The skin of the anterior aspect of the wrist is innervated by the terminal branches of the lateral and medial cutaneous nerves of the forearm. The skin of the palm is innervated by the palmar branches of the ulnar and median nerves (see Fig. 50.40). The palmar skin of the thumb, index and middle fingers and the radial aspect of the ring finger is supplied by the median nerve, while that of the little finger and ulnar side of the ring finger is supplied by the ulnar nerve (Figs 50.3, 50.4).

The cutaneous innervation of the radial aspect of the dorsum of the wrist and hand, as well as the dorsal aspect of the radial three and a half digits as far distally as the nail beds, arises from the terminal branches of the radial nerve, namely: the dorsal digital nerves (Fig. 50.2). Between two and five dorsal digital nerves supply each digit. The cutaneous innervation of the ulnar aspect of the dorsum of the wrist
and hand, and the dorsal aspect of the ulnar one and a half digits as far distally as the nail beds, arises from the dorsal branch of the ulnar nerve, again ending as dorsal digital nerves. The skin of the dorsum of the middle and distal phalanges is also supplied by dorsal branches of the palmar digital nerves.

## NAIL APPARATUS

The nail apparatus consists of the nail plate, proximal and lateral nail folds, nail matrix, nail bed and hyponychium; it is described on page 151; see also Figure 7.18.

## SOFT TISSUES

## Flexor retinaculum

The flexor retinaculum is a strong, fibrous band (see Figs 50.5, 50.25B). It crosses the front of the carpus and converts its anterior concavity into

The pedicled groin flap used to be regarded as the workhorse flap for reconstruction of the hand. This has gradually been replaced by the use of regional flaps based on the radial or posterior interosseous artery and by free flaps. Both radial and ulnar forearm flaps have been used to achieve soft tissue cover of the hand. As they rely on the sacrifice of one of the major arteries to the hand, it is essential, before considering one of these procedures, to demonstrate, using flow studies and angiography, that the remaining vessel, whether radial or ulnar, is adequate.

The radial forearm flap was originally described by surgeons from the Shenyang Military Hospital in 1978 and was consequently known as the 'Chinese flap'. It can be used as a free flap and also as a reversed pedicled fasciocutaneous island flap to cover soft tissue defects of the ipsilateral hand. Its blood supply is based on septocutaneous perforators that arise from the distal part of the radial artery and which supply the skin on the radial side of the lower forearm; these tend to become more sparse proximally. Venous drainage is by the venae comitantes and superficial subcutaneous veins. The ulnar forearm flap is a fasciocutaneous flap based on the ulnar artery distal to its common interosseous branch. A variant on this flap based on the ascending branch of the dorsal ulnar artery was described by Becker and Gilbert (1988). It has the disadvantage of a short pedicle but is useful for achieving cover of defects of the proximal and ulnar side of the palm.

The posterior interosseous island flap, distally based on the dorsal carpal arterial arch via the anastomoses between the posterior and anterior interosseous arteries just lateral to the head of the ulna (Costa et al 2007), was introduced by Zancolli in 1985. Its principal advantages are that it spares both of the major arteries of the forearm and is a good match for the skin colour and texture of the dorsum of the hand. Care must be taken to avoid injury to the adjacent posterior interosseous nerve when harvesting the flap. Doppler studies should be carried out preoperatively to ensure the presence and positioning of the anastomoses between the posterior and anterior interosseous arteries. It has been claimed that most defects of the hand can be treated using this flap; its particular advantage is in the treatment of hand injuries with severe accompanying vascular damage.

The anatomical distribution of the first dorsal metacarpal artery allows a flap of skin over the dorsum of the proximal phalanx of the index finger to be raised on the artery and its accompanying venae comitantes. This flap is particularly useful under certain circumstances for reconstruction of the thumb following injury.

The distribution of the second, third and fourth dorsal metacarpal arteries permits the surgical elevation of flaps of dorsal skin based either proximally, on the dorsal metacarpal arteries proper, or distally, on their direct cutaneous branches. These flaps may be used for reconstructing areas of missing tissue elsewhere in the hand.

The dorsal cutaneous branch of the ulnar artery is constant and can support a flap of skin on the medial aspect of the distal forearm just proximal to the wrist; it is useful in the reconstruction of areas of missing skin in this region.
the carpal tunnel that transmits the flexor tendons of the digits and the median nerve. The retinaculum is short and broad, measuring $2.5-3 \mathrm{~cm}$ both transversely and proximodistally. It is attached medially to the pisiform and the hook of the hamate. Laterally, it splits into superficial and deep laminae. The superficial lamina is attached to the tubercles of the scaphoid and trapezium. The deep lamina is attached to the medial lip of the groove on the trapezium. Together with this groove, the two laminae form a tunnel, lined by a synovial sheath, which contains the tendon of flexor carpi radialis. The retinaculum is crossed superficially by the ulnar vessels and nerve, immediately radial to the pisiform, and by the palmar cutaneous branches of the median and ulnar nerves (see Fig. 50.40A). A slender band of fascia, the superficial part of the flexor retinaculum, bridges the ulnar neurovascular bundle and attaches to the radial side of the pisiform, forming a tunnel (Guyon's canal) that is an occasional site of ulnar nerve entrapment. The tendons of palmaris longus and flexor carpi ulnaris are partly attached to the anterior surface of the retinaculum. Distally, some of the intrinsic muscles of the thumb and little finger are attached to the retinaculum.

Guyon's canal Guyon's canal is a fibro-osseous canal, approximately 4 cm long in the adult, on the anteromedial side of the wrist (Fig. 50.5). The roof is formed by the palmar carpal ligament and palmaris brevis. The floor is formed by the transverse carpal and pisohamate ligaments and, more distally, by the pisometacarpal ligaments and flexor digiti minimi. The ulnar side is bounded by flexor carpi ulnaris, the pisiform bone and abductor digiti minimi, and the medial side is bounded by the extrinsic flexor tendons, the transverse carpal ligament and the hook of the hamate. The fibrous arcade at the origin of the hypothenar muscles lies distally.

The canal transmits the ulnar nerve and artery, together with occasional venae comitantes. The ulnar nerve divides within it at the level of the hook of the hamate into a deep, radial motor branch and a superficial, ulnar sensory branch. If the nerve is compressed proximally, both modalities will be affected, whereas, distal to the bifurcation, only the sensory or motor branch will be compromised. Variations in the branching of the ulnar nerve may occur.

The most common variant involves the formation of abductor digiti minimi, particularly when an accessory head is present.

## Extensor retinaculum

The extensor retinaculum is a strong, fibrous band that extends obliquely across the back of the wrist (Fig. 50.6). It is attached laterally to the anterior border of the radius, medially to the triquetral and pisiform bones, and, in passing across the wrist, to the ridges on the dorsal aspect of the distal end of the radius. It prevents bowstringing of the tendons across the wrist joint.

## Palmar fascial complex

The palmar fascia is a three-dimensional ligamentous system composed of longitudinal, transverse and vertical fibres (Fig. 50.7)

## Longitudinal fibre system

The longitudinal fibres run distally from the tendon of palmaris longus or the flexor retinaculum of the wrist to fan out across the whole width of the central third of the palm, producing four well-defined longitudinal bundles to the index, middle, ring and little fingers. A less welldefined bundle passes to the thumb. Distal to the transverse fibres of the palmar aponeurosis, the longitudinal fibres pass in three layers (McGrouther 1982). The most superficial longitudinal fibres (layer 1) are inserted superficially into the skin of the distal palm between the distal palmar crease and the proximal digital crease. Some superficial fibres pass distally into the palmar midline of the digit. Deeper longitudinal fibres (layer 2) pass deep to the natatory ligament and neurovascular bundles into the skin at the apex of the web space and into the fingers themselves, where they are continuous with Cleland's ligaments and the lateral digital sheet. Deeper still, the longitudinal fibres in layer 3 perforate the deep transverse metacarpal ligament to pass around the sides of the metacarpophalangeal joint and attach to the metacarpal bone and proximal phalanx, and extensor tendon.

## Transverse fibre system

The transverse fibre system consists of the superficial transverse metacarpal (natatory) ligament, the transverse fibres of the palmar aponeurosis and the deep transverse metacarpal ligament.

Fig. 50.6 The synovial sheaths of the tendons on the extensor aspect of the left wrist. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Fig. 50.7 The palmar aponeurosis and distal fascial complex. A, The palmar fascia. B, Structures at the web space. C, The fate of the distal longitudinal fibres. D-E, The normal digital fascia.

## Superficial transverse metacarpal ligament (natatory ligament)

The fibres of the superficial transverse metacarpal ligament cross the apex of the web skin and extend into each digit to blend with the lateral digital sheet. They limit the separation of adjacent fingers and form the distal commissural ligament in the web space of the thumb.

## Transverse fibres of the palmar aponeurosis

The transverse fibres of the palmar aponeurosis represent the deepest layer of the palmar fascia. They lie proximal to the distal palmar crease in a band approximately 2 cm wide, interconnecting the anterior fibres of the flexor tendon sheaths with the fasciae over the thenar and hypothenar muscles. The extension to the first ray forms the proximal commissural ligament.

## Deep transverse metacarpal ligament

The strong fibres of the deep transverse metacarpal ligament lie deep to the palmar aponeurosis and flexor sheaths, and are attached to the volar plates of the metacarpal heads of the fingers.

## Vertical fibre system

The vertical fibres are more delicate. They pass from the dermis, between the longitudinal and transverse fibres, to the fibrous flexor sheaths and the metacarpal bones. They are concentrated on either side of the palmar skin creases, as well as the thenar and hypothenar eminences. A series of vertical septa pass from the transverse fibres of the palmar
aponeurosis to the underlying deep transverse metacarpal ligament, forming compartments that contain the flexor tendons and the lumbricals and neurovascular bundles.

## Digital fascial complex

The superficial fascia within a finger is fibrofatty in the palmar and dorsal aspects, but condenses laterally into the lateral digital sheet (see Fig. 50.7). The flexor sheath represents a well-defined thickening of the fascia and is discussed in detail on page 866. Cleland's ligaments extend from the sides of the phalanges, pass dorsal to the neurovascular bundles, and insert into the lateral digital sheet. Grayson's ligaments are more delicate, may even be discontinuous, and pass from the lateral sides of the phalanges anterior to the neurovascular bundles to insert into the lateral digital sheet. Landsmeer's ligaments are inconsistent anatomical structures made up of transverse and oblique retinacular ligaments.

## Functions of the fascia of the hand

The fascial continuum of the hand performs a number of different, but interrelated, functions. It channels and provides a gliding surface for structures in transit between the forearm and the digits; transmits loads; anchors the skin; protects underlying vessels; and provides a framework for muscle attachments.

## Channelling of structures in transit between forearm and digits

The vertical septa act as spacers between the tendons and neurovascular bundles of the individual digital rays. Where tendons change direction around a concave surface, the channels are thickened. The septa form sheaths with specialized pulleys to prevent the tendon springing away from the underlying skeleton.

## Transmission of loads

At points where compressive loading is applied to the hand, such as the finger pulp and palm, loculi of fat act as shock absorbers. The loculi are contained within defined fibrous boundaries, which means that the shape, but not the volume, of each loculus can change. The compliance or deformability of the boundaries determines the amount of shock absorption. Local 'turgor' (deformability) and blood volume are measures of this anatomical property.

The palm also contains much larger fibrous compartments between skin and skeleton that transmit muscles, tendons and other structures. The honeycomb pattern of these compartments constitutes the palmar shock absorption system. The soft, padded parts of the hand are able to conform to the contours of objects that are grasped, and this permits better interpretation of sensation and better grip.

The hand must also resist tensile loading. Tendons and ligaments are particularly suitable for resisting such forces but many other parts of the fascial continuum, such as the anchorage system of the palm, also play a major role in resisting 'pulling' forces.

