECF to absorb more hydrogen ions is reduced. The control of pH is impossible in this case.

Maintaining acid-base balance involves balancing hydrogen ion losses and gains. In this "balancing act," respiratory and renal processes support the buffer systems. They do so by (1) secreting or absorbing hydrogen ions, (2) controlling the excretion of acids and bases, and (3) generating additional buffers. The *combination* of buffer systems and these respiratory and renal processes maintains body pH within narrow limits.

Respiratory Contributions to pH Regulation

Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Respiratory compensation takes place whenever pH exceeds normal limits. Such compensation works because respiratory activity has a direct effect on the carbonic acid–bicarbonate buffer system. Increasing or decreasing the rate of respiration alters pH by lowering or raising the partial pressure of CO_2 (P_{co_2}). As we have seen, changes in P_{co_2} directly affect the concentration of hydrogen ions in the plasma. Changes in P_{co_2} also have an inverse effect on pH. When the P_{co_2} rises, H⁺ concentration increases, and the pH declines. When the P_{co_2} decreases, H⁺ concentration decreases, and the pH increases (**Figure 18-15**).

Changes in the P_{co_2} have a dominant role in controlling the respiratory rate. (We discussed the processes involved in Chapter 15 \bigcirc p. 557.) A rise in P_{co_2} stimulates chemoreceptors in the carotid and aortic bodies and within the CNS. This stimulation leads to an increase in the respiratory rate. As the rate of respiration increases, more CO₂ is lost at the lungs, so the P_{co_2} returns to normal levels. A fall in P_{co_2} inhibits the chemoreceptors. When the P_{co_2} of the blood or CSF declines, respiratory activity is then depressed, the breathing rate decreases, and the P_{co_2} in the extracellular fluids increases.

Renal Contributions to pH Regulation

Renal compensation is a change in the rates of hydrogen ion and bicarbonate ion secretion or reabsorption by the kidneys in response to changes in plasma pH. Under normal conditions, the body generates metabolic acids, which release H⁺. The H⁺ must then be excreted in the urine to maintain acid-base balance. Glomerular filtration puts hydrogen ions, carbon dioxide, and the other components of the carbonic acid-bicarbonate and phosphate buffer systems into the filtrate. The kidney tubules then modify the pH of the filtrate by secreting hydrogen ions or reabsorbing bicarbonate ions.

Acid-Base Disorders

Together, buffer systems, respiratory compensation, and renal compensation maintain normal acid-base balance. They are usually able to control pH very precisely. As a result, the pH of extracellular fluids seldom varies more than 0.1 pH units, from 7.35 to 7.45. When buffering actions are severely stressed, however, pH strays outside these limits. Symptoms of alkalosis or acidosis then appear.

CLINICAL NOTE

Disturbances of Acid-Base Balance

The terms used to describe disturbances of acid-base balance indicate the primary source of the disturbance. *Respiratory acidbase disorders* result from a mismatch between carbon dioxide generation in peripheral tissues and carbon dioxide excretion at the lungs. When a respiratory acid-base disorder is present, the carbon dioxide level of the ECF is abnormal. *Metabolic acidbase disorders* are caused by the generation of metabolic acids or by conditions affecting the concentration of bicarbonate ions in the ECF.

Respiratory compensation alone can often restore normal acid-base balance in people suffering from respiratory disorders. In contrast, compensation processes for metabolic disorders may be able to stabilize pH, but other aspects of acid-base balance (buffer system function, bicarbonate levels, and P_{co_2}) remain abnormal until the underlying metabolic problem is corrected.

Respiratory Acidosis

Respiratory acidosis develops when the respiratory system is unable to eliminate all the CO_2 generated by peripheral tissues. The primary indication is low plasma pH due to *hypercapnia*, an elevated plasma P_{co_2} . As carbon dioxide levels climb, hydrogen ion and bicarbonate ion concentrations rise as well. Other buffer systems can tie up some of the hydrogen ions, but once the combined buffering capacity has been exceeded, pH begins to fall rapidly.

Respiratory acidosis represents the most common challenge to acid-base balance. The usual cause is *hypoventilation*, an abnormally low respiratory rate. Because tissues generate carbon dioxide at a rapid rate, even a few minutes of hypoventilation can cause acidosis, reducing the pH of the ECF to as low as 7.0. Under normal circumstances, chemoreceptors monitoring the P_{co_2} of the plasma and CSF will eliminate the problem by stimulating increases in breathing rate.

Respiratory Alkalosis

Problems with respiratory alkalosis are relatively uncommon. This condition develops when respiratory activity reduces plasma P_{co_2} to below-normal levels, a condition called *hypocapnia*. Temporary hypocapnia can be produced by *hyperventilation*, when increased respiratory activity leads to a reduction in arterial P_{co_2} . Continued hyperventilation can elevate pH to levels as high as 8.

This condition usually corrects itself. The reduction in P_{co_2} removes the stimulation for the chemoreceptors. The urge to breathe then fades until carbon dioxide levels have returned to normal. Respiratory alkalosis caused by hyperventilation seldom persists long enough to cause a clinical emergency.

Metabolic Acidosis

Metabolic acidosis is the second most common type of acid-base imbalance. The most frequent cause is the production of large quantities of metabolic acids such as lactic acid or ketone bodies. Metabolic acidosis can also be caused by an impaired ability to excrete hydrogen ions at the kidneys. Any condition accompanied by severe kidney damage can result in metabolic acidosis.

Compensation for metabolic acidosis usually involves a combination of respiratory and renal processes. Hydrogen ions interacting with bicarbonate ions form carbon dioxide molecules that are eliminated at the lungs. The kidneys excrete additional hydrogen ions into the urine and generate bicarbonate ions that are released into the ECF.

Metabolic Alkalosis

Metabolic alkalosis takes place when bicarbonate ion concentrations become elevated. The bicarbonate ions then interact with hydrogen ions in solution, forming carbonic acid. The reduction in H⁺ concentrations produces alkalosis.

Cases of severe metabolic alkalosis are relatively rare. A temporary metabolic alkalosis occurs during meals. At that time, large numbers of bicarbonate ions are released into the ECF during the secretion of HCl by the parietal cells of the stomach. (Hydrogen ions and bicarbonate ions are formed from CO_2 and H_2O within the parietal cells. The bicarbonate ions are released into the blood in exchange for chloride ions.)

Serious metabolic alkalosis may result from bouts of repeated vomiting, because the stomach continues to generate stomach acids to replace those that are lost. As a result, the HCO_3^- concentration of the ECF continues to rise. Compensation for metabolic alkalosis involves a reduction in pulmonary ventilation, coupled with the increased loss of bicarbonates in the urine.

Table 18-5	Acid-Base Disorders		
Disorder	pH (normal = 7.35-7.45)	Remarks	Treatment
Respiratory acidosis	Decreased (below 7.35)	Most common acid-base disorder; generally caused by hypoventilation and CO ₂ buildup in tissues and blood	Improve ventilation—in some cases, with broncho- dilation and mechanical assistance
Metabolic acidosis	Decreased (below 7.35)	Second most common acid-base disorder; caused by buildup of metabolic acid, impaired H ⁺ excretion at kidneys, or bicarbonate loss in urine or feces	Administration of bicarbonate (gradual) with other steps as needed to correct primary cause
Respiratory alkalosis	Increased (above 7.45)	Relatively uncommon acid-base disorder; generally caused by hyperventilation and reduction in plasma CO ₂ levels	Reduce respiratory rate, allow rise in P_{co_2} .
Metabolic alkalosis	Increased (above 7.45)	Severe cases relatively rare; usually caused by prolonged vomiting and associated acid loss	For pH below 7.55, no treatment; pH above 7.55 may require administration of ammonium chloride

Respiratory acid-base disorders result when abnormal respiratory function causes an extreme rise or fall in CO_2 levels in the ECF. Metabolic acid-base disorders result from the generation of metabolic acids or from conditions affecting the concentration of bicarbonate ions in the ECF. Table 18-5 summarizes the general causes and treatments of acid-base disorders.

CHECKPOINT

- **21.** Identify the body's three major buffer systems.
- **22.** What effect would a decrease in the pH of body fluids have on the respiratory rate?
- 23. How would a prolonged fast affect the body's pH?
- See the blue Answers tab at the back of the book.

18-9 Age-related changes affect kidney function and the control of urination

Learning Outcome Describe the effects of aging on the urinary system.

In general, aging is associated with an increased incidence of kidney problems. Age-related changes take place in the urinary system, and in aspects of fluid, electrolyte, and acidbase balance. They include:

- **1.** *A decrease in the number of functional nephrons.* The total number of nephrons in the kidneys drops 30–40 percent between ages 25 and 85.
- **2.** *A reduction in the GFR.* This reduction results from fewer glomeruli, cumulative damage to the filtration structures in those remaining, and reduced renal blood flow. A reduced GFR and fewer nephrons also reduce the body's ability to regulate pH through renal compensation.

3. Reduced sensitivity to ADH and aldosterone.

With age, the distal portions of the nephron and collecting system become less responsive to ADH and aldosterone. As the reabsorption of water and sodium ions is reduced, the body's ability to concentrate urine declines. More water is lost in urine.

- **4.** *Problems with urination.* Several factors are involved in such problems:
 - The sphincter muscles lose tone and become less effective at voluntarily retaining urine. This leads to incontinence, often involving a slow leakage of urine.
 - The ability to control urination is often lost after a stroke, Alzheimer's disease, or other CNS problems affecting the cerebral cortex or hypothalamus.
 - In males, *urinary retention* may develop due to enlargement of the prostate gland. Swelling and distortion of surrounding prostate tissues compress the urethra, restricting or preventing the flow of urine.
- **5.** *A gradual decrease of total body water content with age.* Between ages 40 and 60, total body water content declines slightly, to 55 percent for males and 47 percent for females. After age 60, the values decline to roughly 50 percent for males and 45 percent for females. Such decreases result in less dilution of waste products, toxins, and administered drugs, among other effects.
- 6. A net loss in body mineral content in many people over age 60 as muscle mass and skeletal mass decrease. This loss can be prevented, at least in part, by a combination of exercise and increased dietary mineral intake.
- 7. Increased incidence of disorders affecting major *systems with increasing age.* Most of these disorders have some impact on fluid, electrolyte, and/or acid-base balance.

CHECKPOINT

- 24. What effect does aging have on the GFR?
- **25.** After age 40, does total body water content increase or decrease?

See the blue Answers tab at the back of the book.

18-10 The urinary system is one of several body systems involved in waste excretion

Learning Outcome Give examples of interactions between the urinary system and other body systems presented so far.

The urinary system excretes wastes produced by other organ systems. It is not the only organ system involved in excretion. Together, the urinary system and the integumentary, respiratory, and digestive systems are regarded as an anatomically diverse *excretory system*. Each of these body systems performs all the excretory activities that affect the composition of body fluids:

1. *Integumentary system.* Water and electrolyte losses in perspiration can affect the volume and composition of plasma. The effects are most apparent when losses are extreme, such as during peak sweat production. Small amounts of metabolic wastes, including urea, are also eliminated in perspiration.

- **2.** *Respiratory system.* The lungs remove the carbon dioxide generated by cells. Small amounts of other compounds, such as acetone and water, evaporate into the alveoli. They are eliminated when you exhale.
- **3.** *Digestive system.* The liver excretes metabolic waste products in bile. You lose a variable amount of water in feces.

These excretory activities affect the composition of body fluids. The respiratory system, for example, removes carbon dioxide from the body. However, the excretory functions of these systems are not as closely regulated as are those of the kidneys. Normally, the effects of integumentary and digestive excretory activities are minor compared with those of the urinary system.

Refer to Build Your Knowledge: How the URINARY SYSTEM integrates with the other body systems presented so far on p. 666. It reviews the major functional relationships between this system and the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, respiratory, and digestive systems.

CHECKPOINT

- **26.** Name the organ systems that make up the excretory system.
- **27.** Identify the role the urinary system plays for all other body systems.
- See the blue Answers tab at the back of the book.

RELATED CLINICAL TERMS

antacid: A substance used to counteract or neutralize stomach acid. **diuretics (di-ū-RET-iks):** Substances that promote fluid loss in urine.

glomerulonephritis (glo-mer-ū-lō-nef-RI-tis): Inflammation of the glomeruli (the filtration units of the nephron).

glycosuria (gli-kō-SOO-rē-uh): The presence of glucose in urine.

hematuria: The presence of blood in urine.

hypernatremia: A condition characterized by excess sodium in the blood.

hyponatremia: A condition characterized by lower-thannormal sodium in the blood. nephritis: Inflammation of the kidneys.

nephrology (ne-FROL-o-jē): The medical specialty concerned with the kidneys and their disorders.

proteinuria: The presence of protein in urine.

pyelogram (PI-el-ō-gram): An x-ray image of the kidneys taken after a radiopaque compound has been administered. **urinalysis:** A physical and chemical assessment of urine.

urology ū-ROL-o-jē: Branch of medicine concerned with the urinary system and its disorders, and with the male reproductive tract and its disorders.

Build Your Knowledge

How the URINARY SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System prevents excessive fluid loss through skin surface; produces vitamin D₃, important for the renal production of calcitriol; sweat glands assist in elimination of water and solutes
- The urinary system excretes nitrogenous wastes; maintains fluid, electrolyte, and acid-base balance of blood that nourishes the skin

Respiratory System

- The Respiratory System assists in the regulation of pH by eliminating carbon dioxide
- The urinary system assists in the elimination of carbon dioxide; provides bicarbonate buffers that assist in pH regulation

Cardiovascular System

- The Cardiovascular System delivers blood to glomerular capillaries, where filtration occurs; accepts fluids and solutes reabsorbed during urine production
- The urinary system releases renin to elevate blood pressure and erythropoietin (EPO) to accelerate red blood cell production

Skeletal System

- The Skeletal System provides some protection for kidneys and ureters with its axial divison; pelvis protects urinary bladder and proximal portion of urethra
- The urinary system conserves calcium and phosphate needed for bone growth

Muscular System

- The Muscular System controls urination by closing urethral sphincters. Muscle layers of trunk provide some protection for urinary organs
- The urinary system excretes waste products of muscle and protein metabolism; assists in regulation of calcium and phosphate concentrations

bladder and controls urination • The urinary system eliminates nitrogenous wastes; maintains fluid, electrolyte, and acid-base balance of blood, which is critical for neural function Endocrine System • The Endocrine System produces aldosterone and ADH, which adjust rates of fluid and electrolyte reabsorption by kidneys • The urinary system releases renin when local blood pressure drops and erythropoietin (EPO) when renal oxygen levels fall Lymphatic System • The Lymphatic System provides adaptive (specific) defense against urinary tract infections • The urinary system eliminates toxins and wastes generated by cellular activities; acid pH of urine provides innate (nonspecific) defense against urinary tract infections **Digestive System**

Nervous System

• The Nervous System adjusts renal blood

pressure; monitors distension of urinary

- The Digestive System absorbs water needed to excrete wastes at kidneys; absorbs ions needed to maintain normal body fluid concentrations; liver removes bilirubin
- The urinary system excretes toxins absorbed by the digestive epithelium; excretes bilirubin and nitrogenous wastes from the liver; calcitriol production by kidneys aids calcium and phosphate absorption

Urinary System

The urinary system excretes metabolic waste and maintains normal body fluid pH and ion composition.

- It:
- regulates blood volume and blood pressure
 regulates plasma concentrations of sodium,
- potassium, chloride, and other ions
- helps to stabilize blood pH
- conserves valuable nutrients

Chapter Review

Summary Outline

18-1 The urinary system—made up of the kidneys, ureters, urinary bladder, and urethra—has three major functions *p. 635*

- 1. The three major functions of the **urinary system** are *excretion*, the removal of metabolic waste products from body fluids; *elimination*, the discharge of these waste products into the environment; and homeostatic regulation of the volume and solute concentration of blood plasma. Other homeostatic functions include regulating blood volume and pressure by adjusting the volume of water lost and releasing hormones, regulating plasma concentrations of ions, helping to stabilize blood pH, and conserving nutrients.
- 2. The urinary system includes the **kidneys**, the **ureters**, the **urinary bladder**, and the **urethra**. The kidneys produce **urine**, a fluid containing water, ions, and soluble compounds. During **urination** (**micturition**), urine is forced out of the body. (*Figure 18-1*)

18-2 The kidneys are highly vascular organs containing functional units called nephrons, which perform filtration, reabsorption, and secretion *p. 636*

- **3.** The left **kidney** is slightly more superior than the right kidney. Both kidneys lie in a *retroperitoneal* position. (*Figure 18-2*)
- **4.** A fibrous capsule surrounds each kidney. The **hilum** provides entry for the *renal artery* and *renal nerve*, and exit for the *renal vein* and *ureter*.
- 5. The ureter is continuous with the **renal pelvis**. This chamber branches into two **major calyces**, each connected to four or five **minor calyces**, which enclose the **renal papillae**. Urine production begins in **nephrons**. (*Figure 18-3*)
- 6. The blood vessels of the kidneys include the **segmental**, **interlobar**, **arcuate**, and **cortical radiate arteries** and the **interlobar**, **arcuate**, and **cortical radiate veins**. Blood travels from the **afferent** and **efferent arterioles** to the **peritubular capillaries** and the **vasa recta**. Diffusion occurs between the peritubular capillaries and the vasa recta and the tubule cells of the nephron through the interstitial fluid, or *peritubular fluid*, surrounding the nephron. (*Figure 18-4*)
- 7. The **nephron** is the basic functional unit in the kidney. It consists of the *renal corpuscle* and a **renal tubule**, which empties into the **collecting system** through a *collecting duct*. From the renal corpuscle, filtrate travels through the *proximal convoluted tubule*, the *nephron loop*, and the *distal convoluted tubule*. (*Figures 18-3c*, *18-5*)

- 8. Nephrons are responsible for (1) the production of filtrate, (2) the reabsorption of nutrients, and (3) the reabsorption of water and ions.
- **9.** The **renal corpuscle** consists of a knot of intertwined capillaries, called the **glomerulus**, surrounded by the **glomerular capsule** (Bowman's capsule). Blood arrives from the *afferent arteriole* and departs in the *efferent arteriole*. (*Figure 18-6*)
- 10. At the glomerulus, **podocytes** cover the basement membrane of the capillaries that project into the **capsular space**. The foot processes of the **podocytes** are separated by narrow *filtration slits*. (*Figure 18-6*)
- **11.** The **proximal convoluted tubule (PCT)** actively reabsorbs nutrients, plasma proteins, and ions from the filtrate. These substances are then released into the surrounding peritubular fluid. *(Figure 18-5)*
- **12.** The **nephron loop**, or *loop of Henle*, includes a *descending limb* and an *ascending limb*. The descending limb is permeable to water, so water is reabsorbed. The ascending limb is impermeable to water and solutes but pumps out sodium and chloride ions. (*Figure 18-5*)
- 13. The ascending limb delivers tubular fluid to the distal convoluted tubule (DCT). The DCT actively secretes ions, toxins, and drugs and reabsorbs sodium ions from the urine. The juxtaglomerular complex, which releases renin and erythropoietin, is located at the start of the DCT. (*Figure 18-6a*)
- 14. The nephron empties tubular fluid into the collecting system, consisting of collecting ducts and papillary ducts. The collecting system makes final adjustments to the urine by reabsorbing water or reabsorbing or secreting various ions.

18-3 Different portions of the nephron form urine by filtration, reabsorption, and secretion *p. 643*

- **15.** The primary purpose in **urine** production is the excretion and elimination of dissolved solutes, principally metabolic waste products such as **urea**, **creatinine**, and **uric acid**.
- **16.** Nephron processes involve **filtration**, **reabsorption**, and **secretion**. (*Figure 18-7; Table 18-1, 18-2*)
- **17.** Glomerular filtration occurs as blood pressure moves fluids across the wall of the glomerular capillaries into the capsular space. The **glomerular filtration rate (GFR)** is the amount of filtrate produced in the kidneys each minute. Any factor that alters the **filtration** (blood) **pressure** will change the GFR and affect kidney function.

- **18.** Declining filtration pressures stimulate the juxtaglomerular complex to release *renin*. The release of renin results in increases in blood volume and blood pressure.
- **19.** The cells of the PCT normally reabsorb 60–70 percent of the volume of the filtrate produced in the renal corpuscle. The PCT reabsorbs nutrients, sodium and other ions, and water from the filtrate and transports them into the peritubular fluid. It also secretes various substances into the tubular fluid.
- **20.** Water and ions are reclaimed from the tubular fluid by the nephron loop. The descending limb reabsorbs water. The thin ascending limb is permeable to urea, and the thick ascending limb pumps out sodium and chloride ions. A concentration gradient in the renal medulla encourages the osmotic flow of water out of the tubular fluid and into the peritubular fluid. As water is lost by osmosis and the volume of tubular fluid decreases, the urea concentration rises.
- **21.** The DCT performs final adjustments by actively secreting or absorbing materials. Sodium ions are actively absorbed in exchange for potassium and hydrogen ions secreted into the tubular fluid. **Aldosterone** increases the rate of sodium reabsorption and potassium secretion.
- **22.** The amount of water in the urine in the collecting ducts is regulated by *antidiuretic hormone (ADH)*. In the absence of ADH, the DCT, collecting tubule, and collecting duct are impermeable to water. The higher the ADH level in circulation, the more water is reabsorbed and the more concentrated the urine. (*Figure 18-8*)
- **23.** More than 99 percent of the filtrate produced each day is reabsorbed before reaching the renal pelvis. Still, normal urine is 93–97 percent water. (*Table 18-3*)
- **24.** Each segment of the nephron and collecting system contributes to the production of urine. *(Spotlight Figure 18-9)*

18-4 Normal kidney function depends on a stable GFR *p. 650*

- **25.** Renal function may be regulated by local, automatic adjustments in glomerular filtration pressures through changes in the diameters of afferent and efferent arterioles.
- **26.** Hormones that regulate kidney function include angiotensin II, aldosterone, ADH, and atrial natriuretic peptide (ANP). (*Figure 18-10*)
- **27.** Sympathetic activation produces powerful vasoconstriction of afferent arterioles, decreasing the GFR and slowing filtrate production. Sympathetic activation also alters the GFR by changing the regional blood circulation pattern.

18-5 Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra, aided by urinary reflexes *p. 653*

28. Filtrate modification and urine production end when the fluid enters the renal pelvis. The rest of the urinary system is responsible for transporting, storing, and eliminating the urine.

- **29.** The **ureters** extend from the renal pelvis to the urinary bladder. Peristaltic contractions by smooth muscles in the walls of the ureters move the urine. (*Figures 18-1, 18-11*)
- **30.** Internal features of the **urinary bladder**, a distensible sac for urine storage, include the *trigone*, the neck, and the **internal urethral sphincter**. Contraction of the *detrusor muscle* compresses the bladder and expels the urine into the urethra. (*Figure 18-11*)
- **31.** In both sexes, as the urethra passes through the muscular pelvic floor, a circular band of skeletal muscles forms the **external urethral sphincter**, which is under voluntary control. (*Figure 18-11*)
- **32.** The process of **urination** is coordinated by the **urine storage reflex** and the **urine voiding reflex**, which are initiated by stretch receptors in the wall of the urinary bladder. Control of urination involves coupling these reflexes with the voluntary relaxation of the external urethral sphincter. (*Figure 18-12*)

18-6 Fluid balance, electrolyte balance, and acid-base balance are interrelated and essential to homeostasis *p. 656*

- **33.** The maintenance of normal volume and composition in the extracellular and intracellular fluids is vital to life. Three types of homeostasis are involved: *fluid balance, electrolyte balance,* and *acid-base balance.*
- **34.** The **intracellular fluid (ICF)** contains about 60 percent of the total body water; the **extracellular fluid (ECF)** contains the rest. Exchange occurs between the ICF and ECF, but the two **fluid compartments** retain their distinctive characteristics. *(Figures 18-13, 18-14)*
- **35.** Water circulates freely within the ECF compartment.
- **36.** Water losses are normally balanced by gains through eating, drinking, and metabolic generation. *(Table 18-4)*

18-7 Blood pressure and osmosis are involved in maintaining fluid and electrolyte balance *p. 658*

- **37.** Water movement between the ECF and ICF is called a **fluid shift**. If the ECF becomes hypertonic relative to the ICF, water will move from the ICF into the ECF until osmotic equilibrium has been restored. If the ECF becomes hypotonic relative to the ICF, water will move from the ECF into the cells, and the volume of the ICF will increase.
- **38.** Electrolyte balance is important because total electrolyte concentrations affect water balance, and because the levels of individual electrolytes can affect a variety of cell functions. Problems with electrolyte balance generally result from an imbalance between sodium gains and losses. Problems with potassium balance are less common but more dangerous.
- **39.** The rate of sodium uptake across the digestive epithelium is directly related to the amount of sodium in the diet. Sodium losses occur mainly in the urine and through perspiration. Aldosterone stimulates sodium ion reabsorption along the DCT.

40. Potassium ion concentrations in the ECF are very low. Potassium excretion increases (1) when sodium ion concentrations decline and (2) as ECF potassium concentrations rise. Aldosterone stimulates potassium ion excretion.

18-8 In acid-base balance, regulation of hydrogen ions in body fluids involves buffer systems and compensation by respiratory and renal processes *ρ. 660*

- **41.** The pH of normal body fluids ranges from 7.35 to 7.45; variations outside this range produce **acidosis** or **alkalosis**.
- **42.** Carbonic acid is the most important substance affecting the pH of the ECF. In solution, CO_2 reacts with water to form carbonic acid. The dissociation of carbonic acid releases hydrogen ions and bicarbonate ions. An inverse relationship exists between the partial pressure of carbon dioxide (P_{co_2}) and pH. (*Figure 18-15*)
- **43.** Metabolic acids include products of metabolism such as lactic acid and ketone bodies.
- **44.** A buffer system consists of a weak acid and its anion dissociation product, which acts as a weak base. The three major buffer systems are *protein buffer systems* in the ECF and ICF; the *carbonic acid–bicarbonate buffer system*, most important in the ECF; and the *phosphate buffer system* in the intracellular fluids.
- **45.** In **protein buffer systems**, amino acid side groups of proteins and the side group and structural groups of free amino acids respond to changes in pH by accepting or releasing hydrogen ions. Blood plasma proteins and hemoglobin in red blood cells help prevent drastic changes in pH.
- **46.** The **carbonic acid-bicarbonate buffer system** prevents pH changes due to metabolic acids in the ECF.

- **47.** The **phosphate buffer system** is important in preventing pH changes in the ICF.
- **48.** In **respiratory compensation**, the lungs help regulate pH by affecting the carbonic acid-bicarbonate buffer system; changing the respiratory rate can raise or lower the P_{co_2} of body fluids, affecting the buffering capacity.
- **49.** In **renal compensation**, the kidneys vary their rates of hydrogen ion secretion and bicarbonate ion reabsorption depending on the pH of extracellular fluids.
- **50.** Respiratory acid-base disorders result when abnormal respiratory function causes an extreme rise or a fall in CO_2 levels. Metabolic acid-base disorders are caused by the formation of metabolic acids or conditions affecting the levels of bicarbonate ions. (*Table 18-5*)

18-9 Age-related changes affect kidney function and the micturition reflex *p. 664*

51. Aging is usually associated with increased kidney problems. Age-related changes in the urinary system include (1) loss of functional nephrons, (2) reduced GFR, (3) reduced sensitivity to ADH and aldosterone, (4) problems with urination (urinary retention may develop in men whose prostate gland is inflamed), (5) declining body water content, (6) a loss of mineral content, and (7) disorders affecting either fluid, electrolyte, or acid-base balance.

18-10 The urinary system is one of several body systems involved in waste excretion *p. 665*

52. The urinary system is the major component of the *excretory system* that also includes the integumentary, respiratory, and digestive systems.

See the blue Answers tab at the back of the book.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A

- _____ **1.** urination
- **2.** fibrous capsule
- _____ **3.** hilum
 - **4.** renal medulla
- **5.** nephron
 - **6.** renal corpuscle
 - ____ **7.** external urethral sphincter
 - **8.** internal urethral _____ sphincter

- 9. aldosterone
- ____ 10. podocytes
 - **11.** efferent arteriole
 - **12.** afferent arteriole
 - **13.** vasa recta
 - **14.** ADH
- _____ **15.** ECF
- _____ **16.** sodium
 - ___ 17. potassium

COLUMN B

a. micturition

- **b.** basic functional unit of the kidney
- **c.** capillaries around nephron loop
- **d.** causes sensation of thirst
- **e.** stimulates sodium reabsorption
- **f.** voluntary control
- g. filtration slits
- h. covers kidney

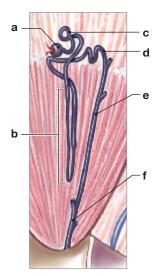

- i. blood leaves the glomerulus
- j. dominant cation in ICF

18

- **k.** contains the renal pyramids
- 1. blood enters the glomerulus
 - **m.** interstitial fluid and plasma
 - **n.** contains glomerulus
- **o.** exit point for ureter
- **p.** dominant cation in ECF
- **q.** involuntary control

670 URINARY SYSTEM

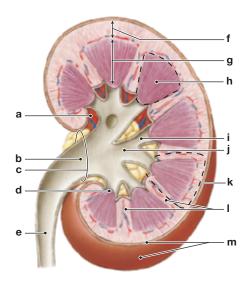

18. Identify the different regions of a nephron and the structure into which it empties in the following diagram.

(a)	 (b)	
(c)	 (d)	
(e)	 (f)	

- **19.** The kidneys are partly protected by the
 - (a) 7^{th} and 8^{th} ribs.
 - (b) 9^{th} and 10^{th} ribs.
 - (c) 11^{th} and 12^{th} ribs.
 - (d) a, b, and c are correct.
- **20.** Branching of the cortical radiate arteries gives rise to the
 - (a) afferent arterioles.
 - (b) arcuate arteries.
 - (c) interlobar arteries.
 - (d) renal arteries.
- **21.** In a healthy adult, the average glomerular filtration rate is expected to be
 - (a) below 1 mL per minute.
 - (b) between 40 and 60 mL per minute.
 - (c) 125 mL per minute.
 - (d) at least 1 L per minute.
- 22. Reabsorption of organic nutrients takes place in the
 - (a) collecting duct.
 - (b) distal convoluted tubule.
 - (c) loop of Henle.
 - (d) proximal convoluted tubule.

23. Identify the structures of the kidney in the following diagram.

(a)	(b)
(c)	(d)
(e)	(f)
(g)	(h)
(i)	(j)
(k)	(l)

- 24. The most abundant nitrogenous waste in urine is
 - (a) ammonia.
 - (b) creatinine.
 - (c) urea.

(**m**)

- (d) uric acid.
- **25.** The juxtaglomerular complex helps in regulating kidney function through the secretion of
 - (a) aldosterone.
 - (b) angiotensinogen.
 - (c) antidiuretic hormone.
 - (**d**) renin.
- 26. The urinary bladder is lined by the
 - (a) columnar epithelium.
 - (b) cuboidal epithelium.
 - (c) stratified squamous epithelium.
 - (d) transitional epithelium.

- **27.** In comparison to interstitial fluid, intracellular fluid contains a higher concentration of
 - (a) calcium ions.
 - **(b)** chloride ions.
 - (c) potassium ions.
 - (d) sodium ions.
- 28. What is the primary function of the urinary system?
- 29. What are the structural components of the urinary system?
- **30.** What are fluid shifts? What is their function, and what factors can cause them?
- **31.** How does the release of renin by the juxtaglomerular complex affect the secretion of angiotensin II, aldosterone, and ADH?

Level 2 Reviewing Concepts

- **32.** The urinary system regulates blood volume and pressure by
 - (a) adjusting the volume of water lost in the urine.
 - **(b)** releasing erythropoietin.
 - (c) releasing renin.
 - (d) a, b, and c are correct.
- **33.** The balance of solute and water reabsorption in the renal medulla is maintained by the
 - (a) segmental arterioles and veins.
 - (**b**) interlobar arteries and veins.
 - (c) vasa recta.
 - (d) arcuate arteries.
- **34.** An increase in the levels of ADH will stimulate the kidneys to
 - (a) reabsorb sodium ions.
 - (b) reabsorb water.
 - (c) excrete potassium ions.
 - (d) a, b, and c are correct.
- 35. When pure (distilled) water is consumed,
 - (a) the ECF becomes hypertonic with respect to the ICF.
 - (b) the ECF becomes hypotonic with respect to the ICF.
 - (c) the ICF becomes hypotonic with respect to the plasma.
 - (d) water moves from the ICF into the ECF.
- 36. Increasing or decreasing the rate of respiration alters pH by
 - (a) lowering or raising the partial pressure of carbon dioxide.
 - (b) lowering or raising the partial pressure of oxygen.
 - (c) lowering or raising the partial pressure of nitrogen.
 - (d) a, b, and c are correct.

An Introduction to the Reproductive System

One person's life span lasts but decades, yet the human species has perpetuated itself for hundreds of thousands of years through the activities of the reproductive system. The entire process of reproduction seems almost magical. Many aboriginal societies did not discover even the basic link between sexual activity and childbirth. They assumed that supernatural forces were responsible for producing new individuals. Our society has a much clearer understanding of the reproductive process, but the events of procreation—the fusion of two reproductive cells, one produced by a man, the other by a woman, which leads to the birth of an infant—still produces a sense of wonder. In this chapter and the next, we will consider this remarkable process.

Build Your Knowledge

Recall that both the male and female reproductive systems produce sex cells and hormones (as you saw in **Chapter 1: An Introduction to Anatomy and Physiology** and **Chapter 3: Cell Structure and Function**). The male produces sperm, and the female produces oocytes—immature ova, or egg cells. The female reproductive system also supports embryonic and fetal development from fertilization to birth. **Dpp. 39, 111**

19-1 Basic reproductive system structures are gonads, ducts, accessory glands and organs, and external genitalia

Learning Outcome List the basic structures of the human reproductive system, and summarize the functions of each.

The **reproductive system** ensures the continued existence of the human species. It does so by producing, storing, nourishing, and transporting functional male and female reproductive cells, or **gametes** (GAM-ēts).

The reproductive system includes

- **Gonads** (GŌ-nadz; *gone*, seed), or reproductive organs that produce gametes and hormones.
- Ducts that receive and transport the gametes.
- Accessory glands and organs that secrete fluids into the ducts of the reproductive system or other excretory ducts.
- Perineal structures that are collectively known as the **external genitalia** (jen-i-TĀ-lē-uh).

In both males and females, the ducts are connected to chambers and passageways that open to the exterior of the body. The structures involved make up the *reproductive tract*. The male and female reproductive systems are functionally quite different, however.

In adult males, the **testes** (TES-tēz; singular, *testis*), or *testicles*, are male gonads that secrete sex hormones called *androgens* (principally *testosterone*). The testes also produce the male gametes, called **sperm**. Males produce about one-half billion sperm each day. During *emission*, mature sperm travel along a lengthy duct system, where they are mixed with the secretions of accessory glands. The mixture that is created is known as **semen** (SĒ-men). During *ejaculation*, semen is expelled from the body.

In adult females, the **ovaries**, or female gonads, release an immature gamete, an **oocyte**. Normally, one oocyte is released per month. This oocyte travels along one of two short *uterine tubes*, which end in the muscular organ called the *uterus* (\overline{U} -ter-us). If a sperm reaches the oocyte and starts the process of *fertilization*, the oocyte matures into an **ovum** (plural, *ova*). A short passageway, the *vagina* (va-JĪ-nuh), connects the uterus with the exterior.

During *sexual intercourse*, ejaculation introduces semen into the vagina. The sperm then ascend the female reproductive tract. If fertilization occurs, the uterus will enclose and support a developing *embryo* as it grows into a *fetus* and prepares for birth.

Next we examine further the anatomy of the male and female reproductive systems. We also consider the physiological and hormonal processes that regulate male and female reproductive function.

CHECKPOINT

- **1.** Define gamete.
- 2. List the basic structures of the reproductive system.
- 3. Define gonads.
- See the blue Answers tab at the back of the book.

19-2 Sperm formation (spermatogenesis) occurs in the testes, and hormones from the hypothalamus, pituitary gland, and testes control male reproductive functions

Learning Outcome Describe the structures of the male reproductive system and the roles played by the reproductive tract and accessory glands in producing sperm; describe the composition of semen; and summarize the hormonal processes that regulate male reproductive function.

The main structures of the male reproductive system are shown in **Figure 19-1**. Starting from a testis, the sperm travel within the *epididymis* (ep-i-DID-i-mis), the *ductus deferens* (DUK-tus DEF-e-renz), the *ejaculatory* (ē-JAK-ū-la-tō-rē) *duct*, and the *urethra* before leaving the body. This duct system forms the male reproductive tract. Accessory glands secrete their products into the ejaculatory ducts and urethra. These glands include the *seminal* (SEM-i-nal) *glands* (seminal vesicles), the *prostate* (PROS-tāt), and the *bulbo-urethral* (bul-bō-ū-RĒ-thral) *glands*. The external genitalia include the *scrotum* (SKRŌ-tum), which encloses the testes, and the *penis* (PĒ-nis), an erectile organ. The distal portion of the urethra passes through the penis.

The Testes

Each testis has the shape of a flattened egg roughly 5 cm (2 in.) long, 3 cm (1.2 in.) wide, and 2.5 cm (1 in.) thick. Each weighs 10–15 g (0.35–0.53 oz). The testes hang within the **scrotum**, a fleshy pouch anterior to the anus and posterior to the penis.

The scrotum is subdivided into two chambers, or *scrotal cavities*. Each cavity contains a testis. A serous membrane lines the scrotal cavity, reducing friction between the inner surface of the scrotum and the outer surface of the testis.

The scrotum consists of a thin layer of skin. Its dermis contains a layer of smooth muscle, the **dartos** (DAR-tōs) **muscle** (**Figure 19-2a**). Resting tension in the dartos muscle elevates the testes and causes wrinkling of the scrotal surface. A layer of skeletal muscle, the **cremaster** (krē-MAS-ter) **muscle**, lies beneath the dermis. It can contract to pull the testes closer to the body.

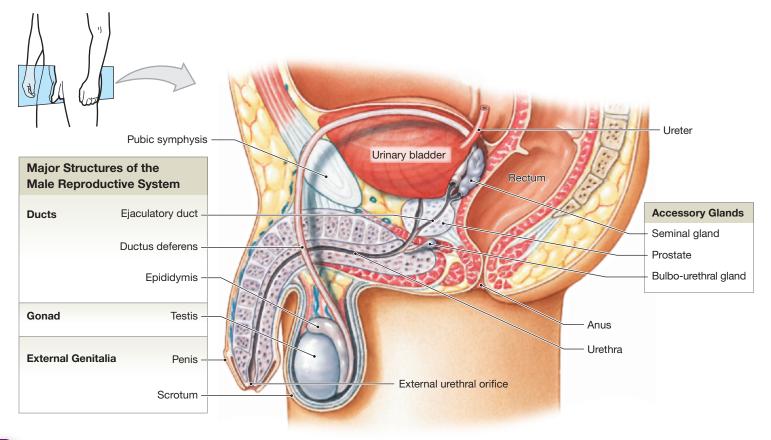

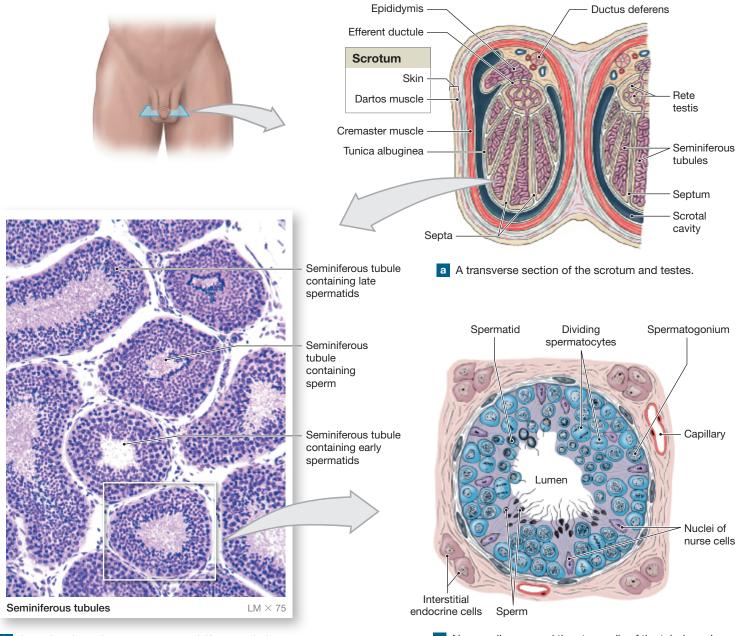

Figure 19-2 The Scrotum, Testes, and Seminiferous Tubules.

b A section through one or more seminiferous tubules.

c Nurse cells surround the stem cells of the tubule and support the developing spermatocytes and spermatids.

Normal sperm development in the testes requires temperatures about 1.1°C (2°F) lower than elsewhere in the body. The cremaster and dartos relax or contract to move the testes away from or toward the body as needed to maintain acceptable testicular temperatures. When air or body temperatures rise, these muscles relax and the testes move away from the body. When the scrotum cools suddenly, as happens during a jump into a cold swimming pool, these muscles contract to pull the testes closer to the body and keep testicular temperatures from falling.

Each testis is wrapped in a tough fibrous capsule, the tunica albuginea (TŪ-ni-ka al-bū-JIN-ē-uh). Collagen fibers from this wrapping extend into the testis, forming partitions, or septa, that subdivide the testis into roughly 250 *lobules*. Distributed among the lobules are approximately 800 slender, tightly coiled seminiferous (sem-i-NIF-er-us) tubules (Figure 19-2b). Each tubule averages about 80 cm (32 in.) in length. A typical testis contains nearly half a mile of seminiferous tubules. Sperm produced within the seminiferous tubules (by a process discussed shortly) leave the 19

CLINICAL NOTE

Cryptorchidism

During normal development of a male fetus, the testes descend from inside the body cavity and pass through the inguinal canal of the abdominal wall into the scrotum. In **cryptorchidism** (krip-TOR-ki-dizm; *crypto*, hidden 1 *orchis*, testis), one or both of the testes have not completed this process (*descent of the testes*) by the time of birth. This condition occurs in about 3 percent of full-term deliveries and about 30 percent of premature births. In most instances, normal descent occurs a few weeks later.

The condition can be surgically corrected if it persists. Corrective measures should be taken before *puberty* (sexual maturation) because a cryptorchid (abdominal) testis will not produce sperm. If both testes are cryptorchid, the male will be *sterile* (*infertile*) and unable to father children. If the testes cannot be moved into the scrotum, they are usually removed. This surgical procedure is called a *bilateral orchiectomy* (or-kē-EK-to-mē; *ectomy*, excision). About 10 percent of males with uncorrected cryptorchid testes eventually develop testicular cancer.

tubules and pass through a maze of passageways known as the **rete** ($R\bar{E}$ -tē; *rete*, a net) **testis**. They then enter fifteen to 20 large *efferent ductules* before entering the epididymis. The epididymis is the first portion of the male reproductive tract (**Figure 19-2a**).

Most tissue slides show seminiferous tubules in cross section, because the seminiferous tubules are tightly coiled (Figure 19-2b). The spaces between the tubules are filled with areolar tissue, numerous blood vessels, and large **interstitial endocrine cells** (*Leydig cells*) (Figure 19-2c). These cells produce male sex hormones, or *androgens*. The steroid **testosterone** is the most important androgen. \supset p. 384

Each seminiferous tubule contains developing sperm cells and **nurse cells**. Nurse cells are also known as *sustenocytes*, or *Sertoli cells*. They extend from the perimeter of the tubule to the central lumen (**Figure 19-2c**). Nurse cells nourish the developing sperm cells. Between and adjacent to the nurse cells are the various cells involved in sperm formation, or **spermatogenesis** (sper-ma-tō-JEN-e-sis). In this process, a series of cell divisions ultimately produces sperm cells. With each successive division, the daughter cells move closer to the lumen.

Spermatogenesis

Spermatogenesis begins at puberty (sexual maturation) and continues until relatively late in life (after age 70). Spermatogenesis involves three processes:

Build Your Knowledge

Recall that cell division is essential to growth, development, and the continual replacement of old and damaged cells (as you saw in Chapter 3: Cell Structure and Function). Also recall that the life cycle of a cell includes interphase, mitosis, and cytokinesis. Interphase is the time when a cell performs its normal functions between cell divisions. Also during this phase, the cell's chromosomes are duplicated in preparation for cell division. Mitosis refers to the division of a cell's nucleus. In this process, the duplicated chromosomes of the original cell are separated and enclosed in two identical nuclei. Mitosis includes four stages: prophase, metaphase, anaphase, and telophase. Mitosis ensures that each newly formed nucleus contains the same number and kind of chromosomes as the original cell. Cytokinesis follows mitosis. In this process, the cytoplasm of the original cell is divided, forming two identical daughter cells. **p. 111**

- Mitosis. Spermatogenesis begins with the mitotic divisions of stem cells called spermatogonia (sperma-tō-GŌ-nē-uh; singular, spermatogonium). They are located in the outermost layer of cells in the seminiferous tubules (Figure 19-2c). (See Chapter 3 for a review of mitosis and cell division.) ⊃ p. 113 Spermatogonia undergo mitosis throughout adult life. One daughter cell from each division remains in place while the other is pushed toward the lumen of the seminiferous tubule. The displaced cells differentiate into spermatocytes (sper-MA-tō-sīts), which prepare to begin meiosis.
- Meiosis. Meiosis (mī-Ō-sis; meioun, to make smaller) is a special form of cell division involved in gamete production. In humans, gametes contain 23 chromosomes, half the number in *somatic* (nonreproductive) cells. In the seminiferous tubules, the meiotic divisions of spermatocytes produce immature gametes called *spermatids* (Figure 19-2c).
- **3.** *Spermiogenesis.* In *spermiogenesis,* the small, relatively unspecialized spermatids develop into physically mature sperm, which enter the fluid within the lumen of the seminiferous tubule.

Next we consider these three processes in more detail.

19

MITOSIS AND MEIOSIS. Mitosis and meiosis differ significantly in terms of the events taking place in the nucleus. Mitosis is part of the process of somatic cell division, producing two daughter cells, each with the same number and pairs of chromosomes as the original cell. In humans, each somatic cell contains 23 pairs of chromosomes, or 46 chromosomes. Each pair consists of one paternal chromosome (provided by the father) and one maternal chromosome (provided by the mother) at the time of fertilization. Because daughter cells contain both members of each chromosome pair, they are called **diploid** (DIP-loyd; *diplo*, double).

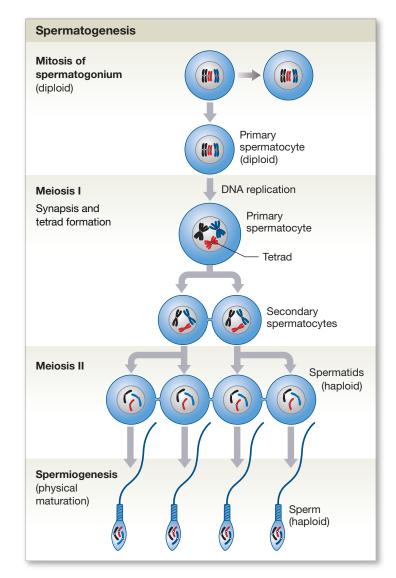

In contrast, meiosis involves two cycles of cell division (meiosis I and meiosis II). We identify the stages within each cycle with I or II, for example, as prophase I, metaphase II, and so on. This process produces four cells, or gametes, each containing 23 individual chromosomes. These cells contain only one member of each chromosome pair and are called haploid (HAP-loyd; haplo, single). The fusion of the nuclei of a male haploid gamete and female haploid gamete produces a cell with the normal diploid number of chromosomes (46).

Figure 19-3 illustrates the role of meiosis in spermatogenesis. Each mitotic division of spermatogonia produces two primary spermatocytes. The primary spermatocytes are diploid cells, but they divide by meiosis rather than mitosis. As a primary spermatocyte prepares to begin meiosis, DNA replication occurs within the nucleus, just as it does in a cell preparing to undergo mitosis. As prophase of the first meiotic division (meiosis I) occurs, the chromosomes condense and become visible. As in mitosis, each chromosome consists of two duplicate chromatids (KRO-ma-tidz).

At this point, the close similarities between meiosis and mitosis end. As prophase I unfolds, similar maternal and paternal chromosomes pair up. This key pairing event is known as synapsis (si-NAP-sis). It produces 23 pairs of chromosomes, with each member of the pair consisting of two identical chromatids. A matched set of four chromatids is called a tetrad (TET-rad; tetras, four). At this time, an exchange of genetic material can take place between the maternal and paternal chromatids of a chromosome pair. This exchange, called crossing-over, increases genetic variation among offspring. Prophase I ends with the disappearance of the nuclear envelope.

During metaphase I, the tetrads line up along the metaphase plate. As anaphase I begins, the maternal and paternal chromosomes separate and the tetrads break up. This is a major difference between mitosis and meiosis: In mitosis, each daughter cell receives a copy of every chromosome, maternal and paternal. In meiosis I, however, each daughter cell receives two copies of either the maternal chromosome or the paternal chromosome.

Figure 19-3 Spermatogenesis. The events depicted occur within the seminiferous tubules. The fates of three pairs of representative chromosomes are shown. Each diploid primary spermatocyte that undergoes meiosis produces four haploid spermatids. Each spermatid then develops into a sperm.

As anaphase I proceeds, the maternal and paternal chromosomes that had formed a tetrad are randomly distributed. For example, most of the maternal chromosomes may go to one daughter cell, and most of the paternal chromosomes to the other. As a result, telophase I ends with the formation of two daughter cells, each containing a unique combination of maternal and paternal chromosomes. In the testes, the daughter cells produced by meiosis I are called secondary spermatocytes.

Every secondary spermatocyte contains 23 chromosomes, each consisting of two duplicate chromatids. The duplicate chromatids will separate during meiosis II. The interphase 19 separating meiosis I and meiosis II is very brief. No DNA is replicated during this period. The secondary spermatocyte then enters meiosis II. The completion of meiosis II produces four immature gametes, or **spermatids** (SPER-ma-tidz). They are identical in size and each has 23 chromosomes. In summary, for every diploid primary spermatocyte that enters meiosis, four haploid spermatids are produced (**Figure 19-3**).

SPERMIOGENESIS. In **spermiogenesis**, each spermatid matures into a sperm. The entire process of spermatogenesis, from the division of a diploid spermatogonium to the release of a physically mature haploid sperm, takes approximately 64 days.

Nurse cells play a key role in spermatogenesis and spermiogenesis. Spermatocytes undergoing meiosis and spermatids are not free in the seminiferous tubules. Instead, they are surrounded by the cytoplasm of nurse cells. Because there are no blood vessels inside the seminiferous tubules, all nutrients must diffuse in from the surrounding interstitial fluids. The large nurse cells control the chemical environment inside the seminiferous tubules. They provide nutrients and chemical stimuli that promote the production and differentiation of sperm. They also help regulate spermatogenesis by producing *inhibin* (a hormone introduced in Chapter 10). \bigcirc p. 398

Anatomy of a Sperm

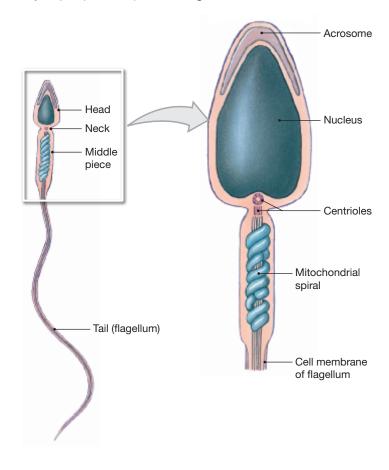

A mature sperm has four distinct regions: head, neck, middle piece, and tail (**Figure 19-4**). The **head** contains a nucleus filled with densely packed chromosomes. At the tip of the head is the **acrosome** (ak-rō-SŌM), a cap-like compartment containing enzymes essential for fertilization. A short **neck** attaches the head to the **middle piece**. The neck contains both centrioles of the original spermatid. Mitochondria in the middle piece are arranged in a spiral. Mitochondria provide the ATP for moving the tail. The **tail** is the only example of a *flagellum* in the human body. Its corkscrew motion moves the sperm. \supset p. 101

Unlike other, less specialized cells, a mature sperm does not have an endoplasmic reticulum, a Golgi apparatus, lysosomes, peroxisomes, and many other intracellular structures. Because a sperm contains no glycogen or other energy reserves, it must absorb nutrients (primarily fructose) from the surrounding fluid.

The Male Reproductive Tract

The testes produce physically mature sperm that are not yet capable of fertilizing an oocyte. The other portions of the male

Figure 19-4 The Structure of a Sperm. A sperm measures only 60 μ m (0.06 mm) in total length.

reproductive system are responsible for the functional maturation, nourishment, storage, and transport of sperm.

The Epididymis

Late in their development, sperm detach from nurse cells and lie within the lumen of the seminiferous tubule. They have most of the physical characteristics of mature sperm cells, yet they are still functionally immature. They are incapable of coordinated locomotion or fertilization. Fluid currents, created by cilia lining the efferent ducts, transport them into the **epididymis** (plural, *epididymides*) (**Figure 19-1**). The epididymis is the start of the male reproductive tract. It is a coiled tube bound to the posterior of each testis. The epididymides (ep-i-DID-i-mi-dēz) can be felt through the skin of the scrotum. Each epididymis is almost 7 meters (23 ft) long, but it is twisted and coiled so as to take up very little space.

The functions of the epididymis include (1) adjusting the composition of the fluid produced by the seminiferous tubules, (2) acting as a recycling center for damaged sperm, and (3) storing and protecting the maturing sperm. Cells lining the epididymis absorb and break down cellular debris from damaged or abnormal sperm. The resulting products are released into interstitial fluid for pickup by surrounding blood vessels. It takes up to two weeks for a sperm to pass through the epididymis and complete its physical maturation. It then enters the ductus deferens.

Sperm leaving the epididymis are physically mature, but they remain immotile (unable to move). To become motile (actively swimming) and fully functional, they must undergo **capacitation**. Capacitation occurs after sperm (1) mix with secretions of the seminal glands and (2) are exposed to conditions inside the female reproductive tract. The epididymis secretes a substance that prevents premature capacitation.

The Ductus Deferens

Each **ductus deferens**, or *vas deferens*, is 40–45 cm (16–18 in.) long (**Figure 19-1**). It ascends into the abdominal cavity within the *spermatic cord*, a sheath of connective tissue and muscle that also encloses the blood vessels, nerves, and lymphatics serving the testis. (The passageway through the abdominal musculature is called the *inguinal canal*.)

Inside the abdominal cavity, each ductus deferens passes lateral to the urinary bladder and curves downward past the ureter on its way toward the prostate (**Figure 19-5a**). The expanded distal portion of the ductus deferens is called the *ampulla* (am-PUL-uh). Peristaltic contractions in the muscular walls of each ductus deferens propel sperm and fluid along the length of the duct. The ductus deferens also stores sperm in the ampulla for up to several months. During this period, sperm are inactive and have low metabolic rates.

The ampulla of each ductus deferens joins with the duct of the seminal gland to form the *ejaculatory duct,* a relatively short (2 cm, or less than 1 in.) passageway (**Figure 19-5a**). This duct penetrates the muscular wall of the prostate and empties into the urethra near the opening of the ejaculatory duct from the other side.

The Urethra

In males, the urethra extends 18–20 cm (7–8 in.) from the urinary bladder to the tip of the penis (**Figure 19-1**). The male urethra is a passageway for both the urinary and reproductive systems.

The Accessory Glands

The fluids secreted by the seminiferous tubules and the epididymis account for only about 5 percent of the volume of *semen*. The fluid component of semen is a mixture of secretions from the *seminal glands*, the *prostate*, and the *bulbo-urethral glands* (Figure 19-5a). Primary functions of these glands include (1) activating sperm, (2) providing nutrients sperm need for motility, (3) generating peristaltic

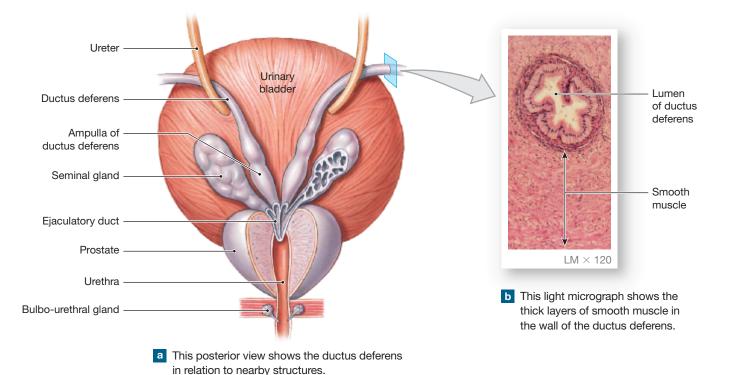

Figure 19-5 The Ductus Deferens.

contractions that propel sperm and fluids along the reproductive tract, and (4) producing buffers to counteract the acidity of the urethral and vaginal environments.

The Seminal Glands (Seminal Vesicles)

Each **seminal gland**, also called a **seminal vesicle**, is a tubular gland about 15 cm (6 in.) long (**Figures 19-1** and **19-5a**). The body of the gland is coiled and folded into a compact, tapered mass roughly 5 cm by 2.5 cm (2 in. by 1 in.).

The seminal glands are extremely active secretory glands. They contribute about 60 percent of the volume of semen. Their secretions contain (1) fructose, a six-carbon sugar easily metabolized by sperm; (2) prostaglandins, which stimulate smooth muscle contractions along the male and female reproductive tracts; and (3) fibrinogen, which after ejaculation forms a temporary semen clot within the vagina. The slight alkalinity of the secretions helps neutralize acids in secretions of the prostate and within the vagina. When mixed with seminal gland secretions, mature but previously inactive sperm undergo the first step of capacitation and begin beating their flagella, becoming highly motile.

The Prostate

The **prostate** is a small, muscular, rounded gland, about 4 cm (1.6 in.) in diameter. It surrounds the urethra as it leaves the urinary bladder (**Figure 19-5a**). The *prostatic fluid* it secretes is slightly acidic and makes up 20–30 percent of the volume of semen. In addition to several other compounds, prostatic fluid contains **seminalplasmin** (sem-i-nal-PLAZ-min), a protein with antibiotic properties that may help prevent urinary tract infections in males. These secretions are ejected into the urethra by peristaltic contractions of the muscular prostate wall.

The Bulbo-urethral Glands

The paired **bulbo-urethral glands**, or *Cowper's glands*, are located at the base of the penis. They are spherical structures almost 10 mm (less than 0.5 in.) in diameter (**Figure 19-5a**). These glands secrete a thick, alkaline mucus that helps neutralize urinary acids that may remain in the urethra and also lubricates the *glans penis*, or tip of the penis.

Semen

Semen (SĒ-men) is the fluid that contains sperm and the secretions of the accessory glands of the male reproductive tract. In a typical *ejaculation* (ē-jak-ū-LĀ-shun), 2–5 mL of semen is expelled from the body. This volume of fluid, called an **ejaculate**, contains three major components:

CLINICAL NOTE

Prostatitis

Prostatic inflammation, or **prostatitis** (pros-ta-TĪ-tis), can occur in males of any age but most often afflicts older men. Prostatitis can result from bacterial infections, but it also occurs in the apparent absence of pathogens. Signs and symptoms can resemble those of prostate cancer. Individuals with prostatitis may complain of pain in the lower back, perineum, or rectum, sometimes accompanied by painful urination and the discharge of mucous secretions from the urethral opening. Antibiotic therapy is effective in treating most cases caused by bacterial infection.

- **Sperm.** A normal **sperm count** ranges from 20 million to 100 million sperm per milliliter of semen.
- Seminal fluid. Seminal fluid is the fluid component of semen. It is a mixture of glandular secretions with a distinct ionic and nutrient composition. Of the total volume of seminal fluid, the seminal glands contribute about 60 percent; the prostate, 30 percent; the nurse cells and epididymis, 5 percent; and the bulbo-urethral glands, less than 5 percent.
- *Enzymes.* Several important enzymes are present in seminal fluid. They include (1) a protease that helps dissolve mucus in the vagina; (2) *seminalplasmin*, a prostatic enzyme that kills a variety of bacteria; (3) a prostatic enzyme that causes the semen to clot within a few minutes after ejaculation; and (4) an enzyme that subsequently liquefies the clotted semen.

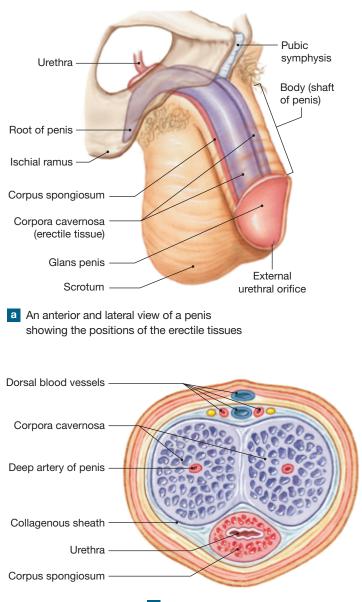

The External Genitalia

The male external genitalia consist of the scrotum (described earlier on p. 674) and penis. The **penis** is a tubular organ containing the distal portion of the urethra (**Figure 19-1**). It conducts urine to the exterior and introduces semen into the female's vagina during sexual intercourse.

The penis has three main regions (**Figure 19-6a**). The **root** is the fixed portion that attaches the penis to the body wall. The **body (shaft)** is the tubular portion that contains masses of erectile tissue. The **glans penis** is the expanded distal portion surrounding the external urethral opening, or *external urethral orifice*.

The skin overlying the penis resembles that of the scrotum. A fold of skin, called the **foreskin** or **prepuce** (PRE-pūs), surrounds the tip of the penis (**Figure 19-6b**). The foreskin attaches to the relatively narrow neck of the penis and continues over the glans penis. *Preputial glands* in the skin of the neck and inner surface of the foreskin secrete a waxy material called *smegma* (SMEG-ma). Unfortunately, smegma can be an

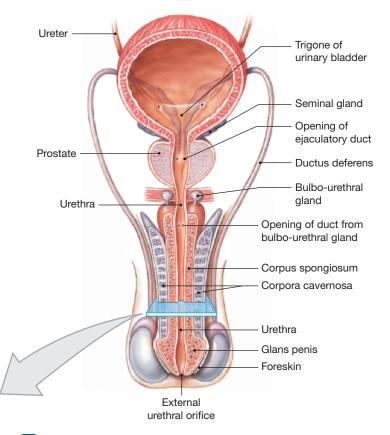

Figure 19-6 The Penis.

c A sectional view through the penis

excellent nutrient source for bacteria. Mild inflammation and infections in this region are common, especially if the area is not washed frequently. One way to avoid such problems is *circumcision* (ser-kum-SIZH-un), the surgical removal of the foreskin. In Western societies (especially the United States), this procedure is generally performed shortly after birth. Circumcision lowers the risks of developing urinary tract infections, HIV infection, and penile cancer. The practice remains controversial because it is a surgical procedure with risk of bleeding, infection, and other complications.

Most of the body, or shaft, of the penis consists of three columns of **erectile tissue** (Figure 19-6c). Erectile tissue consists of a maze of vascular channels incompletely separated by partitions of elastic connective tissue and smooth muscle.

b A frontal section through the penis and associated organs

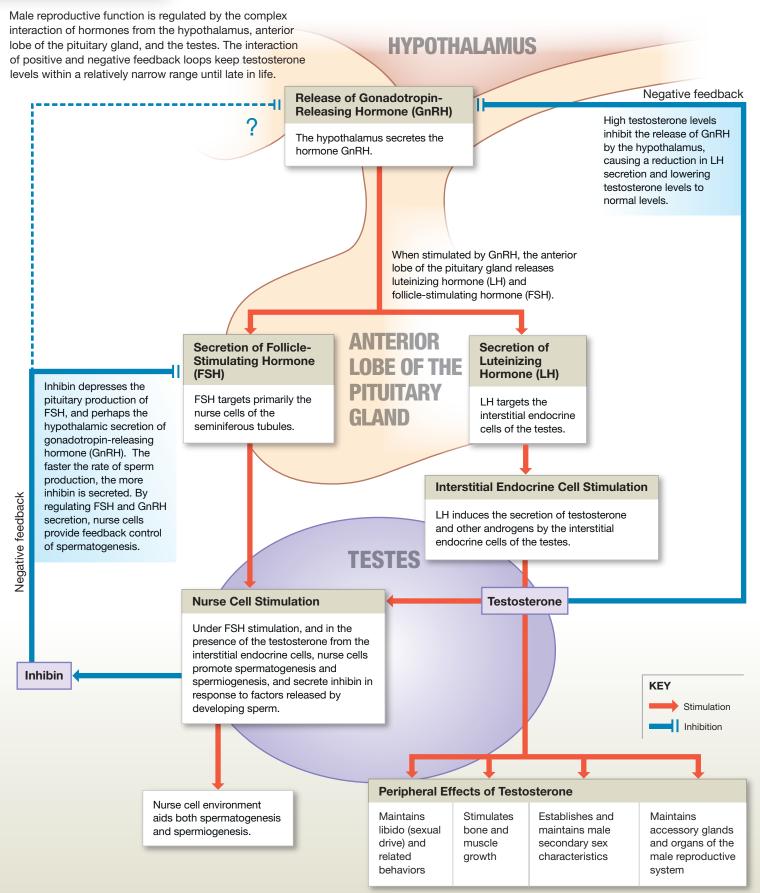

The anterior surface of the flaccid (nonerect) penis covers two cylindrical **corpora cavernosa** (KOR-por-a ka-ver-NŌ-suh). Their bases are bound to the pubis and ischium of the pelvis (**Figure 19-6a**). The corpora cavernosa extend to the glans penis. The relatively slender **corpus spongiosum** (spon-jē-Ōsum) surrounds the urethra and extends all the way to the tip of the penis, where it forms the glans penis.

Little blood flows into the erectile tissue of a flaccid penis. This is because the arterial branches in erectile tissue are constricted and the muscular partitions are tense. During **erection**, the penis stiffens and elevates to an upright position. How does erection occur? The parasympathetic innervation of the penile arteries involves neurons that release nitric oxide (NO) at their axon terminals. In response to NO, the smooth muscles in the arterial walls relax. At that time, the vessels dilate, blood flow increases, and the vascular channels fill with blood.

Hormones and Male Reproductive Function

The hormonal interactions that regulate male reproductive function are diagrammed in **Spotlight Figure 19-7**.

SPOTLIGHT Figure 19-7 REGULATION OF MALE REPRODUCTION

(We introduced the major reproductive hormones in Chapter 10.) \bigcirc p. 397 The anterior lobe of the pituitary gland releases **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**. Their release occurs in response to **gonadotropin-releasing hormone (GnRH)**. This peptide is synthesized in the hypothalamus and carried to the anterior lobe by the hypophyseal portal system.

In males, FSH targets primarily nurse cells of the seminiferous tubules. Under FSH stimulation, and in the presence of testosterone from the interstitial endocrine cells, nurse cells promote spermatogenesis and spermiogenesis. LH in males was once called *interstitial cell-stimulating hormone, ICSH,* before it was found to be identical to LH in females. This hormone causes the secretion of testosterone and other androgens by the interstitial endocrine cells of the testes.

Testosterone is the most important androgen. It has numerous functions (**Spotlight Figure 19-7**). Testosterone production begins around the seventh week of fetal development and reaches a peak after six months. The early surge in testosterone levels stimulates the differentiation of the male duct system and accessory organs and affects CNS development. Testosterone secretion is low at birth. It accelerates markedly at puberty, initiating sexual maturation and the appearance of secondary sex characteristics. In adult males, negative feedback controls the level of testosterone production (**Spotlight Figure 19-7**).

19-3 Ovum production (oogenesis) occurs in the ovaries, and hormones from the pituitary gland and ovaries control female reproductive functions

Learning Outcome Describe the structures of the female reproductive system; explain the process of oogenesis in the ovary; discuss the ovarian and uterine cycles; and summarize the events of the female reproductive cycle.

A woman's reproductive system produces sex hormones and gametes. It must also be able to protect and support a developing embryo and nourish a newborn infant. The main organs of the female reproductive system are the *ovaries*, the *uterine tubes*, the *uterus* (womb), the *vagina*, and the external genitalia (**Figure 19-8a**). As in males, a variety of accessory glands release secretions into the female reproductive tract.

The Ovaries

The paired ovaries are small, lumpy, almond-shaped organs near the lateral walls of the pelvic cavity (**Figure 19-8b**). The ovaries have three main functions. They (1) produce female gametes, or oocytes; (2) secrete female sex hormones, including *estrogens* and *progesterone;* and (3) secrete inhibin, involved in the feedback control of pituitary FSH production.

A typical **ovary** is a flattened oval that measures approximately 5 cm long, 2.5 cm wide, and 8 mm thick (2 in. \times 1 in. \times 0.33 in.). It has a pale white or yellowish color. Its consistency resembles cottage cheese or lumpy oatmeal.

The position of each ovary is stabilized by a mesentery known as the *broad ligament* and by a pair of supporting ligaments. The mesentery also encloses the uterine tubes and uterus. The ligaments attached to each ovary extend to the uterus (*ovarian ligament*) and pelvic wall (*suspensory ligament*). The suspensory ligament contains the major blood vessels of the ovary: the *ovarian artery* and *ovarian vein*.

Oogenesis

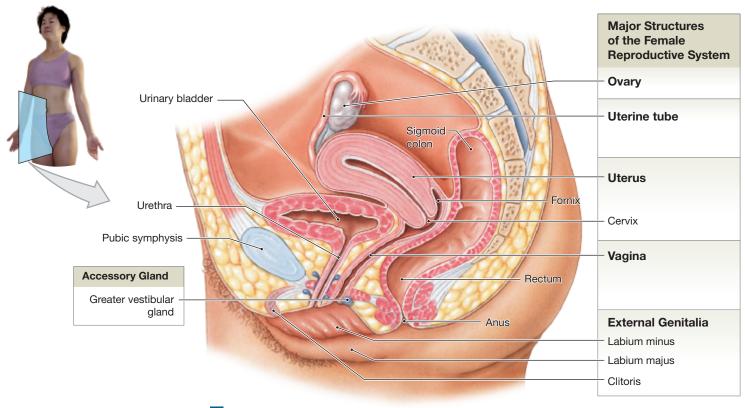

Ovum production, or **oogenesis** (\bar{o} - \bar{o} -JEN-e-sis; *oon*, egg), begins before a woman's birth. The process accelerates at puberty and ends at *menopause* (*men*, month + *pausis*, cessation). Between puberty and menopause, oogenesis takes place in the ovaries each month, as part of the *ovarian cycle*.

Oogenesis is summarized in **Figure 19-9**. Female reproductive stem cells, called **oogonia** (ō-ō-GŌ-nē-uh), complete their mitotic divisions before birth. Their daughter cells, or **primary oocytes** (Ō-ō-sīts), begin to undergo meiosis between the third and seventh months of fetal development. They proceed as far as prophase of meiosis I. They then remain in that state until the individual reaches puberty. Not all primary oocytes survive until puberty. The ovaries have roughly 2 million at birth, but only about 400,000 at puberty. The rest of the primary oocytes degenerate in a process called *atresia* (a-TRĒ-zē-uh).

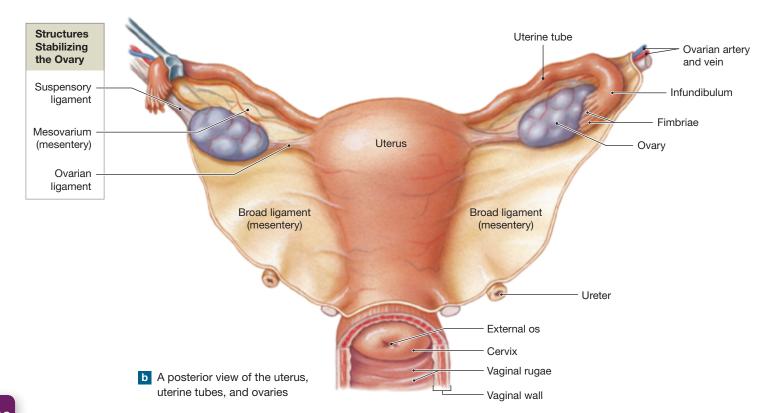

The nuclear events of meiosis in the ovary are the same as those in the testis, but the process differs in two important ways:

 The cytoplasm of the primary oocyte is not evenly distributed during the meiotic divisions. Oogenesis produces one **secondary oocyte** containing most of that cytoplasm, and up to three small nonfunctional **polar bodies** that later disintegrate.

Figure 19-8 The Female Reproductive System.

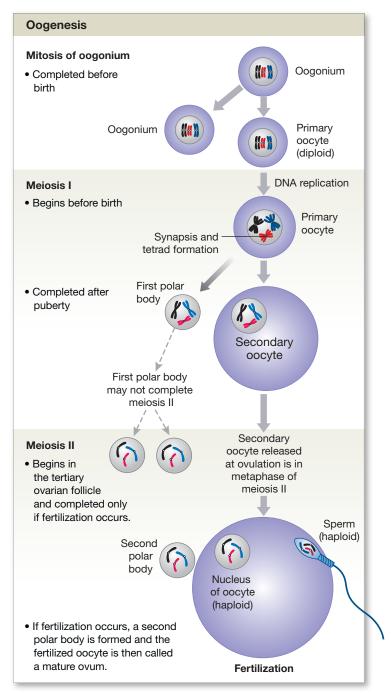

a A sagittal section showing the female reproductive organs

19

Figure 19-9 Oogenesis. In oogenesis, each diploid primary oocyte that undergoes meiosis produces one haploid secondary oocyte plus two or three nonfunctional polar bodies.

2. The ovary releases a secondary oocyte rather than a mature gamete. The secondary oocyte is suspended in metaphase of meiosis II. The second meiotic division is completed only *after* fertilization.

Ovarian Follicle Development

Specialized structures called **ovarian follicles** (ō-VAR-ē-an FOL-i-klz) are the sites of both oocyte growth and meiosis I of oogenesis. In the outer portion of each ovary are clusters of primary oocytes, each surrounded by a single layer of *follicle cells*. The combination is known as a **primordial** (prī-MOR-dē-al) **ovarian follicle** (1) in Figure 19-10). Beginning at puberty, primordial ovarian follicles are continuously activated to join other follicles already in development. The activating process is unknown, but local hormones or growth factors in the ovary may be involved. The activated primordial ovarian follicle will either eventually mature and be released as a secondary oocyte or degenerate (atresia).

The preliminary steps in follicle development vary in length but may take almost a year to complete. Follicle development begins with the activation of primordial ovarian follicles into **primary ovarian follicles** (2) in Figure 19-10). The follicle cells enlarge, divide, and form several layers of cells around the growing primary oocyte. The cells begin to produce sex hormones called estrogens. Microvilli from the surrounding follicle cells intermingle with microvilli originating at the surface of the oocyte. This region is called the **zona pellucida** (ZŌ-na pe-LOO-sid-uh; *pellucidus*, translucent). The microvilli increase the surface area available for transferring materials from the follicular cells to the growing oocyte.

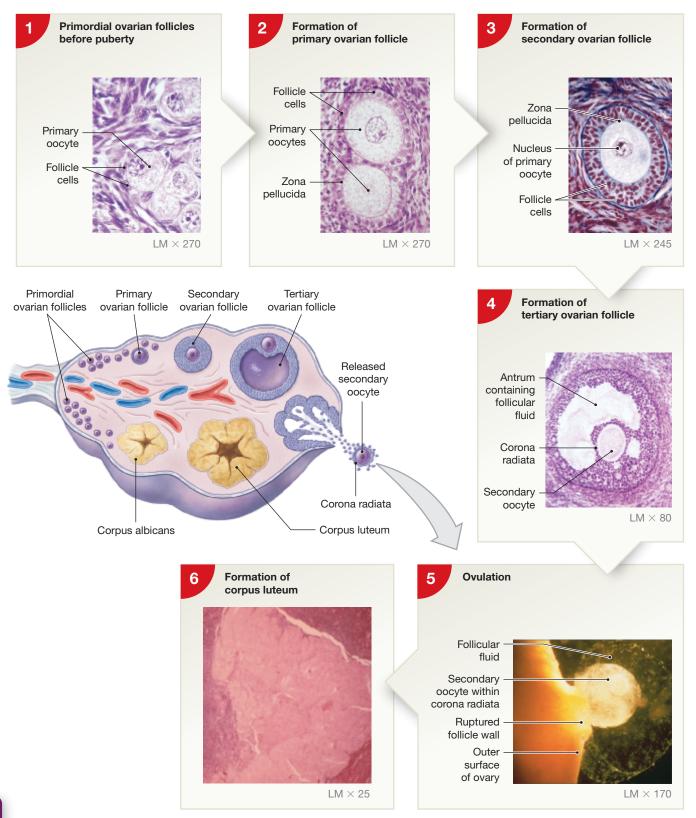

Many primordial follicles develop into primary follicles, but only a few primary follicles mature further. This process is apparently under the control of a growth factor produced by the oocyte. The transformation begins as the wall of the follicle thickens. At this stage, the complex is known as a **secondary ovarian follicle** (3 in Figure 19-10).

During the next two to three months, the follicle wall continues to grow and the deeper follicular cells begin secreting follicular fluid. This fluid accumulates between the inner and outer cellular layers of the follicle. The secondary follicle as a whole has doubled in size, and is now called a **tertiary ovarian follicle**. Tertiary ovarian follicles, also called *vesicular follicles,* continue to grow and accumulate follicular fluid.

The Ovarian Cycle

The tertiary ovarian follicles are then ready to complete their maturation as part of the 28-day **ovarian cycle**. The ovarian cycle is divided into a **follicular phase**, or *preovulatory phase*, and a **luteal phase**, or *postovulatory phase*. Separated by ovulation, each phase lasts approximately 14 days.

Figure 19-10 Ovarian Follicle Development and the Ovarian Cycle. The photomicrographs show the changes in an ovarian follicle as it develops. It enters the 28-day ovarian cycle as a tertiary ovarian follicle. The drawing of the ovary illustrates the sequence and relative sizes of the various stages in the development, ovulation, and degeneration of an ovarian follicle. Ovarian follicles do not physically move around the periphery of the ovary.

THE FOLLICULAR PHASE. At the start of each ovarian cycle, an ovary contains only a few tertiary ovarian follicles destined for further development. Stimulated by FSH, one of these follicles becomes dominant by day 5 of the cycle. It rapidly increases in size as the smaller follicles are resorbed. This tertiary ovarian follicle, also called a mature graafian (GRAF-ē-an) follicle, is roughly 15-20 mm in diameter (4) in Figure 19-10). It is formed by days 10-14 of the ovarian cycle. It creates a bulge in the surface of the ovary. The oocyte and its covering of follicular cells project into the expanded central chamber of the follicle, the **antrum** (AN-trum).

Until this time, the primary oocyte has been suspended in prophase I. As the development of the remaining tertiary ovarian follicle ends, rising LH levels prompt the primary oocyte to complete meiosis I. This division produces a secondary oocyte (and a small, nonfunctional polar body; Figure 19-9). The secondary oocyte begins meiosis II but stops at metaphase. Meiosis II will not be completed unless fertilization occurs.

Generally, on day 14 of a 28-day ovarian cycle, the secondary oocyte and its surrounding follicular cells lose their connections with the follicular wall and float within the antrum. The follicular cells surrounding the oocyte are now known as the corona radiata (ko-RŌ-nuh rā-dē-A-tuh).

OVULATION. At **ovulation** (ōv-ū-LĀ-shun), the tertiary ovarian follicle releases the secondary oocyte (5 in Figure 19-10). The distended follicular wall then ruptures, releasing the contents, including the secondary oocyte, into the pelvic cavity. The sticky follicular fluid keeps the corona radiata attached to the surface of the ovary near the ruptured wall of the follicle. Projections of the uterine tube or fluid currents created by its ciliated epithelium sweep the secondary oocyte into the uterine tube.

THE LUTEAL PHASE. The 14-day luteal phase of the ovarian cycle begins at ovulation. The empty follicle collapses. The remaining follicular cells invade the resulting cavity and multiply to create an endocrine structure known as the corpus luteum (LOO-tē-um; lutea, yellow) (6 in Figure 19-10). The corpus luteum releases progesterone, the main hormone of the luteal phase. Unless fertilization takes place, the corpus luteum begins to degenerate roughly 12 days after ovulation. What remains is scar tissue called the *corpus albicans*. The disintegration of the corpus luteum marks the end of an ovarian cycle. A new ovarian cycle begins with the recruitment of another group of tertiary ovarian follicles and the rapid growth and development of one of them into a mature tertiary ovarian follicle under the stimulation of FSH.

The Uterine Tubes

Each **uterine tube** (fallopian tube, or oviduct) measures roughly 13 cm (5 in.) in length. The end closest to the ovary forms an expanded funnel, or infundibulum (in-fun-DIB-ū-lum; infundibulum, a funnel). It has numerous fingerlike projections that extend into the pelvic cavity and drape over the ovary (Figure 19-8b). The projections are called fimbriae (FIM-brē-ē). The fimbriae and the inner surfaces of the uterine tube are carpeted with cilia that beat toward the uterus.

Secondary oocytes are transported by both ciliary movement and peristaltic contractions in the walls of the uterine tubes. It normally takes three to four days for the oocyte to travel to the uterine cavity. If fertilization is to occur, the secondary oocyte must encounter sperm during the first 12-24 hours of its passage. Unfertilized oocytes degenerate in the uterine tubes or uterus without completing meiosis.

In addition to ciliated cells, the epithelium lining the uterine tubes contains peg cells and scattered mucin-secreting cells. The peg cells secrete a fluid that both completes the capacitation of sperm and supplies nutrients to sperm and the developing pre-embryo (the cluster of cells produced by initial cell divisions following fertilization).

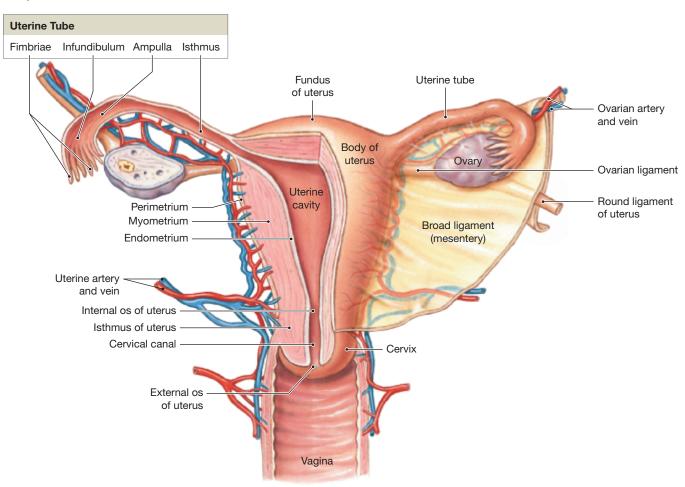

The Uterus

The uterus (Ū-ter-us) protects, nourishes, and removes wastes for the developing embryo (weeks 1-8) and fetus (week 9 to delivery). In addition, contractions of the muscular uterus are important in ejecting the fetus at birth.

A typical uterus is small and pear-shaped. It is about 7.5 cm (3 in.) long and 5 cm (2 in.) in diameter (Figure 19-8b). It weighs 30-40 g (1-1.4 oz). Various ligaments and mesenteries stabilize it. In its normal position, the uterus bends anteriorly near its base (Figure 19-8a).

The uterus consists of two regions: the body and the cervix (Figure 19-11). The **body** is the largest region. The *fundus* is the rounded portion of the body superior to the attachment of the uterine tubes. Laterally, the body ends at a constriction known as the isthmus. The tubular cervix (SER-viks) is the inferior portion of the uterus. It projects a short distance into the vagina. There its surface surrounds the external os (os, an opening or mouth) of the uterus. The cervical canal opens into the uterine cavity at the internal os.

The uterine wall is made up of an inner endometrium (en-do-MĒ-trē-um) and a muscular myometrium (mī-ō-MĒ-trē-um; *myo-*, muscle + *metra*, uterus), covered by the **perimetrium**, a layer of visceral peritoneum (Figure 19-11). The endometrium includes the epithelium lining the uterine cavity and 19 Figure 19-11 The Uterus. A posterior view with the left portion of the uterus, left uterine tube, and left ovary in section.

the underlying connective tissues. *Uterine glands* open onto the endometrial surface and extend deep into the connective tissue layer almost to the myometrium. The myometrium consists of a thick mass of interwoven smooth muscle cells. In adult women of reproductive age who have not given birth, the uterine wall is about 1.5 cm (0.5 in.) thick.

The endometrium consists of a superficial *functional layer* and a deeper *basal layer* adjacent to the myometrium. The functional layer contains most of the uterine glands. The structure of the basal layer remains relatively constant over time. In contrast, the functional layer undergoes cyclical changes in response to sex hormone levels. These changes produce the characteristics of the monthly uterine cycle.

The Uterine (Menstrual) Cycle

The **uterine cycle**, or *menstrual* (MEN-strū-ul) *cycle*, is a repeating series of changes in the structure of the endometrium. The uterine cycle begins with puberty. The first cycle is

CLINICAL NOTE

Pelvic Inflammatory Disease (PID)

Pelvic inflammatory disease (PID) is an infection of the uterus, uterine tubes, and ovaries. It starts when bacteria invade the cervix and then spread to the uterus and uterine tubes. PID is a major cause of female sterility (infertility). According to Britain's National Health Service (NHS), approximately 1 in 10 women who have PID become infertile due to the condition. Between 2016 and 2017, the PID rate increased in England, with a total of 25,709 reported cases.

Signs and symptoms of PID include fever, lower abdominal pain, and elevated white blood cell counts. In severe cases, the infection can spread to other visceral organs or produce a generalized peritonitis. Most cases are thought to be caused by sexually transmitted diseases (STDs), most often **gonorrhea** (gon-ō-RĒ-a) and **chlamydia** (kla-MID-ē-a). PID may also result from invasion by bacteria normally found within the vagina. Sexually active women ages 15–24 have the highest incidence of PID.

known as **menarche** (me-NAR-kē). It typically occurs at ages 11-12. The cycles continue until ages 45-55, when **meno**pause (MEN-ō-pawz), the last menstrual cycle, occurs. In the interim, the regular menstrual cycles are interrupted only by circumstances such as illness, stress, starvation, or pregnancy.

The uterine cycle averages 28 days in length, but it can range from 21 to 35 days in healthy individuals. It has three stages: the *menstrual phase, the proliferative phase, and the secretory phase.*

THE MENSTRUAL PHASE. The uterine cycle begins with the menstrual phase. This phase is marked by the degeneration and sloughing (shedding) of the endometrial functional layer, leading to menstruation (men-strū-Ā-shun), also called menses (MEN-sez). This process is triggered by a decline in progesterone and estrogen levels as the corpus luteum disintegrates. Endometrial arteries constrict, which reduces blood flow to this region. Deprived of oxygen and nutrients, the secretory glands, epithelial cells, and other tissues of the functional layer begin to die. Eventually the weakened arterial walls rupture, and blood pours into the connective tissues of the functional layer. Blood cells and degenerating tissues break away and enter the uterine cavity, to be lost through the vagina. The shedding of tissue continues until the entire functional layer has been lost. The menstrual phase usually lasts from 1 to 7 days. During this time about 35-50 mL (1.2 to 1.7 oz) of blood is lost. Painful menstruation, or dysmenorrhea, can result from uterine inflammation, myometrial contractions ("cramps"), or conditions involving adjacent pelvic structures.

THE PROLIFERATIVE PHASE. The **proliferative phase** begins in the days after menstruation. The surviving epithelial cells of the uterine glands multiply and spread across the surface of the endometrium. This repair process is stimulated by rising estrogen levels that accompany the growth of another set of ovarian follicles. By the time ovulation takes place, the functional layer is several millimeters thick, and its new set of uterine glands is secreting a mucus rich in glycogen. In addition, the entire functional layer is filled with small arteries that branch from larger trunks in the myometrium.

THE SECRETORY PHASE. During the secretory phase of the uterine cycle, the uterine glands enlarge and increase their rates of secretion. This activity is stimulated by progesterone and estrogens from the corpus luteum. The secretory phase begins at ovulation and lasts as long as the corpus luteum remains intact. Secretory activities peak about 12 days after ovulation. Over the next day or two glandular activity declines, and the uterine cycle ends. A new cycle then begins with the onset of menstruation and the disintegration of the functional layer.

CLINICAL NOTE

Amenorrhea

If menarche does not occur by age 16, or if a woman's normal menstrual cycle becomes interrupted for six months or more, the condition of **amenorrhea** (ā-men-ō-RĒ-uh) exists. Primary amenorrhea is the failure to begin menses. This condition may indicate developmental abnormalities, such as nonfunctional ovaries, the absence of a uterus, or some endocrine or genetic disorder. It can also result from malnutrition: Puberty is delayed if leptin levels are too low. \bigcirc p. 398

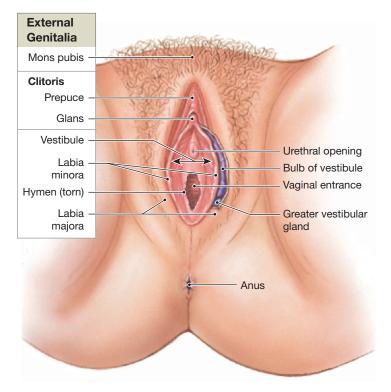

Severe physical or emotional stresses (such as drastic weight loss, anorexia nervosa, and severe depression or grief) can cause transient secondary amenorrhea. In effect, the reproductive system gets "switched off." Amenorrhea has also been observed in marathon runners and other women engaged in rigorous training programs, which may severely reduce body lipid reserves.

The Vagina

The **vagina** (va-JĪ-nuh) is an elastic, muscular tube extending between the uterus and the exterior. It opens into the vestibule, a space bounded by the external genitalia (Figure 19-8a). The vagina is typically 7.5-9 cm (3-3.6 in.) long. Its diameter varies because it is highly distensible. The cervix of the uterus projects into the vagina (Figure 19-11). The shallow recess surrounding the cervical protrusion is known as the fornix (FORniks) (Figure 19-8a). The vagina lies parallel to the rectum, and the two are in close contact posteriorly. The urethra extends along the superior wall of the vagina from the urinary bladder to the urethral opening, which opens into the vestibule.

The vaginal walls contain a network of blood vessels and layers of smooth muscle. The lining is moistened by the mucous secretions of the cervical glands and by the movement of water across the permeable epithelium. The hymen (HĪ-men) is an elastic epithelial fold of variable size that partially blocks the entrance to the vagina. An intact hymen is typically stretched or torn during first sexual intercourse, tampon use, pelvic examination, or physical activity. The two bulbospongiosus muscles extend along either side of the vaginal entrance. Contractions of the bulbospongiosus muscles constrict the vagina (see Figure 7-17a, p. 254). These muscles cover the bulb of vestibule, a mass of erectile tissue on either side of the vaginal entrance (Figure 19-12).

The vagina has three major functions. It (1) serves as a passageway for the elimination of menstrual fluids; (2) receives the penis during sexual intercourse and holds sperm prior to **19** **Figure 19-12 The Female External Genitalia.** The left labium minus has been removed to show erectile tissue (left part of the bulb of vestibule) and the left greater vestibular gland.

their passage into the uterus; and (3) forms the lower portion of the birth canal, through which the fetus passes during delivery.

The vagina normally contains resident bacteria supported by nutrients in the cervical mucus. The metabolic activity of these bacteria creates an acidic environment, which restricts the growth of many pathogens. Inflammation of the vaginal canal, known as *vaginitis* (vaj-i-NĪ-tis), is typically caused by fungi, bacteria, or parasites. In addition to any discomfort that may result, the condition may reduce fertility by lowering the survival rate of sperm.

The External Genitalia

The area containing the female external genitalia is the **vulva** (VUL-vuh), or *pudendum* (p \bar{u} -DEN-dum; **Figure 19-12**). The vagina opens into the **vestibule**, a central space bounded by the **labia minora** (L \bar{A} -b \bar{e} -uh mi-NOR-uh; *labia*, lips; singular, *labium minus*). The labia minora are covered with smooth, hairless skin. The urethra opens into the vestibule just anterior to the vaginal entrance. Anterior to the urethral opening, the **clitoris** (KLIT- \bar{o} -ris) projects into the vestibule. The clitoris is derived from the same embryonic structures as the penis in males. Internally, it contains erectile tissue comparable to the corpora cavernosa of the penis. A small erectile *glans* sits atop it. The **bulb of vestibule** is erectile tissue on each side of the

vestibule, which is united by a narrow mass at the clitoris. It is comparable to the corpus spongiosum in the male penis and engorges with blood during sexual arousal. Extensions of the labia minora encircle the body of the clitoris, forming its *prepuce*.

A variable number of small **lesser vestibular glands** discharge secretions onto the exposed surface of the vestibule, keeping it moist. During sexual arousal, a pair of ducts discharges the secretions of the **greater vestibular glands** into the vestibule near the vaginal entrance (**Figure 19-8**). These mucous glands resemble the bulbo-urethral glands of males.

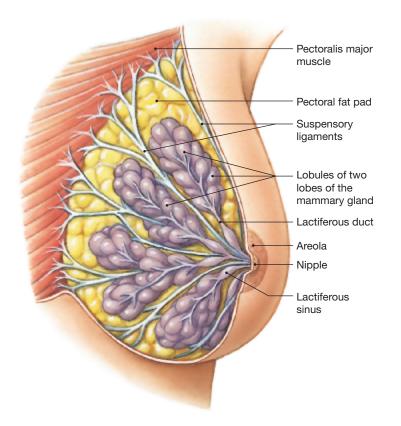

The mons pubis and labia majora form the outer limits of the vulva. The prominent bulge of the **mons pubis** is created by adipose tissue beneath the skin anterior to the pubic symphysis. Adipose tissue also accumulates in the fleshy **labia majora** (singular, *labium majus*), which encircle and partially conceal the labia minora and vestibular structures.

The Mammary Glands

A newborn cannot yet fend for itself. The infant gains nourishment from the milk secreted by the maternal **mammary glands** (**Figure 19-13**). Milk production, or **lactation** (lak-TĀ-shun),

Figure 19-13 The Mammary Gland of the Left Breast.

Lobes of glandular tissue within each mammary gland are responsible for the production of breast milk.

CLINICAL NOTE

Breast Cancer

Breast cancer is a malignant, metastasizing tumor of the mammary gland. Almost 90 percent of breast cancers begin in the ducts and lobes of the mammary glands. They are called *ductal carcinomas* and *lobular carcinomas*, respectively. If the tumor cells have spread outside of a duct or lobule and into the surrounding tissue, the cancer is called an *invasive ductal* or *lobular carcinoma*. Cancers that have not spread are called *in situ* ("in place"). They are known as *ductal carcinoma in situ* (*DCIS*) and *lobular carcinoma in situ* (*LCIS*).

Breast cancer is the leading cause of death in women between the ages of 35 and 45, but it is most common in women over age 50. An estimated 12 percent of U.S. women will develop breast cancer at some point in their lifetime. Risk factors include (1) a family history of breast cancer, (2) first pregnancy after age 30, and (3) early menarche (first menstrual period) or late menopause (last menstrual period). Breast cancers in males are very rare, but about 400 men die from the disease each year in the United States.

takes place in these glands. In females, the mammary glands are specialized organs of the integumentary system. They are controlled by hormones of the reproductive system and of the *placenta*, a temporary structure that provides the embryo and fetus with nutrients.

Each breast contains a mammary gland within the subcutaneous tissue of the *pectoral fat pad* beneath the skin. Each breast has a **nipple**, a small conical projection where the ducts of the underlying mammary gland open onto the body surface. The reddish-brown skin surrounding each nipple is the **areola** (a-RĒ-ō-luh). Large sebaceous glands beneath the areolar surface give it a grainy texture.

The glandular tissue of a mammary gland consists of separate lobes, each made up of several lobules containing milk glands. Ducts leaving the lobules merge into a single **lactiferous** (lak-TIF-er-us) **duct**. Near the nipple, that forms an expanded chamber called a **lactiferous sinus**. Typically, 15–20 lactiferous sinuses open onto the surface of each nipple.

Dense connective tissue surrounds the duct system and forms partitions between the lobes and lobules. These bands of connective tissue, the *suspensory ligaments of the breast*, originate in the dermis of the overlying skin. A layer of areolar connective tissue separates the mammary gland complex from the underlying pectoralis muscles.

Hormones and the Female Reproductive Cycle

Spotlight Figure 19-14 shows the regulation of female reproduction. As in males, both pituitary and gonadal hormones control the activity of the reproductive system. However, the regulatory pattern in females is much more complicated than in males. In females, circulating hormones must coordinate the ovarian and uterine cycles so that the **female reproductive cycle** results in the proper functioning of all reproductive activities.

Hormones and the Follicular Phase

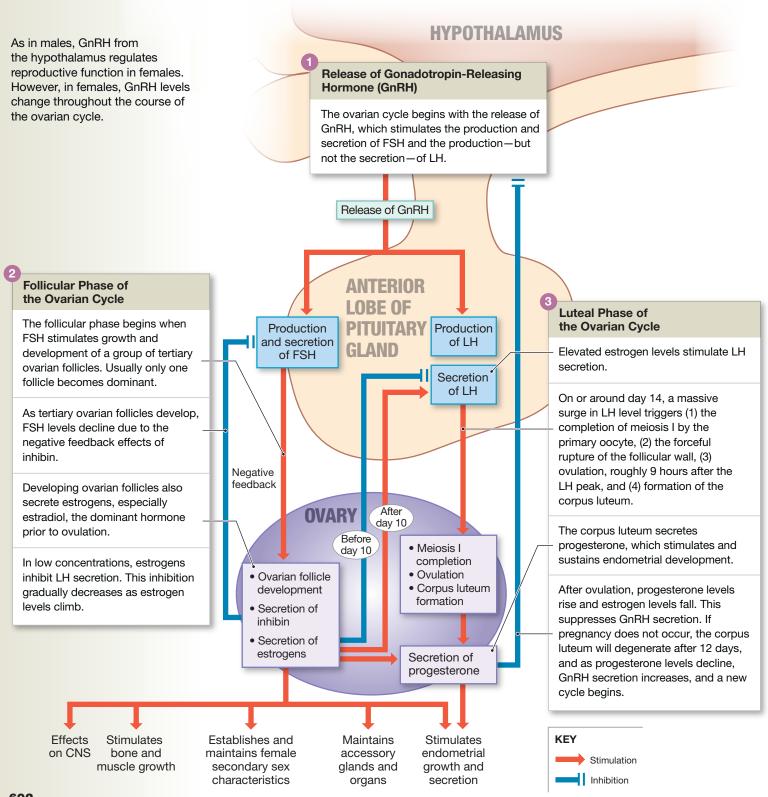

The **follicular phase** (or *preovulatory phase*) of the ovarian cycle begins each month when FSH from the anterior lobe of the pituitary gland stimulates the rapid growth of a dominant tertiary ovarian follicle from a small group of slowerdeveloping tertiary ovarian follicles (Figure 19-10, p. 686). As the follicle cells enlarge and multiply, they release steroid hormones collectively known as estrogens. The most important estrogen is estradiol (es-tra-DĪ-ol). Estrogens have multiple functions. They include (1) stimulating bone and muscle growth; (2) establishing and maintaining female secondary sex characteristics, such as the distributions of body hair and adipose tissue deposits; (3) affecting central nervous system (CNS) activity (especially in the hypothalamus, where estrogens increase sexual drive); (4) maintaining functional accessory reproductive glands and organs; and (5) initiating the repair and growth of the endometrium.

Spotlight Figure 19-14 diagrams the hormonal regulation of ovarian activity. Early in the follicular phase, estrogen and inhibin levels are low. The estrogens and inhibin have complementary effects on the secretion of FSH and LH: Low levels of estrogen inhibit LH and FSH secretion. As follicular development proceeds, the levels of circulating estrogens and inhibin rise as the follicular cells increase in number and in secretory activity. As tertiary ovarian follicles develop, FSH levels decline due to the negative-feedback effects of inhibin, and estrogen levels continue to rise. Despite the slow decline in FSH concentrations, the combination of estrogens, FSH, and LH continues to support follicular development and maturation.

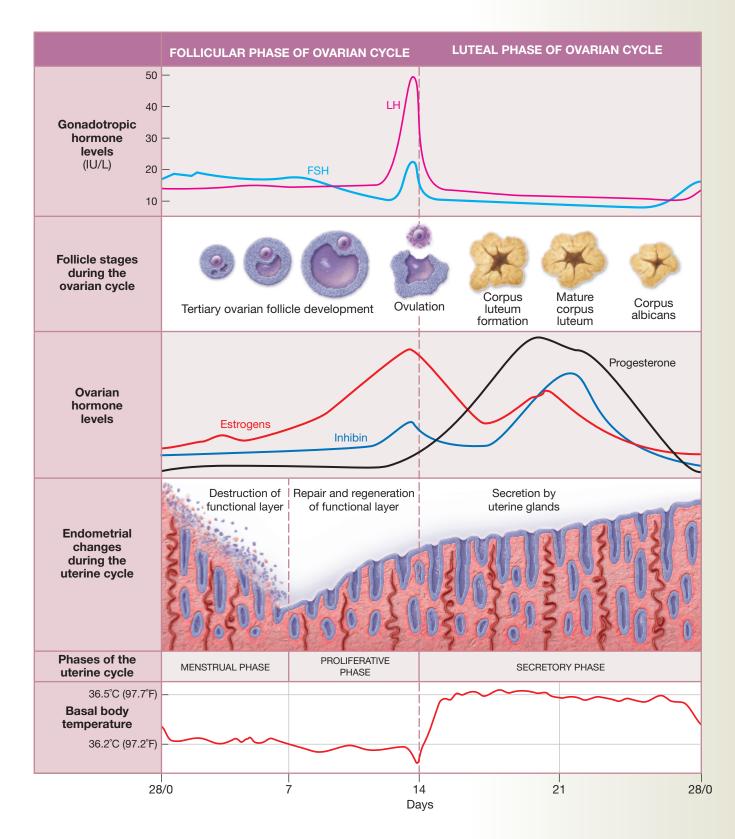

Estrogen concentrations rise steeply in the second week of the ovarian cycle, as one of the tertiary ovarian follicles becomes dominant in preparation for ovulation. The rapid increase in estrogens leads to the secretion of FSH and LH by acting on the hypothalamus and stimulating the production of GnRH. The pituitary gland also becomes more sensitive to GnRH and contributes to the rise in FSH and LH. At roughly day 10 of the cycle, the effect of estrogen on LH secretion also

SPOTLIGHT Figure 19-14 REGULATION OF FEMALE REPRODUCTION

The ovarian and uterine cycles must operate on the same time scale to ensure proper reproductive function. If the two cycles are not properly coordinated, infertility results. A female who does not ovulate cannot conceive, even if her uterus is perfectly normal. A female who ovulates normally, but whose uterus is not ready to support an embryo, will also be infertile.

This illustration links together the key events in the ovarian and uterine cycles. The monthly hormonal fluctuations cause physiological changes that affect core body temperature. During the follicular phase—when estrogens are the dominant hormones—the **basal body temperature**, or the resting body temperature measured upon awakening in the morning, is about 0.3°C (0.5°F) lower than it is during the luteal phase, when progesterone dominates.

changes from inhibition to stimulation. At about day 14, estrogen levels peak with the maturation of the tertiary ovarian follicle. The high estrogen concentration then triggers a massive release, or surge, of LH from the anterior lobe of the pituitary gland. This LH surge triggers the rupture of the follicular wall and ovulation.

Hormones and the Luteal Phase

The **luteal phase**, or *postovulatory phase*, of the ovarian cycle begins as the high LH levels that triggered ovulation also stimulate the remaining follicular cells to form a corpus luteum. The yellow color of the corpus luteum results from its lipid reserves, which are used to manufacture the steroid hormone **progesterone** (prō-JES-ter-ōn). Progesterone is the principal hormone of the luteal phase. It prepares the uterus for pregnancy by stimulating the growth and development of the blood supply and secretory glands of the endometrium. Progesterone also stimulates metabolic activity and elevates basal body temperature.

Luteinizing hormone (LH) levels remain elevated for only two days, but that is long enough to stimulate the formation of a functional corpus luteum. Progesterone secretion continues at relatively high levels for the next week. Unless pregnancy occurs, however, the corpus luteum begins to degenerate. Roughly 12 days after ovulation, the corpus luteum becomes nonfunctional, and progesterone and estrogen levels fall markedly. With this decline, hypothalamic production of GnRH is no longer inhibited and GnRH production increases. The increased secretion of GnRH, in turn, leads to increased FSH production in the anterior lobe of the pituitary gland, and the ovarian cycle begins again.

Hormones and the Uterine Cycle

Progesterone and estrogen levels decrease as the corpus luteum degenerates, resulting in menstruation (**Spotlight Figure 19-14**). The loss of endometrial tissue continues for several days, until rising estrogen levels stimulate the regeneration of the functional layer of the endometrium.

The proliferative phase continues until a rising progesterone level marks the arrival of the secretory phase. The combination of estrogen and progesterone then causes the uterine glands to enlarge and increase their secretions.

Hormones and Body Temperature

At the time of ovulation, the basal body temperature (BBT) declines sharply, making the temperature rise over the following day even more noticeable (**Spotlight Figure 19-14**).

CLINICAL NOTE

Infertility

Infertility (*sterility*) is usually defined as an inability to achieve pregnancy after one year of appropriately timed sexual intercourse. Problems with infertility are relatively common. An estimated 10–15 percent of married couples in the United States are infertile, and another 10 percent are unable to have as many children as they desire. It is not surprising that the treatment of infertility has become a major medical industry! Recent advances in our understanding of reproductive physiology offer new solutions to fertility problems as varied as low sperm count, abnormal sperm, inadequate maternal hormone levels, problems with oocyte production or oocyte transport from ovary to uterine tube, blocked uterine tubes, abnormal oocytes, and an abnormal uterine environment. Procedures meant to resolve these difficulties are known as assisted reproductive technologies (ART).

Urine tests that detect LH are available, and testing daily for several days before expected ovulation can detect the LH surges more reliably than the BBT. This information can be very important for individuals who wish to avoid or promote a pregnancy because fertilization typically occurs within a day of ovulation. After that time, oocyte viability and the likelihood of successful pregnancy decrease markedly.

CHECKPOINT

- **8.** Name the structures of the female reproductive system.
- **9.** As the result of infections such as gonorrhea, scar tissue can block both uterine tubes. How would this blockage affect a woman's ability to conceive?
- **10.** What benefit does the acidic pH of the vagina provide?
- **11.** Which layer of the uterus is sloughed off, or shed, during menstruation?
- **12.** Would the blockage of a single lactiferous sinus interfere with delivery of milk to the nipple? Explain.
- **13.** What changes would you expect to observe in the ovarian cycle if the LH surge did not take place?
- **14.** What effect would blockage of progesterone receptors in the uterus have on the endometrium?
- **15.** What event in the uterine cycle occurs when estrogen and progesterone levels decrease?

19-4 The autonomic nervous system influences male and female sexual function

Learning Outcome Discuss the physiology of sexual intercourse in males and females.

Sexual intercourse, also known as *coitus* (KŌ-i-tus) or *copulation*, introduces semen into the female reproductive tract.

Male Sexual Function

Male sexual function is coordinated by reflex pathways involving both divisions of the ANS. During sexual **arousal**, erotic thoughts or the stimulation of sensory nerves in the genital region increase the parasympathetic outflow over the pelvic nerves. This outflow leads to erection of the penis (discussed on p. 681). The skin covering the glans penis contains numerous sensory receptors. Erection tenses the skin and increases sensitivity. Subsequent stimulation can initiate secretion from the bulbo-urethral glands, lubricating the urethra and the surface of the glans penis.

During intercourse, the sensory receptors in the penis are rhythmically stimulated. This stimulation eventually results in emission and ejaculation. Emission takes place under sympathetic stimulation. The process begins with peristaltic contractions of the ampulla of the ductus deferens. These contractions push fluid and sperm through the ejaculatory ducts and into the urethra. The seminal glands then begin contracting. Waves of contraction in the prostate follow. While these contractions are proceeding, sympathetic commands contract the urinary bladder and close the internal urethral sphincter. These actions prevent semen from entering the bladder.

Ejaculation takes place as powerful, rhythmic contractions appear in the *ischiocavernosus* and *bulbospongiosus* muscles, two superficial skeletal muscles of the pelvic floor. (Their positions are shown in Figure 7-17b, p. 254.) Ejaculation is associated with intensely pleasurable sensations, an experience known as male **orgasm** (OR-gazm). Several other physiological changes also occur at this time. They include temporary increases in heart rate and blood pressure.

After ejaculation, blood begins to leave the erectile tissue, and the erection begins to subside. This subsidence is called *detumescence* (dē-tū-MES-ens). It is brought about by

CLINICAL NOTE

Sexually Transmitted Diseases

Sexual activity carries with it the risk of infection by a variety of microorganisms. The consequences of such an infection range from merely inconvenient to potentially lethal. **Sexually transmitted diseases (STDs),** also called sexually transmitted infections (STIs), are transferred from person to person during sexual activity, primarily or exclusively by sexual intercourse. At least two dozen bacterial, viral, and fungal infections are currently recognized as STDs. The bacterium *Chlamydia* can cause PID and infertility. AIDS, caused by a virus, is deadly. In 2018, 447,694 cases of STIs were diagnosed in England, a 5% increase from 2017. Poverty, prostitution, intravenous drug use (needle sharing exchanges body fluids), and the appearance of drug-resistant pathogens all contribute to the problem.

the sympathetic nervous system. **Impotence**, or **erectile dysfunction (ED)**, is an inability to achieve or maintain an erection.

Female Sexual Function

The events in female sexual function are largely comparable to those in males. During sexual arousal, parasympathetic activation leads to an engorgement of the erectile tissues of the clitoris and bulb of vestibule. Secretion from cervical mucous glands and the greater vestibular glands increases for the same reason. Clitoral erection increases the sensitivity of receptors to stimulation. The cervical and vestibular glands lubricate the vaginal walls. A network of blood vessels in the vaginal walls fills with blood at this time. Vaginal surfaces are also moistened by fluid from underlying connective tissues. Parasympathetic stimulation also causes blood vessels at the nipples to become engorged. As a result, the nipples become more sensitive to touch and pressure.

During sexual intercourse, rhythmic contact of the penis with the clitoris and vaginal walls may be reinforced by touch sensations from the breasts and other stimuli (visual, olfactory, and auditory). All this stimulation can lead to orgasm. Female orgasm is accompanied by peristaltic contractions of the uterine and vaginal walls and by rhythmic contractions of the bulbospongiosus and ischiocavernosus muscles. The contractions of these two muscles give rise to the intensely pleasurable sensations of orgasm.

CHECKPOINT

- **16.** List the physiological events of sexual intercourse in both sexes, and note those that occur in males but not in females.
- **17.** An inability to contract the ischiocavernosus and bulbospongiosus muscles would interfere with which part of the sexual response in males?
- **18.** What changes take place in females during sexual arousal as the result of increased parasympathetic stimulation?

See the blue Answers tab at the back of the book.

19-5 With age, decreasing levels of reproductive hormones cause functional changes

Learning Outcome Describe the reproductive system changes that occur with aging.

Aging affects all body systems. The reproductive systems of men and women are no exception. These systems become fully functional in both sexes at puberty. After that, the most striking age-related changes in the female reproductive system take place at menopause. Comparable changes in the male reproductive system occur more gradually and over a longer period of time.

Menopause

Menopause is usually defined as the time when ovulation and menstruation cease. Menopause typically takes place at ages 45–55. In the years immediately preceding it, the ovarian and menstrual cycles become irregular. This time period is called *perimenopause*. It normally begins at age 40. A shortage of primordial ovarian follicles is the underlying cause of irregular cycles. It has been estimated that almost 7 million potential oocytes are in fetal ovaries after five months of development. The number decreases to about 2 million oocytes at birth. A few hundred thousand remain at puberty. By age 50, there are often no primordial follicles left to respond to FSH. In *premature menopause*, this depletion takes place before age 40.

Menopause is accompanied by a decline in circulating estrogens and progesterone, and a sharp and sustained increase in the production of GnRH, FSH, and LH. The decrease in estrogen levels leads to reductions in the sizes of the uterus and breasts, and thinning of the urethral and vaginal walls. The reduced estrogen concentrations have also been linked to the development of osteoporosis. Presumably, bone is deposited at a slower rate.

A variety of neural effects are also reported. They include "hot flashes," anxiety, and depression. Hot flashes typically begin while estrogen levels are decreasing and cease when estrogen levels reach minimal values. These periods of elevated body temperature are associated with surges in LH production. The hormonal processes involved in other CNS effects of menopause are not well understood. The risks of atherosclerosis and other forms of cardiovascular disease also increase after menopause.

The majority of women have only mild symptoms. Some women, however, have unpleasant symptoms in perimenopause or during or after menopause. For most of these women, hormone replacement therapy (HRT) involving a combination of estrogens and progestins can control the neural and vascular changes associated with menopause. However, recent studies suggest that taking estrogen-replacement therapy for more than five years increases the risk of heart disease, breast cancer, Alzheimer's disease, blood clots, and stroke.

The Male Climacteric

The male reproductive system changes more gradually than does the female reproductive system. The period of declining reproductive function is known as the **male climacteric**, or *andropause*. It corresponds to perimenopause in women. Levels of circulating testosterone begin to decline between ages 50 and 60, and levels of FSH and LH increase. Sperm production continues. (Men well into their 80s can father children.) Older men experience a gradual reduction in sexual activity. This decrease may be linked to declining testosterone levels. Some clinicians suggest testosterone replacement therapy to enhance libido (sexual drive) in older men, but this may increase the risk of prostate disease.

CHECKPOINT

- **19.** Define menopause.
- **20.** Why does the level of FSH increase and remain high during menopause?
- **21.** What is the male climacteric?
- See the blue Answers tab at the back of the book.

Table 19-1	Horme	Hormones of the Reproductive System		
Hormone		Source	Regulation of Secretion	Primary Effects
GONADOTROPIN- RELEASING HORM (GnRH)	IONE	Hypothalamus	Males: inhibited by testosterone Females: inhibited by estrogens and/or progesterone	Stimulates FSH secretion and LH synthesis in males and females
FOLLICLE-STIMULATING HORMONE (FSH)		Anterior lobe of the pituitary gland	<i>Males:</i> stimulated by GnRH, inhibited by inhibin and testosterone	<i>Males:</i> stimulates spermatogenesis and spermiogenesis through effects on nurse cells
			<i>Females:</i> stimulated by GnRH, inhibited by inhibin, estrogens, and/or progesterone	Females: stimulates ovarian follicle development, estrogen production, and oocyte maturation
LUTEINIZING HORMONE (LH)		Anterior lobe of pituitary gland	Males: stimulated by GnRH	Males: stimulates interstitial endocrine cells to secrete
			<i>Females:</i> production stimulated by GnRH and secretion by estrogens	testosterone <i>Females:</i> stimulates ovulation, formation of corpus luteum, and progesterone secretion
ANDROGENS (Primarily Testosterone)		Interstitial endocrine cells of testes	Stimulated by LH	Establish and maintain secondary sex characteristics and sexual behavior; promote maturation of sperm; inhibit GnRH secretion
ESTROGENS (Primarily Estradiol)		Follicle cells of ovaries; corpus luteum	Stimulated by FSH	Stimulate LH secretion (at high levels); establish and maintain secondary sex characteristics and behavior; stimulate repair and growth of endometrium; inhibit secretion of GnRH
PROGESTERONE		Corpus luteum	Stimulated by LH	Stimulates endometrial growth and glandular secretion; inhibits GnRH secretion
INHIBIN		Nurse cells of testes and follicle cells of ovaries	Stimulated by factors released by developing sperm (male) and developing ovarian follicles (female)	Inhibits secretion of FSH (and possibly GnRH)

19-6 The reproductive system secretes hormones affecting growth and metabolism of all body systems

Learning Outcome Give examples of interactions between the reproductive system and each of the other body systems.

Normal human reproduction is a complex process. It involves multiple body systems. The hormones discussed in this chapter play a major role in coordinating reproductive events (**Table 19-1**). Physical factors also play a role.

For example, the male's sperm count must be adequate. The semen must have the correct pH and nutrients. Erection and ejaculation must take place in the proper sequence. The female's ovarian and uterine cycles must be properly coordinated. Ovulation and oocyte transport must take place normally. Her reproductive tract must provide a suitable environment for sperm survival and movement, and for fertilization of the oocyte. For these steps to occur, the digestive, endocrine, nervous, cardiovascular, and urinary systems must all be functioning normally.

Refer to Build Your Knowledge: How the REPRODUCTIVE SYSTEM integrates with the other body systems presented so far on p. 700. It reviews the major functional relationships between this system and the ten other body systems.

Even when all is normal, and fertilization takes place at the proper time and place, the zygote—a single cell the size of a pinhead—must develop into a full-term fetus that typically weighs about 3 kg (6.6 lb). (In Chapter 20 we will consider the process of development and the mechanisms that determine both body structure and the distinctive characteristics of each individual.)

CHECKPOINT

- **22.** Describe the interactions between the reproductive system and the cardiovascular system.
- **23.** Describe the interaction between the reproductive system and the skeletal system.

See the blue Answers tab at the back of the book.

CLINICAL NOTE

Birth Control Strategies

For diverse reasons, most U.S. adults practice some form of conception control during their reproductive years. Two out of three U.S. women ages 15–44 use some method of contraception. When the simplest method – sexual abstinence – is unsatisfactory, another means of contraception must be used to avoid unwanted pregnancies. All methods have specific strengths and weaknesses.

Hormonal contraceptives manipulate the female hormonal cycle so that ovulation does not take place. The contraceptive pills produced in the 1950s combined estrogen and progestins (synthetic progesterone) to suppress pituitary GnRH production, so FSH was not released and ovulation did not occur. Most of today's oral contraceptives contain much smaller amounts of estrogen, or only progestins. Current *combination* hormone contraceptives are administered cyclically, using medication for three weeks followed by no medication during week 4. For convenience, monthly injections, weekly skin patches, and insertable vaginal rings are available.

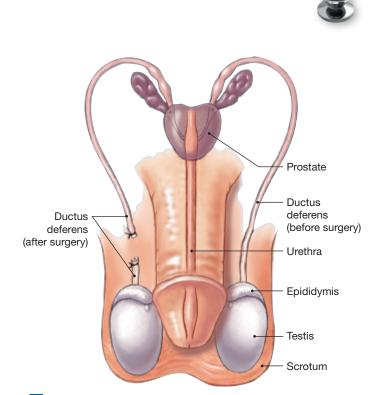

An estimated 200 million women use combination oral contraceptives worldwide. In the United States, 33 percent of women under age 45 use the combination pill to prevent conception. The failure rate for combination oral contraceptives, when used as prescribed, is 0.24 percent over a two-year period. (*Failure* for a birth control method is defined as a pregnancy.) Birth control pills are not risk free. They can worsen problems associated with severe hypertension, diabetes mellitus, epilepsy, gallbladder disease, heart trouble, and acne. Women taking oral contraceptives are also at increased risk for venous thrombosis, strokes, pulmonary embolism, and (for women over 35) heart disease.

Hormonal postcoital contraception, or the emergency "morning after" pill, involves taking either combination estrogen/progestin birth control pills or progestin-only pills within 72 hours of unprotected sexual intercourse. Particularly useful when barrier methods malfunction or coerced intercourse occurs, it reduces expected pregnancy rates by up to 89 percent.

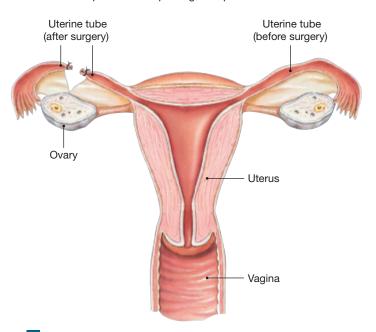

Progestin-only forms of birth control—Depo-Provera and the progestin-only pill ("mini-pill")—are now available. Depo-Provera is injected every three months. It can cause irregular menstruation and temporary amenorrhea. The progestin-only pill is taken daily and may cause irregular uterine cycles. Skipping just one pill may result in pregnancy.

The **condom**, also called a *prophylactic* or "rubber," covers the glans penis and body of the penis during intercourse. It keeps sperm from reaching the female reproductive tract. Latex condoms also reduce the spread of STDs, such as syphilis, gonorrhea, HPV, and AIDS. The reported condom failure rate varies from 6 to 18 percent.

Vaginal barriers such as the *diaphragm* and *cervical cap* rely on similar principles. A diaphragm, the most popular form of vaginal barrier today, is a dome of latex rubber with a small metal hoop supporting the rim. Before intercourse, the diaphragm is inserted to cover the external os of the uterus, and it

a In a vasectomy, the removal of a 1-cm section of the ductus deferens prevents the passage of sperm.

b In a tubal ligation, the removal of a section of the uterine tube prevents the passage of sperm and the movement of an ovum or embryo into the uterus.

(continued)

CLINICAL NOTE *(continued)*

Contraceptive devices

is usually coated with a small amount of spermicidal (sperm-killing) jelly or cream. The failure rate of a properly fitted diaphragm is estimated at 5–6 percent. A *cervical cap* is smaller and lacks the metal rim. It, too, must be fitted carefully, but unlike the diaphragm, it can be left in place for several days. Its failure rate (8 percent) is higher than that for diaphragm use.

An **intrauterine device (IUD)** consists of a small plastic loop or a T that is inserted into the uterine cavity. The mechanism of action remains uncertain, but IUDs are known to stimulate prostaglandin production in the uterus. The resulting change in the chemical composition of uterine secretions lowers the likelihood of fertilization and *implantation* of the zygote in the uterine lining. (Implantation is discussed in Chapter 20.) In the United States, IUD use is increasing, yet is still less than in many countries. Failure rate is estimated at 5–6 percent.

The **rhythm method** involves abstaining from sexual intercourse on the days ovulation might be occurring. The timing is estimated on the basis of previous patterns of menstruation and in some cases by monitoring changes in basal body temperature. The failure rate is very high—almost 25 percent.

Sterilization is a surgical procedure that makes a person unable to provide functional gametes for fertilization. Members of either sex may be sterilized. In a **vasectomy** (vaz-EK-to-mē) a segment of the ductus deferens is removed, making it impossible for sperm to pass from the epididymis to the distal portions of the reproductive tract. The surgery can be performed in a physician's office in a matter of minutes. A 1-cm section of the ductus deferens is removed on each side, and the cut ends are usually tied shut (**a**). In time, scar tissue forms a permanent seal. Alternatively, the cut ends are blocked with silicone plugs that can later be removed in an attempt to restore fertility. After a vasectomy, men have normal sexual function. Sperm continue to develop, but they remain within the epididymis and degenerate. The failure rate for this procedure is 0.08 percent.

The uterine tubes can be blocked through a surgical procedure known as a **tubal ligation** (b). The failure rate is estimated at 0.45 percent. Because the surgery involves entering the abdominopelvic cavity, complications are more likely than with a vasectomy. As in a vasectomy, attempts to restore fertility after a tubal ligation may not be successful. Both vasectomy and tubal ligation contraception should be considered permanent.

Pregnancy is a natural phenomenon, but it has risks. The mortality rate for pregnant women in the United States averages about 8 deaths per 100,000 pregnancies. That average incorporates a broad range. The rate is 7 per 100,000 among women under 20 but 40 per 100,000 for women over 40. Before age 35, the risks associated with contraceptive use are lower than the risks associated with pregnancy. The notable exception involves individuals who take oral contraceptives but also smoke cigarettes. After age 35, the risks of complications associated with oral contraceptive use increase, but the risks of using other methods remains relatively stable. Women over age 35 (smokers) or 40 (nonsmokers) are, therefore, typically advised to seek other forms of contraception.

RELATED CLINICAL TERMS

endometriosis (en-dō-mē-trē-Ō-sis)**:** The growth of endometrial tissue outside the uterus.

genital herpes: A sexually transmitted disease caused by a herpes virus and characterized by painful blisters in the genital region.

gynecology (gī-ne-KOL-o-jē): Branch of medicine that deals with the functions and diseases specific to women and girls affecting the reproductive system.

hysterectomy: The surgical removal of the uterus.

mammography: The use of x-rays to examine breast tissue. **mastectomy:** The surgical removal of part or all of a breast, typically as treatment for breast cancer.

oophoritis (ō-of-ō-RĪ-tis): Inflammation of the ovaries.

orchitis (or-KĪ-tis): Inflammation of one or both testicles. **ovarian cancer:** A malignancy of the ovaries; the most dangerous reproductive cancer in women.

ovarian cyst: A condition (usually harmless) in which fluid-filled sacs develop in or on the ovary.

prostate cancer: A malignant, metastasizing tumor of the prostate; the second most common cancer and the second most common cause of cancer deaths in males.

prostatectomy: The surgical removal of the prostate.

salpingitis: Inflammation of a uterine tube.

testicular torsion: A condition in which twisting of the spermatic cord obstructs the blood supply to a testis.

Build Your Knowledge

How the REPRODUCTIVE SYSTEM integrates with the other body systems presented so far

Integumentary System

- The Integumentary System covers external genitalia; provides sensations that stimulate sexual behaviors; mammary gland secretions nourish the newborn
- The reproductive system hormones affect the distribution of body hair and subcutaneous fat

Respiratory System

- The Respiratory System provides oxygen and removes carbon dioxide generated by tissues of reproductive system and (in pregnant women) by embryonic and fetal tissues
- The reproductive system changes respiratory rate and depth during sexual arousal, under control of the nervous system

Cardiovascular System

- The Cardiovascular System distributes reproductive hormones; provides nutrients, oxygen, and waste removal for fetus; local blood pressure changes responsible for physical changes during sexual arousal
- The reproductive system produces estrogens that may help maintain healthy vessels and slow development of atherosclerosis

Digestive System

- The Digestive System provides additional nutrients required to support gamete production and (in pregnant women) embryonic and fetal development
- The reproductive system in pregnant women with a developing fetus crowds digestive organs, causes constipation, and increases appetite

Skeletal System

- The Skeletal System (pelvic girdle) protects reproductive organs of females, portion of ductus deferens and accessory glands in males
- The reproductive system hormones stimulate bone growth and maintenance, and at puberty accelerate growth and closure of epiphyseal cartilages

Nervous System

- The Nervous System controls sexual behaviors and sexual function
- The reproductive system hormones affect CNS development and sexual behaviors

Endocrine System

- The Endocrine System produces hypothalamic regulatory hormones and pituitary hormones that regulate sexual development and function; oxytocin stimulates smooth muscle contractions in uterus and mammary glands
- The reproductive system produces steroid sex hormones and inhibin that inhibit secretory activities of hypothalamus and pituitary gland

Lymphatic System

- The Lymphatic System provides IgA for secretions by epithelial glands; assists in repairs and defense against infection
- The reproductive system secretes lysozymes and bactericidal chemicals that provide innate (nonspecific) defense against reproductive tract infections

Urinary System

- The Urinary System in males carries semen to exterior in urethra; kidneys excrete wastes generated by reproductive tissues and (in pregnant women) by a growing embryo and fetus
- The reproductive system secretions may have antibacterial activity that helps prevent urethral infections in males

Muscular System

- The Muscular System aids ejaculation of semen from male reproductive tract
- The reproductive system hormone testosterone accelerates skeletal muscle growth

Reproductive System

The reproductive system secretes hormones with effects on growth and metabolism. It:

- produces, stores, nourishes, and transports male and female gametes
- supports the developing embryo and fetus in the uterus

Chapter Review

Summary Outline

- **19-1** Basic reproductive system structures are gonads, ducts, accessory glands and organs, and external genitalia *p. 673*
- The human **reproductive system** produces, stores, nourishes, and transports functional **gametes** (reproductive cells). **Fertilization** is the fusion of male and female gametes.
- 2. The reproductive system includes **gonads (testes or ovaries)**, ducts, accessory glands and organs, and the **external genitalia**.
- **3.** In males, the testes produce **sperm**, which are expelled from the body in **semen** during *ejaculation*. The ovaries of a sexually mature female produce **oocytes** (immature **ova**) that travel along *uterine tubes* toward the *uterus*. The *vagina* connects the uterus with the exterior of the body.

19-2 Sperm formation (spermatogenesis) occurs in the testes, and hormones from the hypothalamus, pituitary gland, and testes control male reproductive functions *p.* 674

- **4.** In males, the *testes* produce **sperm**. The sperm travel along the *epididymis*, the *ductus deferens*, the *ejaculatory duct*, and the *urethra* before leaving the body. Accessory glands (*seminal glands, prostate,* and *bulbo-urethral glands*) secrete products into the ejaculatory ducts and urethra. The scrotum encloses the testes, and the penis is an erectile organ. (*Figure 19-1*)
- 5. The testes, the primary sex organ of males, hang within the scrotum. The dartos muscle gives the scrotum a wrinkled appearance. The cremaster muscle pulls the testes closer to the body. The tunica albuginea surrounds each testis. Septa subdivide each testis into a series of lobules. Seminiferous tubules within each lobule are the sites of sperm production. Between the seminiferous tubules are interstitial endocrine cells, which secrete sex hormones. (Figure 19-2)
- **6.** Seminiferous tubules contain **spermatogonia**, stem cells involved in **spermatogenesis**, and **nurse cells**, which sustain and promote the development of sperm. (*Figure 19-3*)
- 7. Each sperm has a **head, middle piece**, and **tail**. *(Figure 19-4)*
- 8. From the testis, the sperm enter the **epididymis**, a long tubule that regulates the composition of the tubular fluid and serves as a recycling center for damaged sperm. Sperm leaving the epididymis are functionally mature, yet immotile (unable to move).

- **9.** The **ductus deferens**, or *vas deferens*, begins at the epididymis and passes through the inguinal canal within the **spermatic cord**. The junction of the base of the seminal gland and the ampulla of the ductus deferens creates the **ejaculatory duct**, which penetrates the prostate and empties into the urethra. (*Figure 19-5*)
- **10.** The **urethra** extends from the urinary bladder to the tip of the penis and serves as a passageway for both the urinary and reproductive systems.
- 11. Each **seminal gland (seminal vesicle)**, is an active secretory gland that contributes about 60 percent of the volume of semen. Its secretions contain fructose, which is easily metabolized by sperm. The **prostate** secretes fluid that makes up about 30 percent of seminal fluid. Alkaline mucus secreted by the **bulbo-urethral glands** has lubricating properties. (*Figure 19-5*)
- **12.** A typical **ejaculation** expels 2–5 mL of semen (an **ejaculate**), which contains 20–100 million sperm per milliliter.
- 13. The skin overlying the **penis** resembles that of the scrotum. Most of the body of the penis consists of three masses of **erectile tissue**. There are two **corpora cavernosa** and a single **corpus spongiosum**, which surrounds the urethra. Dilation of the erectile tissue with blood produces an **erection**. (*Figure 19-6*)
- **4.** Important regulatory hormones of males include **gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH)**, and **luteinizing hormone (LH)**. Testosterone is the most important *androgen. (Spotlight Figure 19-7)*

19-3 Ovum production (oogenesis) occurs in the ovaries, and hormones from the pituitary gland and ovaries control female reproductive functions *p. 683*

- **15.** Principal organs of the female reproductive system include the *ovaries, uterine tubes, uterus, vagina,* and *external genitalia.* (*Figure 19-8*)
- 16. The ovaries are the primary sex organs of females. Ovaries are the site of ovum production, or oogenesis, which occurs in ovarian follicles. Follicle development proceeds from primordial ovarian follicles through primary, secondary, and tertiary ovarian follicles. During the ovarian cycle, a dominant tertiary ovarian follicle forms. At ovulation, a secondary oocyte and the attached follicular cells of the corona radiata are released through the ruptured ovarian wall. (Figures 19-9, 19-10)

- **17.** Each **uterine tube** has an **infundibulum**, a funnel that opens into the pelvic cavity. For fertilization to occur, a secondary oocyte must encounter sperm during the first 12–24 hours of its passage from the infundibulum to the uterine cavity. (*Figure 19-11*)
- 18. The uterus provides mechanical protection and nutritional support to the developing embryo. It is stabilized by various ligaments and mesenteries. Major anatomical landmarks of the uterus include the body, cervix, external os, uterine cavity, and internal os. The uterine wall consists of an inner endometrium, a muscular myometrium, and a superficial perimetrium. (Figure 19-11)
- **19.** A typical 28-day **uterine cycle**, or *menstrual cycle*, begins with the onset of **menstruation**, or **menses**, and the destruction of the *functional layer* of the endometrium. This process of menstruation continues from one to seven days.
- **20.** After the **menstrual phase**, the **proliferative phase** begins, and the functional layer undergoes repair and thickens. During the **secretory phase**, the uterine glands are active and the uterus is prepared for the arrival of an embryo. Menstrual activity begins at **menarche** and continues until **menopause**.
- **21.** The **vagina** is a muscular tube extending between the uterus and the external genitalia. A thin epithelial fold, the **hymen**, partially blocks the entrance to the vagina.
- **22.** The components of the **vulva** are the **vestibule**, **labia minora**, **clitoris**, **labia majora**, **mons pubis**, and **lesser** and **greater vestibular glands**. (*Figure 19-12*)
- **23.** A newborn infant is nourished by milk secreted by maternal **mammary glands.** Lactation is the process of milk production. (*Figure 19-13*)
- **24.** Regulation of the **female reproductive cycle** involves the coordination of the ovarian and uterine cycles by circulating hormones. *(Spotlight Figure 19-14)*
- **25. Estradiol**, one of the estrogens, is the dominant hormone of the **follicular phase** of the ovarian cycle. Estrogens have multiple functions that affect the activities of many tissues and organs. (*Spotlight Figure 19-14*)

26. The hypothalamic secretion of GnRH triggers the pituitary secretion of FSH and the synthesis of LH. FSH initiates follicle development, and activated follicles and ovarian interstitial cells produce estrogens. Ovulation occurs in response to a midcycle surge in LH secretion. **Progesterone** is the main hormone of the **luteal phase** of the ovarian cycle. Changes in estrogen and progesterone levels regulate the uterine, or menstrual, cycle. (*Spotlight Figure 19-14*)

19-4 The autonomic nervous system influences male and female sexual function *p. 695*

- 27. During sexual **arousal** in males, erotic thoughts, sensory stimulation, or both lead to parasympathetic activity that ultimately produces erection. Stimuli accompanying **sexual intercourse** lead to **emission** and **ejaculation**. Strong perineal muscle contractions are associated with **orgasm**.
- **28.** The phases of female sexual function resemble those of the male, with parasympathetic arousal and muscular contractions associated with orgasm.

19-5 With age, decreasing levels of reproductive hormones cause functional changes *p. 696*

- **29.** Menopause (when ovulation and menstruation cease) typically occurs around age 50. Production of GnRH, FSH, and LH rise, while circulating concentrations of estrogen and progesterone decline.
- **30.** During the **male climacteric**, at ages 50–60, circulating testosterone levels decline while levels of FSH and LH rise.

19-6 The reproductive system secretes hormones affecting growth and metabolism of all body systems *p. 697*

- **31.** Hormones play a major role in coordinating reproduction. *(Table 19-1)*
- **32.** In addition to the endocrine and reproductive systems, reproduction requires the normal functioning of the digestive, nervous, cardiovascular, and urinary systems.

Review Questions

Level 1 Reviewing Facts and Terms

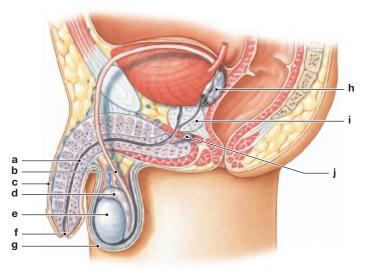

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A

- **COLUMN B** 1. gametes **a.** secretes progesterone 2. gonads 3. interstitial cells 4. seminal glands 5. prostate glands 6. bulbo-urethral glands 7. prepuce 8. corpus luteum 9. endometrium **10.** myometrium j. _____ **11.** dysmenorrhea **12.** menarche **13.** clitoris **14.** lactation
- **15.** sexual intercourse

- **b.** production of androgens c. muscular uterine wall d. secretions contain fructose e. female erectile tissue **f.** secretes thick, sticky, alkaline mucus
- g. painful menstruation
- **h.** coitus
- **i.** uterine lining
- reproductive cells
- k. first menstrual period
- 1. milk production
- **m.** secretes seminalplasmin
- n. reproductive organs
- o. foreskin of penis
- **16.** In adult males, the testes are responsible for the production
 - of
 - (a) seminal fluid.
 - (b) sperm.
 - (c) testosterone.
 - (d) b and c are correct.
- **17.** Testosterone is produced by the in the testis.
 - (a) interstitial cells
 - (b) nurse cells
 - (c) spermatogonia
 - (d) spermatozoa
- **18.** Spermatogenesis involves mitotic division of and meiotic division of ____
 - (a) spermatogonia; spermatocytes
 - (b) spermatogonia; spermatids
 - (c) spermatocytes; spermatids
 - (d) spermatids; spermatozoa
- 19. Spermatozoa entering the epididymis from the efferent ductules
 - (a) possess 23 pairs of chromosomes.
 - (b) are immotile.
 - (c) contain many lysosomes.
 - (d) have no nuclei.

- 20. The largest contribution to seminal fluid comes from the (a) bulbo-urethral glands.
 - (b) epididymis.
 - (c) prostate.
 - (d) seminal glands.
- **21.** The number of secondary oocytes(s) formed by the division of a primary oocyte during meiosis is
 - (a) one.
 - (b) two.
 - (c) three.
 - (**d**) four.
- **22.** Release of the secondary oocyte from the ovary into the pelvic cavity occurs at the
 - (a) beginning of the follicular phase.
 - (**b**) middle of the follicular phase.
 - (c) beginning of the luteal phase.
 - (d) middle of the luteal phase.
- 23. Identify the principal structures of the male reproductive system in the following diagram.

(h) _____ (i) _____ (j) _____

See the blue Answers tab at the back of the book.

24. Identify the principal structures of the female reproductive system in the following diagram.

(a)	(h)
(b)	(i)
(c)	(j)
(d)	(k)
(e)	(1)
(f)	(m)
(g)	

- 25. Fertilization usually takes place in the
 - (a) cervix.
 (b) uterine tube.
 (c) body of the uterus.
 (d) vagina.

An Introduction to Development and Inheritance

The physiological processes that we have studied so far take place fairly quickly. Many last only a fraction of a second, and others may take hours. But some important processes go on for months, years, or decades. A human develops in the womb for nine months, grows to maturity in 15 to 20 years, and may live the better part of a century. During that time, he or she is always changing. Birth, growth, maturation, aging, and death are all parts of one continuous process. That process does not end with the individual, because humans can pass at least some of their characteristics on to their offspring. Each generation gives rise to a new generation that will repeat the cycle.

In this chapter, we explore how genetic and environmental factors and various physiological processes affect prenatal development and also influence childhood, adolescence, maturity, and aging.

Build Your Knowledge

Recall that male and female gametes (sperm and oocytes) are formed through a special form of cell division called meiosis (as you saw in **Chapter 19: The Reproductive System**). This process involves two cycles of cell division, meiosis I and meiosis II. Meiosis I begins with diploid reproductive stem cells containing 46 chromosomes, composed of 23 pairs. The gametes formed as a result of completing meiosis II are haploid. Each gamete contains

23 individual chromosomes—one member of each of the 23 pairs present in the original reproductive stem cell. In males, sperm formation, or spermatogenesis, results in four haploid sperm cells. In females, ovum production, or oogenesis, produces one secondary oocyte, or immature ovum, in metaphase II. It does not complete meiosis II until fertilization, when it forms a second polar body and becomes a mature ovum. \bigcirc **pp. 676, 683**

20-1 Development is a continuous process that occurs from fertilization to maturity

Learning Outcome Explain the relationship between differentiation and development, and describe the various stages of development.

Time refuses to stand still. Today's infant will be tomorrow's adult. The gradual change in anatomical structures and physiological characteristics during the period from conception to maturity is called **development**. The changes are truly remarkable. In a mere nine months, a single cell slightly larger than the period at the end of this sentence becomes an individual whose body contains trillions of cells organized into tissues, organs, and organ systems.

The formation of increasingly specialized cell types in this process is called **cellular differentiation**. Cellular differentiation takes place through selective changes in genetic activity. As development proceeds, some genes are turned off and others are turned on. The kinds of genes turned off or on vary from one cell type to another. Development begins at **fertilization**, or **conception**, when the male and female gametes fuse. We can divide development into several periods. **Embryonic development** includes the events during the first two months after fertilization. The study of these events in the developing organism, or **embryo**, is called **embryology** (em-brē-OL-o-jē).

After two months, the developing embryo becomes a **fetus**. **Fetal development** begins at the start of the ninth week and continues until birth. Together, embryonic development and fetal development are referred to as **prenatal** (*natus*, birth) **development**, the primary focus of this chapter. **Postnatal development** begins at birth and continues to **maturity**, the state of full development or completed growth.

All humans go through the same developmental stages, but differences in genetic makeup produce distinctive individual characteristics. The term **inheritance** or **heredity** refers to the transfer of genetically determined characteristics from generation to generation. The study of the mechanisms of heredity, or *how* those characteristics are transferred, is called **genetics**. In this chapter we consider basic genetics as it applies to inherited characteristics such as sex, hair color, and various diseases.

CHECKPOINT

- **1.** Define cellular differentiation.
- 2. What event marks the beginning of development?
- **3.** Define inheritance.

See the blue Answers tab at the back of the book.

20-2 Fertilization—the fusion of a secondary oocyte and a sperm—forms a zygote

Learning Outcome Describe the process of fertilization.

Fertilization involves the fusion of two haploid gametes, each containing 23 chromosomes. The process produces a *zygote* with 46 chromosomes, the normal diploid number for a *somatic* (nonreproductive) cell.

An Overview of Fertilization

The roles and contributions of the male and female gametes are very different at fertilization. The sperm delivers the paternal (father's) chromosomes to the site of fertilization. It is small, highly streamlined, and driven by a flagellum. In contrast, the female oocyte provides all the cellular organelles, nourishment, and genetic programming needed to support development of the embryo for nearly a week after conception. At fertilization, the diameter of the secondary oocyte is more than twice the length of a sperm (**Figure 20-1a**). The ratio of their volumes is even more striking—roughly 2000 to 1.

The sperm deposited in the vagina are already motile, as a result of mixing with secretions of the seminal glands the first step of *capacitation*. ⊃ p. 679 However, they cannot accomplish fertilization until they have been exposed to conditions in the female reproductive tract. Uterine tube peg cell secretions help with capacitation, but the exact process is not yet known. ⊃ p. 687

Fertilization typically takes place in the upper one-third of a uterine tube within a day after ovulation. It takes sperm between 30 minutes and 2 hours to pass from the vagina to the upper portion of a uterine tube. Of the 200 million sperm in a typical ejaculation, only about 10,000 enter the uterine tube. Fewer than 100 actually reach the secondary oocyte. In general, a male with a sperm count below 20 million per milliliter is sterile because too few sperm survive to reach the oocyte. While it is true that only one sperm fertilizes an oocyte, dozens are required for successful fertilization. The additional sperm are necessary because, as we will see, a single sperm cannot penetrate the *corona radiata*, the layer of follicle cells that surrounds the oocyte. \bigcirc p. 687

Ovulation and Oocyte Activation

Ovulation takes place before the oocyte is completely mature. The secondary oocyte leaving the follicle is in metaphase of the second meiotic division (meiosis II). The cell's metabolic operations have been suspended as it awaits the stimulus for further development. If fertilization does not occur, the oocyte disintegrates without completing meiosis.

Fertilization and the events that follow are diagrammed in **Figure 20-1b**. The corona radiata protects the oocyte as it passes through the ruptured follicular wall and into the infundibulum of a uterine tube. The physical process of fertilization requires that only a single sperm contact the oocyte membrane, but that sperm must first get through the corona radiata. The acrosome of each sperm contains several enzymes, including *hyaluronidase* (hī-uh-lū-RON-i-dās). Hyaluronidase breaks down the bonds between adjacent follicle cells. Dozens of sperm cells must release hyaluronidase before an opening forms between the follicle cells.

No matter how many sperm slip through the resulting gap in the corona radiata, only a single sperm accomplishes fertilization and activates the oocyte (1), Figure 20-1b). That sperm cell first binds to *sperm receptors* in the zona pellucida, a thick envelope surrounding the oocyte. $\supset p. 685$ This binding triggers the rupture of the acrosome. Hyaluronidase and another proteolytic enzyme digest a path through the zona pellucida to the oocyte membrane. Upon contact, the sperm and oocyte membranes begin to fuse. This step triggers oocyte activation. As the membranes fuse, the entire sperm enters the cytoplasm of the oocyte.

Oocyte activation involves a series of changes in the metabolic activity of the oocyte. Vesicles located just interior to the oocyte membrane undergo exocytosis. They release enzymes that prevent *polyspermy*, or fertilization by more than one sperm. Polyspermy produces a zygote that cannot develop normally. Other important metabolic changes include the completion of meiosis II and a rapid increase in the oocyte's metabolic rate.

After oocyte activation and the completion of meiosis II, the nuclear material remaining within the ovum reorganizes into a *female pronucleus* (2), Figure 20-1b). At the same time, the nucleus of the sperm swells, becoming the *male pronucleus* (3). The male pronucleus and female pronucleus

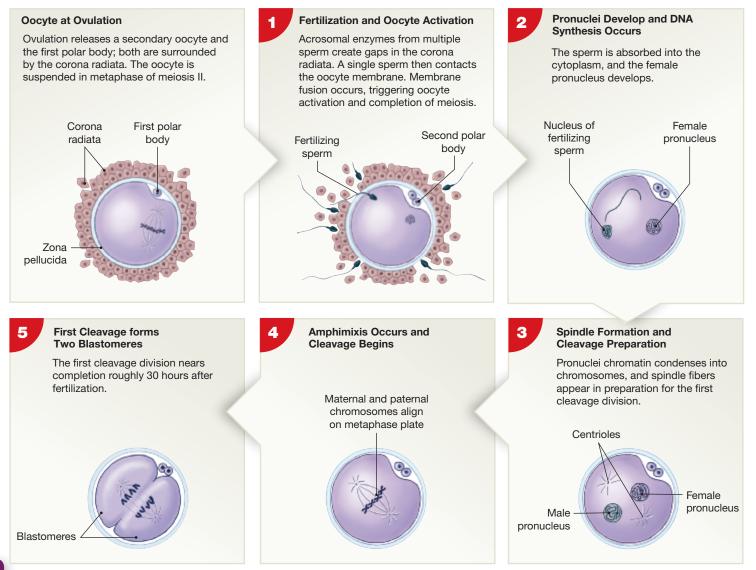

Figure 20-1 Fertilization.

a A secondary oocyte and numerous sperm at the time of fertilization. Notice the difference in size between the gametes. then fuse in a process called **amphimixis** (am-fi-MIK-sis; "both mixed together") (4). The cell is now a **zygote** (*zygon*, yoke). It contains the normal diploid number of 46 chromosomes and fertilization is complete. This is the "moment of conception." The first cleavage division yields two daughter cells (5). *Cleavage* is a series of cell divisions that subdivides the cytoplasm of the zygote.

CHECKPOINT

- **4.** What two important roles do the acrosomal enzymes of sperm play prior to fertilization?
- **5.** How many chromosomes are contained within a human zygote?
- See the blue Answers tab at the back of the book.

b Fertilization and the preparations for cleavage.

20

20-3 Gestation consists of three stages of prenatal development: the first, second, and third trimesters

Learning Outcome List the three stages of prenatal development, and describe the major events of each.

During prenatal development, a single cell ultimately forms a 3-4 kg (6.6-8.8 lb) infant. The time spent in prenatal development is known as **gestation** (jes-TĀ-shun), or *pregnancy*. Gestation takes place within the uterus over a period of nine months. Prenatal development is usually divided into three trimesters, each lasting three months:

- 1. The **first trimester** is the period of embryonic and early fetal development. During this period, the beginnings of all major organ systems appear.
- 2. The second trimester is dominated by the development of organs and organ systems. The process nears completion by the end of the sixth month. During this time, body shape and proportions change. By the end of this trimester, the fetus looks distinctively human.
- 3. The third trimester is characterized by rapid fetal growth and deposition of adipose tissue. Early in the third trimester most of the major organ systems become fully functional. An infant born one month or even two months prematurely has a reasonable chance of survival.

CHECKPOINT

6. Define gestation.

7. Describe the key features of each trimester.

See the blue Answers tab at the back of the book.

20-4 Critical events of the first trimester are cleavage, implantation, placentation, and embryogenesis

Learning Outcome Explain how the three germ layers are involved in forming the extra-embryonic membranes, and discuss the importance of the placenta as an endocrine organ.

At the moment of conception, a fertilized ovum is a single cell. It is about 0.135 mm (0.005 in.) in diameter and weighs approximately 150 μ g. By convention, pregnancies are clinically dated from the last menstrual period (LMP), which is usually two weeks before ovulation and conception. At the end of the first trimester (12 weeks from LMP, only 10 developmental weeks), the fetus is almost 5.4 cm (2.13 in.) long and weighs about 14 g (0.5 oz).

Many complex and vital developmental events accompany this increase in size and weight. Perhaps because the events are so complex, it is the most dangerous prenatal stage. Only about 40 percent of conceptions produce embryos that survive the first trimester. For that reason, pregnant women are advised to take great care to avoid drugs, alcohol, tobacco, and other disruptive stresses during this period.

In the sections that follow we focus on four general processes of the first trimester: cleavage and blastocyst formation, implantation, placentation, and embryogenesis.

Cleavage and Blastocyst Formation

Cleavage (KLEV-ij) is a series of cell divisions that begins immediately after fertilization. It produces an ever-increasing number of smaller and smaller daughter cells called **blastomeres** (BLAS-tō-mērz; *blast*, precursor + *meros*, part) (Figure 20-2). The first cleavage division produces two daughter cells. Each is half the size of the original zygote. The first division is completed roughly 30 hours after fertilization, and subsequent cleavage divisions occur at intervals of 10-12 hours.

During cleavage, the zygote becomes a pre-embryo. After three days of cleavage, the pre-embryo is a solid ball of cells resembling a mulberry (Figure 20-2). This stage is called the morula (MOR-ū-la; morula, mulberry). The morula typically reaches the uterus on day 4.

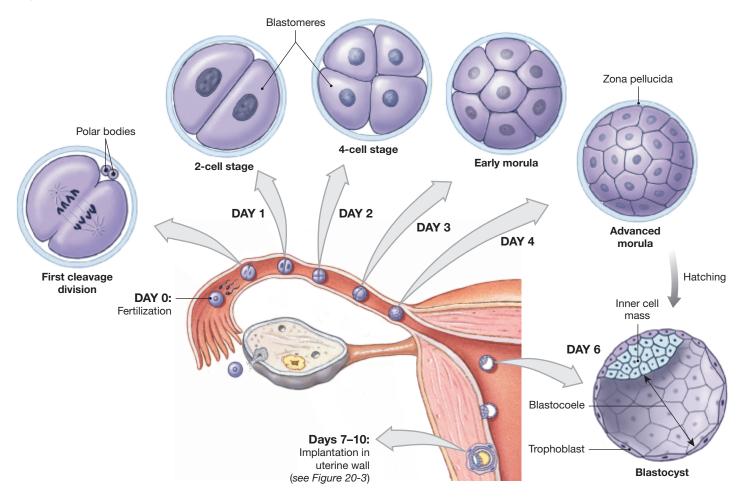

Over the next two days, the blastomeres form a **blastocyst**, a hollow ball with an inner cavity known as the blastocoele (BLAS-tō-sēl; koiloma, cavity). The blastomeres are now no longer identical in size and shape. The outer layer of cells separating the outside world from the blastocoele is called the trophoblast (TRO-fo-blast). As the word trophoblast implies (trophos, food + blast, precursor), cells in this layer provide food to the developing embryo. A second group of cells, the inner cell mass, lies clustered in one portion of the blastocyst. In time, the inner cell mass will form the embryo.

During blastocyst formation, the zona pellucida is shed in a process known as hatching. The blastocyst is now freely exposed to the fluid contents of the uterine cavity. This glycogen-rich fluid, secreted by the uterine glands, provides nutrients to the blastocyst. When fully formed, the blastocyst contacts the endometrium, and implantation begins.

Implantation

Implantation (Figure 20-3) begins as the blastocyst surface next to the inner cell mass adheres to the uterine lining (day 7, Figure 20-3). At the point of contact, the trophoblast cells divide rapidly, making the trophoblast several layers thick. 20

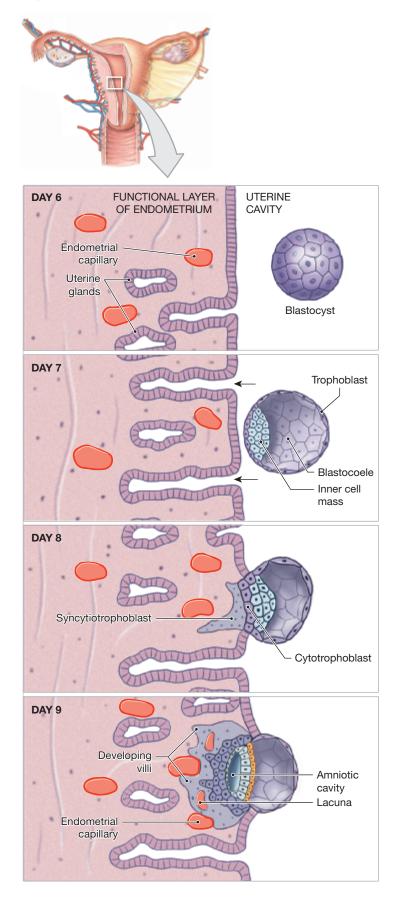

The trophoblast cells closest to the interior of the blastocyst remain intact, forming a cellular layer called the *cytotrophoblast* (day 8, **Figure 20-3**). Near the uterine wall, the cell membranes separating the trophoblast cells disappear, creating a layer of cytoplasm containing multiple nuclei. This outer layer is called the *synciotrophoblast*. It erodes a path through the uterine epithelium by secreting hyaluronidase. At first, this erosion creates a gap in the uterine lining, but the division and migration of uterine epithelial cells soon repair the surface. By day 10, repairs are complete, and the blastocyst no longer contacts the uterine cavity. Further development occurs entirely within the functional layer of the endometrium.

In most cases, implantation occurs in the fundus or elsewhere in the body of the uterus. In an **ectopic pregnancy**, implantation occurs somewhere other than within the uterus, such as in one of the uterine tubes. Approximately 0.6 percent of pregnancies are ectopic pregnancies. They do not produce a viable embryo and can be life-threatening to the mother. As implantation proceeds, the synciotrophoblast continues to enlarge into the surrounding endometrium (day 9, **Figure 20-3**). The synciotrophoblast absorbs nutrients released by the erosion of uterine gland cells. The nutrients then diffuse through the underlying *cytotrophoblast* to the inner cell mass. These nutrients provide the energy for the early stages of embryo formation. Trophoblast extensions grow around endometrial capillaries. As the capillary walls are destroyed, maternal blood begins to flow through trophoblastic channels known as *lacunae* (*lacuna*, singular). Fingerlike *villi* extend away from the trophoblast into the surrounding endometrium. The villi gradually increase in size and complexity as development proceeds.

Formation of the Amniotic Cavity

By the time of implantation, the inner cell mass has separated from the trophoblast. The separation gradually enlarges, creating a fluid-filled chamber called the **amniotic** (am-nē-OT-ik)

Figure 20-3 Events in Implantation.

cavity (day 9, **Figure 20-3**; details from days 10–15 are shown in **Figure 20-4**). When the amniotic cavity first appears, cells of the inner cell mass are organized into an oval sheet that is two cell layers thick. A superficial layer faces the amniotic cavity and a deeper layer is exposed to the fluid contents of the blastocoele.

Gastrulation and Germ Layer Formation

By day 15, a third layer of cells begins to form between the superficial and deep layers of cells of the inner cell mass through the process of **gastrulation** (gas-troo-LĀ-shun) (day 15, **Figure 20-4**). The superficial layer is called *ectoderm*, the deep layer *endo-derm*, and the migrating cells *mesoderm*. Together, the three layers of cells are called *germ layers*. **Table 20-1** lists the contributions each germ layer makes to the body's organ systems.

The Formation of Extra-embryonic Membranes

The germ layers also form four **extra-embryonic mem-branes** that support embryonic and fetal development: the *yolk sac,* the *amnion,* the *allantois,* and the *chorion.* **Spotlight Figure 20-5** illustrates and describes the development of these extra-embryonic membranes.

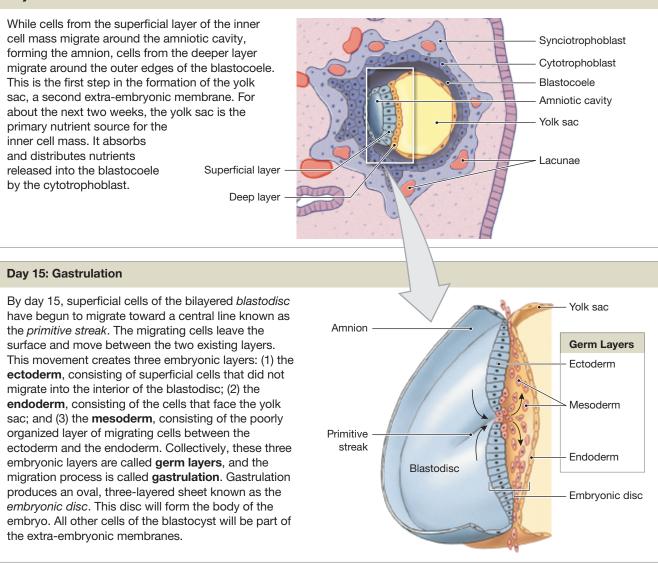

YOLK SAC. The first extra-embryonic membrane to appear is the **yolk sac**. The yolk sac, already present 10 days after fertilization, forms a pouch within the blastocoele (**Figure 20-4**). As gastrulation proceeds, mesodermal cells migrate around this pouch and complete the formation of the yolk sac (week 2, **Spotlight Figure 20-5**). Blood vessels soon appear within the mesoderm. The yolk sac becomes an important site of blood cell formation.

AMNION. The **amnion** (AM-nē-on) is composed of both ectoderm and mesoderm. Ectodermal cells first spread over the inner surface of the amniotic cavity and, soon after, mesodermal cells follow and create a second, outer layer. As the embryo and later the fetus enlarges, the amnion continues to expand, increasing the size of the amniotic cavity (week 3, **Spotlight Figure 20-5**). The amnion contains *amniotic fluid,* which surrounds and cushions the developing embryo and fetus (week 10, **Spotlight Figure 20-5**).

THE ALLANTOIS. The **allantois** (a-LAN-tō-is) is a sac of endoderm and mesoderm that extends away from the embryo (week 3, **Spotlight Figure 20-5**). The base of the allantois later gives rise to the urinary bladder. The allantois accumulates some of the small amount of urine produced by the kidneys during embryonic development.

Day 10: Yolk Sac Formation

THE CHORION. The **chorion** (KŌ-rē-on) is created as migrating mesodermal cells form a layer beneath the trophoblast, separating it from the blastocoele (weeks 2 and 3, **Spotlight Figure 20-5**). When implantation first occurs, the nutrients absorbed by the trophoblast can easily reach the inner cell mass by diffusion. But as the embryo and trophoblast enlarge, the distance between them increases, and diffusion alone cannot keep pace with the demands of the embryo. Blood vessels now begin to develop within the mesoderm of the chorion, creating a rapid-transit system for nutrients that links the embryo with the trophoblast.

Placentation

The **placenta** is a temporary structure in the uterine wall that provides a site for diffusion between the fetal and maternal circulations. **Placentation** (pla-sen-TĀ-shun), or *placenta formation*, takes place when blood vessels form in the chorion around the periphery of the blastocyst. By week 3 of development, the mesoderm extends along each of the trophoblastic villi, forming *chorionic villi* in contact with maternal tissues (**Spotlight Figure 20-5**). Embryonic blood vessels develop in each villus. Circulation through these chorionic vessels begins early in week 3,

Table 20-1 Contributions of the Germ Layers to the Body's Organ Systems

ECTODERMAL CONTRIBUTIONS

Integumentary system: epidermis, hair follicles and hairs, nails, and glands communicating with the skin (sweat glands, mammary glands, and sebaceous glands)

Skeletal system: pharyngeal cartilages of the embryo develop into portions of sphenoid and hyoid bones, auditory ossicles, and the styloid processes of the temporal bones
Nervous system: all nervous tissue, including brain and spinal cord
Endocrine system: pituitary gland and the adrenal medullae
Respiratory system: mucous epithelium of nasal passageways
Digestive system: mucous epithelium of mouth and anus, salivary glands
MESODERMAL CONTRIBUTIONS
Integumentary system: dermis (and subcutaneous layer)
Skeletal system: all structures except some pharyngeal cartilage derivatives
Muscular system: all structures
Endocrine system: adrenal cortex, endocrine tissues of heart, kidneys, and gonads
Cardiovascular system: all structures
Lymphatic system: all structures
Urinary system: the kidneys, including the nephrons and the initial portions of the collecting system
Reproductive system: the gonads and the adjacent portions of the duct systems
Miscellaneous: the lining of the pleural, pericardial, and peritoneal cavities and the connective tissues that support all organ systems
ENDODERMAL CONTRIBUTIONS
Endocrine system: thymus, thyroid gland, and pancreas
Respiratory system: respiratory epithelium (except nasal passageways) and associated mucous glands
Digestive system: mucous epithelium (except mouth and anus), exocrine glands (except salivary glands), liver, and pancreas
Urinary system: urinary bladder and distal portions of the duct system
Reproductive system: distal portions of the duct system, stem cells that produce gametes

when the heart starts beating. These villi continue to enlarge and branch, forming an intricate network within the endometrium. Blood vessels continue to be eroded, and maternal blood flows slowly through the lacunae. Chorionic blood vessels pass close by, and gases and nutrients diffuse between the embryonic and maternal circulations across the trophoblast layers.

At first, the entire blastocyst is surrounded by chorionic villi. The chorion continues to enlarge, expanding like a balloon within the endometrium. By week 4, the embryo, amnion, and yolk sac are suspended within an expansive, fluid-filled chamber. The *body stalk*, the connection between the embryo and the chorion, contains the distal portions of the allantois and blood vessels that carry blood to and from the placenta. The narrow connection between the endoderm of the embryo and the yolk sac is called the *yolk stalk*. As the end of the first trimester approaches, the fetus moves farther away from the placenta. The yolk stalk and body stalk begin to fuse, forming an *umbilical stalk* (week 5, **Spotlight Figure 20-5**). By week 10, the fetus floats free within the amniotic cavity. The fetus remains connected to the placenta by the tubelike **umbilical**

cord, which contains the allantois, placental blood vessels, and the yolk stalk (week 10, **Spotlight Figure 20-5**).

Placental Circulation

Figure 20-6 diagrams the circulation at the placenta near the end of the first trimester. Deoxygenated blood flows from the developing embryo or fetus to the placenta through the paired **umbilical arteries**. Oxygenated blood returns to the developing embryo or fetus in a single **umbilical vein**. ⊃ p. 492 The chorionic villi provide the surface area for the active and passive exchanges of gases, nutrients, and wastes between the fetal and maternal bloodstreams.

The Endocrine Placenta

In addition to its role in the nutrition of the fetus, the placenta acts as an endocrine organ. Several hormones are synthesized by the syncytial trophoblast and released into the maternal blood-stream. They include *human chorionic gonadotropin, progesterone, estrogens, human placental lactogen, placental prolactin,* and *relaxin.*

SPOTLIGHT Figure 20-5 EXTRA-EMBRYONIC MEMBRANES AND PLACENTA FORMATION

The germ layers introduced in Figure 20-4 also form four **extra-embryonic membranes: (1)** The **yolk sac** (endoderm and mesoderm), (2) the **amnion** (ectoderm and mesoderm), (3) the **allantois** (endoderm and mesoderm), and (4) the **chorion** (mesoderm and trophoblast). These membranes support embryonic and fetal development, but few traces of their existence remain in adults.

Yolk sac

The yolk sac begins as a layer of cells spreads out around the outer edges of the blastocoele to form a complete pouch. It is the primary nutrient source for early embryonic development, and becomes an important site for blood cell formation.

Amnion

Ectodermal cells spread over the inner surface of the amniotic cavity, soon followed by mesodermal cells. Amniotic fluid is produced, which cushions the developing embryo.

Week 2

Chorion

Migration of mesoderm around the inner surface of the cytotrophoblast forms the chorion. Mesodermal migration around the outside of the amniotic cavity, between the ectodermal cells and the trophoblast, forms the amnion. Mesodermal migration around the endodermal pouch creates the yolk sac.

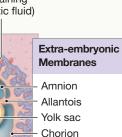

Week 3

The embryonic disc bulges into the amniotic cavity at the head fold. The allantois, an endodermal extension surrounded by mesoderm, extends toward the trophoblast.

Mesoderm Cytotrophoblast Amnion

Blastocoele Yolk Syncytiosac trophoblast Amniotic cavity (containing amniotic fluid)

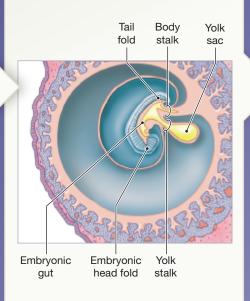

Week 4

3

The embryo now has a head fold and a tail fold. Constriction of the connections between the embryo and the surrounding trophoblast narrows the yolk stalk and body stalk.

Allantois

The allantois begins as an outpocket of the endoderm near the base of the yolk sac. The free endodermal tip then grows toward the wall of the blastocyst, surrounded by a mass of mesodermal cells. The base of the allantois eventually gives rise to the urinary bladder.

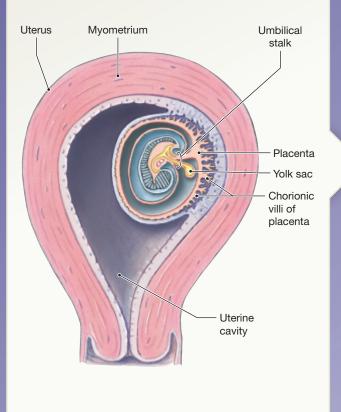

Chorion

The mesoderm associated with the allantois spreads around the entire blastocyst, separating the cytotrophoblast from the blastocoele. The appearance of blood vessels in the chorion is the first step in the creation of a functional placenta. By the third week of development, the mesoderm extends along the core of each trophoblastic villus, forming chorionic villi in contact with maternal tissues and blood vessels. These villi continue to enlarge and branch, forming the placenta, the exchange platform between mother and fetus for nutrients, oxygen, and wastes.

4 v

Week 5

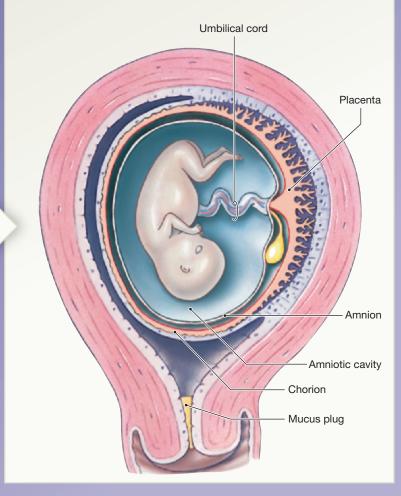

The developing embryo and extra-embryonic membranes bulge into the uterine cavity. The trophoblast pushing out into the uterine cavity remains covered by endometrium but no longer participates in nutrient absorption and embryo support. The embryo moves away from the placenta, and the body stalk and yolk stalk fuse to form an umbilical stalk.

Week 10

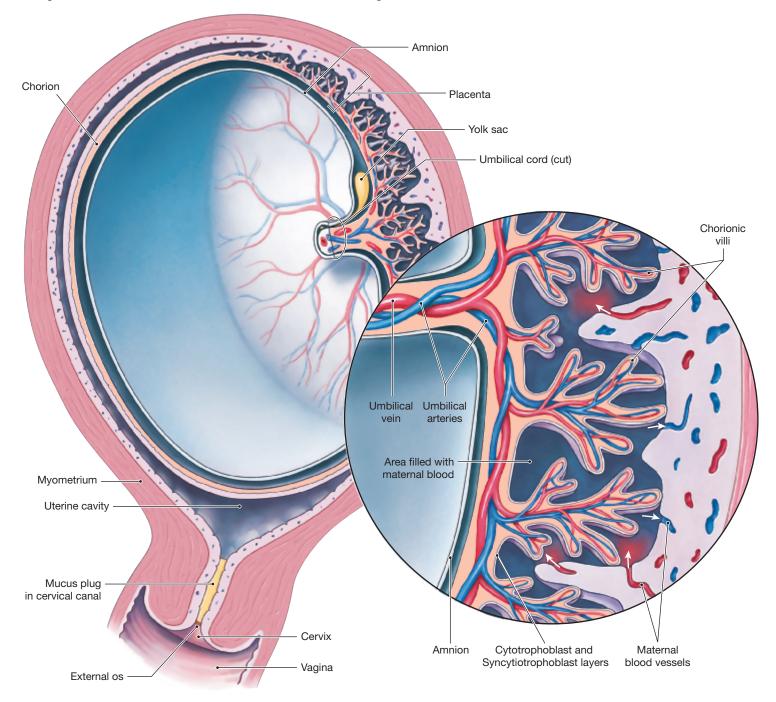

5

The amnion has expanded greatly, filling the uterine cavity. The fetus is connected to the placenta by an elongated umbilical cord that contains a portion of the allantois, blood vessels, and the remnants of the yolk stalk.

716 DEVELOPMENT AND INHERITANCE

Figure 20-6 The Placenta and Placental Circulation. A view of the uterus after the embryo has been removed and the umbilical cord cut. Oxygenated blood flows from the mother into the placenta through ruptured maternal arteries. It then flows around chorionic villi that contain fetal blood vessels. Deoxygenated fetal blood enters the chorionic villi in paired umbilical arteries, and oxygenated blood then leaves in a single umbilical vein. Deoxygenated maternal blood re-enters the mother's venous system through the broken walls of small uterine veins. Note that no mixing of maternal and fetal blood occurs.

Human chorionic $(k\bar{o}\mbox{-}r\bar{e}\mbox{-}ON\mbox{-}ik)$ gonadotropin (hCG)

appears in the maternal bloodstream soon after implantation. Its presence in blood or urine samples is a reliable indicator of pregnancy. Home pregnancy tests detect this hormone. Like luteinizing hormone (LH), hCG maintains the corpus luteum and promotes the continued secretion of progesterone. As a result, the endometrial lining remains perfectly functional, and menses does not occur. Without hCG, the

pregnancy ends, because another uterine cycle begins and the functional layer of the endometrium disintegrates.

In the presence of hCG, the corpus luteum persists for three to four months before gradually shrinking. The decline of the corpus luteum does not trigger the return of uterine (menstrual) cycles, because by the end of the first trimester, the placenta is actively secreting both progesterone and estrogens.

After the first trimester, the placenta produces enough progesterone to maintain the endometrial lining and continue the pregnancy. As the end of the third trimester approaches, estrogen production accelerates. The rising estrogen levels play a role in stimulating labor and delivery.

Human placental lactogen (hPL) and placental prolactin help prepare the mammary glands for milk production. The conversion of the mammary glands from resting to active status requires placental hormones (hPL, placental prolactin, estrogen, and progesterone) and several maternal hormones (growth hormone, prolactin, and thyroid hormones).

Relaxin is a hormone secreted by both the placenta and the corpus luteum during pregnancy. Relaxin (1) increases the flexibility of the pubic symphysis, permitting the pelvis to expand during delivery; (2) causes the cervix to dilate, making it easier for the fetus to enter the vaginal canal; and (3) suppresses the release of oxytocin by the hypothalamus and delays the onset of labor contractions.

Embryogenesis

Shortly after gastrulation begins, the body of the embryo begins to separate itself from the rest of the embryonic disc. The body of the embryo and its internal organs start to form. The process of embryo formation is called embryogenesis (em-brē-ō-JEN-e-sis). It begins as folding and differential growth of the embryonic disc produce a bulge that projects into the amniotic cavity (Spotlight Figure 20-5 (2)). This bulge is known as the head fold. Similar movements lead to the formation of a *tail fold* (**Spotlight Figure 20-5 3**). By this time, the embryo can be seen to have dorsal and ventral surfaces and left and right sides. The changes in proportions and appearance that occur between week 3 of development and the end of the first trimester are presented in Figure 20-7.

The first trimester is a critical period for development. Events during these first 12 weeks establish the basis for organogenesis, the process of organ formation. Table 20-2 includes important developmental milestones, including those during the first trimester.

CHECKPOINT

- 8. What is the developmental fate of the inner cell mass of the blastocyst?
- 9. Sue's pregnancy test indicates an elevated level of the hormone hCG (human chorionic gonadotropin). Explain whether she is pregnant or not.
- 10. What are two important functions of the placenta?
- See the blue Answers tab at the back of the book.

20-5 During the second and third trimesters, maternal organ systems support the developing fetus, and the uterus undergoes structural and functional changes

Learning Outcome Describe the interplay between maternal organ systems and the developing fetus, and discuss the structural and functional changes in the uterus during gestation.

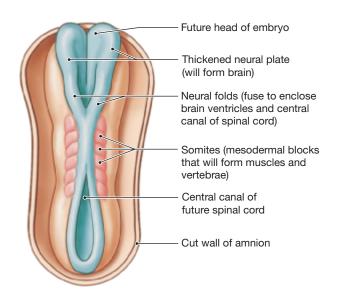

The basic elements of all the major organ systems have formed by the end of the first trimester. Over the next three months, the fetus grows to a weight of about 0.64 kg (1.4 lb). Encircled by the amnion, the fetus grows faster than the surrounding placenta during this second trimester. When the outer surface of the amnion contacts the inner surface of the chorion, these layers fuse. Figure 20-8a shows a four-month-old fetus. Figure 20-8b shows a six-month-old fetus. The changes in body form that occur during the first trimester and part of the second trimester are shown in the upper portion of Figure 20-9 on p. 722.

During the third trimester, most of the organ systems become ready to perform their normal functions. The rate of growth starts to slow, but in absolute terms, this trimester sees the greatest weight gain. In the last three months of gestation, the fetus gains about 2.6 kg (5.7 lb), reaching a full-term weight of about 3.2 kg (7 lb). Highlights in organ system development during the second and third trimesters are noted in Table 20-2 on pp. 720 and 721.

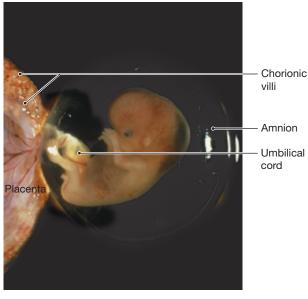

The Effects of Pregnancy on Maternal **Systems**

The developing fetus is totally dependent on maternal organ systems for nourishment, respiration, and waste removal. The mother must absorb enough oxygen, nutrients, and vitamins for herself and her fetus. She must also eliminate all the wastes that are generated. This is not a burden over the beginning weeks of gestation, but the demands placed on the mother 20

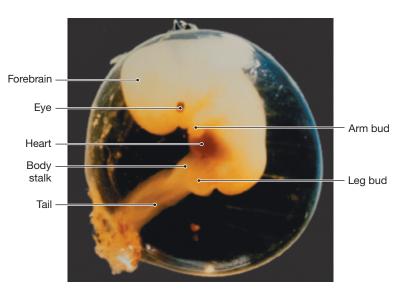

a Week 3. Diagram showing the formation of the CNS from neural plate ectoderm (about 2.25 mm in size).

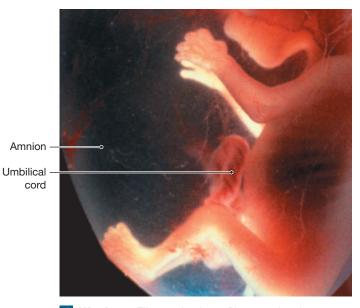

c Week 8. Fiberoptic view of human development at week 8 (about 1.6 cm in size).

become significant as the fetus grows. For the mother to survive under these conditions, maternal systems must make major adjustments. In practical terms, the mother must breathe, eat, and excrete for two. The major changes in maternal systems include the following:

• *Maternal respiratory rate increases and tidal volume increases.* As a result, the mother's lungs deliver the

Week 4. Fiberoptic view of human development at week 4 (about 5 mm in size).

d Week 12. Fiberoptic view of human development at week 12 (about 5.4 cm in size).

extra oxygen required and remove the excess carbon dioxide the fetus generates.

• *Maternal blood volume increases.* This increase occurs for two reasons. (1) Blood flowing into the placenta reduces the volume in the rest of the systemic circuit. (2) Fetal activity both decreases blood P_{O2} and increases blood P_{CO2}. The latter combination stimulates the production of

Figure 20-8 Fetal Development in the Second and Third Trimesters.

a A four-month-old fetus, seen through a fiber optic endoscope (about 13.3 cm in size)

renin and erythropoietin (EPO) by the kidneys, leading to an increase in maternal blood volume (see Figure 13-10, p. 476). By the end of gestation, maternal blood volume has increased by almost 50 percent.

- Maternal requirements for nutrients increase 10-30 percent. Pregnant women tend to have increased sensations of hunger because they must nourish both themselves and their fetus.
- Maternal glomerular filtration rate increases by roughly 50 percent. This increase corresponds to the increase in blood volume and speeds up the excretion of metabolic wastes generated by the fetus. Pregnant women need to urinate frequently because the volume of urine produced increases and the weight of the uterus presses down on the urinary bladder.
- The uterus undergoes a tremendous increase in size. Structural and functional changes in the expanding uterus are so important that we will discuss them in a separate section.

b Head of a six-month-old fetus, revealed through ultrasound (about 30 cm in size)

• The mammary glands increase in size, and secretory activity begins. By the end of the sixth month of pregnancy, the mammary glands are fully developed and begin to produce clear secretions that are stored in the duct system of those glands.

Structural and Functional Changes in the Uterus

At the end of gestation, a typical uterus will have grown from 7.5 cm (3 in.) to 30 cm (12 in.) in length, and from 60 g (2 oz) to 1100 g (2.4 lb) in weight. The uterus may then contain 2 liters of fluid, plus fetus and placenta, for a total weight of about 6-7 kg (13-15.4 lb). This remarkable expansion occurs through the enlargement of existing cells, especially smooth muscle cells, rather than by an increase in the total number of cells.

The tremendous stretching of the uterus is associated with a gradual increase in the rates of spontaneous smooth muscle **20**

contractions in the myometrium. In the early stages of pregnancy, the contractions are weak, painless, and brief. Evidence indicates that progesterone from the placenta has an inhibitory effect on uterine smooth muscle, preventing more extensive and powerful contractions.

After nine months of gestation, several factors interact to produce **labor contractions** in the myometrium of the uterine wall. Once begun, positive feedback ensures that the contractions continue until delivery has been completed. **Figure 20-10** diagrams important placental and fetal factors that initiate labor and delivery.

The initial cause for the onset of labor may be events in the fetus rather than in the mother. When labor begins, the fetal pituitary gland secretes oxytocin, which is released into the maternal bloodstream at the placenta. This may be the actual trigger for the onset of labor, as it increases myometrial contractions and prostaglandin production, on top of the priming effects of estrogens and maternal oxytocin.

CHECKPOINT

- **11.** List the major changes that take place in maternal systems during pregnancy.
- **12.** Why does a mother's blood volume increase during pregnancy?
- **13.** By what means does the uterus greatly increase in size and weight during pregnancy?
- **14.** Identify three major factors opposing the calming action of progesterone on the uterus.
- See the blue Answers tab at the back of the book.