## Anchorage

Skin is retained by fascial ligaments that allow the hand to flex while retaining the skin in position. The palmar creases have been described as skin 'joints'. Fascial anchors may be vertical (perpendicular to the palm), as in the mid-palm, where scattered vertical fibres run from the dermis down into the depths of the hand; horizontal (in the plane of the palm); or oblique to the skin surface.

The insertion of the longitudinal (pretendinous) fibres of the palmar aponeurosis is an example of a well-developed horizontal anchorage system. The most superficial longitudinal fibres insert into the dermis of the distal palm. This arrangement resists horizontal shearing force in gripping tasks, such as holding a hammer, where it prevents distal skin slippage or degloving of the palm during use. The characteristic blisters on the palms of those unaccustomed to such use map out the sites of the skin anchorage points. This anchorage system can be demonstrated by flexing the palm until the skin of the distal palm folds loosely. An attempt to pull the loose skin distally will reveal the anchoring longitudinal fibres of the palmar aponeurosis.

Oblique anchors occur in the fingers where Cleland's ligaments tether the skin of the proximal and middle segments of the digits to the region of the proximal interphalangeal joints.

## Binding

Transversely orientated fascial structures help to maintain the transverse arch of the hand by 'binding' the underlying skeletal structures or the tendon sheaths.

## Limiting or tethering

Joint motion is limited not only by joint ligamentous action, but also, in some cases, by skin tightness. Skin in the interdigital webs is generally reinforced by fascial ligamentous fibres that run just beneath the dermis in a direction that resists stretch; they are well developed in the thumb web.

## Lubrication

There are many other gliding planes, e.g. between periosteum and the extensor apparatus, and between the latter and the skin, on the dorsum of the digits. The flexor tendon sheaths are lined by synovium.

Biomechanical studies of tendons gliding within their sheaths have emphasized the importance of avoiding extreme postures of a joint, which increase the friction between tendon and pulley, as well as the need to establish a smooth, well-lubricated tendon surface after repair. Increased friction within a tendon sheath may, in part, explain the cause of spontaneous rupture of extensor pollicis longus because the gliding resistance of the tendon has been shown to be significantly higher than that of other tendons (An 2007). Synergistic movements in the postrepair phase of recovery have been shown to improve tendon excursion and postoperative function.

Within the carpal tunnel and hand, the median nerve has been shown to glide by up to 3 mm , depending on the position of the elbow and the attitude of the forearm in pronation or supination (Echigo et al 2008). The greatest longitudinal excursion of the median
nerve ( 15.5 mm ) is seen just proximal to the carpal tunnel; similar excursion of the ulnar nerve has been recorded as 14.8 mm in cadavers (Wilgis and Murphy 1986).

## Vascular protection and pumping action

The blood vessels of the palm are surrounded by a cuff of tough fascia or by a fatty pad. When the hand is compressed, as in gripping, these relatively incompressible fascial structures function as a venous pumping mechanism to assist return of blood from the limb. By contrast, large capacitance veins on the dorsum of the hand lie in gliding skin, surrounded by loose areolar tissue, which allows the veins to dilate.

## Framework for muscle attachments

Many of the small muscles of the hand, such as abductor pollicis brevis and palmaris longus, are attached to the fascial skeleton, at least in part. The fascial framework can be visualized as a harness by which muscles can act on the underlying skeleton. The metacarpophalangeal joint is moved by a ring of fascial and ligamentous structures that surrounds the joint and to which tendons are attached.

## Dupuytren's disease

## Available with the Gray's Anatomy e-book

## Digital and palmar spaces

There are many potential spaces within the hand, often with ill-defined margins. The nail fold is a 'U-shaped' space made up of the eponychium and the lateral nail fold. The apical spaces at the tip of the finger are formed by the fibrous attachments of the distal phalanx to the tip of the digital pulp skin. The digital pulp spaces are confined compartments bounded by the digital creases that overlie the joints, and are attached to the underlying pulleys. The synovial flexor tendon sheaths are described on page 879 . The web space is bounded distally by the skin and natatory ligament, by the deep transverse metacarpal ligament posteriorly, and by the deep attachments of the palmar fascia, together with their lateral attachments to the tendon sheaths, proximally. The deep palmar space is a complex, three-dimensional space, limited proximally by the carpal tunnel. It lies deep to the palmar aponeurosis, between the radial and ulnar condensations of vertical fibres that connect the palmar aponeurosis to the thenar and hypothenar eminences. Partitions that pass deeply from the longitudinal bands of the palmar aponeurosis form eight narrow compartments; four contain the digital flexor tendons and four contain the lumbricals and the neurovascular bundles.

Infections of the hand The spaces of the hand limit the spread of infection. Infections in the digit can occur in the nail fold (paronychia); the apical spaces at the very tip of the finger; the distal pulps (a felon); and the flexor sheaths. The flexor synovial sheath of the thumb and the little finger is continuous throughout the palm. Infection may spread to the palm and into other sheaths within the carpal tunnel but sepsis is as serious in those digits whose sheaths do not communicate with the carpal tunnel sheaths (index, middle, ring) as it is in those that do (thumb, little finger). Deep infections in the palm are usually not confined to any particular space.

## Compartment syndrome of the hand

Available with the Gray's Anatomy e-book

## BONES

The skeleton of the hand consists of the carpus, metacarpus and the phalanges.

## CARPUS

The carpus contains eight bones: four each in proximal and distal rows (Figs 50.8-50.9). In radial to ulnar order, the scaphoid, lunate, triquetrum and pisiform make up the proximal row, and the trapezium, trapezoid, capitate and hamate make up the distal row. The pisiform articulates with the palmar surface of the triquetrum. The other three proximal bones form an arch that is convex proximally, and which articulates with the radius and articular disc of the distal radio-ulnar

Dupuytren's disease appears to be inherited as an autosomal dominant trait with incomplete penetrance (MacFarlane 1991, Ling 1963). It has been associated with heavy alcohol consumption, smoking, diabetes, manual work and vibration exposure, and possibly the ingestion of anticonvulsants (Descatha et al 2011). In the proliferative stage of the disease, there is considerable myofibroblast activity, which may be the result of upregulation of the musculo-aponeurotic fibrosarcoma oncogene homologue B (MafB), found in the diseased cord tissue (Lee et al 2006). Mechanical stimuli subsequently cause the alignment of myofibroblasts along the lines of traction, which are later replaced by collagen.

The pattern of contracture is determined by the anatomy of the basic constituents of the palmar and digital fascia. The pretendinous bands that constitute the superficial layer of the palmar aponeurosis (layer 1) are most frequently involved. The development of nodules usually precedes cord formation; the nodules tether the skin to the deep fascia. Contracture of the pretendinous cords causes flexion of the metacarpophalangeal joints. The cords run between the flexor sheaths and the neurovascular bundles. Shortening of the vertical bands (of Grapow) results in the appearance of skin pits and thickening of the skin. Involvement of the natatory ligament restricts abduction of the fingers. None of these changes usually displaces the neurovascular bundle because each component lies superficially in the palm.

The pretendinous cord in the palm extends into a finger as a central cord that lies superficially in the midline. The lateral digital sheet gives rise to a lateral cord that is attached to the skin or flexor tendon sheath near Grayson's ligament, causing a flexion contracture of the proximal interphalangeal joint and, sometimes, displacing the digital neurovascular bundle medially. Spiral cords arise from the pretendinous band in layer 1 of the palmar fascia and pass deeper through layer 2 to become attached to the middle phalanx by Grayson's ligament. They are so named because they spiral round the neurovascular bundle, displacing it proximally, palmarwards and towards the midline as contracture increases, and rendering it vulnerable to injury during fasciectomy (MacFarlane 1974). The distal interphalangeal joint is uncommonly involved because the palmar aponeurosis only extends as far as the sides of the middle phalanx.

An abscess in any of the digital or palmar spaces should always be drained. Incisions should, wherever possible, follow the line of the flexion creases and adhere to the principles of extensile exposure. The motor and palmar cutaneous branches of the median nerve are potentially at risk when draining a thenar space abscess through a palmar incision. A dorsal approach through the first web space, perpendicular to the web itself and between the first and second metacarpals, is to be preferred on anatomical grounds but may not always achieve adequate drainage on its own. The mid-palmar space is best approached through a combination of a transverse distal palmar incision with an oblique longitudinal extension (McDonald et al 2011).

Hypothenar space infections are very rare. They tend to be confined by the hypothenar fascia and result in swelling of the ulnar side of the hand with some flexion and adduction of the little finger. They may be drained by an incision along the ulnar border of the space without significant risk of damage to underlying structures.

There are 10 identifiable compartments in the hand: four contain the dorsal interossei, three contain the palmar interossei, and three contain the thenar and hypothenar muscles and adductor pollicis. Any or all of these compartments may be injured by a rise in intracompartmental pressure. The absolute pressure at which damage is caused has not been determined but is thought to be less than that required in the lower limb. Injury may be caused by blast, burn or crush, and by injection, whether of therapeutic substances at low pressure or of industrial agents at high pressure. Symptoms may be as non-specific as aching of the hand at rest or on exercise, or the hand may become painful with increasing swelling and loss of movement in the digits. On examination, an intrinsic minus-type hand (claw hand) may be seen, with extension of the metacarpophalangeal joints and flexion of the proximal interphalangeal joints. Intracompartmental pressure measurements should be taken; the means by which this is done is not critical (Ortiz and Berger 1998). Any suspicion of a compartment syndrome should be followed by prompt decompression. It is usually possible to decompress thoroughly through two dorsal longitudinal incisions over the second and fourth metacarpals, as well as release of the flexor retinaculum. The dorsal compartments are addressed directly and the volar compartments opened deep by longitudinal incision. (See also Eardley and Stewart (2010).)

Fig. 50.8 A, The carpal and metacarpal bones of the left hand: palmar aspect. B, Sites of muscle attachments (except the dorsal interossei).

Fig. 50.9 A, The carpal and metacarpal bones of the left hand: dorsal aspect. B, Sites of muscle attachments.
joint. The distal concavity of the arch articulates with the capitate and hamate.

The dorsal carpal surface is convex. The palmar surface forms a deeply concave carpal groove, accentuated by the palmar projection of the radial and ulnar borders. The ulnar projection is formed by the pisiform and the hook (hamulus) of the hamate. The pisiform is at the proximal border of the hypothenar eminence, on the ulnar side of the palm, and it is easily felt in front of the triquetrum. The hamulus is concave in a radial direction; its tip is palpable 2.5 cm distal to the pisiform, in line with the radial border of the ring finger. The superficial division of the ulnar nerve can be rolled over it. The radial border of the carpal groove is formed by the tubercles of the scaphoid and trapezium. The former is distal on the anterior scaphoid surface and palpable (sometimes, also visible) as a small medial knob at the proximal
border of the palmar thenar eminence, radial to the tendon of flexor carpi radialis. The tubercle of the trapezium is a vertically rounded ridge on the anterior surface of the bone, slightly hollow medially and just distal and radial to the scaphoid tubercle; it is difficult to palpate. Both the scaphoid and trapezium may be grasped individually, and moved passively, by firm pressure between an opposed index finger and thumb applied to the palmar surface and 'anatomical snuff-box' simultaneously. The carpal groove is made into an osseofibrous carpal tunnel by the flexor retinaculum attached to its margins. The tunnel carries flexor tendons and the median nerve into the hand. The retinaculum strengthens the carpus and augments flexor efficiency. Radiocarpal, intercarpal and carpometacarpal ligaments are attached to the palmar and dorsal surfaces of all of the carpal bones, except the triquetrum and pisiform.

Fig. 50.10 Disarticulated carpal bones.

## Individual carpal bones

## Scaphoid

The scaphoid is the largest element in the proximal carpal row (Fig. 50.10 A , see Figs $50.8,50.9$ ). It has a long axis that is distal, radial and slightly palmar in direction. A round tubercle on the distolateral part of its palmar surface is directed anterolaterally (see Fig. 50.8A), and provides an attachment for the flexor retinaculum and abductor pollicis brevis; it is crossed by the tendon of flexor carpi radialis. The rough dorsal surface is slightly grooved, narrower than the palmar, and pierced by small nutrient foramina, which are often restricted to the distal half. The radial collateral ligament is attached to the lateral surface, which is also narrow and rough. The remaining $42 \%$ of surfaces are all articular. The radial (proximal) surface is convex, proximal and directed proximolaterally; the lunate surface is flat and semilunar, and faces medially; the capitate surface is large, concave, distal, and directed distomedially. The surface for the trapezium and trapezoid is continuous, convex and distal.

The proximal, palmar surface of the non-articulating portion of the scaphoid is supplied by branches from the palmar carpal artery or, in
its absence, by branches of the superficial palmar artery (Oehmke et al 2009). The middle and distal thirds of the palmar surface are supplied by the superficial palmar artery and small radial rami arteries. The distal third may also receive branches from the first dorsal metacarpal artery. The dorsal surface is principally supplied by the dorsal scaphoid artery and by branches of the styloid artery. Variation in this pattern is not uncommon. Intraosseous blood vessels have been found close to the articulating surface.

## Scaphoid bone fractures

Available with the Gray's Anatomy e-book

## Lunate

The lunate is approximately semilunar and articulates between the scaphoid and triquetrum in the proximal carpal row (see Figs 50.850.10B). Its rough palmar surface, almost triangular, is larger and wider than the rough dorsal surface. Its smooth convex proximal surface articulates with the radius and the articular disc of the distal radio-ulnar joint. Its narrow lateral surface bears a flat semilunar facet for the

Gelberman and Menon (1980) describe the proximal 70-80\% of the scaphoid as being supplied by branches of the radial artery that enter along its dorsal ridge, either just distal to the waist (14\%), directly over the waist (59\%) or just proximal to the waist (27\%). They estimated that $14 \%$ of their specimens would have had significant interruption and $59 \%$ a partial interruption to the vascularity of the proximal pole of the scaphoid from a fracture through the waist, and that failure to unite would have resulted in avascular necrosis of the proximal fragment. It has been argued that an inadequate blood supply is unlikely to be the cause of scaphoid non-union after fracture (Oehmke et al 2009), but see also Sendher and Ladd (2013).

The scaphoid is the most frequently fractured carpal bone, typically as a result of a fall on to the outstretched hand. Compson (1998), in a study of the true, rather than the radiological, anatomy of scaphoid fractures, identified three distinct fracture patterns: transverse through the 'surgical waist'; oblique ( $45^{\circ}$ to the surgical waist) in the plane of the dorsal sulcus; and through the proximal pole.
scaphoid. The medial surface, almost square, articulates with the triquetrum and is separated from the distal surface by a curved ridge, usually somewhat concave for articulation with the edge of the hamate in adduction (see Fig. 50.10B, left). The distal surface is deeply concave to fit the medial part of the head of the capitate.

## Kienböck's disease

Available with the Gray's Anatomy e-book

## Triquetrum

The triquetrum is somewhat pyramidal and bears an oval isolated facet for articulation with the pisiform on its distal palmar surface (see Figs 50.8-50.10C). Its medial and dorsal surfaces are confluent, and marked distally by the attachment of the ulnar collateral ligament, but smooth proximally to receive the articular disc of the distal radio-ulnar joint in full adduction. The hamate surface, lateral and distal, is concavoconvex, broad proximally and narrow distally. The lunate surface, almost square, is proximal and lateral.

## Pisiform

The pisiform is a sesamoid bone and is shaped like a pea, with a distolateral long axis (see Figs 50.8, 50.10D). It bears a dorsal flat articular facet for the triquetrum. The tendon of flexor carpi ulnaris and the distal continuations of the tendon, the pisometacarpal and pisohamate ligaments, are all attached to the palmar non-articular area, which surrounds and projects distal to the articular surface.

## Trapezium

The trapezium has a tubercle and groove on its rough palmar surface (see Figs 50.8A, 50.10E). The groove, which is medial, contains the tendon of flexor carpi radialis, and two layers of the flexor retinaculum are attached to its margins. The tubercle is obscured by the thenar muscles that are attached to it (opponens pollicis, flexor pollicis brevis and abductor pollicis brevis) (see Fig. 50.8B). The elongated, rough dorsal surface is related to the radial artery. The large lateral surface is rough for attachment of the radial collateral ligament and capsular ligament of the thumb carpometacarpal joint. A large sellar surface faces distolaterally and articulates with the base of the first metacarpal. Most distally, it projects between the bases of the first and second metacarpal bones and carries a small, quadrilateral, distomedially directed facet that articulates with the base of the second metacarpal. The large medial surface is gently concave for articulation with the trapezoid. The proximal surface is a small, slightly concave facet for articulation with the scaphoid. Its ridge, or 'summit', fits the concavity of the first metacarpal base, and extends in a palmar and lateral direction, at an angle of approximately $60^{\circ}$ with the plane of the second and third metacarpals. Abduction and adduction occur in the plane of the ridge, which is shorter than the corresponding metacarpal groove. Their contours vary reciprocally: they are more curved near the second metacarpal base, whereas the radius of curvature is longer further away from this site. The two surfaces are not completely congruent, and the area of close contact probably moves towards the palm in adduction and dorsally in abduction. While the axis of flexion/extension passes through the trapezium, that for adduction/abduction is in the metacarpal base. Flexion is accompanied by medial rotation, and extension by lateral rotation.

## Trapezoid

The trapezoid is small and irregular. It has a rough palmar surface that is narrower and smaller than its rough dorsal surface (see Figs 50.850.10 F ). The distal surface, which articulates with the grooved base of the second metacarpal, is triangular, convex transversely and concave at right angles to this. The medial surface articulates by a concave facet with the distal part of the capitate, the lateral surface articulates with the trapezium, and the proximal surface articulates with the scaphoid.

## Capitate

The capitate is the central and largest carpal bone. It articulates with the base of the third metacarpal via its triangular distal concavo-convex surface (see Figs 50.8-50.10G). Its lateral border is a concave strip for articulation with the medial side of the base of the second metacarpal. Its dorsomedial angle usually bears a facet for articulation with the base of the fourth metacarpal. The head projects into the concavity formed by the lunate and scaphoid; the proximal surface articulates with the lunate, and the lateral surface with the scaphoid. The facets for the scaphoid and trapezoid, though usually continuous on the distolateral surface, may be separated by a rough interval. The medial surface bears
a large facet for articulation with the hamate, which is deeper proximally where it is partly non-articular. Palmar and dorsal surfaces are roughened for carpal ligaments, the dorsal being the larger.

## Hamate

The hamate is cuneiform and bears an unciform hamulus (hook) that projects from the distal part of its rough palmar surface (see Fig. 50.10 H ). The hamulus is curved with a lateral concavity and its tip inclines laterally, contributing to the medial wall of the carpal tunnel (see Figs 50.8-50.9). The flexor retinaculum is attached to the apex of the hamulus. Distally, on the hamular base, a slight transverse groove may be in contact with the terminal deep branch of the ulnar nerve. The remaining palmar surface, like the dorsal, is roughened for attachment of ligaments. A faint ridge divides the distal surface into a smaller lateral facet that articulates with the base of the fourth metacarpal, and a medial facet for articulation with the base of the fifth. The proximal surface, the thin margin of the wedge, usually bears a narrow facet that contacts the lunate in adduction. The medial surface is a broad strip, convex proximally, concave distally, which articulates with the triquetrum; distally, a narrow medial strip is non-articular. The lateral surface articulates with the capitate by a facet covering all but its distal palmar angle.

## Ossification

Carpal bones are cartilaginous at birth, although ossification may have started in the capitate and hamate. Each carpal bone is ossified from one centre - capitate first and pisiform last; the order in the others varies (Figs 50.11-50.15). The capitate begins to ossify in the second month; the hamate at the end of the third month; the triquetrum in the third year; and the lunate, scaphoid, trapezium and trapezoid in the fourth year in females and fifth year in males. The pisiform begins to ossify in the ninth or tenth year in females, and the twelfth in males. The order varies according to sex, nutrition and, possibly, race. Occasionally, an os centrale occurs between the scaphoid, trapezoid and capitate bones; during the second prenatal month, it is a cartilaginous nodule that usually fuses with the scaphoid. Occasionally, lunate and triquetral elements may fuse. Other fusions and accessory ossicles have also been described.

## METACARPUS

The metacarpus consists of five metacarpal bones, conventionally numbered in radio-ulnar order. These are small long bones, with a distal head, shaft and expanded base. The rounded heads articulate with the proximal phalanges. Their articular surfaces are convex, although less so transversely, and extend further on the palmar surfaces, especially at their margins. The knuckles are produced by the metacarpal heads. The metacarpal bases articulate with the distal carpal row and with each other, except the first and second. The shafts have longitudinally concave palmar surfaces, which form hollows for the palmar muscles. Their dorsal surfaces bear a distal triangular area, which is continued proximally as a round ridge. These flat areas are palpable proximal to the knuckles.

The medial four metacarpals gently diverge proximodistally. The first metacarpal is more anterior and rotated medially on its axis through $90^{\circ}$, so that its morphologically dorsal surface is lateral, its radial border palmar, its palmar surface medial, and its ulnar border dorsal. Hence, the thumb flexes medially across the palm and can be rotated into opposition with each finger. Opposition depends on medial rotation and is important in manual dexterity; when an object is grasped, fingers and thumb encircle it from opposite sides, greatly increasing the power and skill of the grip.

## Individual metacarpal bones

## First metacarpal

The first metacarpal is short and thick (see Figs 50.8-50.9; Fig. 50.16A). Its dorsal (lateral) surface can be felt to face laterally; its long axis diverges distolaterally from its neighbour. The shaft is flattened, dorsally broad and transversely convex. The palmar (medial) surface is longitudinally concave and divided by a ridge into a larger lateral (anterior) and smaller medial (posterior) part. Opponens pollicis is attached to the radial border and adjoining palmar surface; the first dorsal interosseous muscle (radial head) is attached to its ulnar border and adjacent palmar surface. The base is concavo-convex and articulates with the trapezium. Abductor pollicis longus is attached on its lateral

Kienböck's disease, first described in 1910, is avascular necrosis of the lunate. Aetiology remains unclear but is thought to be associated with the arterial blood supply to the lunate. Up to eight small vessels usually enter both the dorsal and the palmar aspects of the bone, three on the dorsal surface and five on the palmar; they divide into smaller branches within the bone. However, in some cadaveric studies, only one vessel has been identified, and it has been inferred that this pattern would render an individual at increased risk of osteonecrosis, particularly if the branching pattern within the bone is limited. Other possible aetiological factors include disruption or obstruction of the venous outflow from the lunate, causing increased intraosseous pressure; negative ulnar variance; trauma; variations in the shape of the lunate; and mechanical factors. The natural history of the disease process is unknown.

While patients generally present with pain and stiffness of the wrist, these symptoms correlate poorly with the radiological findings and, indeed, patients may be asymptomatic. (For further reading, see Cross and Matullo (2014).)

Fig. 50.11 A radiograph of a hand at $21 / 2$ years (male), dorsopalmar projection. Note the early stages of ossification in the epiphyses at the proximal ends of the phalanges and first metacarpal; the distal ends of the remaining metacarpals and radius; and for the capitate, hamate and lunate. Typically, the centre for the lunate is preceded by the centre for the triquetrum. Compare with Figures 50.12 and 50.13.

Fig. 50.12 A radiograph of a hand at $61 / 2$ years (male), dorsopalmar projection. Note the more advanced state of the centres of ossification that were already visible in Figure 50.11, and the appearance of additional centres in the distal ulnar epiphysis and in the triquetrum, scaphoid, trapezium and trapezoid.