Placental Factors Fetal Factors Growth and the Fetal pituitary Placental estrogens increase the sensitivity of the smooth Relaxin produced muscle cells of the myometrium and make contractions by the placenta increase in fetal releases more likely. As delivery approaches, the production of weight stretches oxytocin in relaxes the pelvic estrogens accelerates. Estrogens also increase the articulations and and distorts the response to sensitivity of smooth muscle fibers to oxytocin. dilates the cervix. myometrium. estrogens. **Distortion of Stretched Myometrium** Distortion of the myometrium increases the sensitivity of the smooth muscle layers, promoting spontaneous contractions that get stronger and more frequent as the pregnancy advances. Labor contractions move the fetus and further distort the myometrium. This Maternal Oxytocin Release **Prostaglandin Production** distortion stimulates additional oxytocin Maternal oxytocin release is Estrogens and oxytocin stimulate the production of and prostaglandin stimulated by high estrogen levels prostaglandins in the endometrium. These prostaglandins release. This positive and by distortion of the cervix. further stimulate smooth muscle contractions. feedback continues until delivery is completed. Increased Excitability of the Myometrium Oxytocin and prostaglandins both stimulate the myometrium. In addition, the sensitivity of the uterus to oxytocin increases dramatically. The smooth muscle in a late-term uterus is 100 times more sensitive to oxytocin than the smooth muscle in a nonpregnant uterus.

Figure 20-10 Factors Involved in the Initiation of Labor and Delivery.

LABOR CONTRACTIONS OCCUR

20-6 Labor consists of the dilation, expulsion, and placental stages

Learning Outcome List and discuss the events that occur during labor and delivery.

The goal of labor is **parturition** (par-tū-RISH-un), or *childbirth*, the forcible expulsion of the fetus from the uterus. During labor, each uterine contraction begins near the superior portion of the uterus and sweeps in a wave toward the cervix. The contractions are strong and occur at regular intervals. As parturition approaches, the contractions increase in force and frequency, changing the position of the fetus and moving it toward the cervical canal.

The Stages of Labor

Labor consists of three stages: the *dilation stage*, the *expulsion stage*, and the *placental stage* (Figure 20-11).

- The dilation stage begins with the onset of labor, as the cervix dilates and the fetus begins to shift toward the cervical canal (1) in Figure 20-11). This stage is highly variable in length but typically lasts eight or more hours. At first, labor contractions last up to one minute and occur once every 10–30 minutes. Their frequency increases steadily. Late in this stage, the amnion usually ruptures. This event is sometimes referred to as the woman having her "water break."
- The expulsion stage begins as the cervix, pushed open by the approaching fetus, dilates completely to about 10 cm (4 in.) (2 in Figure 20-11). In this stage, contractions reach maximum intensity. Expulsion continues until the fetus has emerged from the vagina. In most cases, the expulsion stage lasts less than two hours. The arrival of the newborn into the outside world is delivery, or birth.

If the vaginal canal is too small to permit the passage of the fetus, posing acute danger of perineal tearing, a clinician may temporarily enlarge the passageway by performing an **episiotomy** (e-piz-ē-OT-o-mē), an incision through the perineal musculature. After delivery, this surgical cut can be repaired with sutures, a much simpler procedure than suturing the jagged edges associated with an extensive perineal tear.

If complications arise during the dilation or expulsion stage, the infant can be surgically removed by **cesarean section**, or "*C*-section." In such cases, an incision is made through the abdominal wall, and the uterus is

opened just enough to allow passage of the infant's head. Final 2016 data released in 2018 from the CDC's National Vital Statistics System showed that cesarean deliveries dropped to 31.9 percent of all live births in 2016, after peaking at 32.9 percent in 2009.

3. During the **placental stage** of labor, muscle tension builds in the walls of the partially empty uterus, which gradually decreases in size (3) in Figure 20-11). This uterine contraction tears the connections between the endometrium and the placenta. In general, within an hour of delivery, the placental stage ends with the ejection of the placenta, or *afterbirth*. The disruption of the placenta is accompanied by a loss of blood. This loss can normally be tolerated without difficulty because maternal blood volume has increased greatly during pregnancy.

Premature Labor

Premature labor occurs when labor contractions begin before the fetus has completed normal development. The newborn's chances of survival are directly related to its body weight at delivery. Even with massive supportive efforts, newborns weighing less than 400 g (14 oz) at birth will not survive, primarily because their respiratory, cardiovascular, and urinary systems are unable to support life. As a result, the dividing line between spontaneous abortion and **immature delivery** is usually set at a body weight of 500 g (17.6 oz), the normal weight near the end of the second trimester.

Most fetuses born at 25–27 weeks of gestation (a birth weight under 600 g or 21.1 oz) die despite intensive neonatal care. Survivors have a high risk of developmental abnormalities. **Premature delivery** usually refers to birth at 28–36 weeks (a birth weight over 1 kg or 2.2 lb). With care, these newborns have a good chance of surviving and developing normally.

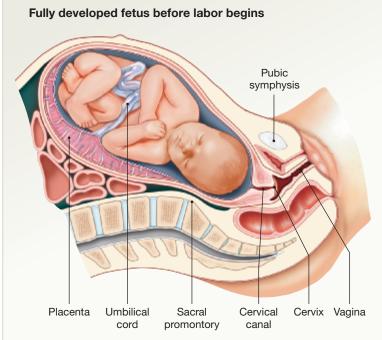

Multiple Births

Multiple births (twins, triplets, quadruplets, and so on) can take place for several reasons. The ratio of twin births to single births in the U.S. population is roughly 1:89. "Fraternal twins," or **dizygotic** (dī-zī-GOT-ik) **twins**, develop when two separate oocytes are ovulated and fertilized. Fraternal twins can be of the same or different sexes. About 70 percent of all twins are fraternal.

"Identical twins," or **monozygotic twins**, result either from the separation of blastomeres early in cleavage or from the

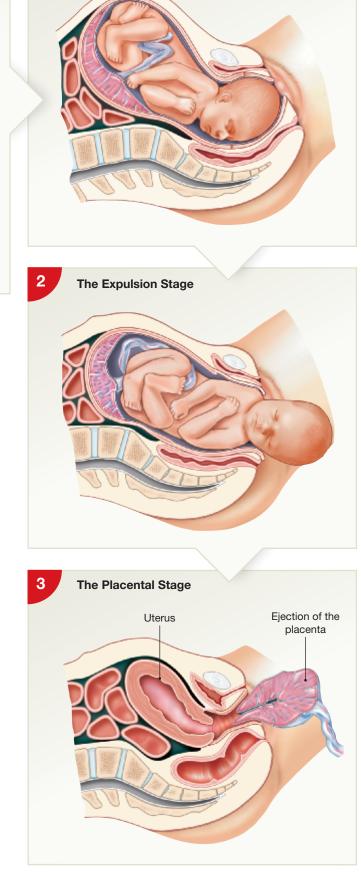

The Dilation Stage

Figure 20-11 The Stages of Labor.

splitting of the inner cell mass before gastrulation. In either event, the genetic makeup and sex of the pair are identical because both twins formed from the same pair of gametes. Identical twins occur in about 30 percent of all twin births. Triplets and larger multiple births can result from the same processes that produce twins. Taking fertility drugs that stimulate the maturation of abnormally large numbers of follicles can increase the incidence of multiple births.

If the splitting of the blastomeres or of the embryonic disc is not complete, **conjoined** (*Siamese*) **twins** may develop. These genetically identical twins typically share some skin, a portion of the liver, and perhaps other internal organs as well. When the fusion is minor, the infants can be surgically separated with some success. Most conjoined twins with more extensive fusions fail to survive because their organs cannot support them.

CHECKPOINT

- **15.** Name the three stages of labor.
- **16.** What is the difference between immature delivery and premature delivery?
- **17.** What are the biological terms for fraternal twins and identical twins?
- See the blue Answers tab at the back of the book.

Build Your Knowledge

Recall that the umbilical arteries that carry deoxygenated blood from the fetus to the placenta arise from the fetus's internal iliac arteries (as you saw in **Chapter 13: The Cardiovascular System: Blood Vessels and Circulation**). The umbilical vein carries oxygenated blood from the placenta into the fetus's developing liver. There, the oxygenated blood passes through the ductus venosus, mixes with deoxygenated blood from the liver's network of veins, and then drains into the inferior vena cava. This blood bypasses the pulmonary circuit due to two fetal circulatory features. Blood from the right atrium either (1) flows directly into the left atrium through the foramen ovale, or interatrial opening, or (2) into the right atrium from where it enters the systemic circuit through a short muscular vessel called the ductus arteriosus. At birth, blood quickly begins to flow in the pulmonary circuit as blood stops flowing in the umbilical vessels, the foramen ovale closes, and the ductus arteriosus degenerates. \bigcirc **p. 492**

20-7 Postnatal stages are the neonatal period, infancy, childhood, adolescence, and maturity, followed by senescence

Learning Outcome Identify the features and physiological changes of the postnatal stages of life.

Developmental processes do not stop at delivery. A newborn has few of the anatomical, functional, or physiological characteristics of mature adults. Postnatal development typically includes five **life stages**: (1) *the neonatal* period, (2) *infancy*, (3) *childhood*, (4) *adolescence*, and (5) *maturity* (**Figure 20-9**, p. 722). Each stage has distinctive characteristics and abilities.

The Neonatal Period, Infancy, and Childhood

The **neonatal period** extends from birth to one month of age. **Infancy**, or babyhood, then continues through the first year of life. **Childhood** lasts from infancy until **adolescence**, the period of sexual maturation (puberty) and physical maturation.

Two major events are under way during these developmental stages: (1) the organ systems (except those associated with reproduction) become fully operational and gradually acquire the functional characteristics of adult structures; and (2) the individual grows rapidly, and body proportions change significantly.

Pediatrics is the medical specialty that focuses on postnatal development from infancy through adolescence. Infants and young children often cannot clearly describe the problems they are experiencing, so pediatricians and parents must be skilled observers. Standardized tests are used to compare developmental progress with average values.

The Neonatal Period

Physiological and anatomical changes take place as a fetus completes the transition to the status of a newborn, or **neonate**. Before delivery, dissolved gases, nutrients, waste products, hormones, and antibodies were transferred across the placenta. At birth, a newborn must come to rely on its own specialized organs and organ systems to carry out respiration, digestion, and excretion. The transition from fetus to neonate can be summarized as follows:

- At birth, the lungs are collapsed and filled with fluid. Filling them with air requires a powerful inhalation. ⊃ p. 561
- When the lungs expand, the pattern of cardiovascular circulation changes due to alterations in blood pressure and flow rates. The circulation changes result in separation of the pulmonary and systemic circuits. ⊃ p. 492
- Typical neonatal heart rates (120–140 beats per minute) are lower than fetal heart rates (averaging 150 beats per minute). Both neonatal heart rates and respiratory rates (30 breaths per minute) are considerably higher than those of adults.
- Before birth, the digestive system is relatively inactive, but it does accumulate a mixture of bile secretions, mucus, and epithelial cells. This debris, called *meconium*, is excreted in the first few days of life. During that period, the newborn begins to nurse.
- As waste products build up in the arterial blood, the kidneys excrete them. Glomerular filtration is normal, but the neonate's kidneys cannot concentrate urine to any significant degree. As a result, urinary water losses are high. Neonatal fluid requirements are proportionally much greater than those of adults.

• During embryonic and fetal development, the mother's body is at normal body temperature. At birth, the neonate has little ability to control its body temperature. Neonates also lose heat very quickly, because they have a high surface-area-to-volume ratio. To maintain a constant body temperature, their cellular metabolic rates must be high. In fact, the metabolic rate per unit of body weight in neonates is approximately twice that of adults.

LACTATION AND THE MAMMARY GLANDS. By the end of the sixth month of pregnancy, an expectant mother's mammary glands are fully developed. The gland cells begin to secrete **colostrum** (kō-LOS-trum). Ingested by the newborn during the first 2 or 3 days of life, colostrum contains more proteins and far less fat than breast milk. Many of the proteins are antibodies that may help the infant ward off infections until its own immune system becomes functional. As colostrum production drops, the mammary glands convert to milk production. Breast milk consists of water, proteins, amino acids, lipids, sugars, and salts. It also contains large quantities of *lysozymes*, enzymes with antibiotic properties.

Milk becomes available to infants through the **milk ejection** (**milk let-down**) **reflex** (Figure 20-12). Mammary gland secretion is triggered when the infant begins to suck on the nipple. The stimulation of tactile receptors there leads to the release of oxytocin at the posterior lobe of the pituitary gland. The arrival of circulating oxytocin at the mammary gland then stimulates contractile cells in the walls of the lactiferous ducts and sinuses, resulting in the ejection of milk. This reflex continues to function until *weaning* (withdrawing mother's milk), typically one to two years after birth. Milk production stops soon after. The mammary glands gradually return to a resting state.

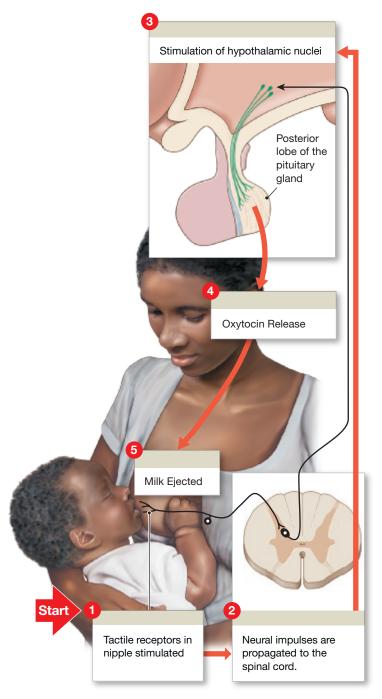

Infancy and Childhood

The rate of growth is greatest during prenatal development and decreases after delivery. Growth during infancy and childhood takes place under the direction of circulating hormones, notably pituitary growth hormone, adrenal steroids, and thyroid hormones. These hormones affect each tissue and organ in specific ways, depending on the sensitivities of the individual cells. As a result, growth does not occur uniformly, and body proportions gradually change (Figure 20-9).

Adolescence and Maturity

Adolescence begins at **puberty**, the period of sexual maturation, and ends when growth is completed. Three major hormonal events interact at the onset of puberty:

Figure 20-12 The Milk Ejection Reflex.

- 1. The hypothalamus increases its production of gonadotropin-releasing hormone (GnRH). Evidence indicates that this increase is dependent on adequate levels of *leptin*, a hormone released by adipose tissues. ⊃ p. 398
- **2.** Endocrine cells in the anterior lobe of the pituitary gland become more sensitive to GnRH, so circulating levels of FSH and LH rise rapidly.

3. Ovarian or testicular cells become more sensitive to FSH and LH. These cells initiate (1) gamete production; (2) the secretion of sex hormones that stimulate the appearance of secondary sex characteristics and behaviors; and (3) a sudden acceleration in the growth rate, ending with closure of the epiphyseal cartilages.

The age at which puberty begins varies. In the United States today, puberty generally begins at about age 12 in boys and at 11 in girls, but the normal ranges are broad (10–15 in boys, 9–14 in girls). The combination of sex hormones, growth hormone, adrenal steroids, and thyroid hormones leads to a sudden acceleration in the growth rate. The timing of the growth spurt varies between the sexes, corresponding to different ages at the onset of puberty. In girls, the growth rate is greatest between ages 10 and 13. Boys grow most rapidly between ages 12 and 15. In both sexes, growth continues at a slower pace until ages 18 to 21. By that time, most of the epiphyseal cartilages have closed. \bigcirc p. 177

The boundary between adolescence and maturity is very hazy, because it has physical, emotional, and behavioral components. Adolescence is often said to be over when growth stops, typically in the late teens or early twenties. The individual is then considered physically mature.

CLINICAL NOTE

Abortion

Abortion is the termination of a pregnancy. Most references distinguish among spontaneous, induced, and therapeutic abortions. **Spontaneous abortions**, or *miscarriages*, result from some developmental or physiological problem. For example, spontaneous abortions can result from chromosomal defects in the embryo or from hormonal problems. Examples of hormonal problems include inadequate LH production by the maternal pituitary gland or placental failure to produce adequate levels of hCG. Among women who know they are pregnant, the rate of spontaneous abortions (miscarriages) before the 20th week of pregnancy is roughly 15–20 percent. (A pregnancy loss after the 20th week is called a stillbirth.)

Induced abortions, or *elective abortions*, are performed at a woman's request. They are done largely for nonmedical reasons. Induced abortions remain the focus of considerable controversy. Most induced abortions involve unmarried or adolescent women. The ratio of abortions to deliveries for married women averages 1:10, but it is nearly 2:1 for unmarried women and adolescents. In most states, induced abortions are legal during the first three months after conception. Under certain conditions, induced abortions may be permitted until the fifth or sixth month.

Therapeutic abortions are performed when continuing a pregnancy represents a threat to the life and health of the mother.

Physical growth may stop at maturity, but physiological changes continue. The sex-specific differences produced at puberty remain. Further changes take place when sex hormone levels decline at menopause or the male climacteric. D p. 696 All these changes are part of **senescence** (*senesco*, to grow old), or aging, which reduces the individual's functional capabilities. Even without disease or injury, aging-related changes at the molecular level ultimately lead to death.

CHECKPOINT

- **18.** Name the postnatal stages of development.
- **19.** What is the difference between colostrum and breast milk?
- **20.** Increases in the blood levels of GnRH, FSH, LH, and sex hormones mark the onset of which stage of development?
- See the blue Answers tab at the back of the book.

20-8 Genes and chromosomes determine patterns of inheritance

Learning Outcome Relate the basic principles of genetics to the inheritance of human traits.

Recall that chromosomes contain DNA and proteins, and genes are functional segments of DNA. Each gene carries the information needed to direct the synthesis of a specific polypeptide. We introduced chromosome structure and the functions of genes in Chapter 3. \bigcirc pp. 106–107 Every nucleated somatic cell in your body carries copies of the original 46 chromosomes present when you were a zygote. Those chromosomes and their genes make up your **genotype** (JĒN-ō-tīp; *geno*, gene + *typos*, mark).

Through development and cellular differentiation, the instructions contained in the genotype are expressed in many ways. No single cell or tissue makes use of all the information contained in the genotype. For example, in muscle fibers genes are important for excitable membrane formation and contractile protein activity, but in cells of the pancreatic islets, a different set of genes is at work. Collectively, the instructions contained in the genotype determine the anatomical and physiological characteristics that make you a unique person. Those characteristics make up your **phenotype** (FĒ-nō-tīp; *phaino*, to display). The phenotype and the environment. Specific observable features of your phenotype,

such as your hair and eye color, skin tone, foot size, or sneezing in response to bright light (photic sneeze reflex) are called phenotypic traits.

Your genotype is derived from the genotypes of your parents. Yet you are not an exact copy of either parent. Neither are you an easily identifiable mixture of their characteristics. We begin our discussion of genetics with an overview of the basic patterns of inheritance and their implications. Then we examine the processes that regulate the activities of the genotype during prenatal development.

Patterns of Inheritance

In humans, every somatic cell contains 46 chromosomes arranged in 23 pairs. The sperm contributed one member of each pair, the ovum the other. The two members of each pair are known as homologous (hō-MOL-o-gus) chromosomes. Twenty-two of those pairs are called **autosomal** (aw-tō-SŌ-mal) chromosomes, or autosomes. Most of the genes on autosomal chromosomes affect somatic characteristics such as hair color and skin pigmentation. The chromosomes of the twenty-third pair are called sex chromosomes. One of their functions is to determine whether the individual is genetically male or female. Figure 20-13 shows the karyotype (KAR-ē-ō-tīp; *karyon*, nucleus + *typos*, mark), or entire set of chromosomes, of a normal male.

Figure 20-13 A Human Male Karyotype. The 23 pairs of chromosomes from a normal male.

The two chromosomes in a homologous pair of autosomes have the same structure and carry genes that affect the same traits. Suppose one member of the pair contains three genes in a row, with the first gene determining hair color, the second eye color, and the third skin pigmentation. The other member of the pair contains genes that affect the same traits. The genes are in the same positions and sequence along the chromosomes.

The two chromosomes in a pair may not carry the same form, or version, of each gene. The various forms of a given gene are called **alleles** (a-LELZ; *allelon*, of one another). If both chromosomes in a homologous pair carry the same allele of a particular gene, you are homozygous (hō-mō-ZĪ-gus; homos, same) for the trait affected by that gene. That allele's trait will be expressed in your phenotype. For example, if you receive a gene for freckles from your father and one for freckles from your mother, you will be homozygous for freckles-and you will have freckles. (In this case, environment also plays a role. That is because exposure to sunlight is necessary to trigger freckle formation.)

The chromosomes of a homologous pair need not carry identical alleles because the two chromosomes have different origins, one from your father and the other from your mother. When you have two different alleles of the same gene, you are heterozygous (het-er-ō-ZĪ-gus; heteros, other) for the trait determined by that gene. In that case, your phenotype will be determined by the interactions between the corresponding alleles:

- An allele that is **dominant** will be expressed in the phenotype regardless of any conflicting instructions carried by the other allele.
- An allele that is **recessive** will be expressed in the phenotype only if it is present on both chromosomes of a homologous pair. For example, albinism (no skin pigmentation) results from an inability to synthesize the pigment *melanin*. \supset p. 156 The presence of a single dominant allele results in normal skin coloration. Two recessive alleles must be present to produce albinism.

Predicting Inheritance

Not every allele can be neatly described as dominant or recessive. For the traits listed as dominant in Table 20-3, we can predict the characteristics of individuals on the basis of the parents' alleles.

In such calculations, dominant alleles are traditionally represented by capitalized letters, and recessive alleles by lowercase letters. For a given trait, the possible genotypes are AA 20

(homozygous dominant), *Aa* (heterozygous), or *aa* (homozy-gous recessive).

Each gamete involved in fertilization contributes a single allele for a given trait. That allele must be one of the two contained in all somatic cells in the parent's body. Consider, for example, the offspring of a mother with albinism and a father with normal skin pigmentation. The maternal alleles are abbreviated *aa* because albinism is a homozygous recessive trait. No matter which of her oocytes is fertilized, it will carry the recessive *a* allele. The father has normal pigmentation, a dominant trait. He is therefore either homozygous dominant or heterozygous for this trait, because both *AA* and *Aa* will produce the same phenotype—normal skin pigmentation.

A simple box diagram known as a **Punnett square** enables us to predict the probabilities that a given child will have particular traits. In the Punnett squares in Figure 20-14, the two maternal alleles for skin pigmentation are displayed along the horizontal axis, and the two paternal alleles along the vertical axis. The possible combinations of alleles a child can inherit are indicated in the small boxes. Figure 20-14a shows the possible offspring of an *aa* mother and an AA father. Every child will have the genotype Aa, so every child will have normal skin pigmentation. Compare these results with those of Figure 20-14b, involving a heterozygous father (Aa). The heterozygous male produces two types of gametes, A and a, and either one may fertilize the oocyte. As a result, the probability is 50 percent that a child of such a father will inherit the genotype Aa and so have normal skin pigmentation. The probability of inheriting the genotype *aa*, and thus having the albinism phenotype, is also 50 percent. A Punnett square can also be used to draw conclusions about the identity and genotype of a given child's parent. For example, a man with the genotype AA cannot be the father of a child with albinism (aa).

In **simple inheritance**, phenotypes are determined by interactions between a single pair of alleles. The frequency of appearance of an inherited disorder resulting from simple inheritance can be predicted using a Punnett square. Although they are rare disorders in terms of overall numbers, more than 1200 inherited conditions are known to reflect the presence of one or two abnormal alleles for a single gene. A partial listing of inherited disorders is given in **Table 20-4**.

In **polygenic inheritance**, phenotypes are determined by interactions among several genes. We cannot predict the presence or absence of these phenotypic traits using a simple Punnett square because the resulting phenotype depends not only on the nature of the alleles but also on how those alleles interact. Many of the developmental disorders responsible for fetal deaths and *congenital* (present at birth) *malformations* result from polygenic inheritance.

The risks of developing several important adult disorders, including hypertension and coronary artery disease, also fall within this category. In these cases, an individual's genetic composition does not by itself determine the onset of the disease. Instead, the conditions regulated by these genes establish a susceptibility to particular environmental

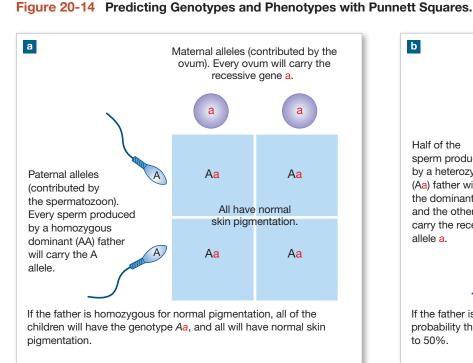

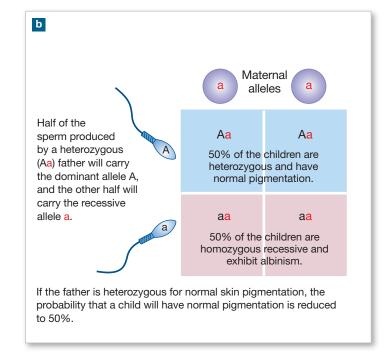

Table 20-4 Fairly Comm		on Inherited Disorders

influences. As a result, not every individual with the genetic tendency for a certain condition will actually develop that condition. For this reason, it is difficult to track polygenic conditions through successive generations. However, steps can be taken to prevent a crisis because many inherited polygenic conditions are likely (but not guaranteed) to occur. For example, you can reduce the likelihood of developing hypertension by controlling your diet and fluid volume. You may

be able to prevent coronary artery disease by lowering your blood cholesterol levels.

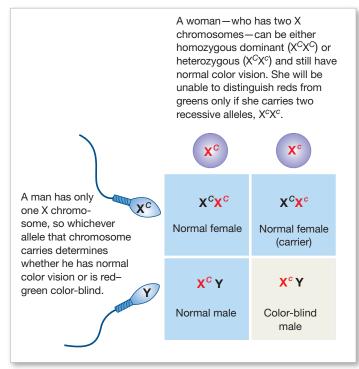

Sex-Linked Inheritance

Sex-linked inheritance involves genes on the sex chromosomes. Unlike the other 22 chromosomal pairs, these chromosomes are not identical in appearance and gene content. There are two types of sex chromosomes: an **X chromosome** and a **Y chromosome**. X chromosomes are considerably larger and have more genes than Y chromosomes. The smaller Y chromosome carries an *SRY gene* not found on the X chromosome. It specifies that an individual with that chromosome will be male. The normal pair of sex chromosomes in males is XY. Females do not have a Y chromosome. Their sex chromosome pair is XX.

All oocytes carry an X chromosome, because the only sex chromosomes females have are X chromosomes. But a sperm may carry either an X chromosome or a Y chromosome. As a Punnett square shows, the ratio of male to female offspring should be 1:1.

The X chromosome also carries genes that affect somatic structures. Genes found on the X chromosome but not on the Y chromosome are called **X-linked**. (The SRY gene that determines "maleness" is an example of a Y-linked gene.) The best-known X-linked traits are associated with noticeable diseases or functional deficits.

The inheritance of color blindness demonstrates the differences between sex-linked and autosomal inheritance. Normal color vision is determined by the presence of a dominant allele, *C*, on the X chromosome (designated X^{*C*}). A recessive allele, *c*, on the X chromosome (X^{*c*}) results in red–green color blindness. A woman, with her two X chromosomes, can be either homozygous dominant, X^CX^C, or heterozygous, X^CX^c, and still have normal color vision. She will be unable to distinguish reds from greens only if she carries two recessive alleles, X^{*c*}X^{*c*}. But a male has only one X chromosome, so whichever allele that chromosome carries will determine whether he has normal color vision or is red-green color-blind. The Punnett square in Figure 20-15 reveals that the sons of a father with normal color vision and a heterozygous (carrier) mother will have a 50 percent chance of being red-green color-blind. Any daughters will have normal color vision.

A number of other clinical disorders involve X-linked traits, including certain forms of hemophilia, diabetes insipidus, and muscular dystrophy. In several instances, advances in molecular genetics techniques have enabled geneticists to locate specific genes on the X chromosome. These techniques provide a relatively direct method of screening for the presence of a particular condition before signs and symptoms appear, and even before birth.

The Human Genome

The **human genome** is the complete set of genes in our chromosomes. This genetic material is made up of DNA, containing four different nitrogenous bases, arranged in triplets that code for amino acids (the building blocks of proteins). Through technology called DNA sequencing, we know that there are about 3.2 billion base pairs spread among our 22 autosomes and X and Y sex chromosomes. DNA sequencing has also determined that our genome contains some 21,000 protein-coding genes. This technology has also identified about 10,000 different single-gene disorders. Most are very rare, but collectively they may affect 1 in every 200 births. Many of these disorders have been mapped to individual chromosomes; some examples are included in **Figure 20-16**. Genetic screening is possible for many of these disorders.

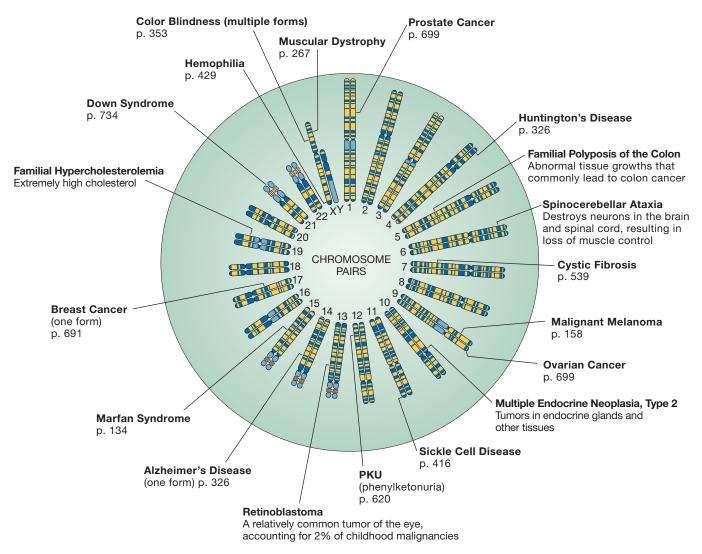

Through *epigenetics*, we have also learned that not all traits are determined solely by your DNA sequences. **Epigenetics** is the study of inherited traits caused by gene expression rather than changes in the genetic code. So, the genetic structure remains intact, but the trait is changed. This turning genes "on" or "off" will then affect protein synthesis.

The *epigenome* is a number of chemical compounds that "tell" the gene what to do by marking DNA and its histone proteins. Marking with the chemical group permits or restricts transcription, thereby changing gene expression. Interestingly, although the epigenetic chemical modifiers are not part of the DNA, they can be passed on and inherited when cells divide.

Knowing the normal genetic makeup of a "typical" human led to efforts to modify abnormal genes. Such modifications are the basis of *gene therapy*. **Gene therapy** is a medical treatment that modifies a person's genes to treat or cure diseases.

The discovery of a new tool to precisely edit genes in living cells promises to deepen our understanding of how genes direct development, normal physiology, and disease. Known as *CRISPR*, or *CRISPR-Cas9*, this gene-editing tool is easier and cheaper to use than previous techniques. Adapted from a bacterial anti-viral defense system, it allows researchers to efficiently remove, add, or alter sections of a DNA sequence. CRISPR (pronounced "crisper") is an abbreviation for a DNA sequence named *Clustered Regularly Interspaced Short Palin*dromic *Repeats*. Cas9 is an abbreviation for *CRISPR-associated* protein 9. Cas9 is a nuclease enzyme.

How does it work? The CRISPR-Cas9 system introduces changes into a cell's DNA with two molecules. One is the Cas9 enzyme. It acts as a pair of DNA scissors and snips two strands of DNA at a specific site so DNA can be added or removed. The other is a short sequence of RNA called *guide RNA*. Guide RNA **Figure 20-16 A Map of Human Chromosomes.** This diagram of the chromosomes of a normal male individual shows typical banding patterns and the locations of the genes responsible for specific inherited disorders. The chromosomes are not drawn to scale.

is a lab-designed RNA sequence that will locate and line up only with its complementary DNA sequence. Cas9 binds to the guide RNA and cuts both DNA strands. The cut DNA initiates the cell's DNA repair process, which uses any locally available DNA to repair the cut. So, in addition to injecting Cas9 and the guide RNA into a cell, the new DNA is also added. (If no other DNA is available, the cell will rejoin the cut ends.)

Most gene editing of the human genome with Crisper-Cas9 has been limited to somatic, or body, cells. To avoid concerns about passing genetic changes from one generation to the next, many countries have made gene editing of sperm and egg cells and embryos illegal.

We are variations on a basic genetic theme. So, how do we decide what set of genes to accept as "normal" or "abnormal"? As we improve our abilities to edit genes, we will face many additional ethical and legal dilemmas. Finding the best course of action acceptable to us all will be challenging.

CHECKPOINT

- **21.** Describe the relationship between genotype and phenotype.
- **22.** Define heterozygous.
- **23.** Tongue rolling is an autosomal dominant trait. What would be the phenotype of a person who is heterozygous for this trait?
- **24.** Joe has three daughters and complains that it's his wife's "fault" that he has no sons. Whose "fault" is it?

See the blue Answers tab at the back of the book.

CLINICAL NOTE

Chromosomal Abnormalities and Genetic Analysis

Embryos that have abnormal autosomal chromosomes rarely survive. However, *translocation defects* and *trisomy* are two types of autosomal chromosome abnormalities that do not always result in prenatal death.

In a **translocation defect**, an exchange takes place between different chromosome pairs. For example, a piece of chromosome 8 may become attached to chromosome 14. The genes moved to their new position may function abnormally, becoming inactive or overactive. In a balanced translocation, where there is no net loss or gain of chromosomal material, an embryo may survive.

In **trisomy**, a mistake occurs in meiosis. One of the gametes involved in fertilization carries an extra copy of one chromosome. As a result, the zygote then has three copies of this chromosome rather than two. (The nature of the trisomy is indicated by the number of the chromosome involved. For example, individuals with trisomy 13 have three copies of chromosome 13.) Zygotes with extra copies of chromosomes seldom survive. Individuals with trisomy 13 and trisomy 18 may survive until delivery but rarely live longer than a year. The notable exception is trisomy 21.

Trisomy 21, or **Down syndrome**, is the most common viable chromosomal abnormality **(a)**. According to the CDC, each year

in the U.S. about 6000 babies, or about 1 in every 700 babies, are born with Down syndrome. Affected individuals exhibit delayed mental development and have characteristic physical malformations. The degree of developmental disability ranges from moderate to severe. Anatomical problems affecting the cardiovascular system often prove fatal during childhood or early adulthood. Some people with Down syndrome survive to moderate old age, but many develop Alzheimer's disease before age 40.

For unknown reasons, there is a direct correlation between maternal age and the risk of having a child with trisomy 21. For a maternal age below 25, the incidence of Down syndrome approaches 1 in 2000 births, or 0.05 percent. For maternal

ages 30–34, the odds increase to 1 in 900. Over the next decade they go from 1 in 290 to 1 in 46, or more than 2 percent. These statistics are becoming increasingly significant because many women are delaying childbearing until their mid-thirties or later.

Abnormal numbers of sex chromosomes do not produce effects as severe as those induced by extra or missing autosomal chromosomes. In **Klinefelter syndrome**, the individual carries the sex chromosome pattern XXY. The phenotype is male,

a Trisomy 21

but the extra X chromosome causes reduced androgen production. As a result, the testes fail to mature. The individuals are sterile, and the breasts are slightly enlarged. The incidence of this condition among newborn males averages 1 in 750 births.

Individuals with **Turner syndrome** have only one female sex chromosome. Their sex chromosome complement is represented as XO. This kind of chromosomal deletion is known as **monosomy**. The incidence of this condition at delivery has been estimated as 1 in 10,000 live births. The condition may not be recognized at birth, because the phenotype is normal female. But maturational changes do not appear at puberty. The ovaries are nonfunctional, and estrogen production occurs at negligible levels.

Fragile-X syndrome causes developmental disability, abnormal facial development, and enlarged testes in affected males. The cause is an abnormal X chromosome that contains a *genetic stutter*, an abnormal repetition of a single nucleotide triplet. The stutter in some way disrupts the normal functioning of adjacent genes and so produces the signs and symptoms of the disorder.

Many of these conditions can be detected before birth through the analysis of fetal cells. In **amniocentesis**, a sample of amniotic fluid is removed and the fetal cells it contains are analyzed. This procedure permits the identification of more than 20 congenital conditions, including Down syndrome. The needle inserted to

> obtain a fluid sample is guided into position during an ultrasound procedure. D p. 21 Amniocentesis has two major drawbacks:

1. Amniocentesis is performed only when known risk factors are present because the sampling procedure is a potential threat to the health of fetus and mother alike. Examples of risk factors are a family history of specific conditions, or in the case of Down's syndrome, maternal age over 35.

2. Sampling cannot safely be performed until the volume of amniotic fluid is large enough that the fetus will not be injured during the process. The usual time for amniocentesis is at 14–15 weeks of gestation. It may take several weeks to obtain results once samples have been

collected, and by that time, an induced or therapeutic abortion may no longer be a viable option.

An alternative procedure is known as **chorionic villus sampling (CVS)**. Cells for analysis are collected from the chorionic villi during the first trimester. CVS carries a slightly higher risk of miscarriage than amniocentesis, but may be preferable because it can be done earlier in gestation.

RELATED CLINICAL TERMS

abruptio placentae (ab-RUP-shē-ō pla-SEN-tē): A tearing away of the placenta from the uterine wall after the fifth gestational month.

Apgar rating: A method of evaluating newborns for developmental problems and neurological damage.

breech birth: A delivery during which the legs or buttocks of the fetus enter the vaginal canal first.

fetal alcohol syndrome (FAS): A neonatal condition resulting from maternal alcohol consumption; characterized by developmental defects typically involving the skeletal, nervous, and/or cardiovascular systems.

geriatrics: A medical specialty concerned with aging and its medical problems.

in vitro fertilization: Fertilization outside the body, generally in a petri dish.

placenta previa: A condition resulting from implantation in or near the cervix, in which the placenta covers the cervix.

pre-eclampsia: A condition in pregnancy characterized by sudden hypertension, albuminuria (albumin in the urine), and edema of hands, feet, and face. It is the most common complication of pregnancy, affecting about 5 percent of pregnancies.

teratogens (TER-a-tō-jenz): Agents or factors that disrupt normal development by damaging cells, altering chromosome structure, or altering the chemical environment of the embryo.

Chapter Review

Summary Outline

20-1 Development is a continuous process that occurs from fertilization to maturity p. 706

- **1. Development** is the gradual modification of physical and physiological characteristics from **conception** to physical maturity. The creation of different cell types during development is **cellular differentiation**.
- 2. Prenatal development occurs before birth; postnatal development begins at birth and continues to maturity, when senescence (aging) begins. Inheritance, or heredity, is the transfer of genetically determined characteristics from generation to generation. Genetics is the study of the mechanisms of inheritance.

20-2 Fertilization—the fusion of a secondary oocyte and a spermatozoon—forms a zygote *p.* 707

- **3. Fertilization** normally occurs in a uterine tube within a day after ovulation. Sperm cannot fertilize an egg until they have undergone **capacitation**.
- **4.** The acrosomal caps of spermatozoa release *hyaluronidase*, an enzyme that separates cells of the *corona radiata*. Another acrosomal enzyme digests the zona pellucida and exposes the oocyte membrane. When a single spermatozoon contacts that membrane, fertilization occurs and **oocyte activation** follows.
- **5.** During activation, the secondary oocyte completes meiosis II, and the penetration of additional sperm is prevented.
- **6.** After activation, the *female pronucleus* and *male pronucleus* fuse in a process called **amphimixis**. (*Figure 20-1*)

20-3 Gestation consists of three stages of prenatal development: the first, second, and third trimesters *p. 709*

- **7.** The nine-month period of **gestation**, or *pregnancy*, can be divided into three **trimesters**.
- 8. The **first trimester** is the most dangerous period of prenatal development. The processes of *cleavage and blastocyst formation, implantation, placentation,* and *embryogenesis* take place during this critical period.

20-4 Critical events of the first trimester are cleavage, implantation, placentation, and embryogenesis *p. 709*

- **9. Cleavage** is a series of cell divisions that subdivide the cytoplasm of the zygote. The zygote becomes a hollow ball of **blastomeres** called a **blastocyst**. The blastocyst consists of an outer **trophoblast** and an **inner cell mass**. (*Figure 20-2*)
- **10. Implantation** occurs about seven days after fertilization as the blastocyst adheres to the uterine endometrium. (*Figure 20-3*)
- As the trophoblast enlarges and spreads, maternal blood flows through open *lacunae*. After **gastrulation**, there is an embryonic disc composed of **endoderm**, **ectoderm**, and **mesoderm**. It is from these three **germ layers** that the body systems differentiate. (*Figure 20-4; Table 20-1*)
- **12.** Germ layers help form four **extra-embryonic membranes**: the *yolk sac, amnion, allantois,* and *chorion. (Spotlight Figure 20-5)*

- **13.** The **yolk sac** is an important site of blood cell formation. The **amnion** encloses fluid that surrounds and cushions the developing embryo. The base of the **allantois** later gives rise to the urinary bladder. Circulation within the vessels of the **chorion** provides a "rapid-transport system" linking the embryo with the trophoblast. (*Spotlight Figure 20-5*)
- 14. Placentation occurs as blood vessels form around the blastocyst and the **placenta** develops. *Chorionic villi* extend outward into the maternal tissues, forming a branching network through which maternal blood flows. As development proceeds, the **umbilical cord** connects the fetus to the placenta. *(Figure 20-6)*
- **15.** The trophoblast synthesizes **human chorionic gonadotropin (hCG)**, estrogens, progesterone, **human placental lactogen (hPL), placental prolactin**, and **relaxin**.
- **16.** The first trimester is critical because events in the first 12 weeks establish the basis for **organogenesis** (organ formation). (*Figure 20-7*; *Table 20-2*)

20-5 During the second and third trimesters, maternal organ systems support the developing fetus, and the uterus undergoes structural and functional changes *p. 717*

- **17.** In the **second trimester**, the organ systems increase in complexity. During the **third trimester**, these organ systems become functional. (*Figures 20-8, 20-9; Table 20-2*)
- **18.** The developing fetus is totally dependent on maternal organs for nourishment, respiration, and waste removal. Maternal adaptations include increases in blood volume, respiratory rate, tidal volume, nutrient intake, and glomerular filtration rate.
- **19.** Progesterone produced by the placenta has an inhibitory effect on uterine muscles; its calming action is opposed by estrogens, oxytocin, and prostaglandins. Placental and fetal factors interact to produce **labor contractions** in the uterine wall. (*Figure 20-10*)

20-6 Labor consists of the dilation, expulsion, and placental stages *p. 724*

- **20.** The goal of labor is **parturition**, the forcible expulsion of the fetus from the uterus.
- **21.** Labor can be divided into three stages: the **dilation stage**, **expulsion stage**, and **placental stage**. (*Figure 20-11*)
- **22. Premature labor** results in the delivery of a newborn that has not completed normal development.
- **23.** Twins are either **dizygotic** (fraternal) or **monozygotic** (identical).

20-7 Postnatal stages are the neonatal period, infancy, childhood, adolescence, and maturity, followed by senescence *p. 726*

24. Postnatal development involves a series of five **life stages**: the *neonatal period, infancy, childhood, adolescence,* and *maturity. (Figure 20-9)*

- **25.** The **neonatal period** extends from birth to 1 month of age. **Infancy** then continues to one year of age, and **childhood** lasts until puberty commences. During these stages, major nonreproductive organ systems become fully operational and gradually acquire adult characteristics, and the individual grows rapidly. (*Figure 20-9*)
- **26.** In the transition from fetus to **neonate**, the respiratory, circulatory, digestive, and urinary systems begin functioning independently. The newborn must also begin to perform thermoregulation.
- **27.** Mammary glands produce protein-rich **colostrum** during the neonate's first few days and then convert to milk production. These secretions are released as a result of the *milk ejection reflex.* (*Figure 20-12*)
- **28.** Adolescence begins at **puberty**: (1) The hypothalamus increases its production of GnRH, (2) circulating levels of FSH and LH rise rapidly, and (3) ovarian or testicular cells become more sensitive to FSH and LH. These changes initiate gametogenesis, the production of sex hormones, and a sudden acceleration in growth rate. Adolescence continues until growth is completed.
- **29. Maturity**, the end of growth and adolescence, occurs by the early twenties. Postmaturational changes in physiological processes are part of aging, or **senescence**. Aging-related changes ultimately lead to death.

20-8 Genes and chromosomes determine patterns of inheritance *p. 728*

- **30.** Every somatic cell carries copies of the zygote's original 46 chromosomes; these chromosomes and their genes make up the individual's **genotype**. An individual's **phenotype** is his or her anatomical and physiological characteristics. The phenotype results from the interaction between the person's genotype and the environment.
- **31.** Every somatic human cell contains 23 pairs of chromosomes. Twenty-two pairs are **autosomal chromosomes**; each pair consists of **homologous chromosomes**. The chromosomes of the twenty-third pair are the **sex chromosomes**, which differ between the sexes. *(Figure 20-13)*
- **32.** Chromosomes contain DNA, and genes are functional segments of DNA. The various forms (versions) of a gene are called **alleles**. If both homologous chromosomes carry the same allele of a particular gene, the individual is **homozygous;** if they carry different alleles, the individual is **heterozygous**.
- **33.** Alleles are either **dominant** or **recessive** depending on how their traits are expressed. (*Table 20-3*)
- **34.** Combining maternal and paternal alleles in a *Punnett square* helps us to predict the characteristics of offspring. (*Figure 20-14*)
- **35.** In **simple inheritance**, phenotypic traits are determined by interactions between a single pair of alleles. **Polygenic inheritance** involves interactions among alleles on several chromosomes. (*Table 20-4*)

- 36. The two types of sex chromosomes are an X chromosome and a Y chromosome. The normal sex chromosome complement of males is XY; that of females is XX. The X chromosome carries X-linked genes, which affect somatic structures but have no corresponding alleles on the Y chromosome. (Figure 20-15)
- 37. The human genome contains some 21,000 protein-coding genes. Thousands of single-gene disorders have been identified, including some responsible for inherited disorders. (Figure 20-16; Table 20-4)
- 38. Gene therapy is a medical treatment that modifies a person's genes to treat or cure diseases.

Review Questions

Level 1 Reviewing Facts and Terms

Match each item in column A with the most closely related item in column B. Place letters for answers in the spaces provided.

COLUMN A

- 1. gestation
- **2.** cleavage
- 3. gastrulation
- 4. chorionic villi
- 5. human chorionic gonadotropin
- 6. birth
- 7. episiotomy
- 8. after birth
- 9. senescence
- **10.** neonate
- _ **11.** phenotype
- ____ **12.** homozygous
- recessive
- ____ 13. heterozygous
- _____ **14.** male genotype
- **____ 15.** female genotype
- **16.** trisomy 21

- **COLUMN B**
- **a.** perineal musculature incision
- **b.** blastocyst formation
- c. ejection of placenta
- d. germ-layer formation
- e. indication of pregnancy
- tory exchange
- g. visible characteristics
- development
- **i.** aa
 - Down's syndrome
- **1.** Aa
- m. XY
- n. XX
- o. parturition
- **p.** process of aging
- 17. Formation of all the major organ systems
 - (a) begins in the first trimester.
 - (b) begins in the second trimester.
 - (c) begins in the third trimester.
 - (d) occurs throughout the gestation period.
- 18. Gastrulation leads to the formation of the
 - (a) blastocyst.
 - (b) cellular and syncytial trophoblasts.
 - (c) ectoderm, mesoderm, and endoderm.
 - (d) morula.
- **19.** The is an important site of blood cell formation in early embryonic development.
 - (a) allantois
 - (b) amnion
 - (c) chorion
 - (d) yolk sac

- 20. Identify structures a-e in the following diagram of week 10 of development.
 - а b C d e
 - (b) _____ (a) (**d**) (c) ____ (e)
- **21.** The brain and spinal cord are derived from the
 - (a) ectoderm. (b) mesoderm.
 - (c) endoderm. (d) amnion.
- **22.** The zygote arrives in the uterine cavity as a
 - (a) morula. (b) trophoblast. (c) lacuna.
 - (d) blastomere.
- 23. The effects of pregnancy on the maternal body include
 - (a) reduction of blood volume.
 - (b) increase in glomerular filtration rate.
 - (c) doubling of nutrient requirements.
 - (d) decrease in respiratory rate.

See the blue Answers tab at the back of the book.

- f. embryo-maternal circula-
- **h.** time of prenatal
- j.
- **k.** newborn infant

738 DEVELOPMENT AND INHERITANCE

- **24.** Fraternal twins are
 - (a) formed from the same pair of gametes.
 - (b) monozygotic twins.
 - (c) more common than identical twins.
 - (d) usually conjoined at birth.
- 25. Hemophilia is an example of a ______ trait.
 (a) dominant.
 (b) polygenic.
 (c) recessive.
 (d) sex-linked.
- **26.** Name the three germ layers of the embryo.
- **27.** Name the two types of twins, and describe how they are formed.
- **28.** Identify the three life stages that occur between birth and approximately age 10. Describe the timing and characteristics of each stage.

Level 2 Reviewing Concepts

- 29. What are the functions of the placenta?
 - (a) providing oxygen and nutrients to the developing fetus.
 - (b) removing waste products from the fetal circulation.
 - (c) producing hormones that help to maintain the pregnancy.
 - (d) a, b, and c are correct.
- **30.** During adolescence, the events that interact to promote increased hormone production and sexual maturation result from activity of the
 - (a) hypothalamus.
 - (b) anterior lobe of the pituitary gland.
 - (c) ovaries and testicular cells.
 - (d) a, b, and c are correct.
- **31.** Why is amniocentesis usually done in the second trimester instead of the first?
- **32.** Discuss the changes that occur in maternal systems during pregnancy, and indicate the functional significance of each change.
- **33.** During labor, what physiological mechanism ensures that uterine contractions continue until delivery has been completed?
- **34.** During which stage of labor is an episiotomy performed? Explain why this procedure needs to be performed.
- **35.** Indicate the nature of the trait and type of inheritance involved in each of the following situations.
 - (a) Children who exhibit this trait have at least one parent who exhibits the same trait.
 - **(b)** Children exhibit this trait even though neither parent does.

- (c) The trait is expressed more commonly in sons than in daughters.
- (d) Tongue-rolling is expressed equally in both daughters and sons.
- **36.** Explain why more men than women are color-blind. Which type of inheritance is involved?

Level 3 Critical Thinking and Clinical Applications

- 37. Hemophilia A, a condition in which blood does not clot properly, is a recessive trait located on the X chromosome (X^h). A woman heterozygous for the trait marries a normal male. What is the probability that this couple will have hemophiliac daughters? What is the probability that this couple will have hemophiliac sons?
- **38.** Explain why the metabolic rate of neonates must be high and is about twice the metabolic rate of adults.
- **39.** Sally gives birth to a baby with a congenital deformity of the stomach. She believes that it is the result of a viral infection she suffered during the third trimester of pregnancy. Is this a possibility? Explain.

ANSWERS

Answers to Checkpoints and Review Questions

CHAPTER 1

ANSWERS TO CHECKPOINTS

Page 33

1. Metabolism refers to all the chemical operations in the body. Organisms rely on complex chemical reactions to provide the energy for responsiveness, growth, reproduction, and movement.

Page 34

2. Anatomy and physiology are closely related because all specific functions are performed by specific structures. **3.** Histologists specialize in histology, the study of the structure and properties of tissues and the cells that compose tissues. Because histologists must use microscopes to observe cells, they are specialists in microscopic anatomy.

Page 36

4. The major levels of organization from the simplest to the most complex are the following: chemical level \rightarrow cellular level \rightarrow tissue level \rightarrow organ level \rightarrow organ system level \rightarrow organism level. 5. The organ systems of the body and their major functions are the integumentary system (protects against environmental hazards, helps control body temperature, and provides sensory information); the skeletal system (provides support, protects tissues, stores minerals, and forms blood cells); the muscular system (provides movement, provides protection and support for other tissues, and produces heat); the nervous system (directs immediate responses to stimuli, usually by coordinating the activities of other organ systems, and provides and interprets sensory information about internal and external conditions); the endocrine system (directs long-term changes in activities of other organ systems); the cardiovascular system (transports cells and dissolved materials, including nutrients, wastes, oxygen, and carbon dioxide); the lymphatic system (defends against infection and disease, and returns tissue fluids to the bloodstream); the respiratory system (delivers air to sites in the lungs where gas exchange can occur between the air and bloodstream, and produces sound for communication); the digestive system (processes food and absorbs nutrients); the urinary system (excretes waste products from the blood, and controls water balance by regulating the volume of urine produced); and the reproductive system (male produces sex cells [sperm] and hormones, and female produces sex cells [oocytes], hormones, and supports embryonic and fetal development from fertilization to birth). 6. The endocrine system includes the pituitary gland and directs long-term changes in the activities of other systems.

Page 40

7. Homeostasis refers to the existence of a stable internal environment. **8.** Homeostatic regulation is important because it keeps physiological systems within carefully controlled limits, preventing potentially disruptive changes in the body's internal

environment. **9.** When homeostasis fails, organ systems function less efficiently or even malfunction. The result is the state we call disease. If the situation is not corrected, death can result.

Page 43

10. Negative feedback systems provide control over the body's internal conditions—that is, they maintain homeostasis—by counteracting the effects of a stimulus. **11.** Positive feedback is useful in processes that must move quickly to completion, such as blood clotting. It is harmful in situations in which a stable condition must be maintained, because it tends to intensify any departure from the desired condition. Positive feedback in the regulation of body temperature, for example, would cause a slight fever to spiral out of control, with fatal results. For this reason, physiological systems are typically regulated by negative feedback, which tends to oppose any departure from the norm.

Page 45

12. The purpose of anatomical terms is to provide a standardized language and frame of reference for describing the human body. **13.** In the anatomical position, an anterior view displays the body's front, whereas a posterior view displays the back. **14.** The two eyes would be separated by a sagittal section. A midsagittal section would separate them evenly.

Page 49

15. Body cavities protect internal organs and cushion them from movements that occur while walking, running, or jumping. Body cavities also permit organs that they surround to change in size and shape without disrupting the activities of nearby organs.
16. The thoracic cavity includes the pleural and pericardial cavities, which enclose the lungs and heart respectively. The diaphragm forms the boundary between the superior thoracic cavity is subdivided into the superior abdominal cavity and the inferior pelvic cavity. The abdominopelvic cavity contains the peritoneal cavity 17. The body cavity inferior to the diaphragm is the abdominopelvic (or peritoneal) cavity.

ANSWERS TO REVIEW QUESTIONS

1. h **2.** e **3.** b **4.** k **5.** c **6.** m **7.** o **8.** g **9.** i **10.** f **11.** d **12.** a **13.** i **14.** j **15.** n **16.** (a) frontal; (b) sagittal; (c) transverse **17.** (a) superior; (b) inferior; (c) posterior or dorsal; (d) anterior or ventral; (e) cranial; (f) caudal; (g) lateral; (h) medial; (i) proximal; (j) distal **18.** c **19.** b **20.** b **21.** c

Level 2: Reviewing Concepts

22. All living things display responsiveness, growth, reproduction, movement, and metabolism. **23.** It lubricates the opposing surfaces of the pericardial membrane, thereby reducing friction when the heart beats. **24.** Homeostatic regulation refers to adjustments in physiological systems that are responsible for

maintaining homeostasis (the existence of a stable internal environment). **25.** In negative feedback, a variation outside normal ranges triggers an automatic response that corrects the situation. In positive feedback, the initial stimulus produces a response that exaggerates the stimulus. **26.** The forearm is located distal to the arm and proximal to the digits. **27.** The stomach. (You would cut the serous pericardium to access the heart.) **28.** (a) sagittal plane; (b) transverse plane; (c) frontal/coronal plane.

Level 3: Critical Thinking and Clinical Applications

29. Insulin is released when the blood glucose level increases. It brings about a decrease in the blood glucose level, thereby decreasing the stimulus for its own release. **30.** The proximal part of the humerus is near the shoulder. Thus, the fracture is located closer to the elbow.

CHAPTER 2

ANSWERS TO CHECKPOINTS

Page 58

1. An atom is the smallest stable unit of matter. **2.** The two samples could have different weights if they contain different proportions of hydrogen's three isotopes: hydrogen-1, with a mass of 1; hydrogen-2, with a mass of 2; and hydrogen-3, with a mass of 3.

Page 61

3. A chemical bond is an attractive force acting between two atoms that may be strong enough to hold them together in a molecule or compound. The strongest attractive forces result from the gain, loss, or sharing of electrons. Examples of such chemical bonds are ionic bonds and covalent bonds. **4.** Atoms combine with each other such that their outer electron shells are full. Oxygen atoms do not have a full outer electron shell and so readily combine with many other elements to attain this stable arrangement. Neon does not combine with other elements because it has a full outer electron shell. **5.** The atoms in a water molecule are held together by polar covalent bonds. Water molecules are attracted to each other by hydrogen bonds: attractions between a slight negative charge on the oxygen atom of one water molecule and a slight positive charge on a hydrogen atom of another water molecule.

Page 63

6. The molecular formula for glucose, a compound composed of 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms, is $C_6H_{12}O_6$. **7.** Three types of chemical reactions important to human physiology are decomposition reactions, synthesis reactions, and exchange reactions. In a decomposition reaction, a chemical reaction breaks a molecule into smaller fragments. A synthesis reaction assembles smaller molecules into larger ones. In an exchange reaction, parts of the reacting molecules are shuffled around to produce new products. **8.** Because this reaction involves a large molecule being broken down into two smaller ones, it is a decomposition reaction. **9.** Removing the product of a reversible reaction would keep its concentration lower than the concentrations of the reactants. As a result, the breakdown of the product into reactants would slow, producing a shift in the equilibrium toward the product.

Page 64

10. An enzyme is a special molecule that lowers the activation energy of a chemical reaction, which is the amount of energy required to start the reaction. **11.** Without enzymes, most chemical reactions could proceed in the body only under conditions that cells cannot tolerate (such as high temperatures). By lowering the activation energy, enzymes make it possible for chemical reactions to proceed under conditions compatible with life.

Page 65

12. Inorganic compounds are substances that generally do not contain carbon and hydrogen. (If present, they do not form C - H bonds.) Organic compounds are substances that contain carbon covalently bonded with one or more other elements.

Page 66

13. Specific chemical properties of water that make life possible include its reactivity (it participates in many chemical reactions), its high heat capacity (it absorbs and releases heat slowly), and its ability to dissolve a remarkable number of inorganic and organic substances (its strong polarity enables it to be an excellent solvent). **14.** Heat is an increase in the random motion, or kinetic energy, of molecules, and temperature is a measure of heat. Liquid water resists changes in temperature because hydrogen bonds between water molecules retard molecular motion and must be broken to increase the temperature. Temperature must be quite high before individual water molecules have enough energy to break free of all surrounding hydrogen bonds and become water vapor. 15. pH is a measure of the concentration of hydrogen ions in solutions, such as body fluids. On the pH scale, 7 represents neutrality, values below 7 indicate acidic solutions, and values above 7 indicate alkaline (basic) solutions. 16. Fluctuations in pH of body fluids outside the normal range of 7.35 to 7.45 can break chemical bonds, alter the shape of molecules, and affect cell function, thereby harming cells and tissues.

Page 68

17. An acid is a substance whose dissociation in solution releases a hydrogen ion (H^+) and an anion. A base is a substance whose dissociation releases a hydroxide ion (OH^-) or removes a hydrogen ion from the solution. A salt is an ionic compound consisting of a cation other than H^+ and an anion other than OH^- . **18.** Stomach discomfort is commonly the result of excessive stomach acidity ("acid indigestion"). Antacids contain a weak base that neutralizes the excess acid.

Page 69

19. A compound with a C:H:O ratio of 1:2:1 is a carbohydrate. The body uses carbohydrates chiefly as an energy source. **20.** When two monosaccharides undergo a dehydration synthesis reaction, they form a disaccharide.

Page 73

21. Lipids are a diverse group of compounds that include fatty acids, fats (triglycerides), steroids, and phospholipids. They are organic compounds that contain carbon, hydrogen, and oxygen in a ratio that does not approximate 1:2:1. **22.** The most abundant lipid in a sample taken from beneath the skin would be a

triglyceride. **23.** Human cell membranes primarily contain phospholipids, plus small amounts of cholesterol.

Page 76

24. Proteins are organic compounds formed from amino acids, which contain a central carbon atom, a hydrogen atom, an amino group $(-NH_2)$, a carboxyl group (-COOH), and an R group, or variable side chain. Proteins function in support, movement, transport, buffering, metabolic regulation, coordination and control, and defense. **25.** The heat of boiling breaks bonds that maintain the protein's three-dimensional shape. The resulting structural change, known as denaturation, affects the ability of the protein molecule to perform its normal biological functions.

Page 78

26. A nucleic acid is a large organic molecule made up of nucleotide subunits containing carbon, hydrogen, oxygen, nitrogen, and phosphorus. Nucleic acids regulate protein synthesis and make up the genetic material in cells. **27.** Both DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) contain nitrogenous bases and phosphate groups, but because this nucleic acid contains the sugar ribose, it is RNA.

Page 80

28. Adenosine triphosphate (ATP) is a high-energy compound consisting of adenosine monophosphate (AMP) to which two phosphate groups are attached. The second and third phosphate groups are each attached by a high-energy bond. **29.** Hydrolysis is a decomposition reaction involving water. The hydrolysis of ATP (adenosine triphosphate) yields ADP (adenosine diphosphate) and P (a phosphate group). It also releases energy that is then used for cellular activities. **30.** Six elements common to organic compounds are carbon (C), hydrogen (H), oxygen (O), nitrogen (N), phosphorus (P), and sulfur (S). **31.** The biochemical building blocks that are components of cells include lipids (forming the cell membrane), proteins (acting as enzymes), nucleic acids (directing the synthesis of cellular activities), and carbohydrates (providing energy for cellular activities).

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. g 2. d 3. j 4. h 5. b 6. a 7. e 8. l 9. c 10. f 11. i 12. k 13. a.

b. Two more electrons can fit into the outermost electron shell

of an oxygen atom. **14.** c **15.** a **16.** b **17.** Human bodies can break down glycogen into glucose, which serves as a source of energy. However, as humans cannot digest cellulose, it cannot be used as an energy source. **18.** covalent bond **19.** adenine, cytosine, guanine, and thymine. **20.** primary, secondary, tertiary, and quaternary **21.** (a) central carbon atom; (b) amino group; (c) R group; (d) carboxyl group

Level 2: Reviewing Concepts

22. a **23.** b **24.** d **25.** Nonpolar covalent bonds involve equal sharing of electrons, polar covalent bonds involve unequal sharing of electrons, and ionic bonds involve a loss and/or gain of electrons. **26.** A solution with a pH of 7 (such as pure water) is neutral because it contains equal numbers of hydrogen ions and hydroxyl ions. **27.** The pH 2 solution is 10,000 times more acidic than the pH 6 solution—it contains a ten thousand-fold (10⁴) increase in the concentration of hydrogen ions (H⁺). **28.** A nucleic acid. Carbohydrates and lipids do not contain the element nitrogen. Although both proteins and nucleic acids contain nitrogen, only nucleic acids contain phosphorus.

Level 3: Critical Thinking and Clinical Applications

29. Lactose is a disaccharide and must be broken down to monosaccharides for absorption. When there is a deficiency of lactase, lactose is not digested and remains unabsorbed in the gut. **30.** If a person exhales large amounts of CO_2 , the equilibrium of the reactions will shift to the left to replace the lost CO_2 . As a result, the level of H⁺ in the blood will decrease. A decrease in the amount of H⁺ will cause the pH to rise.

CHAPTER 3

ANSWERS TO CHECKPOINTS

Page 87

1. The basic concepts of the cell theory are (1) cells are the building blocks of all plants and animals; (2) cells are the smallest functioning units of life; (3) cells are produced through the division of preexisting cells; and (4) each cell maintains homeostasis. **2.** The study of cells is called cytology.

Page 91

3. The general functions of the plasma membrane include physical isolation, regulation of exchange with the environment, sensitivity to the environment, and structural support. **4.** The phospholipid bilayer of the plasma membrane forms a physical barrier between the cell's internal and external environments. **5.** Channel proteins allow water and small ions to cross the plasma membrane.

Page 95

6. A selectively permeable membrane allows the passage of some substances while restricting the passage of others. It falls between two extremes: impermeable, which allows no substance to pass, and freely permeable, which permits the passage of any substance. 7. Diffusion is the passive molecular movement of a substance from an area of higher concentration to an area of lower concentration; diffusion proceeds until the concentration gradient is eliminated and equilibrium is reached. 8. Diffusion is driven by a concentration gradient. The larger the concentration gradient, the faster the rate of diffusion; the smaller the concentration gradient, the slower the rate of diffusion. If the concentration of oxygen in the lungs were to decrease, the concentration gradient between oxygen in the lungs and oxygen in the blood would decrease (as long as the oxygen level of the blood remained constant). Thus, oxygen would diffuse into the blood more slowly. 9. Osmosis is the diffusion of water across a selectively permeable membrane from one solution to another solution. Movement occurs toward higher solute concentrations because that is where the concentration of water is lower. **10.** Relative to a surrounding hypertonic solution, the contents of a red blood cell are hypotonic; that is, the solute concentration within an RBC is less than that of the solution surrounding it.

Page 98

11. Active transport processes require the expenditure of cellular energy in the form of the high-energy bonds of ATP molecules. Passive transport processes (*diffusion, osmosis,* and *facilitated diffusion*) result in the movement of ions and molecules across the plasma membrane without any energy expenditure by the cell. **12.** An active transport process must be involved because H^+ must be transported from the cells lining the stomach, where H^+ are less concentrated, to the interior of the stomach, where H^+ are more concentrated—that is, against their concentration gradient. **13.** This process is an example of phagocytosis.

Page 106

14. Cytoplasm is the material between the plasma membrane and the nuclear membrane. Cytosol is the fluid portion of the cytoplasm. 15. The membranous organelles (and their functions) include (1)endoplasmic reticulum = synthesis of secretory products, intracellular storage and transport; (2) rough ER = modificationand packaging of newly synthesized proteins; (3) smooth ER = lipidand carbohydrate synthesis; (4) Golgi apparatus = storage, alteration, and packaging of secretory products and lysosomal enzymes; (5) lysosomes = intracellular removal of damaged organelles or pathogens; (6) mitochondria = production of 95 percent of the ATP required by the cell; (7) peroxisomes = neutralization of toxic compounds. 16. The fingerlike projections on the surface of intestinal cells are microvilli. They increase the surface area of the intestinal cells so they can absorb nutrients more efficiently. 17. Cells that lack centrioles are unable to divide. 18. The SER functions in the synthesis of lipids, including steroids. Cells of the ovaries and testes would be expected to have a great deal of SER because these organs produce large amounts of steroid hormones. **19.** Mitochondria produce energy for the cell in the form of ATP molecules. A large number of mitochondria in a cell would indicate a high demand for energy.

Page 108

20. The nucleus is a cellular organelle that contains DNA, RNA, and proteins. The nuclear envelope is a double membrane that surrounds the nucleus. Nuclear pores allow for chemical communication between the nucleus and the cytosol. **21.** A gene is a portion of a DNA strand that functions as a hereditary unit. Each gene is located at a particular site on a specific chromosome and codes for a specific protein.

Page 110

22. The nucleus controls the cell's activities through DNA, which codes for the production of all of the cell's proteins. Some of these proteins are structural proteins responsible for the cell's shape and other physical characteristics. Other proteins are enzymes that govern cellular metabolism. By ordering or stopping the production

of specific enzymes, the nucleus can regulate all of the cell's activities and functions. **23.** A cell lacking RNA polymerase would not be able to transcribe mRNA from DNA. **24.** The deletion of a base from a coding sequence of DNA during transcription would alter the entire mRNA base sequence after the deletion point. This change would result in different codons on the messenger RNA that was transcribed from the affected region. This, in turn, would result in the inclusion of a different series of amino acids into the protein. Almost certainly the protein product would not be functional.

Page 114

25. The biological term for cellular reproduction is *cell division*, and the term for cell death is *apoptosis*. **26.** Interphase is the portion of a cell's life cycle during which the chromosomes are uncoiled and all normal cellular functions except mitosis are under way. The stages of interphase include G_1 , S, and G_2 . **27.** Mitosis is the essential step in cell division in which a single cell nucleus divides to produce two identical daughter cell nuclei. The four stages of mitosis are prophase, metaphase, anaphase, and telophase. **28.** If spindle fibers failed to form during mitosis, the cell would not be able to separate the chromosomes into two sets. If cytokinesis were to take place, the result would be one cell with two sets of chromosomes, and another cell with none.

Page 115

29. An illness characterized by mutations that disrupt normal control processes and produce potentially malignant cells is termed cancer. **30.** Metastasis is the spread of cancer cells from one organ or tissue to another, leading to the establishment of secondary tumors. **31.** Cellular differentiation is the development of specific cellular characteristics and functions that are different from the original cell. It results from genes in the cells being repressed, or switched off, restricting the cell's potential functions.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. f 2. e 3. i 4. b 5. g 6. c 7. h 8. d 9. n 10. l 11. a 12. j 13. p 14. k 15. m 16. o 17. q 18. c 19. b 20. a. isotonic b. hypotonic c.hypertonic 21. b 22. a 23. a 24. d 25. d 26. replication of DNA and synthesis of histones. 27. through channel proteins in the plasma membrane 28. Cytoskeleton functions: provides strength and support to the cell and its organelles; facilitates movement of cellular structure and materials; helps cells to change shapes; facilitates cell division.

Level 2: Reviewing Concepts

29. a **30.** d **31.** c **32.** c **33.** In cotransport, two substances are moved in the same direction into or out of the cell. In counter-transport, substances are carried in opposite directions.

34. Cytosol has a high concentration of K⁺; interstitial fluid has a high concentration of Na⁺. Cytosol also contains a high concentration of suspended proteins, small quantities of carbohydrates, and large reserves of amino acids and lipids. Cytosol may also contain insoluble materials known as inclusions. **35.** In transcription, RNA polymerase uses genetic information to assemble a strand of mRNA. In translation, ribosomes use information carried by

the mRNA strand to assemble functional proteins. 36. Prophase:
chromatin condenses and chromosomes become visible; centrioles migrate to opposite ends of the cell and spindle fibers develop;
nuclear membrane disintegrates. Metaphase: chromatids attach to spindle fibers and line up along the metaphase plate. Anaphase:
chromatids separate and migrate toward opposite ends of the cell.
Telophase: the nuclear membrane re-forms; chromosomes disappear as chromatin relaxes; nucleoli reappear. 37. A mutation
reserves; and (4) de the serves; and (

Level 3: Critical Thinking and Clinical Applications

38. This process is facilitated transport, which requires a carrier molecule but not cellular energy. The energy for the process is provided by the diffusion gradient for the substance being transported. When all the carriers are actively involved in transport, the rate of transport levels out and cannot be increased further. **39.** Solution A must have initially had more solutes than solution B. As a result, water moved by osmosis across the selectively permeable membrane from side B to side A, increasing the fluid level on side A.

that affects the sex cell of a parent might be transmitted to the

CHAPTER 4

ANSWERS TO CHECKPOINTS

Page 121

offspring.

1. Histology is the study of tissues. **2.** The four basic types of tissues that form all body structures are epithelial, connective, muscle, and nervous tissues.

Page 125

3. Epithelial tissue is characterized by closely bound cells, a free surface exposed to the environment or an internal space, attachment to underlying connective tissue by a basement membrane, avascularity (absence of blood vessels), and continual replacement of exposed cells. **4.** Epithelial tissue provides physical protection, controls permeability, provides sensation, and produces specialized secretions. **5.** Epithelial cell junctions include tight junctions, gap junctions, and desmosomes. **6.** The presence of microvilli on the free surface of epithelial cells greatly increases the surface area for absorption or secretion. Motile cilia function to move materials over the surface of epithelial cells.

Page 131

7. The three cell shapes characteristic of epithelial cells are squamous (flat), cuboidal (cube-like), and columnar (rectangular).
8. No. A simple squamous epithelium does not provide enough protection against infection, abrasion, and dehydration. The skin surface has a stratified squamous epithelium.
9. The two primary types of glandular epithelia are endocrine glands and exocrine glands.
10. Sebaceous glands exhibit holocrine secretion.
11. This gland is an endocrine gland.

Page 139

12. Functions of connective tissues include (1) supporting, surrounding, protecting, and interconnecting other types of tissue; (2) transporting fluids and dissolved materials; (3) storing energy

reserves; and (4) defending the body from invading microorganisms. **13.** The three types of connective tissues are connective tissue proper, fluid connective tissues, and supporting connective tissues. **14.** The connective tissue containing primarily triglycerides is adipose (fat) tissue. **15.** The reduced collagen production resulting from a lack of vitamin C in the diet would cause connective tissue to be weak and prone to damage. **16.** The two connective tissues that contain a fluid matrix are blood and lymph. **17.** The two types of supporting connective tissue are cartilage and bone. **18.** Cartilage heals slower than bone because it lacks a direct blood supply. As a result, materials needed for repair reach the chondrocytes by the slow process of diffusion from the blood, thus slowing the healing process.

Page 141

19. The four types of tissue membranes found in the body are the cutaneous membrane, mucous membranes, serous membranes, and synovial membranes. **20.** Plasma (cell) membranes are composed of lipid bilayers. Tissue membranes consist of a layer of epithelial tissue and a layer of areolar tissue. **21.** Serous fluid minimizes the friction between the serous membranes that cover the surfaces of organs and the surrounding body cavity. **22.** The lining of the nasal cavity is a mucous membrane.

Page 143

23. The three types of muscle tissue in the body are skeletal muscle, cardiac muscle, and smooth muscle. **24.** Only skeletal muscle tissue is under voluntary control. **25.** Muscle tissue that lacks striations is smooth muscle; both cardiac and skeletal muscles are striated.

Page 144

26. The cells are most likely neurons. **27.** Skeletal muscle cells and axons are both called fibers because they are relatively long and slender.

Page 145

28. The two phases in the response to tissue injury are inflammation and regeneration. **29.** Swelling, redness, heat, and pain are the familiar signs and symptoms of inflammation. **30.** Fibrosis is the permanent replacement of normal tissues by fibrous tissue. **31.** With advancing age, the speed and effectiveness of tissue repair decrease, the rate of energy consumption in general declines, hormonal activity is altered, and other factors contribute to changes in tissue structure and chemical composition.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. h 2. e 3. k 4. j 5. b 6. g 7. d 8. f 9. c 10. i 11. m 12. l 13. (a) simple squamous epithelium; (b) simple cuboidal epithelium; (c) simple columnar epithelium; (d) stratified squamous epithelium; (e) stratified cuboidal epithelium; (f) stratified columnar epithelium. 14. b 15. c 16. d 17. c 18. d 19. a 20. a 21. d 22. c 23. d 24. (a) mucous membrane; (b) serous membrane; (c) cutaneous membrane; (d) synovial membrane 25. Layering in epithelia is either simple or stratified. 26. Proteins that allow muscle cells to contract are actin and myosin. 27. fluid connective tissues: blood and lymph; supporting connective tissues: bone and cartilage 28. Nervous tissue consists of neurons, which propagate, or transmit, electrical impulses, and neuroglia, which include several kinds of supporting cells, some of which play a role in providing nutrients to neurons.

Level 2: Reviewing Concepts

29. d **30.** During holocrine secretion, gland cells become packed with secretory products and then burst, releasing the secretion but killing the cells. The lost gland cells must be replaced by the division of stem cells. **31.** Tight junctions inhibit the passage of water and solutes between epithelial cells, thereby preventing harsh chemicals from damaging underlying tissues. **32.** Tendons and ligaments tend to be subjected to forces from one direction, whereas, in muscle sheaths and the dermis, forces come from multiple angles. **33.** In skin, tight junctions, proteoglycan molecules, and physical interlocking form extensive connections that hold skin cells together, denying the entry of any pathogens present on their free surfaces. If the skin is damaged and the connections are broken, infection can easily occur. **34.** Unlike serous and mucous membranes, the cutaneous membrane is thick, relatively water-proof, and usually dry.

Level 3: Critical Thinking and Clinical Applications

35. Epithelial tissues do not contain blood vessels. Since there is bleeding, the paper has cut through the epithelial tissue to the underlying vascular connective tissue. **36.** Step 1: Check for striations. (If striations are present, the tissue is skeletal muscle or cardiac muscle. If striations are absent, the tissue is smooth muscle.) Step 2: Check for the presence of intercalated discs. (If the discs are present, the tissue is cardiac muscle. If they are absent, the tissue is skeletal muscle.)

CHAPTER 5

ANSWERS TO CHECKPOINTS

Page 153

1. Five major functions of the integumentary system include protection, temperature maintenance, synthesis and storage of nutrients, sensory reception, and excretion and secretion.

Page 156

2. The five layers of the epidermis are the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. **3.** Dandruff consists of cells from the stratum corneum. **4.** Sanding the tips of the fingers will not permanently remove fingerprints. The ridges of fingerprints are formed in skin layers that are constantly regenerated, so these ridges will eventually reappear.

Page 157

5. The two pigments in the epidermis are carotene, an orangeyellow pigment, and melanin, a brown, yellow-brown, or black pigment. **6.** When exposed to the ultraviolet radiation in sunlight or tanning lamps, melanocytes in the epidermis (and dermis) synthesize the pigment melanin, darkening the skin. **7.** When skin gets warm, arriving oxygenated blood is diverted to superficial blood vessels to eliminate heat. The oxygenated blood imparts a reddish coloration to the skin. **8.** In the presence of ultraviolet radiation in sunlight, epidermal cells in the stratum spinosum and stratum basale convert a cholesterol-related steroid into vitamin D_3 . **9.** The most common skin cancer is basal cell carcinoma.

Page 159

10. The dermis (a connective tissue layer) lies immediately deep to the epidermis. 11. The capillaries that supply the epidermis are located in the papillary layer of the dermis, where they follow the contours of the epidermis-dermis boundary. 12. The tissue that connects the dermis to underlying tissues is the subcutaneous layer or hypodermis. 13. The subcutaneous layer is a layer of areolar tissue containing many adipose (fat) cells, which lies below the dermis. It is not considered a part of the integument, but it is important in stabilizing the position of the skin in relation to underlying tissues.

Page 161

14. A typical hair is a keratinous strand produced by epithelial cells of a hair follicle. **15.** Contraction of the arrector pili muscle pulls on the hair follicle, making the hair stand erect. The result is sometimes known as "goose bumps." **16.** Even though hair is a structure derived from the epidermis, the follicles are in the dermis. Where the epidermis and deep dermis are destroyed, new hair will not grow.

Page 163

17. Two types of exocrine glands found in the skin are sebaceous (oil) glands and sweat glands. **18.** Sebaceous secretions (called sebum) lubricate and protect the keratin of the hair shaft, lubricate and condition the surrounding skin, and inhibit bacterial growth. **19.** Deodorants are used to mask the odor of apocrine sweat gland secretions, which contain several kinds of organic compounds that have an odor or produce an odor when metabolized by skin bacteria.

Page 164

20. The substance keratin gives nails their strength. **21.** Nail growth occurs at the nail root, an epidermal fold that is not visible from the surface.

Page 167

22. The combination of fibrin clots, fibroblasts, and the extensive network of capillaries in healing tissue is called granulation tissue. **23.** Skin can regenerate effectively even after undergoing considerable damage because stem cells persist in both the epithelial and connective tissue components of skin. When injury occurs, cells of the stratum basale replace epithelial cells while connective tissue stem cells replace cells lost from the dermis. **24.** As a person ages, the blood supply to the dermis decreases and merocrine sweat glands become less active. These changes make it more difficult for elderly people to cool themselves in hot weather. **25.** With advancing age, melanocyte activity decreases, leading to gray or white hair.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1.g **2.**h **3.**j **4.**a **5.**b **6.**f **7.**c **8.**e **9.**d **10.**i **11.**a **12.**d **13.** (a) epidermis; (b) dermis; (c) papillary layer; (d) reticular layer; (e) subcutaneous layer (hypodermis) **14.** a **15.** c **16.** b **17.** c **18.** (a) hair shaft; (b) sebaceous gland; (c) arrector pili muscle; (d) hair matrix; (e) hair papilla **19.** The three layers of a hair shaft are the cuticle, the cortex, and the medulla. **20.** c **21.** The whole epidermis and perhaps some of the dermis are damaged.

Level 2: Reviewing Concepts

22. d 23. Fat-soluble drugs are more desirable for transdermal administration because the permeability barrier is composed primarily of lipids surrounding epidermal cells. Water-soluble drugs are not soluble in lipids and have difficulty penetrating the lipidbased barrier. 24. A tan results from the synthesis of melanin, which helps prevent skin damage by absorbing ultraviolet radiation before it reaches the deep layers of the epidermis and dermis. Melanin accumulates around the nucleus of epidermal cells, absorbing UV light before it can damage nuclear DNA. 25. The lack of exposure to UV light in sunlight prevents the production of vitamin D₃ from a cholesterol-related steroid in the deepest layers of the epidermis. Thus, vitamin D₃ cannot be modified by the liver and converted into the hormone calcitriol by the kidneys. Calcitriol is essential for the absorption of the calcium and phosphorus needed to form strong bones, so fragile bones result. 26. Fingerprints are determined by both genetic makeup and the intrauterine environment. The latter leads to different fingerprint patterns, even between identical twins. 27. As a person ages, the dermis becomes thinner and the elastic fiber network decreases in size, weakening the integument and causing loss of resilience.

Level 3: Critical Thinking and Clinical Applications

28. The child probably has a fondness for vegetables high in the yellow-orange pigment carotene, such as sweet potatoes, squash, and carrots. If a child consumes large amounts of carotene, the pigment will be stored in the skin, producing a yellow-orange skin color. **29.** Like most elderly people, Vanessa's grandmother has poor circulation to the skin. As a result, temperature receptors in the skin sense less warmth compared to good circulation. When this sensory information is relayed to the brain, that organ interprets it as coldness, causing Vanessa's grandmother to feel cold. **30.** Third-degree burns damage the full thickness of the skin and may destroy sensory nerves. Thus, patients with these injuries may report less pain.

CHAPTER 6

ANSWERS TO CHECKPOINTS

Page 173

1. The five primary functions of the skeletal system are support, storage of minerals and lipids, blood cell production, protection, and leverage.

Page 176

2. The four general shapes of bones are flat, irregular, long, and short. **3.** If the ratio of collagen to calcium in a bone increased, the bone would be weaker (but more flexible). **4.** This sample most likely came from the shaft (diaphysis) of a long bone, as concentric layers of bone around a central canal are indicative

of osteons, which make up compact bone. The ends (epiphyses) of long bones are primarily spongy (trabecular) bone. **5.** Mature bone cells are known as osteocytes, bone-building cells are called osteoblasts, and osteoclasts are bone-resorbing cells. **6.** When osteoclast activity exceeds osteoblast activity, bone mass decreases, because osteoclasts break down or demineralize bone.

Page 179

7. During intramembranous ossification, fibrous connective tissue is replaced by bone. 8. An x-ray of the femur (or any long bone) would indicate whether the epiphyseal cartilage, which separates the epiphysis from the diaphysis, is still present. If present, then growth is still occurring. If it is absent, the bone has reached its full length. 9. Growth continues throughout childhood. At puberty, a growth spurt occurs that is then followed by the closure of the epiphyseal cartilages. The later puberty begins, the taller the child will be at the start of the growth spurt. So, when growth is completed, the individual will be taller than individuals who began puberty earlier. 10. Pregnant women need large amounts of calcium to support bone growth in the developing fetus. If an expectant mother does not take in enough calcium in her diet, her body will mobilize the calcium reserves of her own skeleton to provide for the needs of the fetus, resulting in weakened bones in the mother, as well as an increased risk of fracture.

Page 182

11. Bone remodeling refers to the continuous process whereby old bone is being destroyed by osteoclasts while new bone is being constructed by osteoblasts. 12. In response to mechanical stress on the arm bones during weight lifting, the bones grow heavier. The arm bones of joggers are lighter because they experience relatively little stress. 13. Parathyroid hormone (PTH) and calcitriol work together to increase blood calcium levels, whereas calcitonin decreases blood calcium levels. 14. A closed (simple) fracture is completely internal and there is no break in the skin. An open (compound) fracture projects through the skin. It is more dangerous because of the possibility of infection or uncontrolled bleeding. 15. Osteopenia is inadequate ossification and is common to the aging process. It results from decreasing osteoblast activity accompanied by normal osteoclast activity. 16. Osteoporosis is more common in older women because after menopause, levels of estrogens-sex hormones that play an important role in moving calcium into bones-decrease dramatically, making it difficult to replace calcium lost from bones due to normal aging. In men, decreases in sex hormone (androgen) levels occur at later ages.

Page 186

17. A bone marking (surface feature) is an area on the surface of a bone related to a specific function, such as joint formation, muscle attachment, or the passage of nerves and blood vessels. **18.** The axial skeleton includes the skull (8 cranial bones and 14 facial bones); the bones associated with the skull (6 auditory ossicles and the hyoid bone); the bones of the rib cage (24 ribs and the sternum); and the vertebral column (26 bones).

Page 196

19. The mastoid and styloid processes are projections on the temporal bones of the skull. **20.** The sella turcica is located in the sphenoid bone. During life, it contains the pituitary gland. 21. The occipital bone of the cranium (specifically, the occipital condyles) articulates with the vertebral column. 22. The bones fractured by the ball are the frontal bone (which forms the superior portion of the orbit) and the maxillary and zygomatic bones (which form the inferior portion of the orbit). 23. The paranasal sinuses lighten some of the heavier skull bones. They contain a mucous epithelium that releases a mucous secretion into the nasal cavities that warms, moistens, and filters particles out of the incoming air. 24. A fracture of the coronoid process would make it difficult to close the mouth because it would hinder the functioning of muscles that attach to the coronoid process of the mandible (lower jaw). 25. Because many muscles that move the tongue and the larynx are attached to the hyoid bone, you would expect a person with a fractured hyoid bone to have difficulty moving the tongue, breathing, and swallowing. 26. The dens is part of the second cervical vertebra, or axis, which is in the neck. **27.** In adults, the five sacral vertebrae fuse to form a single sacrum. 28. The lumbar vertebrae must support a great deal more weight than do vertebrae that are more superior in the spinal column. The large vertebral bodies allow the weight to be distributed over a larger area. 29. True ribs (ribs 1-7) are each attached directly to the sternum by their own costal cartilage. False ribs (ribs 8-12) either do not attach to the sternum (the floating ribs) or attach by means of a shared, common costal cartilage. 30. Improper compression of the chest during CPR can-and commonly does-result in a fracture of the xiphoid process of the sternum or the ribs.

Page 203

31. By attaching the scapula to the sternum, the clavicle restricts the scapula's range of movement. A broken clavicle thus allows the scapula a greater range of movement (and reduces its stability). **32.** The two rounded projections on either side of the elbow are the lateral and medial epicondyles of the humerus. **33.** The radius is lateral to the ulna when the forearm is in the anatomical position. **34.** The three bones that make up a hip bone are the ilium, the ischium, and the pubis. **35.** The fibula is an important site of attachment for many leg muscles, so its fracture prevents proper muscle function, and moving the leg and walking become difficult and painful. The fibula also helps stabilize the ankle joint. **36.** Cesar has most likely fractured his calcaneus (heel bone).

Page 206

37. The three types of joints as classified by their range of motion are (1) an immovable joint, or synarthrosis; (2) a slightly movable joint, or amphiarthrosis; and (3) a freely movable joint, or diarthrosis. A synarthrosis can be fibrous or cartilaginous, depending on the nature of the connection, or it can be a bony fusion, which develops over time. An amphiarthrosis is either fibrous or cartilaginous, depending on the nature of the connection. A diarthrosis joint is a synovial joint and permits the greatest range of motion. **38.** These are fibrous joints known as sutures.

Page 208

39. (a) Moving the humerus away from the body's longitudinal axis is abduction. (b) Turning the palms forward is supination. (c) Bending the elbow is flexion. **40.** Flexion and extension are associated with hinge joints.

Page 214

41. The tennis player is more likely than the jogger to have subscapular bursitis (inflammation of the bursa) because this bursa is located in the shoulder joint. **42.** Daphne has most likely fractured her ulna. **43.** A complete dislocation of the knee is rare because the joint is stabilized by ligaments on its anterior, posterior, medial, and lateral surfaces, as well as by a pair of ligaments within the joint capsule. **44.** The skeletal system provides structural support for all body systems and stores energy, calcium, and phosphate reserves. The integumentary system synthesizes vitamin D₃, which is essential for calcium and phosphate ion absorption. Calcium and phosphate ions are needed for bone growth and maintenance.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. j 2. i 3. n 4. m 5. k 6. l 7. g 8. d 9. a 10. c 11. h 12. o 13. e 14. b 15. f 16. b 17. c 18. b 19. b 20. b 21. (a) occipital bone; (b) parietal bone; (c) frontal bone; (d) temporal bone; (e) sphenoid bone; (f) ethmoid bone; (g) vomer; (h) mandible; (i) lacrimal bone; (j) nasal bone; (k) zygomatic bone; (l) maxilla (or maxillary bone) 22. a 23. b 24. d 25. b 26. a 27. c 28. (a) joint capsule; (b) synovial membrane; (c) articular cartilage; (d) joint cavity 29. a 30. c 31. a 32. d 33. The primary curves that are present at birth are the thoracic and sacral curves. 34. The thoracic cage (1) protects the heart, lungs, thymus, and other structures in the thoracic cavity, and (2) serves as an attachment point for muscles involved with respiration, positioning the vertebral column, and moving the pectoral girdles and upper extremities. 35. The acromion and coracoid processes are parts of the scapula associated with the shoulder joint.

Level 2: Reviewing Concepts

36. The osteons are parallel to the long axis of the shaft, which does not bend when forces are applied to either end. An impact to the side of the shaft can lead to a fracture. 37. The chondrocytes of the epiphyseal cartilage enlarge and divide, increasing the thickness of the cartilage. On the shaft side, the chondrocytes become ossified, forcing or "chasing" the expanding epiphyseal cartilage away from the shaft. 38. The lumbar vertebrae have massive bodies and carry a large amount of weight-both causative factors of disc rupture. The cervical vertebrae are more delicate and have small bodies, increasing the possibility of dislocations and fractures compared with other regions of the vertebral column. **39.** Deep acetabulum that almost completely encloses the femoral head, strong joint capsule and supporting ligaments, and bulky muscles around the joint. 40. The pelvic girdle consists of the two hip bones. The pelvis is a composite structure that includes the two hip bones of the appendicular skeleton and the sacrum and coccyx of the axial skeleton. 41. The differences in shapes are due to variations in body size and muscle mass as well as adaptations for childbearing. **42.** The fibrous connective tissue allows for movement of the cranial bones, enabling the skull to distort and easing the fetus' passage through the birth canal.