Fig. 50.14 A radiograph of an adult hand, dorsopalmar projection. Key: 1, head of middle phalanx of middle finger; 2, head of proximal phalanx of ring finger; 3 , shaft of proximal phalanx of ring finger; 4, head of fifth metacarpal; 5 , shaft of fifth metacarpal; 6 , base of fifth metacarpal; 7, hook of hamate; 8 , triquetrum; 9 , hamate; 10 , pisiform; 11, styloid process of ulna; 12, lunate; 13, head of ulna; 14, distal phalanx of index finger; 15, distal phalanx of thumb; 16, proximal phalanx of thumb; 17, sesamoid bone; 18, trapezoid; 19, trapezium; 20, capitate; 21, scaphoid; 22 , styloid process of radius; 23, distal radio-ulnar joint; 24, radius.
of the second palmar interosseous, and a dorsal strip for attachment of the radial head of the second dorsal interosseous.

## Third metacarpal

The third metacarpal has a short styloid process, projecting proximally from the radial side of the dorsal surface (see Figs 50.8-50.9; Fig. 50.16 C ). Its base articulates with the capitate by a facet anteriorly convex but dorsally concave where it invades the styloid process on the lateral aspect of its base. A strip-like facet, constricted centrally, articulates with the bases of the second metacarpal (laterally) and the fourth metacarpal (medially), the latter by two oval facets. The palmar facet may be absent; less frequently, the facets are connected proximally by a narrow bridge. The palmar surface of the base receives a slip from the tendon of flexor carpi radialis; extensor carpi radialis brevis is attached

Fig. 50.15 The approximate dates of ossification of the individual bones of the hand and their epiphyses.
to its dorsal surface, beyond the styloid process. The shaft resembles that of the second metacarpal. The ulnar head of the second dorsal interosseous is attached to its lateral surface; the radial head of the third dorsal interosseous is attached to its medial surface, and the transverse head of adductor pollicis is attached to the intervening palmar ridge in its distal two-thirds. Its dorsal surface is covered by the extensor tendon.

## Fourth metacarpal

The fourth metacarpal is shorter and thinner than the second and third (see Figs 50.8-50.9; Fig. 50.16D). On its base, it displays two lateral oval facets for articulation with the base of the third metacarpal; the dorsal is usually larger and proximally in contact with the capitate. A single medial elongated facet is for articulation with the base of the fifth metacarpal. The quadrangular proximal surface articulates with the hamate; it is anteriorly convex and dorsally concave. The shaft is like the second, but a faint ridge on its lateral surface separates the attachments of the third palmar interosseous and the ulnar head of the third dorsal interosseous. The radial head of the fourth dorsal interosseous is attached to the medial surface.

## Fifth metacarpal

The fifth metacarpal (see Figs 50.8-50.9; Fig. 50.16E) differs in its medial basal surface, which is non-articular and bears a tubercle for extensor carpi ulnaris. The lateral basal surface is a facet, transversely concave, convex from palm to dorsum, for articulation with the hamate. A lateral strip articulates with the base of the fourth metacarpal. The shaft bears a triangular dorsal area that almost reaches the base; the lateral surface inclines dorsally only at its proximal end. Opponens digiti minimi is attached to the medial surface. The lateral surface is divided by a ridge, which is sometimes sharp, into a palmar strip for the attachment of the fourth palmar interosseous and a dorsal strip for the ulnar part of the fourth dorsal interosseous.

## Ossification

Each metacarpal ossifies from a primary centre for the shaft and a secondary centre that is in the base of the first metacarpal and in the heads of the other four (see Figs 50.11-50.15). Ossification begins in the midshaft about the ninth week. Centres for the second to fifth metacarpal heads appear in that order in the second year in females, and between $11 / 2$ to $21 / 2$ years in males. They unite with the shafts about the fifteenth or sixteenth year in females, and the eighteenth or nineteenth in males. The first metacarpal base begins to ossify late in the second

year in females, early in the third year in males, uniting before the fifteenth year in females and seventeenth in males. Sometimes, the styloid process of the third metacarpal is a separate ossicle. The thumb metacarpal ossifies like a phalanx, and some authorities therefore consider that the thumb skeleton consists of three phalanges. Others believe that the distal phalanx represents fused middle and distal phalanges, a condition occasionally observed in the fifth toe. When the thumb has three phalanges, the metacarpal has a distal and a proximal epiphysis. It occasionally bifurcates distally. When it does, the medial branch has no distal epiphysis and bears two phalanges, while the lateral branch shows a distal epiphysis, and three phalanges. The existence of only a distal metacarpal epiphysis may be associated with a greater range of movement at the metacarpophalangeal joint. In the thumb, the carpometacarpal joint has the wider range, and the first metacarpal has a basal epiphysis. A distal epiphysis may appear in the first, and a proximal epiphysis in the second, metacarpal.

Fig. 50.17 Joints and ligaments of the left hand. (A) Palmar aspect: extrinsic ligaments. (B) Palmar aspect: intrinsic ligaments. (C) Dorsal aspect.

## PHALANGES

There are 14 phalanges, three in each finger and two in the thumb (see Fig. 50.15). Each has a head, shaft and proximal base. The shaft tapers distally, its dorsal surface transversely convex. The palmar surface is transversely flat but gently concave anteriorly in its long axis. The bases of the proximal phalanges carry concave, oval facets adapted to the metacarpal heads. Their own heads are smoothly grooved like pulleys and encroach more on to the palmar surfaces. The bases of the middle phalanges carry two concave facets separated by a smooth ridge, conforming to the heads of the proximal phalanges. The bases of the distal phalanges are adapted to the pulley-like heads of the middle phalanges. The heads of the distal phalanges are non-articular and carry a rough, crescentic palmar tuberosity, to which the pulps of the fingertips are attached.

Articular ligaments and numerous muscles are attached to the phalanges. The tendon of flexor digitorum profundus is attached to the palmar aspect of the base of the phalanx and the tendon of extensor digitorum to its dorsal surface. The tendon of flexor digitorum superficialis and its fibrous sheath are attached to the sides of the middle phalanx, and a part of extensor digitorum is attached to the base dorsally. The fibrous flexor sheath is attached to the sides of a proximal phalanx, part of the corresponding dorsal interosseous is attached to its base laterally, and another dorsal interosseous is attached medially.

The phalanges of the little finger and the thumb differ. Abductor and flexor digiti minimi are attached to the medial side of the base of the proximal phalanx of the little finger. The tendon of extensor pollicis brevis and the oblique head of adductor pollicis (dorsally), and the oblique and transverse heads of adductor pollicis, sometimes conjoined with the first palmar interosseous (medially), are attached to the base of the proximal phalanx of the thumb.

## Ossification

Phalanges are ossified from a primary centre for the shaft and a proximal epiphysial centre (see Figs 50.11-50.15). Ossification begins prenatally in shafts as follows: distal phalanges in the eighth or ninth week,
proximal phalanges in the tenth, and middle phalanges in the eleventh week or later. Epiphyseal centres appear in proximal phalanges early in the second year (females), or later in the same year (males), and in middle and distal phalanges in the second year (females), or third or fourth year (males). All epiphyses unite about the fifteenth to sixteenth year in females, and seventeenth to eighteenth year in males.

## JOINTS

## RADIOCARPAL (WRIST) JOINT

Articulating surfaces The radiocarpal joint is a synovial, biaxial and ellipsoid joint formed by articulation of the distal end of the radius and the articular disc of the triangular fibrocartilage with the scaphoid, lunate and triquetrum (Figs 50.17-50.18). In the neutral position of the wrist, only the scaphoid and lunate are in contact with the radius and articular disc; the triquetrum comes into apposition with the disc only in full adduction of the wrist joint. The radial articular surface and distal discal surface form an almost elliptical, concave surface with a transverse long axis. The radial surface is bisected by a low ridge into two concavities. A similar ridge usually appears between the medial radial concavity and the concave distal discal surface. The proximal articular surfaces of the scaphoid, lunate and triquetrum and their interosseous ligaments form a smooth convex surface that is received into the proximal concavity.

Fibrous capsule The fibrous capsule is lined by synovial membrane that is usually separate from that of the distal radio-ulnar and intercarpal joints. A protruding prestyloid recess (recessus sacciformis), anterior to the articular disc, is present and ascends close to the styloid process. The recess is bounded distally by the fibrocartilaginous meniscus, which projects from the ulnar collateral ligament between the tip of the ulnar styloid process and the triquetrum; both are clothed with hyaline articular cartilage. The meniscus may ossify. The capsule is strengthened by palmar radiocarpal and ulnocarpal, dorsal radiocarpal and radial and ulnar collateral ligaments.

Synovial membrane The synovial membrane lines the fibrous capsule.

Muscles producing movement Movements accompany those of the intercarpal and midcarpal joints, and are described on page 874.

## CARPAL JOINTS

The intercarpal joints connect the carpal bones. Their articular surfaces are saddle-shaped, ellipsoid or spheroidal. The carpal bones are connected by an extensive array of ligaments, not all of which are specifically named. The flexor retinaculum is an accessory intercarpal ligament.

## Joints of the proximal carpal row

Joints of the proximal carpal row are between the scaphoid, lunate and triquetrum. In addition, the pisiform articulates with the palmar surface of the triquetrum at a small, oval, almost flat, synovial pisotriquetral joint. A thin capsule surrounds the joint. The synovial cavity is usually separate but may communicate with that of the radiocarpal joint.

## Joints of the distal carpal row

Joints of the distal carpal row are between the trapezium, trapezoid, capitate and hamate. There is little movement at these joints.

## Midcarpal joint

The midcarpal joint, between the scaphoid, lunate and triquetrum (proximally), and trapezium, trapezoid, capitate and hamate (distally), is a compound articulation that may be divided descriptively into medial and lateral parts. Throughout most of the medial compartment, the convexity formed by the head of the capitate and hamate articulates with a reciprocal concavity formed by the scaphoid, lunate and much of the triquetrum. However, most medially, the curvatures are reversed, forming a compound sellar joint. In the lateral compartment, the trapezium and trapezoid articulate with the scaphoid, forming a second planosellar compound articulation.

Carpal synovial membrane The extensive carpal synovial membrane lines an irregular articular cavity. Its proximal part is between the distal surfaces of the scaphoid, lunate and triquetrum, and the proximal surfaces of the second carpal row. It has proximal prolongations between the scaphoid and lunate, and lunate and triquetrum, and three distal prolongations between the four bones of the second row. The prolongation between the trapezium and trapezoid and/or between the trapezoid and capitate is often continuous with corresponding carpometacarpal joints, either from the second to the fifth, or from the second and third only. In the latter case, the joint between the hamate and fourth and fifth metacarpal bones has a separate synovial membrane and the carpometacarpal interosseous ligament is interposed.

Synovial cavities of carpometacarpal joints are prolonged slightly between the metacarpal bases. The synovial joint between the pisiform and triquetrum is usually isolated.

## Wrist ligaments

The distal radio-ulnar joint and triangular fibrocartilage complex are described on pages 845-848.

Intracapsular ligaments lie between the fibrous and synovial layers of the wrist joint; their margins may not be distinct. Extracapsular ligaments are superficial to the fibrous layer. Most wrist ligaments lie within the joint capsule; the only exceptions are the flexor and extensor retinacula and the pisotriquetral ligament. The wrist ligaments are further classified into extrinsic and intrinsic named ligaments. Some of the extrinsic ligaments have superficial and deep parts; the latter are identifiable at wrist arthroscopy but the former are not. Wrist ligaments are conventionally named from proximal to distal and from radial to ulnar, e.g. the radioscaphocapitate ligament passes between the radius, scaphoid and capitate.

## Extrinsic ligaments

The extrinsic ligaments connect the carpus with the forearm bones. They tend to be longer than the intrinsic ligaments and are approximately one-third as strong.

## Extrinsic palmar carpal ligaments

When the synovial lining of the carpal tunnel is dissected away, two V-shaped ligamentous bands are visible with their apices lying distally (see Fig. 50.17A). The limbs of the ' V ' take origin from the radius and ulna, respectively; the apex of one ' V ' attaches to the distal row and that of the second ' $V$ ' to the proximal row.