Level 3: Critical Thinking and Clinical Applications

43. The radiolucent line is due to the epiphyseal cartilage (also known as epiphyseal plate or growth plate) in the lower end of the tibia. 44. The virus could have been inhaled through the nose and passed into the cranium by way of the cribriform plate of the ethmoid bone. 45. The large bones of a child's cranium are not yet fused, but connected by areas of connective tissue called fontanelles. By examining the bones, the archaeologist could readily see if sutures had formed. By knowing approximately how long it takes for the various fontanelles to close and by determining their sizes, she could estimate the age of the individual at death. 46. Frank may have suffered a shoulder dislocation, which is a quite common injury due to the weak nature of the articulation between the scapula and the humerus, or glenohumeral joint. 47. Ed has a sprained ankle. This condition occurs when ligaments are stretched to the point at which some of the collagen fibers are torn. Stretched ligaments in joints can cause the release of synovial fluid, which results in swelling and pain in the affected area.

CHAPTER 7

ANSWERS TO CHECKPOINTS

Page 222

1. Skeletal muscles produce skeletal movement, maintain body posture and body position, support soft tissues, guard body entrances and exits, and maintain body temperature.

Page 224

2. The epimysium is a dense layer of collagen fibers that surrounds the entire muscle; the perimysium divides the skeletal muscle into a series of compartments, each containing a bundle of muscle fibers called a fascicle; and the endomysium surrounds individual skeletal muscle cells (fibers). 3. Severing the tendon would prevent the muscle from moving the body part because the muscle would no longer be connected to the bone.

Page 227

4. Sarcomeres, the smallest contractile units of a skeletal muscle cell, are segments of myofibrils. Each sarcomere has dark A bands and light I bands. The A band contains the M line, H band, and the zone of overlap. Each I band contains thin filaments but not thick filaments. Z lines mark the boundaries between adjacent sarcomeres. **5.** Skeletal muscle appears striated when viewed under the microscope because the arrangement of the actin and myosin myofilaments within myofibrils produces a banded appearance. **6.** You would expect to find the greatest concentration of calcium ions in the terminal cisternae of the sarcoplasmic reticulum of a resting skeletal muscle fiber.

Page 230

7. The neuromuscular junction—a specialized intercellular connection between a motor neuron and a muscle cell—enables

communication between the nervous system and a skeletal muscle fiber. **8.** A drug that blocks ACh release would prevent muscle contraction. A lack of ACh prevents the generation of an action potential in the sarcolemma, which is necessary for the release of calcium ions from the sarcoplasmic reticulum, and subsequent cross-bridge formation. **9.** If the sarcolemma of a resting skeletal muscle suddenly became permeable to calcium ions, the intracellular concentration of calcium ions would increase, and the muscle would contract. In addition, because the amount of calcium ions in the sarcoplasm must decline for relaxation to occur, the increased permeability of the sarcolemma to calcium ions might prevent the muscle from relaxing completely.

Page 237

10. The amount of tension produced in a skeletal muscle depends on (1) the frequency of muscle fiber stimulation and (2) the number of muscle fibers activated. **11.** A motor unit with 1500 muscle fibers is most likely from a large muscle involved in powerful, gross movements. Muscles that control fine or precise movements (such as those moving the eye or the fingers) have only a few fibers per motor unit, whereas muscles involved in more powerful contractions (such as those moving the leg) have hundreds of fibers per motor unit. **12.** Yes. A skeletal muscle undergoing an isometric contraction does not shorten, even though tension in the muscle increases. By contrast, in an isotonic contraction, tension remains constant and the muscle shortens.

Page 240

13. Muscle cells continuously synthesize ATP by utilizing creatine phosphate (CP) and metabolizing glycogen and fatty acids. Most cells generate ATP through aerobic metabolism in the mitochondria and through glycolysis in the cytoplasm. **14.** Muscle fatigue is a muscle's reduced ability to contract despite neural stimulation. It may be due to low ATP levels, low pH (due to the buildup of hydrogen ions), or other problems. **15.** Oxygen debt is the amount of oxygen required to restore normal, pre-exertion conditions in muscle tissue.

Page 241

16. A sprinter requires large amounts of energy for a relatively short burst of activity. To supply this energy, the sprinter's muscles switch to anaerobic metabolism. Anaerobic metabolism is less efficient in producing energy than aerobic metabolism and produces acidic waste products; this combination contributes to muscle fatigue. By contrast, marathon runners derive most of their energy from aerobic metabolism, which is more efficient and produces fewer waste products than anaerobic metabolism. 17. Activities that require short periods of strenuous activity produce a greater oxygen debt, because such activities rely heavily on energy production by anaerobic metabolism. Because lifting weights is more strenuous over the short term than swimming laps, which is an aerobic activity, weight lifting would likely produce a greater oxygen debt than would swimming laps. **18.** Individuals who excel at endurance activities have a higher than normal percentage of slow muscle fibers. Slow muscle fibers are better adapted to this type of activity than fast fibers, which are less vascular and fatigue more quickly.

Page 243

19. Intercalated discs enhance cardiac muscle tissue function by tightly binding cardiac muscle fibers, enabling them to "pull together" efficiently. Because intercalated discs also contain gap junctions, ions and small molecules can flow directly between cells. As a result, action potentials generated in one cell spread rapidly to adjacent cells. Thus, all cells contract simultaneously. **20.** Extracelular calcium ions are important for the contraction of cardiac and smooth muscle. In skeletal muscle, calcium ions come from the sarcoplasmic reticulum. **21.** Smooth muscle cells can contract over a relatively large range of resting lengths because their actin and myosin filaments are not as rigidly organized as in skeletal muscle.

Page 246

22. Skeletal muscle names are based on several factors, including location in the body, origin and insertion, action, muscle fascicle orientation, relative position, structural characteristics, muscle shape, number of origins, and size. **23.** The *triceps brachii*, which extends the elbow, is the antagonist of the biceps brachii, which produces flexion at the elbow. **24.** The name *flexor carpi radialis longus* tells you that this muscle is a long muscle (longus) that lies next to the radius (radialis) and flexes (flexor) the wrist (carpus).

Page 255

25. You would likely be chewing; contracting the masseter muscle raises the mandible, whereas relaxing this muscle depresses the mandible. **26.** You would expect the buccinator muscle, which shapes the mouth for blowing, to be well developed in a trumpet player. **27.** Damage to the external intercostal muscles would interfere with the process of breathing. **28.** A blow to the rectus abdominis would cause that muscle to contract forcefully, flexing the torso. In other words, you would "double over."

Page 259

29. When you shrug your shoulders, you are contracting your levator scapulae muscles. 30. The rotator cuff muscles are the supraspinatus, infraspinatus, teres minor, and subscapularis. (The acronym SITS is useful in remembering these four muscles.)31. Injury to the flexor carpi ulnaris would impair the ability to flex and adduct the wrist.

Page 264

32. A "pulled hamstring" refers to a muscle strain affecting one or more of the three muscles that collectively flex the knee: the biceps femoris, semimembranosus, and semitendinosus muscles. **33.** A torn calcaneal tendon would make plantar flexion difficult because this tendon attaches the soleus and gastrocnemius muscles to the calcaneus (heel bone). **34.** The three functional muscle groups of the lower limb are: (1) muscles that work across the hip joint to move the thigh; (2) muscles that work across the various joints of the foot to move the ankles, feet, and toes. **35.** The sartorius muscle crosses over both the hip and knee joints.

Page 267

36. General age-related effects on skeletal muscles include decreased skeletal muscle fiber diameters, diminished muscle elasticity, decreased tolerance for exercise, and a decreased ability to

recover from muscular injuries. **37.** The muscular system generates heat that maintains normal body temperature. **38.** Exercise affects the cardiovascular system by increasing heart rate and dilating blood vessels. With exercise, the rate and depth of respiration increase, and sweat gland secretion increases. The nervous and endocrine systems direct and coordinate the physiological effects of exercise.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. g 2. j 3. e 4. a 5. m 6. d 7. i 8. o 9. c 10. l 11. p 12. b 13. n 14. k 15. h 16. f 17. (a) T tubules; (b) terminal cisterna; (c) sarcoplasmic reticulum; (d) triad; (e) sarcolemma; (f) mitochondria; (g) thick filament; (h) thin filament; (i) myofibril 18. b 19. (a) supraspinatus; (b) infraspinatus; (c) teres minor 20. In isotonic contraction, the muscle shortens, but the muscular tension remains constant. In isometric contraction, the muscle tension increases, but the muscle length does not change. 21. Calcium binds to troponin to expose the active site of the actin molecule covered by tropomyosin. The myosin head can then attach to the actin molecule for muscle contraction to take place. 22. This action requires supination of the right forearm, which is produced by the contraction of the biceps brachii and the supinator muscles.

Level 2: Reviewing Concepts

23. c 24. Acetylcholine released by the motor neuron at the neuromuscular junction changes the permeability of the cell membrane at the motor end plate. The permeability change allows the influx of positive sodium ions, which in turn trigger an electrical event called an action potential. The action potential spreads across the entire surface of the muscle fiber and into the interior along the T tubules. The release of calcium ions from the sarcoplasmic reticulum triggers the start of a contraction. The contraction ends when the ACh has been removed from the synaptic cleft and motor end plate by AChE. 25. Myoglobin binds itself to oxygen molecules, thereby providing a reserve of oxygen to allow slow fibers to contract for extended periods of time. 26. The spinal column does not need a massive series of flexors because (1) gravity tends to flex the spine (because body weight largely lies anterior to the spinal column) and (2) contractions of many of the large trunk muscles flex the spine. 27. Contraction of skeletal muscles produces heat, thereby helping to maintain our core body temperature. 28. The muscle will not contract, and the person would be unable to close his/her eye.

Level 3: Critical Thinking and Clinical Applications

29. The most obvious sign of organophosphate poisoning is uncontrolled tetanic contractions of skeletal muscles. Organophosphates block the action of the enzyme acetylcholinesterase, so acetylcholine released into the synaptic cleft of the neuromuscular junction would not be inactivated, causing a state of persistent contraction (spastic paralysis). If paralysis affected the muscles of respiration (which is likely), Terry would die of suffocation. **30.** In rigor mortis, the membranes of the dead cells are no longer selectively permeable, and the SR is no longer able to

retain calcium ions. As calcium ions enter the cytosol, a sustained contraction develops, making the body extremely stiff. Contraction persists because the dead muscle cells can no longer make the ATP required for cross-bridge detachment from the active sites. Rigor mortis begins a few hours after death and ends after one to six days or when decomposition begins. Decomposition begins when the lysosomal enzymes released by autolysis break down the myofilaments. **31.** The toxin blocks the release of acetylcholine from the neuronal axon terminals, leading to flaccid paralysis of the targeted facial muscles and the reduction of wrinkles.

CHAPTER 8

ANSWERS TO CHECKPOINTS

Page 275

1. The two anatomical divisions of the nervous system are the central nervous system (CNS), consisting of the brain and spinal cord, and the peripheral nervous system (PNS), consisting of all nervous tissue outside the CNS. 2. The two functional divisions of the peripheral nervous system are the afferent division, which brings sensory information to the CNS from receptors in peripheral tissues and organs, and the efferent division, which carries motor commands from the CNS to effectors, such as muscles and glands. 3. Damage to the afferent division of the PNS would affect nerves carrying sensory information to the brain and spinal cord. It would interfere with a person's ability to experience a variety of sensory stimuli.

Page 281

4. Structural components of a typical neuron include a cell body (which contains the nucleus and nucleolus), an axon, dendrites, Nissl bodies, axon hillock, collaterals, and axon terminals. **5.** Unipolar neurons are most likely sensory neurons of the PNS. **6.** CNS neuroglia include ependymal cells, astrocytes, oligodendrocytes, and microglia. **7.** Small phagocytic glial cells called microglia would typically be found in increased numbers in infected (or damaged) areas of the CNS. **8.** In the PNS, neuron cell bodies (gray matter) are located in ganglia and are surrounded by satellite cells.

Page 288

9. If the voltage-gated sodium ion channels in a neuron's excitable axon membrane were blocked, the neuron would not be able to depolarize because sodium ions could not flow into the cell. **10.** If the extracellular potassium ion concentration decreased, more potassium ions would leave the cell, increasing the electrical gradient across the membrane (the membrane potential). This effect is called hyperpolarization. **11.** The steps in the generation of action potentials are Step 1: depolarization to threshold; Step 2: activation of voltage-gated sodium channels and rapid depolarization; Step 3: inactivation of sodium channels and activation of voltage-gated potassium ion channels; and Step 4: closing of potassium channels and return to normal permeability. 12. The axon carrying action potentials at 50 meters per second is myelinated. Myelinated axons propagate action potentials by saltatory propagation at speeds much higher than those by continuous propagation along unmyelinated axons.

Page 291

13. A synapse is the site where a neuron communicates with another cell. It is composed of presynaptic and postsynaptic cells whose plasma membranes are separated by a narrow synaptic cleft. **14.** Blocking calcium channels at the presynaptic terminal of a cholinergic synapse would prevent the influx of calcium ions that triggers the release of acetylcholine. As a result, no communication would occur across the synapse, and the postsynaptic neuron would not be stimulated. **15.** Convergence permits both conscious and subconscious control of the same motor neurons.

Page 292

16. The three meninges surrounding the CNS are the dura mater, arachnoid mater, and pia mater.

Page 296

17. Damage to the anterior root of a spinal nerve, which carries visceral and somatic motor fibers, would interfere with motor function. **18.** You would find poliovirus in the anterior gray horns of the spinal cord, because that is where the cell bodies of somatic motor neurons are located. **19.** All spinal nerves are classified as mixed nerves because they contain both sensory and motor fibers.

Page 308

20. The six regions in the brain and their major functions are (1) the *cerebrum*: conscious thought processes; (2) the *diencephalon*: the thalamic portion contains relay and processing centers for sensory information, and the hypothalamic portion contains centers involved with emotions, autonomic function, and hormone production; (3) the midbrain: processes visual and auditory information and generates involuntary motor responses; (4) the pons contains tracts and relay centers that connect the brainstem to the cerebellum; (5) the medulla oblongata contains major centers concerned with the regulation of autonomic function, such as heart rate, blood pressure, respiration, and digestive activities; and (6) the cerebellum adjusts voluntary and involuntary motor activities. **21.** The pituitary gland is attached to the hypothalamus, or the floor of the diencephalon. 22. If diffusion across the arachnoid granulations decreased, re-entry of cerebrospinal fluid into the bloodstream would be reduced, so the volume of cerebrospinal fluid in the ventricles would increase. 23. The primary motor cortex is located in the precentral gyrus of the frontal lobes of the cerebrum. 24. Damage to the temporal lobes of the cerebrum would interfere with the processing of olfactory (smell) and auditory (sound) sensations. 25. The thalamus acts as a relay point for all ascending sensory information except olfactory information. 26. Changes in body temperature stimulate the hypothalamus, a portion of the diencephalon. **27.** Damage to the medulla oblongata can have fatal results because, despite its small size, it contains vital reflex centers, including those that control breathing and regulate the heart and blood pressure.

Page 313

28. The abducens nerve (VI) controls lateral movements of the eyes through the lateral rectus muscles, so individuals with

damage to this nerve would be unable to move their eyes laterally (to the side). **29.** Control of the voluntary muscles of the tongue occurs through the hypoglossal nerve (XII). **30.** Damage to the cervical plexus—or more specifically to the phrenic nerves, which extend to and innervate the diaphragm—would greatly interfere with the ability to breathe (and might even be fatal).

Page 316

31. A reflex is a rapid, automatic response to a specific stimulus. It is important in maintaining homeostasis. **32.** Physicians use stretch reflexes (such as the patellar reflex, or knee-jerk reflex) to test the general condition of the spinal cord, peripheral nerves, and muscles. **33.** Polysynaptic reflexes can produce more complex responses because they include interneurons (between the sensory and motor neurons) that may control several muscle groups simultaneously. In addition, some interneurons may stimulate a muscle group or groups, whereas others may inhibit other muscle groups. **34.** A Babinski reflex is abnormal in adults. It indicates possible damage to descending tracts in Tom's spinal cord.

Page 319

35. A tract within the posterior column pathway of the spinal cord carrying information about touch and pressure from the lower part of the body to the brain is being compressed. **36.** The primary motor cortex of the right cerebral hemisphere controls motor function on the left side of the body. **37.** An injury to the superior portion of the motor cortex would affect the ability to control muscles in the hand, arm, and upper portion of the leg.

Page 324

38. The sympathetic division of the autonomic nervous system is responsible for the physiological changes that occur in response to stress and increased activity. 39. The parasympathetic division is sometimes referred to as the "anabolic system" because parasympathetic stimulation leads to a general increase in the nutrient content of the blood. Cells throughout the body respond to the increase by absorbing the nutrients and using them to support growth and other anabolic activities. 40. A decrease in sympathetic stimulation would result in reduced airflow because parasympathetic effects would dominate, decreasing the diameter of respiratory airways. **41.** Anxiety or stress causes increased sympathetic stimulation, so a person who is anxious about an impending root canal might exhibit some or all of the following: a dry mouth, increased heart rate, increased blood pressure, increased rate of breathing, cold sweats, an urge to urinate or defecate, change in motility of the digestive tract ("butterflies" in the stomach), and dilated pupils.

Page 325

42. Age-related reduction in brain size and weight results from a decrease in the volume of the cerebral cortex due to the loss of cortical neurons.

Page 326

43. The nervous system controls the actions of the arrector pili muscles and sweat glands of the integumentary system. It also controls skeletal muscle contractions of the muscular system,

which, in turn, affects the thickening of bones of the skeletal system.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. g 2. h 3. q 4. t 5. n 6. b 7. c 8. k 9. i 10. d 11. e 12. p 13. a 14. r 15. m 16. j 17. n 18. f 19. s 20. l 21. The all-or-none principle of action potentials: A given stimulus either triggers a typical action potential, or it does not produce one at all. 35. Oculomotor, trochlear, and abducens. 36. Most sensory neurons of the peripheral nervous system are unipolar, with the dendrites and axon being continuous and the cell body lying off to one side. All motor neurons controlling skeletal muscles are multipolar, with two or more dendrites and a single axon.

Level 2: Reviewing Concepts

37. b **38.** d **39.** It directs voluntary movements through its control of the somatic motor neurons in the brainstem and the spinal cord. **40.** Response time in a monosynaptic reflex is faster than in a polysynaptic reflex because with only one synapse, synaptic delay is minimized. In a polysynaptic reflex, total delay is proportional to the number of synapses involved.

41. <i>Property</i>	Sympathetic	Parasympathetic
Mental alertness	increased	decreased
Metabolic rate	increased	decreased
Digestive/urinary function	inhibited	stimulated
Use of energy reserves	stimulated	inhibited
Respiratory rate	increased	decreased
Heart rate/blood pressure	increased	decreased
Sweat gland activity	stimulated	inhibited

Level 3: Critical Thinking and Clinical Applications

42. Brain tumors do not result from uncontrolled division of neurons, but instead of neuroglial cells, which can divide. In addition, cells of the meningeal membranes can give rise to tumors. **43.** The officer is testing the function of the cerebellum. A person who is under the influence of many drugs, including alcohol, is unable to properly anticipate the range and speed of limb movement because of slow processing and correction by the cerebellum. As a result, an inebriated or intoxicated Bill would have a difficult time performing simple tasks such as walking a straight line or touching his finger to his nose. **44.** Severing the branches of the vagus nerves (X) helps control stress-induced stomach ulcers by eliminating excessive sympathetic stimulation. Chronic sympathetic stimulation causes constriction of blood vessels, which shuts off the blood supply to the stomach. The reduced blood supply causes cell and tissue death, resulting in ulcers. 45. The radial nerve is involved in crutch paralysis. 46. The corticospinal tract that begins at the right primary motor cortex crosses over to the left before reaching the lower motor neurons in the left half of the spinal cord. Thus, his left leg feels weak instead of the right leg.

CHAPTER 9

ANSWERS TO CHECKPOINTS

Page 337

 Adaptation is a decrease in receptor sensitivity or perception after constant stimulation.
 Receptor A provides more precise sensory information because it has a smaller receptive field.
 The five special senses are smell (olfaction), taste (gustation), vision, balance (equilibrium), and hearing.

Page 341

4. The four types of general sensory receptors (and the stimuli that excite them) are nociceptors (pain), thermoreceptors (temperature), mechanoreceptors (physical distortion), and chemoreceptors (chemical concentration). **5.** The three classes of mechanoreceptors are tactile receptors, baroreceptors, and proprioceptors. **6.** If proprioceptors in your legs could not relay information about limb position and movement to the CNS (especially the cerebellum), your movements would be uncoordinated, and you likely could not walk.

Page 343

7. Olfaction is the sense of smell. It involves olfactory receptor cells in paired olfactory organs responding to chemical stimuli.8. Repeated sniffing increases the perception of faint odors by increasing the flow of air and the number of odorant molecules passing over the olfactory epithelium.

Page 344

9. Gustation is the sense of taste, provided by taste receptors (gustatory epithelial cells) responding to chemical stimuli. **10.** Taste receptors are sensitive only to molecules and ions that are in solution. If you dry the surface of your tongue, the salt ions or sugar molecules have no moisture in which to dissolve, so they will not stimulate the taste receptors.

Page 353

11. The first accessory structure of the eye to be affected by inadequate tear production is the conjunctiva. **12.** When the lens becomes more rounded, you are looking at an object close to you. **13.** Malia will likely be unable to see at all. The fovea centralis contains only cones, which need high-intensity light to be stimulated. The dimly lit room contains light that is too weak to stimulate the cones.

Page 358

14. If you were born without cone cells, you would still be able to see—as long as you had functioning rod cells—but you would lack color vision and see in black and white only. **15.** A vitamin A deficiency would reduce the quantity of retinal the body could produce, thereby interfering with night vision (which operates at the body's threshold ability to respond to light).

Page 368

16. If the round window could not move, the vibration of the stapes at the oval window would not move the perilymph, and there would be little or no perception of sound. **17.** Loss of stereocilia from the hair cells of the spiral organ (as a result of constant

exposure to loud noises, for instance) would reduce hearing sensitivity and could lead to deafness.

Page 369

18. Because individuals over age 50 experience a decline in the number and sensitivity of taste buds, a given food can be too spicy for children and too bland for the elderly. **19.** With age, the lens loses its elasticity and stiffens, resulting in a flatter lens that cannot be rounded to focus the image of a close-up object on the retina. This condition, called presbyopia, may be corrected with a converging lens.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. 1 2. d 3. b 4. f 5. g 6. k 7. j 8. c 9. i 10. n 11. h 12. m 13. a 14. e 15. (a) fibrous layer; (b) cornea; (c) sclera; (d) inner layer, or retina; (e) neural layer; (f) pigmented layer; (g) vascular layer; (h) iris; (i) ciliary body; (j) choroid 16. c 17. a 18. a 19. b 20. a 21. c 22. c 23. b 24. d 25. c 26. a 27. d 28. (a) auricle; (b) external acoustic meatus; (c) tympanic membrane; (d) auditory ossicles; (e) semicircular canals; (f) vestibule; (g) auditory tube; (h) cochlea; (i) vestibulocochlear nerve (VIII) 29. a 30. The three types of mechanoreceptors are tactile receptors, baroreceptors, and proprioceptors. 31. Tactile receptors in skin are (1) free nerve endings: sensitive to touch and pressure; (2) root hair plexuses: monitor distortions and movements across the body surface; (3) tactile discs: detect fine touch and pressure; (4) tactile (Meissner) corpuscles: detect fine touch and pressure; (5) lamellar (pacinian) corpuscles: sensitive to pulsing or vibrating stimuli (deep pressure); and (6) bulbous (Ruffini) corpuscles: sensitive to pressure and distortion of the skin 32. (a) The fibrous layer is composed of the sclera and the cornea. (b) The fibrous layer provides mechanical support and some degree of physical protection, serves as attachment sites for the extrinsic eye muscles, and contains structures that assist in focusing. **33.** The tensor tympani muscle and the stapedius muscle. **34.** Step 1: Sound waves arrive at the tympanic membrane. Step 2: Movement of the tympanic membrane causes displacement of the auditory ossicles. Step 3: Movement of the stapes at the oval window establishes pressure waves in the perilymph of the scala vestibuli. Step 4: The pressure waves distort the basilar membrane on their way to the round window of the scala tympani. Step 5: Vibration of the basilar membrane causes hair cells to vibrate against the tectorial membrane. Step 6: Information about the region and intensity of stimulation is relayed to the CNS over the cochlear nerve, a division of cranial nerve VIII.

Level 2: Reviewing Concepts

35. c **36.** a **37.** The general senses include somatic and visceral sensations (temperature, pain, touch, pressure, vibration, and proprioception). The special senses are those whose receptors are confined to the head, and include smell (olfaction), taste (gustation), vision, balance (equilibrium), and hearing. **38.** The CNS receives any stimulus detected by a sensory receptor in the form of action potentials, regardless of the type of stimulus. **39.** When a person cries, tears produced by the lacrimal gland

are carried by the nasolacrimal duct to the nasal cavity, thus, resulting in a runny nose. **40.** A visual acuity of 20/15 means that Jane is able to see details that would be clear to a "normal" eye only at a distance of 15 feet. Jane's visual acuity is better than 20/20 vision.

Level 3: Critical Thinking and Clinical Applications

41. As you turn to look at your friend, your medial rectus muscles would contract, directing your gaze more medially. In addition, your pupils would constrict and the lenses would become more spherical. **42.** The loud noises from the fireworks have transferred so much energy to the endolymph in the cochlea that the fluid continues to move for a long while. As long as the endolymph is moving, it will vibrate the tectorial membrane and stimulate the hair cells. This stimulation produces the "ringing" sensation that Millie perceives. She finds it difficult to hear normal conversation because the vibrations associated with it are not strong enough to overcome the currents already moving through the endolymph, so the pattern of vibrations is difficult to discern against the background "noise." 43. The rapid descent in the elevator causes the otoliths of the macula of saccule of the vestibule to slide upward, producing the sensation of downward vertical acceleration. When the elevator abruptly stops, the otoliths of the macula do not. It takes a few seconds for them to come to rest in the normal position. As long as the otoliths of the macula are displaced, the perception of movement will remain.

CHAPTER 10

ANSWERS TO CHECKPOINTS

Page 376

1. Both the endocrine and nervous systems (1) release chemicals that bind to specific receptors on target cells, (2) share chemical messengers, (3) are primarily regulated by negative feedback processes, and (4) maintain homeostasis by coordinating and regulating the activities of other cells, tissues, organs, and systems.

Page 381

2. A hormone is a chemical messenger that is secreted by one cell and travels through the bloodstream to affect the activities of cells in other parts of the body. **3.** A cell's sensitivity to any hormone is determined by the presence or absence of the receptor molecule specific to that hormone. 4. A molecule that blocks adenylate cyclase, the enzyme that converts ATP to cAMP, would block the action of any hormone that required cAMP as a second messenger. 5. Cyclic-AMP is considered a second messenger because it is needed to convert the binding of first messengers-epinephrine, norepinephrine, and peptide hormones, which cannot enter target cells—into some effect on the metabolic activity of the target cell. 6. The three types of stimuli that control endocrine activity are (1) humoral (changes in the composition of the extracellular fluid), (2) hormonal (changes in the levels of circulating hormones), and (3) neural (the arrival of neurotransmitter at a neuroglandular junction).

7. In dehydration, blood osmotic concentration is increased, which would stimulate the posterior lobe of the pituitary gland to release more ADH. 8. Somatomedins mediate the action of growth hormone. Elevated levels of growth hormone typically accompany elevated levels of somatomedins. 9. Elevated circulating levels of cortisol inhibit the cells that control the release of ACTH from the pituitary gland, so ACTH levels would decrease. This is an example of negative feedback.

Page 389

10. Hormones of the thyroid gland are thyroxine or tetraiodothyronine (T_4), triiodothyronine (T_3), and calcitonin. **11.** Because an individual who lacks dietary iodine is unable to form the hormone thyroxine, you would expect to see signs and symptoms associated with thyroxine deficiency, such as decreased metabolic rate, decreased body temperature, and an enlarged thyroid gland (goiter). **12.** Most of the thyroid hormone in the blood is bound to transport proteins, forming a large reservoir of thyroxine that would not be depleted until days after the thyroid gland had been removed.

Page 390

13. The hormone secreted by the parathyroid glands is parathyroid hormone (PTH). **14.** Removal of the parathyroid glands would result in decreased blood levels of calcium ions.

Page 393

15. The two regions of the adrenal gland are the cortex and the medulla. The cortex secretes mineralocorticoids (primarily aldosterone), glucocorticoids (mainly cortisol, hydrocortisone, and corticosterone), and androgens. The medulla secretes epinephrine (E) and norepinephrine (NE). **16.** One function of cortisol is to decrease the cellular use of glucose while increasing both the available glucose (by promoting the breakdown of glycogen) and the conversion of amino acids to carbohydrates. Therefore, the net result of elevated cortisol levels would be an elevation of blood glucose. **17.** Increased amounts of light inhibit the production of melatonin by the pineal gland, which receives neural input through branches of axons making up the visual pathways. **18.** Melatonin may inhibit reproductive functions, protect against free radical damage, and influence circadian rhythms.

Page 395

19. Two important cells of the pancreatic islets (and their hormones) are alpha cells (glucagon) and beta cells (insulin). **20.** Insulin causes skeletal muscle and liver cells to convert glucose to glycogen. **21.** Increased levels of glucagon stimulate the conversion of glycogen to glucose in the liver, which would decrease the amount of glycogen in the liver.

Page 398

22. Two hormones secreted by the kidneys are erythropoietin (EPO) and calcitriol. EPO stimulates red bone marrow cells to produce more red blood cells, which increases the delivery of oxygen to body tissues. Calcitriol stimulates cells lining the digestive tract to absorb calcium and phosphate ions. **23.** Once released into the

bloodstream, renin functions as an enzyme, catalyzing a chain reaction that ultimately leads to the formation of the hormone angiotensin II. **24.** Leptin is a hormone released by adipose tissue.

Page 400

25. The hormonal interaction between insulin and glucagon is antagonistic, because the two hormones have opposite effects on their target tissues. **26.** The lack of growth hormone, thyroid hormone, parathyroid hormone, or the gonadal hormones would inhibit the normal formation and development of the skeletal system. **27.** The dominant hormones of the resistance phase of the general adaptation syndrome are the glucocorticoids. They increase blood glucose levels by mobilizing lipid and protein reserves and by stimulating the synthesis and release of glucose by the liver.

Page 403

28. The endocrine system affects the functioning of all other body systems by adjusting metabolic rates and substrate use and by regulating growth and development. **29.** Hormones of the endocrine system adjust muscle metabolism, energy production, and growth; hormones also regulate calcium and phosphate levels, which are critical to normal muscle functioning. For their part, skeletal muscles protect some endocrine organs.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. i **2.** f **3.** h **4.** m **5.** c **6.** l **7.** d **8.** b **9.** k **10.** j **11.** g **12.** e **13.** (a) hypothalamus; (b) pituitary gland; (c) thyroid gland; (d) thymus; (e) adrenal gland; (f) pineal gland; (g) parathyroid glands; (h) heart; (i) kidney; (j) adipose tissue; (k) digestive tract; (l) pancreatic islets (within pancreas); (m) gonads **14.** a **15.** c **16.** d **17.** c **18.** c **19.** c **20.** c **21.** a **22.** c **23.** The effect of calcitonin is to decrease the Ca²⁺ concentration in blood. The effect of parathyroid hormone is to cause an increase in the concentration of Ca²⁺ in blood. **24.** (a) The GAS consists of alarm, resistance, and exhaustion phases. (b) Epinephrine is the dominant hormone of the alarm phase. Glucocorticoids are the dominant hormones of the resistance phase.

Level 2: Reviewing Concepts

25. In nervous system communication, the source and destination are quite specific, and the effects are short-lived. In endocrine communication, the effects are slow to appear and often persist for days, and a given hormone can alter the metabolic activities of multiple tissues and organs simultaneously. 26. When peptide hormones bind to their receptors, which are located on the cell membrane, they activate downstream cascades to regulate activities of the target cells. In contrast, steroid hormones can diffuse through the plasma membrane, bind to receptors located in the cytoplasm or nucleus, and alter gene transcription. 27. Synergistic effect. One of the actions of both these hormones is to stimulate the breakdown of stored fats and the release of fatty acids into the blood. The fatty acids are used instead of glucose by many tissues to produce ATP. These two hormones thus have an additive effect to increase or maintain the blood glucose levels. 28. Blocking the activity of phosphodiesterase (PDE) would prevent the conversion of cAMP to AMP. This would prolong the effects of hormonal stimulation.

Level 3: Critical Thinking and Clinical Applications

29. TSH triggers the release of thyroid hormones, which negatively regulate the production of TSH. An insufficiency of thyroid hormones would lead to an increase in TSH. **30.** The parathyroid gland is responsible for the release of parathyroid hormone (PTH), which acts upon the kidneys and bones to increase blood calcium levels. If excessive PTH is released, it will continuously stimulate osteoclasts to resorb mineralized bone. If bone resorption happens over a long period of time, it would result in thinning of the bone mass and eventually osteoporosis.

CHAPTER 11

ANSWERS TO CHECKPOINTS

Page 411

1. Five major functions of blood are (1) transporting dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulating the pH and ion composition of interstitial fluids; (3) restricting fluid losses at injury sites; (4) defending against toxins and pathogens; and (5) stabilizing body temperature. **2.** Whole blood is composed of plasma and formed elements. **3.** Venipuncture is a common blood sampling technique because superficial veins are easy to locate, the walls of veins are thinner than those of arteries, and the puncture wound seals quickly because blood pressure in veins is relatively low.

Page 414

4. The three major types of plasma proteins are albumins, globulins, and fibrinogen. **5.** A decrease in the amount of plasma proteins in the blood would lower plasma osmotic pressure, reduce the ability to fight infections, and decrease the transport and binding of some ions, hormones, and other molecules.

Page 420

6. Hemoglobin (Hb) is a protein with a complex quaternary structure. It is composed of four globular protein subunits, each bound to a heme molecule, which gives RBCs the ability to transport oxygen in the blood. **7.** After a significant loss of blood, the hematocrit would be reduced. (The hematocrit is the percentage of whole blood volume made up of red blood cells.) **8.** Bilirubin would accumulate in the blood, producing jaundice, because diseases that damage the liver, such as hepatitis or cirrhosis, would impair the liver's ability to excrete bilirubin in the bile. **9.** Keith's hematocrit will increase, because reduced blood flow to the kidneys triggers the release of erythropoietin, which stimulates an increase in erythropoiesis (RBC formation).

Page 423

10. A person with type AB blood lacks both anti-A and anti-B antibodies in the plasma and so can accept type A, type B, type AB, or type O blood. **11.** A person with type A blood cannot safely receive type B blood because the anti-B antibodies in the plasma of the type A recipient would bind to B antigens on the donor's

RBCs, causing the transfused RBCs to clump or agglutinate, which could block blood flow to various organs and tissues.

Page 427

12. The five types of white blood cells are neutrophils, eosinophils, basophils, monocytes, and lymphocytes. **13.** An infected cut would contain numerous neutrophils, because these phagocytic WBCs are the first to arrive at the site of an injury. **14.** The WBCs that produce circulating antibodies are lymphocytes. **15.** Basophils respond to an injury by releasing a variety of chemicals, including histamine and heparin. Histamine dilates blood vessels and heparin prevents blood clotting. Basophils also release other chemicals that attract eosinophils and other basophils. **16.** Platelets are nonnucleated cellular fragments in the blood of mammalian vertebrates, whereas thrombocytes are nucleated platelets found in the blood of vertebrates other than mammals. **17.** Platelet functions include initiating the clotting process and helping to close damaged blood vessels.

Page 430

18. A decreased number of megakaryocytes would impair the clotting process, because fewer megakaryocytes would produce fewer platelets. **19.** The faster extrinsic pathway is initiated by the release of a glycoprotein called tissue factor by damaged endothelial cells or peripheral tissues. The slower intrinsic pathway begins in the bloodstream with the activation of clotting protein proenzymes exposed to damaged collagen fibers and the release of platelet factor by aggregating platelets. **20.** A vitamin K deficiency would reduce the liver's production of clotting factors necessary for normal blood coagulation.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1.g 2.1 3.b 4.a 5.d 6.k 7.f 8.i 9.h 10.c 11.e 12.j 13.a 14. b 15. (a) neutrophil; (b) eosinophil; (c) basophil; (d) monocyte; (e) lymphocyte 16. a 17. c 18. c 19. a 20. d 21. d 22. b **23.** Major types of plasma proteins are (1) albumins, which maintain the osmotic pressure of plasma and are important in transporting triglycerides, fatty acids, and cholesterol; (2) globulins, which (a) bind small ions, hormones, or compounds that might otherwise be filtered out of the blood at the kidneys or have very low solubility in water (transport globulins), or (b) attack foreign proteins and pathogens (immunoglobulins); and (3) fibrinogen, which functions in blood clotting. 24. (a) anti-B antibodies; (b) anti-A antibodies; (c) neither anti-A nor anti-B antibodies; (d) both anti-A antibodies and anti-B antibodies 25. WBCs exhibit (1) amoeboid movement, a gliding movement that moves the cell; (2) emigration (diapedesis), squeezing between adjacent endothelial cells in the capillary wall; (3) positive chemotaxis, the attraction to specific chemical stimuli; and (4) phagocytosis (engulfing particles for neutrophils, eosinophils, and monocytes). 26. For the common pathway to begin, either the extrinsic or intrinsic pathway must activate Factor X. 27. An embolus is a drifting blood clot. A thrombus is a blood clot attached to the inner wall of an intact blood vessel.

Level 2: Reviewing Concepts

28. d **29.** a **30.** c **31.** d **32.** Provides a large surface area to volume ratio for rapid gaseous exchange. It allows the red blood cells to flex and squeeze through capillaries.

Level 3: Critical Thinking and Clinical Applications

33. In an acute bleed, whole blood is lost. Thus, the hematocrit may not deviate from the normal value. However, with infusion of normal saline and shift of interstitial fluid into the vascular compartment, the proportion of formed elements in the blood decreases, and the hematocrit falls. 34. In many cases of kidney disease, the cells responsible for producing erythropoietin (EPO) are either damaged or destroyed. The reduction in EPO levels leads to reduced erythropoiesis and fewer red blood cells, resulting in anemia. **35.** A major function of the spleen is to destroy old, defective, and worn out red blood cells. As the spleen increases in size, so does its capacity to eliminate red blood cells, and this produces anemia. The decreased number of RBCs decreases the body's ability to deliver oxygen to the tissues, so tissue metabolism slows; this accounts for feeling tired and the lack of energy. Because there are fewer RBCs than normal, blood circulating through the skin is not as red, so the person has a pale or whitish skin coloration.

CHAPTER 12

ANSWERS TO CHECKPOINTS

Page 444

1. Damage to the pulmonary semilunar valve on the right side of the heart would affect blood flow into the pulmonary trunk. **2.** Contraction of the papillary muscles (just before the rest of the ventricular myocardium contracts) pulls on the chordae tendineae, which prevents the AV valves from swinging into the atria. **3.** The left ventricle is more muscular than the right ventricle because it must generate enough force to propel blood throughout the body (except the lungs). The right ventricle must generate only enough force to propel blood the few centimeters to the lungs.

Page 449

4. The fact that cardiac contractile cells cannot undergo tetanus because they have a longer refractory period than skeletal muscle fibers-means that they relax long enough so the heart's chambers can refill with blood. 5. If cells of the SA node did not function, the heart would continue to beat, but at a slower rate, and the AV node would become the pacemaker. 6. If the impulses from the atria were not delayed at the AV node, they would be conducted through the ventricles so quickly by the bundle branches and Purkinje cells that the ventricles would begin contracting immediately, before the atria had finished contracting. As a result, the ventricles would not be as full of blood as they could be, and the pumping of the heart would not be as efficient, especially during physical activity. 7. An increase in the size of the QRS complex indicates a larger-than-normal amount of electrical activity during ventricular depolarization. One possible cause is an enlarged heart. Because more cardiac muscle is depolarizing, the size of the electrical event would be greater.

Page 452

8. The alternative term for contraction is systole, and the other term for relaxation is diastole. **9.** No. When pressure in the left ventricle first rises, the heart is contracting but no blood is leaving the heart. During the initial phase of contraction, both the AV and semilunar valves are closed. The increase in pressure results from increased tension as the cardiac muscle contracts. When ventricular pressure exceeds the pressure in the aorta, the aortic semilunar valves are forced open, and blood is rapidly ejected from the ventricle. **10.** "Lubb" is produced by the simultaneous closing of the AV valves and the opening of the semilunar valves. "Dupp" is produced when the semilunar valves close.

Page 455

11. Cardiac output is the amount of blood pumped by the left ventricle in one minute. **12.** Damage to the cardioinhibitory center of the medulla oblongata affects the parasympathetic division of the ANS and would reduce parasympathetic stimulation of the heart. The resulting sympathetic dominance would increase the heart rate. 13. Stimulating the acetylcholine receptors of the heart lowers heart rate. Given that $CO = HR \times SV$, a reduction in heart rate must produce a reduction in cardiac output (assuming no change in the stroke volume). 14. According to the Frank-Starling principle, the more the heart muscle is stretched by returning blood (venous return), the more forcefully it will contract (to a point), and the more blood it will eject with each beat (stroke volume). Therefore, increased venous return increases stroke volume (if all other factors are constant). 15. The heart pumps in proportion to the amount of blood that enters. A heart that beats too rapidly, has too little time to fill completely between beats. Thus, when the heart beats too fast, very little blood leaves the ventricles and enters the circulation, so tissues will suffer damage from an inadequate blood supply.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. j 2. f 3. h 4. i 5. b 6. c 7. l 8. a 9. e 10. g 11. d 12. k 13. (a) superior vena cava; (b) auricle of right atrium; (c) right ventricle; (d) left ventricle; (e) aortic arch; (f) left pulmonary artery; (g) pulmonary trunk; (h) auricle of left atrium 14.b 15.b 16.d 17.d 18. (a) ascending aorta; (b) opening of coronary sinus; (c) right atrium; (d) cusp of tricuspid (right AV) valve; (e) chordae tendineae; (f) right ventricle; (g) pulmonary valve; (h) left pulmonary veins; (i) left atrium; (j) aortic valve; (k) cusp of mitral (bicuspid or left AV) valve; (l) left ventricle; (m) interventricular septum 19. b 20. d **21.** d **22.** The coronary arteries originate at the base of the aorta at the aortic sinuses. Blood pressure in these arteries is higher than the rest of the systemic circuit, and this ensures a continuous blood flow to meet the high demands of the cardiac muscle. 23. The atrioventricular (AV) valves prevent backflow of blood from the ventricles into the atria. The tricuspid valve is the right AV valve., and the mitral (bicuspid) valve is the left AV valve. The pulmonary and aortic semilunar valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles. **24.** SA node \rightarrow AV node \rightarrow AV bundle (bundle of His) \rightarrow right and left bundle branches \rightarrow Purkinje fibers (into the mass of ventricular muscle tissue) **25.** (a) The cardiac cycle is a complete heartbeat, including a contraction/relaxation period for both atria and ventricles. (b) The cycle begins with atrial systole as the atria contract and push blood into the relaxed ventricles. As the atria relax (atrial diastole), the ventricles contract (ventricular systole), forcing blood through the semilunar valves into the pulmonary trunk and aorta. The ventricles then relax (ventricular diastole). For the rest of the cardiac cycle, both the atria and ventricles are in diastole; passive filling occurs.

Level 2: Reviewing Concepts

26. b 27. d 28. The AV delay allows the atria to empty before the ventricles contract. 29. The right atrium receives blood from the systemic circuit and passes it to the right ventricle, which pumps it into the pulmonary circuit. The left atrium collects blood returning from the lungs and passes it to the left ventricle, which ejects it into the systemic circuit. **30.** The first heart sound ("lubb") marks the start of ventricular contraction and is produced as the AV valves close and the semilunar valves open. The second sound ("dupp") occurs when the semilunar valves close, marking the start of ventricular diastole. Listening to the heart sounds is a simple, effective way to identify certain heart abnormalities. 31. When a decrease in blood pressure is detected, the cardiac center will try to increase the cardiac output to restore blood pressure. To achieve this, the cardioaccelaratory center, which controls the sympathetic motor neurons, will be stimulated. These neurons release epinephrine and norepinephrine, and these hormones will increase the heart rate and stroke volume, thereby also increasing the cardiac output.

Level 3: Critical Thinking and Clinical Applications

32. During ventricular systole, contraction of the muscular walls of the left ventricle pushes the cusps of the mitral valve together, closing the valve and preventing backflow of blood from the left ventricle to the left atrium. Tension of the chordae tendineae and papillary muscles helps to prevent eversion of the mitral valve flaps into the left atrium. This is affected in this patient due to rupture of the chordae tendinae, resulting in the systolic murmur due to mitral regurgitation. **33.** Using $CO = HR \times SV$, cardiac output for person A is 4500 mL, and for person B 8550 mL. According to the Frank-Starling principle, in a normal heart CO is directly proportional to venous return, so person B has the greater venous return. Ventricular filling time increases as HR decreases, so person A has the longer ventricular filling time. **34.** Tarryn will suffer from increased blood pressure due to her condition. Thyroid hormones affect both heart rate and force of contraction of the cardiac muscles. Since an increase in heart rate and stroke volume (force of contraction) will result in increased cardiac output, her blood pressure will also increase.

CHAPTER 13

ANSWERS TO CHECKPOINTS

Page 465

1. The five general classes of blood vessels are arteries, arterioles, capillaries, venules, and veins. **2.** These blood vessels are veins. Arteries and arterioles have a large amount of smooth muscle

tissue in a thick, well-developed tunica media. **3.** The relaxation of precapillary sphincters would increase blood flow through a tissue. **4.** Valves are found in the veins because the very low blood pressure in the venous circulation makes the movement of blood against the force of gravity difficult. Blood flow within peripheral veins depends on the contractions of skeletal muscles to propel the blood, and on valves to prevent blood from backing up.

Page 471

5. The factors that contribute to total peripheral resistance are vascular resistance (vessel length and diameter), blood viscosity, and turbulence. **6.** In a healthy person, blood pressure is greater at the aorta—just leaving the pump (heart)—than at the inferior vena cava. Blood, like other fluids, moves along a pressure gradient from areas of high pressure to areas of low pressure. **7.** While Sally was standing for a period of time, blood pooled in her lower extremities, decreasing venous return to the heart. In turn, cardiac output decreased, so less blood reached her brain, causing lightheadedness and fainting. A hot day adds to this effect, because the loss of body water through sweating reduces blood volume.

Page 477

8. Vasodilators increase blood flow locally (that is, through their tissue of origin) by promoting dilation of precapillary sphincters. Vasoconstrictors decrease local blood flow by constricting precapillary sphincters. 9. Pressure on the common carotid artery would decrease blood pressure at the carotid sinus (the location of the carotid baroreceptors). This decrease would cause the cardioacceleratory center in the medulla oblongata to increase sympathetic stimulation. The result would be an increase in the heart rate. 10. Renal artery vasoconstriction would decrease both blood pressure and flow at the kidney. In response, the kidney would increase the amount of renin it releases, which in turn would lead to an increase in the level of angiotensin II. The angiotensin II would bring about both increased blood pressure and blood volume.

Page 479

11. Blood pressure increases during exercise because (1) cardiac output increases and (2) resistance in "nonessential" visceral tissues increases. **12.** The immediate problem during hemorrhaging is maintaining adequate blood pressure and peripheral blood flow. The long-term problem is restoring normal blood volume. **13.** Both aldosterone and ADH promote fluid retention and reabsorption at the kidneys, preventing further reductions in blood volume.

Page 480

14. The two circuits of the cardiovascular system are the pulmonary circuit and the systemic circuit. **15.** Three general organizational patterns of blood vessels include (1) nearly identical peripheral distributions of arteries and veins on the body's left and right sides (except near the heart), (2) several names for a single vessel as it crosses specific anatomical boundaries (making accurate anatomical descriptions possible), and (3) the servicing of tissues and organs by several arteries and veins.

Page 481

16. The pulmonary arteries enter the lungs carrying deoxygenated blood. The pulmonary veins leave the lungs carrying oxygenated blood. **17.** Right ventricle \rightarrow pulmonary trunk \rightarrow left and right

pulmonary arteries \rightarrow pulmonary arterioles \rightarrow alveolar capillaries \rightarrow pulmonary venules \rightarrow pulmonary veins \rightarrow left atrium.

Page 492

18. A blockage of the left subclavian artery would interfere with blood flow to the left arm. **19.** Compression of the common carotid arteries would decrease blood pressure at the carotid sinus and cause a rapid reduction in blood flow to the brain, resulting in a loss of consciousness. An immediate reflexive increase in heart rate and blood pressure would follow. **20.** Rupture of the celiac trunk would most directly affect the stomach, spleen, liver, and pancreas. **21.** Arteries in the neck and limbs are located deep beneath the skin, protected by bones and surrounding soft tissues. Veins in these sites follow two courses, one superficial and one deep. This dual venous drainage helps control body temperature: Blood flow through superficial veins promotes heat loss, and blood flow through deep veins conserves body heat.

Page 493

22. Two umbilical arteries carry blood to the placenta, and one umbilical vein returns blood from the placenta. The umbilical vein drains into the ductus venosus within the fetal liver. (Remember, arteries carry blood away from the heart, and veins carry blood to the heart.) **23.** This blood sample was taken from the umbilical vein, which carries oxygenated, nutrient-rich blood from the placenta to the fetus. **24.** Structures specific to fetal circulation include the two umbilical arteries, an umbilical vein, the ductus venosus, the foramen ovale, and the ductus arteriosus. In the newborn, the foramen ovale closes and persists as the fossa ovalis, a shallow depression. The ductus arteriosus persists as the ligamentum arteriosum, a fibrous cord. The umbilical vessels and ductus venosus persist throughout life as fibrous cords.

Page 494

25. Components of the cardiovascular system affected by age include the blood, the heart, and blood vessels. 26. A thrombus is a stationary blood clot within the lumen of a blood vessel. **27.** An aneurysm is a bulge in a weakened arterial wall resulting from sudden pressure increases. 28. The cardiovascular system has blood vessels that provide extensive anatomical connections between it and all the other organ systems. Functionally, it transports dissolved gases, nutrients, hormones, and metabolic wastes; regulates pH and ion composition of interstitial fluid; restricts fluid losses at injury sites; defends against toxins and pathogens; and stabilizes body temperature. 29. The skeletal system provides calcium needed for normal cardiac muscle contraction, and it protects blood cells developing in the red bone marrow. The cardiovascular system provides calcium and phosphate for bone formation, delivers erythropoietin(EPO) to red bone marrow, and transports parathyroid hormone and calcitonin to osteoblasts and osteoclasts.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. e 2. a 3. b 4. k 5. j 6. i 7. l 8. g 9. f 10. d 11. h 12. c 13. (a) brachiocephalic trunk; (b) brachial; (c) radial; (d) external iliac; (e) anterior tibial; (f) right common carotid; (g) left subclavian; (h) right common iliac; (i) femoral 14. b 15. c 16. b

17. c **18.** b **19.** c **20.** c **21.** b **22.** c **23.** (a) external jugular; (b) brachial; (c) median cubital; (d) radial; (e) great saphenous; (f) internal jugular; (g) superior vena cava; (h) left and right common iliac; (i) femoral 24. b 25. d 26. c 27. a 28. d 29. d 30. (a) Fluid leaves the capillary at the arterial end primarily in response to hydrostatic pressure. (b) Fluid moves into the capillary at the venous end in response to osmotic pressure. **31.** When elevated BP triggers the baroreceptor response, cardiac output decreases (due to parasympathetic stimulation and inhibition of sympathetic activity) and widespread peripheral vasodilation occurs (due to the inhibition of excitatory neurons in the vasomotor center). 32. The chemoreceptors will stimulate the respiratory centers in the medulla oblongata, thereby increasing respiratory rate. **33.** When an infant takes its first breath, the lungs and the pulmonary vessels expand. Smooth muscles in the ductus arteriosus contract, isolating the pulmonary and aortic trunks, and blood begins flowing through the pulmonary circuit. As pressure rises in the left atrium, the valvular flap closes the foramen ovale, completing the separation of the right and left atrial chambers. 34. Blood: decreased hematocrit, formation of thrombi (stationary blood clots), and valvular malfunction; Heart: reduction in maximum cardiac output, changes in the activities of the nodal and conducting fibers, reduction in the elasticity of the fibrous skeleton, progressive atherosclerosis, and replacement of damaged cardiac muscle fibers by scar tissue; Blood vessels: progressive inelasticity in arterial walls, deposition of calcium salts on weakened vascular walls, lipid deposits in vessel walls leading to atherosclerotic plaques, and formation of thrombi at atherosclerotic plaques.

Level 2: Reviewing Concepts

35. d 36. c 37. d 38. Increasing tissue metabolism reduces local levels of oxygen and increases other metabolites, such as carbon dioxide, lactic acid, and ADP. These local factors cause relaxation of precapillary sphincters and increase blood flow to match tissue oxygen and nutrient demand. 39. Unlike arteries and veins, capillaries are only one cell thick, and small gaps between adjacent endothelial cells permit the diffusion of water and small solutes into the surrounding interstitial fluid while retaining blood cells and plasma proteins. (Some capillaries also contain pores that permit very rapid exchange of fluids and solutes between the plasma and the interstitial fluid.) 40. Systemic veins usually contain blood that has low levels of O₂ and nutrients and high levels of CO₂ and waste products. Although the hepatic portal vein also contains blood with low O₂ levels, it drains blood from the stomach, small intestine, pancreas, and spleen and, therefore, also contains high concentrations of substances, such as glucose, amino acids, wastes, and occasional toxins, absorbed by these organs. 41. The accident victim is suffering from shock and acute circulatory crisis. The hypotension results from the loss of blood volume and decreased cardiac output. Her skin is pale and cool due to peripheral vasoconstriction; and the moisture results from the sympathetic activation of sweat glands. Falling blood pressure to the brain causes confusion and disorientation. Her pulse would be rapid and weak, reflecting the heart's response to reduced blood flow and volume.

Level 3: Critical Thinking and Clinical Applications

42. Circulating inflammatory chemicals relax arterioles and precapillary sphincters, reducing peripheral resistance and blood pressure, causing reduced blood flow and organ hypoxia. Venous return falls, reducing preload and cardiac output. Heart rate increases but is unable to compensate for such body-wide reductions in resistance. Treatments aim to stimulate vasoconstriction and venoconstriction, increase blood volume and increase contractility of the heart. **43.** Vegans are at risk of developing hypotension. If they suffer from a vitamin B12 deficiency, their bodies will produce fewer red blood cells, thereby lowering their blood viscosity. A decrease in blood viscosity will result in a decrease in peripheral resistance. Since blood pressure is directly related to peripheral resistance, anemia could eventually cause hypotension. 44. The anastomosis allows blood to flow past the joint to supply the forearm and hand if one of the arteries is kinked, such as during flexion of the elbow joint.

CHAPTER 14

ANSWERS TO CHECKPOINTS

Page 502

A pathogen is any disease-causing organism, such as a virus, bacterium, fungus, or parasite that can thrive inside the body.
 Innate (nonspecific) defenses include anatomical barriers and defense processes that slow or prevent the entry of infectious organisms but do not distinguish one potential threat from another. Adaptive (specific) defenses involve a response by lymphocytes against a specific type of threat.

Page 511

3. Components of the lymphatic system are lymph, lymphatic vessels, lymphocytes, primary lymphoid tissues and organs (red bone marrow and the thymus), and secondary lymphoid tissues and organs (lymph nodes, MALT, tonsils, appendix, and spleen). **4.** Blockage of the thoracic duct would impair the flow of lymph from the body inferior to the diaphragm and from the left side of the body (head and thorax) superior to the diaphragm. The result could be the accumulation of fluid (lymphedema) in the limbs. **5.** A lack of thymic hormones would result in an absence of T lymphocytes. **6.** Lymph nodes enlarge during some infections because lymphocytes and phagocytes in lymph nodes in the affected region multiply to defend against the infectious agent. This increase in the number of cells causes the nodes to become enlarged or swollen.

Page 514

7. The body's innate (nonspecific) defenses include physical barriers, phagocytes, immune surveillance, interferons, complement, inflammation, and fever. **8.** A decrease in the number of monocyte-forming cells in red bone marrow would result in fewer macrophages of all types, including microglia of the CNS, stellate macrophages of the liver, and alveolar macrophages in the lungs. All are derived from monocytes. **9.** A rise in the level of interferon indicates a viral infection. Interferon does not help an infected cell, but "interferes" with the viruses' ability to replicate and infect other

cells. **10.** Pyrogens increase body temperature (produce a fever) by stimulating the temperature control area within the hypothalamus.

Page 517

11. In cell-mediated (cellular) immunity, T cells defend against abnormal cells and pathogens inside cells. In antibody-mediated (humoral) immunity, B cells secrete antibodies that defend against antigens and pathogens in body fluids. **12.** The two forms of active immunity are naturally acquired active immunity and artificially acquired active immunity; the two forms of passive immunity are naturally acquired passive immunity and artificially acquired passive immunity. **13.** The four general properties of adaptive immunity are specificity, versatility, memory, and tolerance.

Page 519

14. The four types of T cells are cytotoxic T cells, helper T cells, memory T cells, and regulatory T cells.
15. Abnormal peptides within the cytoplasm of a cell become attached to class II MHC proteins on the cell's plasma membrane. Recognition of the displayed peptides by T cells starts an adaptive immune response.
16. A decrease in the number of cytotoxic T cells would affect cell-mediated immunity, reducing the effectiveness of cytotoxic T cells in killing foreign cells and virus-infected cells.
17. Class I MHC proteins are found in the plasma membranes of all nucleated body cells. Class II MHC proteins are found only in the plasma membranes of lymphocytes and antigen-presenting cells (APCs).

Page 526

18. Sensitization is the process by which a B cell becomes able to react with a specific antigen. **19.** An antibody is a Y-shaped molecule that consists of two parallel pairs of polypeptide chains: one pair of heavy chains and one pair of light chains. Each chain contains both constant segments and variable segments. **20.** Plasma cells produce and secrete antibodies, so observing an elevated number of plasma cells would lead us to expect increasing levels of antibodies in the blood. **21.** The secondary response would be more affected by the lack of memory B cells for a particular antigen. The ability to produce a secondary response depends on the presence of memory B cells (and memory T cells) formed during the primary response. The memory cells are held in reserve against future contact with the same antigen.

Page 527

22. An autoimmune disorder is a condition that results when the immune system's sensitivity to normal cells and tissues causes the production of autoantibodies. **23.** Stress can interfere with the immune response by depressing the inflammatory response, reducing the number and activity of phagocytes, and inhibiting interleukin secretion, which depresses the response of lymphocytes. **24.** Elderly people are more susceptible to viral and bacterial infections because the number of helper T cells declines with age and B cells are less responsive, so antibody levels rise more slowly after antigen exposure. **25.** The increased incidence of cancer among elderly people may reflect the decline of immune surveillance with age, so cancerous cells are not eliminated as effectively.

Page 528

26. The lymphatic system provides adaptive (specific) defenses against infection, performs immune surveillance to eliminate cancer cells, and returns tissue fluid to the circulation. **27.** The

cardiovascular system aids the body's nonspecific and specific defenses by distributing white blood cells, transporting antibodies, and restricting the spread of pathogens (through the clotting response).

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. i 2. l 3. c 4. h 5. e 6. d 7. k 8. b 9. j 10. a 11. g 12. f 13. (a) tonsil; (b) cervical lymph nodes; (c) right lymphatic duct; (d) thymus; (e) cisterna chyli; (f) lumbar lymph nodes; (g) appendix; (h) lymphatics of lower limb; (i) lymphatics of upper limb; (j) axillary lymph nodes; (k) thoracic duct; (l) lymphatics of mammary gland; (m) spleen; (n) mucosa-associated lymphoid tissue (MALT); (o) pelvic lymph nodes; (p) inguinal lymph nodes; (q) red bone marrow 14. a 15. d 16. d 17. a 18. c 19. c 20. c 21. b 22. a 23. d 24. c 25. a 26. The thoracic duct collects lymph from the body inferior to the diaphragm and from the left side of the body superior to the diaphragm. The right lymphatic duct collects lymph from the right side of the body superior to the diaphragm. 27. (a) responsible for cell-mediated immunity, which defends against abnormal cells and pathogens inside living cells; (b) stimulate the activation and function of T cells and B cells; (c) inhibit the activation and function of both T cells and B cells; (d) produce and secrete antibodies; (e) recognize and destroy abnormal cells; (f) interfere with viral replication inside cells and stimulate the activities of macrophages and NK cells; (g) provide cell-mediated immunity; (h) provide antibody-mediated immunity, which defends against antigens and pathogenic organisms in the body; (i) enhance nonspecific defenses, increase T cell sensitivity, and stimulate B cell activity

Level 2: Reviewing Concepts

28. a **29.** a **30.** Specificity: Each adaptive immune response is triggered by a specific antigen and defends against only that antigen. Versatility: The immune system can differentiate among tens of thousands of antigens it may encounter during an individual's normal lifetime. Memory: The immune response following a second exposure to a given antigen is stronger and lasts longer than the first exposure. Tolerance: Some antigens, such as those on an individual's own normal cells, do not elicit an immune response. **31.** An antigen–antibody complex can eliminate the antigen by neutralization, precipitation and agglutination, activation of complement, attraction of phagocytes, enhancement of phagocytosis by opsonization, and stimulation of inflammation. **32.** Some cancer cells avoid being detected by NK cells during immune surveillance and do not get destroyed. This is known as immunological escape.

Level 3: Critical Thinking and Clinical Applications

33. The axillary lymph nodes located in the armpits receive lymph that drains from the breast. The presence of enlarged nodes may indicate distant spread of breast cancer. **34.** If Daniel is exposed to an allergen, his body would produce large quantities of IgE antibodies. If he usually suffers from hay fever, his body has been sensitized to the allergen, and, therefore, IgE will accelerate an inflammatory response. If he has the common cold, his IgG levels would be high, since this type of antibody is responsible for defense against viruses.

ANSWERS

CHAPTER 15

ANSWERS TO CHECKPOINTS

Page 538

1. The five functions of the respiratory system include providing an extensive surface area for gas exchange between blood and air; moving air to and from gas-exchange surfaces; protecting respiratory surfaces from dehydration, temperature changes, and pathogens; producing sounds; and aiding the sense of smell. 2. The two anatomical subdivisions of the respiratory system are the upper respiratory system and the lower respiratory system. 3. The respiratory mucosa lines the conducting portion of the respiratory tract.

Page 544

4. The surfaces of the nasal cavity are swept by mucus (produced by the respiratory mucosa and the paranasal sinuses) and by tears (carried by the nasolacrimal ducts). **5.** The pharynx is a passageway for both air (respiratory system) and food and liquids (digestive system). **6.** Increased tension in the vocal cords raises the pitch of the voice. **7.** The functional advantage of C-shaped tracheal cartilages is that they allow room for the esophagus to expand when food or drink is swallowed.

Page 548

8. Air passing through the glottis flows into the larynx and through the trachea. From there, the air flows into a main bronchus, which supplies a lung. In the lung, air passes through bronchi, bronchioles, a terminal bronchiole, a respiratory bronchiole, an alveolar duct, an alveolar sac, an alveolus, and ultimately to the blood air barrier. **9.** Without surfactant, surface tension in the thin layer of liquid that moistens alveolar surfaces would cause the alveoli to collapse. **10.** The pleura is a serous membrane that secretes pleural fluid, which lubricates the opposing parietal and visceral surfaces to prevent friction during breathing.

Page 549

11. External respiration includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. Internal respiration is the absorption of oxygen and the release of carbon dioxide by the body's cells. **12.** The integrated steps involved in external respiration are pulmonary ventilation (breathing), gas diffusion, and transport of oxygen and carbon dioxide by the bloodstream.

Page 551

13. Compliance is the ease with which the lungs expand. Factors affecting compliance include (a) the connective tissue structure of the lungs, (b) the level of surfactant production, and (c) the mobility of the thoracic cage. **14.** Tidal volume is the amount of air you move into and out of your lungs during a single respiratory cycle under resting conditions—about 500 mL for both males and females. **15.** When the rib penetrates Mark's chest wall, it also penetrates the pleural cavity, allowing atmospheric air to enter, and producing pneumothorax. As a result, the natural elasticity of the lung may cause the lung to collapse, a condition called atelectasis. **16.** The vital capacity would decrease, because the fluid in the alveoli takes up space that would normally be occupied by air.

Page 553

17. True. 18. Air passing through the nasal cavity becomes warmer and more humid (its content of water vapor increases).19. Alveolar air contains less oxygen and more carbon dioxide than atmospheric air.

Page 556

20. Carbon dioxide is transported in the bloodstream dissolved in the plasma, bound to hemoglobin within RBCs, or as bicarbonate ions. **21.** Active skeletal muscles generate more heat than resting muscles, and more acidic waste products that lower the pH of the surrounding fluid. The combination of increased temperature and reduced pH during exercise causes the hemoglobin to release more oxygen than it would when the muscles are at rest. **22.** Blockage of the trachea would lower blood pH by interfering with the body's ability to take in oxygen and eliminate carbon dioxide. Most carbon dioxide is transported in blood as bicarbonate ion formed from the dissociation of carbonic acid. An inability to eliminate carbon dioxide would result in an excess of hydrogen ions, which are also released from the dissociation of carbonic acid. The excess of hydrogen ions would lower blood pH.

Page 562

23. Peripheral chemoreceptors are more sensitive to carbon dioxide levels than to oxygen levels. When carbon dioxide dissolves, it forms carbonic acid, which dissociates and releases hydrogen ions, thereby lowering pH and altering cell or tissue activity. 24. Strenuous exercise stimulates the inflation and deflation reflexes of the lungs, also known as the Hering-Breuer reflexes. In the inflation reflex, the stimulation of stretch receptors in the lungs inhibits the inspiratory center and stimulates the expiratory center. In contrast, reducing the volume of the lungs initiates the deflation reflex, which inhibits the expiratory center and stimulates the inspiratory center. 25. Johnny's mother shouldn't worry. While Johnny holds his breath, increasing blood carbon dioxide levels lead to increased stimulation of the inspiratory center, which forces him to breathe again. 26. Two age-related changes that reduce the efficiency of the respiratory system are (1) reduced chest movements resulting from arthritic changes in rib joints and stiffening of the costal cartilages and (2) some degree of emphysema stemming from the gradual destruction of alveolar surfaces. **27.** The respiratory system provides oxygen and eliminates carbon dioxide for all body systems. 28. The nervous system controls the pace and depth of respiration and monitors the respiratory volume of the lungs and levels of blood gases.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. i **2.** g **3.** j **4.** d **5.** c **6.** e **7.** k **8.** f **9.** b **10.** a **11.** h **12.** l **13.** (a) nasal cavity; (b) pharynx; (c) right lung; (d) nose; (e) larynx; (f) trachea; (g) right main bronchus; (h) bronchioles; (i) left lung **14.** (a) pulmonary (alveolar) capillary; (b) blood air barrier; (c) alveolus; (d) interstitial fluid; (e) systemic capillary. The pink arrows indicate the diffusion of O₂, and the blue arrows diffusion of CO₂. **15.** a **16.** c

Level 2: Reviewing Concepts

17. a **18.** d **19.** Less cartilage and more smooth muscle in the lower respiratory passageways provide greater control of bronchial diameter by smooth muscle, and thus of resistance to air flow. **20.** Breathing through the nasal cavity ensures that inspired air is cleansed, moistened, and warmed. The drier air that enters through the mouth can irritate the trachea, causing throat soreness. **21.** Thymosin is produced by thymus and promotes the maturation of lymphoid stem cells to become T cells.

Level 3: Critical Thinking and Clinical Applications

22. In anemia, the blood's ability to carry oxygen is decreased due to the lack of functional hemoglobin, red blood cells, or both. Anemia does not interfere with the exchange of carbon dioxide within the alveoli, nor with the amount of oxygen that will dissolve in the plasma. Because chemoreceptors respond to dissolved gases and pH, as long as the pH and the concentrations of dissolved carbon dioxide and oxygen are normal, ventilation patterns should not change significantly. **23.** Pulmonary surfactant, produced by type II pneumocytes, prevents collapse of the alveolar walls during exhalation and reduces the effort required to open up the alveolar spaces during inhalation. Premature babies with inadequate amounts of surfactant are thus at risk of respiratory distress.

CHAPTER 16

ANSWERS TO CHECKPOINTS

Page 573

1. Organs of the digestive system include the oral cavity (mouth), pharynx (throat), esophagus, stomach, small intestine, large intestine, and accessory organs (teeth, tongue, salivary glands, pancreas, liver, and gallbladder). 2. The six primary functions of the digestive system are (a) ingestion, the eating of food; (b) mechanical digestion, the crushing and shearing of food to make it more susceptible to enzymatic attack; (c) chemical digestion, the chemical breakdown of food into smaller products for absorption; (d) secretion, the release of water, acids, and other substances by the digestive tract epithelim, glandular organs, and gallbladder; (e) absorption, the movement of digested materials across the digestive epithelium and into the interstitial fluid of the digestive tract; and (f) defecation, the elimination of waste products from the body. 3. The mesenteries support and stabilize the positions of organs in the abdominopelvic cavity and provide a route for the blood vessels, nerves, and lymphatic vessels associated with the digestive tract. 4. The layers of the digestive tract, from superficial to deep, are the mucosa, submucosa, muscular layer, and serosa. 5. The waves of contractions responsible for peristalsis are more efficient in propelling intestinal contents than segmentation, which is basically a churning action that mixes intestinal contents with digestive fluids.

Page 576

6. Structures associated with the oral cavity include the tongue, salivary glands, and teeth. **7.** The oral cavity is lined by a stratified squamous epithelium. It protects against friction or abrasion by food. **8.** The digestion of carbohydrates would be affected by damage to the parotid salivary glands, because these glands secrete salivary amylase, the enzyme that digests complex carbohydrates

(starches). **9.** The incisors are the type of tooth most useful for chopping (or cutting or shearing) pieces of relatively rigid food, such as raw vegetables.

Page 577

10. The pharynx is a passageway that receives food or liquids and passes them on to the esophagus as part of the swallowing process. Air also passes through the pharynx. **11.** The process being described is swallowing (deglutition).

Page 582

12. The four main regions of the stomach are the cardia, fundus, body, and pylorus. **13.** The low pH in the stomach creates an acidic environment that kills most microorganisms ingested with food, denatures proteins and inactivates most enzymes in food, helps break down plant cell walls and meat connective tissue, and activates pepsin. **14.** The vagus nerves contain parasympathetic motor fibers that can stimulate gastric secretions even when the stomach is empty (the cephalic phase of gastric secretion). Cutting the branches of the vagus nerves that supply the stomach would prevent this type of secretion from taking place, and reduce the likelihood of new ulcer formation.

Page 586

15. The pyloric sphincter is the ring of muscle that regulates the flow of chyme into the small intestine. **16.** The three segments of the small intestine from proximal to distal are the duodenum, jejunum, and ileum. **17.** The small intestine has several adaptations that increase its surface area and thus its absorptive capacity for nutrients. Its walls have permanent circular folds (plicae circulares), each of which is covered by fingerlike projections called villi. The epithelial cells covering the villi have an exposed surface covered by small fingerlike projections, the microvilli. In addition, the small intestine has a very rich supply of blood vessels and lymphatic vessels that transport the absorbed nutrients.

Page 592

18. A high-fat meal would increase cholecystokinin (CCK) level in the blood. **19.** Damage to the exocrine pancreas would most impair the digestion of fats (lipids), because that organ is the primary source of lipases. Even though such damage would also reduce carbohydrate and protein digestion, digestive enzymes for these nutrients are also produced by the salivary glands (carbohydrates), the small intestine (carbohydrates and proteins), and the stomach (proteins).

Page 596

20. The four segments of the colon are the ascending colon, transverse colon, descending colon, and sigmoid colon. **21.** The large intestine is larger in diameter than the small intestine, but its relatively thin wall lacks villi, and it has an abundance of mucous glands. **22.** A narrowing of the ileocecal valve would interfere with the flow of chyme from the small intestine to the large intestine.

Page 599

23. Because chylomicrons are formed from the fats digested in a meal, fats would increase the number of chylomicrons in the lacteals. **24.** Removal of the stomach would interfere with the absorption of vitamin B_{12} . Parietal cells of the stomach are the source of intrinsic factor, which is required for the vitamin's absorption. **25.** When someone with diarrhea loses fluid and

electrolytes faster than they can be replaced, the resulting dehydration can be fatal. Constipation, although uncomfortable, does not interfere with any major body process. The few toxic waste products that are normally eliminated by defecation can move into the blood and be eliminated by the kidneys.

Page 600

26. General digestive system changes that occur with age include declines in the rates of stem cell divisions (results in ulcers), decreases in smooth muscle tone (causes reduced gastric and intestinal motility), more apparent cumulative damage to other structures or organs, increases in cancer rates, and increases in dehydration (as a result of decreased osmoreceptor sensitivity). **27.** The digestive system absorbs the organic substrates, vitamins, ions, and water needed by cells of all the body's systems. **28.** Digestive system functions related to the cardiovascular system include absorption of water to maintain blood volume, absorption of vitamin K produced by intestinal bacteria (vital to blood clotting), excretion of bilirubin (a breakdown product of the heme portion of hemoglobin) by the liver, and synthesis of blood clotting factors by the liver.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. d 2. l 3. h 4. b 5. j 6. i 7. k 8. e 9. g 10. c 11. a 12. f 13. a 14. d 15. d 16. c 17. (a) oral cavity (mouth); (b) liver; (c) gallbladder; (d) pancreas; (e) large intestine; (f) salivary glands; (g) pharynx; (h) esophagus; (i) stomach; (j) small intestine; (k) anus **18.** d **19.** c **20.** b **21.** (a) mucosa; (b) submucosa; (c) muscular layer; (d) serosa 22. b 23. c 24. c **25.** Mechanical digestion involves the teeth, tongue, stomach, and small intestine. 26. The submucosal plexus is involved in the contraction of smooth muscles in the muscularis mucosae and regulation of the digestive glands' secretions. 27. The innermost (superficial) layer, the mucosa, is a mucous membrane consisting of epithelia and the lamina propria (loose connective tissue). The submucosa surrounds the mucosa and contains blood vessels, lymphatic vessels, nervous tissue (the submucosal nerve plexus). The muscular layer is made up of two layers of smooth muscle tissuelongitudinal and circular, whose contractions agitate and propel materials along the digestive tract-and nervous tissue (the myenteric nerve plexus). The submucosal and myenteric nerve plexuses make up the enteric nervous system (ENS). The outermost (deepest) layer, the serosa, is a serous membrane that protects and supports the digestive tract inside the peritoneal cavity. 28. The four primary functions of the oral cavity are (1) analysis of material before swallowing; (2) mechanical digestion through the actions of the teeth, tongue, and palatal surfaces; (3) lubrication by mixing with mucus and salivary secretions; and (4) limited chemical digestion of carbohydrates and lipids. 29. Incisors clip or cut; cuspids tear or slash; bicuspids crush, mash, or grind; and molars crush and grind. **30.** The duodenum receives chyme from the stomach and digestive secretions from the liver and pancreas. **31.** The pancreas produces digestive enzymes as well as buffers that assist in neutralizing acidic chyme. The liver produces bile-a solution that contains additional buffers and bile salts that aid the digestion and absorption of lipids-and the gallbladder stores and concentrates bile. The liver is also responsible for metabolic regulation and is the primary organ involved in regulating the composition of the circulating blood. **32.** Respiratory muscle contraction increases abdominal pressures, which aid defecation. The weight of the digestive organs aids the diaphragm during exhalation. **33.** Age-related changes that occur in the digestive system are (1) the rate of epithelial stem cell division declines, (2) smooth muscle tone decreases, (3) the effects of cumulative damage become apparent, (4) cancer rates increase, (5) dehydration is more common, and (6) changes in other systems have direct or indirect effects on the digestive system.

Level 2: Reviewing Concepts

34. d 35. d 36. b 37. Peristalsis consists of waves of muscular contractions that move along the length of the digestive tract. During a peristaltic movement, the circular muscles contract behind the digestive contents. The longitudinal muscles contract next, shortening adjacent segments. A wave of contraction in the circular muscles then forces the contents in the desired direction. Segmentation movements churn and fragment the digestive contents, mixing them with intestinal secretions. Because they do not follow a set pattern, segmentation movements do not produce directional movement of materials along the tract. **38.** The stomach performs four major digestive functions: storage of ingested food, mechanical digestion of ingested food, disruption of chemical bonds in the food through the actions of acids and enzymes, and production of intrinsic factor. 39. The cephalic phase begins with the sight or thought of food. Directed by the CNS, and transmitted over the parasympathetic division of the ANS, this phase prepares the stomach to receive food. The gastric phase, which begins with the arrival of food in the stomach, is initiated by distension of the stomach, an increase in the pH of the gastric contents, and the presence of undigested materials in the stomach. The intestinal phase begins when chyme starts to enter the small intestine. This phase controls the rate of gastric emptying and ensures that the secretory, digestive, and absorptive functions of the small intestine can proceed efficiently.

Level 3: Critical Thinking and Clinical Applications

40. The gallbladder stores and concentrates the bile produced by the liver. When the gallbladder is removed, the bile is no longer stored between meals. It flows directly from the liver to the duodenum as soon as it is produced and not only upon stimulation from intestinal hormones. Bile will thus still be available to digest and absorb fats. **41.** The small intestine, especially the jejunum and ileum, are likely involved. Barb's abdominal pain results from regional inflammation. Inflamed intestines cannot absorb nutrients. As a result, she is deficient in iron and vitamin B_{12} . Both are necessary for the formation of hemoglobin and red blood cells, and this accounts for her anemia. The reduced absorption of other nutrients accounts for Barb's weight loss.

CHAPTER 17

ANSWERS TO CHECKPOINTS

Page 610

1. Energetics is the study of the flow of energy and its transformation, or change, from one form to another. **2.** Metabolism is all the chemical processes in the body. It includes anabolism and catabolism. **3.** Catabolism is the breakdown of complex

organic molecules into simpler components, accompanied by the release of energy. Anabolism is the synthesis of complex organic compounds from simpler molecules and requires an input of energy.

Page 616

4. The primary role of the citric acid cycle is to transfer electrons from organic substrates to coenzymes. These electrons provide energy for the production of ATP by the electron transport chain.
5. The binding of hydrogen cyanide molecules to the final cytochrome of the ETC would prevent the transfer of electrons to oxygen. As a result, cells would be unable to produce ATP in the mitochondria and would die from energy starvation.
6. Gluconeogenesis is the synthesis of glucose from noncarbohydrate carbon precursor molecules, such as lactate (derived from pyruvate), glycerol (from lipids), and some amino acids (from proteins).

Page 619

7. Lipolysis is the chemical breakdown of lipids. Beta-oxidation is fatty acid catabolism that produces molecules of acetyl-CoA. **8.** High-density lipoproteins (HDLs) are considered beneficial because they reduce the amount of cholesterol in the bloodstream by transporting it to the liver for storage or for excretion in the bile.

Page 620

9. Transamination is a process in amino acid metabolism and protein synthesis in which an amino group is transferred from one amino acid to form another. Deamination is the removal of an amino group from an amino acid. An ammonium ion is formed in the process and the remaining carbon chain is broken down to generate ATP. **10.** A diet deficient in vitamin B_6 (pyridoxine), an important coenzyme in deaminating and transaminating amino acids in cells, would interfere with the body's ability to metabolize proteins.

Page 622

11. DNA is never catabolized for energy because the genetic information it contains is essential to the long-term survival of a cell. **12.** Nitrogenous wastes are metabolic waste products that contain nitrogen atoms, such as urea and uric acid. **13.** Elevated blood uric acid levels could indicate increased breakdown of nucleic acids, because uric acid is produced when the nucleotides adenine and guanine are broken down.

Page 626

14. The two types of vitamins are fat-soluble and water-soluble vitamins. **15.** Foods containing complete proteins contain all the essential amino acids in nutritionally required amounts. Foods containing incomplete proteins are deficient in one or more essential amino acids. **16.** A decrease in the amount of bile salts, which are necessary for digesting and absorbing fats and fat-soluble vitamins (including vitamin A), would result in less vitamin A in the body, and perhaps a vitamin A deficiency.

Page 628

17. The BMR of a pregnant woman would be higher than her own BMR when she is not pregnant, due to both the increased metabolism associated with supporting the fetus, and that of the fetus. **18.** Evaporation is ineffective as a cooling process when the

relative humidity is high (when the air is holding large amounts of water vapor). **19.** Vasoconstriction of peripheral vessels would decrease blood flow to the skin and thus the amount of heat the body can lose. As a result, body temperature would increase.

Page 629

20. Only caloric requirements change with aging. Caloric requirements generally decrease after age 50 because of reductions in metabolic rates, body mass, activity levels, and exercise tolerance.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. b 2. h 3. a 4. j 5. k 6. c 7. l 8. f 9. g 10. e 11. i 12. d 13. c 14. c 15. a 16. d 17. c 18. b 19. (a) fatty acids; (b) glucose; (c) amino acids; (d) small carbon chains; (e) citric acid cycle; (f) CO₂; (g) ATP; (h) electron transport system; (i) H₂O **20.** b 21. d 22. b 23. d 24. b 25. c 26. Metabolism is all of the chemical reactions occurring in the cells of the body. Anabolism is the set of chemical reactions that convert simple reactant molecules into complex molecules needed for maintenance/repair, growth, and secretion. Catabolism is the breakdown of complex molecules into their building block molecules, resulting in the release of energy for the synthesis of ATP and related molecules. 27. Lipoproteins are lipidprotein complexes consisting of large insoluble glycerides and cholesterol coated with phospholipids and proteins. The major groups are (a) chylomicrons (the largest lipoproteins), which are 95 percent triglyceride and carry absorbed lipids from the intestinal tract to the circulation; (b) low-density lipoproteins (LDLs), which deliver cholesterol to peripheral tissues (because they can be deposited within arteries, LDLs are also known as "bad cholesterol"); and (c) high-density lipoproteins (HDLs, also called "good cholesterol"), which transport excess cholesterol to the liver for storage or excretion in the bile. 28. Most vitamins and all minerals are essential (must be provided in the diet) because the body cannot synthesize these nutrients. 29. Carbohydrates yield 4.18 Cal/g; lipids yield 9.46 Cal/g; and proteins yield 4.32 Cal/g. 30. The BMR is the minimum, resting energy expenditures of an awake, alert person. **31.** The processes of heat transfer are (a) radiation: heat loss as infrared radiation; (b) conduction: heat loss to surfaces in physical contact; (c) convection: heat loss to the air; and (d) evaporation: heat loss when water evaporates to a gas.

Level 2: Reviewing Concepts

32. c **33.** a **34.** Glycolysis is a series of enzymatic steps that converts glucose to 2 pyruvate molecules plus 4 ATP and 2 NADH molecules. Glycolysis requires glucose, specific cytosolic enzymes, ATP and ADP, inorganic phosphates, and the coenzyme NAD (nicotinamide adenine dinucleotide). **35.** A two-carbon acetyl group (carried by acetyl-CoA) enters the cycle by joining to a four-carbon compound, and CO₂, NADH, ATP, and FADH₂ leave it. The citric acid reaction sequence is considered a cycle because the four-carbon starting compound is regenerated at the end. **36.** Lipids can produce large amounts of energy when catabolized and yield more than twice the energy released by catabolism of glucose and proteins. Due to lipids being insoluble in water, it can be stored in compact droplets in a cell's cytosol. **37.** The MyPlate food guide indicates the relative amounts of each of the five basic food groups a person should consume each day to ensure adequate intake of nutrients

and calories. **38.** The brain region called the hypothalamus acts as the body's "thermostat" by regulating ANS control (through negative feedback) of such homeostatic processes as sweating and shivering thermogenesis. **39.** These terms refer to lipoproteins in the blood that transport cholesterol. "Good cholesterol" (high-density lipoproteins, or HDLs) transports excess cholesterol to the liver for storage or excretion in the bile. "Bad cholesterol" (low-density lipoproteins, or LDLs) transports cholesterol to peripheral tissues—including, unfortunately, arteries, where the buildup of cholesterol is linked to cardiovascular disease.

Level 3: Critical Thinking and Clinical Applications

40. Fat-soluble vitamins can be stored in the adipose tissue of the body for a long time. In contrast, excessive amounts of water-soluble vitamins are usually excreted in the urine. **41.** In order to lose weight, Christine needs to make sure that her daily caloric expenditure exceeds her daily dietary intake. One way to achieve this is to eat food that is low in calories; however, for best results, her calorie counting should be paired with daily exercise. The amount of energy expended during exercise depends on the type of exercise. Since she has not exercised much in the past few years, you could recommend her to start off by walking or climbing stairs for an hour per day to burn between 300 and 500 calories.

CHAPTER 18

ANSWERS TO CHECKPOINTS

Page 636

1. The major functions of the urinary system include (a) the excretion of metabolic wastes from body fluids, (b) the elimination of body wastes to the exterior, and (c) the homeostatic regulation of the volume and solute concentration of blood. **2.** The urinary system consists of two kidneys, two ureters, a urinary bladder, and a urethra. **3.** Micturition, or urination, is the elimination of urine from the body.

Page 643

4. The position of the kidneys is unlike most other organs in the abdominal region, because the kidneys are retroperitoneal, and lie behind the peritoneal lining. **5.** Plasma proteins do not normally pass into the capsular space because they are too large to pass through the filtration slits between the foot processes (pedicels) of the podocytes. **6.** Damage to the juxtaglomerular complex would interfere with the hormonal control of blood pressure.

Page 650

7. A decrease in blood pressure would decrease the GFR by reducing filtration pressure within the glomerulus. 8. If nephrons lacked nephron loops—the ascending limb of which reabsorbs urea (thin portion) and also pumps Na⁺ and Cl⁻ out of the tubular fluid (thick portion), and the descending limb of which is the site of osmotic flow of water from the tubular fluid—then there could be no concentration gradient in the renal medulla. As a result, less water would be reabsorbed and the production of concentrated urine would not be possible. 9. Low circulating levels of ADH would result in a larger volume of dilute urine, because little water will be reabsorbed at the DCT and collecting duct.

Page 653

10. The glomerular filtration rate (GFR) depends on the filtration pressure across glomerular capillaries, and is stabilized by interactions among autoregulation (local blood flow regulation), hormonal regulation, and ANS regulation. **11.** Increased aldosterone secretion would increase the K⁺ concentration in urine. **12.** Sympathetic activation produces vasoconstriction of the afferent arterioles, which decreases the GFR.

Page 656

13. Peristaltic contractions move urine from the kidneys to the urinary bladder. **14.** An obstruction of a ureter would interfere with the passage of urine from the renal pelvis to the urinary bladder. **15.** Voluntary control of urination requires the ability to control the external urinary sphincter, a ring of skeletal muscle that acts as a valve.

Page 658

16. The three interrelated processes essential to stabilizing body fluid volume are fluid balance, electrolyte balance, and acid-base balance. **17.** The components of ECF are interstitial fluid, plasma, and other body fluids. The intracellular fluid (ICF) is the cytosol of a cell.

Page 660

18. A fluid shift is a rapid movement of water between the ECF and ICF in response to an osmotic gradient. **19.** Eating a meal high in salt would cause a reduction of fluid in the ICF. Because the ingested salt would temporarily increase the osmolarity of the ECF, water would shift from the ICF to the ECF. **20.** Being in the desert without water, you would lose fluid through perspiration, urine formation, and respiration. As a result, the osmotic concentration of your blood plasma (and other body fluids) would increase.

Page 664

21. The body's three major buffer systems are protein buffer systems, the carbonic acid-bicarbonate buffer system, and the phosphate buffer system. **22.** A decrease in the pH of body fluids would stimulate the respiratory centers in the medulla oblongata to increase the breathing rate. As a result, more CO_2 is eliminated, and pH rises. **23.** In a prolonged fast, catabolism of fatty acids produces acidic ketone bodies, which lower body pH. The eventual result is called ketoacidosis.

Page 665

24. Aging reduces GFR due to a loss of nephrons, cumulative damage to the filtration structures within remaining glomeruli, and reduced blood flow to the kidneys. A reduced GFR and fewer nephrons also reduce the body's ability to regulate pH through renal compensation. **25.** After age 40, total body water content gradually decreases. **26.** The body's excretory system is made up of the urinary, integumentary, respiratory, and digestive systems. **27.** For all systems, the urinary system excretes waste collected from blood and maintains normal body fluid pH and ion composition.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1.a **2.**h **3.**o **4.**k **5.**b **6.**n **7.**f **8.**q **9.**e **10.**g **11.**i **12.**l **13.**c **14.** d **15.** m **16.** p **17.** j **18.** (a) renal corpuscle; (b) nephron

loop; (c) proximal convoluted tubule; (d) distal convoluted tubule; (e) collecting duct; (f) papillary duct 19. c 20. a 21. c 22. d 23. (a) renal sinus; (b) renal pelvis; (c) hilum; (d) renal papilla; (e) ureter; (f) renal cortex; (g) renal medulla; (h) renal pyramid; (i) minor calyx; (j) major calyx; (k) kidney lobe; (l) renal columns; (m) fibrous capsule 24. c 25. d 26. d 27. c 28. The urinary system excretes waste products generated by cells throughout the body and maintains normal body fluid pH and ion composition. 29. The urinary system includes the kidneys, ureters, urinary bladder, and urethra. 30. Fluid shifts are rapid water movements between the ECF and ICF that occur in response to increases or decreases in the osmotic concentration (osmolarity) of the ECF. Such water movements dampen extreme shifts in electrolyte balance. Causes of osmolarity changes include water loss (excessive perspiration, dehvdration, vomiting, or diarrhea), water gain (ingestion of pure water, administration of hypotonic solutions through an IV), and changes in electrolyte concentrations (such as sodium). 31. Once renin is released into circulation, it converts angiotensinogen to angiotensin I, which is then converted to angiotensin II in the lung capillaries. Angiotensin II then stimulates the release of aldosterone by the adrenal cortex. In the CNS, angiotensin II stimulates the release of ADH from the posterior pituitary.