Radioscaphocapitate ligament The radioscaphocapitate ligament originates from the radial styloid and the palmar lip of the radius, and has three parts. The radial part inserts on to the lateral aspect of the waist of the scaphoid (radial collateral ligament). The middle part continues as part of the distal ' V ' and inserts on to the distal pole of the scaphoid. The ulnar part passes over the proximal pole of the scaphoid towards the mid-carpus and blends with the fibres that originate from the ulnar side of the triangular fibrocartilage complex to form the arcuate ligament over the palmar aspect of the capitate. A few of the fibres of the radioscaphocapitate ligament attach to the body of the capitate. There is a discrete interval between the inferior margin of this ligament and the palmar horn of the lunate (the space of Poirier).

Long radiolunate ligament The long radiolunate ligament arises adjacent to the radioscaphocapitate ligament on the palmar lip of the radius, passes over and supports the proximal pole of the scaphoid, and inserts into the palmar horn of the lunate. It is discrete from the radioscaphocapitate ligament, from which it is separated by the interligamentous sulcus, continuous with the space of Poirier.
Radioscapholunate (ligament of Testut) The radioscapholunate ligament is covered by a thick synovial lining and is a visible landmark during wrist arthroscopy.

Short radiolunate ligament The short radiolunate ligament is part of the proximal ' $V$ '. It arises from the palmar lip of the lunate fossa of the radius and passes directly to the palmar horn of the lunate. On the ulnar side, its fibres blend with those of the palmar triangular fibrocartilage complex as they pass to their insertion on the lunate.

Ulnolunate ligament The ulnolunate ligament originates from the palmar aspect of the ulna adjacent to the short radiolunate ligament and inserts on to the palmar horn of the lunate. Part of this fibre complex arches radially and blends with part of the radioscaphocapitate complex to form the arcuate ligament.

Ulnotriquetral (ulnar collateral) ligament The ulnotriquetral ligament arises from the palmar aspect of the ulna, inserts into the medial aspect of the triquetrum, and continues distally to a further attachment to the medial aspect of the hamate. The ulnolunate and ulnotriquetral ligaments are also attached to the marginal ligament of the triangular fibrocartilage complex.

## Extrinsic dorsal carpal ligaments

The dorsal wrist ligaments are comparatively thin and are reinforced by the floor and septa of the fibrous tunnels for the six dorsal compartments. The extrinsic dorsal carpal ligaments and the intrinsic dorsal intercarpal ligaments have a ' Z 'shaped configuration (see Fig. 50.17C).

Dorsal radiolunotriquetral ligament The dorsal radiolunotriquetral ligament has superficial and deep components. The superficial part connects the radius and triquetrum, and the deep part connects the radius, lunate and triquetrum. The wide superficial component arises from the dorsal margin of the distal radius and courses ulnarwards to insert on the dorsal edge of the triquetrum. The deep component takes a narrower origin from the ulnar aspect of the distal dorsal radius and passes in an ulnar direction to attach to part of the lunotriquetral articulation and the intrinsic lunotriquetral ligament.

## Intrinsic ligaments

The intrinsic ligaments of the wrist are attached to carpal bones (see Fig. 50.17B). They are stronger and shorter than extrinsic ligaments and are connected with the extrinsic ligament complexes by interdigitating fibres. The intrinsic ligaments are subdivided into ligaments that connect the carpal bones of the proximal and distal rows, respectively, and ligaments that connect the rows by crossing over the midcarpal joint.

Proximal row interosseous ligaments The scapholunate and lunotriquetral ligaments are clinically and biomechanically important structures. In the sagittal plane, they have an approximately horseshoeshape configuration with palmar, midcarpal and dorsal components. The scapholunate ligament contains short transverse fibres connecting the dorsal aspect of the respective bones and more obliquely orientated fibres connecting the palmar aspect. The tighter dorsal component of the ligament acts as a hinge facilitating flexion and extension of the scaphoid. The ligament continues in its midcarpal section as an interosseous membrane. The lunotriquetral ligament has similar dorsal, midcarpal interosseous and palmar components, but the fibres of the dorsal and palmar components are similarly orientated, which precludes the same pattern of preferential movement as occurs between the lunate and scaphoid. The interosseous membranes of the scapholunate and lunotriquetral ligaments separate the midcarpal from the radiocarpal joint spaces. Dye injected into one of these joint spaces that leaks to the other denotes a tear of one of these ligaments.

Distal row interosseous ligaments The strong distal row interosseous ligaments connect and stabilize the capitate, hamate, trapezium and trapezoid. They have superficial and deep components, and, unlike the ligaments of the proximal row, are seldom torn.

Palmar midcarpal ligaments The fan-shaped palmar scaphocapitate-trapezoid ligament arises from the scaphoid. It has two parts, the scaphotrapeziotrapezoidal ligament and the more ulnar scaphocapitate ligament. The triquetrohamate and triquetrocapitate ligaments lie towards the ulnar side of the carpus.

Dorsal midcarpal ligaments The dorsal intercarpal ligament assists in stabilization of the proximal carpal row. It arises from the trapezoid and distal pole of scaphoid, and passes across the dorsal horn of the lunate to be attached to the triquetrum. The ligament forms the floor of the fourth and fifth extensor compartments. The lateral scaphotrapeziotrapezoidal ligament is on the radial side.

## Arthroscopy of the wrist and hand

Arthroscopy of the wrist joint may be carried out through up to 11 described portals, although only a few of these are favoured; most are dorsally situated. Some are, as de Smet (2002) has described, 'frighteningly' close to key anatomical structures. Consequently, only the skin should be incised when establishing a portal, and the remaining dissection should be carried out with blunt artery forceps and using blunt probes presaged by the introduction of a 22 gauge needle.

## MOVEMENTS AND LOADING OF THE WRIST JOINT

## Movements of the wrist (carpal kinematics)

The movements at the radiocarpal and intercarpal joints are considered together. The approximate ranges of active movement are flexion $\left(85^{\circ}\right)$, extension $\left(85^{\circ}\right)$, adduction (ulnar deviation) $\left(45^{\circ}\right)$, abduction (radial deviation) $\left(15^{\circ}\right)$ and circumduction (all measurements are approximate).

The range of flexion is greater at the radiocarpal joint, while in extension there is more movement at the midcarpal joint (Fig. 50.19). Hence, the proximal surfaces extend further posteriorly on the lunate and scaphoid bones. These movements are limited chiefly by antagonistic muscles; therefore, the range of flexion is perceptibly diminished when the fingers are flexed, due to increased tension in the extensors. Only when the joints are forced to the limits of flexion or extension are the dorsal or palmar ligaments fully stretched.

During extension of the wrist, the distal carpal bones rotate into extension with slight radial deviation, while during the 'dart-throwing' movement (from radial deviation and extension into ulnar deviation and flexion), movement occurs almost entirely at the distal row of the carpus.

Most adduction occurs at the radiocarpal joint. The lunate articulates with both the radius and articular disc when the hand is in the midposition but, in adduction, it articulates solely with the radius, and the triquetrum now comes into contact with the articular disc (Fig. 50.20A). Much of the proximal articular surface of the scaphoid becomes subcapsular beneath the radial collateral ligament and forms a smooth, convex, palpable prominence in the floor of the 'anatomical snuff-box'.

Abduction from the neutral position occurs at the midcarpal joint. Radiographs of abducted hands show that the capitate rotates round an anteroposterior axis so that its head passes medially and the hamate conforms to this; the distance between the lunate and the apex of the hamate is increased (Fig. 50.20B). The scaphoid rotates around a transverse axis, and its proximal articular surface moves away from the capsule to articulate solely with the radius. Movements are limited by antagonistic muscles and, at extremes, by the carpal collateral ligaments.

The proximal row (scaphoid, lunate and triquetrum) is an intercalated segment; no tendons insert on to the bones of the row. It is inherently unstable and controlled by specific retaining and gliding ligaments. Its relative position is determined by the spatial configurations of the radius, triangular fibrocartilage complex and ulna on one side, and the rigid distal carpal row on the other. The proximal carpal row is subject to two opposing moments: the scaphoid straddles the proximal and distal rows and tends to rotate the proximal row into flexion under axial load and radial deviation. At the same time, there is a force tending to extend the proximal row, which is initiated by the distal row and transmitted via the midcarpal ligaments to the triquetrum (Fig. 50.21). Stability of the midcarpal joint is thus ensured during both movement and loading.

The distal carpal row (trapezium, trapezoid, capitate and hamate) can be regarded as one rigid structure. The scaphoid bridges the proximal and distal carpal rows and provides a functional couple between the two.

## Muscles producing movements

Flexion Flexors carpi radialis and ulnaris and palmaris longus produce flexion, assisted by flexors digitorum superficialis and profundus, and flexor pollicis longus.

Extension Extensors carpi radialis longus, brevis and ulnaris, assisted by extensors digitorum, digiti minimi, indicis and pollicis longus, produce extension.

Adduction (ulnar deviation) Flexor and extensor carpi ulnaris produce adduction.

Fig．50．21 The effect of axial loading on the rotatory movements of the bones of the wrist．A，The scaphoid flexes but is constrained on its palmar aspect by the scaphotrapeziotrapezoidal ligaments and dorsally by the scapholunate ligament．B，The lunate follows the scaphoid into flexion and is restrained by the dorsal radiolunate ligament．C，The triquetrum flexes with the scaphoid and lunate；it is constrained on its palmar aspect by the triquetrohamate and triquetrocapitate ligaments，and dorsally by the radiotriquetral ligament．

There are five possible dorsal portals（1－2，3－4，4－5，6－R，6－U）for viewing the radiocarpal joint and two（MCR，MCU）for the midcarpal joint．These are named by their relation to the six extensor compart－ ments．The 1－2 portal is usually avoided because the radial artery lies a mean 3 mm （range $1-5 \mathrm{~mm}$ ）radially，as do branches of the super－ ficial radial nerve（range $1-6 \mathrm{~mm}$ ）（Abrams et al 1994）．The 3－4 portal is normally used as the main viewing portal and the $4-5$ portal for instrumentation．The dorsal cutaneous branch of the ulnar nerve lies within 2.5 mm of the $6-\mathrm{R}$ portal．Inflow is via the arthroscope（in the $3-4$ portal）and outflow through a separate $6-U$ portal．The articular surfaces of the scaphoid and lunate are seen distally，linked by the scapholunate ligament．Proximally，the triangular fibrocartilage complex may be viewed．Tears of its central portion are commonly seen in older patients；congenital perforations are occasionally found．Bucket handle tears of the triangular fibrocartilage complex may be excised，or repaired if they occur in the peripheral vascularized portion．The radial midcar－ pal portal is used to view the scaphocapitate joint．The ulnar midcarpal portal is used for instrumentation and for viewing the ulnar portion of the midcarpal joint．

Volar portals（radial，VR，midcarpal，VMC and ulnar，VU）are less favoured but retain certain advantages，including the ability to view the dorsal capsule，the dorsal radiocarpal ligament and the palmar sub－ regions of the scapholunate and lunotriquetral interosseous ligaments． Use of the volar radial portal carries with it the potential for damage to flexor carpi radialis，the palmar cutaneous branch of the median nerve and the lateral cutaneous nerve of the forearm，all of which can run close to，but not within 3 mm of，the portal．The volar ulnar portal lies more than 5 mm away from the ulnar neurovascular bundle，provided the entry point in the capsule is deep to the ulnar edge of the profundus tendons（Slutsky 2002）．

The carpus was originally thought to move simply as proximal and distal rows（row or rigid body theory）（Johnston 1907）．According to this view，during the composite movement of wrist flexion and exten－ sion，approximately two－thirds of movement occurs at the radiocarpal joint and one－third at the midcarpal joint．The carpus was later judged to move in lateral central and medial columns more than it did in rows， and the radius－lunate－capitate was described as a three－bar linkage system（column theory）（Navarro 1921）．This theory was modified （Taleisnik 1976）to incorporate the specific stabilizing role of the scaphoid as it bridges the proximal and distal rows．A further theory proposed that the bones were linked by their ligaments in a ring con－ figuration，so that any breakage of the key links leads to instability（ring theory）．Most recently，the＇four－unit＇theory suggests that the distal carpal row moves as a single unit，and the scaphoid，lunate and tri－ quetrum move in complex but characteristic relationships that are dependent on the given movement．Clinical observation provides some support for each of these theories．

Fig. 50.19 A, A radiograph of the hand and wrist in full flexion: lateral aspect. Compare with $B$, and note the relative positions of the capitate and lunate, and the lunate and radius. B, A radiograph of the hand and wrist: lateral aspect. The long axes of the third metacarpal, capitate and lunate are, approximately, in line with the long axis of the radius. Note the relative positions of the capitate and lunate, and the lunate and radius. C, A radiograph of the hand and wrist in full extension: lateral aspect. Compare with $B$ and note the alterations in the relative positions of the capitate and lunate, and the lunate and the radius. Key: 1, capitate; 2, lunate; 3 , tubercle of the trapezium; 4, tubercle of the scaphoid.