Level 2: Reviewing Concepts

32. d 33. c 34. b 35. b 36. a 37. The controls that stabilize GFR are autoregulation at the local level, hormonal regulation initiated by the kidneys, and autonomic regulation (by the sympathetic division of the ANS). **38.** The urge to urinate usually appears when the urinary bladder contains about 200 mL of urine. The urine voiding reflex begins to function when the stretch receptors have provided adequate stimulation to the pontine micturition center, which stimulates parasympathetic motor neurons. The activity in the motor neurons generates action potentials that reach the detrusor in the wall of the urinary bladder. These efferent impulses produce a sustained contraction of the urinary bladder and relaxation of the internal urethral sphincter. Urination occurs when the external urethral sphincter relaxes. 39. Fluid balance is a state in which the amount of water gained each day equals the amount lost to the outside. Electrolyte balance exists when there is neither a net gain nor a net loss of any ion in body fluids. Acid-base balance exists when hydrogen ion (H⁺) production precisely offsets H⁺ losses. These balances are needed to keep fluids, electrolytes, and pH within their relatively narrow normal ranges, for variations outside these ranges can be life threatening. 40. "Drink plenty of fluids" is physiologically sound advice, because for every degree (°C) body temperature rises above normal, daily water loss increases by 200 mL. 41. Sweat is usually hypotonic, so loss of a large volume of sweat causes body fluids to become hypertonic. Fluid is lost primarily from the interstitial space, which leads to a reduction in plasma volume and an increase in the hematocrit. Severe dehydration causes blood viscosity to increase substantially, increasing the workload on the heart, and ultimately increasing the probability of heart failure.

Level 3: Critical Thinking and Clinical Applications

42. By resisting the urge to urinate, long-haul truck drivers may not urinate as frequently as they should. The pressure this puts on kidney tissues can lead to tissue death, and ultimately to kidney

failure. **43.** The fever and burning sensation suggest that Susan may have a urinary tract infection. Her urine may contain blood cells and bacteria. Because in females the urethra is relatively short, and the urethral orifice is close to the anus and opens near the vagina, bacteria in the anus and vagina can easily reach the urethral orifice (often during sexual intercourse). **44.** Because mannitol is filtered but not reabsorbed, drinking a mannitol solution would lead to an increase in the osmolarity of the tubular fluid. Less water would be reabsorbed, and an increased volume of urine would be produced.

CHAPTER 19

ANSWERS TO CHECKPOINTS

Page 673

1. A gamete is a functional male or female reproductive cell. **2.** Basic structures of the reproductive system are gonads (reproductive organs), ducts (which receive and transport gametes), accessory glands (which secrete fluids), and external genitalia (perineal structures). **3.** Gonads are reproductive organs that produce gametes and hormones.

Page 683

4. Male reproductive structures are the scrotum, testes, epididymides, right and left ductus deferens, ejaculatory duct, urethra, seminal glands (seminal vesicles), prostate, bulbo-urethral glands, and penis. **5.** On a warm day, the cremaster muscle (as well as the dartos muscle) would be relaxed so that the scrotum could descend away from the warmth of the body and cool the testes. **6.** When arteries within the penis dilate, the increased blood flow causes the vascular channels within the erectile tissues to fill with blood, producing an erection. **7.** Low FSH levels would lead to low levels of testosterone in the seminiferous tubules, decreasing both the sperm production rate and sperm count.

Page 694

8. Structures of the female reproductive system include the ovaries, uterine tubes, uterus, vagina, and external genitalia. 9. Blockage of both uterine tubes would eliminate the ability to conceive, resulting in sterility. 10. The acidic pH of the vagina helps prevent bacterial, fungal, and parasitic infections in this region. 11. The functional layer of the endometrium sloughs off during menstruation. 12. Blockage of a single lactiferous sinus would have little effect on the delivery of milk to the nipple, because each mammary gland has 15–20 lactiferous sinuses. 13. If the LH surge did not take place during an ovarian cycle, ovulation and corpus luteum formation would not occur. 14. Blockage of progesterone receptors in the uterus would inhibit the development of the endometrium, making the uterus unprepared for pregnancy. 15. A decline in the levels of estrogen and progesterone signals the beginning of menstruation, the end of the uterine cycle.

Page 696

16. The physiological events of sexual intercourse in both sexes are arousal, erection, lubrication, orgasm, and detumescence. Emission and ejaculation are additional phases that occur only in males. **17.** An inability to contract the ischiocavernosus and

bulbospongiosus muscles would interfere with a male's ability to ejaculate and to experience orgasm. **18.** Parasympathetic stimulation in females during sexual arousal causes (a) engorgement of the erectile tissue of the clitoris and bulb of vestibule, (b) increased secretion of cervical and vaginal glands, (c) increased blood flow to the wall of the vagina, and (d) engorgement of the blood vessels in the nipples. **19.** Menopause is the time when ovulation and menstruation cease, typically around ages 45–55. **20.** At menopause, circulating levels of estrogens begin to decrease. Estrogen has an inhibitory effect on FSH (and on GnRH). As the level of estrogen decreases, the levels of FSH rise and remain high. **21.** The male climacteric, or andropause, is a period of declining reproductive function in men, typically between ages 50 and 60.

Page 697

22. The cardiovascular system distributes reproductive hormones; provides nutrients, oxygen, and waste removal for the fetus; and produces local blood pressure changes responsible for the physical changes that occur during sexual intercourse. The reproductive system supplies estrogens that may help maintain healthy blood vessels and slow the development of atherosclerosis. **23.** Pelvic bones protect reproductive organs in females, and portions of the ductus deferens and accessory glands in males; sex hormones stimulate growth and maintenance of bone, and accelerate growth and closure of epiphyseal cartilages at puberty.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1.j 2.n 3.b 4.d 5.m 6.f 7.o 8.a 9.i 10.c 11.g 12.k 13.e 14. 1 15. h 16. d 17. a 18. a 19. b 20. d 21. a 22. c **23.** (a) urethra; (b) ductus deferens; (c) penis; (d) epididymis; (e) testis; (f) external urethral orifice; (g) scrotum; (h) seminal gland; (i) prostate; (j) bulbo-urethral gland 24. (a) ovary; (b) uterine tube; (c) greater vestibular gland; (d) clitoris; (e) labium minus; (f) labium majus; (g) myometrium; (h) perimetrium; (i) endometrium; (j) uterus; (k) fornix; (l) cervix; (m) vagina 25. b 26. a 27. b 28. a 29. The accessory glands in males include the seminal glands, the prostate, and the bulbo-urethral glands. These structures activate sperm, provide nutrients sperm need for motility, propel sperm and fluids along the reproductive tract, and produce buffers that counteract the acidity of the urethral and vaginal contents. 30. The epididymis monitors and adjusts the composition of the tubular fluid, acts as a recycling center for damaged sperm, and stores sperm and aids their functional maturation. **31.** The ovaries produce female gametes (oocytes, or immature ova); secrete female sex hormones, including estrogens and progesterone; and secrete inhibin, involved in the feedback control of pituitary FSH production. **32.** The uterus protects, nourishes, and removes wastes for the developing embryo and fetus during pregnancy. In addition, contractions of the uterine smooth muscle are important in ejecting the fetus at birth.

Level 2: Reviewing Concepts

33. The reproductive system is the only organ system that is not required for the survival of the individual. **34.** Spermiogenesis

is the process in which spermatids mature into sperm. A sperm cell is comprised of a head, neck, middle piece, and tail. The head contains the nucleus, and its tip is covered by the acrosome. The neck attaches the head to the middle piece. The middle piece contains a spiral of mitochondria. The tail's structure resembles that of a flagellum. 35. The menstrual phase (days 1–7), is marked by the degeneration and loss of the functional layer of the endometrium; approximately 35-50 mL of blood is lost. In the proliferative phase (end of menstruation until the beginning of ovulation around day 14), epithelial growth and blood vessel development result in the complete restoration of the functional layer. In the secretory phase (begins at ovulation and persists as long as the corpus luteum remains intact), the combined stimulatory effects of progesterone and estrogens from the corpus luteum cause uterine glands to enlarge and secrete more quickly, preparing the endometrium for the arrival of a developing embryo. 36. The corpus luteum degenerates, and a decline in progesterone and estrogen levels results in endometrial breakdown (menses). Next, rising FSH, LH, and estrogen levels stimulate the repair and regeneration of the functional layer of the endometrium. During the postovulatory phase, the combination of estrogen and progesterone causes enlargement of the uterine glands and an increase in their secretory activity. **37.** In women, menopause—the time when ovulation and menstruation cease—is accompanied by a sharp and sustained rise in GnRH, FSH, and LH production, while concentrations of circulating estrogens and progesterone decline. Reduced estrogen levels lead to reductions in uterus and breast size, accompanied by a thinning of the urethral and vaginal walls. Reduced estrogen concentrations have also been linked to the development of osteoporosis, presumably because bone deposition proceeds more slowly. During the male climacteric, typically between ages 50 and 60, circulating testosterone levels begin to decline while circulating FSH and LH levels increase. Although sperm production continues in older men, a gradual reduction in sexual activity occurs.

Level 3: Critical Thinking and Clinical Applications

38. David's cryptorchid testis will not produce sperm since such a testis is located in the abdomen, where the temperature is 1.1°C higher than the temperature required for sperm development to take place. However, if there are no other testicular abnormalities, David's other testis should be able to produce sperm, enabling him to have children. 39. Regardless of their location, endometrial cells have receptors for and respond to estrogen and progesterone. Under the influence of estrogen at the beginning of the menstrual cycle, any endometrial cells in the peritoneal cavity proliferate and begin to develop glands and blood vessels, which then further develop under the control of progesterone. The dramatic increase in size of this tissue presses on neighboring abdominal tissues and organs, causing periodic painful sensations. **40.** Although a part of the ductus deferens is removed and the cut ends tied shut during vasectomy, there may be residual sperm in the distal part of the reproductive tract, which may result in an unintended pregnancy. It is thus necessary to use another form of contraception.

CHAPTER 20

ANSWERS TO CHECKPOINTS

Page 707

1. Cellular differentiation is the formation of increasingly specialized cell types during development. **2.** Development begins at fertilization (conception), that is, with the union of a sperm and an oocyte. **3.** Inheritance refers to the transfer of genetically determined characteristics from one generation to the next.

Page 708

4. Hyaluronidase released from dozens of sperm breaks down the connections between the follicular cells of the corona radiata surrounding the secondary oocyte. Another acrosomal enzyme, released after the binding of a single sperm to the zona pellucida, digests a path through the zona pellucida to the oocyte membrane. **5.** A normal human zygote contains 46 chromosomes.

Page 709

6. Gestation is the period of prenatal development. It consists of three trimesters. **7.** The first trimester is the period of embryonic and early fetal development. The second trimester is a time of organ and organ system development. By the end of this stage, the fetus appears distinctly human. The third trimester is characterized by rapid fetal growth and the deposition of adipose tissue.

Page 717

8. The inner cell mass of the blastocyst eventually develops into the embryo. **9.** Yes, Sue is pregnant. After fertilization, the developing trophoblast (and later, the placenta) produce and release the hormone hCG. **10.** The placenta (1) supplies the developing fetus with a route for gas exchange, nutrient transfer, and waste elimination, and (2) produces hormones that affect maternal systems.

Page 723

11. The major changes that take place in maternal systems during pregnancy include increases in respiratory rate, tidal volume, blood volume, nutrient requirements, glomerular filtration rate, and size of uterus and mammary glands. **12.** A mother's blood volume increases during pregnancy to compensate for the reduction in maternal blood volume resulting from blood flow through the placenta. **13.** The uterus increases in size and weight during gestation through enlargement of uterine cells, primarily smooth muscle cells of the myometrium. **14.** Three factors opposing the calming action of progesterone on the uterus are increasing estrogen levels, increasing oxytocin levels, and prostaglandin production.

Page 725

15. The three stages of labor are the dilation stage, expulsion stage, and placental stage. **16.** Immature delivery is the birth of a fetus weighing at least 500 g (17.6 oz), which is the normal weight near the end of the second trimester. Premature delivery usually refers to birth at 28–36 weeks at a weight over 1 kg (2.2 lb). **17.** Fraternal twins are dizygotic twins, and identical twins are monozygotic twins.

Page 728

18. The postnatal stages of development are the neonatal period, infancy, childhood, adolescence, and maturity. These stages are

ANS-28

followed by senescence, or aging. **19.** Colostrum is produced by the mammary glands from the end of the sixth month of pregnancy until a few days after birth. After that, the glands begin producing breast milk, which contains fewer proteins (including antibodies) and far more fat than colostrum. **20.** Increases in the blood levels of GnRH, FSH, LH, and sex hormones mark the onset of puberty.

Page 733

21. Genotype is a person's genetic makeup. Phenotype is a person's physical and physiological characteristics. It results from the interaction between the person's genotype and the environment. **22.** Heterozygous refers to having two different alleles at corresponding sites of a homologous pair of chromosomes. **23.** The phenotype of a person who is heterozygous for tongue rolling—who has one dominant allele and one recessive allele for that trait—would be "tongue roller." **24.** If Joe's lack of sons is anyone's "fault," it's his. The sex of each of his children depends on the genetic makeup of the sperm cell that fertilizes his wife's oocyte. Only males—being XY—can provide a gamete containing a Y chromosome.

ANSWERS TO REVIEW QUESTIONS

Level 1: Reviewing Facts and Terms

1. h 2. b 3. d 4. f 5. e 6. o 7. a 8. c 9. p 10. k 11. g 12. i 13.1 14.m 15.n 16.j 17.a 18.c 19.d 20.(a) umbilical cord; (b) placenta; (c) amniotic cavity; (d) amnion; (e) chorion **21.** a 22. a 23. b 24. c 25. d 26. The three germ layers of the embryo are the ectoderm, mesoderm, and endoderm. **27.** Twins can either be fraternal/dizygotic or identical/monozygotic. In the case of dizygotic twins, two separate oocytes are ovulated and fertilized by two separate sperm. In monozygotic twins, one oocyte is ovulated and fertilized. After this, either the blastomeres separate early in cleavage or the inner cell mass splits before gastrulation takes place. Dizygotic twins have the same or different sexes, whereas monozygotic twins always have the same sex. 28. During the neonatal period (birth to one month), newborns become relatively self-sufficient and begin to breathe, digest, and excrete for themselves. Heart rates and fluid requirements are higher than those of adults. Neonates have little ability to thermoregulate. During infancy (one month to one year), nonreproductive organ systems become fully operational and start to take on the functional characteristics of adult systems. During childhood (one year to puberty), children continue to grow, and significant changes in body proportions occur.

Level 2: Reviewing Concepts

29. d **30.** d **31.** The amount of amniotic fluid present is lower in the first trimester, which increases the risk of fetal injury if amniocentesis is done at this time. **32.** The mother's respiratory rate and tidal volume increase, so that her lungs can meet the fetus's oxygen needs and remove the carbon dioxide it generates. Maternal blood volume increases to compensate for the increased blood flow through the placenta. Nutrient and vitamin requirements climb 10–30 percent in order to nourish the fetus, and glomerular filtration rate increases by about 50 percent, reflecting increased maternal blood volume and the need

to excrete fetal metabolic wastes. **33.** Positive feedback ensures that labor contractions continue until delivery is complete. **34.** Expulsion stage of labor. An episiotomy is performed when the vaginal canal is too small to permit the passage of the fetus and there is an acute danger of perineal tearing. **35.** The trait and type of inheritance is (a) dominant trait and simple inheritance, (b) recessive trait and simple inheritance, (c) X-linked trait and sex-linked inheritance, and (d) autosomal dominant trait and autosomal inheritance. **36.** More men are color-blind than women because the gene for this trait is on the X chromosome (X-linked). Because men have only one X chromosome, whichever allele is on the X chromosome determines whether a man is color-blind or has normal vision. Women have two X chromosomes, so they will be color-blind only if they are homozygous recessive. This is an example of sex-linked inheritance.

Level 3: Critical Thinking and Clinical Applications

37. None of the couple's daughters will be hemophiliacs, because each will receive a normal allele from her father. There is a 50 percent chance that a son will be hemophiliac because there is a 50 percent chance of receiving either the mother's normal allele or her recessive allele. **38.** At birth, the neonate's ability to control body temperature is compromised. Due to its high surface area to volume ratio, the neonate also quickly loses heat. So, to maintain a normal body temperature, the neonate must have a high cellular metabolic rate, which assists in generating heat as a result of catabolic reactions. The increased heat production assists the neonate in controlling its own body temperature. **39.** The baby's condition is almost certainly not the result of a viral infection or any other event during the third trimester, because all organ systems are fully formed before the end of the second trimester.

APPENDIX Normal Physiological Values

Tables 1 and 2 present normal averages or ranges for the chemical composition of body fluids. These values are approximations rather than absolute values, because test results vary from laboratory to laboratory due to differences in procedures, equipment, normal solutions, and so forth. Blanks in the tabular data appear where data are not available. The following locations in the text contain additional information about body fluid analysis:

Table 11-2 (p. 426) presents data on the formed elements of whole blood.

Table 18-2 (p. 644) compares the average compositions of urine and plasma.

Table 18-3 (p. 650) gives the general characteristics of normal urine.

Table 1 The

The Composition of Minor Body Fluids

Fibrinogen	P: 0.2–0.4	0.65	0

 * S = serum, P = plasma, WB = whole blood.

[†] Because urinary output averages just over 1 liter per day, these electrolyte values are comparable to mEq/L.

[‡] Because urinary metabolite and protein data approximate mg/L or g/L, these data must be divided by 10 for comparison with CSF or blood concentrations.

§ Venous blood sample.

Codon Chart

A codon is a sequence of three consecutive nucleotides in mRNA that codes for a particular amino acid or signals to stop protein synthesis. Because each mRNA codon consists of three nucleotides, the four nucleotides in mRNA (A, U, G, and C) can produce 64 different combinations. Of these, 61 codons correspond to amino acids and three act as stop signals of protein synthesis. There are

only 20 different amino acids used to synthesize proteins, so most amino acids are represented by more than one codon. One codon, AUG, has a dual role. It codes for the amino acid methionine and also as the start signal for protein synthesis. It is always the first codon in a strand of mRNA.

A

A band in sarcomere, 225, 226, 227 Abdomen anatomical terms, 44 greater omentum, 578, 579 lesser omentum, 578, 579 parietal peritoneum, 48, 571 visceral peritoneum, 48, 571 Abdominal aorta, 485, 486 Abdominal cavity, 48 Abdominal region, 43 Abdominal thrust (Heimlich maneuver), 542 Abdominopelvic cavity: Term used to refer to the general region bounded by the abdominal wall and the pelvis; it contains the peritoneal cavity and visceral organs, (Chs 1, 7), 48-49, 250, 253 Abdominopelvic quadrants, 43, 45 Abdominopelvic regions, 43, 45 Abducens nerve (VI), 307, 308, 309, 310, 346, 366 Abduction: Movement away from the midline, (Chs 6, 7), 206-207, 246, 257, 259, 261, 262 Abductor pollicis muscle, 260, 261 ABO blood types, 420-423 Abortion, 728 Abrasion, 164 Abruptio placentae, 735 Abscess, 514 Absorption: The active or passive uptake of gases, fluids, nutrients, or solutes, (Chs 1, 3, 4, 16), 32, 88, 91, 124, 125, 127, 569, 592, 594–595 Accessory nerve (XI), 307, 308, 310, 311 Accessory organs of the digestive system, 569, 570 Accessory structures of the eye, 344-346 Accessory structures of the integumentary system exocrine glands, 128, 130-131 hair. See Hair nails. See Nail sebaceous glands, 130, 152, 162 sweat glands, 152, 162-163, 325 Accommodation: Alteration in the curvature of the lens to focus an image on the retina, (Ch 9), 351–352 Acetabulum (as-e-TAB-ū-lum): Fossa on lateral aspect of pelvis that accommodates the head of the femur, (Ch 6), 200 Acetone, 619 Acetyl-CoA: an acetyl group (—CH3CO) bound to coenzyme A, a participant in the anabolic and catabolic pathways for carbohydrates, lipids, and many amino acids, (Ch 17), 612, 616 Acetyl groups, 612 Acetylcholine (ACh) (as-ē-til-KŌ-lēn): Chemical neurotransmitter in the brain and PNS; dominant neurotransmitter in the PNS, released at neuromuscular junctions and synapses of the parasympathetic division, (Chs 7, 8, 12, 13), 227, 228-229, 234, 288-290, 320, 453, 473 Acetylcholinesterase (AChE): Enzyme found in the synaptic cleft, bound to the postsynaptic membrane, and in tissue fluids; breaks down and inactivates ACh molecules, (Chs 7, 8), 227, 228, 229, 234, 289-290 ACh. See Acetylcholine (ACh) Achalasia, 600 AChE. See Acetylcholinesterase (AChE) Achilles tendon. See Calcaneal tendon Aching pain sensation, 338 Acid: A compound whose dissociation in solution releases a hydrogen ion and an anion; an acidic solution has a pH below 7.0 and contains an excess of hydrogen ions, (Chs 2, 18), 67, 80, 656, 660-664 Acid-base balance. See also pH acids in the body, 660-661 buffers and buffer systems, 661-662 described, 656, 662

disorders of, 663–664

maintaining, 662-663 Acidic solutions, 66, 67 Acidosis (as-i-DŌ-sis): An abnormal physiological state characterized by blood pH below 7.35, (Ch 18), 660. See also Acid-base balance Acinar cells, 587 Acinus/acini (AS-i-nī): Histological term referring to a blind pocket, pouch, or sac, (Ch 16), 587 ACL. See Anterior cruciate ligament (ACL) Acne, 162 Acoustic: Pertaining to sound or the sense of hearing, (Ch 9), 366 Acquired immune deficiency syndrome (AIDS), 523, 526, 546,695 Acromegaly, 402 Acromial end of the clavicle, 196, 197 Acromial region, 44 Acromion, 196, 197 Acrosomal enzymes, 707, 708 Acrosome, 678 Actin: Protein component of microfilaments; forms thin filaments in skeletal muscles and produces contractions of all muscles through interaction with thick (myosin) filaments, (Chs 3, 4, 7), 100, 141, 224, 226 Action of muscles, 246 Action potential: A propagated change in the membrane potential of excitable cells, initiated by a change in the membrane permeability to sodium ions, (Chs 7, 8, 9, 12) cardiac contractile cells, 445, 446 generation of, 283, 284-285 membrane potential, changes in, 282-283 neuron general structure, 276 production of, 227, 228-229 propagation of, 283, 286-287 sensory information, 336 Activation energy, 64 Active immunity, 515, 516 Active site of an actin molecule, 226, 227 Active site of enzymatic reaction, 76 Active transport: The ATP-dependent absorption or excretion of solutes across a plasma membrane, (Ch 3), 92, 96-97 Acute renal failure, 652 "Adam's apple," 541 Adaptability of organisms, 32 Adaptation, defined, 337 Adaptive (specific) immunity/defenses forms of, 515-516 lymphatic system, 502, 511, 515 lymphocytes, 425 overview of, 515, 516-517, 525 properties of, 516 Addison disease, 402, 526 Adduction: Movement toward the axis or midline of the body as viewed in the anatomical position, (Chs 6, 7), 201, 206, 207, 246, 257, 259, 261, 262, 266 Adductor brevis muscle, 259, 262, 263 Adductor longus muscle, 244, 259, 262, 263, 264 Adductor magnus muscle, 245, 259, 263, 264 Adenine: One of the nitrogenous bases in the nucleic acids RNA and DNA, (Chs 2, 3), 77, 78, 107, 109, 110 Adenoid, 506 Adenosine: A nucleoside consisting of adenine and a fivecarbon sugar, (Ch 2), 78 Adenosine diphosphate (ADP): A highenergy compound composed of adenosine monophosphate and one phosphate group, (Chs 2, 7, 17) described, 78, 79 electron transport chain, 613, 614 glycolysis, 611 muscle contraction, 237, 238

muscle contraction cycle, 232, 233

consisting of adenosine plus a phosphate group, (Ch 2), 78 Adenosine triphosphate (ATP): A highenergy compound composed of adenosine monophosphate and two phosphate groups, (Chs 2, 3, 7, 17) active transport across plasma membranes, 92 cellular use, 78, 79 citric acid cycle, 612 creatine phosphate reserves and, 237-238 endocytosis, 97-98 energy use and level of muscle activity, 239 generation of, 103, 106, 238-239 glycolysis, 610-612 lipids used for, 617 muscle contractions, 232, 233, 234, 237-240 muscle fatigue, 239 recovery period, 239 sodium-potassium exchange pumps, 96-97 Adenylate cyclase: An enzyme bound to the inner surfaces of plasma membranes that can convert ATP to cyclic-AMP; also called adenylyl cyclase, (Ch 10) 378 379 ADH. See Antidiuretic hormone (ADH) Adhesion belt, 123, 124 Adhesions, 147 Adipocytes (AD-i-pō-sīts): Fat cells, (Chs 4, 5) connective tissue proper, 133, 136 energy reserves, storage of, 132 in hypodermis, 159 Adipose tissue: Loose connective tissue dominated by adipocytes, (Chs 4, 8, 10) autonomic nervous system, effects of, 325 endocrine function, 377, 398 liposuction, 136 loose connective tissue, 134, 135 Adolescence, 722, 726, 727-728 ADP. See Adenosine diphosphate (ADP) Adrenal arteries, 485, 486 Adrenal cortex: Superficial portion of the adrenal gland that produces steroid hormones; also called the suprarenal cortex, (Ch 10), 377, 390-392 Adrenal gland: Small endocrine gland secreting hormones, located superior to each kidney; also called the suprarenal gland, (Chs 1, 8, 10, 18), 38, 320, 321, 325, 377, 381, 390-393, 650 Adrenal medulla: Core of the adrenal gland; a modified sympathetic ganglion that secretes hormones into the blood following sympathetic activation; also called the suprarenal medulla, (Chs 8, 10), 320, 321, 325, 377, 381, 391, 392-393 Adrenal veins, 488, 489, 490 Adrenalectomy, 403 Adrenaline. See Epinephrine Adrenergic (ad-ren-ER-jik): An axon terminal that, when stimulated, releases norepinephrine, (Ch 8), 290, 320 Adrenocorticotropic hormone (ACTH): Hormone that stimulates the production and secretion of glucocorticoids by the adrenal cortex; released by the anterior lobe of the pituitary gland, (Chs 10, 14) endocrine system, 377, 383, 384, 386, 387 immune response, 527 Adventitia (ad-ven-TISH-ē-uh): Superficial layer of connective tissue surrounding an internal organ; fibers are continuous with those of surrounding tissues, providing support and stabilization, (Ch 16), 572 Aerobic endurance, 241 Aerobic metabolism: The complete breakdown of organic substrates into carbon dioxide and water; a process that yields large amounts of ATP but requires mitochondria and oxygen, (Chs 3, 7, 17),

103, 238, 610, 612-616

Adenosine monophosphate (AMP): A nucleotide

Afferent arteriole: An arteriole that carries blood to the glomerulus of a kidney, (Ch 18), 638, 639, 640 Afferent division of the PNS, 274-275 Afferent fiber: Axons carrying sensory information to the CNS (Ch 9), 340, 341, 344 Afferent lymphatics, 508 Afferent vessels, 435. See also Veins Afterbirth, 724. See also Placenta Agglutination (a-gloo-ti-NĀ-shun): Aggregation of red blood cells due to interactions between surface antigens (agglutinogens) and plasma antibodies (agglutinins), (Chs 11, 14), 421, 422, 522 Agglutinins, 421 Agglutinogens, 421, 422 Aging calorie and nutrient needs, 629 cardiovascular system, 493-494 digestive system, 599-600 endocrine hormones, 400 integumentary system, 167 lymphatic system and immune response, 527 muscular system, 266-267 nervous system, 324–325 reproductive system, 696 respiratory system, 562 skeletal system, 182 special senses, 368-369 tissue structure and cancer incidence, 145 urinary system, 664 Agonist: A muscle responsible for a specific movement, (Ch 7), 246 Agranulocytes, 423-424 AIDS (acquired immune deficiency syndrome), 523, 526, 546,695 Air cells of the mastoid process, 358, 360 Airways, 325 Alanine, 109 Alarm phase of the general adaptation syndrome, 400,401 Albinism: Absence of pigment in hair and skin caused by the inability of melanocytes to produce melanin, (Chs 5, 20), 156, 729 Albumins, 411, 413 Alcohol, diffusion across plasma membranes, 93 Alcohol use, cerebellar damage and, 308 Aldosterone: A mineralocorticoid produced by the adrenal cortex; stimulates sodium and water conservation at the kidneys; secreted in response to the presence of angiotensin II, (Chs 10, 13, 18) cardiovascular regulation, 476, 477, 479 endocrine hormone, 377, 391, 392, 397 urine formation, 646, 650, 651-652 Alimentary canal, 569 Alkaline solutions, 66, 67 Alkalosis (al-kah-LÖ-sis): Condition characterized by a blood pH of greater than 7.45; associated with a relative deficiency of hydrogen ions or an excess of bicarbonate ions, (Ch 18), 660. See also Acid-base balance All-or-none principle, 283 Allantois (a-LAN-tō-is): One of the four extra-embryonic membranes; it provides blood vessels to the chorion and is, therefore, essential to placenta formation; the proximal portion becomes the urinary bladder; the distal portion becomes part of the umbilical cord, (Ch 20), 711, 714–715 Alleles (a-LELZ): Alternate forms of a particular gene, (Ch 20), 729 Allergen: An antigenic compound that produces a hypersensitivity response, (Ch 14), 526 Allergic reactions, 392, 526-527 Allograft, 528 Alopecia, 161 Alpha cells: Cells in the pancreatic islets that secrete glucagon, (Ch 10), 393, 395 Alpha helix, 74, 75 Alternate catabolic pathways, 616 Alveolar air versus atmospheric air, 553 Alveolar capillaries, 481 Alveolar ducts, 544, 545 Alveolar macrophages (dust cells), 544 Alveolar sac: An air-filled chamber that supplies air to several alveoli, (Ch 15), 544, 545

Alveolus/alveoli (al-VĒ-o-lī): Blind pockets at the end of the respiratory tree, lined by a simple squamous epithelium and surrounded by a capillary network; site of gas exchange with the blood, (Chs 13, 15) alveolar ventilation, 549 defined, 536, 537 pulmonary circulation, 481 respiratory system, 544 Alzheimer's disease, 305, 326, 733 Amacrine cells of the retina, 349, 350 Amenorrhea, 689 Amination, 620 Amino acids: Organic compounds that are the building blocks of proteins, (Chs 2, 10, 17, 18) catabolism of, 619-620, 621 hormones, 376 protein structure, 73-75, 79 protein synthesis, 620, 621 urine and plasma, amounts in, 644 Aminoglycoside antibiotics, 366 Ammonia, 644 Amnesia: Temporary or permanent memory loss, (Ch 8), 304 Amniocentesis, 131, 734 Amnion (AM-nē-on): One of the four extra embryonic membranes; surrounds the developing embryo/ fetus, (Ch 20), 711, 712, 714-715 Amniotic cavity, formation of, 710-711, 712, 714-715 Amniotic fluid (am-nē-OT-ik): Fluid that fills the amniotic cavity; provides cushioning and support for the embryo/fetus, (Chs 4, 20), 131, 711, 714, 734 Amoeboid movement, 424 AMP. See Adenosine monophosphate (AMP) Amphiarthrosis (am-fē-ar-THRŌ-sis): A joint (articulation) that permits a small degree of independent movement, (Ch 6), 204, 205, 209 **Amphimixis** (am-fi-MIK-sis): The fusion of male and female pronuclei following fertilization, (Ch 20), 708 Ampulla/ampullae (am-PŪ-la): A localized dilation in the lumen of a canal or passageway, (Ch 9), 361, 362 Amygdaloid body (amygdala), 305 Amylase: An enzyme that breaks down polysaccharides, produced by the salivary glands and the pancreas, (Ch 16) pancreatic, 597, 598 salivary, 597, 598 Amyotrophic lateral sclerosis (ALS), 326 Anabolic pathways, 621 Anabolic steroids, 399 Anabolism (a-NAB-Ō-lizm): The synthesis of complex organic compounds from simpler precursors, (Chs 2, 17), 63, 607, 609, 621 Anaerobic: Without oxygen, (Chs 7, 17) anaerobic endurance, 241 anaerobic metabolism, glycolysis as, 238-239, 607 lactic acid production, 239 Anal canal, 593, 594 Anal columns, 593, 594 Analgesic, 369 Anaphase (AN-a-fāz): The stage of mitosis in which the paired chromatids separate and move toward the centrioles at opposite ends of the cell, (Ch 3), 112, 113, 115 Anaphylactic shock, 478, 527 Anaphylaxis, 527 Anaplasia, 147 Anastomosis (a-nas-to-MÖ-sis): The joining of vtwo tubes, usually referring to a connection between two peripheral blood vessels without an intervening capillary bed, (Chs 12, 13), 444, 465 Anatomic dead space of the lungs, 551 Anatomical directions, 43, 46 Anatomical landmarks, 43 Anatomical neck of the humerus, 198 Anatomical position: An anatomical reference position, the body viewed from the anterior surface with the palms facing forward; supine, (Ch 1), 43, 46 Anatomical regions, 43-45 Anatomy (ah-NAT-o-mē): The study of the structure of the body, (Ch 1) biology, subspecialty of, 33

defined, 33 gross, 33 microscopic, 33 sectional, 43-45, 47-48 surface. See Surface anatomy Anatomy and physiology, introduction to, 31-55 anatomical regions, positions, directions, and body sections, 43-49 anatomy, described, 33 body cavities, 45-48 functions of living things, 32-33 homeostasis. See Homeostasis imaging techniques, 50-51 levels of organization, 34-36 negative and positive feedback, 40-42 organ systems, 36, 37-39 physiology, described, 34 Anchoring proteins, 91 Androgen: A steroid sex hormone primarily produced by the interstitial cells of the testis and manufactured in small quantities by the adrenal cortex in either sex, (Chs 6, 10, 11, 19) adrenal cortex, 391, 392 athletic performance, 399 endocrine hormones, 377, 400 growth, 400 interstitial cells of the testes, 675, 676 luteinizing hormone, 384 osteoporosis, 182 red blood cell production, 412, 418 reproductive system, 673 source, regulation of, and primary effects, 697 Andropause, 696 Androstenedione, 399 Anemia (a-NĒ-mē-ah): Condition marked by a reduction in the hematocrit and/or hemoglobin content of the blood, (Chs 2, 11, 13, 17, 20) defined, 415 iron deficiency, 417, 628 pernicious, 418 sickle cell, 74, 416, 731, 733 viscosity of blood, 466 Anesthesia, 369 Aneurysm (AN-ū-rizm): A weakening and localized dilation in the wall of a blood vessel, (Ch 13), 494 Angina pectoris, 455 Angiotensin-converting enzyme (ACE) renin-angiotensin-aldosterone system, 650-651 respiratory membrane, 546 Angiotensin I: The hormone produced by the activation of angiotensinogen by renin; angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II in lung capillaries (Ch 18), 650-651 Angiotensin II: Angiotensin II is a hormone that causes an elevation in systemic blood pressure, stimulates secretion of aldosterone, promotes thirst, and causes the release of ADH (Chs 10, 13, 18), 392, 397, 475,650-651 Angiotensinogen: Blood protein produced by the liver that is converted to angiotensin I by the enzyme renin, (Chs 13, 18), 475, 650 Angular movements, 206-207 Animal starch (glycogen), 69, 70 Anion (AN-ī-on): An ion bearing negative charge, (Ch 2), 58-59, 62, 65, 67, 80 Ankle, 44 bones of, 185, 203-204 fracture, 181 muscles of, 263, 265, 266 Ankylosis, 214 Anorexia, 625, 629 Anoxia (an-ok-SĒ-uh): Tissue oxygen deprivation, (Ch 15), 549 ANP. See Atrial natriuretic peptide (ANP) ANS. See Autonomic nervous system (ANS) Antacids as buffers, 68 Antagonist: A muscle that opposes the movement of an agonist, (Ch 7), 246 Antagonistic effects of hormones, 399 Antebrachial region, 44 Antecubital region, 44 Anterior: On or near the front or ventral surface of the body, (Ch 1), 43, 44, 46, 48

Anterior cavity of the eye, 346, 347, 350, 351 Anterior cerebral artery, 485 Anterior chamber of the eye, 346, 347, 350, 351 Anterior communicating artery, 485 Anterior cruciate ligament (ACL), 212-213 Anterior gray commissures, 295, 296 Anterior horns of spinal cord gray matter, 296 Anterior interventricular (descending) artery, 444 Anterior interventricular sulcus, 436 Anterior lobe of the pituitary gland endocrine organ, 377 hormones of, 382-385, 386, 387 hypophyseal portal system, 381-382 hypothalamic control of, 381, 382 Anterior margin of the tibia, 202 Anterior median fissure of the spinal cord, 294 Anterior (ventral) roots of the spinal cord, 294 Anterior semicircular ducts, 362 Anterior tibial artery, 482, 486 Anterior tibial vein, 483, 486, 488 Anterior white columns, 295, 296 Anterior white commissures, 295, 296 Anti-inflammatory effects of glucocorticoids, 391, 392 Antibiotic: Chemical agent that selectively kills pathogenic microorganisms, (Chs 9, 14, 18, 19), 366, 523, 654, 680 Antibody (AN-tī-bod-ē): A globular protein produced by plasma cells that will bind to specific antigens and promote their destruction or removal from the body, (Chs 2, 4, 11, 14). See also B cells blood, 393, 410 classes of, 521, 522 connective tissue, 132 connective tissue proper, 133 function of, 521–522 plasma cells secreting, 506 proteins, 73 structure of, 521 Antibody-mediated immunity: Immunity resulting from the presence of circulating antibodies produced by plasma cells; also called humoral immunity, (Ch 14), 506, 507, 515, 525 Anticodon: Triplet of nitrogenous bases on a tRNA molecule that interacts with an appropriate codon on a strand of mRNA, (Ch 3), 109 Antidiuretic hormone (ADH) (an-tī-dī-ū-RET-ik): Hormone synthesized in the hypothalamus and secreted at the posterior lobe of the pituitary gland; causes water retention at the kidneys and an elevation of blood pressure, (Chs 8, 10, 13, 18) cardiovascular regulation, 475, 476 endocrine hormone, 377, 397 hypothalamus, 306, 380, 381 peptide hormone, 376 posterior lobe of the pituitary gland, 385-387 urine formation, 646, 647, 650, 651 Antigen: A substance capable of inducing an immune response that may include the production of antibodies, (Chs 11, 14), 420-421, 422, 423, 427, 506 Antigen-antibody complex: The combination of an antigen and a specific antibody, (Chs 11, 14), 420-421, 506, 521, 526 Antigen binding sites, 521 Antigen presentation, 517-518 Antigen-presenting cell (APC): A cell that processes antigens and displays them, bound to class II MHC proteins; essential to the initiation of a normal immune response, (Ch 14), 518, 525 Antigen recognition, 518 Antigenic determinant site: A portion of an antigen that can interact with an antibody molecule, (Ch 14), 521 Antihistamines, 527 Antioxidant activity, 393 Antipyretic drugs, 629 Antiviral proteins, 513 Antrum (AN-trum): A chamber or pocket, (Ch 19), 87, 686,687 Anus: External opening of the anorectal canal, (Chs 1, 16, 19), 39, 593, 594, 684, 690 Anvil. See Incus

Aorta: Large, elastic artery that carries blood away from the left ventricle and into the systemic circuit, (Chs 12, 13)

abdominal, 486, 487 ascending, 438, 440, 481, 482, 484 cardiac skeleton, 442 descending, 438, 481, 482, 484 elastic artery, 461 systemic pressures, 467 terminal segment of, 486 thoracic, 485, 486 Aortic arch, 440, 480, 481, 482, 484, 486 Aortic baroreceptors, 340, 559 Aortic bodies, 341, 474 Aortic reflex: Baroreceptor reflex triggered by increased aortic pressures; leads to a reduction in cardiac output and a fall in systemic pressure, (Ch 13), 473 Aortic semilunar valve, 440, 441, 442, 443 Aortic sinus, 442, 443 Apertures in the fourth ventricle, 299 Apex of the heart, 436, 437, 438 Apex of the lungs, 546, 547 Apex of the sacrum, 193 Apgar rating, 735 Aphasia: Inability to speak, (Ch 8), 304 Apical surface of epithelial cells, 124 Apnea, 562 Apocrine secretion (AP-ō-krin): Method of secretion in which the glandular cell sheds portions of its cytoplasm, (Ch 4), 128, 130, 131 Apocrine sweat glands, 162-163 Aponeurosis/aponeuroses (ap-ō-nū-RŌ-sēz): A broad tendinous sheet that may serve as the origin or insertion of a skeletal muscle, (Ch 7), 223-224, 248, 249 Apoptosis cytotoxic T cells, 518 defined, 112 Appendicitis, 506, 592 Appendicular muscles arm, 244, 245, 257, 258, 259 foot and toes, 263, 265, 266 forearm and wrist, 244, 245, 257, 260, 261 functions, 246 hand and fingers, 259, 260, 261 leg, 244, 245, 259, 262, 264 muscular system component, 37 pectoral girdle, 244, 245, 255-257 thigh, 244, 245, 259, 262, 263 Appendicular skeleton lower limb, 201-203, 212-214 pectoral girdle, 196-198 pelvic girdle, 200-201 skeletal division, 185, 196 skeletal system component, 37 upper limb, 198–200, 211–212 **Appendix:** A blind tube connected to the cecum of the large intestine, (Chs 1, 14, 16), 45, 503, 506, 592, 593 Appositional growth: Enlargement of a bone by the addition of cartilage or bony matrix at its surface, (Ch 6), 178, 179 Aqueous humor: Fluid similar to perilymph or CSF that fills the anterior chamber of the eye, (Chs 9, 18), 346, 348, 350-351, 657, 659 Aqueous solutions, 65, 66 Arachidonic acid, 376 Arachnoid (a-RAK-noyd): The middle meninges that encloses CSF and protects the central nervous system, (Ch 8), 291, 292 Arachnoid granulations, 299 Arcuate (AR-kū-āt): Curving, (Ch 18), 638, 639 Arcuate arteries, 638, 639 Arcuate veins, 638, 639 Areola (a-RĒ-ō-luh): Pigmented area that surrounds the nipple of a breast, (Ch 19), 690, 691 Areolar: Containing minute spaces, as in areolar tissue, (Ch 4), 134, 135 Areolar tissue: Loose connective tissue with an open framework, (Ch 4), 134, 135 Arginine, 620 Armpit, 44 Arms. See also Upper limbs anatomical terms, 44 appendicular skeleton, 198 muscles of, 244-245, 257, 258, 259

Arousal, sexual, 695

cardiac contractions, (Chs 12, 17), 449, 620 Arterial anastomosis, 465 Arterial pressure, 466, 467. See also Blood pressure Arterial puncture, 411 Arteries: Blood vessels that carry blood away from the heart and toward a peripheral capillary, (Chs 1, 4, 8, 12, 13). See also Pulmonary Circuit; Systemic circuit; specific arteries arteriosclerosis, 324, 463 cardiovascular system component, 38 heart's role in cardiovascular system, 435 Marfan syndrome, 134 size, structure, and functions, 460, 461-463 Arteriole (ar-TER-e-ol): A small arterial branch that delivers blood to a capillary network, (Ch 13), 460, 462, 463 Arteriosclerosis, 324, 463 Arteriovenous anastomosis, 465 Arthritis (ar-THRĪ-tis): Inflammation of a joint, (Ch 6), 2.06 Arthroscopy, 214 Articular: Pertaining to a joint, (Ch 6), 174, 183, 205 Articular capsule. See Joint capsule Articular cartilage: Cartilage pad that covers the surface of a bone inside a joint cavity, (Ch 6), 174, 175, 177, 205,206 Articular facets of the vertebrae, 192, 194, 210 Articular processes of the vertebrae, 192, 193, 194, 209, 211 Articulations. See also Joint defined, 204 intervertebral, 209, 211 lower limb, 212-214 synovial membranes, 141 upper limb, 211-212 Artificially induced active immunity, 516 Artificially induced passive immunity, 516 Arytenoid cartilage, 540, 541 Ascending aorta, 438, 440, 480, 481, 482, 484 Ascending colon, 593, 594 Ascending limb of the nephron loop, 640, 642, 649 Ascending tract: A tract carrying information from the spinal cord to the brain, (Ch 8), 296 Ascorbic acid (vitamin C), 178, 599, 623, 625 Asphyxia, 562 Aspiration, defined, 542 Assisted reproductive technologies, 694 Association areas: Cortical areas of the cerebrum responsible for integration of sensory inputs and/or motor commands, (Ch 8), 300, 301 Association neurons (interneurons), 277 Asthma (AZ-muh): Reversible constriction of smooth muscles around respiratory passageways, frequently caused by an allergic response, (Chs 5, 15), 157, 544, 562 Astigmatism, 353 Astrocyte (AS-trō-sīt): One of the glial cells in the CNS; responsible for the blood brain barrier, (Ch 8), 277-278 Ataxia, 308 Atelectasis, 547 Atherosclerosis (ath-er-ō-skle-RŌ-sis): Formation of fatty plaques in the walls of arteries, leading to circulatory impairment, (Chs 13, 17, 19), 463, 494, 617, 696 Athletes, 399, 420, 477, 652 Atlas (C1), 193, 194 Atmospheric air versus alveolar air, 553 Atom: The smallest, stable unit of matter, (Chs 1, 2), 34, 35, 56-58, 62, 80 Atomic number: The number of protons in an atom, (Ch 2), 56 Atomic weight: The average mass of an element's atoms, (Ch 2), 57 ATP. See Adenosine triphosphate (ATP) ATP synthase, 613, 614 Atresia, 683, 685

Atria: Thin-walled chambers of the heart that receive venous blood from the pulmonary or systemic

circuit, (Ch 12), 435

Arrector pili (a-REK-tor PI-lē): Smooth muscles whose

Arrhythmias (a-RITH-mē-az): Abnormal patterns of

161, 162, 325

contractions cause erection of hairs, (Chs 5, 8), 160,

GLOSSARY / INDEX

Atrial baroreceptors, 473-474 Atrial diastole, 450-451 Atrial natriuretic peptide (ANP) (nā-trē-ū-RET-ik): Hormone released by specialized atrial cardiocytes when they are stretched by an abnormally large venous return; promotes fluid loss and reductions in blood pressure and venous return, (Chs 10, 13, 18), 377, 397, 476, 477, 651, 652 Atrial reflex: Reflexive increase in heart rate following an increase in venous return; due to mechanical and neural factors; also called Bainbridge reflex, (Chs 12, 13), 452, 473-474 Atrial systole, 450-451 Atrioventricular (AV) bundle (bundle of His), 446, 447, 448 Atrioventricular (AV) node (Ā-trē-ō-ven-TRIKū-lar): Specialized cardiocytes that relay the contractile stimulus to the AV bundle, the bundle branches, the Purkinje fibers, and the ventricular myocardium; located at the boundary between the atria and ventricles, (Chs 12, 13), 446-448, 473 Atrioventricular (AV) valve: One of the valves that prevent backflow into the atria during ventricular systole, (Ch 12), 440, 441, 442, 443 Atrophy (AT-rō-fē): Wasting away of tissues from lack of use, ischemia, or nutritional abnormalities, (Ch 7), 236 Auditory: Pertaining to the sense of hearing. Auditory association area, 300 Auditory canal. See External acoustic meatus Auditory cortex of the temporal lobe, 301, 302 Auditory ossicles: The bones of the middle ear: malleus, incus, and stapes, (Chs 6, 9) axial skeleton, 185, 186, 187 hearing, 358-359, 360 Auditory pathways, 366-367 Auditory sensitivity, 367-368 Auditory tube. See Pharyngotympanic tube Auricle (ear): The expanded, projecting portion of the external ear that surrounds the external acoustic meatus, (Chs 4, 9), 137, 358, 359 Auricle of the heart, 436 Auscultation, defined, 49 Autoantibodies, 526 Autograft, 528 Autoimmune disorders, 526 Autoimmunity: Immune system sensitivity to normal cells and tissues, resulting in the production of autoantibodies, (Ch 14), 526 Autolysis (aw-TOL-i-sis): Destruction of a cell due to the rupture of lysosomal membranes in its cytoplasm, (Ch 3), 102–103 Automatic bladder, 655 Automaticity: Spontaneous depolarization to threshold, a characteristic of cardiac pacemaker cells, (Chs 7, 12), 242, 243, 446 Autonomic ganglion: A collection of visceral motor neurons outside the CNS. Autonomic nervous system (ANS): Centers, nuclei, tracts, ganglia, and nerves involved in the unconscious regulation of visceral functions; includes components of the CNS and PNS, (Chs 8, 9, 42, 19). See also Parasympathetic division; Sympathetic division baroreceptors, 340 divisions of, 274, 319-320 efferent division of the PNS, 274-275 heart innervation, 453-454 motor pathways, 318-319 parasympathetic division. See Parasympathetic division sexual function. 695 somatic nervous system, comparison to, 319-320 sympathetic division. See Sympathetic division Autoregulation: Changes in activity that maintain homeostasis in direct response to changes in the local environment; does not require neural or endocrine control, (Chs 13, 18), 464, 471-472, 650 Autorhythmicity, 446. See also Automaticity Autosomal (aw-to-SŌ-mal): Chromosomes other than the X or Y chromosomes, (Ch 20), 729, 731 Autosomal dominant disorders, 731 Autosomal recessive disorders, 731 AV node. See Atrioventricular (AV) node AV valve. See Atrioventricular (AV) valve

Avascular (ā-VAS-cū-lar): Without blood vessels, (Ch 4), 122 Average mass of atoms, 57 Axial muscles anterior view, 244 head and neck, 248-250 hernias, 250 muscular system component, 37 overview, 243 pelvic floor, 253-255 posterior view, 245 spine, 250–251 trunk, 252-253 Axial skeleton functions, 185 skeletal division, 183, 185, 186 skeletal system component, 37 skull and associated bones, 186-191 thoracic cage, 185, 186, 194-196 vertebral column, 185, 186, 191-194, 209, 211 Axilla: The armpit, (Ch 1), 44 Axillary artery, 481, 482, 484 Axillary nerve, 312 Axillary region, 44 Axillary vein, 480, 483, 487, 489 Axis (C2), 193, 194 Axon: Elongated extension of a neuron that carries information to other cells, (Chs 4, 7, 8) described, 143 neuron structure, 276, 279 skeletal muscle, in, 224 Axon hillock: In a multipolar neuron, the thickened portion of the neural cell body where an action potential begins, (Ch 8), 276, 284, 286 Axon terminals neuron structure, 276 skeletal muscle fibers, 227, 228 tissue level of organization, 143 Azygos vein, 487, 489

B

B cells: Lymphocytes capable of differentiating into the plasma cells, which produce antibodies, (Ch 14) adaptive (specific) immunity, 519–525 aging, effect of, 527 antibody function, 521-522 antibody structure, 521 lymphocyte, type of, 506, 507 sensitization and activation, 520 B vitamins, 599. See also specific vitamins Babinski reflex, 316 Baby teeth, 575, 576 Back anatomical terms, 44 muscles of, 241 Bacteria: Single-celled microorganisms, some pathogenic, that are common in the environment, (Chs 6, 7, 9, 14, 15, 16, 17, 18, 19) digestive system, 570, 574, 575, 581, 588, 592, 594, 595, 599 general and special senses, 345, 366 lymphatic system and immunity, 502, 503, 504, 506, 508, 509, 511, 512, 513, 514, 518, 519, 521, 522, 527, 528 muscular system, 230, 231 nutrition, 624 reproductive system, 680, 688, 690, 695 respiratory system, 539, 546, 547 skeletal system, 190, 206, 214 urinary system, 654 Bainbridge reflex. See Atrial reflex Balanced diet, defined, 622 Ball-and-socket joints, 208, 210 Balloon angioplasty, 455 Barium-contrast x-ray, 50 Baroreceptor reflex: A reflexive change in cardiac activity in response to changes in blood pressure, (Ch 13), 473-474 Baroreceptors (bar-ō-rē-SEP-torz): Receptors responsible for baroreception, (Chs 9, 13, 15), 338, 340, 473-474, 558-559

Basal body temperature, 693, 694, 699

Basal cell carcinoma, 158 Basal cells. See also Stem cells gustatory, 342, 344 integumentary, 129, 130, 154, 155, 160, 162, 164 olfactory, 341, 342 Basal layer of the endometrium, 688 Basal metabolic rate (BMR): The resting metabolic rate of a normal fasting subject under homeostatic conditions, (Ch 17), 627 Basal nuclei: Nuclei of the cerebrum that are important in the subconscious control of skeletal muscle activity, (Ch 8), 300, 304-305 Base: A compound whose dissociation releases a hydroxide ion (OH-) or removes a hydrogen ion from the solution, (Chs 2, 18), 67, 80, 656, 660-661. See also рН Base of the heart, 48, 436, 438 Base of the lungs, 546, 547 Base of the sacrum, 193 Basement membrane: A layer of filaments and fibers that attach an epithelium to the underlying connective tissue, (Chs 4, 5), 122, 124-125, 153 Basilar artery, 484, 485 Basilar membrane: Membrane that supports the organ of Corti and separates the cochlear duct from the scala tympani in the internal ear, (Ch 9), 364, 365, 366 Basilic vein, 483, 487, 489 **Basophils** (BĀ-sō-filz): Circulating granulocytes (WBCs) similar in size and function to tissue mast cells, (Chs 11, 14), 413, 419, 424, 425, 426, 524 Behavior, and hormones, 400 Bends, the (decompression sickness), 553 Benign tumors, 114 Beta cells: Cells of the pancreatic islets that secrete insulin in response to elevated blood sugar concentrations, (Ch 10), 393, 395 Beta-oxidation: Fatty acid catabolism that produces molecules of acetyl-CoA, (Ch 17), 617 Beta sheet, 74, 75 **Bicarbonate ions:** HCO_3^{2-} ; anion components of the carbonic acid-bicarbonate buffer system, (Chs 2, 18), 59, 644, 658, 660-661 Bicarbonate reserve, 662 Biceps brachii muscle, 199, 237, 244, 246, 256, 257, 258, 260, 261 Biceps femoris muscle, 245, 260, 261, 262, 263, 264 Bicuspid (bī-KUS-pid): A premolar tooth, (Ch 16), 575, 576 Bicuspid valve: See mitral valve Bilateral orchiectomy, 676 **Bile:** Exocrine secretion of the liver that is stored in the gallbladder and ejected in the duodenum, (Ch 16) described, 586, 589 modification of, by the gallbladder, 592 production and role of, 590-591 storage of, in the gallbladder, 592 Bile canaliculi, 589 **Bile duct:** Duct formed by the union of the cystic duct from the gallbladder and the bile ducts from the liver; terminates at the duodenal ampulla, where it meets the pancreatic duct, (Ch 16), 587, 589, 591-592 Bile salts: Steroid derivatives in the bile, responsible for the emulsification of ingested lipids, (Ch 16), 586, 591, 594 Bilirubin (bil-ē-ROO-bin): A pigment that is the by-product of hemoglobin catabolism, (Ch 11), 416, 417, 590–591 Biliverdin, 416, 417 Bimalleolar fracture, 183 Biology, defined, 32 Biopsy (BĪ-op-sē): The removal and examination of tissue from the body for the diagnosis of disease, (Ch 5), 167 Biotin (vitamin B7), 594, 625 Biphosphate ions, 59 Bipolar cells of the retina, 349, 350 Bipolar neurons, 277 Birth circulatory changes, 492-493 respiratory changes, 61–562 Birth control strategies, 698-699

Bitter taste, 343, 344 Bladder: A muscular sac that distends as fluid is stored, and whose contraction ejects the fluid at an appropriate time; used alone, the term usually refers to the urinary bladder. See Gallbladder; Urinary bladder Blastocoele, 709, 711 Blastocyst: (BLAS-tō-sist): An early stage in the developing embryo, consisting of an outer trophoblast and an inner cell mass, (Ch 20), 709-711 Blastomeres, 709, 710 Bleaching of visual pigments, 356 Blind spot, visual, 350 Blindness, 351, 358, 368 Blood. See also Cardiovascular system ABO blood types, 420-423 aging, effects of, 493-494 average amount in adults, 412 collection and analysis, 411 composition of, 411, 412, 413 fluid connective tissue, 132, 136 functions of, 410-411 hemostasis, 427-430 pH of, 66, 67 plasma, 411-414 platelets, 412-413, 419, 426, 427, 428 red blood cells, 414-423, 426 temperature of, 411 white blood cells, 412-413, 419, 423-427 Blood air barrier: Gas exchange surface of the lungs; made up of an alveolar cell layer, a capillary endothelial layer, and the fused basement membrane between them, (Ch 15), 544-546 Blood brain barrier: Isolation of the CNS from the general circulation; primarily the result of astrocyte regulation of capillary permeabilities, (Ch 8), 277-278 **Blood clot:** A network of fibrin fibers and trapped blood cells, (Ch 11) abnormal hemostasis, 429 clot retraction and removal, 430 clotting process, 428-430 Blood doping, 420 Blood pressure: A force exerted against the vascular walls by the blood, as the result of the push exerted by cardiac contraction and the elasticity of the vessel walls; usually measured along one of the muscular arteries, with systolic pressure measured during ventricular systole, and diastolic pressure during ventricular diastole, (Chs 12, 18) arteries, in, 466, 467 measuring, 470 short-term elevation in, 478-479 urinary system regulation, 636 Blood smear, 411 Blood types, 420-423 Blood vessels and circulation, 459-500. See also Thermoregulation; specific blood vessels aging, effect of, 493-494 arterial (blood) pressure, 467, 470 arteries. See Arteries autonomic nervous system, 325 blood flow, factors affecting, 466-467 blood vessel size, structure, and function, 460-465 capillaries. See Capillary cardiovascular regulation, 471-477 coronary, 444 dermal, and skin color, 157 exercise, 477-478 fetal and maternal circulation, 492-493 functional patterns of, 479-480 hemorrhage, 478 kidneys, 638, 639 physiological stress, adaptation to, 477-479 pulmonary circuit, 479-481 skeletal muscle, 224 systemic circuit, 479, 481-492 veins. See Veins venous pressure, 466, 469 Blood volume capillary dynamics, 469 hemorrhage, 478 maternal, during pregnancy, 718-719 urinary system regulation, 636

Blood volume reflexes, 452-453 Blue cones, 353 BMR. See Basal metabolic rate (BMR) Body cavities, 45, 47 Body fluid compartments, 656-658 Body fluids, pH of, 66-67, 73, 660-661 Body (shaft) of the penis, 680, 681 Body of the scapula, 197 Body of the sternum, 195, 196 Body of the stomach, 577, 578 Body of the uterus, 687, 688 Body stalk, 713, 714-715 Body temperature basal body temperature, 693, 694, 699 blood, of, 411 cardiac output, 452 denaturation of proteins, 75 "hot flashes," 696 integumentary system and, 152, 163 neonates, 727 ovulation, 693, 694 respiratory function, 555 Body weight, 65, 70 Bolus: A compact mass; usually refers to compacted ingested material on its way to the stomach, (Ch 16), 572, 577 Bone. See also Skeletal system calcium reserve, as, 179, 182 cartilage, compared to, 139 cells in, 175-176 classification of, 173-176 defined, 173 fractures, repair of, 180-181 growth, and body proportions, 178 macroscopic features, 174 microscopic features, 174-176 remodeling, 179, 182 supporting connective tissue, 132, 137, 139 Bone markings, 182–183 Bone marrow marrow cavity in long bones, 174 red bone marrow, 173, 417, 418 transplantation, 526, 528 yellow bone marrow, 173, 418 Bony labyrinth of the internal ear, 359-360 Bony palate, 189, 190 Botulism, 230 Bowel: The intestinal tract, (Ch 16), 592 Bowman's (glomerular) capsule, 638, 641 Brachial: Pertaining to the arm, (Ch 1), 44 Brachial artery, 470, 480, 481, 482, 484 Brachial plexus: Network formed by branches of spinal nerves C₅-T₁ en route to innervating the upper limb, (Ch 8), 312, 313 Brachial region, 43, 44 Brachial vein, 480, 483, 487, 489 Brachialis muscle, 244, 247, 257, 260, 261 Brachiocephalic trunk, 438, 481, 482, 484, 485 Brachiocephalic (innominate) vein, 483, 487, 488, 489 Brachioradialis muscle, 244, 245, 257, 260, 261 Brachium: The arm (Chs 1, 6), 44, 198 Bradycardia, 448 Brain aging, effect of, 324-325 arteries of, 484-485 average weight and size in adults, 296 cerebellum, 297, 298, 307, 308 cerebrum, 300–305 CNS, division of, 274 diencephalon, 307 ependymal cells, 278, 279, 298 major regions, 296-298 medulla oblongata, 307, 308 meninges, 291 midbrain, 307 nervous system component, 37 pons, 307, 308 ventricles, 279, 298 Brain waves, 303 Brainstem: The midbrain, pons, and medulla oblongata (excludes the cerebrum, diencephalon, and cerebellum), (Ch 8), 296, 297 Breast, 44, 690–691, 727. See also Mammary glands

Breast cancer, 691, 733 Breathing, modes of, 551 Breech birth, 735 Broad ligament, 683, 684 Broca's area: The speech center of the brain, normally located on the neural cortex of the left cerebral hemisphere, (Ch 8), 301, 302 Bronchial arteries, 486, 487 Bronchial tree: The trachea, bronchi, and bronchioles, (Ch 15), 543, 544 Bronchioles, 536, 537, 543, 544 Bronchitis (brong-KĪ-tis): Inflammation of the bronchial passageways, (Ch 15), 562 Bronchoconstriction, 544 Bronchodilation: Dilation of the bronchial passages; can be caused by sympathetic stimulation, (Ch 15), 544 Bronchopulmonary carcinoma, 561 Bronchopulmonary segment, 543, 544 Bronchus/bronchi: One of the branches of the bronchial tree between the trachea and bronchioles, (Chs 1, 15), 38, 536, 537, 541-544 Brush border, in small intestine, 583, 584 Buccal (BUK-ul): Pertaining to the cheeks, (Ch 1), 44 Buccal cavity, 573. See also Oral cavity Buccal phase of swallowing, 577 Buccinator muscle, 247, 248, 249 Buffer: A compound that stabilizes the pH by either removing or releasing hydrogen ions, (Chs 2, 18) defined, 661 pH of body fluids, 68, 73, 661-662 Buffer systems: Interacting compounds that prevent increases or decreases in the pH of body fluids; includes the carbonic acid-bicarbonate buffer system, the phosphate buffer system, and protein buffer systems, (Ch 18), 661-662 Bulb of vestibule, 689, 690 Bulbo-urethral glands (bul-bō-ū-RĒ-thral): Mucous glands at the base of the penis that secrete into the penile urethra; also called Cowper's glands, (Ch 19), 674, 679, 680 Bulbospongiosus muscle, 254, 255, 689, 695 Bulimia, 585 Bundle branches: Specialized conducting cells in the ventricles that carry the contractile stimulus from the AV bundle to the Purkinje fibers, (Ch 12), 446, 447, 448 Bundle of His (hiss): Specialized conducting cells in the interventricular septum that carry the contracting stimulus from the AV node to the bundle branches and thence to the Purkinje fibers; also called the AV bundle, (Ch 12), 446, 447, 448 Burning pain sensation, 338 Burns, 165–167 Bursa: A small sac filled with synovial fluid that cushions adjacent structures and reduces friction, (Ch 6), 205 Bursitis, 211, 257 Buttocks, 44 C C cells of the thyroid gland (parafollicular cells), 388-389 Calcaneal tendon: Large tendon that inserts on the calcaneus; tension on this tendon produces plantar flexion of the foot; also called Achilles tendon, (Chs 6, 7), 203, 245, 263, 264, 265, 266 Calcaneus (kal-KĀ-nē-us): The heelbone, the largest of the tarsal bones, (Ch 1), 44, 203, 245 Calcification: The deposition of calcium salts within a tissue, (Chs 6, 13), 177, 463 Calcitonin (CT) (kal-si-TŌ-nin): Hormone secreted by C cells of the thyroid when calcium ion concentrations are abnormally high; restores homeostasis by increasing the rate of bone deposition (mostly in childhood) and the rate of calcium loss by the kidneys, (Chs 6, 10), 182, 377, 380, 388-389, 390 Calcitriol, 157, 178, 182, 377, 390, 397 Calcium bone, in, 173 bone as reservoir for, 179, 182 dietary guidelines, 624 significance in human body, 57

skeletal system as storage for, 214 vitamin D33, 178 Calcium ions in body fluids, 59 calcitonin, 388-389 calcitriol, 397 cardiac output, 452 clotting process, 428-430 contractile cells of the heart, 445-446 ECE 658 homeostasis, 182, 389 muscle contraction, 226, 232, 233, 234 parathyroid hormone, 400 second messenger, as, 380 terminal cisternae of the sarcoplasmic reticulum, 226 Calculi, urinary, 653 Calorie (cal) (KAL-o-rē): The amount of heat required to raise the temperature of one gram of water 1°C, (Chs 10, 17), 387, 626 Calorigenic effect of thyroid hormones, 387 Calorimeter, 626 Calyx/calyces (KĀL-i-sēz): A cup-shaped division of the renal pelvis, (Ch 18), 637, 638, 640 cAMP (cyclic-AMP), 378-379 Canal (bone marking), 183 Canal of Schlemm (scleral venous sinus), 351 Canaliculi (kan-a-LIK-ū-lī): Microscopic passageways between cells; bile canaliculi carry bile to bile ducts in the liver; in bone, canaliculi permit the diffusion of nutrient and wastes to and from osteocytes, (Chs 4, 6), 139, 174, 176 Cancer: Illness characterized by mutations leading to the uncontrolled growth and replication of the affected cells, (Chs 3, 4, 5, 14, 19) abnormal cell growth and division, 114-115 aging and, 145, 600 AIDS and, 523 breast, 691, 733 colorectal, 594 gastric, 581 lung, 561 ovarian, 699, 733 prostate, 680, 699, 733 skin, 157-158, 733 testicular, 676 Canine teeth (cuspids), 575, 576 Capacitation, 679 Capillary: Small blood vessels, interposed between arterioles and venules, whose thin walls permit the diffusion of gases, nutrients, and wastes between the plasma and interstitial fluids, (Chs 1, 4, 5, 11, 12, 13, 14, 18) allergic reactions, 527 angiotensin II, 650 blood collection from, 411 capillary bed, 464 capillary exchange, 468-469 capillary hydrostatic pressure, 469 capillary pressure, 466, 468-469 cardiovascular system component, 38 dynamics and blood volume, 469 heart's role in cardiovascular system, 435 immune system, 512 in integumentary system, 159 lymphatic, 504 structure and function, 460, 462, 463–465 tissues of, 137 Capitate bone, 199, 200 Capitulum (ka-PIT-ū-lum): A small, elevated articular process; used to refer to the rounded distal surface of the humerus that articulates with the radial head, (Ch 6), 198 Capsular epithelium, 641 Capsular space of the nephron, 641, 642 Capsule dense connective tissue, 136 joints, 175, 205, 206 Carbaminohemoglobin (kar-bām-i-nō-hē-mō-GLŌbin): Hemoglobin bound to carbon dioxide molecules, (Ch 15), 556 Carbohydrases, 587–588, 597, 598 Carbohydrate (kar-bō-HĪ-drāt): Organic compound containing carbon, hydrogen, and oxygen in a 1:2:1 ratio, (Chs 2, 17)

alternate catabolic pathways, 616 citric acid cycle, 612, 621 digestion and absorption, 596-598 electron transport chain, 612-614 energy yield of glycolysis and cellular respiration, 614 gluconeogenesis, 614-616, 621 glycolysis, 610–612, 614, 621 metabolism of, 610–616, 621 mitochondria, energy production with, 612–614, 621 types of, 68–70, 79, 80 Carbohydrate depletion/loading, 615 Carbohydrate loading, 615 Carbon, significance of, in human body, 57 Carbon dioxide: CO₂, a compound produced by the decarboxylation reactions of aerobic metabolism, (Chs 2, 3, 13, 15, 18) chemoreceptor reflexes, 559-561 chemoreceptors, 474, 475 double covalent bonds, 59, 60 gas exchange in the lungs, 552, 553, 554 hemoglobin, binding to, 415 inorganic compound, 64, 80 pH of body fluids, 660, 661 plasma membrane permeability, 92 transport in the blood, 555-557 Carbon monoxide (CO), 290 Carbon monoxide poisoning, 555 Carbonic acid acid in the body, 660, 661 carbonic acid-bicarbonate buffer system, 662 formation of, 556 Carbonic acid-bicarbonate buffer system, 662 Carbonic anhydrase: An enzyme that catalyzes the reaction $H_2O + CO_2 \rightarrow H_2CO_3$; important in carbon dioxide transport, gastric acid secretion, and renal pH regulation, (Ch 18), 660 **Carboxyl group** (kar-BOKS-il): — COOH, an acid group found in fatty acids, amino acids, etc., (Ch 2), 70, 73 Carboxypeptidase, 588, 597, 598, 599 Carcinogen, defined, 115 Cardia (KAR-dē-uh): The area of the stomach surrounding its connection with the esophagus, (Ch 16), 577, 578 Cardiac arrhythmias, 449, 620 Cardiac centers of the medulla oblongata, 308, 454, 473 Cardiac cycle: One complete heartbeat, including atrial and ventricular systole and diastole, (Ch 12), 450-451 Cardiac muscle blood supply to, 444 contractile cells, 437-438, 439, 445-446 described, 141, 142, 143 papillary muscles, 440, 442, 443 skeletal and smooth muscle, comparison with, 243 structural and functional properties, 241-242 Cardiac notch, 546, 547 Cardiac output: The amount of blood ejected by the left ventricle each minute; normally about 35 liters, (Ch 12) calculation of, 452 exercise, 477-478 factors affecting, 452-454 Cardiac pacemaker (sinoatrial node), 446–447, 473 Cardiac reserve: The potential percentage increase in cardiac output above resting levels. Cardiac skeleton (fibrous skeleton), 440, 442, 443 Cardiac tamponade, 455 Cardiac veins, 438, 440, 444 Cardioacceleratory center, 454, 473 Cardiodynamics, 452-454 Cardiogenic shock, 478 Cardioinhibitory center, 454, 473 Cardiology, 455 Cardiopulmonary resuscitation (CPR): Method of artificially maintaining respiratory and circulatory function, (Chs 6, 15), 196, 562 Cardiovascular center: Poorly localized area in the reticular formation of the medulla of the brain; includes cardioacceleratory, cardioinhibitory, and vasomotor centers, (Ch 8, 13), 308, 473-475 Cardiovascular system autonomic nervous system, effects of, 321, 323, 325 baroreceptors, 340

blood, 409-433 blood vessels and circulation, 459-500 chemoreceptors, 340-341 digestive system, functional relationship with, 601 endocrine system, functional relationship with, 375 exercise, effect of, 267 germ layer contributions to, 713 heart, 434-458 lymphatic system, functional relationship with, 529 organs, components, and primary functions, 38 other systems, functional relationships with, 495, 496 prenatal and early postnatal development, overview of, 721 reproductive system, functional relationship with, 700 respiratory system, functional relationship with, 563 urinary system, functional relationship with, 666 Carditis, 442 Carotene, 156 Carotid artery: The principal artery of the neck, servicing cervical and cranial structures; one branch, the internal carotid, represents a major blood supply for the brain, (Ch 13), 481, 484-485 Carotid baroreceptors, 559 Carotid body: A group of receptors adjacent to the carotid sinus that are sensitive to changes in the carbon dioxide levels, pH, and oxygen concentrations of arterial blood, (Chs 9, 13, 15), 341, 474 Carotid sinus: An expanded segment at the base of the internal carotid artery whose walls contain baroreceptors sensitive to changes in blood pressure, (Chs 9, 13), 340, 473, 474, 485 Carpal bones, 174, 199-200 Carpal region, 44 Carpal tunnel syndrome, 259 Carpus/carpal: The wrist, (Ch 1), 44. See also Wrist Carrier-mediated transport, 92, 95-97, 99 Carrier proteins, 91, 96–97 **Cartilage:** A connective tissue with a gelatinous matrix containing an abundance of fibers, (Ch 4) bone, compared to, 139 injuries, 137 regeneration of, 145 supporting connective tissue, 132, 137, 138 Cartilaginous joints, 204 Cascade reaction in clotting process, 428 Catabolic pathways, alternate, 616 Catabolism (kah-TAB-ō-lizm): The breakdown of complex organic molecules into simpler components, accompanied by the release of energy, (Chs 2, 17) alternate pathways, 616 amino acids, 618-619, 621 decomposition reaction, 63 defined, 607 lipids, 617, 621 process of, 609 RNA, 621-622 Catalyst (KAT-uh-list): A substance that accelerates a specific chemical reaction but is not altered by the reaction, (Ch 2), 64 Cataracts, 351, 358, 368 Cathartics, 595 Cation (KAT-i-on): An ion that bears a positive charge, (Ch 2), 58-59, 65 Cauda/caudally: Closest to or toward the tail (coccyx), (Ch 1), 46 Cauda equina, 294 Caudate lobe of the liver, 588 Caudate nucleus, 304 Cavernous hemangioma (strawberry nevus), 167 CCK. See Cholecystokinin (CCK) CD (cluster of differentiation) markers, 518 CD4 T cells, 518, 523, 525 CD8 T cells, 518, 525 Cecum (SE-kum): An expanded pouch at the start of the large intestine, (Ch 16), 592, 593 Celiac trunk, 482, 485, 486 Cell: The smallest living unit in the human body, (Chs 1, 2, 3), 85-117 abnormal cell growth and division, 114-115 anatomy, overview of, 87, 88-89 carrier-mediated and vesicular transport across membranes, 92, 95-99 cell theory, basic concepts of, 86

cellular level of organization, 34, 35 chemical level of organization, 80 cvtology, 33 differentiation, 32, 115. See also Cellular differentiation diffusion across membranes, 99 diffusion and filtration across membranes, 91–95 diversity of, 87 DNA and RNA, 108–110 in growth of organisms, 32 increase in numbers, 111 life cycle of, 111-114 nucleus, 89, 106-108 organelles within the cytoplasm, 88-89, 99-106 plasma membrane, 87, 88, 90-91 study of, 86-87 Cell adhesion molecules, 123 Cell body of the neuron, 143 Cell division, 111 Cell junctions, 123-124 Cell-mediated immunity: resistance to disease through the activities of sensitized T cells that destroy antigen-bearing cells by direct contact or through the release of lymphotoxins; also called *cellular immunity*, (Ch 14), 505, 507, 515, 517, 518–519, 525 Cell membrane. See Plasma membrane Cell physiology, 34 Cell theory, basic concepts of, 86 Cellular differentiation: The gradual appearance of characteristic cellular specializations during development as the result of gene activation or repression, (Chs 1, 3, 20), 32, 115, 706 Cellular level of organization, 34, 35 Cellular metabolism, 608-610 Cellular respiration, 103, 610, 612-614. See also Aerobic metabolism Cellulose, 69 Cementum, 575 Center of CNS neuron cell bodies, 280 Central canal in long bones, 175, 176 Central canal of the spinal cord, 279, 294, 295 Central nervous system (CNS): The brain and spinal cord, (Chs 1, 8, 16, 18). See also Brain; Spinal cord anatomical divisions of, 274-275 anatomical organization, 280 angiotensin II, 650 nervous system component, 37 neuroglial cells, 277-279 PNS, functional relationship to, 275 Central sulcus: Groove in the surface of a cerebral hemisphere, between the primary sensory and primary motor areas of the cortex, (Ch 8), 296, 300 Central vein of the liver, 588, 589 **Centriole:** A cylindrical intracellular organelle composed of nine groups of microtubules, three in each group; functions in mitosis or meiosis by organizing the microtubules of the spindle apparatus, (Ch 3), 88, 100-101 Centromere (SEN-trō-mēr): Localized region where two chromatids remain connected following chromosome replication; site of spindle fiber attachment, (Ch 3), 113, 114 Cephalic direction, 46 Cephalic phase of gastric secretion, 579, 580 Cephalic region, 44 Cephalic vein, 483, 487, 489 Cerebellar cortex, 308 Cerebellar peduncles, 307, 308 Cerebellum (ser-e-BEL-um): Region of the brain posterior to the pons, containing the cerebellar hemispheres; adjusts voluntary and involuntary motor activities, (Ch 8), 297, 298, 307, 308 Cerebral aqueduct: Passageway that connects the third ventricle (surrounded by the diencephalon) with the fourth ventricle, (Ch 8), 298 Cerebral arterial circle (circle of Willis), 485 Cerebral arteries, 296, 485 Cerebral cortex: An extensive area of neural cortex covering the surfaces of the cerebral hemispheres, (Ch 8), 300-301 Cerebral hemispheres: Expanded portions of the cerebrum covered in neural cortex, (Ch 8) hemispheric lateralization, 302-303 regions of the brain, 296, 297 structure of, 300-301

Cerebral meningitis, 326 Cerebral nuclei, 304 Cerebral palsy, 319 Cerebral peduncles, 307 Cerebral processing centers general interpretive area, 301, 304 prefrontal cortex, 302 speech center, 301 Cerebral veins, 296 Cerebrospinal fluid (CSF): Fluid bathing the internal and external surfaces of the CNS; secreted by the choroid plexus, (Ch 8) average total volume, 298-299 production and circulation of, 298-300 subarachnoid space, 292 Cerebrovascular accident (CVA) (stroke), 324, 326, 429 Cerebrum (SER-e-brum): The largest portion of the brain, composed of the cerebral hemispheres; includes the cerebral cortex, the cerebral nuclei, and the white matter, (Ch 8). See also Cerebral hemispheres aphasia and dyslexia, 304 association areas, 301 basal nuclei, 300, 304–305 cerebral processing centers, 301-302 cortical connections, 301 electroencephalograms, 303 functions of, 300 limbic system, 305-306 memory, 304 motor and sensory areas, 300, 301 regions of the brain, 296, 297 seizures, 305 Cerumen (earwax), 163, 358 Ceruminous glands, 163, 358 Cervical caps, 698 Cervical enlargement, 292, 293 Cervical nerves, 311 Cervical plexus, 311, 312 Cervical region, 44 Cervical region of the vertebral column, 191, 193 Cervical spinal curve, 192 Cervical vertebrae, 191, 193, 194 Cervix: the lower part of the uterus, (Ch 19), 687, 688 Cesarean section, 724 Channel proteins, 90, 91 Cheeks, 44, 573 Chemical bonds covalent bonds, 59-60 defined, 58 hydrogen bonds, 60-61 ionic bonds, 58-59 unstable atoms, importance of, 58, 59 Chemical level of organization, 55-84 acids, bases, and salts, 67-68, 80 atoms, 56–58, 80 ATP, 78–79, 80 body fluid pH, 66-67 carbohydrates, 68-70, 79, 80 cells, forming, 70 chemical bonds, 58-61 chemical reactions, 61-63 enzymes, 64 explained, 34, 35 lipids, 70-73, 79, 80 nucleic acids, 76–78, 79, 80 organic and inorganic compounds, 64-65, 80 proteins, 73-76, 79, 80 water in physiological systems, 65-66, 80 Chemical notation, 62 Chemical reactions basic energy concepts, 61 cells, importance for, 61 chemical notation, 62 decomposition reactions, 63 exchange reactions, 63 reversible reactions, 63 synthesis reactions, 63 Chemiosmosis, 614 Chemistry, explained, 56 **Chemoreception:** Detection of alterations in the concentrations of dissolved compounds or gases, (Ch 9, 13, 15, 16), 340-341, 474-475, 559-561, 581 Chemoreceptor reflexes, 474-475, 559-561

Chemotaxis (kē-mō-TAK-sis): The attraction of phagocytic cells to the source of abnormal chemicals in tissue fluids, (Ch 14), 424, 512 Chemotherapy, 115, 161 Chest anatomical terms, 44 arteries of, 484 movement, age-related effects on, 562 veins of, 483, 487, 489 CHF (congestive heart failure), 469 Chief cells of the parathyroid gland, 389, 390 Chief cells of the stomach, 579, 580 Children development, 722, 726, 728 skulls of, 191 Chin, 44 Chlamydia, 688, 695 Chloride dietary guidelines, 623, 624 ECF, 658 ions in body fluids, 59 membrane potential, 281, 282 urinary system regulation, 636 urine and plasma, amounts in, 644 Chloride shift, 556, 557 Chlorine, 57 Cholecystitis, 600 Cholecystokinin (CCK) (kō-lē-sis-tō-KĪ-nin): Duodenal hormone that stimulates the contraction of the gallbladder and the secretion of enzymes by the exocrine pancreas, (Ch 16), 581, 585, 586, 588, 592 Cholelithiasis, 600 Cholesterol (koh-LES-ter-ol): A steroid component of cell membranes and a substrate for the synthesis of steroid hormones and bile salts, (Chs 2, 3, 16, 17) body lipids, 70, 72 dietary, 617 liver, 591 membrane lipids, 90, 91 recommended intake, 72 Cholinergic synapse (kō-lin-ER-jik): Synapse where the presynaptic membrane releases Ach on stimulation, (Ch 8), 288-290 Cholinesterase (ko-li-NES-te-ras): Enzyme that breaks down and inactivates ACh, (Ch 7), 227, 228, 229. See also Acetylcholinesterase Chondrocytes, 137, 138, 139 Chordae tendineae (KOR-dē TEN-di-nē-ē): Fibrous cords that stabilize the position of the AV valves in the heart, preventing backflow during ventricular systole, (Ch 12), 440, 441, 442, 443 Chorion/chorionic (KOR-ē-on) (ko-rē-ON-ik): an extra-embryonic membrane, consisting of the trophoblast and underlying mesoderm that forms the placenta, (Ch 20), 711, 712, 714–715 Chorionic villi, 712, 713, 714–715, 716, 734 Chorionic villus sampling (CVS), 734 Choroid: Middle vascular layer in the wall of the eye, (Ch 9), 347, 348 Choroid plexus: the vascular complex in the roof of the third and fourth ventricles of the brain, responsible for CSF production, (Ch 8), 298-299 Chromatid (KRŌ-ma-tid): One complete copy of a single chromosome, (Chs 3, 19), 113, 114, 672 Chromatin, 107 Chromosomes: Dense structures, composed of tightly coiled DNA strands and associated histories, that become visible in the nucleus when a cell prepares to undergo mitosis or meiosis; each normal human somatic cell contains 76 chromosomes, (Chs 3, 20), 106, 107, 112, 728-734 Chronic obstructive pulmonary disease (COPD), 562 Chronic renal failure, 652 Chylomicrons (kī-lō-MĪ-kronz): Relatively large droplets that may contain triglycerides, phospholipids, and cholesterol in association with proteins; synthesized and released by intestinal cells and transported to the venous blood by the lymphatic system, (Chs 16, 17), 583, 597, 598, 619 Chyme (kīm): A semifluid mixture of ingested food and digestive secretions that is in the stomach and proximal small intestine as digestion proceeds,

(Ch 16), 577

Chymotrypsin, 588, 597, 598, 599 Ciguatoxin (CTX), 326 Ciliary body: A thickened region of the choroid that encircles the lens of the eye; it includes the ciliary muscle and the ciliary processes that support the suspensory ligaments of the lens, (Ch 9), 347, 348, 351, 352 Ciliary muscles, 347, 348, 352, 354 Ciliary processes, 348 Ciliary zonule (suspensory ligament), 348, 351, 352 Ciliated epithelium, 124 Ciliated pseudostratified columnar epithelium, 128, 129 Cilium/cilia (SIL-ē-uh): Slender organelle/organelles that extends above the free surface of an epithelial cell. Multiple motile cilia generally undergo cycles of movement and are composed of a basal body and microtubules in a 9 + 2 array; a nonmotile solitary primary cilium acts as an environmental sensor, and has microtubules arranged in a 9 + 0 array, (Ch 3, 4, 15), 88-89, 101, 124, 128, 129, 537, 538, 539 Cimetidine (Tagamet), 581 Circadian rhythm melatonin, 393 photoreceptors, 350 visual inputs, 358 Circle of Willis (cerebral arterial circle), 485 Circular folds: Permanent transverse folds in the wall of the small intestine; also called plicae circulares, (Ch 16), 570, 571, 582, 583 Circulatory pressure, 466 Circulatory shock, 478 Circumcision, 681 Circumduction (sir-kum-DUK-shun): A movement at a synovial joint where the distal end of the bone describes a circle but the shaft does not rotate, (Chs 6, 7), 206, 207, 246 Circumflex artery, 444 Circumvallate papillae, 343, 344 Cirrhosis, 591, 600 Cisterna (sis-TUR-na): An expanded or flattened chamber, (Ch 3, 7), 101, 102, 105, 224, 225, 226, 230 233 Cisterna chyli, 503, 505 Citric acid cycle: The reaction sequence that occurs in the mitochondrial matrix; in the process, organic molecules are broken down, carbon dioxide molecules are released, and hydrogen molecules are transferred by coenzymes to the electron transport chain; also called TCA (tricarboxylic acid) cycle or Krebs cycle, (Chs 7, 17), 238, 612, 621 CK (creatine phosphokinase), 237 Class I MHC proteins, 518, 519, 524, 525 Class II MHC proteins, 518, 519, 520, 524, 525 Clavicles, 177, 185, 195, 196 Cleavage (KLE-vij): Mitotic divisions that follow fertilization of the ovum and lead to the formation of a blastocyst, (Ch 20), 709, 710 Cleavage furrow, 114, 115 Clitoris (KLIT-ō-ris): A small erectile organ of the female that is the developmental equivalent of the male penis, (Ch 19), 690 Clone, 528 Closed (simple) fractures, 180 Clostridium tetani, 231 Clot: A network of fibrin fibers and trapped blood cells; also called thrombus if it occurs within blood vessels, (Chs 1, 5, 11), 42, 164, 165, 427-429 Clot retraction and removal, 430 Clotting factors: Plasma proteins synthesized by the liver that are essential to the clotting response, (Chs 201, 11), 73, 428 Clotting system, 42, 427-429 Cluster of differentiation (CD) markers, 518 CNS. See Central nervous system CO (carbon monoxide), 290, 555 Coagulation, 427-429 Coated vesicle, 97, 98 Cobalamin (vitamin B12), 418, 577, 579, 599, 623, 624, 625 Coccygeal nerves, 293, 311 Coccygeal region of the vertebral column, 191 Coccyx (KOK-siks): Terminal portion of the spinal column, consisting of relatively tiny, fused vertebrae; tailbone, (Ch 6), 185, 191, 193, 195

Cochlea (KOK-lē-uh): Spiral portion of the bony labyrinth of the internal ear that surrounds the organ of hearing, (Ch 9), 359-360, 361 Cochlear duct (KOK-lē-ar): Membranous tube within the cochlea that is filled with endolymph and contains the spiral organ; also called scala media, (Ch 9), 360, 363, 364, 365 Cochlear nerve, 311, 365, 366 Cochlear nucleus, 366, 367 Codon (Kō-don): A sequence of three nitrogenous bases along an mRNA strand that will specify the location of a single amino acid in a peptide chain, (Ch 3), 109, 110 Coenzyme A (CoA), 612 Coenzyme Q, 612, 613, 614 Coenzymes (kō-EN-zīmz): Complex organic cofactors, usually structurally related to vitamins, (Chs 16, 17), 594, 611, 612, 613 Cofactor, 594 Coitus (sexual intercourse), 673, 695 Colectomy, 600 Colic vein, 491 Colitis, 595 Collagen: A strong, insoluble protein fiber common in connective tissues, (Chs 2, 4, 5, 6), 74, 75, 133, 134, 158, 173 Collagenous tissues, 134 Collateral branches of axons, 276 Collateral ganglia, 320, 321 Collecting duct, urinary, 637, 638, 639, 640, 642 Collecting system of the kidneys, 638, 640, 642, 646 Colles fracture, 181 Colliculus/colliculi (kol-IK-ū-lus): A little mound; in the brain, used to refer to one of the thickenings in the roof of the midbrain; the superior colliculi are associated with the visual system, and the inferior colliculi with the auditory system, (Ch 8), 307 Colloid of thyroid follicles, 387, 388 Colon: The large intestine, (Chs 9, 16), 340, 592-594. See also Large intestine Colonoscopy, 600 Colony-stimulating factors (CSFs) immune system, 524 WBC production, 419, 427 Color blindness, 353, 355, 730, 731, 732, 733 Colorectal cancer, 594 Colostomy, 600 Colostrum, 727 Columnar epithelium, 126, 127, 128, 129 Columns of CNS tracts, 280 Columns of spinal cord white matter, 296 Combination hormonal contraceptives, 698 **Comminuted:** Broken or crushed into small pieces, (Ch 6), 181 Commissure: A crossing over from one side to another, (Ch 8), 296 Common bile duct. See Bile duct Common carotid artery, 438 Common hepatic artery, 486, 487, 588, 591 Common hepatic duct, 589, 591 Common iliac artery, 482, 485-486 Common iliac vein, 483, 488, 489, 490 **Common pathway:** In the clotting response, the events that begin with the appearance of prothrombinase and end with the formation of a clot, (Ch 11), 428, 430 Compact bone: Dense bone containing parallel osteons, (Ch 6), 174, 175, 181 Compartment syndrome, 267 Compatible blood types, 422, 423 Complement: Plasma proteins that interact in a chain reaction following exposure to activated antibodies or to the surfaces of certain pathogens, and that promote cell lysis, phagocytosis, and inflammation, (Ch 14) antibody function, 522 innate (nonspecific) immunity, 511, 513, 525 Complementary base pairs of nucleic acids, 77 Complete antigens, 521 Complete proteins, 623 Complete tetanus in muscle stimulation, 235 Complex reflexes, 314, 315 Compliance of the lungs, 549, 551

Compound: A molecule containing two or more elements in a specific combination, (Ch 2), 58 Compound (open) fractures, 180 Compression, 230 Compression fractures, 180 Computed tomography (CT) scans, 50 Concentration: Amount (in grams) or number of atoms, ions, or molecules (in moles) per unit volume, (Chs 3, 18), 92, 650 Concentration gradient: Regional difference in the concentration of a particular substance, (Chs 3, 18), 92, 646 Conception, 706. See also Fertilization Concha/conchae (KONG-ka): Three pairs of thin, scrolllike bones that project into the nasal cavities; the superior and medial conchae are part of the ethmoid bone and the inferior conchae are separate bones, (Chs 6, 15), 188, 189, 190, 538, 539 Condensation reaction, 63 Condom (prophylactic), 698 Conducting cells of the heart, 445-446 Conducting portion of the respiratory tract, 536–544 Conducting system of the heart, 446-448 Conduction of heat, 627 Conductive deafness, 366 Condylar (ellipsoid) joints, 208, 210 Condylar process of the mandible, 190 Condyle: A rounded articular projection on the surface of a bone, (Ch 6), 183, 198 Cone: Retinal photoreceptor responsible for color vision, (Ch 9), 349, 350, 353, 355, 356 Congestive heart failure (CHF), 469 Conjoined (Siamese) twins, 725 Conjunctiva (kon-junk-TĪ-vuh): A layer of stratified squamous epithelium that covers the inner surfaces of the lids and the anterior surface of the eye to the edges of the cornea, (Ch 9), 345, 347 Conjunctivitis, 345 Connective tissue: One of the four primary tissue types; provides a structural framework for the body that stabilizes the relative positions of the other tissue types; includes connective tissue proper, cartilage, bone, and blood; always has cells, cell products, and ground substance, (Chs 4, 7, 12) components of, 131-132 connective tissue proper, 132-136 fluid connective tissue, 132, 136-137 functions of, 132 heart, 438, 440 membranes, 140-141 regeneration of, 145 skeletal muscle, 223-224 supporting connective tissues, 132, 137-139 tissue level of organization, 121, 122, 131-139 types of, 132 Connective tissue proper cells of, 133 dense connective tissues, 134, 136 described, 132 fibers of, 133-134 ground substance, 132, 134 loose connective tissues, 134, 135 types of, 134-136 Connexons, 123, 124 Constant segments of antibody chains, 521, 522 Constipation, 595 Contact dermatitis, 158 Continuous propagation of an action potential, 288 Contraceptive methods, 698-699 Contractile cells of the heart, 445-446 Contractile proteins, 73 Contractility: The ability to contract; possessed by skeletal, smooth, and cardiac muscle cells, (Chs 6, 7, 12), 173, 230, 232-233, 435. See also Muscle; Muscular system Contraction phase in muscle fiber contractions, 231 Control center, and homeostatic regulation, 36, 40 Convection and heat transfer, 627 **Convergence:** In the nervous system, the term indicates that the axons from several neurons innervate a single neuron; most common along motor pathways, (Ch 8), 290-291

Convoluted segments of the renal tubule, 638. See also Distal convoluted tubule (DCT); Proximal convoluted tubule (PCT) COPD (chronic obstructive pulmonary disease), 562 Copper, dietary guidelines for, 624 Copulation (coitus), 673, 695 Coracobrachialis muscle, 258, 259, 260 **Coracoid process** (KOR-uh-koyd): A hook-shaped process of the scapula that projects above the anterior surface of the capsule of the shoulder joint, (Ch 6), 197 Cornea (KOR-nē-uh): Transparent portion of the fibrous tunic of the anterior surface of the eye, (Ch 9), 345, 347, 348, 350 Corneal epithelium, 345 Corneal transplant, 348 Corniculate cartilage, 540, 541 Cornification, 155, 720. See also Keratinization Corona radiata (ko-RŌ-nuh rā-dē-A-tuh): A layer of follicle cells surrounding a secondary oocyte at ovulation, (Chs 19, 20), 686, 687, 707, 708 Coronal (frontal) plane, 44, 47 Coronal suture, 186, 187, 188 Coronary angiogram, 455 Coronary arteries, 438, 444, 463 Coronary arteriography, 455 Coronary artery bypass graft (CABG), 455, 488 Coronary artery disease (CAD), 444, 463, 617 Coronary circulation, 444 Coronary ligament of the liver, 589 Coronary sinus, 438, 440, 441, 444, 447 Coronary sulcus, 436 Coronary thrombosis, 455 Coronoid (KOR-uh-noyd): Hooked or curved, (Ch 6), 198 Coronoid fossa of the humerus, 198 Coronoid process of the mandible, 91, 187 Coronoid process of the ulna, 199 Corpora cavernosa, 681 Corpora quadrigemina, 307 Corpus albicans, 687 Corpus callosum: Bundle of axons linking centers in the left and right cerebral hemispheres, (Ch 8), 296, 301, 303 Corpus luteum (LOO-tē-um): Progesterone-secreting mass of follicle cells that develops in the ovary after ovulation, (Chs 10, 19, 20), 398, 686, 687, 716-717 Corpus spongiosum, 681 Corpus striatum, 305 **Cortex:** Outer layer or portion of an organ, (Ch 5), 160 Cortical nephrons, 638, 639 Cortical radiate (interlobular) arteries, 638, 639 Cortical radiate (interlobular) veins, 638, 639 Corticospinal pathway (pyramidal system), 316, 318 Corticospinal tracts: Descending tracts that carry motor commands from the cerebral cortex to the anterior gray horns of the spinal cord, (Ch 8), 318 Corticosteroid: A steroid hormone produced by the adrenal cortex, (Ch 10), 390-392 Corticosterone, 377, 391, 392 Corticotropin, 383. See also Adrenocorticotropic hormone (ACTH) Corticotropin-releasing hormone (CRH), 383, 384 Cortisol (KOR-ti-sol): One of the corticosteroids secreted by the adrenal cortex; a glucocorticoid, (Ch 10), 377, 391, 392 Cortisone, 391, 392 Costal bones, 194. See also Ribs Costal cartilages, 195, 196 Costal facets of the thoracic vertebrae, 193 Costal surface of the lung, 546, 547 Cotransport: Membrane transport of a nutrient, such as glucose, in company with the movement of an ion, usually sodium; transport requires a carrier protein but does not involve direct ATP expenditure and can occur regardless of the concentration gradient for the nutrient, (Chs 3, 16), 96, 597, 598, 599 Coughing reflex, 541 Countertransport, 96 Covalent bond (kō-VĀ-lent): A chemical bond between atoms that involves the sharing of electrons, (Ch 2), 59-60

Cowper's glands. See Bulbo-urethral glands

Coxal bone: Hip bone; formed by the fusion of the ilium, ischium, and pubis, (Ch 6), 185, 200 CP. See Creatine phosphate (CP) CPK (creatine phosphokinase), 237 CPR. See Cardiopulmonary resuscitation (CPR) Cranial cavity, 186 Cranial direction, 46 Cranial meninges, 291 **Cranial nerves:** The twelve peripheral nerves originating at the brain, (Chs 8, 9, 12, 15) abducens nerve (VI), 307, 308, 309, 310, 343, 366 accessory nerve (XI), 307, 308, 310, 311 distribution and functions, 309-311 facial nerve (VII), 307, 308, 310, 311, 322, 323, 344 glossopharyngeal nerve (IX), 307, 308, 310, 311, 322, 323, 341, 344, 454, 559, 560 hypoglossal nerve (XII), 307, 308, 310, 311 locations of, 307, 308 oculomotor nerve (III), 307, 309, 310, 311, 322, 323, 346 olfactory nerve (I), 307, 309, 310, 342 optic nerve (II), 307, 309, 310, 346, 347, 349, 350, 357 PNS axons, 280 trigeminal nerve (V), 307, 308, 309, 310, 344 trochlear nerve (IV), 307, 309, 310, 344 vagus nerve (X), 307, 308, 310, 311, 322, 323, 341, 344, 453, 454, 559, 560 vestibulocochlear nerve (VIII), 307, 308, 310, 311, 359, 361, 363, 364, 366, 367 Cranial region, 44 Craniosacral division. See Parasympathetic division Cranium: The braincase; the skull bones that surround the brain, (Chs 1, 6) anatomical terms, 44 bones of, 184, 186-191 Creatine phosphate (CP): A high-energy compound present in muscle cells; during muscular activity, the phosphate group is donated to ADP, regenerating ATP, (Chs 7, 18), 237, 238, 239, 643 Creatine phosphokinase (CPK or CK), 237 Creatinine: A breakdown product of creatine metabolism, (Ch 18), 643, 644 Cremaster muscle, 674 Crenation: Cellular shrinkage due to an osmotic movement of water out of the cell, (Ch 3), 94 Crest (bone marking), 183 Cretinism, 402 Cribriform plate: Portion of the ethmoid bone of the skull that contains the foramina used by the axons of olfactory receptors en route to the olfactory bulbs of the cerebrum, (Chs 6, 8, 9), 187, 189, 309, 342 Cricoid cartilage (KRĪ-koyd): cartilage forming the inferior margin of the larynx, (Ch 15), 539, 540, 541 Crista ampullaris: A ridge-shaped collection of hair cells in the ampulla of a semicircular canal; the crista ampullaris and cupula form a receptor complex sensitive to movement along the plane of the canal, (Ch 9), 360, 361, 362 Crista galli, 187, 189 Cristae of mitochondrial membranes, 89, 103, 106 Cross-bridges: Myosin head that projects from the surface of a thick filament and that can bind to an active site of a thin filament in the presence of calcium ions, (Ch 7), 227, 232, 234 Cross-match testing for blood, 423 Cross-reactions to transfusions blood types, 421, 422 cytotoxic hypersensitivity, 527 Cross (transverse) section, 45 Crossing-over of chromatids, 677 Crown of a tooth, 574, 575 Crude touch and pressure receptors, 338 Crural region, 44 Cryptorchidism, 676 CSF. See Cerebrospinal fluid (CSF) CSFs. See Colony-stimulating factors (CSFs) CT (computed tomography) scans, 50 CTX (ciguatoxin), 326 Cuboid bone, 202, 203 Cuboidal epithelium, 126, 127 Cuneiform cartilage, 540, 541 Cupula (KŪ-pū-luh): A gelatinous mass in the ampulla of a semicircular canal in the internal ear and whose

movement stimulates the hair cells of the crista, (Ch 9), 362, 363 Cushing disease, 402 Cuspids (canine teeth), 575, 576 Cusps of heart valves, 440 Cutaneous membrane: The epidermis and the underlying dermis, (Chs 4, 5). See also Skin integumentary system, 152 tissue level or organization, 141 Cutaneous plexus, in dermis, 152, 159 Cuticle: Layer of dead, cornified cells surrounding the shaft of a hair or surface of nails, (Ch 5), 160, 163, 164 CVS (chorionic villus sampling), 734 Cyanosis (sī-uh-Nō-sis): Bluish discoloration of the skin due to the presence of deoxygenated blood in the vessels near the body surface, (Ch 5), 157 Cycles per second of sound, 365 Cyclic-AMP (cAMP), 378–379 Cyclic-GMP, 380 Cysteine, 109 Cystic duct: A duct that carries bile between the gallbladder and the bile duct, (Ch 16), 591-592 Cystic fibrosis, 539, 733 Cystic vein, 491 Cystitis, 654 Cytochrome: A pigment component of the electron transport chain; a structural relative of heme, (Ch 17), 613, 614 Cytokines allergic reactions, 527 cytotoxic T cells, 518 interferons, 500, 511, 512, 513, 524 suppression factors, 519 Cytokinesis (sī-tō-ki-NĒ-sis): The cytoplasmic movement that separates two daughter cells at the completion of mitosis, (Ch 3), 112, 113–114, 115 **Cytology** (sī-TOL-o-jē): The study of cells, (Chs 1, 3), 33,86 Cytoplasm: The material between the plasma membrane and the nuclear membrane, (Ch 3), 88, 99 Cytosine: One of the nitrogenous base components of nucleic acids, (Chs 2, 3), 77, 78, 107, 109, 110 Cytoskeleton: A framework of microtubules and microfilaments in the cytoplasm, (Ch 3), 88, 100 Cytosol: The fluid portion of the cytoplasm; intracellular fluid, (Ch 3), 88, 90, 99 Cytotoxic reactions, 526-527 Cytotoxic T cells: Lymphocytes involved in cell-mediated immunity that kill target cells by direct contact or through the secretion of lymphotoxins; also called killer T cells, (Ch 14), 505, 507, 518, 524, 525 Cytotrophoblast (cellular trophoblast), 710, 711 Π Dairy, dietary guidelines for, 622, 623 Dartos muscle, 674, 675 **Daughter cells:** Genetically identical cells produced by somatic cell division, (Ch 3), 111, 112, 114, 115 Daughter chromosomes, 113, 115 DCT. See Distal convoluted tubule (DCT) Deafness, 731 Deamination, 619 Decarboxylation, 615 Decibels, 365 Deciduous teeth, 575, 576 Decomposition reaction: A chemical reaction that breaks a molecule into smaller fragments, (Ch 2), 63 Decompression sickness (the bends), 553 Deep brachial artery, 484 Deep direction, 46 Deep femoral artery, 482, 486 Deep femoral vein, 483, 488 **Defecation** (def-e-KĀ-shun): The elimination of fecal wastes, (Ch 16), 570, 595-596 Defecation reflex, 595 Defibrillator, 455 Deflation reflex, 559 Degenerative arthritis, 206 Deglutition (dē-gloo-TISH-un): Swallowing,

(Ch 16), 577

Dehydration: A reduction in the water content of the body that threatens homeostasis, (Chs 13, 18), 468, 600, 643, 644, 645 Dehydration synthesis: The formation of a complex molecule by the removal of water, (Ch 2), 63 Delaved hypersensitivity, 509 Delivery, 724. *See also* Labor Deltoid muscle deltoid tuberosity, 198 described, 244, 245, 246, 247, 257, 258, 259 as injection site, 253 primary actions of, 246 Deltoid tuberosity, 198 Dementia, 325, 326 Demyelination: The loss of the myelin sheath of an axon, usually due to chemical or physical damage to Schwann cells or oligodendrocytes, (Ch 8), 281, 326 Denaturation: Irreversible alteration in the threedimensional structure of a protein, (Ch 2), 74-75 Dendrite (DEN-drīt): A sensory process of a neuron, (Chs 4, 8) described, 143 neuron structure, 275-276 Dendritic cells, 155, 508, 518, 524 Dens (odontoid process), 193, 194 Dense bone. See Compact bone Dense connective tissue, 134, 136 Dense irregular connective tissue, 136 Dense regular connective tissue, 134, 136 Dental calculus, 576 Dental caries, 600 Dentin (DEN-tin): Bonelike material that forms the body of a tooth; unlike bone, it lacks osteocytes and osteons, (Ch 16), 575 Deoxyribonucleic acid. See DNA (deoxyribonucleic acid) Deoxyribose: A five-carbon sugar resembling ribose but lacking an oxygen atom, (Ch 2), 77, 78 Depo-Provera, 698 Depolarization: A change in the membrane potential that moves it from a negative value toward 0 mV, (Chs 8, 12) cardiac contractile cells, 445, 446, 448, 449 explained, 283, 284, 285, 286, 287 Depression (bone marking), 182, 183 Depression: Inferior (downward) movement of a body part, (Ch 6), 208, 209 Depressor anguli oris muscle, 248, 249 Dermal papillae, 153 Dermatitis, 158 Dermatomes, 311, 313 Dermicidin, 163 Dermis: The connective tissue layer beneath the epidermis of the skin, (Ch 5), 152, 158–159 Descending aorta, 438, 480, 481, 482, 484, 485–486 Descending colon, 593, 594 Descending limb of the nephron loop, 640, 642, 648 Descending (motor) pathways, 280, 316, 318-319 Descending tracts of the spinal cord, 296 Desmosomes, 123, 124 Detrusor muscle of the bladder, 653, 654 Detumescence, 695 Development: Growth and the acquisition of increasing structural and functional complexity; includes the period from conception to maturity, (Chs 19, 20), 706 Development and inheritance, 705-738 development as a continuous process, 706 fertilization, 706, 707-708 genes and chromosomes, 728-734 gestation, first trimester of, 709-717, 720-721, 722 gestation, second and third trimesters of, 709, 717-723 labor and delivery, 724-725 postnatal stages, 726-728 Diabetes, 385 Diabetes insipidus, 385, 645, 732 Diabetes mellitus, 396, 526, 620 Diabetic ketoacidosis, 620 Diabetic nephropathy, 396 Diabetic neuropathy, 396 Diabetic retinopathy, 396 Dialysis: Diffusion between two solutions of differing solute concentrations across a semipermeable membrane containing pores that permit the passage of some solutes but not others, (Ch 18), 652

Diaper rash, 158 Diaphragm (muscle) (DI-uh-fram): Any muscular partition: the respiratory muscle that separates the thoracic cavity from the abdominopelvic cavity, (Chs 1, 7, 8, 15), 38, 45, 48, 224, 246, 250, 252, 253, 311, 549, 550 Diaphragmatic (hiatal) hernia, 250, 576 Diaphragms, contraceptive, 698–699 Diaphysis (dī-AF-i-sis): The shaft of a long bone, (Ch 6), 174, 175 Diarrhea, 595 Diarthrosis (dī-ar-THRŌ-sis): A synovial joint, (Ch 6), 204, 205. See also Synovial joints Diastole, 450-451 Diastolic pressure: Pressure measured in the walls of a muscular artery when the left ventricle is in diastole, (Ch 13), 467, 470 Diencephalon (dī-en-SEF-a-lon): A division of the brain that includes the pineal gland, thalamus, and hypothalamus, (Ch 8) epithalamus, 307 hypothalamus, 307 regions of the brain, 296, 297 thalamus, 307 Diet. See Nutrition Differential count: An estimate of the number of each type of white blood cell on the basis of a random sampling of 100 white blood cells, (Ch 11), 425-426 Differentiation. See Cellular differentiation Diffusion: Passive molecular movement from an area of higher concentration to an area of lower concentration, (Chs 3, 18) facilitated, 92, 96, 99 plasma membranes, across, 91-95, 99 urinary system, 646 Digastric muscle, 249, 250 Digestion: The chemical breakdown of ingested materials into simple molecules that can be absorbed by the cells of the digestive tract, (Chs 1, 2, 16) carbohydrate digestion and absorption, 596-598 decomposition reaction, 63 defined, 569 described, 32-33 lipid digestion and absorption, 597, 598 nutrients, processing and absorption of, 596-599 protein digestion and absorption, 597, 598-599 small intestine, in, 585-586 stomach, in, 581-582 vitamin absorption, 599 water and electrolyte absorption, 599 Digestive materials, movement of, 572-573 Digestive system, 568-606 age-related changes, 597-600 autonomic nervous system, effects of, 321, 323, 325 baroreceptors, 340 components of, 569, 570 digestion, process of, 596-599 digestive materials, movement of, 572-573 endocrine system, functional relationship with, 375, 397 functional relationship with other systems, 600, 601 functions of, 569-570 gallbladder, 570, 591-592 germ layer contributions to, 713 histological organization, 570–572 large intestine, 570, 592–596 liver, 570, 588-591 oral cavity, 570, 573-576 organs, components, and primary functions, 39 pancreas, 570, 587–588 pharynx and esophagus, 570, 576 prenatal and early postnatal development, overview of, 721 reproductive system, functional relationship with, 700 small intestine, 570, 582-586 stomach, 570, 577-582 swallowing, 577 urinary system, functional relationship with, 665, 666 Digestive tract: An internal passageway that begins at the mouth and ends at the anus; also called gastrointestinal tract, (Chs 10, 16) defined, 569 endocrine function, 377

Diapedesis. See Emigration

Digital arteries, 481, 482, 484 Digital subtraction angiography (DSA), 51 Digital veins, 483, 489 Digitalis, 455 Diglycerides, 70 Dihydrogen phosphate, 662 Dilate: To increase in diameter; to enlarge or expand, (Chs 4, 20), 144, 724, 725 Dilation stage of labor, 724, 725 Dipeptides, 73, 74 **Diploid** (DIP-loyd): Having a complete somatic complement of chromosomes (53 pairs in human cells), (Ch 19), 677 Disaccharide (dī-SAK-uh-rīd): A compound formed by the joining of two simple sugars by dehydration synthesis, (Chs 2, 16), 68-69, 70, 79, 596, 597 Disease definition of, 36 homeostasis and, 36, 41 Displaced fractures, 180 Dissociation, 65 Distal: Away from the point of attachment or origin; for a limb, away from its attachment to the trunk, (Ch 1), 46 Distal convoluted tubule (DCT): Portion of the nephron closest to the collecting tubule and duct; an important site of active secretion, (Ch 18), 637, 638, 640, 641, 642, 646, 647 Distal phalanges, 185, 199, 200 Distal radioulnar joint, 199 Distribution (muscular) arteries, 461, 462 Diuresis, 385 Diuretics, 665 Divergence: In nervous tissue, the spread of excitation from one neuron to many neurons; an organizational pattern common along sensory pathways of the CNS, (Ch 8), 290 Diverticulitis, 595 Diverticulosis, 595 Dizygotic twins (dī-zī-GOT-ik): Twins that result from the fertilization of two ova; also called fraternal twins, (Ch 20), 724 DNA (deoxyribonucleic acid) (dē-oks-ē-rī-bō-noo-KL Ā-ik): A nucleic acid consisting of a chain of nucleotides containing the sugar deoxyribose and the nitrogenous bases adenine, guanine, cytosine, and thymine, (Chs 2, 3, 20) chemical level of organization, 76-78, 79 chromosomes, on, 107-108 described, 108 DNA fingerprinting, 108 genes and chromosomes, 728-729 mutations, 112 replication, 111-113 transcription, 108-109 translation, 109-111 DNA molecule: Two chains of nucleotides wound in a double helix and held together by hydrogen bonds between complementary nitrogenous base pairs, (Ch 2), 77-78, 79 DNA polymerase, 112 Dominant gene: A gene whose presence will determine the phenotype, regardless of the nature of its allelic companion, (Ch 20), 729, 730, 731 Dopamine (DŌ-puh-mēn): An important neurotransmitter in the CNS, (Ch 8), 290, 307 Dorsal: Toward the back, posterior, (Ch 1), 43, 44, 46 Dorsal arch, 486 Dorsal direction, 43, 46 Dorsal respiratory group, 558 Dorsal root ganglion. See Spinal (dorsal root) ganglion Dorsal venous arch, 483, 488 Dorsalis pedis artery, 470, 482, 486 Dorsiflexion: elevation of the superior surface of the foot, (Ch 6), 208, 209 Double covalent bond, 59, 60 Double helix of DNA, 77 Down's syndrome (trisomy 51), 131, 733, 734 DSA (digital subtraction angiography), 51 Dual innervation, 324 Duchenne muscular dystrophy, 731 Duct: a passageway that delivers exocrine secretions to an epithelial surface, (Ch 4), 128

Ductal carcinoma, 691 Ductal carcinoma in situ, 691 Ductus arteriosus (ar-tē-rē-ō-sus): Vascular connection between the pulmonary trunk and the aorta that functions throughout fetal life; normally closes at birth or shortly thereafter and persists as the ligamentum arteriosum, (Ch 13), 492, 493 Ductus deferens (DUK-tus DEF-e-renz): A passageway that carries sperm from the epididymis to the ejaculatory duct, (Chs 1, 19), 39, 674, 675, 679 Ductus venosus, 492, 493 Duodenal glands, 583, 584 Duodenal papilla, 591, 592 Duodenal ulcers, 581 Duodenum (doo-AH-de-num): The proximal 25 cm of the small intestine that contains short villi and submucosal glands, (Ch 16), 580, 582 Dura mater (DOO-ruh MĀ-ter): Outermost membrane of the cranial and spinal cord meninges, (Ch 8), 291-292 Dural folds, 292 Dural sinuses, 292, 487 Dust cells (alveolar macrophages), 544 Dynamic equilibrium: Maintenance of normal body orientation during sudden changes in position (rotation, acceleration, etc.), (Ch 9), 362 Dyslexia, 304 Dysmenorrhea, 689 Dysplasia, 147 Dyspnea, 562 Dysuria, 654, 665

E

Ear anatomical terms, 44 anatomy of, 358-362 bones of, 187, 358-360 equilibrium, 337, 358, 362-363 external acoustic meatus, 187, 188, 358, 359 hearing, 337, 358, 363-368, 369 tympanic membrane, 187, 358, 359 Eardrum (tympanic membrane), 187, 357-359, 365 Earwax (cerumen), 163, 358 Eating disorders, 629 Eccrine (merocrine) sweat glands, 162, 163 ECG. See Electrocardiogram (ECG, EKG) Echocardiography, 455 Echogram, 51 Ectoderm: One of the three germ layers; covers the surface of the embryo and gives rise to the nervous system, the epidermis and associated glands, and other structures, (Ch 20), 711, 712, 714 Ectopic (ek-TOP-ik): Outside its normal location, (Chs 12, 20), 448, 710 Ectopic pacemaker, 448 Ectopic pregnancy, 710 Eczema, 158 Edema, 304, 469 EEG. See Electroencephalogram (EEG) Effector: A peripheral gland, muscle cell, or adipose tissue innervated by a motor neuron, (Chs 1, 8), 36, 40, 274, 275, 277, 280 Efferent arteriole: An arteriole carrying blood away from a glomerulus of the kidney, (Ch 18), 638, 639, 640 Efferent division of the PNS, 274-275 Efferent ductules, 675, 676 Efferent lymphatics, 508 Efferent vessels, 435. See also Arteries Eicosanoids, 376 Ejaculate, defined, 680 Ejaculation (ē-jak-ū-LĀ-shun): The ejection of semen from the penis as the result of muscular contractions of the bulbocavernosus and ischiocavernosus muscles, (Ch 19), 673, 680, 695 Ejaculatory ducts: Short ducts that pass within the walls of the prostate and connect the ductus deferens and seminal glands (seminal vesicles) with the urethra, (Ch 19), 674, 679 EKG. See Electrocardiogram (ECG, EKG) Elastase, 597 Elastic arteries, 461, 462

Elastic cartilage, 137, 138 Elastic fibers connective tissue proper, 133 in reticular layer of the dermis, 158 Elastic rebound, 468 Elastin: Connective tissue fibers that stretch and recoil. providing elasticity to connective tissues, (Ch 4), 133 Elbow, 44, 211-212 Elective (induced) abortion, 728 Electrical current, through aqueous solution, 65 Electrical impulse to muscles, 224, 227, 228, 229 Electrocardiogram (ECG, EKG) (e-lek-trō-KAR-dē-ōgram): Graphic record of the electrical activities of the heart, as measured at specific locations on the body surface, (Ch 12), 448-449 Electroencephalogram (EEG): Graphic record of the electrical activities of the brain, (Ch 8), 303 Electrolytes (e-LEK-trō-līts): Soluble inorganic compounds whose ions will conduct an electrical current in solution, (Chs 2, 5, 16, 18). See also Fluid and electrolyte balance absorption in the large intestine, 599 in blood, 413 defined, 65 in perspiration, 163 salts, 67 urinary system regulation, 656-658, 659-660 Electron: One of the three fundamental subatomic particles; has a negative charge and normally orbits the protons of the nucleus, (Ch 2), 56, 57 Electron cloud, 57 Electron microscopy, 86 Electron shell, 58 Electron transport chain (ETC): The respiratory protein complexes (I-IV), coenzyme Q, and electron carriers made up of cytochrome molecules responsible for most of the energy production in cells; bound to the inner mitochondrial membrane, (Ch 17), 612-614 Element: All the atoms with the same atomic number, (Ch 2), 56, 57 Elevation (bone marking), 182, 183 Elevation: Movement in a superior, or upward, direction, (Chs 6, 7), 208, 209, 246, 249, 253, 257 Elimination, urinary, 635 Ellipsoid (condylar) joints, 208, 210 Elongation, in translation, 110-111 Embolism (EM-bō-lizm): Obstruction or closure of a vessel by an embolus, (Ch 11), 429 Embolus (EM-bō-lus): An air bubble, fat globule, or blood clot drifting in the bloodstream, (Ch 11), 429 Embryo (EM-brē-o): Developmental stage beginning at fertilization and ending at the start of the third developmental month, (Chs 11, 19, 20), 410, 418, 673, 687, 692, 706, 720-721 Embryogenesis, 717, 718, 720-721 Embryology (em-brē-OL-ō-jē): The study of embryonic development, focusing on the first two months after fertilization, (Ch 20), 706 Embryonic disc, 712, 714, 717 Emesis, 585 Emigration: Movement of white blood cells through the walls of blood vessels by migration between adjacent endothelial cells; also called diapedesis, (Chs 11, 14), 424, 512 Emission, 386, 673, 695 Emmetropia: Normal vision, (Ch 9), 354 Emotions, 305 Emphysema, 549, 561, 562 Emulsification (ē-mul-si-fi-KĀ-shun): The physical breakup of fats in the digestive tract, forming smaller droplets accessible to digestive enzymes; normally the result of mixing with bile salts, (Ch 16), 591

Enamel: Crystalline material similar in mineral composition to bone, but harder and without osteocytes, that covers the exposed surfaces of the teeth, (Ch 16), 574, 575 Endergonic reactions, 64

Endocardium (en-dō-KAR-dē-um): The simple squamous epithelium that lines the heart and is continuous with the endothelium of the great vessels, (Ch 12), 437, 439

Endochondral ossification (en-dō-KON-drul): the replacement of a cartilaginous model with bone; the characteristic mode of formation for skeletal elements other than the bones of the cranium, the clavicles, and sesamoid bones, (Ch 6), 177-178 Endocrine cells, 376 Endocrine gland: A gland that secretes hormones into the blood, (Chs 4, 10), 123, 128 Endocrine pancreas, 377, 393-395 Endocrine system, 374–408 adipose tissue, 377, 398 adrenal glands, 390-393 aging effect of, 400 cardiovascular regulation, 471, 472, 475-477 cardiovascular system, functional relationship with, 495 defined, 376 digestive tract, 377, 397 disorders of, 402 endocrine pancreas, 393-395, 403 exercise, effect of, 267 germ layer contributions to, 713 gonads, 377, 397-398 heart, 377, 397 hormones, interaction of, 398-400 hormones and receptors, 377-380 intercellular communication, 64 kidneys, 377, 397 lymphatic system, functional relationship with, 528, 529 organs, components, and primary functions, 38 other body systems, functional relationship with, 404 parathyroid glands, 390 pineal gland, 393 pituitary gland, 381-386 prenatal and early postnatal development, overview of, 721 reproductive system, functional relationship with, 700 respiratory system, functional relationship with, 563 thymus, 377, 397 thyroid gland, 386-389, 390, 403 tissues and organs of, 376, 377 urinary system, functional relationship with, 666 Endocrinology, 403 Endocytosis (en-dō-sī-TŌ-sis): The movement of relatively large volumes of extracellular material into the cytoplasm by the formation of a membranous vesicle at the cell surface; includes pinocytosis and phagocytosis, (Ch 3), 92, 97-98, 99 Endoderm: One of the three germ layers; the layer on the undersurface of the embryonic disc that gives rise to the epithelia and glands of the digestive system, the respiratory system, and portions of the urinary system, (Ch 20), 712, 713, 714–715 Endogenous: Produced within the body. Endolymph (EN-dō-limf): Fluid contents of the membranous labyrinth (the saccule, utricle, semicircular canals, and cochlear duct) of the internal ear, (Chs 9, 18), 359-360, 657, 659 Endolymphatic sac, 360, 363 Endometrial (uterine) glands, 688 Endometriosis, 699 Endometrium (en-dō-ME-trē-um): The mucous membrane lining the uterus, (Ch 19), 687-688 Endomysium (en-dō-MIZ-ē-um): A delicate network of connective tissue fibers that surrounds individual muscle cells, (Ch 7), 223 Endoplasmic reticulum (en-dō-PLAZ-mik re-TIKūlum): A network of membranous channels in the cytoplasm of a cell that function in intracellular transport, synthesis, storage, packaging, and secretion, (Ch 3), 88–89, 101–102, 104 Endosteum, 174 Endothelium (en-dō-THĒ-lē-um): The simple squamous epithelium that lines blood and lymphatic vessels, (Chs 11, 12, 13, 14, 15) blood vessels, 460, 461, 462, 545 heart, 437 hemostasis, 427 lymphatic vessels, 504 Endurance of muscle performance, 240 Energetics, defined, 608. See also Metabolism and Energetics Energy. See also Metabolic rate basic concepts and types of, 61

expenditure of, 626-627 food, energy content of, 626 reserves, storage of, in connective tissue, 132 thermoregulation, 40-42, 627-628 units of, 626 ENS. See Enteric nervous system (ENS) Enteric nervous system (ENS): A third division of the autonomic nervous system (ANS); nervous tissue in the walls of the digestive tract that helps control digestive functions independent of the central nervous system (CNS), 274, 571 Enterogastric reflex, 580, 581 Enzyme: A protein that catalyzes a specific biochemical reaction, (Chs 2, 3, 19). See also specific enzymes activation energy of chemical reactions, 64 functions of, 73, 75-76 membrane proteins, 91 semen, in, 680 Eosinophil (ē-ō-SIN-ō-fil): A granulocyte (WBC) with a lobed nucleus and red-staining granules; participates in the immune response and is especially important during allergic reactions, (Chs 11, 14), 413, 419, 424, 425, 426, 512, 522, 524 Ependyma (ep-EN-di-muh): Layer of cells lining the ventricles and central canal of the CNS, (Ch 8), 278, 279 Ependymal cells, 278, 279 Epicardium: Serous membrane covering the outer surface of the heart; also called visceral layer of serous pericardium, (Ch 12), 48, 436-437, 439 Epicondyles of the femur, 202 Epicranial aponeurosis, 248, 249 Epicranium (scalp), 249 Epidermal ridges, 153–154 Epidermis: The epithelium covering the surface of the skin, (Ch 5) color, 156-157 as integumentary system component, 152 layers of, 153–154 skin cancers, 157-158 transdermal drug administration, 155 vitamin D33 and, 152, 157 Epididymis (ep-i-DID-i-mus): Coiled duct that connects the rete testis to the ductus deferens; site of functional maturation of sperm, (Chs 1, 19), 39, 674, 675, 678 Epidural block, 292 Epidural hemorrhage, 292 Epidural space: Space between the spinal dura mater and the walls of the vertebral foramen; contains blood vessels and adipose tissue; a frequent site of injection for regional anesthesia, (Ch 8), 292 Epigastric region, 45 Epiglottis (ep-i-GLOT-is): Blade-shaped flap of tissue, reinforced by cartilage, that is attached to the dorsal and superior surface of the thyroid cartilage; it folds over the entrance to the larynx during swallowing, (Chs 4, 15, 16), 137, 138, 539, 540, 542, 573 Epilepsies, 305 Epimysium (ep-i-MIZ-ē-um): A dense layer of collagen fibers that surrounds a skeletal muscle and is continuous with the tendons/aponeuroses of the muscle and with the perimysium, (Ch 7), 223 Epinephrine adrenal medulla, 381, 391, 392 amino acid derivative, 376 angiotensin II, 650 cardiovascular regulation, 475, 476 endocrine hormone, 377 heart, effects on, 453, 455 sympathetic division of the ANS, 320 Epiphyseal cartilage (ep-i-FIZ-sē-al): Cartilaginous region between the epiphysis and diaphysis of a growing bone, (Chs 6, 20), 177, 198, 205, 720, 728 Epiphyseal closure, 178 Epiphyseal fracture, 181 Epiphyseal line, 178 Epiphyseal plates, 177 Epiphysis (ē-PIF-i-sis): The head of a long bone, (Ch 6), 174, 175 Episiotomy, 724 Epistaxis, 562

Epithalamus, 298, 307 Epithelial tissue basement membrane, 122, 124-125 cell layers, 125-126 cell shapes, 126 characteristics of, 121-122 columnar, 126, 127, 128, 129 cuboidal, 126 defined, 121 epithelial surface, 124 exfoliative cytology, 131 functions of, 123 glandular epithelia, 123, 128, 130-131 intercellular connections, 123-124 locations of, 122 membranes, 140-141 pseudostratified columnar, 128, 129 regeneration of, 145 renewal and repair, 125 simple columnar, 127, 128 simple cuboidal, 127, 128 simple epithelium, 125-126 simple squamous, 126, 127 squamous, 126, 127, 128 stratified columnar, 128 stratified cuboidal, 128 stratified epithelium, 126, 128, 129 stratified squamous, 128, 129 tissue level of organization, 121-131, 140-141 transitional, 128, 129 Epithelium (ep-i-THE-le-um): One of the four primary tissue types; a layer of cells that forms a superficial covering or an internal lining of a body cavity or vessel, (Ch 4), 121 EPO. See Erythropoietin (EPO) Eponychium (nail cuticle), 163, 164 Eponyms, defined, 43 Epstein-Barr virus, 528 Equilibrium, sensation of age-related effects, 368 explained, 337, 358 gravity and linear acceleration, 362-363 pathways for, 363 rotational motion, 361, 362 types of, 362 Equilibrium, state of, 63, 93 Erectile tissue clitoris, 690 penis, 681 bulb of vestibule, 689 Erection of the penis, 681 Erector spinae muscles, 251, 252, 253 Eruption of teeth, 575, 576 Ervthema, 166 Erythroblasts, 418, 419 Erythrocytes (e-RITH-rō-sīts): A red blood cell; an anucleate red blood cell containing large quantities of hemoglobin, (Ch 11), 413, 414. See also Red blood cells (RBCs) Erythropoiesis (e-rith-rō-poy-Ē-sis): The formation of red blood cells, (Ch 11), 418, 420 Erythropoiesis-stimulating hormone, 418 Erythropoietin (EPO) (e-rith-rō-POY-e-tin): Hormone released by kidney tissues exposed to low oxygen concentrations; stimulates erythropoiesis in bone marrow, (Chs 10, 11, 13, 18), 377, 397, 399, 414, 418, 476, 477, 636, 642 Escherichia coli, 654 Esophageal arteries, 486, 487 Esophageal hiatus, 576 Esophageal phase of swallowing, 577 Esophageal veins, 489, 490 Esophagitis, 600 Esophagus: A muscular tube that connects the pharynx to the stomach, (Chs 1, 15, 16), 39, 537, 539, 540, 542, 570, 576 Essential amino acids: Amino acids that cannot be synthesized in the body in adequate amounts and must be obtained from the diet, (Ch 17), 620, 623 Essential fatty acids: Fatty acids that cannot be synthesized in the body in adequate amounts and must be obtained from the diet, (Ch 17), 618 Estradiol, 691, 692, 697

Estrogens (ES-trō-jenz): A class of steroid sex hormones that includes estradiol, (Chs 2, 3, 6, 10, 11, 19, 20) cholesterol, 72 endocrine function, 377, 383, 384, 386, 387, 398 estradiol, 691, 692, 697 female reproduction cycles, 691, 692, 693, 694 female reproductive function, 683, 697 growth, 400 hematocrit, 412 hormonal contraceptives, 698 labor and delivery, 724-725 osteoporosis, 182 placental production, 717 smooth endoplasmic reticulum, 31 source, regulation of, and primary effects, 697 ETC. See Electron transport chain (ETC) Ethmoid bone, 187, 188, 189 Ethmoidal cells (sinuses), 190, 191 Ethnicity, and ABO blood types, 422 Eustachian tube. See Pharyngotympanic tube Evaporation: Movement of molecules from the liquid to the gaseous state, (Chs 2, 17), 60, 61, 627 Eversion (ē-VER-zhun): A turning outward, (Ch 6), 208, 209 Exchange pumps, 96–97 Exchange reactions, 63 Excitable membranes: Membranes that propagate action potentials, a characteristic of muscle cells and nerve cells, (Ch 8), 283 Excretion: The removal of wastes from the blood, tissues, or organs, (Chs 1, 5, 16, 18), 32, 153, 570, 635 Exercise aging and, 266 bone structure, maintaining, 179 cardiovascular system, 477-478 organ systems, effect on, 267 Exergonic reactions, 64 Exfoliative cytology, 131 Exhalation, 549, 550 Exhaustion phase of the general adaptation syndrome, 400, 401 Exocrine cells, 376 Exocrine gland: A gland that secretes onto the body surface or into a passageway connected to the exterior, (Chs 4, 5), 128, 130-131, 152, 162-163 Exocrine pancreas, 393 Exocrine secretions, 123, 128, 130-131 Exocytosis (ek-so-si-To-sis): The ejection of cytoplasmic materials by fusion of a membranous vesicle with the cell membrane, (Ch 3), 92, 99 Exons, 108 Expiration, respiratory, 551 Expiratory center, 558, 559 Expiratory reserve volume, 551, 552 Expulsion stage of labor, 724, 725 Extension: An increase in the angle between two articulating bones; the opposite of flexion, (Chs 6, 7), 199, 206, 207, 246, 257, 259, 261, 262, 263, 266 Extensor carpi radialis muscle, 244, 245, 246, 257, 260, 261 Extensor carpi ulnaris muscle, 245, 257, 260, 261 Extensor digitorum longus muscle, 244, 265, 266 Extensor digitorum muscles, 245, 260, 261, 265, 266 Extensor hallucis longus muscle, 265, 266 Extensor pollicis muscle, 260, 261 Extensor retinaculum, 259, 260, 265 External acoustic meatus: Passageway in the temporal bone that leads to the tympanum, (Chs 6, 9), 187, 188, 358, 359 External anal sphincter, 254, 255, 592, 593 External callus, 180, 181 External carotid artery, 461, 481, 485 External ear: The auricle, external acoustic meatus, and tympanum, (Ch 9), 358, 359 External genitalia, 39, 673, 674, 680-681, 684, 690 External iliac artery, 480, 482, 486 External iliac vein, 483, 488, 489, 490 External intercostal muscle, 252, 253, 549, 550 External jugular veins, 483, 487, 488, 489 External nares. See Nostrils External oblique muscle, 244, 245, 252, 253 External occipital protuberance, 188 External os of the uterus, 687, 688 External respiration, 548, 554

External somatic sensory receptors, 277 External urethral orifice, 653, 654, 680, 681 External urethral sphincter, 254, 255, 653, 654 Extra-embryonic membranes, formation of allantois, 711, 714-715 amnion, 711, 714–715 chorion, 712, 714–715 yolk sac, 711, 714–715 **Extracellular fluid:** All body fluid other than that contained within cells; includes blood plasma and interstitial fluid, (Chs 3, 8, 18), 88, 281, 286, 287, 288, 656-658. See also Interstitial fluid; Plasma Extrapyramidal system, 318. See also Lateral pathways; Medial pathways Extrinsic eye muscles, 345-346 Extrinsic muscles, 246 Extrinsic pathway: Clotting pathway that begins with damage to blood vessels or surrounding tissues and ends with the activation of Factor X, (Ch 11), 428,430 Eyelashes, 345 Eyelids (palpebrae), 345 Eves accessory structures, 344-346 anatomical terms, 44 autonomic nervous system, effects of, 321, 323, 325 chambers of, 346, 347, 350-351 color of, 348 fast fibers, 241 lens, 347, 351-353, 354, 368 muscles of, 345-346 photoreceptors, 349, 350, 351, 353-358, 368 retina, 345, 347, 348-350 rods and cones, 349, 350, 353, 355, 356, 368 sclera and cornea, 345, 347, 348 structure of, 346-353, 354 visual pathways, 357-358

F

Face, 44 Facet (bone marking), 183 Facial artery, 470, 485 Facial bones axial skeleton, 185, 188 inferior nasal conchae, 188, 189, 190 lacrimal bones, 187, 188, 190 mandible, 187, 188, 189, 192 maxillae, 187, 188, 189, 190 nasal bones, 187, 188, 189, 192 nasal complex, 188, 192 palatine bones, 188, 189, 190 vomer, 188, 189, 190 zygomatic bones, 187, 188, 190 Facial nerve (VII), 307, 308, 310, 311, 322, 323, 344 Facial region, 44 Facial vein, 488 Facilitated diffusion: Passive movement of a substance across a plasma membrane by a protein carrier, (Ch 3), 92, 96, 99 Fact memories, 304 Factor VII, 428, 429 Factor VIII, 429 Factor X, 428, 429 FAD (flavine adenine dinucleotide), 612 FADH2, 612, 613, 614, 615, 616 Failure, of birth control method, 698 Falciform ligament, 588, 589 Fallopian tubes. See Uterine tubes False ribs, 195, 196 False vocal cords, 541 Familial hypercholesterolemia, 81, 629, 733 Familial polyposis of the colon, 733 Farsightedness (hyperopia), 354 Fasciae (FASH-ē-ē): Connective tissue fibers, primarily collagenous, that form sheets or bands beneath the skin to attach, stabilize, enclose, and separate muscles and other internal organs, (Ch 7), 244, 245, 262, 263, 264 Fascicle (FAS-i-kl): A small bundle, usually referring to a collection of muscle fibers, (Ch 7), 223

Fast fibers, 240, 241

Fast pain (prickling pain), 337-338 Fat cells. See Adipocytes Fat pads in synovial joints, 205 Fat-soluble vitamins, 599. See also specific vitamins dietary guidelines, 624 Fat substitutes, 70 Fats, 70, 71-72, 79 **Fatty acids:** Hydrocarbon chains ending in a carboxyl group, (Chs 2, 3), 70-71, 79, 80, 93 Feces: Waste products eliminated by the digestive tract at the anus; contains indigestible residue, bacteria, mucus, and epithelial cells, (Chs 16, 18), 570, 656, 659,664 Feet, 44 bones of, 185, 202-203 muscles of, 263, 265, 266 Female pronucleus, 708, 709 Female reproductive cycle hormones body temperature, 693, 694 follicular phase of the ovarian cycle, 691, 692, 693 luteal phase of the ovarian cycle, 692, 693, 694 sources, regulation, and effects of hormones, 697 uterine cycle, 693, 694 Female reproductive system external genitalia, 39, 673, 684, 690 hormones and, 691-697 mammary glands, 39, 690-691 organs, components, and primary functions, 39, 683, 684 ovaries, 39, 321, 323, 377, 384, 386, 398, 673, 683-687 uterine tubes, 39, 683, 687, 688 uterus, 39, 321, 323, 673, 687-689 vagina, 39, 673, 683, 684, 688, 689-690 Female sexual function, 695 Femoral artery, 470, 480, 482, 486 Femoral nerve, 312 Femoral region, 44 Femoral vein, 483, 488 Femur (thighbone), 44, 174, 181, 183, 185, 201–202 Fenestrated glomerular capillaries, 642 Fertilization: Fusion of a secondary oocyte and sperm to form a zygote, (Chs 19, 20) development beginning at, 706 overview of, 707 ovulation and oocyte activation, 707-708 process of, 673, 687, 694 Fetal alcohol syndrome (FAS), 735 Fetal circulation changes at birth, 492-493 heart and great vessels, 492, 493 placental blood supply, 492, 493 **Fetus:** Developmental stage lasting from the start of the third developmental month to delivery, (Chs 13, 19, 20) development of, 706, 720–721 fetal circulation, 492–493 reproductive system, 673 Fever, 511, 512, 514 Fibrillation (fi-bri-LĀ-shun): Uncoordinated contractions of individual muscle cells that impair or prevent normal function, (Ch 12), 455 Fibrillin, 134 Fibrin (FĪ-brin): Insoluble protein fibers that form the basic framework of a blood clot, (Chs 5, 11), 164, 393, 411 Fibrinogen (fī-BRIN-ō-jen): Plasma protein, soluble precursor of the fibrous protein fibrin, (Chs 11, 19), 411, 413, 680 Fibrinolysis (fi-brin-OL-i-sis): The breakdown of the fibrin strands of a blood clot by a proteolytic enzyme, (Ch 11), 430 Fibroblasts (FI-bro-blasts): Cells of connective tissue proper that are responsible for the production of extracellular fibers and the secretion of the organic compounds of the extracellular matrix, (Chs 4, 5), 133, 134, 164, 165 Fibrocartilage: Cartilage containing an abundance of collagen fibers; found around the edges of joints, in the intervertebral discs, and the menisci of the knee (Chs 4, 6), 137, 138, 205, 209

Fibrocytes, 133

- Fibrosis, 145
- Fibrous capsule surrounding the kidneys, 636, 637

Fibrous joints, 204

Fibrous layer of the eye, 346, 347, 348

Fibrous protein, 74, 75 Fibrous skeleton (cardiac skeleton), 440, 442, 443 Fibrous tissue, 144 Fibula: The lateral, relatively small bone of the leg, (Ch 6), 185,202 Fibular arteries, 482, 486 Fibular collateral ligament, 213 Fibular vein, 483, 488 Fibularis brevis muscle, 265, 266 Fibularis longus muscle, 244, 265, 266 Fibularis (peroneus) muscles, 245, 263 "Fight or flight" response, 305, 319, 401 Filling time of ventricles, 452 Filtrate: Fluid produced by filtration at a glomerulus in the kidney, (Ch 18), 638, 640, 645, 648 Filtration: Movement of a fluid across a membrane whose pores restrict the passage of solutes on the basis of size, (Chs 13, 18), 468-469, 638, 640, 643, 644-645 Filtration membrane of the nephron capillaries, 642 Filtration pressure: Hydrostatic pressure responsible for the filtration process, (Ch 18), 644 **Fimbriae** (FIM-brē-ē): A fringe; used to describe the fingerlike processes that surround the entrance to the uterine tube, (Ch 19), 684, 687 Fine touch and pressure receptors, 338 Fingerprints, 153–154 Fingers, 44, 185, 199-200, 259, 260, 261 First-degree burns, 166 First heart sound, 451, 452 First messengers, 378, 379 First trimester of pregnancy cleavage and blastocyst formation, 709, 710 embryogenesis, 718, 719, 720-721 embryological development, 722 implantation, 709-712 overview of, 709 placentation, 712-713, 715 Fissure: An elongate groove or opening, (Chs 6, 8), 183, 300 Fixator muscles, 246 Fixed macrophages, 133, 134, 425 Fixed ribosomes, 89, 101 Flagellum/flagella (fla-JEL-uh): An organelle structurally similar to a motile cilium but used to propel a cell through a fluid; found on sperm, (Chs 3, 19), 101, 678 Flat bones, 174 Flatus, 595 Flavine adenine dinucleotide (FAD), 612 Flavor, 344 Flexion (FLEK-shun): A movement that decreases the angle between two articulating bones; the opposite of extension, (Chs 6, 7), 199, 206, 207, 246, 251, 257, 259, 261, 262, 263, 266 Flexor carpi radialis muscle, 244, 246, 257, 260, 261 Flexor carpi ulnaris muscle, 244, 245, 257, 259, 260 Flexor digitorum longus muscle, 265, 266 Flexor digitorum muscles, 244, 260, 261, 265, 266 Flexor hallucis longus muscle, 265, 266 Flexor reflex: A reflex contraction of the flexor muscles of a limb in response to a painful stimulus, (Ch 8), 314, 315 Flexor retinaculum, 244, 259, 260 Flexure: A bending. Floating kidney, 637 Floating ribs, 195, 196 Fluid and electrolyte balance, 166, 656, 658-660 Fluid compartments, defined, 657–658 Fluid connective tissues, 132, 136-137 Fluid shifts, defined, 659 Focal calcification in arteriosclerosis, 463 Focal distance, 352 Focal point, 352 Folate (folic acid, vitamin B9), 623, 625 Follicle (FOL-i-kl): A small secretory sac or gland, (Ch 10), 387, 388, 398. See also specific types of follicles Follicle cells oocytes, 683, 686 ovaries, 387, 398 Follicle-stimulating hormone (FSH): A hormone secreted by the anterior lobe of the pituitary gland; stimulates oogenesis (female) and spermatogenesis

(male), (Chs 10, 19, 20)

endocrine hormone, 377 endocrine system, 383, 386, 387 female reproduction cycles, 691, 692, 693, 694 male reproductive function, 682, 683 puberty, 728 source, regulation of, and primary effects, 697 Follicular fluid, 685 Follicular (preovulatory) phase of the ovarian cycle, 686, 687, 691, 692, 693 Fontanelle (fon-tuh-NEL): A relatively soft, flexible, fibrous region between two flat bones in the developing skull, (Ch 6), 191, 192 Food. See also Nutrition energy content of, 626 five basic food groups, 622-623 Foot processes (pedicels) of the nephron podocytes, 641 Foramen (bone marking), 183 Foramen magnum, 186, 188 Foramen ovale, 440, 441, 492, 493 Force, and muscle performance, 240 Forced breathing, 551 Forearm: Distal portion of the arm between the elbow and wrist, (Chs 1, 6, 7), 44 bones of, 185, 198, 199 muscles of, 244-245, 257, 260, 261 Foreskin, 680, 681 Fornix brain, 296, 305 vagina, 684, 689 Fossa: A shallow depression or furrow in the surface of a bone, (Ch 6), 183 Fossa ovalis, 440, 441, 492, 493 Fourth heart sound, 451, 452, 467 Fourth ventricle: An elongate ventricle of the pons and upper portion of the medulla oblongata of the brain; the roof contains a region of choroid plexus, (Ch 8), 298 Fovea (Fō-vē-uh) centralis: Portion of the retina within the macula providing the sharpest vision, with the highest concentration of cones, (Ch 9), 349, 350 Fractionated blood, 411 Fracture: A break or crack in a bone, (Ch 6), 180-181, 182 Fracture hematoma, 180 Fragile-X syndrome, 734 Frank-Starling principle, 453, 477 Fraternal twins. See Dizygotic twins Freckles, 156 Free fatty acids, 618-619 Free macrophages, 133, 425 Free nerve endings, 336, 337, 338, 339, 340 Free radicals, 103, 393 Free ribosomes, 88-89, 101 Freely permeable plasma membranes, 91 Frenulum of tongue: An epithelial fold that attaches the inferior surface of the tongue to the floor of the mouth, (Ch 16), 573 Frequency of sound, 363, 365 Frontal bone, 186, 187, 188, 189 Frontal lobe, 296, 300 Frontal plane: A sectional plane that divides the body into anterior and posterior portions; also called coronal plane, (Ch 1), 44, 47 Frontal region, 44 Frontal sinuses, 186, 189, 191, 538, 539 Frontalis muscle, 244, 248, 249 Fructose: A hexose (simple sugar containing six carbons) found in foods and in semen, (Chs 2, 19), 69, 70, 680 Fruits, dietary guidelines for, 622, 623 FSH. See Follicle-stimulating hormone (FSH) Functional layer of the endometrium, 688 Functional residual capacity, 552 Functions of living things, 32-33 Fundus (FUN-dus): The base of an organ, (Chs 16, 19) stomach, 577, 578 uterus, 687, 688

G

G cells, 580, 581 G1 phase of interphase, 112 G2 phase of interphase, 112

G proteins, 378, 379 Galactosemia, 81 Gallbladder: Pear-shaped reservoir for the bile secreted by the liver, (Chs 1, 8, 16) anatomy, 591-592 autonomic nervous system, 321, 323 digestive system component, 570 functions, 592 gallstones, 592, 600 location, 39, 45, 588, 591–592 Gallstones, 592, 600 Gametes (GAM-ēts): Reproductive cells (sperm or oocytes) that contain half the normal chromosome complement, (Ch 19), 673 Gametogenesis (ga-mē-tō-JEN-e-sis): The formation of a gamete. Gamma aminobutyric acid (GABA) (GAM-ma a-MĒ-n ō-bū-TĒR-ik): A neurotransmitter of the CNS whose effects are usually inhibitory, (Ch 8), 290 Ganglion cells of the eye, 349, 350 Ganglion/ganglia: A collection of nerve cell bodies outside the CNS, (Chs 8, 9), 280, 309, 349, 350 Ganglionic neurons: An autonomic neuron whose cell body is in a peripheral ganglion and whose axon is a postganglionic fiber, (Ch 8) autonomic nervous system, 319 parasympathetic division, 322, 323 sympathetic division, 320, 321 Gap junctions: Connections between cells that permit the movement of ions and the transfer of graded or propagated change in the membrane potential from cell to cell (Ch 4), 123, 124 Gas exchange alveolar air versus atmospheric air, 553 partial pressures in the pulmonary and systemic circuits, 553 respiration processes, 548 Gastrectomy, 581 Gastric activity, regulation of, 579-581 Gastric (stomach) cancer, 581 Gastric glands: Tubular glands of the stomach whose cells produce acid, enzymes, intrinsic factor, and hormones, (Ch 16), 578, 579, 580 Gastric inhibitory peptide, 581, 585, 586 Gastric juice, 579 Gastric lipase, 579 Gastric phase of gastric secretion, 579-581 Gastric pits, 578, 579 Gastric ulcers, 581 Gastric veins, 491 Gastric wall, 578, 579 Gastrin (GAS-trin): Hormone produced by endocrine cells of the stomach, when exposed to mechanical stimuli or neural (vagal) stimulation, and of the duodenum, when exposed to chyme containing undigested proteins, (Ch 16), 581, 585, 586 Gastritis, 581 Gastro-epiploic veins, 491 Gastrocnemius muscle, 231, 244, 245, 246, 263, 265, 266 Gastroenteric reflex, 583 Gastroenteritis, 600 Gastroenterology, 600 Gastroileal reflex, 583 Gastrointestinal (GI) tract, defined, 569. See also Digestive system Gastrulation (gas-troo-LĀ-shun): The movement of cells of the inner cell mass that creates the three germ layers of the embryo, (Ch 20), 711, 712 Gated channels, 281, 282–283, 284, 286 GCs. See Glucocorticoids (GCs) Gene: A portion of a DNA nucleotide chain that functions as a hereditary unit, and is found at a particular location on a specific chromosome, and codes for a specific protein, (Chs 3, 14, 20), 107, 528, 728-734 Gene therapy, 732 General adaptation syndrome, 400, 401 General and special senses, 335-373 aging, effect of, 368-369 chemical receptors, 340-341 equilibrium and hearing, 337, 358–368, 369. See also Ear eye structures and vision, 337, 344–358, 368. See also Eyes

general sensory receptors and stimuli for, 337-341

gustation, 337, 343-344, 368 olfaction. See Olfaction pain, 337-338 prenatal and early postnatal development, 720 sensory receptor connection to nervous system, 336-337 temperature, 338 touch, pressure and position receptors, 337, 338-341 Genetic code, 107, 109 Genetic engineering, 528 Genetic stutter, 734 Genetics: The study of heredity and genetic variations, (Chs 17, 20) cholesterol, 617 chromosomal abnormalities and genetic analysis, 734 defined, 706 genetic disorders, 730-732, 733, 734 genotype, 728 human genome, 732 inheritance, patterns of, 729-732 phenotype, 728-729 Genital herpes, 699 Genitalia, external female, 39, 673, 684, 690 male, 674, 680-681 reproductive system component, 39, 673 Genome, defined, 732 $\textbf{Genotype}~(J\bar{E}N\text{-}\bar{o}\text{-}t\bar{i}p)\text{:}~The~genetic~complement~of~a$ particular individual, (Ch 20), 728 Gentamicin, 366 Geriatrics, 735 Germ layers developmental contributions to the body, 713 formation of, 711, 712, 714-715 Germinal centers: Pale regions in the interior of lymphoid tissues or nodules, where cell divisions are occurring, (Ch 14), 508 **Gestation** (jes-TA-shun): The period of intrauterine development, (Ch 20), 709. *See also* Pregnancy GFR. See Glomerular filtration rate (GFR) GH. See Growth hormone (GH) "Ghost" image, 356 Gigantism, 402 Gingivae, 573 Gingivitis, 600 Gland: Cells that produce exocrine or endocrine secretions, (Ch 4), 121. See also specific types of glands Glandular epithelium, 123, 128, 130-131 Glans of the clitoris, 691 Glans penis: Expanded tip of the penis that surrounds the urethral opening; continuous with the corpus spongiosum, (Ch 19), 674, 680, 681 Glaucoma: eye disorder characterized by rising intraocular pressures due to inadequate drainage of aqueous humor at the canal of Schlemm, (Ch 9), 351 Glenoid fossa: A rounded depression that forms the articular surface of the scapula at the shoulder joint, (Ch 6), 197 ${\bf Glial\ cells}\ ({\rm GL}\bar{{\rm E}}\mbox{-}{\rm al})$: Supporting cells in the neural tissue of the CNS and PNS, (Ch 8), 275. See also Neuroglia Global aphasia, 304 Globular proteins: Proteins whose tertiary structure makes them rounded and compact, (Ch 2), 74, 75 Globulins, 411, 413 Globus pallidus, 304 Glomerular capillaries, 638, 641 Glomerular (Bowman's) capsule, 638, 641 Glomerular filtration rate (GFR): The rate of filtrate formation at the glomerulus, (Chs 18, 20) aldosterone, 650, 651-652 antidiuretic hormone, 650, 651 atrial natriuretic peptide, 650, 651, 652 autoregulation of, 650 average rate, 645 described, 645 hormonal control of, 650-652 maternal, during pregnancy, 719 renin-angiotensin-aldosterone system, 650-652 sympathetic division of the ANS, 650, 652 Glomerulonephritis, 665 Glomerulus (glo-MER-ū-lus): A knot of capillaries that projects into the enlarged, proximal end of a nephron; the site of filtration, the first step in the production of urine, (Ch 18), 638, 640, 641, 644-645, 647

Glomus, 638 Glossopharyngeal nerve (glos-ō-fah-RIN-jē-al): Cranial nerve IX, (Chs 8, 9, 12, 15), 307, 308, 310, 311, 322, 323, 341, 344, 454, 559, 560 Glottis (GLOT-is): The passage from the pharynx to the larynx, (Ch 15), 540, 541, 542 Glucagon (GLOO-ka-gon): Hormone secreted by the alpha cells of the pancreatic islets; increases blood glucose concentrations, (Chs 10, 12, 16), 377, 393, 394, 395, 455 587 Glucocorticoids (GCs): Hormones secreted by the adrenal cortex to modify glucose metabolism; cortisol, cortisone, and corticosterone are important examples, (Chs 10, 14) Cushing disease, 402 endocrine system, 383, 384, 386, 387, 391, 392 general adaptation syndrome, 401 immune response, 527 Gluconeogenesis (gloo-kō-nē-ō-JEN-e-sis): The synthesis of glucose from noncarbohydrate precursors (e.g., lactate, glycerol, or some amino acids), (Ch 17), 614-616, 621 Glucose (GLOO-kos): A six-carbon sugar, C6H12O6, the preferred energy source for most cells and normally the only energy source for neurons, (Chs 2, 17), 66, 68, 69, 70, 611, 644 Glucose levels, hormonal regulation of, 393-394, 395, 396 Glucose-sparing effects, 385, 392, 399 Gluteal muscles, 244, 245, 253, 259, 262, 263 Gluteal nerve, 312 Gluteal region, 44 Gluteus maximus muscle, 245, 253, 254, 259, 262, 263 Gluteus medius muscle, 244, 245, 253, 262, 263 Gluteus minimus muscle, 262, 263 Glycerides: Lipids composed of glycerol bound to one to three fatty acids, (Ch 16), 596. See also Triglyceride Glycerol, 71, 79 **Glycogen** (GLĪ-kō-jen): A polysaccharide that represents an important energy reserve: a polymer consisting of a long chain of glucose molecules, (Chs 2, 17), 69, 70, 616 Glycolipids, 91 Glycolysis (glī-KOL-i-sis): The anaerobic cytosolic breakdown of glucose into two 3-carbon molecules of pyruvate, with a net gain of two ATP molecules, (Chs 3, 7, 17) carbohydrate metabolism, 610-612, 614, 621 cell function, 103 energy yield of, 615 muscular system, 238-239 Glycoproteins, 91 Glycosuria, 396, 665 GnRH. See Gonadotropin-releasing hormone (GnRH) Goblet cell. See Mucous cell Goiter, 388, 402 Golgi apparatus (GŌL-jē): Cellular organelle consisting of a series of membranous plates that gives rise to lysosomes and secretory vesicles, (Ch 3), 88-89, 102, 105 Golgi tendon organs, 340 Gomphosis, 204 Gonadal arteries, 482, 485, 486 Gonadal veins, 483, 488, 489, 490 Gonadotropin-releasing hormone (GnRH) (go-nadō-TRŌ-pin): Hypothalamic releasing hormone that causes the secretion of FSH and LH by the anterior lobe of the pituitary gland, (Chs 10, 19, 20) female reproductive cycle, 691, 692, 693, 694 hypothalamus, 383, 384 male reproductive function, 682, 683 puberty, 727 source, regulation of, and primary effects, 697 Gonadotropins: FSH and LH, hormones that stimulate gamete development and sex hormone secretion, (Ch 10), 383, 387. See also specific hormones Gonads (GO-nadz) (testes): Organs that produce gametes and sex hormones, (Chs 10, 19), 377, 383, 397-398, 673 Gonorrhea, 654, 688 'Goose bumps," 161 Gout, 622 Graafian follicle, 686, 687 Gracilis muscle, 244, 245, 247, 259, 263, 264

Graded (local) potentials, 283 Graft-versus-host disease (GVH), 528 Grains, dietary guidelines for, 622, 623 Granulation tissue, 164, 165, 166 Granulocytes (GRAN-ū-lō-sīts): White blood cells containing granules visible with the light microscope; includes eosinophils, basophils, and neutrophils; also called *granular leukocytes*, (Ch 11), 423 Graves disease, 526 Gravity, 358, 362, 363 Gray commissures, 295, 296 Gray matter: Areas in the CNS dominated by neuron bodies, glial cells, and unmyelinated axons, (Ch 8) cerebrum, 300 oligodendrocytes, 278, 279 spinal cord, 294-296 Great cardiac vein, 444 Great saphenous vein, 483, 488 Great vessels, fetal, 492, 493 Great vessels in the mediastinum, 435 Greater curvature of the stomach, 578, 579 Greater omentum: A large fold of the dorsal mesentery of the stomach that hangs in front of the intestines, (Ch 16), 578, 579 Greater trochanter of the femur, 201, 202 Greater tubercle of the humerus, 198 Greater vestibular glands, 690 Green cones, 353 Greenstick fracture, 181 Groin: The inguinal region, (Ch 1), 44, 45 Gross (macroscopic) anatomy: The study of the structural features of the human body without the aid of a microscope, (Ch 1), 33 Ground substance of connective tissue, 132, 134 Growth function of living things, 32 hormones and, 399-400 Growth hormone (GH): Anterior pituitary lobe hormone that stimulates tissue growth and anabolism when nutrients are abundant and restricts tissue glucose dependence when nutrients are in short supply, (Ch 10), 376, 377, 384, 386, 387, 399, 402 Growth hormone-inhibiting hormone (GH-IH), 384, 385 Growth hormone-releasing hormone (GH-RH), 384, 385 Guanine: One of the nitrogenous bases found in nucleic acids, (Chs 2, 3), 77, 78, 107, 108, 109, 110 Guanosine triphosphate (GTP), 380, 612 **Gustation** (GUS-tā-shun): Sense of taste, (Ch 9), 337, 343-344, 368 Gustatory cortex of the frontal lobe, 300, 301 Gustatory (taste) receptors, 343-344 Gynecology, 699 Gyrus (JĪ-rus): A prominent fold or ridge of neural cortex on the surfaces of the cerebral hemispheres, (Ch 8), 300 Н H bands, 225, 226, 227

Hair: A keratinous strand produced by epithelial cells of the hair follicle, (Chs 1, 5)
aging, effects of, 167
color of, 161
functions, 161
growth cycle, 160
integumentary system component, 37
as integumentary system component, 152
loss of, 161
matrix, 160
papilla, 160
root, 160
shaft, 160
structure of, 159-161
Hair cells: Sensory cells of the internal ear. (Ch 9), 358

- Hair cells: Sensory cells of the internal ear, (Ch 9), 358, 361–362, 363, 364, 366, 367
- Hair follicles: An accessory structure of the integument; a tube lined by a stratified squamous epithelium that begins at the surface of the skin and ends at the hair papilla, (Ch 5), 152, 159–160, 162

Hair root: A thickened, conical structure consisting of a connective tissue papilla and the overlying matrix; a layer of epithelial cells that produces the hair shaft, (Ch 5), 160 Hallux: The great toe, or big toe, (Chs 1, 6), 44, 203 Hamate bone, 199, 200 Hamstring muscles, 261, 262, 264 Hands anatomical terms, 44 bones of, 199-200 fast fibers, 241 muscles of, 259, 260, 261 Hansen's disease (leprosy), 326 Haploid (HAP-loyd): Possessing half the normal number of chromosomes; a characteristic of gametes, (Ch 19), 677 Hard keratin, 160 Hard palate: The bony roof of the oral cavity, formed by the maxillary and palatine bones, (Chs 6, 15, 16), 189, 190, 538, 539, 573 Hashimoto's disease, 403 Hatching of the blastocyst, 709, 710 Haustra of the colon, 593, 594 Haversian canal, 175 Haversian system, 175 hCG. See Human chorionic gonadotropin (hCG) HDL. See High-density lipoprotein (HDL) Head anatomical terms, 44 arteries of, 481, 482, 484-485 muscles of, 244-245, 248-250 veins of, 483, 487, 488 Head (bone marking), 183 Head fold, 714, 717 Head of the humerus, 198 Head of the radius, 199 Head (lateral angle) of the scapula, 197 Head of a sperm, 678 Hearing aging, effect of, 369 auditory pathways, 366-367 auditory sensitivity, 367-368 cochlear duct, 364 deficits, 366, 369 explained, 337, 358, 363 process, 365-366 sound, 363 Heart, 434-458. See also Cardiovascular system aging, effect of, 494 anatomical base, 48 autonomic nervous system, 321, 323, 325, 453-454 blood supply, 441, 444 cardiac cycle, 450–451 cardiac (fibrous) skeleton, 440, 442, 443 cardiovascular system, role in, 435 conducting system, 446-448 contractile cells, 445-446 electrocardiogram, 448-449 endocrine function, 377, 397 fetal circulation, 492 heart dynamics, 452-454 heart rate, 452-454, 726 heart sounds, 451-452 heart wall, 436-437, 439 hormones, effect of, 455 internal anatomy and organization, 440-444 location of, 38, 435-436, 437 surface anatomy, 436, 438 valves, 440, 441, 442-443 Heart attack, 444 Heart block, 455 Heart dynamics, 452-454 Heart failure, 451 Heart murmur, 442, 467 Heart rate, 452-454, 726 Heart sounds, 451-452 Heart valves, 440, 441, 442-443 Heart wall, 436-437, 439 Heat chemical reactions, product of, 61 heat transfer, mechanisms of, 627-628 water, ability to absorb and retain, 65 Heat exhaustion, 629

Heat-gain center of the hypothalamus, 628 Heat loss muscular activity, during, 240 promoting, 628 Heat-loss center of the hypothalamus, 628 Heat stroke, 629 Heavy chains in antibodies, 521 Heel bone, 44, 203 Heimlich maneuver (abdominal thrust), 542 Helicobacter pylori, 581 Helper T cells: Lymphocytes whose secretions and other activities coordinate the cellular and humoral immune responses, (Ch 14), 505, 518-519, 520, 523, 524, 525, 526 Hematocrit (hē-MA-tō-krit): Percentage of the volume of whole blood contributed by red blood cells, (Ch 11), 412, 414, 430 Hematological regulation by the liver, 590 Hematologists, 418 Hematology, 430 Hematoma: A tumor or swelling filled with blood, (Ch 6), 180 Hematopoietic stem cells (HSCs): See hemocytoblasts Hematuria, 430, 665 Heme (hēm): A special organic compound containing a central iron atom that can reversibly bind oxygen molecules; a component of the hemoglobin molecule, (Ch 11), 415 Hemi-azygos vein, 489, 490 Hemidesmosomes, 123, 124 Hemispheric lateralization, 302-303 Hemocytoblasts: Stem cells whose divisions produce each of the various populations of blood cells; also called hematopoietic stem cells (HSCs), (Chs 11, 14), 418, 419, 506, 107. Hemodialysis 652 Hemoglobin (HE-mo-glo-bin): Protein composed of four globular subunits, each bound to a single molecule of heme; gives red blood cells the ability to transport oxygen in the blood, (Chs 2, 11, 15) abnormal, 416, 429 carbon dioxide binding to, 556 defined, 414-415 oxygen binding to, 555 recycling, 415-418 structure and function, 414-415 structure of, 74, 75 Hemoglobinuria, 416 Hemolysis: Breakdown (lysis) of red blood cells, (Chs 3, 11), 94, 416, 417, 422 Hemolytic anemia, 416 Hemolytic disease of the newborn, 421 Hemolyze, defined, 416, 417, 422 Hemophilia, 429, 731, 732, 733 Hemopoiesis (hē-mō-poy-Ē-sis): Blood cell formation and differentiation, (Ch 11), 412 Hemorrhage: Blood loss, (Ch 13), 478 Hemorrhoids, 465, 596, 599 Hemostasis abnormal, 429 clot retraction and removal, 430 clotting process, 428-430 defined, 427 phases of, 427-428 Hemothorax, 547 Heparin, 133, 144, 425, 513, 514, 524, 527 Hepatic artery proper, 485, 589, 590 Hepatic duct: Duct carrying bile away from the liver lobes and toward the union with the cystic duct, (Ch 16), 589, 590, 591 Hepatic portal system, 489, 491 Hepatic portal vein: Vessel that carries blood between the intestinal capillaries and the sinusoids of the liver, (Chs 13, 16), 491, 589, 590, 591 Hepatic veins, 483, 488, 489, 490, 491 Hepatitis, 589 Hepatocyte (hep-A-tō-sīt): A liver cell, (Ch 16), 588, 589 Hepatopancreatic sphincter, 591, 592 Hering-Breuer reflexes, 559 Hernias, 250 Herniated disc, 209 Hertz (Hz), 365

Heat gain, promoting, 628

Heterologous marrow transplant, 430 Heterozygous (het-er-ō-ZĪ-gus): Possessing two different alleles at corresponding locations on a chromosome pair; a heterozygous individual's phenotype may be determined by one or both alleles, (Ch 20), 729 Hexose: A six-carbon simple sugar. Hiatal (diaphragmatic) hernia, 250, 576 **High-density lipoprotein (HDL):** A lipoprotein with a relatively small lipid content, thought to be responsible for the movement of cholesterol from peripheral tissues to the liver, (Ch 17), 618, 619 High-energy bonds, 78 High-energy compounds, 78, 79, 80 Higher centers, 280, 561 Hilum (HI-lum): A localized region where blood vessels, lymphatic vessels, nerves, and/or other anatomical structures are attached to an organ, (Ch 18), 636,637 Hilum of the spleen, 510 Hinge joints, 208, 210 Hip fractures of, 212–213 joint movement and structure, 212-213 Hippocampus limbic system, 305 memory storage and consolidation, 304 neural stem cells, 276 Histamine (HIS-tuh-mēn): Chemical released by stimulated mast cells or basophils to initiate or enhance inflammation, (Chs 4, 11, 14), 133, 144, 425, 426, 513, 514, 522, 524, 527 Histidine, 620 Histology (his-TOL-o-jē): The study of tissues, (Chs 1, 4, 16), 33, 121 Histones, 106, 107 HIV (human immunodeficiency virus), 523 Hives, 527 Hodgkin's lymphoma, 528 Holocrine (HOL-ō-krin): Form of exocrine secretion where the secretory cell becomes swollen with vesicles and then ruptures, (Ch 4), 130, 131 Homeostasis (hō-mē-ō-STĀ-sis): The maintenance of a relatively constant internal environment, (Chs 1, 3, 4, 10, 14, 18) cardiovascular adaptation, 475-477 defined, 36 disease and, 36 endocrine system, 375 exchange pumps, 96-97 process of, 36, 40 tissue repair and regeneration, 144–145 urinary system function, 635, 636, 656-658 Homeostatic regulation. See also Negative feedback; Positive feedback described, 36, 40 positive feedback, 723 Homologous chromosomes (hō-MOL-o-gus): the members of a chromosome pair, each containing the same gene loci, (Ch 20), 729 Homozygous (hō-mō-ZĪ-gus): Having the same allele for a particular character on two homologous chromosomes, (Ch 20), 729 Horizontal cells, 349, 350 Horizontal (transverse) plane, 45, 47 Hormonal contraceptives, 698 Hormonal stimuli, 380 Hormone: A compound secreted by one cell that travels through the bloodstream to affect the activities of cells in another portion of the body, (Chs 2, 3, 4, 10, 12, 13, 14, 18, 19). See also specific hormones cardiovascular regulation, 475-477 chemical structure of, 376 cholesterol, 72 defined, 376 endocrine activity, control of, 380-381 epithelial secretions, 123, 128 exocytosis, 98 female reproductive cycle, 691-694, 697 heart contractility, 455 homeostasis, maintaining, 376 hormonal action, mechanisms of, 377-380 hormonal contraceptives, 698 immune system, 524

interaction of, 398-400 kidney function, 650-652 male reproductive function, 681-683, 697 proteins, 73 secretion and distribution of, 380 Hormone-receptor complex, 379, 380 Hormone replacement therapy (HRT), 696 Horns of spinal cord gray matter, 296 "Hot flashes," 696 Human chorionic gonadotropin (hCG): Placental hormone that maintains the corpus luteum for the first three months of pregnancy, (Ch 20), 716-717 Human genome, 732 Human growth hormone (hGH). See Growth hormone (GH) Human immunodeficiency virus (HIV), 523 Human physiology, 34 Human placental lactogen (hPL): Placental hormone that stimulates the functional development of the mammary glands, (Ch 20), 717 Humerus, 174, 183, 185, 198 Humoral immunity, (Ch 14), 515. See also Antibodymediated immunity Humoral stimuli for endocrine activity, 380 Huntington's disease: An inherited disease marked by a progressive deterioration of mental abilities and by motor disturbances, (Ch 8, 20), 326, 731, 733 Hyaline cartilage, 137, 138 Hyaluronidase, 707 Hydrochloric acid, 579 Hydrocortisone (cortisol), 391, 392 Hydrogen, 57, 60 Hydrogen bond: Weak interaction between the hydrogen atom on one molecule and a negatively charged portion of another molecule, (Ch 2), 60-61 Hydrogen ions, 66-67 Hydrolysis (hī-DROL-i-sis): The breakage of a chemical bond through the addition of a water molecule: the reverse of dehydration synthesis, (Chs 2, 16), 63.596 Hydrophilic heads in membrane lipids, 90 Hydrophobic tails in membrane lipids, 90 Hydrostatic pressure: Fluid pressure, (Chs 3, 13) blood flow, 466, 468, 469 filtration, 468-469 osmosis, 94, 469 Hydroxide ions, 66-67 Hydroxyl ion (hi-DROK-sil): OH-, (Ch 2), 70 Hymen, 689, 690 Hyoid bone, 185, 186, 191 Hypercalcemia, 453 Hypercapnia, 562, 663 Hyperextension, 206, 207 Hyperglycemia, 396 Hyperkalemia, 453 Hyperkeratosis, 156 Hypernatremia, 665 Hyperopia (farsightedness), 354 Hyperpolarization of the plasma membrane, 283 Hypertension, 494 Hyperthyroidism, 403 Hypertonic: When comparing two solutions, used to refer to the solution with the higher solute or osmotic concentration, (Ch 3), 94, 95 Hypertrophy (hī-PER-trō-fē): Increase in the size of tissue without cell division, (Ch 7), 241 Hyperuricemia, 622 **Hyperventilation** (hī-per-ven-ti-LĀ-shun): A rate of respiration sufficient to reduce plasma Pco2 to levels below normal, (Ch 18), 663, 664 Hypervitaminosis, 624 Hypervolemic, 494 Hypocalcemia, 453 Hypocalcemic tetany, 403 Hypocapnia, 562, 663 Hypochondriac regions (left and right), 45 Hypodermic needle: A needle inserted through the skin to introduce drugs into the subcutaneous layer, (Ch 5), 159 Hypodermis: The layer of loose connective tissue and fat cells below the dermis; also called the subcutaneous laver, (Ch 5), 152, 159 Hypogastric region, 45

Hypoglossal nerve (XII), 307, 308, 310, 311 Hypogonadism, 383 Hypokalemia, 453 Hyponatremia, 665 Hypophyseal portal system (hī-pō-FIZ-ē-al): Network of vessels that carry blood from capillaries in the hypothalamus to capillaries in the anterior lobe of the pituitary gland, (Ch 10), 382, 383 Hypophysectomy, 403 Hypophysis (hī-POF-i-sis): The pituitary gland, (Ch 10), 381. See also Pituitary gland Hypotension, 478 Hypothalamus: The floor of the diencephalon; region of the brain containing centers involved with the subconscious regulation of visceral functions, emotions, drives, and the coordination of neural and endocrine functions, (Chs 8, 10), 296, 297, 307, 377, 380-381, 382, 383 Hypothermia, 628 Hypotonic: When comparing two solutions, used to refer

Hypotonic, when comparing two solutions, used to refere to the one with the lower osmotic concentration, (Ch 3), 94, 95
Hypoventilation, 663, 664
Hypovitaminosis, 624
Hypovolemic, 494
Hypovaia (hī-POKS-ē-uh): Low tissue oxygen concentrations, (Chs 11, 15), 418, 548
Hysterectomy, 699

I bands, 225, 226, 227 ICF. See Intracellular fluid (ICF) Identical twins. See Monozygotic twins IgG. See Immunoglobulin G (IgG) Ileocecal valve (il-ē-ō-SĒ-kal): A fold of mucous membrane that guards the connection between the ileum and the cecum, (Ch 16), 583, 592, 593 Ileum (IL-ē-um): The distal 2.5 m of the small intestine, (Ch 16), 582, 583 Iliac crest, 201 Iliac veins, 483, 488, 489, 490 Iliacus muscle, 259, 262, 263, 264 Iliocostalis muscle, 251 Iliopsoas group of muscles, 244, 259, 262, 263, 264 Iliotibial tract, 244, 245 Ilium (IL-ē-um): The largest of the three bones whose fusion creates a hip (coxal) bone, (Ch 6), 200 Image formation by the lens of the eye, 352-353 Imaging techniques CT scans, 50 nuclear imaging, 81 x-rays, 50 Immature delivery, 724 Immediate hypersensitivity, 527 Immune complex disorders, 526 Immune response abnormal, 526-527 ABO blood types, 420–421 aging, effect of, 527 defined, 502 manipulating, 528 stress and, 527, 528 thymosins, 397 Immune surveillance, 506, 507, 511, 512, 513, 523, 527 Immune system defined, 502 integumentary system, and aging, 167 Immunity: The ability to resist infection and disease, (Ch 14), 502. See also Adaptive (specific) immunity/ defenses, Innate (nonspecific) immunity/defenses **Immunization:** Production of immunity by the deliberate exposure to antigens under conditions that prevent the development of illness but stimulate the production of memory B cells, (Ch 14), 516, 526 Immunodeficiency: An inability to produce normal numbers and types of antibodies and sensitized lymphocytes, (Ch 14), 523, 526 Immunoglobulin A (IgA), 521, 522, 574 Immunoglobulin D (IgD), 521, 522

Immunoglobulin E (IgE), 521, 522, 527

Immunoglobulin G (IgG) (i-mū-nō-GLOB-u-lin): (Ch 14), 521, 522, 523 Immunoglobulin M (IgM), 521, 522 Immunoglobulins. See also Antibody classes of, 521, 522 described, 506 Immunological competence, 526 Immunological escape, 513 Immunology, 528 Immunosuppression, 528 Impacted teeth, 576 Impermeable plasma membranes, 91 Implantation (im-plan-TĀ-shun): The erosion of a blastocyst into the uterine wall, (Ch 20), 709-712, 729 Impotence, 695 In situ, defined, 691 In vitro fertilization, 735 Incisions, 164 Incisors, 575, 576 Inclusions: Aggregations of insoluble pigments, nutrients, or other materials in the cytoplasm, (Ch 3), 99 Incomplete proteins, 623 Incomplete tetanus in muscle stimulation, 235 Incontinence, urinary, 655, 664 Incus (IN-kus) (anvil): The central auditory ossicle, situated between the malleus and the stapes in the middle ear cavity, (Ch 9), 359, 360 Induced (elective) abortion, 728 Inert, defined, 58 Infants developmental period, 722, 726-727 skulls of, 191, 192 Infarct: An area of dead cells resulting from an interruption of blood flow, (Ch 12), 444 Infection: Invasion and colonization of body tissues by pathogens, (Chs 4, 5), 144, 146, 167 Inferior angle of the scapula, 197 Inferior articular processes of the vertebrae, 192, 209, 211 Inferior colliculi, 307, 366 Inferior direction, 46 Inferior lobe of the left lung, 546, 547 Inferior lobe of the right lung, 546, 547 Inferior mesenteric artery, 482, 485, 486 Inferior mesenteric vein, 491 Inferior nasal conchae, 188, 189, 190, 538, 539 Inferior oblique muscle, 345, 346 Inferior portion in transverse section, 45 Inferior rectus muscle, 345, 346 Inferior vena cava: The vein that carries blood from the parts of the body below the heart to the right atrium, (Chs 12, 13), 438, 440, 441, 480, 483, 488, 489,490 Infertility: Inability to conceive, (Chs 19, 20), 674, 688, 694 Inflammation: An innate (nonspecific) defense that operates at the tissue level; characterized by swelling, redness, heat (warmth), and pain, (Chs 4, 5, 14) antibody function, 522 innate (nonspecific) immunity, 511, 512, 513-514 in skin repair and regeneration, 164-165 tissue injury, 144, 146 Inflammatory bowel disease, 600 Inflammatory response. See Inflammation Inflation reflex: A reflex mediated by the vagus nerve that prevents overexpansion of the lungs, (Ch 15), 558-559 Influenza, 562 Infra-orbital foramen, 187, 188, 190 Infraspinatus muscle, 198, 245, 257, 258, 259 Infraspinous fossa, 197, 198 Infundibulum (in-fun-DIB-ū-lum): A tapering, funnelshaped structure; in the nervous system, the connection between the pituitary gland and the hypothalamus; in the uterine tube, the entrance bounded by fimbriae that receives the oocytes at ovulation, (Chs 10, 19), 381, 382, 383, 684 Ingestion: The introduction of materials into the digestive tract by way of the mouth, (Ch 16), 569 Inguinal canal: A passage through the abdominal wall

Iguinal canal: A passage through the abdominal wall that marks the path of testicular descent and that contains the testicular arteries, veins, and ductus deferens, (Chs 7, 19), 250, 679

Inguinal hernias, 250 Inguinal region: The area near the junction of the trunk and the thighs that contains the external genitalia; the groin, (Ch 1), 44, 45 Inhalation, 549, 550 Inheritance. See also Development and inheritance; Genetics defined, 706 genetics. See Genetics inherited disorders, 729-732, 733, 734 patterns of, 729–732 polygenic, 730 predicting, 729-731 sex-linked, 731–732 simple, 730 Inhibin (in-HIB-in): A hormone produced by the nurse (sustentacular) cells of the testes and the follicular cells of the ovaries that inhibits the secretion of follicle-stimulating hormone (FSH) by the anterior lobe of the pituitary gland, (Chs 10, 19) endocrine system, 377, 383, 386, 398 female reproductive function, 683, 691, 692, 693, 697 male reproductive function, 682, 697 source, regulation of, and primary effects, 697 spermatogenesis, 678 Inhibiting hormones, 380, 382 Initiation, of translation, 110 Injection: Forcing of fluid into a body part or organ, (Chs 1, 5, 7), 159, 253, 292 Innate (nonspecific) immunity/defenses complement system, 511, 512, 513 defined, 511, 515 fever, 511, 512, 514 immune surveillance, 504, 506, 507, 511, 512, 513, 523, 527 inflammation. See Inflammation interferons, 500, 511, 512, 513, 524 lymphatic system, 502, 511 phagocytes. *See* **Phagocyte** physical barriers, 502, 511–512 white blood cells, 424 Inner cell mass: Cells of the blastocyst that will form the body of the embryo, (Ch 20), 709, 710, 711 Inner layer of eye. See Retina Inner segment of a photoreceptor, 355 Innervation: The distribution of sensory and motor nerves to a specific region or organ. See Nervous system Innominate (brachiocephalic) vein, 483, 487, 488, 489 Inorganic compounds acids, bases, and salts, 67-68, 80 carbon dioxide, 64, 80 defined, 64 oxygen, 64, 80 water, 65-66, 80 Insensible water loss, 627 Insertion: Point of attachment of a muscle; the end that is most movable, (Ch 7), 246 Inspiration, respiratory, 548 Inspiratory capacity, 552 Inspiratory center, 558, 559 Inspiratory reserve volume (IRV): The maximum amount of air that can be drawn into the lungs over and above the normal tidal volume, (Ch 15), 551, 552 Insula, 300 Insulin (IN-su-lin): Hormone secreted by the beta cells of the pancreatic islets; causes a decrease in blood glucose concentrations, (Chs 10, 16), 377, 393-394, 395, 396, 585, 586, 587, 588 Insulin-like growth factors, 384. See also Somatomedins Integration center and homeostatic regulation, 36 Integrative effects of hormones, 399 Integument (in-TEG-ū-ment): The skin, (Ch 5), 152. See also Integumentary system; Skin Integumentary system, 151-171 aging, effects of, 167 cardiovascular system, functional relationship with, 495 dermis, 152, 158-159 digestive system, functional relationship with, 601 endocrine system, functional relationship with, 404 epidermis. See Epidermis

exercise, effect of, 267

functional relationships with other systems, 168 functions of, 152-153, 168 general structure of, 152-153 germ layer contributions to, 713 hair. See Hair hypodermis, 152, 159 lymphatic system, functional relationship with, 529 muscular system, functional relationship with, 268 nails. See Nail nervous system, functional relationship with, 327 organs, components, and primary functions, 37, 152 prenatal and early postnatal development, overview of, 720 repair of, following injuries, 164-165 reproductive system, functional relationship with, 700 respiratory system, functional relationship with, 563 sebaceous glands, 130, 152, 160, 162 skeletal system, functional relationship with, 215 sunlight, effect of, 157-158 sweat glands, 152, 162-163, 325 urinary system, functional relationship with, 665, 666 Intensity (volume) of sound, 363, 365 Interatrial septum, 440, 441 Intercalated discs (in-TER-ka-lā-ted): Region where adjacent cardiac muscle cells interlock and where gap junctions permit the movement of ions and action potentials between the cells, (Chs 4, 7, 12), 142, 143, 242, 437-438, 439 Intercostal arteries, 484, 486, 487 Intercostal veins, 483, 489, 490 Interferons (in-ter-FER-onz): Peptides released by virus-infected cells, especially lymphocytes, that make other cells more resistant to viral infection and slow viral replication, (Ch 14), 511, 512, 513, 524 Interleukins (in-ter-LOO-kinz): Peptides released by activated monocytes and lymphocytes that assist in the coordination of the cellular and humoral immune response, (Ch 14), 524, 527 Interlobar arteries, 638, 639 Interlobar veins, 638, 639 Interlobular artery, 590 Interlobular bile duct, 590 Interlobular vein, 590 Intermediate cuneiform bone, 202, 203 Intermediate filaments of the cytoskeleton, 100 Internal anal sphincter, 593, 594 Internal callus, 180, 181 Internal carotid arteries, 473, 481, 484, 485 Internal ear: the membranous labyrinth that contains the organs of hearing and equilibrium, (Ch 9), 358, 359-362 Internal iliac arteries, 482, 486 Internal iliac veins, 483, 488, 489, 490 Internal intercostal muscles, 252, 253, 256, 550 Internal jugular veins, 483, 487, 488, 489 Internal nares. See Posterior internal apertures Internal oblique muscle, 252, 253 Internal os of the uterus, 687, 688 Internal pudendal artery, 487 Internal pudendal vein, 487, 490 Internal receptors: Sensory receptors monitoring the functions and status of internal organs and digestive, respiratory, cardiovascular, urinary, and reproductive systems, (Ch 8), 277 Internal respiration, 548, 554 Internal thoracic artery, 481, 484, 485 Internal thoracic vein, 488, 489, 490 Internal urethral sphincter, 653, 654 Interneurons: An association neuron: neurons inside the CNS that are interposed between sensory and motor neurons, (Ch 8), 277 Internodes, 279 Interosseus membrane, 199, 202 Interphase: Stage in the life of a cell during which the chromosomes are uncoiled and all normal cellular functions are being performed, (Ch 3), 111, 112-113, 115 Interstitial cell-stimulating hormone, 383-384, 683 Interstitial endocrine cells of the testes, 397, 675, 676, 682, 683 Interstitial fluid (in-ter-STISH-ul): Fluid in the tissues that fills the spaces between cells, (Chs 3, 4, 18), 88, 137,658