Abduction (radial deviation) Flexor carpi radialis, extensors carpi radialis longus and brevis, with abductor pollicis longus and extensor pollicis brevis, produce abduction.

Flexor carpi ulnaris is stronger than extensor carpi ulnaris, which, in turn, is stronger than extensors carpi radialis longus and brevis, and flexor carpi radialis. The other muscles are all weaker. It is for this reason that these muscles tend to be selected for the major tendon transfers around the wrist (Brand 1985). During flexion and extension, flexor carpi radialis, flexor carpi ulnaris and extensor carpi radialis brevis have a greater excursion than extensor carpi radialis longus and extensor

Fig. 50.20 A, A radiograph of the hand in full adduction (ulnar deviation): dorsopalmar projection. The arrows point to the scaphoid on the radial side and to the pisiform on the ulnar side. Compare with B and observe that the movements occur at both the radiocarpal and intercarpal joints. B, A radiograph of the same hand in full abduction (radial deviation). The arrows point to the hamate and pisiform. Compare with A and note that: the scaphoid and lunate have passed medially (ulnarly) so that the latter articulates to a large extent with the articular disc of the distal radio-ulnar joint; the pisiform is now widely separated from the styloid process of the ulna; the scaphoid, having rotated round a transverse axis, is much foreshortened; the apex of the hamate has been thrust away from the lunate by the rotation of the capitate around an anteroposterior axis; a gap has opened up between the distal portions of the hamate and triquetrum; and the long axes of the capitate and lunate are now almost in the same straight line.
carpi ulnaris. During radial and ulnar deviation, extensor carpi radialis longus and extensor carpi ulnaris have a greater excursion, whereas that of flexor carpi radialis is relatively small. The axes of rotation for flexion/ extension and radial/ulnar deviation intersect at a point in the proximal part of the capitate bone. Flexor carpi radialis and flexor carpi ulnaris are most efficient in flexion, extensor carpi radialis brevis in extension, extensor carpi radialis longus in radial deviation and extensor carpi ulnaris in ulnar deviation (Horii et al 1993).

## Loading of the wrist (carpal kinetics)

Axial loading, i.e. load or force applied along a line parallel to the long bones of the arm, occurs in clenching the fist. In most activities, loading is multiplanar with a combination of vectors of force. Grasping an object whilst lifting it against gravity with the elbow in flexion causes transverse and axial loading.

## Force transmission

## Radiocarpal joint

The radiocarpal and ulnocarpal articulations can be described in terms of specific fossae, namely: the scaphoid and lunate fossae of the radius,
and the facet formed by the distal aspect of the triangular fibrocartilage complex. The scaphoid fossa contributes $43 \%$, the lunate fossa $46 \%$, and the triangular fibrocartilage complex $11 \%$ of the total area of this articulating surface. Under physiological conditions, the contact area between this surface and the proximal carpal row is about $20 \%$. Greater contact is seen in forearm supination, radial deviation and dorsiflexion of the wrist. Lesser contact occurs in forearm pronation, ulnar deviation and palmar flexion of the wrist. Axial loading increases the contact area to a maximum of about $40 \%$. Force across the joint also varies with the position of the forearm and the degree of wrist flexion. For a given load in wrist-neutral position, $50 \%$ of force passes across the scaphoid fossa $35 \%$ through the lunate fossa and $15 \%$ across the triangular fibrocartilage complex. With a power grip, there is slight ulnar deviation and the proportion of force passing across the scaphoid and lunate fossae reverses.

## Midcarpal joint

With the wrist in neutral position, $50-60 \%$ of a given load is transmitted from the distal row through the capitate to the scaphoid and lunate. Up to $30 \%$ of the load is transmitted via the scaphotrapeziotrapezoid joint and up to $20 \%$ via the hamate-triquetral joint.

## Distal radio-ulnar joint (DRUJ)

See page 845 .

## Specific actions

See Video 50.1.

## Power grip

In power grip, the wrist is positioned in mid-dorsiflexion and the object is tightly gripped. Force is transmitted from the hand and wrist via the radiocarpal joint and triangular fibrocartilage complex to both bones of the forearm, through the elbow joint to the humerus, and from there, via the glenohumeral joint, to the pectoral girdle. Dynamic muscle action accounts for transmission of a large part of the force; a smaller proportion is transmitted through the osseoligamentous structures. The distribution of force between the radius and ulna varies dynamically and depends on the absolute value of load, degree of forearm rotation and position of the carpus relative to the forearm.

## Hammer action

The action exemplified by hammering, where the wrist alternates between the dorsoradial and the palmar-ulnar position, is an important movement for a wide variety of activities. It is believed that load distributes dynamically as the position of the carpus moves relative to the forearm and there are consequent changes in the relative position of the carpal bones.

## Carpal instability

The upper limb has evolved to facilitate the placing of the hand in space for prehension. However, mobility of the hand on the forearm has evolved at the expense of stability. A wrist is said to be kinetically unstable when it cannot bear physiological loads without giving way or causing injury. A wrist is kinematically unstable when it exhibits sudden changes in carpal alignment, i.e. during a specific movement, there is a 'clunk' as one or more of the carpal bones moves abnormally with respect to the others. Stability of the various joints, so that the bones maintain normal anatomical relations with respect to each other throughout the normal range of motion, is essential for physiological load-bearing.

## CARPOMETACARPAL JOINTS

The first carpometacarpal joint (CMCJ), or basal joint of the thumb, is a saddle joint that permits opposition of the thumb. The second to fifth carpometacarpal joints exhibit an increasing range of movement, progressing from the radial to the ulnar side. Thus, there is little mobility at the base of the index ray but considerable mobility at the base of the small finger ray, which facilitates 'cupping' of the palm of the hand. Compressive forces between the metacarpals and the distal carpal row are estimated to be upwards of ten times the forces at the tips of the fingers during 'pinch' or 'chuck' grip.

## Carpometacarpal joint of the thumb

Articulating surfaces The carpometacarpal joint of the thumb is a sellar (saddle) joint between the first metacarpal base and trapezium. Its extensive articular surfaces and their topology ensure that the joint enjoys a wide mobility.

Ligaments The first metacarpal and trapezium are connected by lateral, anterior and posterior ligaments and a fibrous capsule. The broad lateral ligament runs from the lateral surface of the trapezium to the radial side of the metacarpal base. The palmar and dorsal ligaments are oblique bands that converge to the ulnar side of the metacarpal base from the palmar and dorsal surfaces of the trapezium, respectively.

Synovial membrane The synovial membrane lines the joint capsule and is separate from it.

Joint movements Except at initiation, flexion is accompanied by medial rotation, and medial rotation involves flexion. Linkage of movements is due largely to the shape of the articular surfaces and to the obliquity of the dorsal ligament (which, when taut, anchors the ulnar side of the metacarpal base while its radial side continues to move). Contraction of flexor pollicis brevis, assisted by opponens pollicis, produces medial rotation with flexion; combined with abduction, this opposes the thumb pulp to the pulps of the slightly flexed fingers. Full extension of the thumb metacarpal entails slight lateral rotation, attributable to the saddle shape of the joint and to the action of the palmar ligament (which is similar to that of the dorsal ligament in flexion). (For further reading, see Edmunds (2011), Ladd et al (2013).)

Muscles producing movements The muscles producing movements at the carpometacarpal joint of the thumb are as follows.

Flexion Flexion is produced by flexor pollicis brevis and opponens pollicis, aided by flexor pollicis longus when the other joints of the thumb are flexed.

Extension Extension is produced by abductor pollicis longus and extensors pollicis brevis and longus.

Abduction Abduction is produced by abductors pollicis brevis and longus.

## Adduction Adduction is produced by adductor pollicis.

Opposition Opponens pollicis and flexor brevis pollicis simultaneously flex and medially rotate the abducted thumb. Interpulpal pressure, or that generated by digital grasping, is increased by adductor pollicis and flexor pollicis longus.

Circumduction Circumduction is produced by extensors, abductors, flexors and adductors acting consecutively in this, or reverse, order.

## Second to fifth carpometacarpal joints

The second to fifth carpometacarpal joints are synovial ellipsoid joints between the carpus and second to fifth metacarpals. Although widely classed as plane, they have curved articular surfaces that are often of complex saddle shape. The bones are united by articular capsules and by dorsal, palmar and interosseous ligaments.

Ligaments The dorsal ligaments are the strongest, and connect the dorsal surfaces of the carpal and metacarpal bones. The second metacarpal has two ligaments, from the trapezium and trapezoid; the third has two, from the trapezoid and capitate; the fourth has two, from the capitate and hamate; and the fifth has a single band from the hamate, which is continuous with a similar palmar ligament, forming an incomplete capsule.

The palmar ligaments are similar, except that the third metacarpal has three: a lateral from the trapezium, superficial to the tendon sheath of flexor carpi radialis, an intermediate from the capitate, and a medial from the hamate.

The interosseous ligaments consist of two short, thick, fibrous bands. They are limited to one part of the carpometacarpal articulation and connect contiguous distal margins of the capitate and hamate with adjacent surfaces of the third and fourth metacarpal bones; they may be united proximally.

Some degree of carpal instability may occur as part of inherent hypermobility in affected individuals. Usually, it occurs only after rupture or attenuation of intrinsic and extrinsic carpal ligaments and may be detected either clinically or radiologically as malalignment of the carpal bones (Fig. 50.22). In theory, any pattern of traumatic carpal instability is possible. In practice, certain patterns predominate.

When axially loaded, the distal row of the carpus compresses the proximal row, causing the scaphoid to rotate into flexion and pronation. Provided the scapholunate and lunotriquetral ligaments remain intact, the load is transmitted to the lunate and triquetrum. If the midcarpal stabilizers are disrupted, the proximal row of the carpus will be loaded into flexion, producing the characteristic pattern of volar intercalated segment instability (VISI). In the proximal row, the scaphoid exhibits the greatest range of movement, the lunate less and the triquetrum the least. Consequently, the scapholunate and lunotriquetral ligaments tighten as the scaphoid is progressively flexed, thereby increasing the intrinsic stability of the proximal row. If, however, the scapholunate ligaments have been disrupted (scapholunate dissociation), the scaphoid can flex excessively and loading of the lunate and triquetrum by the distal row of the carpus will force them into abnormal extension (dorsal intercalated segment instability, or DISI).

Fig. 50.22 Scapholunate dissociation. A, Anteroposterior view. B, Lateral view. Dissociation between the scaphoid and lunate, as shown here, leads to collapse of the scaphoid into flexion and the lunate into extension (dorsal intercalated segment instability, or DISI), thus removing the inbuilt tension across the proximal row. This causes the gap between the scaphoid and lunate in A.

Synovial membranes The synovial membranes are often continuous with those of the intercarpal joints. Occasionally, the joint between the hamate and fourth and fifth metacarpal bones has a separate synovial cavity, bounded laterally by the medial interosseous ligament and its extensions to the palmar and dorsal parts of the capsule.

Muscles producing movements Slight gliding movements are effected by the long flexor and extensor muscles of the digits.

## INTERMETACARPAL JOINTS

Articulating surfaces The second to fifth metacarpal bases articulate reciprocally by small cartilage-covered facets connected by dorsal, palmar and interosseous ligaments.

Fibrous capsule The intermetacarpal joints have fibrous capsules.
Ligaments The dorsal and palmar ligaments pass transversely from bone to bone. The interosseous ligaments connect contiguous surfaces just distal to their articular facets.

Synovial membranes The synovial membranes are continuous with those of the carpometacarpal articulations.

Movements at the carpometacarpal and intermetacarpal joints Movements at the carpometacarpal and intermetacarpal articulations are limited to slight gliding, sufficient to permit some flexionextension and adjunct rotation; ranges vary in different joints. They are partly accessory movements occurring when the palm is 'cupped', as in grasping an object. The fifth metacarpal is most movable and the second and third are the least mobile. These variations are easily demonstrated by opposing each digit to the thumb over the palmar centre. About two-thirds of the movements are those of the thumb, as described above, but during opposition, the carpometacarpal and metacarpal joints of the little finger become flexed, abducted and laterally rotated, accounting for the remaining third of the movement. The close-packed position probably coincides with carpal extension. A further accessory movement is spiral twisting of the whole metacarpus on the carpus.

Muscles producing movements The flexors and extensors of the second to fifth digits move the carpometacarpal and intermetacarpal joints.

## METACARPOPHALANGEAL JOINTS

The metacarpal heads are adapted to shallow concavities on the phalangeal bases; they are not regularly convex but are partially divided on their palmar aspects and, thus, almost bicondylar.

Fibrous capsule The metacarpophalangeal joints all have fibrous capsules.

Ligaments Each metacarpophalangeal joint has a palmar and two collateral ligaments.

Palmar ligaments The palmar ligaments (volar plates) are unusual. They are thick, dense and fibrocartilaginous, and are sited between, and connected to, the collateral ligaments. They are attached loosely to the metacarpals but firmly to the phalangeal bases. Their palmar aspects are blended with the deep transverse palmar ligaments and are grooved for the flexor tendons, whose fibrous sheaths connect with the sides of the grooves. Their deep surfaces increase articular areas for the metacarpal heads.

Deep transverse metacarpal ligaments The deep transverse metacarpal ligaments are three short, wide, flat bands that connect the palmar ligaments of the second to fifth metacarpophalangeal joints. They are related anteriorly to the lumbricals and digital vessels and nerves, and posteriorly to the interossei. Bands from the digital slips of the central palmar aponeurosis join their palmar surfaces. On both sides of the third and fourth metacarpophalangeal joints, but only the ulnar side of the second and radial side of the fifth joints, transverse bands of the dorsal digital expansions join the deep transverse metacarpal ligaments. The lumbricals and the phalangeal attachments of the dorsal interossei lie anterior to this band; the remaining attachments of the dorsal and palmar interossei are posterior to it (see Fig. 50.29).

Fig. 50.23 The metacarpophalangeal and digital joints of the left third finger: medial aspect.

Collateral ligaments The collateral ligaments are strong, round cords that flank the joints. Each is attached to the posterior tubercle and adjacent pit on the side of its metacarpal head, and each passes distoanteriorly to the side of the anterior aspect of its phalangeal base (Fig. 50.23).

Synovial membrane The metacarpophalangeal joints are lined by a synovial membrane.

Joint movements These include flexion, extension, adduction, abduction, circumduction and limited rotation. Rotation accompanies flexion-extension, e.g. when the finger flexes and rotates to place its tip near the centre of the palm. The range of rotation is frequently increased as a result of the resistance of a grasped object. Active flexion is $90^{\circ}$ or more, whereas extension ranges from $10^{\circ}$ (index) to $30^{\circ}$ (little); both movements are limited mostly by antagonistic muscles. The metacarpophalangeal joint of the thumb has a flexion-extension range of approximately $60^{\circ}$, which is almost entirely flexion. Slight lateral rotation accompanies digital flexion of digits 3-5. Flexion of the index finger may be accompanied by minimal lateral rotation or no rotation; a small degree of medial rotation is frequently observed. Other movements are adduction-abduction (maximal range $25^{\circ}$ ), which invariably accompanies the corresponding carpometacarpal movements and increases their combined range; and slight rotation, which accompanies flexionextension. Of the second to fifth metacarpophalangeal joints, the second is most mobile in adduction-abduction (approximately $30^{\circ}$ ), followed by the fifth, fourth and third.

Accessory movements Accessory movements are further rotation (most marked in the thumb), anteroposterior and lateral translation of a phalanx or metacarpal, and distraction.

Muscles producing movements The muscles producing movements at the metacarpophalangeal joints are as follows.

Flexion Flexion is produced by flexors digitorum superficialis and profundus, assisted by the lumbricals, interossei and flexor digiti minimi brevis (in the little finger). In the thumb, flexors pollicis longus and brevis, and the first palmar interosseous, are involved.

Extension Extension is produced by extensor digitorum, assisted in the second and fifth digits by extensor indicis and extensor digiti minimi, respectively. In the thumb, extensors pollicis longus and brevis are involved.

Adduction In extended fingers, adduction is produced by the palmar interossei; the long flexors are predominant during flexion. In the
thumb, limited metacarpophalangeal adduction is possible and may be attributable to adductor pollicis and the first palmar interosseous.

Abduction In extended fingers, abduction is produced by the dorsal interossei, assisted by the long extensors (except in the middle finger), and abductor digiti minimi in the minimus. In the thumb, abductor pollicis brevis (which also contributes to opposition) is involved. When the fingers are flexed at the interphalangeal joints, active abduction is restricted (it is virtually zero when metacarpophalangeal and interphalangeal joints are flexed); if the long digital flexors are inactive, passive abduction is free. Inability to abduct actively in this position may be due to shortening of the dorsal interossei and abductor digiti minimi by flexion, but the altered line of pull of the interossei relative to the axis of movement is probably the determining factor.

## INTERPHALANGEAL JOINTS

The interphalangeal joints are uniaxial hinge joints (see Fig. 50.23).
Fibrous capsule Each interphalangeal joint has a fibrous capsule.
Ligaments Each interphalangeal joint has a palmar ligament (the volar plate) and two collateral ligaments (Fig. 50.24). The long extensor tendons take the place of the dorsal capsular ligaments. Extensions from the extensor expansion, each collateral ligament and the palmar ligament all pass into the joint cavity and provide a significant increase to the articular surface area of the phalangeal base; their deformable nature improves joint congruence.

Palmar ligament (volar plate) The volar plate constitutes the floor of the interphalangeal joint. In the proximal interphalangeal joint, the distal end of the volar plate is thickened laterally where it is firmly attached to the base of the middle phalanx at the position of the true collateral ligament attachment. Centrally, it is more delicate and blends with the volar periosteum of the middle phalanx. Proximally, the volar plate is also very delicate in its central portion, but it is thickened laterally to form the 'check rein ligaments', which attach to the periosteum of the proximal phalanx just within the walls of the A2 pulley component of the fibrous flexor sheath. Nutrient branches of the digital

Fig. 50.24 Anatomy of the volar plate at a proximal interphalangeal joint. The blood vessel supplying the flexor tendons via the vincula brevum is shown; the mesentery forming the vinculum has been omitted.
arteries pass underneath these check ligaments to reach the vinculae (see Fig. 50.24).

Collateral ligaments The collateral ligaments pass from the lateral aspect of the head of one phalanx to the volar aspect of the base of the adjacent phalanx. An accessory component to the collateral ligament arises in continuity with the main ligament and passes in a volar direction to attach to the volar plate.

Synovial membrane Each interphalangeal joint has a synovial lining.

Factors maintaining stability Stability is conferred by the articular contours of the joint surfaces and the collateral ligaments. The flexor and extensor tendons and retinacular ligaments provide secondary stabilization. Stability against hyperextension of the proximal interphalangeal joint is enhanced by the three-dimensional box arrangement that is produced by the collateral ligament-volar plate complex.

Joint movements Active movements at the interphalangeal joints are flexion and extension, and are greater in range at the proximal joints. Flexion is considerable, whereas extension is limited by tension of the digital flexors and terminated by tension in the palmar ligaments and non-articular compression. Full extension is the close-packed position. Flexion and extension are accompanied by slight rotation; during flexion, this turns the digital pulps slightly laterally, i.e. to face the opposed thumb, and an opposite rotation occurs during extension.

Accessory movements Accessory movements are limited rotation, abduction, adduction and anteroposterior translation. They permit the fingers to adapt to the shapes of gripped objects and help to protect against stresses and strains.

Muscles producing movements The muscles producing movements at the interphalangeal joints are as follows.

Flexion Flexion is produced at the proximal interphalangeal joints by the flexors digitorum superficialis and profundus; at distal interphalangeal joints, by flexor digitorum profundus; and at the thumb interphalangeal joint, by flexor pollicis longus.

Extension Extension is produced by extensors digitorum, digiti minimi and pollicis longus, in association with abductor pollicis longus and extensor pollicis brevis. Extension occurs simultaneously in both joints in digits 2-5.

Simultaneous flexion at the metacarpophalangeal joints and extension at the interphalangeal joints of a digit are essential for the fine movements of writing, drawing, threading a needle, etc. The lumbricals and interossei are primary agents in flexing the metacarpophalangeal joints and also in extending the interphalangeal joints via their attachments to the dorsal digital expansions.

## VASCULAR SUPPLY OF THE JOINTS OF THE WRIST AND HAND

The radiocarpal joint is supplied by branches of the anterior interosseous artery, anterior and posterior carpal branches of the radial and ulnar arteries, palmar and dorsal metacarpal arteries, and recurrent rami of the deep palmar arch. The carpal joints are supplied by the posterior carpal branches of the radial and ulnar arteries, and by the anterior interosseous artery. The carpometacarpal joint of the thumb receives its blood supply from the radial artery and its first dorsal metacarpal branch. The second to fifth carpometacarpal joints are supplied by the posterior carpal branches of the radial and ulnar arteries, by twigs from

The ulnar collateral ligament of the metacarpophalangeal joint of the thumb may be avulsed from its distal attachment to the base of the proximal phalanx by a combination of forced extension and radial deviation of the joint. The injury was reported to occur in gamekeepers while breaking the necks of game, but can occur following simple falls on to the outstretched hand, especially in skiers who have the straps of ski poles wrapped around their thumbs.

The ulnar collateral ligament is normally covered by the aponeurotic insertion of the tendon of adductor pollicis. Following avulsion, the proximal end can become superficially displaced around the proximal free edge of the aponeurotic insertion of the adductor. This soft tissue interposition prevents the ends of the avulsed ligament from healing. If left untreated, a firm, palpable, inflammatory swelling occurs. Surgical repair requires division of the aponeurotic insertion of adductor pollicis, followed by bony reattachment of the avulsed ligament and repair of the aponeurosis.

The comparable injury to the radial collateral ligament is less common and constitutes only $10-42 \%$ of collateral ligament injuries (Edelstein et al 2008). It is caused by sudden, forced adduction of the metacarpophalangeal joint as the result of a fall or during ball games. The ligament may be ruptured in its mid-substance or avulsed from either bony attachment. Early identification is essential because the proximal phalanx of the thumb will subluxate ulnarwards and may rotate, leading to degeneration of the articular surface. Interposition of the torn or avulsed portion is uncommon because the adductor aponeurosis lies over the radial collateral ligament.

Mallet finger is a traumatic rupture, avulsion fracture or laceration of the terminal slip of the extensor tendon to the terminal phalanx of the finger that can result from forced flexion of the distal phalanx of the fully extended finger; it is a well-known injury in cricketers. The patient is unable to extend the terminal phalanx actively, although the distal interphalangeal joint can be extended passively.