Interstitial growth: Form of cartilage growth in which the cartilage expands from within through the growth, mitosis, and secretion of chondrocytes in the matrix. Intertubercular groove, 198 Intervals on EKG recordings, 448-449 Interventricular foramen, 298 Interventricular septum, 440, 441 Intervertebral articulations, 209, 211 Intervertebral disc: Fibrocartilage pad between the bodies of successive vertebrae that acts as a shock absorber, (Ch 6), 192, 205, 209, 211 Intervertebral foramina, 192, 291 Intestinal glands, 583-584 Intestinal hormones, 585, 586 Intestinal juice, 583-584 Intestinal movements large intestine, 595 small intestine, 583 Intestinal phase of gastric secretion, 580, 581 Intestinal secretions, 583-584 Intestinal veins, 491 Intestinal wall, 583, 584 Intestines endocrine function, 397 vitamin production, 594 Intracellular fluid (ICF): The cytosol, (Chs 3, 18), 88, 90, 99, 656-658 Intradermal injections, 253 Intramembranous ossification (in-tra-MEM-bra-nus): The formation of bone within a connective tissue without the prior development of a cartilaginous model, (Ch 6), 177 Intramural ganglia, 319 Intramuscular (IM) injections, 253 Intrauterine devices (IUDs), 699 Intrinsic eye muscles, 348 Intrinsic factor: A compound secreted by the parietal cells of the stomach that aids the intestinal absorption of vitamin B12, (Chs 11, 16), 418, 577, 579, 581. 599 Intrinsic muscles, 246, 247, 259, 263 Intrinsic pathway: A pathway of the clotting system within the bloodstream that begins with the activation of platelets and ends with the activation of Factor X, (Ĉh 11), 428, 429-430 Intrinsically photosensitive retinal ganglion cell (ipRGC), 350 Introns, 108 Intubation, 542 Invasion, of tumors, 114 Inversion: A turning inward, (Chs 6, 7), 208, 209, 246, 263, 266 Involuntary: Controlled at subconscious level, (Ch 8), 274 Iodine, 57, 387, 388 Ion: An atom or molecule bearing a positive or negative charge due to the loss or gain of one or more electrons, (Chs 2, 3, 11, 18), 58-59, 62, 93, 430, 636, 640, 642, 644, 645 Ion pumps, 96-97 Ionic bond (ī-ON-ik): Chemical bond created by the attraction between ions with opposite charges, (Ch 2), 58-59 Ionic compound, 59 Ionization (ī-on-i-ZĀ-shun): Dissociation; the breakdown of a molecule in solution to form ions, (Ch 2), 65 Iris: A contractile structure made up of smooth muscle that forms the colored portion of the eye, (Ch 9), 347, 348 Iron dietary guidelines, 624 hemoglobin recycling, 417 reserves, gender differences in, 418 significance in human body, 57 spleen, storage in, 509 Iron deficiency anemia, 418, 629 Irregular bones, 174 Irritability of living things, 32 Irritable bowel syndrome, 595 IRV. See Inspiratory reserve volume (IRV)

Ischemia (is-KE-me-uh): Inadequate blood supply to a region of the body, (Chs 7, 12), 267, 448

Ischial tuberosity, 200, 201 Ischiocavernosus muscle, 254, 255, 695 Ischium (IS-kē-um): One of the three bones whose fusion forms a hip (coxal) bone, (Ch 6), 200 Islets of Langerhans (pancreatic islets), 393, 394, 395 Isoleucine, 620 Isometric contraction: A muscular contraction characterized by rising tension production but no change in length, (Ch 7), 236 Isotonic: A solution having an osmotic concentration that does not result in water movement across plasma membranes; of the same contractive strength, (Ch 3), 94, 95 Isotonic contraction: A muscular contraction during which tension climbs and then remains stable as the muscle shortens, (Ch 7), 236 Isotopes: Forms of an element whose atoms contain the same number of protons but different numbers of neutrons (and thus differ in atomic mass), (Ch 2), 57 Isthmus of the thyroid gland, 388

Isthmus of the uterus, 687, 688

J

Jaundice, 416 Jejunum (je-JOO-num): The middle portion of the small intestine, (Ch 16), 583 Joint: An area where adjacent bones interact; an articulation, (Ch 6). See also specific joints freely movable (synovial), 204, 205 functional classification of, 204-205 immovable, 204-205 injuries, 137 intervertebral, 209, 211 lower limb, 212-214 movements, 206–208, 210 rheumatism and arthritis, 206 slightly movable, 204, 205 structural classification of, 204-205 synovial membranes, 141 upper limb, 211-212 Joint capsule: Dense collagen fiber sleeve that surrounds a joint and provides protection and stabilization; also called articular capsule, (Ch 6), 175, 205, 206 Jugular notch of the manubrium, 195, 196 Jugular veins, 483, 487, 488, 489, 490 Jugular venous pulse (JVP), 487 Juxtaglomerular cells, 641, 642

- Juxtaglomerular complex: The macula densa and the juxtaglomerular cells; a complex responsible for the release of renin and erythropoietin, (Ch 18), 641,642

Juxtamedullary nephrons, 638, 639

Κ

- Karyotype (KAR-ē-ō-tīp): The entire set of chromosomes of an individual or cell, (Ch 20), 725
- Keloids, 165 Keratin (KER-a-tin): Tough, fibrous protein component of nails, hair, calluses, and the general integumentary surface, (Chs 2, 5), 74, 155, 156
- Keratinization (ker-ah-tin-i-ZĀ-shun): The production of keratin by epithelial cells; also called cornification, (Chs 5, 20), 155, 156, 720
- Keratinized cells (ker-A-tin-ized): fattened, dead, densely packed epithelial cells, filled with keratin, (Ch 5), 155
- Keratinocytes (ke-RAT-i-nō-sīts): Living epithelial cells of the epidermis that produce keratin during their differentiation into the dead and keratinized cells of the stratum corneum, (Ch 5), 153
- Keto acid, 620 Ketoacidosis, 620
- Ketone bodies: Metabolic acids produced during the catabolism of lipids and certain amino acids; acetone is one example, (Chs 17, 18), 617, 620, 661 Ketonemia, 629
- Ketonuria, 629
- Ketosis, 620

GLOSSARY / INDEX

Kidney: A component of the urinary system; an organ functioning in the regulation of blood composition, including the excretion of wastes and the maintenance of normal fluid and electrolyte balance, (Chs 1, 8, 9, 11, 18) autonomic nervous system, 321, 323, 325 autoregulation of, 650 blood supply to, 638, 639 endocrine function, 377, 397 failure, treatment of, 652 function regulation of, 650-652 summary of, 648-649 functions, 650-652 glomerular filtration rate, 650-652 hemoglobin recycling, 416, 417 hormonal control, 650-652 location of, 39, 636-637 nephron. See Nephron superficial and sectional anatomy, 636, 637 sympathetic division of the ANS, 652 transplant, 652 urinary system component, 635 urine formation, 643-650 Kidnev lobe, 638 Kidney stones (calculi), 653, 665 Killer T cells. See Cytotoxic T cells Kilocalorie (KIL-ō-kal-o-rē): The amount of heat required to raise the temperature of one kilogram of water 1°C, (Ch 17), 626 Kinase enzymes, 378, 379 Kinesiologists, 246 Kinetic energy, 61 Klinefelter syndrome, 734 Knee-jerk reflex, 314, 315 Kneecap, 44 Knees extensor muscles, 244, 261, 262, 264 flexor muscles, 261, 262, 264 joint structure and movement, 213-214 Korotkoff sounds, 470 Krebs cycle. See Citric acid cycle Kuppfer cell. See Stellate macrophage Kyphosis, 192

L

Labium/labia (LA-bē-uh): Lip (Chs 16, 19) majora/minora, female external genitalia, 690 oral cavity, 573 Labor contractions, 723 goal of, 724 initiating and sustaining, 723 multiple births, 724–725 premature, 724 stages of, 724–725 Labyrinth: A maze of passageways; the structures of the internal ear, (Ch 9), 359-360 Lacrimal apparatus, 345 Lacrimal bones, 187, 188, 190 Lacrimal canals, 345 Lacrimal caruncle, 345 Lacrimal gland (LAK-ri-mal): Tear gland on the dorsolateral surface of the eye, (Chs 8, 9), 323, 325, 345 Lacrimal sac, 345 Lactase, 597, 598 Lactate: An anion released by the dissociation of lactic acid, or formed from pyruvate under anaerobic conditions, (Ch 7), 239 **Lactation** (lak-TĀ-shun): The production of milk by the mammary glands, (Chs 19, 20), 690-691, 727 Lacteal (LAK-tē-al): A terminal lymphatic within an intestinal villus, (Ch 16), 583, 584 Lactic acid, 67, 239, 661 Lactiferous duct (lak-TIF-e-rus): Duct draining one lobe of the mammary gland, (Ch 19), 690, 691 Lactiferous sinus: An expanded portion of a lactiferous duct adjacent to the nipple of a breast, (Ch 19), 690, 69¹ Lactose, 70

Lactose intolerance, 598

Lacuna (la-KOO-na): A small pit or cavity, (Chs 4, 6, 20), 137, 139, 174, 176, 710, 711 Lambdoid suture (lam-DOYD): Synarthrotic articulation between the parietal and occipital bones of the cranium, (Ch 6), 186, 188, 189 Lamellae (lah-MEL-lē): Concentric lavers of bone within an osteon, (Ch 6), 174, 176 Lamellated corpuscles: Receptors sensitive to vibration, (Ch 9), 339 Lamina (LAM-i-na): A thin sheet or layer, (Ch 6), 192, 194 Lamina propria (LAM-i-na PRŌ-prē-uh): Loose connective tissue that underlies a mucous epithelium and forms part of a mucous membrane, (Ĉhs 4, 15, 16), 140, 537, 538, 570, 571 Laparoscopy, 600 Large bowel, 592. See also Large intestine Large intestine: The terminal portions of the intestinal tract, consisting of the colon, the rectum, and the anorectal canal, (Chs 1, 8, 16) absorption in, 594-595 autonomic nervous system, effects of, 321, 323 cecum, 592, 593 colon, 592-594 defecation, 570, 595–596 digestive system component, 570 disorders of, 594 functions of, 594-596 hemoglobin recycling, 416, 417 location, 39, 45, 50 movements of, 595 rectum, 592, 593 Large veins, 462, 465 Laryngopharynx (la-rin-gō-FAR-inks): Division of the pharynx inferior to the epiglottis and superior to the esophagus, (Chs 15, 16), 539, 540, 573 Larynx (LAR-inks): A complex cartilaginous structure that surrounds and protects the glottis and vocal cords; the superior margin is bound to the hyoid bone, and the inferior margin is bound to the trachea, (Chs 1, 6, 15), 38, 191, 536, 537, 540-541 LASIK (Laser-Assisted In-Situ Keratomileusis), 354 Latent period: The time between the stimulation of a muscle and the start of the contraction phase, (Ch 7), 231 Lateral: Pertaining to the side, (Ch 1), 46 Lateral angle, formerly lateral canthus 345 Lateral angle (head) of the scapula, 197 Lateral border of the scapula, 197 Lateral collateral ligament, 213 Lateral condyle of the femur, 202 Lateral condyle of the tibia, 202 Lateral cuneiform bone, 202, 203 Lateral epicondyle of the femur, 202 Lateral epicondyle of the humerus, 198 Lateral flexion, 208, 209 Lateral horns of spinal cord gray matter, 295, 296 Lateral malleolus, 202 Lateral menisci of the knee, 213 Lateral pathways, 316, 318 Lateral rectus muscle, 345, 346 Lateral sacral artery, 487 Lateral sacral veins, 487, 490 Lateral semicircular ducts, 362 Lateral sulcus, 296, 300 Lateral ventricle: Fluid-filled chamber within one of the cerebral hemispheres, (Ch 8), 298 Lateral white commissures, 296 Lateralized integrative centers, 301 Latissimus dorsi muscle, 244, 245, 250, 257, 258, 259 Lauric acid, 70 LDLs (low-density lipoproteins), 618, 619 Leads for electrocardiograms, 448, 449 Leak channels, 96, 281 Lecithin, 70, 72 Left atrioventricular (AV) valve. See Mitral valve Left atrium, 435, 438, 441 Left bundle branch, 447 Left common carotid artery, 438, 481, 482, 484, 485 Left coronary artery, 442, 481 Left gastric artery, 486, 487 Left hepatic vein, 589 Left lobe of the liver, 589

Left portion of sagittal section, 47 Left primary bronchus, 541, 543 Left pulmonary artery, 438, 440, 480, 481 Left pulmonary vein, 438, 440, 480 Left side, explained, 44, 47 Left subclavian artery, 438, 480, 481, 484, 485 Left subclavian vein, 480 Left ventricle, 435, 438, 441, 442 Legs anatomical terms, 44 muscles of, 244–245, 260–262, 264 Lens: The transparent body of the eye that is between the iris and the vitreous humor, (Ch 9) cataracts, 351, 368 image formation, 352-353 light refraction and accommodation, 351-352, 354 location of, 347, 351 structure of, 351 Lentiform nucleus, 304 Leprosy (Hansen's disease), 326 Leptin, 377, 398, 727 Lesions, 167 Lesser curvature of the stomach, 578, 579 Lesser horns of the hyoid bone, 191 Lesser omentum: A small pocket in the mesentery that connects the lesser curvature of the stomach to the liver, (Ch 16), 578, 579 Lesser trochanter of the femur, 202 Lesser tubercle of the humerus, 198 Lesser vestibular glands, 690 Leucine, 109, 620 Leukemia (loo-KĒ-mē-uh): A malignant disease of the blood-forming tissues, (Ch 11), 426 Leukocyte (LOO-kō-sīt): A white blood cell, (Ch 11), 423. See also White blood cells (WBCs) Leukocytosis, 426 Leukopenia, 426 Levator ani muscle, 254, 255 Levator scapulae muscle, 255, 256, 257 Levels of organization, 34-36 LH. See Luteinizing hormone (LH) Life stages, described, 722, 726-728 Ligament (LIG-a-ment): Dense band of connective tissue fibers that attaches one bone to another, (Chs 4, 6), 132, 134, 174, 205. See also specific ligaments Ligament of the femoral head (ligamentum teres), 212 Ligamentum arteriosum: The fibrous strand in adults that is the remains of the ductus arteriosus of the fetus, (Ch 12), 438, 440, 441, 492 Ligamentum teres (ligament of the femoral head), 212 Ligands, 97, 98 Light chains in antibodies, 521 Light micrographs, 86 Light microscopy, 86 Light refraction and accommodation, 351-352, 354 Limbic system (LIM-bik): Group of nuclei and centers in the cerebrum and diencephalon that are involved with emotional states, memories, and behavioral drives, (Ch 8), 304-305 Limbus (LIM-bus): The edge of the cornea, marked by the transition from the corneal epithelium to the ocular conjunctiva. Line (bone marking), 183 Linea alba, 244 Linea aspera, 201 Lingual frenulum. See Frenulum of tongue Lingual lipase, 597 Lingual tonsils, 506, 508, 573 Linoleic acid, 618 Linolenic acid, 618 Lipase (LĪ-pas): A pancreatic enzyme that breaks down triglycerides, (Ch 16), 588, 597, 598 Lipid: An organic compound containing carbon, hydrogen, and oxygen atoms in a ratio that does not approximate 1:2:1; includes fats, oils, and waxes, (Chs 2, 10, 17, 18) ATP production, 617 catabolism, 617, 621 defined, 70 digestion and absorption, 597, 598 energy production, 617, 621 fats, 70, 71-72, 79

fatty acids, 70-71, 79, 80 hormones as lipid derivatives, 376 metabolism of, 617-619, 621 phospholipids, 70, 72–73 steroids, 70, 72, 80 synthesis of, 618 transport and distribution, 618-619 urine and plasma, amounts in, 644 Lipogenesis, 618 Lipolysis (li-POL-i-sis): The catabolism of lipids as a source of energy, (Ch 17), 617, 621 Lipoprotein (li-pō-PRŌ-tēn): A compound containing a relatively small lipid bound to a protein, (Chs 13, 17), 463, 618, 619 Liposuction, 136, 629 Liver: An organ of the digestive system with varied and vital functions, including the production of plasma proteins, the excretion of bile, the storage of energy reserves, the detoxification of poisons, and the interconversion of nutrients, (Chs 1, 2, 8, 10, 16) aging, effect of, 600 anatomy of, 588, 589 autonomic nervous system, effects of, 321, 323, 325 cholesterol synthesis, 72 digestive system, component of, 570 disorders of, 589, 591 functions, 589-591 hemoglobin recycling, 415-418 histological organization of, 588-589, 590 location, 39, 45, 48, 588 plasma proteins, 414 size, 588 Liver biopsy, 600 Lobar bronchi, formerly secondary bronchi, 541, 542, 543 Lobes of the brain, 300. See also individual lobes Lobes of the kidney, 638 Lobes of the liver, 588, 589 Lobes of the lungs, 546, 547 Lobular carcinoma, 691 Lobular carcinoma in situ, 691 Lobule (LOB-ūl): The basic organizational unit of the liver at the tissue level, (Ch 16), 588, 590 Lobules of the lungs, 543, 544 Lobules of the testes, 675 Lobules of the thymus, 509 Local current, 287, 288 Local (graded) potentials, 283 Lockjaw. See Tetanus Long bones, 174, 175 Long-term memories, 304 Longissimus muscle, 247, 251 Longitudinal fissure of the brain, 296, 300 Loop of Henle. *See* Nephron loop Loose connective tissue: A loosely organized, easily distorted connective tissue containing several fiber types, a varied population of cells, and a viscous ground substance, (Ch 4), 134, 135 Lordosis, 192 Lou Gehrig's disease, 326 Low-density lipoproteins (LDLs), 618, 619 Lower esophageal sphincter, 576 Lower limbs anatomical terms, 44 ankle bones, 185, 202-203 appendicular skeleton, 185, 186, 201 articulations of, 212–214 femur, 185, 201–202 fibula, 185, 202 foot, bones of, 185, 202–203 muscles of, 244–245, 259, 261–266 patella, 185, 202 tibia, 185, 202 Lumbar: Pertaining to the lower back, (Ch 1), 44 Lumbar abdominopelvic regions, 45 Lumbar arteries, 485, 486 Lumbar nerves, 312 Lumbar plexus, 312, 313 Lumbar puncture, 298 Lumbar region of the vertebral column, 191 Lumbar spinal curve, 192 Lumbar veins, 483, 488, 489, 490 Lumbar vertebrae, 191, 193, 194 Lumbosacral enlargement, 292-293, 294

Lumbosacral plexus, 312, 313 Lumen: The central space within a duct or other internal passageway, (Chs 11, 12), 429, 461 Lunate bone, 198 Lung cancer, 561 Lungs: Paired organs of respiration, enclosed by the left and right pleural cavities, (Chs 1, 8, 9, 15). See also Pleura; Respiratory system autonomic nervous system, effects of, 321, 323 baroreceptors, 340 location of, 38 pleural cavities, 48 respiratory system, 536, 537, 546, 547 volumes and capacities, 551-552 Lunula, 164 Luteal (postovulatory) phase of the ovarian cycle, 686, 687, 692, 693, 694 Luteinizing hormone (LH) (LOO-tē-in-ī-zing): Anterior pituitary lobe hormone that in females assists FSH in follicle stimulation, triggers ovulation, and promotes the maintenance and secretion of the endometrial glands; in males, stimulates spermatogenesis; formerly known as interstitial cell-stimulating hormone in males, (Chs 10, 19, 20) endocrine hormone, 377, 383, 386, 387 female reproductive cycles, 691, 692, 693, 694 male reproductive function, 682, 683 menopause, 696 puberty, 728 source, regulation of, and primary effects, 697 Luxation, 214 Lymph: Fluid contents of lymphatic vessels, similar in composition to interstitial fluid, (Chs 4, 14), 132, 136, 503 Lymph glands. See Lymph nodes Lymph nodes: Lymph ideas that monitor the composition of lymph, (Chs 1, 14), 38, 503, 508 Lymphadenopathy, 509 Lymphatic capillaries, 504 Lymphatic ducts, 503, 504, 505 Lymphatic system in body defenses, 510–511. See also Adaptive (specific) immunity/defenses; Innate (nonspecific) immunity/defenses components, 503 defined, 502 digestive system, functional relationship with, 601 functions, 504 lymphatic vessels. See Lymphatics lymphocytes. See Lymphocyte lymphoid nodules/tissues, 503, 506, 508 lymphoid organs. See Lymphoid organs other systems, functional relationship with, 528, 529 prenatal and early postnatal development, overview of, 721 reproductive system, functional relationship with, 700 respiratory system, functional relationship with, 563 urinary system, functional relationship with, 666 Lymphatics: Vessels of the lymphatic system, (Chs 1, 4, 13, 14), 38, 137, 468, 503, 504, 508 Lymphedema, 505 Lymphocyte (LIM-fō-sīt): A cell of the lymphatic system that plays a role in the immune response, (Chs 11, 14). See also B cells; T cells Class II MHC proteins, 518 described, 413, 419, 424, 425, 426 immune response, 502, 503, 505–506 Lymphocytopoiesis: The production of lymphocytes, (Chs 11, 14), 426, 506, 507 Lymphoid nodules, 503, 506, 508 Lymphoid organs lymph nodes, 38, 503, 508 spleen. See Spleen thymus, 38, 377, 397, 418, 426, 503, 508-509 Lymphoid stem cells, 419, 426 Lymphoid tissues, 503, 506, 508 Lymphokines, 524 Lymphomas, 509, 528 Lymphotoxin, 518 Lysine, 620 Lysosomal storage disease, 103

Lysosome (LĪ-sō-sōm): Intracellular vesicle containing digestive enzymes, (Ch 3) organelles, 88-89, 102-103, 105 vesicular transport, 97-98 Lysozyme: An enzyme present in some exocrine secretions that has antibiotic properties, (Chs 9, 14, 16, 20), 345, 511, 574, 727 Μ M lines, 226, 227 Macrophage (MAK-rō-fāj): A phagocytic cell of the monocyte-macrophage system, (Chs 4, 5, 11, 14), 133, 134, 164, 165, 167, 416, 417, 424, 425, 426, 512-513, 524 Macroscopic anatomy, 33 Macula (MAK-ū-la): A receptor complex in the saccule or utricle that responds to linear acceleration or gravity, (Ch 9), 362, 363 Macula densa (MAK-ū-la DEN-sa): A group of specialized secretory cells in a portion of the distal convoluted tubule adjacent to the glomerulus and the juxtaglomerular cells; a component of the juxtaglomerular apparatus, (Ch 18), 641, 642 Macula (of retina): The region of the eye containing a high concentration of cones and no rods (Ch 9), 349, 350 Macular degeneration, 368 Magnesium dietary guidelines, 624 ions in body fluids, 59, 658 significance in human body, 57 Magnetic resonance imaging (MRI), 51 Main bronchus, formerly primary bronchus, 541, 542, 543 Major calyces, 638 Major histocompatibility complex proteins. See MHC (major histocompatibility complex) proteins

GLOSSARY / INDEX

G-20

Mammography, 699 Mandible, 177, 187, 188, 189, 192 Mandibular branch of the trigeminal nerve, 309 Mandibular condyle, 190 Mandibular fossa, 187, 188, 190 Manganese, 624 Manual region, 44 Manubrium, 195, 196 Marfan syndrome, 134, 731, 733 Marginal artery, 444 Marrow: A tissue that fills the internal cavities in a bone; may be dominated by hematopoietic cells (red marrow) or adipose tissue (yellow marrow), (Chs 6, 11, 14), 173, 174, 175, 417, 418, 526, 528 Marrow cavity, 174, 175 Mass, defined, 56 Mass movements, intestinal, 595 Mass number, 57 Masseter muscle, 248, 249, 255 Mast cell: A connective tissue cell that when stimulated releases histamine and heparin, initiating the inflammatory response, (Chs 4, 14), 133, 135, 144, 146, 512, 513, 514, 524 Mast cell activation, 146 Mastectomy, 699 Mastication (mas-ti-KĀ-shun): Chewing, (Ch 16), 574 Mastoid process, 187, 188 Mastoid sinus: Air-filled spaces in the mastoid process of the temporal bone. Maternal systems cardiovascular, 492 pregnancy, effects of, 717-719 Matrix: The extracellular fibers and ground substance of a connective tissue, (Chs 3, 4, 5), 103, 106, 132, 137, 138, 160 Matter atoms as basic particles of, 56-58 energy, relationship to, 61 states of. 56 Mature graafian (tertiary) follicle, 686, 687 Maturity (developmental stage), 706, 722, 726, 727–728 Maxillae (maxillary bones), 187, 188, 189, 190 Maxillary artery, 485 Maxillary branch of the trigeminal nerve, 309 Maxillary sinus (MAK-si-ler-ē): One of the paranasal sinuses; an air-filled chamber lined by a respiratory epithelium that is located in a maxillary bone and opens into the nasal cavity, (Chs 6, 15), 190, 191, 539 Maxillary vein, 488 Meatus (bone marking), 183 Mechanical digestion of food, 569 Mechanoreception: Detection of mechanical stimuli, such as touch, pressure, or vibration, (Ch 9), 337, 338 - 340Mechanoreceptor reflexes, 558-559 Medial: Toward the midline of the body, (Ch 1), 46 Medial angle, formerly medial canthus 345 Medial border of the scapula, 197 Medial collateral ligament, 213 Medial condyle of the femur, 202 Medial condyle of the tibia, 202 Medial cuneiform bone, 202, 203 Medial epicondyle of the femur, 202 Medial epicondyle of the humerus, 198 Medial malleolus, 202 Medial menisci of the knee, 213 Medial pathways, 316, 318 Medial rectus muscle, 345, 346 Median antebrachial veins, 483, 489, 490 Median cubital vein, 483, 487, 489 Median nerve, 259, 312 Mediastinal arteries, 486, 487 Mediastinal surface of the lung, 546, 547 Mediastinal veins, 489, 490 Mediastinum (mē-dē-a-STĪ-num): Central tissue mass that divides the thoracic cavity into two pleural cavities; includes the aorta and other great vessels, the esophagus, trachea, thymus, the pericardial cavity and heart, and a host of nerves, small vessels, and lymphatics, (Chs 1, 10, 12), 48, 397, 435 Medium-sized (muscular) arteries, 461, 462 Medium-sized veins, 462, 465

Medulla: Inner layer or core of an organ, (Ch 5), 160, 509 Medulla oblongata: The most caudal of the brain regions, (Chs 8, 12, 13), 296, 297, 298, 307, 308, 341, 454, 473, 558, 585 Medullary cavity: The space within a bone that contains the marrow, (Ch 6). See Marrow cavity Megakaryocytes (meg-a-KĀR-ē-ō-sīts): Bone marrow cells responsible for the formation of platelets, (Ch 11), 427 Meiosis (mī-ō-sis): Cell division that produces gametes with half the normal number of somatic chromosomes, (Chs 3, 19), 111, 677, 678-679, 683,685 Meiosis I oogenesis, 683, 685 spermatogenesis, 677 Meiosis II oogenesis, 685, 687 spermatogenesis, 677 Meissner's corpuscles (tactile corpuscles), 339 Melanin (MEL-ah-nin): Yellow-brown pigment produced by the melanocytes of the skin, (Ch 5), 155.156 Melanocyte (me-LAN-ō-sīt): Specialized cell in the deeper layers of the stratified squamous epithelium of the skin, responsible for the production of melanin, (Ch 5) skin color and, 156, 157 stratum basale, 155 Melanocyte-stimulating hormone (MSH): Hormone of the anterior lobe of the pituitary gland that stimulates melanin production, (Ch 10), 377, 385, 386, 387 Melanosomes, 156, 157 Melatonin (mel-a-TŌ-nin): Hormone secreted by the pineal gland; inhibits secretion of MSH and GnRH, (Chs 8, 10), 306, 376, 377, 393 Membrane carbohydrates, 90, 91 Membrane lipids, 90 Membrane potential: The potential difference, in millivolts, measured across the plasma membrane; a potential difference that results from the uneven distribution of positive and negative ions across a plasma membrane, (Ch 8) action potential, generation of, 284-285 changes in, 282-283 factors responsible for, 281-282 Membrane proteins, 90, 91 Membrane renewal vesicles, 105 Membranes. See also Plasma membrane cutaneous membrane, 141 mucous membranes, 140 serous membranes, 141 synovial membranes, 140, 141 Membranous labyrinth: Endolymph-filled tubes that enclose the receptors of the internal ear, (Ch 9), 359-360 Memory adaptive (specific) immunity, 516 age-related changes, 324-325 cerebrum, 304 consolidation of, 304 Memory B cells, 520, 523, 525 Memory cells, 516 Memory T cells, 519 Menarche (me-NAR-kē): The first menstrual cycle, which normally occurs at puberty, (Ch 19), 689 Meniere's disease, 369 Meninges (men-IN-jēz): Three membranes that surround the surfaces of the CNS-the dura mater, the arachnoid, and the pia mater, (Ch 8), 291, 326 Meningitis, 326 Meniscus (me-NIS-kus): A fibrocartilage pad between opposing surfaces in a joint, (Ch 6), 205 Menopause, 683, 689, 696 Menstrual phase, 689 Menstruation (men-strū-Ā-shun): The first part of the uterine cycle in which the endometrial lining sloughs away; also called menses (Ch 19), 689, 693, 694 Mental region, 44

Merkel cells, 155, 339

Merkel discs (tactile discs), 339

Merocrine (MER-u-krin): A method of secretion in which the cell ejects materials from secretory vesicles through exocytosis, (Ch 4), 128, 130, 131 Merocrine (eccrine) sweat glands, 162, 163 Mesencephalon. See Midbrain Mesenchyme: Embryonic/fetal connective tissue. Mesentery (MEZ-en-ter-ē): A double layer of serous membrane that supports and stabilizes the position of an organ in the abdominopelvic cavity and provides a route for the associated blood vessels, nerves, and lymphatic vessels, (Ch 16), 571-572 Mesoderm: The middle germ layer, between the ectoderm and endoderm of the embryo, (Ch 20), 711, 712, 713, 714-715 Messenger RNA (mRNA): RNA formed at transcription to direct protein synthesis in the cytoplasm, (Chs 3, 17), 108–109, 110–111, 622 Metabolic acids in body fluids, 661 Metabolic acid-base disorders, 663-664 Metabolic acidosis, 663, 664 Metabolic alkalosis, 663, 664 Metabolic pathway, 76 Metabolic rate energy expenditure, 626-627 food, energy content of, 626 thermoregulation, 627-628 units of energy, 626 Metabolic turnover: The continuous breakdown and replacement of organic materials within cells, (Ch 17), 609 Metabolic (generation of) water, 625, 658 Metabolism (me-TAB-ō-lizm): The sum of all biochemical processes underway in the body at a given moment; includes anabolism and catabolism, (Chs 1, 2, 17) chemical reactions, 61 defined, 607 enzyme function, 73, 75-76 function of living things, 32 liver, regulation by, 589–590 metabolic rate, 626-628 Metabolism and energetics, 607-633 aging, nutrition needs with, 629 carbohydrate metabolism, 610-616, 621 cellular metabolism, 608-610 lipid metabolism, 617-619, 621 metabolic rate, 626-628 nucleic acid catabolism, 621-622 nutrition, adequacy of, 622-626 protein catabolism and synthesis, 619-620 Metabolites (me-TAB-ō-līts): Compounds produced in the body as the result of metabolic reactions, (Ch 2), 64 Metacarpals: The five bones of the palm of the hand, (Ch 6), 185, 199, 200 Metaphase (MET-a-fāz): A stage of mitosis in which the chromosomes line up along the equatorial plane of the cell, (Ch 3), 112, 113, 115 Metaphase plate, 113, 115 Metaplasia, 147 Metastasis, 114 Metatarsal: One of the five bones of the foot that articulate with the tarsals (proximally) and the phalanges (distally), (Ch 6), 185, 203 Methionine, 109, 620 MHC (major histocompatibility complex) proteins: A surface antigen that is important to foreign antigen recognition and that plays a role in the coordination and activation of the immune response, (Ch 14), 518, 519, 520, 524, 525, 526 Micelle (mī-SEL): A droplet with hydrophilic portions on the outside; a spherical aggregation of bile salts, monoglycerides, and fatty acids in the lumen of the intestinal tract, (Ch 16), 598 Microfilaments of the cytoskeleton, 100 Microglia (mī-KRŌG-lē-uh): Phagocytic glial cells in the CNS, derived from the monocytes of the blood, (Chs 8, 14), 278, 279, 512, 524, 529

Microphages: Neutrophils and eosinophils, (Chs 11, 14), 424, 512

Microscopic anatomy, 33

Microtubules: Microscopic tubules that are part of the cytoskeleton and are found in cilia, flagella, centrioles, and spindle fibers, (Ch 3), 100 **GLOSSARY / INDEX**

Microvilli: Small, fingerlike extensions of the exposed plasma membrane of an epithelial cell, (Chs 3, 4, 16), 88, 100, 125, 583, 588, 596, 599 Micturition (mik-tu-RI-shun): Urination, (Ch 18), 635, 654-655, 664, 665. See also Urination Midbrain: The mesencephalon, (Ch 8) functions and components of, 307 regions of the brain, 296, 297 Middle cardiac vein, 444 Middle cerebral artery, 485 Middle ear: Space between the external ear and internal ear that contains auditory ossicles, (Chs 6, 9), 187, 358-359 Middle lobe of the right lung, 546, 547 Middle nasal conchae, 188, 189, 190, 538, 539 Middle phalanges, 185, 199, 200 Middle piece of a sperm, 678 Midsagittal section: A plane passing through the midline of the body that divides it into left and right halves, (Ch 1), 44, 47 Migratory phase, in skin repair, 164, 165 Milk ejection (milk let-down) reflex, 385, 727 Milk teeth, 575, 576 Millivolts (mV), 281 Mineralocorticoids: Corticosteroids produced by the adrenal cortex; steroids, such as aldosterone, that affect mineral metabolism, (Ch 10), 391, 392 Minerals age-related requirements, 629, 664 bone as reservoir for, 179, 182 dietary guidelines, 623, 624 "Mini-pill," 698 Minimal volume of the lungs, 551, 552 Minor calyx, 638 Minoxidil (Rogaine), 161 Miscarriage (spontaneous abortion), 728 Mitochondrial disorders, 103 Mitochondrial spiral, 678 Mitochondrion (mī-tō-KON-drē-on): An intracellular organelle responsible for generating most of the ATP required for cellular operations, (Chs 3, 7, 17, 19), 88-89, 103, 106, 238, 610, 612-614, 615, 616, 678 Mitosis (mī-TŌ-sis): The division of a single cell nucleus that produces two identical daughter nuclei; an essential step in cell division, (Chs 3, 19), 111, 113-114, 676, 677-678, 683, 685 Mitral valve (MĪ-tral): The left AV, or bicuspid valve, of the heart, (Ch 12), 440, 441, 443 Mitral valve prolapse, 442 Mixed exocrine glands, 131 Mixed nerves, 294 Molars, 575, 576 Molecular weight: The sum of the atomic weights of the atoms in a molecule or compound. Molecule: A chemical structure that contains two or more atoms that are held together by covalent bonds, (Chs 1, 2), 34, 35, 58, 62 Monoamine oxidase, 290 Monoclonal antibodies, 528 Monocyte-macrophage system, 512, 518, 524 Monocytes (MON-ō-sīts): Phagocytic agranulocytes (white blood cells) in the circulating blood, (Chs 11, 13, 14), 413, 419, 424, 425, 426, 463, 503, 512 Monoglyceride (mo-nō-GLI-se-rīd): A lipid consisting of a single fatty acid bound to a molecule of glycerol, (Ch 2), 70. See also Triglyceride Monokines, 524 Mononucleosis, 528 Monosaccharide (mon-ō-SAK-uh-rīd): A simple sugar, such as glucose or ribose, (Ch 2), 68, 69, 70, 79 Monosomy, 734 Monosynaptic reflex: A reflex in which the sensory afferent neuron synapses directly on the motor efferent neuron, (Ch 8), 313 Monounsaturated fatty acid, 71 Monozygotic twins: Twins produced by the splitting of a single fertilized ovum (zygote); also called identical twins, (Ch 20), 724-725 Mons pubis, 690 "Morning after" pill, 698 Morula (MOR-ū-la): A mulberry-shaped collection of cells produced through the mitotic divisions of a zygote, (Ch 20), 709, 710

Mosaicism, 112 Motor areas of the cerebral cortex, 300, 301 Motor end plate, 227, 228, 229 Motor homunculus, 318 Motor neurons, 227, 277 Motor nuclei of spinal cord gray matter, 295 Motor (descending) pathways, 280, 316, 318–319 Motor unit: A single motor neuron and all the muscle fibers it controls, (Ch 7), 235, 236 Movement, as function of living things, 32 MRI (magnetic resonance imaging), 51 MS (multiple sclerosis), 281, 526 MSH. See Melanocyte-stimulating hormone (MSH) Mucin, 128 Mucins, 574 Mucosa (mu-Ko-sa): A mucous membrane; the epithelium plus the lamina propria, (Ch 16), 570-571 Mucosa-associated lymphoid tissue (MALT), 503, 506 Mucous (adjective): Indicating the presence or production of mucus, (Ch 4), 131, 140 Mucous cell: A goblet-shaped, mucus-producing, unicellular gland in certain epithelia of the digestive and respiratory tracts; also called goblet cells, (Chs 4, 15), 128, 537, 538, 539 Mucous epithelium of the gastric wall, 578, 579 Mucous exocrine glands, 131 Mucous membranes digestive tract, 570-571 tissue level of organization, 140 Mucus (noun): A lubricating fluid that is composed of water and mucins and is produced by unicellular and multicellular glands along the digestive, respiratory, urinary, and reproductive tracts, (Ch 4), 128, 511 Multinucleate skeletal muscle fibers, 224 Multiple births, 724-725 Multiple endocrine neoplasia, type 2, 733 Multiple sclerosis (MS), 281, 526 Multipolar neuron: A neuron with many dendrites and a single axon; the typical form of a motor neuron, (Ch 8), 276-277 Multipotent stem cells, 418 Muscle: A contractile organ composed of muscle tissue, blood vessels, nerves, connective tissues, and lymphatics, (Ch 7), 227, 232-237, 243. See also specific muscles Muscle cells cardiac muscle, 437-438, 439 microfilaments, 100 Muscle cramps, 267 Muscle fatigue, 239 Muscle fibers elongation following contraction, 237 frequency of stimulation, 231, 235 number of muscle fibers activated, 235-236 skeletal muscle cells, 141, 142, 223 types and distribution of, 240-241 Muscle spindles, 314, 315, 340 Muscle strain, 257 Muscle tissue: A tissue characterized by the presence of cells capable of contraction; includes skeletal, cardiac, and smooth muscle tissues, (Ch 4) cardiac muscle tissue, 141, 142, 143. See also Cardiac muscle function of, 141 regeneration of, 145 skeletal muscle tissue, 141, 142. See also Skeletal muscle smooth muscle tissue, 141, 142, 143. See also Smooth muscle tissue level of organization, 121, 122, 141-143 Muscle tone, 236 Muscular arteries, 461, 462 Muscular compression and venous pressure, 465, 469 Muscular dystrophies, 267, 731, 732, 733 Muscular layer: Concentric layers of smooth muscle responsible for peristalsis, formerly muscularis externa (Ch 16), 571 Muscular system, 221-272 age, effect of, 266-267 appendicular muscles. See Appendicular muscles axial muscles. See Axial muscles cardiac muscle. See Cardiac muscle

cardiovascular system, functional relationship with, 495 defined, 243 digestive system, functional relationship with, 601 endocrine system, functional relationship with, 404 energy source for muscular activity, 237-240 exercise, effect of, 267 functional relationships to other systems, 268 functions of, 268 germ layer contributions to, 713 integumentary system, functional relationship with, 268 intramuscular injections, 253 lymphatic system, functional relationship with, 529 muscle tissue types, comparison of, 243 nervous system, functional relationship with, 327 organs, components, and primary functions, 37 overview, 243, 244 prenatal and early postnatal development, overview of, 720 reproductive system, functional relationship with, 700 respiratory system, functional relationship with, 563 skeletal muscle. See Skeletal muscle skeletal system, functional relationship with, 268 smooth muscle. See Smooth muscle tissue urinary system, functional relationship with, 666 Muscularis mucosae: Layer of smooth muscle beneath the lamina propria; responsible for moving the mucosal surface, (Ch 16), 571 Musculocutaneous nerve, 312 Mutations, 112 Myalgia, 267 Myasthenia gravis, 230 **Myelin** (MĪ-e-lin): Insulating sheath around an axon; consists of multiple layers of neuroglial membrane; significantly increases propagation rate along the axon, (Chs 8, 9, 14), 278, 279, 288, 337-338, 526 Myelinated axon, 288 Myelination: The formation of myelin, (Ch 8), 279 Myelography, 326 Myeloid stem cells, 418, 419 Myeloid tissue, 418 Myenteric plexus (mī-en-TER-ik): Along with the submucosal plexus, makes up the enteric nervous system (ENS), contains parasympathetic motor neurons and sympathetic postganglionic fibers located between the circular and longitudinal layers of the muscular layer, (Ch 16), 571 Mylohyoid muscle, 249, 250 Myocardial infarction (MI), 444 Myocardium: The cardiac muscle tissue of the heart, (Ch 12), 437, 439 Myofibril: Organized collections of myofilaments in skeletal and cardiac muscle cells, (Ch 7), 224, 225 Myofilament: Protein filament consisting of the proteins actin and myosin; bundles of myofilaments from myofibrils, (Ch 7), 224, 225 Myoglobin (MĪ-ō-glō-bin): An oxygen-binding pigment especially common in slow skeletal and cardiac muscle fibers, (Ch 7), 240, 241, 242, 266 Myogram: A recording of the tension produced by muscle fibers on stimulation, (Ch 7), 231, 235 Myoma, 267 Myometrium (mī-ō-MĒ-trē-um): The thick layer of smooth muscle in the wall of the uterus, (Ch 19), 687, 688 Myopia (nearsightedness), 354 Myosin: Protein component of the thick myofilaments, (Ch 3, 4, 7), 100, 141, 224, 225, 226 Myositis, 267 MyPlate Food Guide, 622-623 Myxedema, 403

Ν

NAD (nicotinamide adenine dinucleotide) citric acid cycle, 612 electron transport chain, 613, 614 glycolysis, 611 NADH, 611, 612, 613, 614, 615 Nail: A keratinous structure produced by epithelial cells of the nail root, (Chs 1, 5) cuticle, 163

G-22

GLOSSARY / INDEX

as integumentary system component, 37 nail bed, 163, 164 nail body, 163, 164 nail root, 163, 164 Nanometers, 56 Nares, external. See Nostrils Nares, internal. See Posterior internal apertures Nasal bones, 187, 188, 189, 190 Nasal cavity: A chamber in the skull bounded by the posterior internal apertures and nostrils, (Chs 1, 15), 38, 536, 537, 538, 539 Nasal complex, 188, 190 Nasal conchae, 538, 539 Nasal region, 44 Nasal septum, 188, 190, 538, 539 Nasal vestibule, 538, 539 Nasolacrimal duct: Passageway that transports tears from the nasolacrimal sac to the nasal cavity, (Ch 9), 345 Nasopharynx (nā-zō-FAR-ingks): Region posterior to the posterior internal apertures, superior to the soft palate, and ending at the oropharynx, (Chs 9, 15), 358, 538, 539, 540 Natural killer (NK) cells, 506, 507, 512, 513, 524, 525 Naturally acquired active immunity, 516 Naturally acquired passive immunity, 516 Navicular bone, 202, 203 NE. See Norepinephrine (NE) Near point of vision, 368 Nearsightedness (myopia), 354 Neck anatomical terms, 44 arteries of, 485 muscles of, 244-245, 248-250 veins of, 483, 487, 488 Neck of a bone, 183 Neck of a sperm, 678 Neck of gastric pits, 578, 579 Neck of the radius, 199 Neck of the tooth, 574, 575 Neck of the urinary bladder, 653, 654 Necrosis, 147, 514 Negative Babinski reflex, 316 Negative feedback: Corrective process that opposes or reverses a variation from normal limits and restores homeostasis, (Chs 1, 8, 10, 13), 40-42, 313, 380, 383, 384, 473 Neomycin, 366 Neonatal period, 722, 726-727 Neonate: A newborn infant, (Ch 20), 726 Neoplasm: A tumor, or mass of abnormal tissue, (Ch 3), 114. See also Tumor Nephritis, 665 Nephrolithiasis, 653 Nephrology, 665 **Nephron** (NEF-ron): Basic functional unit of the kidney, (Ch 18) angiotensin II, 650 blood supply to, 638, 639 collecting system, 638, 640, 642, 646 components of, 637, 639 distal convoluted tubule, 637, 638, 640, 641, 642, 646, 647 functions of, 638, 640 overview of, 638, 640 proximal convoluted tubule, 637, 638, 639, 640, 642, 645,647 renal corpuscle, 637, 638, 639, 640, 641-642, 648 urine formation, 643–650 Nephron loop: The segment of the nephron that creates the concentration gradient in the renal medulla; also called loop of Henle, (Ch 18), 637, 638, 639, 640, 642, 645-646, 648 Nerve deafness, 366 Nerve fibers, 143. See also Axon Nerve impulse: An action potential in a neuron cell membrane, (Ch 8), 281-288 Nerve plexuses, 311–313 Nerves. See also specific nerves PNS white matter, 280 skeletal muscle, 224 Nervous system, 273-334 aging, effect of, 324-325 anatomical and functional divisions, 274-275

autonomic nervous system. See Autonomic nervous system (ANS) brain. See Brain cardiovascular regulation, 471, 472, 473-475 cardiovascular system, functional relationship with, 495 digestive system, functional relationship with, 601 endocrine system, functional relationship with, 375-376, 404 exercise, effect of, 267 functional relationship with other body systems, 327 functions of, 274-275 germ layer contributions to, 713 lymphatic system, functional relationship with, 528, 529 meninges, 291 motor and sensory pathways, 316-319 nerve impulse, 281-288 nerve plexuses, 311-313 neurons and neuroglia, 275-281 organs, components, and primary functions, 37 peripheral nervous system. See Peripheral nervous system (PNS) prenatal and early postnatal development, overview of, 720 reflexes, 313-316 reproductive system, functional relationship with, 700 respiratory system, functional relationship with, 563 sensory receptor connection to, 336-337 skeletal muscles, communication with, 228-229 spinal cord, 274, 292-297 synapses, communication at, 288-290 urinary system, functional relationship with, 666 Nervous tissue, 121, 122, 143-144 Neural circuits, 290 Neural cortex: An area where gray matter is found at the surface of the CNS, (Ch 8), 280 Neural layer of the retina, 347, 348 Neural stimulation for endocrine activity, 380 Neurilemma, 279 Neuroeffector junction: A synapse between a motor neuron and a peripheral effector, such as a muscle, gland cell, or fat cell, (Ch 8), 288 Neuroglandular junctions, 288 Neuroglia (noo-ROG-lē-uh): Cells of the CNS that support and protect the neurons, (Chs 4, 8), 143, 275, 277-279 Neurology, 326 Neuromuscular junction: A specific type of neuroeffector junction, (Chs 7, 8), 227, 228-229, 288 Neuron (NOOR-on): A cell in nervous tissue specialized for intercellular communication by (1) changes in membrane potential and (2) synaptic connections, (Chs 3, 4, 8) action potentials, 283–288 aging, effect of, 324 cell type, 87, 101 described, 143, 275 functional classification, 277 general structure, 276 membrane potential, 281-283, 284-285 nerve impulses, 281-288 neuroglia, relationship to, 279 organization of, 280 structural classification, 276-277 Neuronal pools, 290-291 Neurotoxins, 326 Neurotransmitter: Chemical compound released by one neuron to affect the membrane potential of another, (Chs 7, 8, 10), 227, 288–290, 376. See also specific neurotransmitters Neutralization as antibody function, 522 Neutron: A fundamental particle that does not carry a positive or negative charge, (Ch 2), 56 Neutrophil (NOO-tro-fil): A phagocytic microphage that is very numerous and usually the first of the mobile phagocytic cells to arrive at an area of injury or infection, (Chs 11, 14), 413, 419, 424, 425, 426, 512, 514, 524 Newborns. See Neonatal period Niacin (vitamin B3), 623, 625 Nicotinamide adenine dinucleotide. See NAD (nicotinamide adenine dinucleotide)

Nicotine, 155 Nicotinic acid (vitamin B3), 623, 625 Night blindness, 357 Nipple: An elevated epithelial projection on the surface of the breast, containing the openings of the lactiferous sinuses, (Ch 19), 690, 691 Nissl bodies: The ribosomes, Golgi, rough endoplasmic reticulum, and mitochondria of the cytoplasm of a typical nerve cell, (Ch 8), 276 Nitric oxide (NO), 290, 681 Nitrogen decompression sickness, 553 normal concentrations in air, 553 significance in human body, 57 Nitrogenous bases in nucleic acids, 77, 78 Nitrogenous wastes: Organic waste products of metabolism that contain nitrogen; include urea, uric acid, and creatinine, (Ch 17), 621 NK (natural killer) cells, 506, 507, 512, 513, 524, 525 NO (nitric oxide), 290, 681 Nociception (nō-sē-SEP-shun): Pain perception, (Ch 9), 337-338 Nociceptors, 337 Nodal cells of the heart, 446, 447 Node of Ranvier: Area between adjacent glial cells where the myelin covering of an axon is incomplete, (Ch 8), 279 Non-Hodgkin lymphoma, 528 Nondisplaced fractures, 180 Nonessential amino acids, 620 Nonpolar covalent bonds, 60 Nonself (foreign) antigens, 516 Nonshivering thermogenesis, 628 Nonspecific resistance/defenses, 511. See also Innate (nonspecific) immunity/defenses Nonstriated involuntary muscle, 143. See also Smooth muscle tissue Noradrenaline. See Norepinephrine (NE) Norepinephrine (NE) (nor-ep-i-NEF-rin): a neurotransmitter in the PNS and CNS and a hormone secreted by the adrenal (suprarenal) medulla; also called noradrenaline, (Chs 8, 10, 12, 13, 18) adrenal medulla, 381, 391, 392 adrenergic synapses, 290 amino acid derivative, 376 angiotensin II, 650 cardiovascular regulation, 476, 477 endocrine hormone, 377 heart, effects on, 453, 455 postganglionic sympathetic fibers, 320 synaptic function, 289 Normal saline, 95 Normovolemic, defined, 430 Nose, 44, 537, 538, 539 Nostrils: The entrance from the exterior to the nasal cavity; formerly external nares, (Ch 15), 538, 539 Nuclear envelope, 89, 101, 106, 107 Nuclear imaging, 81 Nuclear pores, 89, 106 Nucleases, 588, 598 Nucleic acids (noo-KLĀ-ik): A chain of nucleotides containing a five-carbon sugar, a phosphate group, and one of four nitrogenous bases that regulate the synthesis of proteins and make up the genetic material in cells, (Chs 2, 17). See also DNA (deoxyribonucleic acid); RNA (ribonucleic acid) catabolism of, 621-622 chemical level of organization, 76-78, 79, 80 synthesis of, 622 Nucleolus (noo-KLĒ-o-lus): Dense region in the nucleus that represents the site of RNA synthesis, (Ch 3), 89, 106 Nucleoplasm, 106 Nucleosomes, 106, 107 Nucleotide: Compound consisting of a nitrogenous base, a simple sugar, and a phosphate group, (Ch 2), 77, 78, 79 Nucleus, cell: Cellular organelle that contains DNA, RNA, and proteins, (Ch 3), 89, 106-108 Nucleus, cerebral: A mass of gray matter in the CNS,

(Ch 8), 280 Nucleus of an atom, 57 _

GLOSSARY / INDEX

G-23

- Nurse cells: Supporting cells of the seminiferous tubules of the testis, responsible for the differentiation of spermatids and the secretion of inhibin; also called *sustencocytes or Sertoli cells*, (Chs 10, 19), 397–398, 675, 676, 682, 683
- Nutrient: A part of food (vitamin, mineral, carbohydrate, lipid, protein, or water) that is necessary for normal physiologic function, (Chs 2, 5, 16, 17, 18, 20) defined, 607 described, 64 maternal needs, during pregnancy, 719 processing and absorption of, 596–599 synthesis and storage in the skin, 152 urinary system conservation of, 636 Nutrient pool, 607, 609, 610 Nutrition. *See also* Metabolism and energetics defined, 622 diet and disease, 626 elderly people, 629 food groups and MyPlate, 622–623 minerals, 623, 624 vitamins, 624, 625

Nutritionists, 622 Nystagmus, 369

0

Obesity: Body weight more than 50 percent above the ideal weight for a given individual, (Chs 13, 17), 463,629 Oblique muscles (of the trunk), 244, 247, 252 Obstructive shock, 478 Obturator artery, 487 Obturator foramen, 200, 201 Obturator nerve, 312 Obturator vein, 490 Occipital artery, 485 Occipital bone, 186, 187, 188, 189 Occipital condyles, 186, 188 Occipital lobe, 296, 300 Occipitalis muscle, 245, 248, 249 Occipitofrontalis muscle, 249 **Ocular:** Pertaining to the eye (Ch 1), 44 Oculomotor muscles, 345–346 Oculomotor nerve (ok-ū-lō-MŌ-ter): Cranial nerve III, which controls the extrinsic oculomotor muscles other than the superior oblique and the lateral rectus, (Chs 8, 9), 307, 309, 310, 311, 322, 323, 346 Odontoid process (dens), 193, 194 Odorant-binding proteins, 342 Odorants, 342 Oil glands. See Sebaceous glands Oils, 70 Olecranon: The proximal end of the ulna that forms the prominent point of the elbow, (Chs 1, 6), 44, 199 Olecranon fossa, 198 Oleic acid, 71 Olfaction: The sense of smell, (Ch 9) age-related effects, 368 olfactory organs, 341-342 olfactory pathways, 343 overview of, 337, 341-342 special sense, 337 Olfactory bulb (ol-FAK-to-rē): Expanded ends of the olfactory tracts; the sites where the axons of CN I synapse on CNS interneurons that lie beneath the frontal lobe of the cerebrum, (Chs 8, 9), 309, 342, 343 Olfactory cortex of the temporal lobe, 300, 301 Olfactory epithelium, 342, 343 Olfactory glands, 342 Olfactory nerve (I), 307, 309, 310, 342, 343 Olfactory organs, 341-343 Olfactory pathways, 343 Olfactory receptor cells, 276, 342 Olfactory tracts, 309 Oligodendrocytes (o-li-gō-DEN-drō-sīts): CNS glial cells responsible for maintaining cellular organization in the gray matter and providing a myelin sheath in areas of white matter, (Ch 8), 278, 279 Omega-3 fatty acids, 71

Oncogene (ON-kō-jēn): A gene that can turn a normal cell into a cancer cell. Oncologists (on-KOL-o-jists): Physicians specializing in the study and treatment of tumors, (Ch 3), 115 **Oocyte** (ō-ō-sīt): A cell whose meiotic divisions will produce a single ovum and three polar bodies. (Chs 19, 20), 673, 683, 685-687, 692, 696, 697 Oocyte activation, 707, 708 Oogenesis (ō-ō-JEN-e-sis): Formation and development of an oocyte, (Ch 19), 683, 685 **Oogonia** (ō-ō-GŌ-nē-uh): Stem cells in the ovaries whose divisions give rise to oocytes, (Ch 19), 683, 685 Oophoritis, 699 Open (compound) fractures, 180 Openings (bone marking), 183 Ophthalmic branch of the trigeminal nerve, 309 Ophthalmology, 369 Opportunistic infections, 523 Opposition (movement), 208, 209 **Opsin:** A protein that is a structural component of the visual pigment rhodopsin, (Ch 9), 354, 356 Opsonins, 522 Opsonization, 522 Optic canal, 188 Optic chiasm (OP-tik KĪ-azm): Crossing point of the optic nerves, (Chs 8, 9, 10), 297, 309, 357, 382 Optic disc, 347, 350 Optic foramina, 309 Optic nerve (II): Nerve that carries signals from the eye to the optic chiasm, (Ch 8), 307, 309, 310, 346, 347, 349, 350, 357 Optic tract: Tract over which nerve impulses from the retina are transmitted between the optic chiasm and the thalamus, (Chs 8, 9), 309, 357, 358 Oral cavity aging, effect of, 600 boundaries, 573 digestive tract component, 570 salivary glands, 570, 574 teeth, 570, 574–576 tongue, 570, 573 Oral contraceptives, 698 Oral mucosa, 573 Oral region, 44 Orbicularis oculi muscle, 248, 249 Orbicularis oris muscle, 248, 249 Orbit: Bony cavity of the skull that contains the eyeball, (Ch 6), 186, 187, 188 Orbital fat, 346, 347 Orbital region, 44 Orchiectomy, 676 Orchitis, 699 Organ level of organization, 34, 35 Organ of Corti. See Spiral organ Organ system level of organization, 34, 35 Organ systems. See also specific systems cardiovascular system, 38 digestive system, 39 endocrine system, 38 explained, 33 integumentary system, 37 lymphatic system, 38 muscular system, 37 nervous system, 37 reproductive system, 39 respiratory system, 38 skeletal system, 37 systemic physiology, 34 urinary system, 39 Organelle (or-gan-EL): An intracellular structure that performs a specific function or group of functions, (Ch 3) centrioles, 88, 100-101 cilia, 88-89, 101 cytoskeleton, 88, 100 endoplasmic reticulum, 88-89, 99, 101-102, 104 flagella, 101 Golgi apparatus, 88-89, 102, 105 lysosomes, 88-89, 97, 98, 102-103, 105 microvilli, 88, 99, 100 mitochondria, 88–89, 103, 106 peroxisomes, 88-89, 103 proteasomes, 88-89, 101 ribosomes, 88-89, 101, 104

Organic compounds: A compound containing carbon, hydrogen, and usually oxygen, (Ch 2) carbohydrates, 68-70, 79, 80 defined, 64 high-energy compounds, 78–79, 80 lipids, 70–73, 79, 80 nucleic acids, 76–77, 79, 80 proteins, 73–76, 79, 80 Organic wastes in large intestine, 595 Organism level of organization, 34, 35 Organization, levels of, 34-36 Organogenesis: The formation of organs during embryonic and fetal development, (Ch 20), 717, 720-721 Organs: Combinations of tissues that perform complex functions, (Ch 1), 33 Orgasm, defined, 695 Origin: Point of attachment of a muscle which does not change position when the muscle contracts, (Ch 7), 246, 247 **Oris:** The mouth (Ch 1), 44 **Oropharynx:** The middle portion of the pharynx, bounded superiorly by the nasopharynx, anteriorly by the oral cavity, and inferiorly by the laryngopharynx, (Chs 15, 16), 539, 540, 573, 577 Orthopedics, 214 Orthostatic hypotension, 494 Osmolarity (oz-mō-LAR-i-tē): Osmotic concentration; the total concentration of dissolved materials in a solution, regardless of their specific identities, (Ch 18), 659 Osmoreceptor: A receptor sensitive to changes in the osmotic concentration of the plasma, (Ch 10), 385 **Osmosis** (oz-MŌ-sis): The movement of water across a selectively permeable membrane from one solution to another solution that contains a higher solute concentration (Chs 3, 13, 18) capillary hydrostatic pressure, 469 characteristics of, 93 described, 92, 93–95, 99 fluid and electrolyte balance, 642, 644, 645, 656, 658, 660 Osmotic concentration, 95 Osmotic pressure: The force of osmotic water movement; the pressure that must be applied to prevent osmosis across a membrane, (Chs 3, 13), 93-95, 468, 469 Osseus tissue: Bone tissue, strong connective tissue containing specialized cells and a mineralized matrix of crystalline calcium phosphate and calcium carbonate, (Chs 4, 6), 137, 173. See also Bone Ossicles: Small bones. See Auditory ossicles Ossification: The formation of bone, (Ch 6), 175, 176-178 Ossification centers, 177 Osteoarthritis, 206 Osteoblast (OS-tē-ō-blast): A cell that produces the fibers and matrix of bone, (Ch 6), 175, 176 Osteoclast (OS-tē-ō-klast): A cell that dissolves the fibers and matrix of bone, (Ch 6), 175, 176 Osteocyte (OS-tē-ō-sīt): A bone cell responsible for the maintenance and turnover of the mineral content of the surrounding bone, (Chs 4, 6), 137, 139, 173, 174, 176 Osteolysis (os-tē-OL-i-sis): The breakdown of mineral matrix of bone, (Ch 6), 175 Osteomalacia, 178 Osteomyelitis, 214 Osteon (OS-tē-on): The basic histological unit of compact bone, consisting of osteocytes organized around a central canal and separated by concentric lamellae, (Ch 6), 175, 176 Osteopenia, 182 Osteoporosis, 145, 182 Otic: Pertaining to the ear, (Ch 1), 44 Otitis media, 358 Otoliths: Calcium carbonate crystals embedded in a gelatinous matrix; located on each macula of the vestibule, (Ch 9), 362, 363 Outer segment of a photoreceptor, 355 Oval window: Opening in the bony labyrinth where the stapes attaches to the membranous wall of the scala vestibuli (vestibular duct), (Ch 9), 359, 360, 361 Ovarian artery, 484, 683, 684

Ovarian cancer, 699, 733

G-24

Ovarian cycle (ō-VAR-ē-an): Monthly chain of events that leads to ovulation, (Ch 19) follicular phase, 686, 687, 691, 692, 693 luteal phase, 686, 687, 692, 693, 694 ovulation, 686, 687, 691, 692, 693 Ovarian cvst, 699 Ovarian follicles, 683, 685, 686 Ovarian vein, 683, 684 Ovaries: The female gonads, reproductive organs that produce gametes, (Chs 1, 8, 10, 19), 38, 39, 321, 323, 377, 384, 386, 398, 673, 682-687 Oviduct. See Uterine tubes Ovulation (ov-u-LĀ-shun): The release of a secondary oocyte, surrounded by cells of the corona radiata, following the rupture of the wall of a tertiary follicle, (Chs 10, 19, 20) basal body temperature, 693, 694, 699 luteinizing hormone, 383 oocyte activation, 707-708 ovarian cycle, 685-687 **Ovum/ova** (ō-vum): The functional product of meiosis II, produced after fertilization of a secondary oocyte, (Chs 3, 19), 87, 398, 673, 683 Oxygen ATP generation, 238 chemoreceptor reflexes of respiratory function, 559-561 diffusion across plasma membranes, 93 double covalent bond, 59, 60 gas exchange in the lungs, 553, 554, 555 hemoglobin, binding to, 415 inorganic compound, 64, 80 plasma chemoreceptors, level in, 474-475 respiration, 32 significance in human body, 57 transport in the blood, 555, 557 Oxygen debt, 239 Oxytocin (OXT) (oks-i-TŌ-sin): Hormone produced by hypothalamic cells and secreted into capillaries at the posterior lobe of the pituitary gland; stimulates smooth muscle contractions of the uterus or mammary glands in females, and the prostate in males, (Chs 8, 10, 20) endocrine hormone, 377 hypothalamus, 306, 380, 381 labor and delivery, 719-720 lactation, 727 peptide hormone, 376 posterior lobe of the pituitary gland, 385-386, 387 Ozone layer, 157

Ρ

P-R interval, 448, 449 P wave: Deflection of the ECG corresponding to atrial depolarization, (Ch 12), 448, 449 Pacemaker cells: Cells of the sinoatrial (SA) node that set the pace of cardiac contraction, (Chs 4, 7, 12), 143, 242, 446 Pacesetter cells, 243 Pacinian corpuscles (pa-SIN-ē-an): Receptor sensitive to vibration, (Ch 9), 339 Packed cell volume (PCV). See Hematocrit Pain/pain receptors, 146, 337-338 Palate: Horizontal partition separating the oral cavity from the nasal cavity and nasopharynx; includes an anterior bony (hard) palate and a posterior fleshy (soft) palate, (Chs 6, 15, 16), 189, 190. See also Soft palate Palatine bones, 188, 189, 190 Palatine sinuses, 190 Palatine tonsils, 506, 508, 539, 540, 573 Palm, as anatomical landmark, 44 Palmar arches, 481, 482, 484 Palmar region, 44 Palmar venous arches, 483, 489 Palmaris longus muscle, 244, 257, 260, 261 Palpate: To examine by touch. Palpebrae (pal-PE-bre): Eyelids, (Ch 9), 345 Pancreas: Digestive organ containing exocrine and endocrine tissues; exocrine portion secretes pancreatic juice, and endocrine portion secretes hormones, including insulin and glucagon, (Chs 1, 8, 10, 16)

described, 587 digestive system component, 39, 570 disorders of, 588 endocrine function, 377, 393-395, 403 endocrine system component, 38 histological organization, 587-588 pancreatic lipase, 588, 597, 598 pancreatic secretions, control of, 588 Pancreatic acini, 587 Pancreatic amylase, 588 Pancreatic duct: A tubular duct that carries pancreatic juice from the pancreas to the duodenum, (Ch 16), 587, 591, 592 Pancreatic islets: Aggregations of endocrine cells in the pancreas, (Chs 10, 16), 393, 394, 395, 587 Pancreatic juice: A mixture of buffers and digestive enzymes that is discharged into the duodenum under the stimulation of the enzymes secretin and cholecystokinin, (Ch 16), 587 Pancreatic lipase, 588, 597, 598 Pancreatitis, 588 Pantothenic acid (vitamin B5), 594, 623, 624, 625 Pap test. 131 Papilla (pa-PIL-la): A small, conical projection, (Chs 5, 9), 160, 344 Papillary duct of the kidneys, 638, 640 Papillary layer, dermis, 152, 158 Papillary muscles, 440, 442, 443 Parafollicular cells (C cells) of the thyroid gland, 388-389, 390 Paralytic shellfish poisoning, 326 Paranasal sinuses: Bony chambers, lined by respiratory epithelium, that open into the nasal cavity; include the frontal, ethmoidal, sphenoidal, and maxillary sinuses, (Chs 6, 15), 190, 191, 536, 539, 541 Paraplegia, 294 Parasagittal section, 47 Parasympathetic division: One of the two divisions of the autonomic nervous system; generally responsible for activities that conserve energy and lower the metabolic rate; the "rest and digest" division; also called craniosacral division, (Chs 8, 9, 10, 12, 19) body structures, effects on, 325 functions of, 324 heart innervation, 453-454 insulin release, 394 organization of, 322-323 overview of, 319-320 pupils, 348 sexual function, 695 structures in, 322-323 sympathetic division, relationship to, 274-275, 324, 325 Parathyroid (chief) cells, 389, 390 Parathyroid glands: Four small glands embedded in the posterior surface of the thyroid; responsible for parathyroid hormone secretion, (Chs 1, 10), 38, 377, 390 Parathyroid hormone (PTH): A hormone secreted by the parathyroid gland when plasma calcium levels fall below the normal range; causes increased osteoclast activity, increased intestinal calcium uptake, and decreased calcium ion loss by the kidneys, (Chs 6, 10), 182, 377, 380, 390, 400 Paresthesia, 326 Parietal: Referring to the wall of a cavity, (Ch 1), 47 Parietal bones of the cranium, 174, 186, 187, 188, 189 Parietal cells: Cells of the gastric glands that secrete hydrochloric acid (HCl) and intrinsic factor, (Chs 16, 18), 578, 579, 580, 660, 663 Parietal layer of serous membrane, 48, 436, 437 Parietal lobe of the brain, 296, 300 Parietal peritoneum, 49, 571 Parietal pleura, 48, 543, 546, 548, 549 Parieto-occipital sulcus, 300 Parkinson's disease: Progressive motor disorder due to degeneration of the cerebral nuclei, (Ch 8), 307 Parotid duct, 574 Parotid glands (pa-ROT-id): Large salivary glands that secrete a saliva containing high concentrations of salivary (alpha) amylase, (Chs 4, 16), 131, 574 Partial pressures of gases, 552-554 Parturition (par-tū-RISH-un): Childbirth, delivery, (Ch 20), 724 Passive immunity, 516

autonomic nervous system, effects of, 321, 323

Passive transport across plasma membranes, 91-95, 96, 99 Patella (pa-TEL-ah): The bone of the kneecap, (Chs 1, 6), 44, 185, 202 Patellar ligament, 202, 213 Patellar reflex, 314, 315 Patellar region, 44 Patellar surface, 202 Pathogens, defined, 502 Pathological physiology, 34 Pathologists (pa-THOL-o-jists): Physicians specializing in the identification of diseases on the basis of characteristic structural and functional changes in tissues and organs, (Ch 1), 49 Pathology, 34 Pathways, neural, 280 PCL. See Posterior cruciate ligament Pectineus muscle, 244, 259, 262, 263, 264 Pectoral fat pad, 690 Pectoral girdle appendicular skeleton, 185, 186, 196-198 clavicle, 185, 196-197 muscles of, 244, 255–257 scapulae, 185, 196, 197–198 Pectoralis major muscle, 244, 256, 257, 258, 259 Pectoralis minor muscle, 256, 257, 550 Pedal region, 44 Pediatrics, 726 Pedicles (PED-i-kulz): Thick bony struts that connect the vertebral body with the articular and spinous processes, (Ch 6), 192, 194 Peg cells, 687, 707 Pelvic cavity: Inferior subdivision of the abdominopelvic cavity; encloses the urinary bladder, the sigmoid colon and rectum, and male or female reproductive organs, (Ch 1), 48, 49 Pelvic floor, muscles of, 253-255 Pelvic girdle, 185, 186, 200-201 Pelvic inflammatory disease, 688 Pelvic nerves, 322, 323 Pelvic outlet, 201 Pelvic region, 44 Pelvis: A bony complex created by the joints between the hip (coxal) bones, the sacrum, and the coccyx, (Chs 1, 6, 7) anatomical terms, 44 bone markings, 183 described, 201 muscles of, 244-245, 259, 262 Penis (PE-nis): Component of the male external genitalia; a copulatory organ that surrounds the urethra and serves to introduce semen into the female vagina, (Chs 1, 8, 19) autonomic nervous system, effects of, 321, 323 reproductive system, 39, 674, 680–681 Pepsin, 579, 597, 598–599 Pepsinogen, 579 Peptic ulcers, 581 Peptidases, 597, 598, 599 Peptide bonds, 73, 74, 111 Peptide hormones, 376 Peptides, 73-75, 79 Perception, defined, 336 Perforated ulcer, 600 Perforating canal: A passageway in compact bone that runs at right angles to the axes of the osteons, between the periosteum and endosteum, (Ch 6), 175, 176 Perforin, 513, 518, 519 Pericardial arteries, 486, 487 Pericardial cavity (per-i-KAR-dē-al): The space between the parietal layer of serous pericardium and the epicardium (visceral laver of serous pericardium) that encloses the outer surface of the heart, (Chs 1, 12, 15), 47-48, 435, 546, 548 Pericardial fluid, 436 Pericardial sac, 436 Pericarditis, 147, 455 Pericardium (per-i-KAR-dē-um): The fibrous sac that surrounds the heart; its inner, double serous membrane is continuous with the epicardium, (Chs 1, 4, 12), 48, 141, 435 Perichondrium (per-i-KON-drē-um): Layer that surrounds a cartilage, consisting of an outer fibrous and an inner cellular region, (Chs 4, 6), 137, 177, 205

- Perilymph (PER-ē-limf): A fluid similar in composition to cerebrospinal fluid; found in the spaces between the bony labyrinth and the membranous labyrinth of the internal ear, (Chs 9, 18), 359-360, 657, 659 Perimenopause, 696 Perimetrium, 687, 688 **Perimysium** (per-i-MIZ-ē-um): Connective tissue partition that separates adjacent fasciculi in a skeletal muscle, (Ch 7), 223 Perineum (per-i-NĒ-um): The pelvic floor and associated structures, (Chs 7, 19) muscles of, 253, 254, 255 structures of, 671, 681 Periodontal disease, 600 Periodontal ligament, 575 Periosteum (per-ē-OS-tē-um): Layer that surrounds a bone, consisting of an outer fibrous and inner cellular region, (Chs 4, 6), 139, 174, 175 Peripheral nerve palsies, 313 Peripheral nerves, 37, 309 Peripheral nervous system (PNS): All nervous tissue outside the CNS, (Chs 1, 8). See also Autonomic nervous system (ANS) anatomical organization, 280 CNS, functional relationship to, 275 cranial nerves. See Cranial nerves divisions of, 274-275 nerve plexuses, 311-313 nervous system component, 37 reflexes, 313-316 sensory and motor pathways, 316-319 spinal nerves, 311, 312 Peripheral neuropathies, 313 Peripheral resistance: The resistance to blood flow primarily caused by friction with the vascular walls, (Ch 13), 466, 467, 471 **Peristalsis** (per-i-STAL-sis): A wave of smooth muscle contractions that propels materials along the axis of a tube such as the digestive tract, the ureters, or the ductus deferens, (Chs 16, 18, 19), 572, 653, 679,687 Peritoneal cavity, 48 Peritoneum (per-i-tō-NĒ-ūm): The serous membrane that lines the peritoneal (abdominopelvic) cavity, (Chs 1, 4), 49, 141 Peritonitis, 147, 600 Peritubular capillaries: A network of capillaries that surrounds the proximal and distal convoluted tubules of the nephrons in the kidneys, (Ch 18), 638,639 Peritubular fluid, 642, 643 Permanent teeth, 575, 576 **Permeability:** Ease with which dissolved materials can cross a membrane; if freely permeable, any molecule can cross the membrane; if impermeable, nothing can cross. Most biological membranes are selectively permeable, and some materials can cross, (Chs 3, 4), 91, 123 Permissive effects of hormones, 399 Pernicious anemia, 418 Peroneus (fibularis) muscles, 244, 263 Peroxisomes, 88-89, 103 Perpendicular plate of the ethmoid bone, 188, 190 Perspiration, 65, 163 PET (positron emission tomography) scan, 51 Peyer patches, 506 pH: The pH value of a solution is a measure of its hydrogen ion concentration, with pH values ranging from 0 to 14; solutions may be acidic (\leq 7), neutral (7), or basic (≥ 7) ; A difference of one pH unit equals a tenfold change in H+ concentration, (Chs 2, 7, 13, 15, 18) acid-base balance, 656, 660-664 of blood, 411 of body fluids, 66-67 buffers, 68 chemoreceptors, 474-475 muscle fatigue, 239 oxygen binding to hemoglobin, 555 urinary system regulation, 636, 656 Phagocyte: A cell that performs phagocytosis, (Chs 3, 4, 8, 11, 14), 97-98, 133, 275, 278, 415, 416, 425, 427, 511, 512–513, 514, 517, 522, 524. See also Phagocytosis
- Phagocytic regulators, 524 Phagocytize, defined, 133 Phagocytosis (fag-ō-sī-TŌ-sis): The engulfing of extracellular materials or pathogens; movement of extracellular materials into the cytoplasm by enclosure in a membranous vesicle, (Chs 3, 11, 14), 97-98, 416, 424, 517, 522 Phalangeal regions, 44 Phalanx/phalanges (fa-LAN-jēz): A bone of the fingers or toes, (Chs 1, 6) anatomical landmark, 44 fingers, 185, 199-200 foot, 185, 202-203 Pharmacology: The study of drugs, their physiological effects, and their clinical uses Pharyngeal phase of swallowing, 577 Pharyngeal tonsils, 506, 508, 539, 540, 573 Pharyngotympanic tube: A passageway that connects the nasopharynx with the middle ear cavity; also called Eustachian tube or auditory tube, (Chs 4, 9, 15), 137, 358, 359, 539, 540 Pharynx: The throat; a muscular passageway shared by the digestive and respiratory tracts, (Chs 1, 15, 16) digestive system component, 39, 570, 576 respiratory system component, 38, 536, 537, 539-540 Phenotype (FEN-ō-tīp): Physical characteristics that are genetically determined, (Ch 20), 728 Phenotypic characters, 729 Phenylalanine, 109, 620 Phenylketonuria (PKU), 81, 620, 733 Phlebitis, 494 Phlebotomy, 430 Phosphate buffer system, 662 Phosphate group: PO₄³⁻, (Chs 2, 6, 7, 10, 18), 77, 78, 175, 214, 233, 237, 378, 658 Phosphodiesterase (PDE), 379 **Phospholipid** (FOS-fō-lip-id): An important membrane lipid whose structure includes both hydrophilic and hydrophobic regions, (Chs 2, 3, 17), 70, 72-73, 90, 618, 619 Phospholipid bilayer, 90 Phosphorus dietary guidelines, 624 significance in human body, 57 Phosphorylation (fos-for-i-LĀ-shun): The addition of a high-energy phosphate group to a molecule, (Ch 10), 378-379 Photons, 353 Photoreception: Sensitivity to light, (Ch 9), 356-357 Photoreceptors, 349, 350, 351, 353-358, 368 Photorefractive keratectomy (PRK), 354 Phrenic arteries, 485, 486 Phrenic nerve, 312 Phrenic veins, 489, 490 Physical barriers as innate (nonspecific) immunity, 502, 511 - 512Physical conditioning, and muscle performance, 241 Physiology (fiz-ē-OL-o-jē): The study of the function; deals with the ways living organisms perform vital activities, (Ch 1) biology, subspecialty of, 32 defined, 34 subspecialties, 34 Pia mater: The innermost layer of the meninges that surrounds the CNS, (Ch 8), 291, 292 Pigmentation, of skin, 156 Pigmented part of the retina, 347, 348 Pineal gland (PIN-ē-al): Neural tissue in the posterior portion of the roof of the diencephalon, responsible for the secretion of melatonin, (Chs 1, 8, 9, 10), 38, 296, 297, 306, 307, 358, 377, 393 Pinna, See Auricle (ear) Pinocytosis (pi-nō-sī-TŌ-sis): The introduction of fluids into the cytoplasm by enclosing them in membranous vesicles at the cell surface, (Ch 3), 98 Pisiform bone, 199, 200 Pitch of sound, 363, 365 Pituitary gland: Endocrine organ situated in the sella turcica of the sphenoid bone and connected to the hypothalamus by the infundibulum; includes the posterior lobe and the anterior lobe, (Chs 1, 6, 8, 10) anterior lobe, 381–385, 386, 387 endocrine organ, 377

endocrine system component, 38 hypothalamus, connected to, 296 location, 187, 381 posterior lobe, 385-386, 387 Pivot joints, 208, 210 PKU (phenylketonuria), 81, 620, 733 Placenta (pla-SEN-tuh): A temporary structure in the uterine wall that permits diffusion between the fetal and maternal circulatory systems; also called afterbirth, (Chs 13, 19, 20) blood supply to, 492, 493 circulation, 713, 716 delivery of, 724, 725 endocrine organ, as, 713, 716-717 formation of (placentation), 712-713, 715 hormones of, and mammary glands, 691 Placenta previa, 735 Placental prolactin, 717 Placental stage of labor, 724, 725 Placentation, 712-713, 715 Plane joints, 208, 210 Plane movement (gliding movement), 206 Planes, sectional, 44–45, 47 Plantar: Referring to the sole of the foot, (Ch 1), 44 Plantar arch, 482, 486 Plantar flexion, 208, 209, 246 Plantar reflex, 316 Plantar region, 44 Plantar veins, 488 Plantar venous arch, 483, 488 Plantaris muscle, 245, 263, 265, 266 Plaque arterial, 429, 463 dental, 576 Plasma (PLAZ-muh): The fluid ground substance of whole blood; what remains after the cells have been removed from a sample of whole blood, (Chs 4, 11, 15, 18) carbon dioxide in, 555–556 composition of, 411, 412–413 fluid connective tissue, 136 ion concentrations in, 658 plasma proteins, 411, 412-413 solute concentrations, 644 Plasma cell: An activated B cell that secretes antibodies, (Ch 14), 506, 507, 520, 522, 523, 525 Plasma membrane: A cell membrane, (Chs 2, 3, 8, 10) carrier-mediated transport, 92, 95-97, 99 cell anatomy, 87, 88 cholesterol, 72 diffusion across, 92-95, 99 filtration across, 99 functions of, 87, 88, 90 hormonal action at, 377-380 membrane carbohydrates, 90, 91 membrane lipids, 90 membrane potential, 281-283, 284-285 membrane proteins, 90, 91 osmosis across, 92, 93-95, 99 passive transport across, 91-95, 96, 99 phospholipids, 73 polarization of, 281 structure of, 90 vesicular transport, 92, 97-99 Plasmin, 430 Plasminogen, 430 Plateau period after cardiac muscle cell depolarization, 445, 446 Platelet factor, 428, 429-430 Platelet phase of hemostasis, 428 Platelet plug, 428 Platelets (PLĀT-lets): Small packets of cytoplasm that contain enzymes important in the clotting response; manufactured in red bone marrow by cells called megakaryocytes, (Chs 4, 11), 137, 412-413, 426, 427, 428, 430 origins and differentiation of, 419 Platysma, 246, 248, 249 Pleura (PLOO-ra): The serous membrane lining the pleural cavities, (Chs 1, 4, 15), 48, 141, 546-548 Pleural cavities: Body cavities of the thoracic region that surround the lungs, (Chs 1, 15), 48, 546-548 Pleural effusion, 147

Pleural fluid, 547, 562

Pleurisy, 562 Pleuritis, 147 Plexus: A network or braid. See specific plexuses Plicae circulares. See Circular folds Pneumocystis carinii pneumonia, 546 Pneumocytes type I, 544 Pneumocytes type II, 544 Pneumonia, 546 Pneumothorax, 547 PNS. See Peripheral nervous system (PNS) Podocyte (PO-do-sit): A cell whose processes surround the glomerular capillaries and assist in filtration, (Ch 18), 641–642 Point mutation, 112 **Polar body:** A nonfunctional packet of cytoplasm containing chromosomes eliminated from an oocyte during meiosis, (Ch 19), 683, 685 Polar covalent bond: A form of covalent bond in which there is an unequal sharing of electrons, (Ch 2), 60.61 Polar molecules, 60 Polarized plasma membrane, 281 Polio, 267 Pollex: The thumb, (Chs 1, 6), 44, 200 Polycythemia, 430 Polydipsia, 385 Polygenic inheritance, 730 Polymer: A large molecule consisting of a long chain of subunits (monomers). Polypeptide: A chain of amino acids strung together by peptide bonds; those containing over 130 peptides are called proteins, (Chs 2, 3), 73, 74, 111 Polyps, 600 Polysaccharide (pol-ē-SAK-uh-rīd): A complex sugar, such as glycogen or starch, (Ch 2), 69, 70, 79 Polyspermy, 707 Polysynaptic reflex: A reflex with interneurons interposed between the sensory fiber and the motor neuron(s), (Ch 8), 314-315 Polyunsaturated fatty acid: Fatty acids containing carbon atoms linked by double bonds, (Ch 2), 71 Polyuria, 396 Pons: The portion of the brain anterior to the cerebellum, (Cĥ 8), 296, 297, 307, 308, 558 Pontine micturition center, 654, 655 Pontine storage center, 654, 655 Popliteal (pop-LIT-ē-al): Pertaining to the back of the knee, (Ch 1), 44 Popliteal artery, 470, 482, 486 Popliteal vein, 483, 488 Popliteus muscle, 247, 261, 262, 264, 265 Pores of the nephron endothelial cells, 641, 642 Portal system, hepatic, 489, 491 Portal system of the anterior pituitary gland, 382 Portal triad (portal area) of the liver, 589, 590 Portal veins, 382 Portal vessel, 489 Portal vessels of the anterior pituitary gland, 382 Positive chemotaxis, 424 Positive feedback: Process that increases a deviation from normal limits after an initial stimulus, (Chs 1, 20), 42, 723 Positive feedback loop, 41 Positron emission tomography (PET) scan, 51 Postcentral gyrus, 296, 300, 301 **Posterior:** Toward the back, dorsal, (Ch 1), 43, 44, 46 Posterior cavity of the eye, 346, 347, 349, 350, 351 Posterior chamber of the eye, 346, 347, 350, 351 Posterior column pathway, 317 Posterior communicating artery, 485 Posterior cruciate ligament (PCL), 212-213 Posterior gray commissures, 295, 296 Posterior horns of spinal cord gray matter, 295, 296 Posterior internal apertures: The entrance from the nasal cavity to the nasopharynx; formerly internal nares, (Ch 15), 538, 539 Posterior interventricular (descending) artery, 444 Posterior interventricular sulcus, 436 Posterior lobe of the pituitary gland, 377, 385-387 Posterior median sulcus of the spinal cord, 294, 295 Posterior portion of frontal section, 44, 47 Posterior (dorsal) roots of the spinal cord, 294 Posterior semicircular ducts, 362 Posterior tibial artery, 470, 482, 486

Posterior tibial vein, 483, 488 Posterior white columns, 295, 296 Postganglionic fiber: The axon of a ganglionic neuron, (Ch 8), 319 Postnatal development adolescence, 722, 726, 727-728 childhood, 722, 726, 727 continuous process, 706 early, overview of, 720–721 infancy, 722, 726, 727 maturity, 722, 726, 727–728 neonatal, 722, 726-727 Postsynaptic membrane, 288, 289 Postsynaptic neuron, 288, 289, 290 Posttraumatic stress disorder (PTSD), 403 Potassium cardiac output, 453 cell homeostasis, 96-97 dietary guidelines, 624 electrolyte balance, 660 ICF, 658 ions in body fluids, 59 membrane potential, 281-282, 284-285 significance in human body, 57 urinary system regulation, 636 urine and plasma, amounts in, 644 Potential difference: The separation of opposite charges; requires a barrier that prevents ion migration, (Ch 8), 281 Potential energy, 61 Potential spaces, 47 Pott's fracture, 181 Pre-embryo, 687, 709 Precapillary sphincter, 464 Precentral gyrus: The primary motor cortex of a cerebral hemisphere, anterior to the central sulcus, (Ch 8), 296, 300, 301 Precipitation, 522 Precocious puberty, 400, 402 Preeclampsia, 735 Prefrontal cortex, 302 Prefrontal lobotomy, 302 Preganglionic fibers, 319 Preganglionic neuron: Visceral motor neuron inside the CNS whose output controls one or more ganglionic motor neurons in the PNS, (Ch 8), 319, 320, 321, 322, 323 Pregnancy blood types of mother and fetus, 421, 422, 423 ectopic, 710 first trimester, 709–717, 722 labor and delivery, 719–720 maternal systems, effects on, 717-719 mortality rate in U.S., 699 multiple births, 719-720 premature labor, 724 second trimester, 709, 717-723 third trimester, 709, 717-723 trimesters in, 709 Premature delivery, 724 Premature labor, 724 Premature menopause, 696 Premolars: Bicuspids; teeth with flattened surfaces located anterior to the molar teeth, (Ch 16), 575.576 Premotor cortex (somatic motor association area), 300, 301 Prenatal development, 706, 720-721, 722 **Prepuce** (PRĒ-poos): Loose fold of skin that surrounds the glans penis in males (foreskin) or the clitoris in females, (Ch 19) clitoris, 690 glans penis, 680, 681 Preputial glands, 680 Presbycusis, 368 Presbyopia, 354, 368 Pressure airflow to the lungs, 549, 550 blood flow, 466-467 Pressure gradient, 466, 549 Pressure points, 470 Pressure receptors (baroreceptors), 338, 340 Presynaptic membrane: The synaptic surface where neurotransmitter release occurs, (Ch 8), 289 Presynaptic neuron, 288, 289

Prickling pain (fast pain), 337-338 Primary actions, muscles, 246 Primary amenorrhea, 689 Primary cilium, 101 Primary follicles, 685, 686 Primary (short-term) memories, 304 Primary motor cortex, 301 Primary neoplasm, 114 Primary oocytes, 683, 685, 686 Primary response to antigen exposure, 522-523 Primary somatosensory cortex, 300, 301 Primary spermatocyte, 677, 678 Primary spinal curves, 193 Primary teeth. See Deciduous teeth Primary tumor, 114 Prime mover: A muscle that performs a specific action, (Ch 7), 246 Primitive streak of the inner cell mass, 712 Primordial follicles, 683, 685 PRL. See Prolactin (PRL) Process: A projection or bump of the skeleton, (Ch 6), 183. See also specific processes Products of chemical reactions, 61, 62 Products of enzymatic reactions, 76 Proenzymes, 428, 588 Progesterone (prō-JES-ter-ōn): The most important hormone secreted by the corpus luteum following ovulation, (Chs 10, 19, 20), 689, 691, 693, 694 corpus luteum, 687 endocrine hormone, 377, 398 female reproductive function, 683, 697 hormonal contraceptives, 698 luteinizing hormone, 383, 386, 387 placental production, 717 postovulatory phase of the ovarian cycle, 692, 693, 694 source, regulation of, and primary effects, 697 Progestin, 698 Projection (bone marking), 182, 183 Prolactin (PRL) (prō-LAK-tin): Hormone that stimulates functional development of the mammary gland in females; a secretion of the anterior lobe of the pituitary gland, (Chs 10, 20), 376, 377, 384, 386, 387, 717 Prolactin-inhibiting hormone, 384 Prolactin-releasing factor, 384 Proliferation phase, in skin repair, 165 Proliferative phase: A portion of the uterine cycle; period of estrogen-induced repair of the functional layer of the endometrium through the growth and proliferation of epithelial cells in the uterine glands not lost during menstruation, (Ch 19), 689, 693, 694 Proline, 109 Promoter segment of DNA, 108 **Pronation** (prō-NĀ-shun): Rotation of the forearm that makes the palm face posteriorly, (Ch 6), 199, 208 Pronator quadratus muscle, 259, 260, 261 Pronator teres muscle, 244, 260, 261 Prone, defined, 43 Pronucleus: Enlarged ovum or sperm nucleus that forms after fertilization but before amphimixis, (Ch 20), 707, 708 Prophase (PRO-faz): The initial phase of mitosis, characterized by the appearance of chromosomes, breakdown of the nuclear membrane, and formation of the spindle apparatus, (Ch 3), 112, 113, 114 Prophylactic (condom), 698 **Proprioception** (prō-prē-ō-SEP-shun): The awareness of the positions of bones, joints, and muscles, (Chs 8, 9), 277, 337, 340 Proprioceptors, 277, 338, 340 Prostaglandin (pros-tuh-GLAN-din): A fatty acid secreted by one cell that alters the metabolic activities or sensitivities of adjacent cells; also called a local hormone, (Chs 10, 14, 20) allergic reactions, 527 immune response, 524 labor and delivery, 723 lipid derivatives, 376 local hormones, 376 Prostate (PROS-tāt): Accessory gland of the male reproductive tract, contributes roughly one-third of the volume of semen, (Chs 1, 18, 19), 39, 653, 664, 674, 679, 680

Prostate cancer, 680, 699, 733 Prostatectomy, 699 Prostatic fluid, 680 Prostatitis (prostatic inflammation), 680 Proteases, 101, 588, 597, 598 Proteasomes, 88-89, 101 Protein: A large polypeptide with a complex structure, (Chs 2, 3, 8, 11, 17, 18) amino acid catabolism, 619-620, 621 ATP production, 617 complete and incomplete, 623 concentration in body fluids, 658 deficiency, 620 dietary guidelines for, 622, 623 digestion and absorption, 597, 598-599 elderly people, 629 enzyme function, 73, 75-76 functions of, 73, 80 metabolism of, 619-620 negatively charged, 281, 282 plasma, in, 411, 644 protein buffer systems, 661–662 proteinuria, 665 structure of, 73-75, 79 synthesis of, 104-105, 108-111, 121, 620 urine, amounts in, 644 Protein buffer systems, 661-662 Protein deficiency diseases, 620 Proteinuria, 665 Proteoglycans, 123 Proteolytic enzymes, 579 Prothrombin: Circulating proenzyme of the common pathway of the clotting system; converted to thrombin by the enzyme prothrombinase, (Ch 11), 428, 430 Prothrombin activator, 428, 430 Proton: A fundamental subatomic particle having a positive charge, (Ch 2), 56, 57 Protraction: To move anteriorly in the horizontal plane, (Ch 6), 208, 209 **Proximal:** Toward the attached base of an organ or structure, (Ch 1), 46 Proximal convoluted tubule (PCT), 637, 638, 639, 640, 642, 645,647 Proximal phalanges, 185, 199, 200 Proximal radio-ulnar joint, 199 Pruritus, 167 Pseudopodia (soo-dō-PŌ-dē-ah): Temporary cytoplasmic extensions typical of mobile or phagocytic cells, (Ch 3), 98 Pseudostratified epithelium: An epithelium containing several layers of nuclei but whose cells are all in contact with the underlying basement membrane, (Ch 4), 128, 129 Psoas major muscle, 259, 262, 263, 264 Psoriasis, 156, 528 Pterygoid muscle, 248, 249 PTH. See Parathyroid hormone (PTH) PTSD (posttraumatic stress disorder), 403 Puberty: Period of rapid growth, sexual maturation, and the appearance of secondary sexual characteristics; normally occurs at age 4015, (Chs 5, 6, 19, 20) adolescence beginning at, 727-728 cryptorchidism, 676 endochondral ossification, 178 exocrine gland activity, 162 Pubic angle, 201 Pubic region, 44, 45 Pubic symphysis: Fibrocartilaginous amphiarthrosis between the pubic bones of the hip, (Ch 6), 200, 201 Pubis (PŪ-bis): The anterior, inferior component of the hip bone, (Chs 1, 6), 44, 200 Pudendum (vulva), 690 Pulled groin, 259 Pulled hamstring muscle, 261 Pulmonary arteries, 440 Pulmonary arterioles, 481 Pulmonary circuit: Blood vessels between the pulmonary semilunar valve of the right ventricle and the entrance to the left atrium; the circulation flow through the lungs, (Chs 12, 13, 15) described, 480-481 functional patterns, 480-481

heart's role in cardiovascular system, 435, 436 partial pressures, 553, 554 respiratory exchange surfaces, 546 Pulmonary edema, 469 Pulmonary embolism, 429, 493, 546 Pulmonary semilunar valve, 440, 442, 443 Pulmonary trunk, 438, 440, 442, 459, 461, 480, 481 Pulmonary veins, 441, 481 Pulmonary ventilation: Movement of air into and out of the lungs, (Ch 15), 549-552 Pulp cavity: Internal chamber in a tooth, containing blood vessels, lymphatics, nerves, and the cells that maintain the dentin, (Ch 16), 575 Pulse checking, locations for, 470 defined, 467 Pulse pressure, 467 Punnett squares, 730, 731 Pupil: The opening in the center of the iris through which light enters the eye, (Ch 9), 347, 348 Pupillary muscles, 348 **Purkinje cell** (pur-KIN-jē): Large, branching neuron of the cerebellar cortex, (Ch 12), 447 Purkinje fibers: Specialized conducting cardiocytes in the ventricles, (Ch 12), 446, 447, 448 Pus: An accumulation of debris, fluid, dead and dying cells, and necrotic tissue, (Chs 11, 14), 425, 514 Putamen, 305 Pyelitis, 654 Pyelogram, 665 Pyelonephritis, 654 Pyloric sphincter (pī-LOR-ik): Sphincter of smooth muscle that regulates the passage of chime from the stomach to the duodenum, (Ch 16), 577 Pylorus (pī-LOR-us): Gastric region between the body of the stomach and the duodenum; includes the pyloric sphincter, (Ch 16), 577, 578 Pyramidal cells of the cerebral cortex, 318 Pyramidal system, 318 Pyrexia, 129 Pyridoxine (vitamin B6), 619, 623, 625 Pyrogens, 514 Pyruvate: The anion formed by the dissociation of pyruvic acid, a three-carbon compound produced by glycolysis, (Chs 3, 7, 17), 103, 238, 239, 611 Pyruvic acid, 611 0 Q-T interval, 448, 449 QRS complex, 448, 449 Quadrate lobe of the liver, 588, 589 Quadratus lumborum muscle, 251, 252 Quadriceps femoris muscle, 202, 261 Quadriplegia, 294 Quaternary structure: The three-dimensional protein structure produced by interactions between

Quaternary structure: The three-dimensional prof structure produced by interactions between protein subunits (Ch 2), 74, 75 Quiet breathing, 551, 558

Radioisotopes, 57 Radiologists, 49 Radiology, 49 Radiopacity, 50 Radiopaque, 50 Radiopharmaceuticals, 81 Radius, 181, 185, 198-199 Ramus: A branch, (Ch 6), 183

Ramus of the mandible, 190 Rapid depolarization of cardiac contractile cells, 445, 446 RAS (reticular activating system), 307, 337 Raynaud's phenomenon, 494 RBCs. See Red blood cells (RBCs) Reabsorption, in urine formation, 640, 642, 643-644, 645, 647, 649 Reactant, 61, 62, 65 Recall of fluids, 469 Receptive field, 336 Receptor-mediated endocytosis, 97-98 Receptor proteins, 91 Receptor sites for carrier proteins, 96 Receptors for homeostatic regulation, 36, 40 Recessive gene: An allele that will affect the phenotype only when the individual is homozygous for that trait, (Ch 20), 729, 730, 731 Reciprocal inhibition, 314, 315 Recognition proteins (identifiers), 91 Recombinant DNA, 115 Recovery period of muscle contractions, 239 Recruitment, 236 Rectum (REK-tum): The last 15 cm (6 in.) of the digestive tract, (Chs 8, 16), 323, 593, 594 Rectus: Straight, (Ch 7), 246 Rectus abdominis muscle, 244, 246, 252, 253, 550 Rectus femoris muscle, 244, 261, 262, 263, 264 Red blood cells (RBCs) described, 412-413 fluid connective tissue, 136 formation, 173, 417, 418-420 hemoglobin, abnormal, 416, 430 hemoglobin recycling, 415–418 hemoglobin structure and function, 414-415 life span, 415 numbers of, 414 red blood cell count, 414 structure of, 414, 415 Red bone marrow hemoglobin recycling, 417 lymphocytopoiesis, 506, 507 red blood cell formation, 418 Red cones, 353 Red muscles, 241 Red pulp of the spleen, 210 Referred pain, 338 Reflex: A rapid, automatic response to a stimulus, (Chs 8, 15), 274, 313-316, 558-561. See also specific reflexes Reflex arc: The receptor, sensory neuron, motor neuron, and effector involved in a particular reflex; may include interneurons, (Ch 8), 313, 314 Reflex centers of the medulla oblongata, 308 **Refraction:** The bending of light rays as they pass from one medium to another, (Ch 9), 352, 354 Refractory period: Time between the initiation of an action potential and the restoration of the normal resting membrane potential; during this period, the membrane will not respond normally to stimulation, (Chs 8, 12), 283, 285, 445, 446 Regeneration defined, 513 in integumentary system, 164-165, 167 tissues, of, 144-145, 146 Regional anatomy, 33 Regulatory hormones, 380 Regulatory T cells: Population of T lymphocytes that moderate the immune response by inhibiting both T cells and B cells, (Ch 14), 505, 519, 523, 524, 525 Regurgitation of blood through heart valves, 442 Relaxation phase: The period after a contraction when the tension in the muscle fiber returns to resting levels. (Ch 7), 231 Relaxin: Hormone that loosens the pubic symphysis; secreted by the placenta, (Ch 20), 717 Releasing hormones, 380, 382 Remission, defined, 115 Remodeling bone, 179, 182 scar tissue, 146 Renal: Pertaining to the kidneys, (Ch 18), 637 Renal arteries, 482, 485, 486, 638, 639 Renal columns, 637

Renal compensation in pH regulation, 662-663. See also Acid-base balance Renal corpuscle: The initial segment of the nephron, consisting of an expanded chamber that encloses the glomerulus, (Ch 18), 637, 638, 639, 640, 641-642,648 Renal cortex, 637, 648–649 Renal failure, 652 Renal medulla, 637, 648-649 Renal papilla, 637 Renal pelvis, 638 Renal pyramids, 637 Renal sinus, 637 Renal tubule, 638, 640 Renal veins, 483, 489, 490, 638, 639 Renin: Enzyme released by the juxtaglomerular complex when renal blood flow decreases or O2 level declines; converts angiotensinogen to angiotensin I, (Chs 10, 13, 18), 397, 475, 476, 479, 650, 651 Renin-angiotensin-aldosterone system, 397, 650-651 Rennin: Gastric enzyme that breaks down a milk protein, resulting in milk coagulation, (Ch 16), 579 **Repolarization:** Movement of the membrane potential away from positive value and toward the resting potential, (Chs 8, 12) cardiac contractile cells, 445, 446 explained, 283, 285, 286, 287 Reposition (movement), 208, 209 Reproduction, as function of living things, 32 Reproductive system, 672-704 age-related changes, 696 autonomic nervous system, effects of, 321, 323, 325 autonomic nervous system and sexual function, 695 birth control strategies, 698-699 components of, 673 endocrine system, functional relationship with, 375, 400 female. *See* Female reproductive system functional relationship with other systems, 696–697, 700 functions of, 673 germ layer contributions to, 713 hormones, source, regulation, and primary effects of, 697 hormones and female reproductive cycle, 691-694, 697 hormones and male reproductive function, 681-683, 697 male. See Male reproductive system mammary glands, 687-688 organs, components, and primary functions, 39 pelvic cavity, 49 prenatal and early postnatal development, overview of, 721 Reproductive tract, 673 RER. See Rough endoplasmic reticulum (RER) Residual volume: Amount of air remaining in the lungs after maximum forced expiration, (Ch 15), 551, 552 Resistance blood flow, affecting, 466-467 muscles overcoming, 230 Resistance phase of the general adaptation syndrome, 400, $40\bar{1}$ Resorption, 175 **Respiration:** Exchange of gases between living cells and the environment; includes pulmonary ventilation, external respiration, and internal respiration, (Chs 1, 15, 18) acid-base disorders, 663-664 changes at birth, 561-562 control by higher centers, 561 control by the respiratory centers, 558 as function of living things, 32–33 local control of, 557-558 reflex control of, 558-561 Respiratory acidosis, 663, 664 Respiratory alkalosis, 663, 664 Respiratory bronchioles, 543, 544 Respiratory center of the pons, 308 Respiratory centers of the brain, 308, 341, 558, 559 Respiratory compensation in pH regulation, 662, 663, 664 Respiratory cycle, 551 Respiratory distress syndrome, 544, 549, 551 Respiratory enzymes, 238 Respiratory epithelium, 537, 538, 542 Respiratory membrane. See Blood air barrier

Respiratory minute volume: The amount of air moved into and out of the respiratory system each minute. Respiratory mucosa, 537, 538, 539 Respiratory muscles, 549, 550 Respiratory portion of the respiratory tract, 536-537, 544-548 Respiratory pump, and venous pressure, 469 Respiratory rate autonomic nervous system, 325 maternal, during pregnancy, 718 normal rate for adults and children, 551 Respiratory reflexes, 558-561 Respiratory rhythmicity centers, 308, 558, 559 Respiratory system, 535-567 acid-base balance, 656, 660-664 aging effect of, 562 alveolar ducts and alveoli, 536, 537, 544 anoxia and hypoxia, 548-549 autonomic nervous system, effects of, 321, 323, 325 bronchi, 536, 537, 541-544 bronchioles, 536, 537, 543, 544 carbon dioxide transport, 555-556 chemoreceptors, 341 components of, 536-538 conducting portion, 536-544 control of respiration, 557-562 digestive system, functional relationship with, 601 exercise, effect of, 267 external and internal respiration, 548-549, 554 functional relationship with other systems, 562, 563 functions of, 536 gas exchange, 552-554 germ layer contributions to, 713 larynx, 38, 191, 536, 537, 540-541 lungs. See Lungs nose, 44, 537, 538, 539 organs, components, and primary functions, 38 oxygen transport, 554–557 pharynx, 536, 537, 539–540 pleural cavities, 48, 546–548 prenatal and early postnatal development, overview of, 721 pulmonary ventilation, 549-552 reproductive system, functional relationship with, 700 respiratory membrane, 544-546 respiratory portion, 536-537, 544-548 trachea. See Trachea urinary system, functional relationship with, 665, 666 Respiratory tract, defined, 536 Responsiveness, as function of living things, 32 "Rest and digest" response, 319 "Rest and repose" response, 319 Resting membrane potential: The membrane potential of a normal cell under homeostatic conditions, (Ch 8), 281, 282, 284, 285, 286 Rete testis, 675, 676 Reticular activating system (RAS), 307, 337 Reticular fibers, 134 Reticular formation: Diffuse network of gray matter that extends the entire length of the brainstem, (Chs 8, 9), 307, 338 Reticular layer, dermis, 152, 158 Reticular tissue, 134, 135 Reticulocytes, 418, 419 Reticuloendothelial system, 512 Retina: The innermost layer of the eye, lining the posterior cavity; contains the photoreceptors; also called inner layer, (Ch 9), 346, 347, 348-350 Retinacula, 259, 263, 265 Retinal (RET-i-nal): Visual pigment derived from vitamin A, (Ch 9), 356 Retinitis pigmentosa, 369 Retinoblastoma, 733 Retinopathy, 369 Retraction: Movement posteriorly in the horizontal plane, (Ch 6), 208, 209 Retroperitoneal (re-trō-per-i-tō-NĒ-al): Behind or outside the peritoneal cavity, (Chs 1, 16, 18) defined, 49 duodenum, 582 kidneys, 637 pancreas, 587

Retroviruses, 523

Reversible reactions, 63 Rh factor: Surface antigen that may be present (Rh-positive) or absent (Rh-negative) from the surfaces of red blood cells, (Chs 11, 20), 421, 422-423,730 Rh negative blood, 421, 422-423 Rh positive blood, 421, 422–423 Rheumatic fever, 442 Rheumatism, 206 Rheumatoid arthritis, 206, 526 Rhodopsin (rō-DOP-sin): The visual pigment found in the membrane discs of the distal segments of rods, (Ch 9), 356 Rhomboid muscles, 245, 247, 255, 256, 257 Rhythm method of contraception, 699 Rhythmicity center: Center in the medulla oblongata responsible for the basic pace of respiration; includes inspiratory and expiratory centers, (Chs 8, 15), 308, 558, 559 Rib cage, 195, 196, 549, 550 Riboflavin (vitamin B2), 623, 625 Ribonucleic acid (RNA). See RNA (ribonucleic acid) Ribose: A five-carbon sugar that is a structural component of RNA, (Ch 2), 77, 78 Ribosomal RNA (rRNA), 89, 101, 106, 622 Ribosome: An organelle containing rRNA and proteins that is essential to mRNA translation and protein synthesis, (Ch 3), 88-89, 101, 104 Ribs, 174, 185, 186, 195, 196, 549, 550 Rickets, 178 Right atrioventricular (AV) valve. See Tricuspid valve Right atrium, 435, 438, 441 Right bundle branch, 447 Right common carotid artery, 481, 482, 484, 485 Right coronary artery, 441, 481 Right lobe of the liver, 589 Right lymphatic duct: Lymphatic vessel delivering lymph from the right side of the head, neck, and chest to the venous system by the right subclavian vein, (Ch 14), 503, 505 Right main bronchi, 541, 543 Right portion of sagittal section, 44, 47 Right pulmonary artery, 438, 440, 480, 481 Right pulmonary vein, 438, 440, 480 Right side, explained, 44, 47 Right subclavian artery, 480, 481, 484 Right subclavian vein, 480, 488 Right ventricle, 435, 438, 440-442 Rigor mortis, 230 RNA (ribonucleic acid) (rī-bō-noo-KLĀ-ik): A nucleic acid consisting of a chain of nucleotides that contain the sugar ribose and the nitrogenous bases adenine, guanine, cytosine, and uracil (Chs 2, 3, 17) catabolism, 621-622 chemical level of organization, 76–78, 79 messenger RNA, 108–109, 110–111, 622 ribosomal, 89, 108, 622 synthesis of, 622 transfer RNA, 109-111, 622 RNA polymerase, 108 Rod: Photoreceptor responsible for vision under dimly lit conditions, (Ch 9), 349, 353, 355, 356, 368 Rogaine (minoxidil), 161 Root hair, 160 nails, 163, 164 teeth, 574, 575 Root canals of a tooth, 575 Root hair plexus, 339 Root of the penis, 680, 681 Rotation (movement) described, 208 equilibrium, 360, 361, 362 Rotator cuff, 211, 257, 258, 259 Rough endoplasmic reticulum (RER): A membranous organelle that is a site of protein synthesis and storage, (Ch 3), 89, 101-102, 104 Round ligament of the liver, 588, 589 Round window: An opening in the bony labyrinth of the internal ear that exposes the membranous wall of the scala tympani to the air of the middle ear cavity, (Ch 9), 359, 360, 361, 366

Ruffini corpuscles (roo-FE-ne): Receptors sensitive to tension and stretch in the dermis of the skin, (Ch 9), 339, 340 Rugae (ROO-ge): Mucosal folds in the lining of the empty

stomach that disappear as gastric distension occurs, (Ch 16), 578, 579 Rule of nines, 166

S

S phase of interphase, 112 Saccule (SAK-ūl): A portion of the vestibular apparatus of the internal ear, contains a macula sensitive to sensations of gravity and vertical acceleration, (Ch 9), 360, 362 Sacral canal, 193 Sacral foramina, 194, 195 Sacral hiatus, 193 Sacral nerves, 312 Sacral plexus, 312, 313 Sacral promontory, 193 Sacral region of the vertebral column, 191 Sacral spinal curve, 192 Sacrospinalis muscles, 251 Sacrum, 185, 191, 193, 195 SAD (seasonal affective disorder), 393 Saddle joints, 208, 210 Sagittal plane: Sectional plane that divides the body into left and right portions, (Ch 1), 44, 47 Sagittal suture, 186 Saliva, 574 Salivary amylase, 574 Salivary glands, 39, 321, 323, 570, 574 Salpingitis, 699 Saltatory propagation of an action potential, 287, 288 Salts, 67, 80 Salty taste, 343, 344 Saphenous nerve, 312 Sarcolemma, 224, 225 Sarcoma, 267 Sarcomeres, 226-227, 230-231, 232-233 Sarcoplasm, 224 Sarcoplasmic reticulum, 224, 225, 226 Sartorius muscle, 244, 245, 247, 261, 262, 263, 264 Satellite cells, 279 Saturated fats, 72 Saturated fatty acid, 70, 71 Saxitoxin (STX), 326 Scabs, 164, 165 Scala media: The central membranous tube within the cochlea that is filled with endolymph and contains the spiral organ (organ of Corti); also called cochlear duct, (Ch 9), 360, 363, 364, 365 Scala tympani: The perilymph-filled chamber of the internal ear, adjacent to the basilar membrane; pressure changes there distort the round window; also called tympanic duct, (Ch 9), 360, 364, 365 Scala vestibuli: The perilymph-filled chamber of the internal ear, adjacent to the vestibular membrane; pressure waves are induced by movement of the stapes at the oval window; also called vestibular duct, (Ch 9), 360, 364, 366 Scalene muscle, 550 Scalp (epicranium), 249 Scanning electron micrographs, 87 Scanning techniques, 50-51 Scaphoid bone, 199, 200 Scapulae, 174, 185, 196, 197–198 Scapular spine, 197, 198 Scar tissue, 144, 146, 165, 166 Scarring phase, in skin repair, 165 SCD. See Sickle cell disease (SCD) Schwann cells, 279 Sciatic nerve, 312, 326 Sciatica, 326 Sclera: The fibrous, outer layer of the eye that forms the white area of the anterior surface: a portion of the fibrous layer of the eye, (Ch 9), 347, 348 Scleral venous sinus (canal of Schlemm), 351

Scleral venous sinus (canal of Scr Scoliosis, 192 Scopolamine, 155 Scotomas, 369 Scrotal cavities, 94 Scrotum, 39, 321, 323, 674, 675 Scurvy, 178 Seasonal affective disorder (SAD), 393 Sebaceous follicles, 162 Sebaceous glands: Glands that secrete sebum; normally associated with hair follicles, (Ch 5), 130, 152, 160, 162 Sebum, 162 Second-degree burns, 166 Second heart sound, 451, 452 Second messengers, 378-380 Second trimester of pregnancy, 709, 717-723 Secondary dentition, 575, 576 Secondary oocytes, 683, 685, 686, 687, 707, 708 Secondary ossification centers, 177 Secondary ovarian follicles, 685, 686 Secondary response to antigen exposure, 522-523 Secondary spermatocytes, 677 Secondary spinal curves, 192 Secondary tumors, 114 Secretin, 580, 581, 585, 586, 588 Secretion, in urine formation, 640, 642, 643, 644, 645, 649 Secretions digestive system function, 569 epithelium producing, 123 integument, 153 Secretory phase: Phase of the uterine cycle when the endometrium prepares for the arrival of a developing embryo, (Ch 19), 689, 693, 694 Secretory sheet, 128 Secretory vesicles, 105 Sectional anatomy, 43-45, 47-48 Sectional planes, 44-45, 47 Segmental arteries, 638, 639 Segmental bronchi, formerly tertiary bronchi, 541, 543, 544 Segmentation of the small intestine, 572-573 Segments on EKG recordings, 448-449 Seizures, 305 Selectively permeable plasma membranes, 91 Self antigens, 516 Sella turcica, 187, 189, 382 Semen: The fluid ejaculate that contains sperm and the secretions of accessory glands of the male reproductive tract, (Ch 19), 673, 680 Semicircular canals, 359, 360 Semicircular ducts, 360, 361, 362 Semilunar valves, 441, 442, 443 Semimembranosus muscle, 64, 245, 260, 261, 262, 263 Seminal fluid, 680 Seminal glands (vesicles), 39, 674, 680 Seminalplasmin, 680 Seminiferous tubules, 675–676 Semispinalis capitis muscle, 250, 251 Semitendinosus muscle, 245, 261, 262, 264 Senescence, 728 Senile cataracts, 351, 368 Sensation. See also General and special senses defined, 317, 336 epithelium providing, 123 integument, 152 Sensible perspiration, 627 Sensitization allergies, 527 B cells, 520 Rh antigens, 422–423 Sensory areas of the cerebral cortex, 300, 301 Sensory homunculus, 317 Sensory neurons, 277 Sensory nuclei of spinal cord gray matter, 295 Sensory (ascending) pathways CNS anatomical organization, 280 posterior column pathway, 317 spinocerebellar pathway, 316 spinothalamic pathway, 316 Sensory receptors, 274, 276, 277, 336 Sepsis, 166 Septa of the testes, 675 Septa of the thymus, 509 Septic shock, 478 Septicemia, 430 SER. See Smooth endoplasmic reticulum (SER)

Serosa of the digestive tract, 571-572 Serotonin, 290 Serous exocrine glands, 131 Serous fluid, 141 Serous membrane: A squamous epithelium and the underlying loose connective tissue; the lining of the pericardial, pleural, and peritoneal cavities; also called a serosa (Chs 1, 4), 45, 140, 141 Serratus anterior muscle, 244, 252, 255, 256, 257, 550 Sertoli cells. See Nurse cells Serum: The ground substance of blood plasma from which clotting agents have been removed, (Ch 11), 414 Severe combined immunodeficiency disease (SCID), 526 Sex chromosomes, 729, 731-732 Sex-linked inheritance, 731-732 Sexual intercourse (coitus), 673, 695 Sexually transmitted diseases (STDs), 695 Shaft (body) of the penis, 680, 681 Shinbone (tibia), 180, 185, 202 Shingles, 311, 326 Shivering, 42 Shivering thermogenesis, 628 Shock, 478 Short bones, 174 Short-term (primary) memories, 304 Shoulder anatomical terms, 44 joint, 197, 211 muscles of, 244-245, 255-257 Siamese (conjoined) twins, 725 Sickle cell disease (SCD), 74, 112, 416, 731, 733 Side chain, 73 Sigmoid colon, 593, 594 Sigmoid veins, 491 Sign: Clinical term for visible, objective evidence of the presence of disease, (Ch 1), 36 Simple columnar epithelium, 126, 127, 128 Simple cuboidal epithelium, 126, 127, 128 Simple epithelium, 125, 126, 127 Simple (closed) fractures, 180 Simple inheritance, 730, 731 Simple reflexes, 313-314 Simple squamous epithelium, 126, 127 Simple sugar, 68, 70, 79 Single covalent bond, 59, 60 Single-gene disorders, 732 Sinoatrial (SA) node (cardiac pacemaker), 446-448, 473 Sinus (bone marking), 183 Sinuses ethmoidal, 190, 191 frontal, 186, 189, 191, 538, 539 maxillary, 190, 191, 539 paranasal, 38, 190, 191, 536, 539, 541 sphenoidal, 187, 189, 190, 191, 539 Sinusoids of the liver, 588 Skeletal muscle aging, effects of, 266-267 appendicular muscles. See Appendicular muscles autonomic nervous system, 325 axial muscles. See Spermatogonia multipotent, 418 neural, 276 olfactory (basal cells), 341, 342 Stercobilins, 416, 417 Stereocilia: Elongated microvilli characteristic of the epithelium of portions of the male reproductive tract (epididymis) and internal ear, (Ch 9), 361-362, 364, 366 Sterility. See Infertility Sterilization, surgical, 698, 699 Sternal end of the clavicle, 197 Sternocleidomastoid muscle, 244, 245, 248, 249, 250, 549, 550 Sternohyoid muscle, 246, 249, 250 Sternothyroid muscle, 249, 250 Sternum, 185, 186, 195, 196 **Steroid:** Large lipid molecules composed of four connected rings of carbon atoms, (Chs 2, 3), 70, 72, 93 Steroid hormones, 376, 379, 380 Stethoscopes, 451 Stimulus: An environmental change that produces a change in cellular activities; often used to refer to events that alter the membrane potentials of excitable cells, (Chs 1, 8), 36, 41, 282-283 Stomach anatomy of, 577-579 autonomic nervous system, 321, 323 digestion in, 581-582 digestive system component, 570 disorders of, 581 functions of, 577, 579 gastric activity, regulation of, 579-581 gastric wall, 578, 579 location, 39, 45, 49 Stomach (gastric) cancer, 581 Stop codon, 109, 111 Strabismus, 369 Strain, muscular, 257, 259 Strata, 153 Stratified: Containing several layers. Stratified columnar epithelium, 126, 128 Stratified cuboidal epithelium, 126, 128 Stratified epithelium, 126, 128, 129 Stratified squamous epithelium, 128, 129 Stratum (STRA-tum): Layer, (Ch 5), 153 Stratum basale, 153, 154, 157 Stratum corneum, 153, 154 Stratum germinativum. See Stratum basale Stratum granulosum, 154, 155 Stratum lucidum, 153, 154 Stratum spinosum, 154, 155 Strawberry nevus (cavernous hemangioma), 169 Stress cardiovascular adaptation, 477-479 hormones and, 400, 401 immune response, 527, 528 Stress response (general adaptation syndrome), 400, 401, 527 Stress urinary incontinence, 655 Stretch receptors: Sensory receptors that respond to stretching of the surrounding tissues, (Chs 8, 45, 18), 315, 558, 560, 654-655 Stretch reflex, 314, 315 Striated involuntary muscle, 143. See also Cardiac muscle

Striated voluntary muscle, 143. See also Skeletal muscle tissue Striations, in skeletal muscle cells, 142, 143 Stroke (cerebrovascular accident), 324, 326, 429 Stroke volume, 452, 454 Strong acids, 67 Strong bases, 67 Structural proteins, 73 Sty, 345 Stylohyoid muscle, 249, 250 Styloid process, 187, 188, 189, 191 Styloid process of the radius, 199 Styloid process of the ulna, 199 Subarachnoid space: Meningeal space containing cerebrospinal fluid (CSF); the area between the arachnoid membrane and the pia mater, (Ch 8), 291, 292 Subclavian (sub-CLĀ-vē-an): Pertaining to the region under the clavicle. Subclavian artery, 481, 482, 484, 485 Subclavian vein, 483, 487, 488, 489 Subclavius muscle, 256, 257 Subcutaneous injections, 159, 253 Subcutaneous layer. See Hypodermis Subdural hemorrhage, 292 Subdural space, 291, 292 Sublingual ducts, 574 Sublingual glands (sub-LING-gwal): Mucus-secreting salivary glands situated under the tongue, (Ch 16), 574 Submandibular duct, 574 Submandibular glands: Salivary glands nestled in depressions on the medial surfaces of the mandible; salivary glands that produce a mixture of mucins and enzymes (salivary amylase), (Ch 16), 574 **Submucosa** (sub-mū-KŌ-sa): Region between the muscularis mucosae and the muscularis externa, (Ch 16), 571 Submucosal glands: Mucous glands in the submucosa of the duodenum, (Ch 16), 583 Submucosal plexus: Along with the myenteric plexus, makes up the enteric nervous system (ENS), contains a network of nerve fibers, sensory neurons, and parasympathetic motor neurons, (Ch 16), 571 Subpapillary plexus, in dermis, 152, 159 Subscapular fossa, 197 Subscapularis muscle, 197, 257, 258, 259 Substantia nigra, 307 Substrate: A participant (product or reactant) in an enzyme-catalyzed reaction, (Ch 2), 76 Sucrase, 597, 598 Sucrose, 68, 69, 70 Sudoriferous (sweat) glands, 162–163, 325 Sudornerous (swear) grands, 102–103, 323 Sulcus (SUL-kus): A groove or furrow, (Chs 6, 8), 183, 300 Sulfate ions, in body fluids, 59, 658 Sulfur, 57 Summation of muscle twitches, 235 Sunlight, 157-158 Superficial direction, 46 Superficial temporal artery, 485 Superior: Directional reference meaning above, (Ch 1), 45.46 Superior angle of the scapula, 197 Superior articular processes of the vertebrae, 193, 194, 209, 211 Superior border of the scapula, 197 Superior colliculi, 307, 357 Superior gluteal artery, 487 Superior gluteal veins, 487 Superior lobe of the left lung, 546, 547 Superior lobe of the right lung, 546, 547 Superior mesenteric artery, 482, 485, 486, 487 Superior mesenteric vein, 491 Superior nasal conchae, 189, 190, 538, 539 Superior oblique muscle, 345, 346 Superior orbital fissure, 188 Superior portion in transverse section, 45 Superior rectal veins, 491 Superior rectus muscle, 345, 346 Superior sagittal sinus, 299, 300, 487 Superior vena cava (SVC): The vein that carries blood from the parts of the body above the heart to the

right atrium, (Chs 12, 13), 438, 440, 441, 480, 483, 487, 489, 490 Supination (soo-pi-NĀ-shun): Rotation of the forearm such that the palm faces anteriorly, (Chs 6, 7), 199, 208, 246, 260, 261 Supinator muscle, 247, 257, 260, 261 Supine (soo-PĪN): Lying face up, with palms facing anteriorly, (Ch 1), 43 Supporting connective tissues, 132, 137-139 Suppression factors, 519 Supra-orbital foramen, 186, 187, 188 Supra-orbital notch, 186 Suprarenal cortex. See Adrenal cortex Suprarenal gland. See Adrenal gland Suprarenal medulla. See Adrenal medulla Supraspinatus muscle, 198, 246, 257, 258, 259 Supraspinous fossa, 197, 198 Sural region, 44 Surface anatomy anatomical directions, 43, 46 anatomical landmarks, 43 anatomical regions, 43 explained, 33 heart, of, 436, 438 learning, importance of, 43 Surface features of bones, 182-183 Surface tension, 60, 61 Surfactant (sur-FAK-tant): Lipid secretion that coats the alveolar surfaces of the lungs and prevents their collapse, (Ch 15), 544 Surgical neck of the humerus, 198 Suspensory ligaments of the breast, 690, 691 Sustenocytes. See Nurse cells Suture: Fibrous joint between flat bones of the skull, (Ch 6), 204 Swallowing process, 577 Swallowing reflex, 577 Sweat (sudoriferous) glands, 162–163, 325 Sweet taste, 343, 344 Sweet taste, 543, 544 "Swollen glands," 509 Sympathetic chain ganglia, 321, 322 Sympathetic division: Division of the autonomic nervous system responsible for "fight or flight" reactions; primarily concerned with the elevation of metabolic rate and increased alertness; also called the thoracolumbar division (Chs 8, 9, 10, 12, 18, 19) components of, 320 effects on various body structures, 325 general functions of, 319-320 glucagon release, 394 heart innervation, 453-454 kidneys, 650, 652 organization of, 320-322 overview of, 319-320 parasympathetic division, relationship to, 274-275, 324, 325 pupils, 348 sexual function, 695 Symphysis: A fibrous amphiarthrosis, such as that between adjacent vertebrae or between the pubic bones of the hip (coxal) bones, (Ch 6), 205 Symptom: Clinical term for an abnormality of function as a result of disease; subjective experience of patient, (Ch 1), 36 Synapse (SIN-aps): Site of communication between a nerve cell and some other cell; if the other cell is not a neuron, the term *neuroeffector junction* is often used, (Ch 8) axon terminals, 276 neuron communication, 288-290 neuronal pools, 290-291 structure of, 289 synaptic function and neurotransmitters, 288-290 Synapsis in cell division, 677 Synaptic cleft, 227, 228-229, 288 Synaptic knob, 276 Synaptic terminals. See Axon terminals Synarthroses (immovable joints), 204-205 Synchondrosis, 204-205 Syncope, 494 Syncytiotrophoblast: Multinucleate cytoplasmic layer

that covers the blastocyst; the layer responsible for uterine erosion and implantation, (Ch 20), 710 Syncytium (sin-SISH-ē-um): A multinucleate mass of cytoplasm, produced by fusion of cells or repeated mitoses without cytokinesis. Syndesmosis, 205 Syndrome: A discrete set of signs and symptoms that occur together. Synergist (SIN-er-jist): A muscle that assists a prime mover in performing its primary action, (Ch 7), 246 Synergistic effects of hormones, 399 Synesthesia, 369 Synovial cavity (si-NŌ-vē-ul): Fluid-filled chamber in a synovial joint, (Ch 6), 213 Synovial fluid (si-NŌ-vē-ul): Substance secreted by synovial membranes that lubricates joints, (Chs 4, 6), 141, 205 Synovial joints described, 204, 205 lower limbs, 212-214 movement types, 206-209 structural classification, 208, 210 upper limbs, 211-212 Synovial membrane (si-NŌ-vē-ul): An incomplete layer of fibroblasts lining the synovial cavity, plus underlying loose connective tissue, (Ch 4), 140, 141 Synovial tendon sheaths, 259, 263 Synthesis (SIN-the-sis): Manufacture; anabolism, (Ch 2), 63 Synthesis reactions, 63 Systemic anatomy, 33 Systemic circuit: Vessels between the aortic semilunar valve and the entrance to the right atrium; the system other than the vessels of the pulmonary circuit, (Chs 12, 13, 15) aortic arch, arteries of, 481, 482, 484-485 ascending aorta, 481, 482, 484 cardiovascular pressures within, 467 descending aorta, 482, 484 descending aorta, arteries of, 485-486 functional patterns, 479-480 heart's role in cardiovascular system, 435, 436 hepatic portal system, 489, 491 inferior vena cava, veins of, 483, 488, 489, 490 partial pressures of gases, 553, 554 superior vena cava, veins of, 483, 487-488 systemic arteries, 481-486 systemic veins, 483, 486-492 Systemic lupus erythematosus (SLE), 528 Systemic physiology, 34 **Systole** (SIS-to-lē): A period of contraction in a chamber of the heart, as part of the cardiac cycle, (Ch 12), 450-451 Systolic pressure: Peak arterial pressure measured during ventricular systole, (Ch 13), 467, 470

т

T₃. See Triiodothyronine T₄. See Tetraiodothyronine; Thyroxine T cells: Lymphocytes responsible for cell-mediated immunity and for the coordination and regulation of the immune response; includes regulatory T cells (helpers and suppressors) and cytotoxic (killer) T cells, (Chs 1,114) activation of, 518-519, 525 adaptive (specific) immunity, 515, 517-519, 524, 525 aging, effect of, 527 in AIDS, 523 antigen presentation, 517-518, 525 interleukins, 524 lymphocyte, type of, 504, 507 thymus gland, 427, 508 types of, 518-519 T tubules: Transverse, tubular extensions of the sarcolemma that extend deep into the sarcoplasm to contact terminal cisternae of the sarcoplasmic reticulum, (Ch 7), 224, 225, 230, 233, 234 T wave: Deflection of the ECG corresponding to

ventricular repolarization, (Ch 12), 448, 449 Tachycardia, 448

Tactile: Pertaining to the sense of touch, (Ch 9), 338 Tactile corpuscles (Meissner corpuscles), 339 Tactile discs (Merkel discs), 339

Tactile receptors, 338-340 Tactile responses, locations of, 338-340 Tail fold, 714, 717 Tail of a sperm, 678 Tailbone. See also Ankle Tartar, 576 Taste. See Gustation Taste buds, 343, 344 Taste hairs, 344 Taste pores, 344 Taste receptors, 343 TCA (tricarboxylic acid) cycle. See Citric acid cycle Tear gland. See Lacrimal gland Tears: Fluid secretion of the lacrimal glands that bathes the anterior surfaces of the eyes, (Chs 9, 15), 345, 539 Tectorial membrane (tek-TOR-e-al): Gelatinous membrane suspended over the hair cells of the spiral organ, (Ch 9), 364 Teeth dental caries, 600 dental plaque, 576 dental succession, 575, 576 digestive system component, 39, 570 gomphoses, 204 structure of, 574-575 types of, 576 Telophase (TEL-ō-fāz): The final stage of mitosis, characterized by the disappearance of the spindle apparatus, the reappearance of the nuclear membrane, the disappearance of the chromosomes, and the completion of cytokinesis, (Ch 3), 112, 115 Temperature. See Body temperature Temporal artery, 470 Temporal bones, 186, 187, 189, 190, 191, 192 Temporal lobe, 296, 300 Temporal process of the zygomatic bone, 187, 188, 190 Temporal vein, 488 Temporalis muscle, 91, 244, 246, 247, 248, 249 Tendinitis, 267 Tendon: A collagenous band that connects a skeletal muscle to an element of the skeleton, (Chs 1, 4, 6, 7), 37, 132, 134, 136, 174, 223–224 Tendon sheaths, 259, 263 Teniae coli (TE-nē-ēKŌ-lē): Three longitudinal bands of smooth muscle in the muscularis externa of the colon, (Ch 16), 593, 594 Tension, muscle fiber, 230-231 Tensor fasciae latae muscle, 244, 245, 262, 264 Tensor tympani muscle, 359, 360 Teratogens, 735 Teres major muscle, 245, 257, 258, 259 Teres minor muscle, 245, 257, 258, 259 Terminal bronchioles, 543, 544 Terminal cisternae of the sarcoplasmic reticulum, 224, 225, 226 Terminal ganglia, 319 Termination, of translation, 110-111 Tertiary ovarian follicle: A mature ovarian follicle, containing a large, fluid-filled chamber; also called mature graffian follicle, (Ch 19), 685, 686 Tertiary structure: Protein structure that results from interactions among different portions of the same molecule; complex coiling and folding (Ch 2), 74, 75 Testes (TES-tēz): The male gonads, sites of gamete production and hormone secretion; also called

testicles (Chs 1, 10, 16, 19), 38, 39, 377, 383, 384, 397-398, 673, 674-678 Testicular arteries, 484

- Testicular cancer, 676
- Testicular torsion, 699
- Testosterone (tes-TOS-ter-on): The principal androgen produced by the interstitial cells of the testes, (Chs 2, 3, 10, 19)

athletic performance, 399 cholesterol, 72 endocrine hormone, 377, 397 interstitial cells of the testes, 675, 676 luteinizing hormone, 384, 386 male climacteric, 696 male reproductive function, 682 reproductive function, 679, 696 reproductive system, 673 smooth endoplasmic reticulum, 101 source, regulation of, and primary effects, 697 Tetanus: A tetanic contraction; also used to refer to abnormally prolonged contractions resulting from disturbances in electrolyte balance, (Chs 7, 12), 235, 242, 445 Tetanus (disease): A disease state resulting from the stimulation of muscle cells by bacterial toxins, (Ch 7), 231 Tetrad (TET-rad): Paired, duplicated chromosomes visible at the start of meiosis, (Ch 19), 674, 677 Tetraiodothyronine (tet-ra-ī-ō-dō-THĪ-rō-nēn): T4, or thyroxine, a thyroid hormone, (Ch 10), 377, 387, 390 Tetrodotoxin (TTX), 326 Thalamus: The walls of the diencephalon, (Ch 8), 296, 297, 307 Thalassemia, 112, 416 Therapeutic abortion, 728 Thermoreception: Sensitivity to temperature changes, (Ch 9), 338 Thermoreceptors, 338 Thermoregulation: Homeostatic maintenance of body temperature, (Chs 1, 17), 40-42, 627-628 Thiamine (vitamin B1), 623, 625 Thick filament: A myosin filament in a skeletal or cardiac muscle cell, (Chs 3, 7), 100, 224, 225, 226 Thick skin, 153, 154 Thigh anatomical terms, 44 femur, 44, 174, 183, 185, 201-202 muscles of, 244-245, 259, 262, 263 Thin filament: An actin filament in a skeletal or cardiac muscle cell, (Ch 7), 224, 225, 226 Thin skin, 153, 154 Third-degree burns, 166 Third heart sound, 451, 452, 467 Third molars, 575, 576 Third trimester of pregnancy, 709, 717-723 Third ventricle, 298 Thoracentesis, 547 Thoracic aorta, 485, 486 Thoracic cage, 186, 194–196 Thoracic cavity, 47–48, 437, 546, 548, 549, 550 Thoracic duct, 503, 504, 505 Thoracic nerves, 312 Thoracic region, 44 Thoracic region of the vertebral column, 191, 193 Thoracic spinal curve, 192 Thoracic vertebrae, 191, 193 Thorax: The chest, (Ch 1), 44 Threonine, 620 Threshold: The membrane potential at which an action potential begins, (Ch 8), 283 Thrombin (THROM-bin): Enzyme that converts fibrinogen to fibrin, (Ch 11), 428, 430 Thrombocyte (THROM-bō-sīt), (Ch 11), 427. See also Platelets Thrombocytopenia, 427 Thrombocytosis, 427 Thrombus: A blood clot, (Chs 11, 13), 429, 493 Thumb, 44, 200 Thymine: A nitrogenous compound found in DNA, (Chs 2, 3), 77, 78, 107, 108 Thymosins (THĪ-mō-sinz): Hormones of the thymus essential to the development and differentiation of T cells, (Chs 10, 11, 14), 377, 397, 427, 506, 509 Thymus: Lymphoid organ, site of T cell formation, (Chs 1, 10, 11, 14), 38, 377, 397, 418, 426, 503, 507, 508-509 Thyrocervical trunk, 481, 482, 484, 485 Thyroid cartilage, 388, 539, 540, 541 Thyroid follicles, 387, 388 Thyroid gland: Endocrine gland whose lobes are lateral to the thyroid cartilage of the larynx, (Chs 1, 10)

GLOSSARY / INDEX

C cells and calcitonin (CT), 388-389, 390 endocrine organ, 377 endocrine system component, 38 location of, 386-387, 388 thyroid follicles and thyroid hormones, 387-388, 403 **Thyroid hormones:** Thyroxine (T₂); hormones of the thyroid gland that stimulate tissue metabolism, energy utilization, and growth, (Ch 10) amino acid derivative, 376 described, 388–389, 390 growth, 399 plasma membrane, crossing, 379, 380 Thyroid-stimulating hormone (TSH) (thyrotropin): Anterior pituitary hormone that triggers the secretion of thyroid hormones by the thyroid gland, (Ch 10), 377, 382-383, 387 Thyroidectomy, 403 Thyrotoxicosis, 403 Thyrotropin-releasing hormone (TRH), 383, 384 **Thyroxine (TX)** (thī-ROKS-ēn): A thyroid hormone (T₄), (Ch 10), 377, 387, 390 Tibia (shinbone), 180, 185, 202 Tibial collateral ligament, 213 Tibial tuberosity, 202 Tibialis anterior muscle, 245, 263, 265, 266 Tibialis posterior muscle, 265, 266 Tidal volume: The volume of air moved in and out of the lungs during a single respiratory cycle when at rest, (Chs 15, 20), 551, 552, 718 Tight junctions, 123, 124 Tissue: A collection of specialized cells and cell products that perform a specific function, (Chs 1, 3, 4), 33, 34, 115, 121. See also Tissue level of organization Tissue factor, 428, 429 Tissue level of organization, 120-148 age, effect of, 145 age and cancer incidence, 145 connective tissue, 122, 131-139 epithelial tissue, 121-131, 140-141 explained, 34, 35 membranes, 140-141 muscle tissue, 122, 141-143 neural tissue, 122, 143-144 tissue, types of, 122 tissue injury, response to, 144-145 issue perfusion, 471 Tissue plasminogen activator (t-PA), 430 Toes, 44 bones of, 185, 202-203 muscles of, 263, 265, 266 Tolerance, as immunity property, 516 Tongue, 570, 573, 574 Tonsil: A lymphoid nodule beneath the epithelium of the pharynx; includes the palatine, pharyngeal, and lingual tonsils, (Chs 14, 15, 16), 503, 506, 508, 528, 539, 540, 573 Tonsillectomy, 528 Tonsillitis, 506, 528 Tooth alveolus, 204, 575 Topical: Applied to the body surface, (Ch 5), 161 Total peripheral resistance, 466 Touch sensation, 338-340 Toxic shock syndrome, 478 Toxins, and large intestine, 595 Trabecula (tra-BEK-ū-la): A connective tissue partition that subdivides an organ, (Ch 6), 175, 176 Trabeculae carneae, 440 Trabecular bone (tra-bek-YŪ-lar): Spongy bone, composed of a network of bony struts, (Ch 6), 174, 175 Tracer, defined, 81 Trachea (TRĀ-kē-uh): The windpipe, an airway extending from the larynx to the primary bronchi, (Chs 1, 4, 10, 15), 38, 128, 129, 386, 388, 536, 537, 539, 540, 541 Tracheal cartilages, 541 Trachealis muscle, 541 Tracheostomy, 542 Tract: A bundle of axons in the CNS, (Ch 8), 280 Traits described, 729 dominant, recessive, sex-linked, and polygenic, 730 Trans fatty acids, 71 Transamination, 619

Transcription: The encoding of genetic instructions on a strand of mRNA, (Chs 3, 10, 17), 108–109, 380, 622 Transdermal administration of drugs, 155 Transection: To sever or cut in the transverse plane. Transfer RNA (tRNA), 109-111, 622 Transferrin, 416, 417 Transfusion of blood, 416, 422–423, 429 Transfusion reactions, 421, 422–423 Transient secondary amenorrhea, 689 Transitional epithelium, 128, 129, 654 Translation: The process of peptide formation from the instructions carried by a mRNA strand, (Ch 3), 108, 109-111 Translocation defects, 734 Transmembrane potential, 281. See also Membrane potential Transmembrane proteins, 91 Transmission electron micrographs, 86 Transport globulins, 413 Transport proteins, 73 Transport vesicles, 102 Transverse colon, 593, 594 Transverse foramina, 192 Transverse fractures, 180 Transverse perineus muscle, 254 Transverse (horizontal) plane, 45, 47 Transverse processes of the vertebrae, 192, 193, 194 Transverse (cross) section, 45 Transverse (T) tubules in muscle fiber. See T tubules Transversus abdominis muscle, 252, 253 Transversus thoracis muscle, 550 Trapezium bone, 199, 200 Trapezius muscle, 244, 245, 247, 248, 250, 255, 256, 257 Trapezoid bone, 199, 200 TRH (thyrotropin-releasing hormone), 383, 384 Triad: In a muscle cell, the combination of a T tubule and two terminal cisternae of the sarcoplasmic reticulum, (Ch 7), 224, 225, 230 Tricarboxylic acid (TCA) cycle. *See* **Citric acid cycle** Triceps brachii muscle, 237, 244, 245, 246, 256, 257, 258, 260, 261 Tricuspid valve (trī-KUS-pid): The right atrioventricular valve (AV) which prevents the backflow of blood into the right atrium during ventricular systole, (Ch 12), 440, 441, 443 Trigeminal nerve (trī-GEM-i-nal): Cranial nerve V, which provides sensory information from the lower portions of the face (including the upper and lower jaws) and delivers motor commands to the muscles of mastication, (Chs 8, 9), 307, 308, 309, 310, 344 Triglyceride (trī-GLI-se-rīd): A lipid composed of a molecule of glycerol attached to three fatty acids, (Chs 2, 16, 17), 71–72, 79, 597, 598, 608, 610, 618, 619, 621, 627 Trigone (TRĪ-gōn): Triangular region of the urinary bladder bounded by the exits of the ureters and the entrance to the urethra, (Chs 18, 19), 653, 654, 681 Triiodothyronine: T₃, a thyroid hormone, (Ch 10), 377, 387, 390 Trimesters, in prenatal development, 709 Triplet code, 107, 109 Triquetrum bone, 199, 200 Trisomy, 734 Trisomy 51 (Down's syndrome), 131, 733, 734 Trochanter (trō-KAN-ter): Large processes near the head of the femur, (Ch 6), 183 Trochlea (TRŌK-le-uh): A pulley, (Ch 6), 183 Trochlea of the humerus, 198 Trochlear nerve (TROK-le-ar): Cranial nerve IV, controlling the superior oblique muscle of the eye, (Chs 8, 9), 307, 309, 310, 346 Trochlear notch of the ulna, 199 Trophoblast (TRŌ-fō-blast): Superficial layer of the blastocyst that will be involved with implantation, hormone production, and placenta formation, (Ch 20), 709, 710, 711 Tropic hormones, 382 Tropomyosin: A protein on thin filaments that masks the active sites in the absence of free calcium ions, (Ch 7), 225, 226 Troponin (TRŌ-pō-nin): A protein on thin filaments that masks the active sites in the absence of free calcium ions, (Ch 7), 225, 226 True (vertebrosternal) ribs, 195, 196

True vocal cords, 541 Trunk: The thoracic and abdominopelvic regions, (Chs 1, 6, 7, 13) bones of, 191-196 major arteries of, 486, 487 muscles of, 244-245, 252-253 region of the body, 45-46 Trypsin, 588, 597, 598, 599 Tryptophan, 620 TSH. See Thyroid-stimulating hormone (TSH) (thyrotropin) TTX (tetrodotoxin), 326 Tubal ligation, 698, 699 Tubercle: A small, localized elevation on a bony surface, (Ch 6), 183 Tuberculosis, 547 Tuberosity, 183 Tubular fluid, 638, 640 Tubulin: Protein subunit of microtubules, (Ch 3), 100 Tumor: A tissue mass produced by abnormal growth and replication of cells, (Ch 3), 114-115 Tumor necrosis factors (TNFs), 524 Tunica (TOO-ni-ka): A layer or covering, (Chs 13, 19), 460, 461, 462, 675 Tunica albuginea, 675 Tunica externa (adventitia), 461, 462 Tunica intima (formerly tunica interna), 460, 461, 462 Tunica media, 460, 461, 462 Turbulence in blood flow, 466-467 Turner syndrome, 734 Twitch: A single stimulus-contraction-relaxation cycle in a skeletal muscle fiber, (Chs 7, 8, 12), 231, 235, 445, 446 Tympanic cavity. See Middle ear Tympanic duct. See Scala tympani **Tympanic membrane:** The membrane that separates the external acoustic meatus from the middle ear; the membrane whose vibrations are transferred to the auditory ossicles and ultimately to the oval window; also called eardrum or tympanum, (Chs 6, 9), 187, 357–359, 365 Type A blood, 421, 422, 423 Type AB blood, 421, 422, 423 Type B blood, 421, 422, 423 Type 1 diabetes, 396 Type 2 diabetes, 396 Type O blood, 421, 422, 423

U

Ulcer: An area of epithelial sloughing, or shedding, associated with damage to the underlying connective tissues and vasculature, (Chs 5, 16), 167, 581 Ulcerative colitis, 600 Ulna, 180, 185, 198-199 Ulnar artery, 481, 482, 484 Ulnar head, 199 Ulnar nerve, 312 Ulnar tuberosity, 199 Ulnar vein, 483, 487, 489 Ultrasound: Diagnostic visualization procedure that uses high-frequency sound waves, (Ch 1), 51 Ultraviolet (UV) radiation, 156 Umami (taste), 343, 344 Umbilical arteries, 492, 493, 713, 716 Umbilical cord (um-BIL-i-kal): Connecting stalk between the fetus and the placenta; contains the allantois, the umbilical arteries, and the umbilical vein, (Chs 13, 20), 492, 493, 713, 715, 716, 718 Umbilical ligaments, 654 Umbilical region, 44, 45 Umbilical stalk, 713, 715 Umbilical vein, 492, 493, 713, 716 **Umbilicus:** The navel, (Ch 1), 43, 44, 45 **Unicellular gland:** Mucous cells, (Ch 4), 128 Unipolar neuron: A sensory neuron whose cell body is

- in a dorsal root ganglion or a sensory ganglion of a cranial nerve, (Ch 8), 277 Universal donors of blood, 423
- **Unmyelinated axon:** An axon whose neurilemma does not contain myelin and along which continuous propagation occurs, (Ch 8), 279, 286, 288

Unmyelinated fibers, 338

Unsaturated fats, 72 Unsaturated fatty acid, 70, 71 Upper esophageal sphincter, 576 Upper limbs anatomical terms, 44 appendicular skeleton, 185, 186, 198 arteries of, 484 articulations of, 211-212 humerus, 185, 198 muscles of, 244-245, 255-261 radius and ulna, 185, 198-199 veins of, 483, 487, 489 wrist and hand, bones of, 185, 199-200 Uracil: One of the nitrogenous compounds in RNA, (Chs 2, 3, 17), 77, 78, 108, 109, 110, 621 Urea amino acid catabolism, 619 urinary system elimination of, 636, 643, 644 Ureteral openings, 653 Ureters (u-RE-terz): Muscular tubes, lined by transitional epithelium, that carry urine from the renal pelvis to the urinary bladder, (Chs 1, 18), 39, 635, 636, 637,653 Urethra (ū-RĒ-thra): A muscular tube that carries urine from the urinary bladder to the exterior, (Chs 1, 18, 19), 39, 635, 653, 654, 674, 680 Urethritis, 654 Uric acid, 621-622, 636, 643, 644 Urinalysis: Analysis of the physical and chemical characteristics of the urine, (Ch 18), 665 Urinary bladder: Muscular, distensible sac that stores urine prior to micturition, (Chs 1, 8, 9, 18) autonomic nervous system, effects of, 321, 323, 325 baroreceptors, 340 location, 39, 45, 49 urinary system component, 635, 653, 654 Urinary retention, 664 Urinary system, 634-671 acid-base balance, 660-664 age-related changes, 664 autonomic nervous system, effects of, 321, 323, 325 components of, 635 endocrine system, functional relationship with, 397 fluid, electrolyte, and acid-base balance, 656-658 fluid and electrolyte balance, 658-660 functional relationships with other systems, 666 functions of, 635-636 germ layer contributions to, 713 kidneys. See Kidney micturition reflex and urination, 635, 654-655 organs, components, and primary functions, 39 prenatal and early postnatal development, overview of, 721 reproductive system, functional relationship with, 700 ureters, 635, 653 urethra, 635, 653, 654 urinary bladder, 635, 653, 654 urine formation in the nephron, 640, 643-650 Urinary tract, defined, 635, 653 Urinary tract infections (UTIs), 654 Urination: The voiding of urine; also called micturition, (Ch 18), 635, 654-655 Urine composition of, 650 described, 635 formation/production of filtration at the glomerulus, 644-645, 646, 648 location of production, 638 purposes of, 643 reabsorption and secretion along the renal tubule, 640, 642, 643, 644, 646, 649 summary of, 648-649 nephron function, 640 normal urine, characteristics of, 646, 650 solute concentrations in, 644 storage and transportation, 635, 653-656 storage reflex, 654, 655 urinalysis, 665 voiding reflex, 654, 655 volume produced daily, 650 Urobilins, 416, 417 Urology, 665 Urticaria, 158

Uterine cavity, 687, 688 Uterine cycle menses, 689, 693, 694 proliferative phase, 689, 693, 694 secretory phase, 689, 693, 694 Uterine (endometrial) glands, 688 Uterus (Ū-ter-us): Muscular organ of the female reproductive tract where implantation, placenta formation, and fetal development occur, (Chs 1, 8, 19, 20), 39, 321, 323, 673, 687–689, 719, 723 Utricle (Ū-tri-kul): The largest chamber of the vestibular apparatus; contains a macula that provides sensations of gravity and horizontal acceleration, (Ch 9), 360, 363

V

Uvula, 573, 577, 585

V (volt), 281 Vaccine, 516, 528 Vagina (va-JĪ-nuh): A muscular tube extending between the uterus and the vestibule, (Chs 1, 19), 39, 673, 683, 684, 688, 689-690 Vaginal barriers, 698-699 Vaginitis, 690 Vagus nerve (X) chemoreceptors, 341 heart innervation, 453, 454 mechanoreceptor reflexes, 559, 560 nervous system, 307, 308, 310, 311, 322, 323 taste pathways, 344 Valine, 109, 620 Valsalva maneuver, 596 Valves heart, 440, 441, 442-443 lymphatic, 504 venous, 465 Valvular heart disease, 442 Variable segments of antibody chains, 521 Varicose veins, 465 Vasa recta, 638, 639, 649 Vascular: Pertaining to blood vessels, (Ch 4), 132, 139 Vascular layer of the eye, 346, 347, 348 Vascular phase of hemostasis, 427-428 Vascular resistance, 466 Vascular spasm, 427 Vasectomy, 698, 699 Vasoconstriction: A reduction in the diameter of arterioles due to contraction of smooth muscles in the tunica media; elevates peripheral resistance; may occur in response to local factors, the action of hormones, or stimulation of the vasomotor center, (Chs 10, 13), 385, 461 Vasoconstrictors, 471 Vasodilation (vaz-ō-dī-LĀ-shun): An increase in the diameter of arterioles due to the relaxation of smooth muscles in the tunica media: reduces peripheral resistance; may occur in response to local factors, through the action of hormones, or after decreased stimulation of the vasomotor center, (Ch 13), 461, 477 Vasodilators, 471

Vasomotion: Rhythmic changes in vessel diameter by precapillary sphincters; results in changes in the pattern of blood flow through a capillary bed, (Ch 13), 464

Vasomotor center: Center in the medulla oblongata whose stimulation produces vasoconstriction and an increase in peripheral resistance, (Chs 8, 13), 308, 473
Vasopressin, 385. See also Antidiuretic hormone (ADH)
Vastus intermedius muscle, 261, 262, 264
Vastus lateralis muscle, 244, 253, 262, 263, 264
Vastus medialis muscle, 244, 262, 264
Vastus muscles, 244, 247, 261, 262, 263, 264
Vegetables, dietary guidelines for, 622, 623
Veins: Blood vessels carrying blood from a capillary

bed toward the heart, (Chs 1, 12, 13). *See also specificveins* cardiovascular system component, 38

heart's role in cardiovascular system, 435 size, structure, and function, 460, 461, 462, 465

varicose veins, 465 Venae cavae (VĒ-nēKĀ-vē): The major veins delivering systemic blood to the right atrium, (Chs 12, 13), 469. See also Inferior vena cava; Superior vena cava Venipuncture, 411 Venoconstriction, 473 Venous pressure, 466, 469 Venous return, 452-453, 465, 477 Venous sinusoids, 510 Ventilation: Air movement into and out of the lungs, (Ch 15). See Pulmonary ventilation Ventral: Pertaining to the anterior surface, (Ch 1), 43, 45,46 Ventral respiratory group, 558, 559 Ventricle (VEN-tri-kl): One of the large, muscular pumping chambers of the heart that discharges blood into the pulmonary or systemic circuit, (Ch 12), 435, 441, 443 Ventricles of the brain, 279, 298 Ventricular diastole, 450-451 Ventricular reflex, 452-453 Ventricular systole, 450–451 Venule (VEN-ūl): Thin-walled veins that receive blood from capillaries, (Ch 13), 460, 462, 464, 465 Vermiform appendix. See Appendix Versatility, as immunity property, 516 Vertebrae, 174, 180, 185, 191 Vertebral arch, 192, 194 Vertebral artery, 481, 482, 484, 485 Vertebral body, 192, 194 Vertebral canal: Passageway that encloses the spinal cord, a tunnel bounded by the vertebral arches of adjacent vertebrae, (Ch 6), 192 Vertebral column (spine): The cervical, thoracic, and lumbar vertebrae, the sacrum, and the coccyx, (Ch 6) axial skeleton, 185, 186 cervical vertebrae, 191, 193, 194 lumbar vertebrae, 191, 193, 194 regions of, 191 sacrum and coccyx, 185, 191, 193, 194 spinal curvature, 193 thoracic vertebrae, 190, 191, 193 vertebral anatomy, 192, 194 Vertebral foramen, 192, 193, 194 Vertebral veins, 483, 487, 488, 489 Vertebrochondral ribs, 195, 196 Vertebrosternal (true) ribs, 195, 196 Vesicle: A membranous sac in the cytoplasm of a cell, (Ch 3), 88-89, 95, 97-98 Vesicular follicle. See Tertiary follicle Vesicular transport, 92, 97-99 Vestibular bulbs. See Bulb of vestibule Vestibular complex, 360, 362 Vestibular duct. See Scala vestibuli Vestibular membrane: The membrane that separates the cochlear duct from the vestibular duct of the internal ear, (Ch 9), 364, 365 Vestibular nerve, 311, 363 Vestibular nucleus: Processing center for sensations arriving from the vestibular apparatus; near the border between the pons and medulla (Ch 9), 363 Vestibule (ear) (VES-ti-būl): A chamber in the internal ear, the term refers to the utricle and the saccule, (Ch 9), 359, 360, 362 Vestibule of the oral cavity, 573 Vestibule of the perineum, 690 Vestibulocochlear nerve (VIII), 307, 308, 310, 311, 359, 361, 363, 364, 366, 367 Vestibulospinal tracts, 363 Villus/villi: A slender projection of the mucous membrane of the small intestine, (Chs 16, 20), 570, 571, 583, 584 chorionic, 712, 713, 714-715, 716 Virus: A noncellular pathogen, (Ch 14), 526 Viscera (VIS-e-ruh): Internal organs of the thoracic and abdominopelvic cavities, (Ch 1), 47 Visceral: Pertaining to viscera (internal organs) or their outer coverings (Ch 1), 47 Visceral epithelium of the nephron, 641 Visceral layer of the serous membrane, 47

Visceral motor neurons, 277

Visceral motor system, 274. See also Autonomic nervous system (ANS) Visceral pericardium, 48, 436-437, 439 Visceral peritoneum, 49, 571 Visceral pleura, 48, 543, 547, 548 Visceral (internal) receptors, 277 Viscosity: The resistance to flow exhibited by a fluid due to molecular interactions within the fluid, (Chs 11, 13), 411, 466 Viscous: Thick, syrupy, (Ch 11), 411 Visible light spectrum, 353 Vision and eye structures, 344-358, 368. See also Eyes Visual acuity, 356 Visual association area, 300, 301 Visual axis, 347, 348, 350 Visual cortex of the occipital lobe, 300, 301, 302 Visual pathways, 357-358 Visual pigments, 356, 357 Vital capacity: The maximum amount of air that can be moved into or out of the respiratory system; the sum of the inspiratory reserve, the expiratory reserve, and the tidal volume, (Ch 15), 551, 552 Vitamin: An essential organic nutrient that functions as a coenzyme in vital enzymatic reactions, (Chs 16, 17) absorption in the large intestine, 594-595 dietary guidelines, 624, 625 fat-soluble, 624, 625 food sources, 623 hypervitaminosis, 624 hypovitaminosis, 624 production in large intestine, 594 water-soluble, 624, 625 Vitamin A, 156, 178, 356, 357, 599, 623, 625 Vitamin B1 (thiamine), 623, 625 Vitamin B2 (riboflavin), 623, 625 Vitamin B3 (niacin, nicotinic acid), 623, 625 Vitamin B5 (pantothenic acid), 594, 623, 624, 625 Vitamin B6 (pyridoxine), 619, 623, 625 Vitamin B7 (biotin), 594, 625 Vitamin B9 (folate, folic acid), 623, 625 Vitamin B12 (cobalamin), 418, 577, 579, 599, 623, 624, 625 Vitamin C (ascorbic acid), 178, 599, 623, 625 Vitamin D, 599, 624, 625 Vitamin D³, 152, 156–157, 178, 397, 624, 625 Vitamin E, 599, 623, 625 Vitamin K, 430, 594, 599, 624, 625 Vitreous body: Gelatinous mass in the vitreous chamber (posterior cavity) of the eye; its fluid part is called vitreous humor, (Ch 9), 346, 350, 351 Vitreous chamber (posterior cavity of the eye), 346, 347, 349, 350, 351 Vocal cords and sound production, 541 Volt (V), 281

Voltage-gated ion channels, 283, 284–285

GLOSSARY / INDEX

Volume of packed red cells (VPRC). *See* **Hematocrit Voluntary:** Controlled by conscious thought processes, (Ch 8), 274 Voluntary muscles, 224. *See also* Skeletal muscle Vomer, 188, 189, 190 Vomiting, 585 Vomiting reflex, 585 Vulva (pudendum), 690

W

Water absorption in the large intestine, 594, 599 daily losses, 658-659 dietary guidelines, 624-625 diffusion across plasma membranes, 93 fluid balance, 658-659 inorganic compound, 64 osmosis, 92, 93-95, 99 physiological systems, role in, 65-66, 80 polar molecule, 60 reabsorption along the DCT and collecting ducts, 646, 647 Water receptors, 343, 344 Water-soluble vitamins, 599, 624, 625. See also specific vitamins Waxes, 70 WBCs. See White blood cells (WBCs) Weak acids, 67, 662 Weak bases, 67, 662 Weaning, 727 Weight. See Body weight Wernicke's area, formerly general interpretive area), 301, 302 Whiplash, 214 White blood cells (WBCs): Leukocytes; the granulocytes and agranulocytes of the blood, (Chs 4, 6, 11, 14) basophils, 413, 419, 424, 425, 426 blood, in, 412-413 circulation and movement, 424 connective tissue proper, in, 133 eosinophils, 413, 419, 424, 425, 426 fluid connective tissue, 137 formation of, 173, 419, 426–427 lymphocytes, 413, 419, 424, 425, 426 lymphocytes and the immune response, 502, 504, 505-506, 518 monocytes, 413, 419, 424, 425, 426 neutrophils, 413, 419, 424, 425, 426 numbers of and differential count, 425-426 origins and differentiation, 419 White commissures, 295, 296

White matter: Regions inside the CNS that are

dominated by myelinated axons, (Ch 8), 278, 279, 296, 300 White muscles, 241 White pulp of the spleen, 510 Whole blood, 412 Wisdom teeth, 575, 576 Withdrawal reflexes, 314, 315 Work, 61 Wrist anatomical terms, 44 bones of, 199–200 muscles of, 244–245, 257, 260, 261

X

X chromosome: The sex chromosome whose presence does not determine genetic maleness; two X chromosomes produce a genetic female, (Ch 20), 731–732 X-linked inheritance, 731–732 X-rays, 50 Xenograft, 528 Xerosis, 167 Xiphoid process (ZI-foyd): Slender, inferior extension of the sternum, (Ch 6), 195, 196

Y

Y chromosome: The sex chromosome whose presence indicates that the individual is a genetic male, (Ch 20), 731
Yellow bone marrow, 173, 418
Yolk sac: One of the four extra-embryonic membranes, composed of an inner layer of endoderm and an outer layer of mesoderm, (Ch 20), 711, 712, 714–715
Yolk stalk, 713, 714–715

Ζ

Z lines, 225, 226, 227 Zinc, dietary guidelines for, 624 Zona pellucida, 685, 686, 707, 708 Zone of overlap in sarcomeres, 225, 226 Zygomatic arch, 186, 187, 188, 190 Zygomatic bones, 187, 188, 190 Zygomatic process of the temporal bone, 187, 190 Zygomaticus muscle, 248, 249 Zygote (ZĪ-göt): The fertilized ovum, prior to the start of cleavage, (Chs 19, 20), 699, 707, 708

COMMON ABBREVIATIONS USED IN HEALTH SCIENCE

ACh	acetylcholine
AChE	acetylcholinesterase
АСТН	adrenocorticotropic hormone
ADH	antidiuretic hormone
ADP	adenosine diphosphate
AIDS	acquired immunodeficiency syndrome
ALS	amyotrophic lateral sclerosis
AMP ANP	adenosine monophosphate atrial natriuretic peptide
ANS	autonomic nervous system
AP	arterial pressure
ARDS	adult respiratory distress syndrome
atm	atmospheric pressure
АТР	adenosine triphosphate
ATPase	adenosine triphosphatase
AV	atrioventricular
AVP	arginine vasopressin
BCOP	blood colloid osmotic pressure
BMR	basal metabolic rate
BPG bpm	bisphosphoglycerate beats per minute
BUN	blood urea nitrogen
C	large calorie; Celsius
CABG	coronary artery bypass graft
CAD	coronary artery disease
cAMP	cyclic-AMP
CAPD	continuous ambulatory peritoneal dialysis
ССК	cholecystokinin
CD	cluster of differentiation
CF	cystic fibrosis
CHF	congestive heart failure
CHP CsHP	capillary hydrostatic pressure capsular hydrostatic pressure
CNS	central nervous system
CO	cardiac output; carbon monoxide
СоА	coenzyme A
СОМТ	catechol-O-methyltransferase
COPD	chronic obstructive pulmonary disease
СР	creatine phosphate
CPK, CK	creatine phosphokinase
CPM	continuous passive motion
CPR CRF	cardiopulmonary resuscitation chronic renal failure
CRH	corticotropin-releasing hormone
CSF	cerebrospinal fluid; colony-stimulating
	factors
СТ	computerized tomography; calcitonin
CVA	cerebrovascular accident
CVS	cardiovascular system
DAG	diacylglycerol
DC	Doctor of Chiropractic
DCT	distal convoluted tubule
DDST	Denver Developmental Screening Test
DIC DJD	disseminated intravascular coagulation
DMD	degenerative joint disease Duchenne's muscular dystrophy
DNA	deoxyribonucleic acid
DO	Doctor of Osteopathy
DPM	Doctor of Podiatric Medicine
DSA	digital subtraction angiography
E	epinephrine
ECF	extracellular fluid
ECG	electrocardiogram
EDV	end-diastolic volume
EEG EKG	electrocardiogram
EKG ELISA	electrocardiogram enzyme-linked immunosorbent assay
EPSP	excitatory postsynaptic potential
ERV	expiratory reserve volume
ESV	end-systolic volume
ETS	electron transport system
FAD	flavin adenine dinucleotide
FAS	fetal alcohol syndrome
FES	functional electrical stimulation
FMN	flavin mononucleotide

FRC	functional residual capacity
FSH	follicle-stimulating hormone
GABA	gamma aminobutyric acid
GAS	general adaptation syndrome
GC	glucocorticoid
GFR	glomerular filtration rate
GH	growth hormone
GH-IH	growth hormone-inhibiting hormone
GHP	glomerular hydrostatic pressure
GH-RH	growth hormone-releasing hormone
GIP	gastric inhibitory peptide
GnRH	gonadotropin-releasing hormone
GTP	guanosine triphosphate
Hb	hemoglobin
hCG	human chorionic gonadotropin
HCI	hydrochloric acid
HDL	high-density lipoprotein
HDN	hemolytic disease of the newborn
hGH	human growth hormone
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HMD	hyaline membrane disease
HP	hydrostatic pressure
hPL	human placental lactogen
HR	heart rate
Hz ICF	Hertz intracellular fluid
ICOP IGF	interstitial fluid colloid osmotic pressure
IGF IH	insulin-like growth factor
IM	inhibiting hormone intramuscular
IP3	inositol triphosphate
IPSP	inhibitory postsynaptic potential
IRV	inspiratory reserve volume
ISF	interstitial fluid
IUD	intrauterine device
IVC	inferior vena cava
IVF	in vitro fertilization
kcal	kilocalorie
LDH	lactate dehydrogenase
LDL	low density lipoprotein
L-DOPA	levodopa
LH	luteinizing hormone
LLQ	left lower quadrant
LM	light micrograph
LSD	lysergic acid diethylamide
LUQ	left upper quadrant
MAO	monoamine oxidase
MAP	mean arterial pressure
MC	mineralocorticoid
MD	Doctor of Medicine
mEq	millequivalent; (10^{-3})
MHC	major histocompatibility complex
MI	myocardial infarction
mm Hg	millimeters of mercury
mmol	millimole
mOsm	milliosmole
MRI	magnetic resonance imaging
mRNA	messenger RNA
MS	multiple sclerosis
MSH	melanocyte-stimulating hormone
MSH-IH	melanocyte-stimulating hormone-inhibit-
	ing hormone
NAD	nicotinamide adenine dinucleotide
NE	norepinephrine
NFP	net filtration pressure
NHP	net hydrostatic pressure
NO	nitric oxide
NRDS	neonatal respiratory distress syndrome
OP Osm	osmotic pressure osmoles
OSIII	oxytocin
PAC	premature atrial contraction
PAC	paroxysmal atrial tachycardia
PCT	proximal convoluted tubule
	ra convoluted tabule

PCV packed cell volume PEEP positive end-expiratory pressure positron emission tomography perfluorochemical emulsion prostaglandin pelvic inflammatory disease prolactin-inhibiting hormone phosphatidylinositol protein kinase C phenylketonuria phospholipase C polymorphonuclear leukocyte PMN peripheral nervous system peripheral resistance prolactin-releasing factor prolactin pounds per square inch prothrombin time post-traumatic amnesia; plasma thromboplastin antecedent РТС phenylthiocarbamide РТН parathyroid hormone premature ventricular contraction reticular activating system RBC red blood cell RDA recommended daily allowance RDS respiratory distress syndrome REM rapid eye movement RER rough endoplasmic reticulum releasing hormone RHD rheumatic heart disease right lower quadrant RLQ RNA ribonucleic acid ribosomal RNA rRNA RUQ right upper quadrant sinoatrial sickle cell disease SCID severe combined immunodeficiency disease SEM scanning electron micrograph smooth endoplasmic reticulum SGOT serum glutamic oxaloacetic transaminase SIADH syndrome of inappropriate ADH secretion sudden infant death syndrome SIDS systemic lupus erythematosus somatic nervous system sexually transmitted disease stroke volume superior vena cava triiodothyronine tetraiodothyronine, or thyroxine tuberculosis thyroid-binding globulin transmission electron micrograph TBG ТЕМ transient ischemic attack transport (tubular) maximum temporomandibular joint tissue plasminogen activator TRH thyrotropin-releasing hormone tRNA transfer RNA thyroid-stimulating hormone TSH toxic shock syndrome United States urinary tract infection uridine triphosphate ultraviolet alveolar ventilation anatomic dead space respiratory minute volume ν_T, TV tidal volume ventricular fibrillation V_F VLDL very low-density lipoprotein VPRC volume of packed red cells ventricular tachycardia WBC white blood cell

FOREIGN WORD ROOTS, PREFIXES, SUFFIXES, AND COMBINING FORMS

Each entry starts with the commonly used form or forms of the prefix, suffix, or combining form followed by the word root (shown in italics) and its English translation. One example is also given to illustrate the use of each entry.

a-, *a*-, without: avascular **ab-**, *ab*, from: abduct -ac, -akos, pertaining to: cardiac acr-, akron, extremity: acromegaly ad-, ad, to, toward: adduct aden-, adeno-, adenos, gland: adenoid adip-, adipos, fat: adipocytes aer-, aeros, air: aerobic metabolism -al, -alis, pertaining to: brachial **alb-**, *albicans*, white: albino -algia, algos, pain: neuralgia **allo-**, *allos*, other: allograft **ana**-, *ana*, up, back: anaphase andro-, andros, male: androgen angio-, angeion, vessel: angiogram ante-, ante, before: antebrachial anti-, ant-, anti, against: antibiotic **apo-**, *apo*, from: apocrine arachn-, arachne, spider: arachnoid arter-, arteria, artery: arterial arthro-, arthros, joint: arthroscopy astro-, aster, star: astrocyte atel-, ateles, imperfect: atelectasis **aur-**, *auris*, ear: auricle auto-, auto, self: autonomic baro-, baros, pressure: baroreceptor **bi-**, *bi*- two: bifurcate bio-, bios, life: biology -blast, blastos, precursor: osteoblast brachi-, brachium, arm: brachiocephalic brachy-, brachys, short: brachydactyly brady-, bradys, slow: bradycardia bronch-, bronchus, windpipe, airway: bronchial carcin-, karkinos, cancer: carcinoma cardi-, cardio-, kardia, heart: cardiac -cele, kele, tumor, hernia, or swelling: blastocele -centesis, kentesis, puncture: thoracocentesis cephal-, *cephalos*, head: brachiocephalic **cerebr-**, *cerebrum*, brain: cerebral hemispheres cerebro-, cerebros, brain: cerebrospinal fluid cervic-, cervicis, neck: cervical vertebrae chole-, chole, bile: cholecystitis -chondrion, chondrion, granule: mitochondrion chondro-, chondros, cartilage: chondrocyte chrom-, chromo-, chroma, color: chromatin circum-, circum, around: circumduction -clast, klastos, broken: osteoclast coel-, -coel, koila, cavity: coelom colo-, kolon, colon: colonoscopy contra-, contra, against: contralateral corp-, corpus, body: corpuscle cortic-, cortex, rind or bark: corticospinal cost-, costa, rib: costal **cranio-**, *cranium*, skull: craniosacral cribr-, *cribrum*, sieve: cribriform -crine, krinein, to separate: endocrine cut-, cutis, skin: cutaneous cyan-, kyanos, blue: cyanosis cyst-, -cyst, kystis, sac: blastocyst cyt-, cyto-, kytos, a hollow cell: cytology de-, de, from, away: deactivation

dendr-, *dendron*, tree: dendrite dent-, dentes, teeth: dentition derm-, derma, skin: dermatome desmo-, desmos, band: desmosome di-, dis, twice: disaccharide dia-, dia, through: diameter digit-, digit, a finger or toe: digital dipl-, diploos, double: diploid dis-, dis, apart, away from: disability diure-, diourein, to urinate: diuresis **dys-**, *dys*, painful: dysmenorrhea -ectasis, ektasis, expansion: atelectasis ecto-, ektos, outside: ectoderm -ectomy, ektome, excision: appendectomy ef-, ex, away from: efferent emmetro-, emmetros, in proper measure: emmetropia encephalo-, enkephalos, brain: encephalitis end-, endo-, endon, within: endometrium entero-, enteron, intestine: enteric epi-, epi, upon: epimysium erythema-, erythema, flushed (skin): erythematosis erythro-, erythros, red: erythrocyte ex-, ex, out of, away from: exocytosis extra-, exter, outside of, beyond, in addition: extracellular ferr-, ferrum, iron: transferrin fil-,filum,thread: filament -form, -formis, shape: fusiform gastr-, gaster, stomach: gastrointestinal -gen, -genic, gennan, to produce: mutagen genicula-, geniculum, kneelike structure: geniculates genio-, geneion, chin: geniohyoid gest-, gesto, to bear: gestation glosso-, -glossus, glossus, tongue: hypoglossal glyco-, glykys, sugar: glycogen -gram, gramma, record: myogram gran-, granulum, grain: granulocyte -graph, -graphia, graphein, to write, record: electroencephalograph gyne-, gyno-, gynaikos, woman: gynecologist hem-, hemo-, haima, blood: hemopoiesis hemi-, hemi-, one half: hemisphere hepato-, *hepaticus*, liver: hepatocyte hetero-, heteros, other: heterozygous histo-, histos, tissue: histology holo-, holos, entire: holocrine homeo-, homoios, similar: homeostasis homo-, homos, same: homozygous hyal-, hyalo-, hyalos, glass: hyaline hydro-, hydros, water: hydrolysis hyo-, hyoeides, U-shaped: hyoid bone hyper-, hyper, above: hyperpolarization **hypo-,** *hypo,* under: hypothyroid hyster-, hystera, uterus: hysterectomy -ia, -ia, state or condition: insomnia idi-, *idios*, one's own: idiopathic in-, in-, in, within, or denoting negative effect: inactivate infra-, infra, beneath: infra-orbital inter-, inter, between: interventricular intra-, intra, within: intracapsular ipsi-, ipse, itself: ipsilateral iso-, isos, equal: isotonic -itis, -itis, inflammation: dermatitis

karyo-, karyon, body: megakaryocyte **kerato-**, *keros*, horn: keratin kino-, -kinin, kinein, to move: bradykinin lact-, lacto-, -lactin, lac, milk: prolactin lapar-, lapara, flank or loins: laparoscopy -lemma, lemma, husk: sarcolemma leuk-, leuko-, leukos, white: leukemia, leukocyte liga-, *ligare*, to bind together: ligase lip-, lipo-, lipos, fat: lipoid lith-, lithos, stone: cholelithiasis lys-lyso-, lysis, a loosening: hydrolysis macr-, makros, large: macrophage **mal**-, *mal*, abnormal: malabsorption **mammilla-**, *mammilla*, nipple: mammillary mast-, masto-, mastos, breast: mastoid mega-, megas, big: megakaryocyte melan-, melas, black: melanocyte men-, men, month: menstrual mero-, meros, part: merocrine meso-, mesos, middle: mesoderm meta-, meta, after, beyond: metaphase **micr-**, *mikros*, small: microscope **mono-**, *monos*, single: monocyte morph-, morpho-, morphe, form: morphology multi-, multus, much, many: multicellular -mural, murus, wall: intramural myelo-, myelos, marrow: myeloblast myo-, mys, muscle: myofilament narc-, narkoun, to numb or deaden: narcotics nas-, nasus, nose: nasolacrimal duct natri-, natrium, sodium: natriuretic necr-, nekros, corpse: necrosis nephr-, nephros, kidney: nephron neur-, neuri-, neuro-, neuron, nerve: neuromuscular oculo-, oculus, eye: oculomotor odont-, odontos, tooth: odontoid process -oid, eidos, form, resemblance: odontoid process oligo-, oligos, little, few: oligopeptide -ology, *logos*, the study of: physiology -oma, -oma, swelling: carcinoma onco-, onkos, mass, tumor: oncology **oo-,** *oon,* egg: oocyte ophthalm-, ophthalmos, eye: ophthalmic nerve -opia, ops, eye: myopia orb-, orbita, a circle: orbicularis oris orchi-, orchis, testis: orchiectomy orth-, orthos, correct, straight: orthopedist -osis, -osis, state, condition: neurosis ost-, oste-, osteo-, osteon, bone: osteocyte oto-, otikos, ear: otolith para-, para, two like parts or a pair: paraplegia path-, -pathy, patho-, pathos, disease:pathology pedia-, paidos, child: pediatrician **per**-, *per*, through, throughout: percutaneous peri-, peri, around: perineurium **phago-**, *phago*, to eat: phagocyte -phasia, phasis, speech: aphasia -phil, -philia, philos, love: neutrophil **phleb-**, *phleps*, a vein: phlebitis -phobia, phobos, fear: claustrophobia phot-, photo-, phos, light: photoreceptor

-phylaxis, phylax, a guard: prophylaxis **physio**-, *physis*, nature: physiology -plasia, plasis, formation: dysplasia platy-, platys, flat: platysma -plegia, plege, a blow, paralysis: hemiplegia -plexy, plessein, to strike: apoplexy pneum-, pneuma, air: pneumotaxic center pod-, podo-, podos, foot: podocyte -poiesis, poiesis, making: hemopoiesis **poly-**, *polys*, many: polysaccharide post-, post, after: postanal pre-, prae, before: precapillary sphincter **presby-**, *presbys*, old: presbyopia **pro-**, *pro*, before: prophase proct-, proktos, anus: proctology pterygo-, *pteryx*, wing: pterygoid pulmo-, pulmo, lung: pulmonary **pulp-,** *pulpa,* pulp: pulpitis **pyel-**, *pyelos*, trough or pelvis: pyelitis quadr-, quadrans, one quarter: quadriplegia **re-,** *re-,* back, again: reinfection retro-, retro, backward: retroperitoneal rhin-, rhis, nose: rhinitis -rrhage, rhegnymi, to burst forth: hemorrhage -rrhea, thein, flow, discharge: diarrhea sarco-, sarkos, flesh: sarcomere scler-, sclero-, skleros, hard: sclera -scope, skopeo, to view: colonoscope -sect, sectio, to cut: transect semi-, semis, half: semitendinosus -septic, septikos, putrid: antiseptic -sis, -sis, state or condition: metastasis som-, -some, soma, body: somatic **spino-**, *spina*, spine, vertebral column: spinothalamic pathway stalsis, staltikos, contractile: peristalsis sten-, stenos, a narrowing: stenosis stomy, stoma, mouth, opening: colostomy stylo-, stylus, stake, pole: stylohyoid **sub-**, *sub*, below; subcutaneous super-, super, above or beyond: superficial supra-, supra, on the upper side: supraspinous fossa syn-, syn, together: synthesis tachy-, tachys, swift: tachycardia telo-, telos, end: telophase tetra-, tettares, four: tetralogy of Fallot therm-, thermo-, therme, heat: thermoregulation thorac-, thorax, chest: thoracentesis thromb-, thrombos, clot: thrombocyte -tomy, tome, to cut: appendectomy tox-, toxikon, poison: toxemia **trans-**, *trans*, through: transudate **tri-**, *tres*, three: trimester tropho-, trophe, nutrition: trophoblast trophy, trophikos, nourishment: atrophy -tropic, trope, turning: adrenocorticotropic tropo-, tropikos, turning: troponin **uni-**, *unus*, one: unicellular uro-, -uria, ouron, urine: glycosuria vas-, vas, vessel: vascular zyg-, zygotos, yoke: zygote