Swan neck deformity involves hyperextension of the proximal interphalangeal joint, together with distal interphalangeal joint flexion, caused by relative overactivity of the extensors acting at the proximal interphalangeal joint compared with the flexors. It arises as a result of intrinsic muscle spasm, long-standing mallet finger or dysfunction of flexor digitorum superficialis; it can only occur if there is also some laxity of the volar plate.

Boutonnière deformity is a flexion deformity of the proximal interphalangeal joint following either division or laxity in the central slip of the extensor tendon (which normally inserts into the base of the middle phalanx). An essential feature is hyperextension at the distal interphalangeal joint. The deformity usually occurs as a result of either trauma or rheumatoid arthritis, causing the lateral bands of the extensor tendon to migrate in a volar direction and the head of the proximal phalanx to migrate dorsally. Initially, the deformity is passively correctable, but, with time, the soft tissues around the joint contract and a fixed deformity results.
the anterior interosseous artery, and from the palmar digital arteries The metacarpophalangeal joints receive their blood supply from the dorsal and palmar metacarpal arteries, the arteria princeps pollicis, and the arteria radialis indicis. The interphalangeal joints are supplied by branches from the palmar digital arteries.

## INNERVATION OF THE JOINTS OF THE WRIST AND HAND

The radiocarpal joint is innervated by the anterior and posterior interosseous nerves, with contributions from the median, ulnar and radial nerves. The anterior interosseous nerve and posterior interosseous nerve innervate the central two-thirds of the anterior and posterior wrist joint capsule, including the radiocarpal joint. These appear to be pure afferent nerve fibres with mechanoreceptor endings, of which there are an average of 10 in each dorsal radiocarpal ligament (Tomita et al 2007). In the palmar radiocarpal ligaments, however, Golgi organs, Pacinian corpuscles, Ruffini endings and free nerve endings are found (Petrie et al 1997). An uneven distribution of these throughout the ligaments would suggest specific functional adaptation but the precise nature of this is unclear. The carpometacarpal joint of the thumb is innervated by articular twigs from the posterior interosseous nerve and the superficial branch of the radial nerve. The second to fifth carpometacarpal joints are innervated by branches of the ulnar nerve, the anterior interosseous, and the superficial radial and dorsal ulnar nerves. The metacarpophalangeal joints are innervated by twigs from the palmar digital branches of the median and ulnar nerve, the deep terminal branch of the ulnar nerve, and the posterior interosseous nerve. The interphalangeal joints are innervated by the palmar digital branches of the median nerve (to the thumb, index, middle and ring fingers), and the ulnar nerve (to the ring and little fingers).

## MUSCLES

## EXTRINSIC LONG FLEXORS AND EXTENSORS

The extrinsic long flexors and extensors are described on pages 848855. The flexor and extensor retinacula are described on pages 863,864 .

## Long flexor tendon apparatus

## Flexor tendon sheaths

The fibrous sheaths of the flexor tendons are specialized parts of the palmar fascia. Each finger has an osseo-aponeurotic tunnel that extends from midpalm to the distal phalanx. The thumb has a tunnel for flexor pollicis longus that extends from the metacarpal to the distal phalanx. The proximal border is, to some extent, a matter of definition because the transverse fibres of the palmar aponeurosis may be considered to be a part of the pulley system. The sheath consists of arcuate fibres that arch anteriorly over bone, tendons (where the sheath is required to be stiff) and the centres of joints (where a bucket-handle of arcuate fibres is a mechanically favourable arrangement). In contrast, where the sheath is required to fold to permit joint flexion, it consists of cruciate fibres. These fibrous sheaths are lined by a thin synovial membrane that provides a sealed lubrication system containing synovial fluid. The synovial membrane extends from the distal phalanx to midpalm in the case of the index, middle and ring fingers, and further proximally in the case of the little finger (Fig. 50.25). The sheaths around the thumb and little finger are continuous with the flexor sheaths in front of the wrist. The parietal synovial membrane is reflected on to the surface of the flexor tendon, forming a visceral synovium.

A standard nomenclature for the anular (A) and cruciform (C) pulleys is used (Doyle and Blythe 1975). The usual pattern is as follows (see Fig. 50.25). The A1 pulley is situated anterior to the palmar cartilaginous plate of the metacarpophalangeal joint and may extend over the proximal part of the proximal phalanx. The A2 overlies the middle third of the proximal phalanx. It is the strongest pulley and arises from well-defined longitudinal ridges on the palmar aspect of the phalanx. Its distal edge is well developed. A pouch or recess of synovium extends superficial to the free edge of the pulley fibres so that the free edge forms a lip protruding into the synovial space. A3 is a narrow pulley lying palmar to the proximal interphalangeal joint. A4 overlies the middle third of the middle phalanx, and A5 overlies the distal interphalangeal joint. The cruciate fibres are numbered in a slightly different manner. C 0 is palmar to the metacarpophalangeal joint. There are two cruciate zones, C1 and C2, at the proximal interphalangeal joint, and they lie
just proximal and distal, respectively, to A3. At the distal interphalangeal joint, there is one pronounced cruciate system, C3, which lies between A4 and A5. Variations occur frequently. During flexion, the cruciate fibres become orientated more transversely in the digits, and the edges of adjacent anular pulleys approximate so that they form, in full flexion, a continuous tunnel of transversely orientated fibres. Surgically, the most important pulleys that prevent bowstringing of the flexor tendons are the A2 and A4 pulleys.

In the thumb, there are three constant pulleys: two anular and one oblique (Fig. 50.26). The A1 pulley is located at the metacarpophalangeal joint. The oblique pulley is located over the mid-portion of the proximal phalanx and its fibres pass from the ulnar aspect proximally to the radial aspect dorsally. The A2 pulley is thinner than the A1 pulley and is situated just proximal to the interphalangeal joint. The oblique pulley is the most important pulley in the thumb for maintaining the action of flexor pollicis longus.

## Synovial sheaths of the carpal flexor tendons

Two synovial sheaths envelop the flexor tendons as they traverse the carpal tunnel: one for flexors digitorum superficialis and profundus, the other for flexor pollicis longus. These sheaths typically extend into the forearm for 2.5 cm proximal to the flexor retinaculum and, occasionally, communicate with each other deep to it. The sheath of the flexors digitorum tendons reaches about halfway along the metacarpal bones, where it ends in blind diverticula around the tendons to the index, middle and ring fingers (see Fig. 50.25). The sheath is prolonged around the tendons to the little finger and is usually continuous with their digital synovial sheath. A transverse section through the carpus shows that the tendons are invaginated into the sheath from the lateral side (Fig. 50.27). The parietal layer lines the flexor retinaculum and the floor of the carpal tunnel, and is reflected laterally as the visceral layer over the tendons of flexor digitorum superficialis ventrally and flexor digitorum profundus dorsally. Medially, a recess formed by the visceral layer of the sheath insinuates between the two groups of tendons and passes laterally for a variable distance. The sheath of flexor pollicis longus, which is usually separate, is continued along the thumb as far as the insertion of the tendon.

## Vincula

The phenomenon of tendon gliding within a fibrous sheath requires a very specialized arrangement of the vascular supply. Folds of synovial membrane containing a loose plexus of fascial fibres carry blood vessels to the tendons at certain defined points. These folds, vincula tendinum (Fig. 50.28), are of two kinds. Vincula brevia, of which there are two in each finger, are attached to the deep surfaces of the tendons near to their insertions. There is, thus, one vinculum brevium attaching flexor digitorum profundus to the region of the distal interphalangeal joint, and a more proximal vinculum deep to flexor digitorum superficialis at the proximal interphalangeal joint. Vincula longa are filiform; usually two are attached to each superficial tendon, one to each deep tendon.

## Trigger finger

## Available with the Gray's Anatomy e-book

## Synovial sheaths of the carpal extensor tendons

Six tunnels deep to the extensor retinaculum transmit the extensor tendons, each containing a synovial sheath. The tendons of abductor pollicis longus and extensor pollicis brevis lie in a tunnel on the lateral side of the styloid process of the radius; there may be a separate synovial sheath for each, or the tendon of the abductor may be double. The tendons of extensors carpi radiales longus and brevis lie behind the styloid process; the tendon of extensor pollicis longus lies on the medial side of the dorsal tubercle of the radius; the tendons of extensors digitorum and indicis lie in a tunnel on the medial side of the tubercle; the tendon of extensor digiti minimi lies opposite the interval between the radius and ulna; and the tendon of extensor carpi ulnaris lies between the head and the styloid process of the ulna. The tendon sheaths of abductor pollicis longus, extensors pollicis brevis and longus, extensors carpi radiales and extensor carpi ulnaris stop immediately proximal to the bases of the metacarpal bones, while those of extensors digitorum, indicis and digiti minimi are sometimes prolonged a little more distally along the metacarpus.

## De Quervain's tenovaginitis

Available with the Gray's Anatomy e-book

Trigger finger is a stenosing tenovaginitis that affects the fibrous flexor sheaths of the fingers or thumb within the palm. The affected sheath thickens and entraps the contained tendons, which become constricted at the site of entrapment and bulge distal to it. This produces a distinct nodule in the palm of the hand and the finger now snaps as the tendon nodule passes through the constriction on flexing the finger. The corresponding extensor muscle is insufficiently powerful to extend the affected finger, so the patient does this passively, accompanied by a painful snap. Treatment frequently requires surgical division of the A1 pulley of the flexor sheath to relieve the stricture.

De Quervain's tenovaginitis is a stenosing tenovaginitis of unknown aetiology that occurs in the first dorsal compartment at the level of the radial styloid. It involves the common extensor sheath containing the tendons of abductor pollicis longus and extensor pollicis brevis. There is palpable thickening of the tendon sheath with painful limitation of extension of the thumb. Treatment frequently requires division of the thickened sheath, care being taken to avoid the adjacent superficial radial nerve; division of the sheath produces no functional impairment.

Fig. 50.25 Synovial sheaths of the tendons and fibrous flexor tendon sheaths on the flexor aspect of the left wrist and hand. The synovial sheaths are shown in blue. A, The lateral aspect, showing the anular and cruciate pulleys of the flexor tendon sheath. B, The palmar aspect, showing the synovial sheaths. Details of the anular and cruciate pulleys are shown on the middle finger; the extension of the digital arteries and nerves to the end of this finger have been omitted for clarity. C, Variation in the arrangement of the synovial sheaths to the digits.

## Extensor tendon apparatus

The extensor digitorum tendons emerge through the fourth dorsal compartment on to the dorsum of the hand, where they are joined together distally by a varying pattern of oblique interconnections, the juncturae tendinae. These typically pass in a distal direction from middle finger to index finger, and from ring finger to middle and little fingers. Proximal lacerations to the middle finger extensor tendon may result in only partial loss of extension because of these tendinous interconnections.

At the level of the metacarpophalangeal joint, each extensor tendon is held in a central position over the dorsum of the joint by a flat, fibrous extensor expansion (Fig. 50.29). The expansion extends on to the dorsum of the proximal phalanx of each digit, forming a movable hood that moves distally when the metacarpophalangeal joint is flexed, and proximally when it is extended. Each extensor tendon blends with the extensor expansion along its central axis and is separated from the metacarpophalangeal joint by a small bursa. The expansion is triangular
in shape, with its base proximal. It receives the conjoined tendons of the interosseous and lumbrical muscles and is almost translucent between its margins and the tendon of extensor digitorum. Transverse fibres (the sagittal bands) pass to the volar plate and transverse metacarpal ligaments, separating the phalangeal attachment of the dorsal interosseous from the rest of the muscle, and the palmar interosseous from the lumbrical muscle. Injuries to the sagittal bands can lead to subluxation of the extensor tendon.

The margins of the extensor expansions are thickened on the radial side by the tendons of the lumbrical and interosseous muscles, and on the ulnar side either by the tendon of an interosseous alone or, in the case of the fifth digit, by abductor digiti minimi.

The tendons of the interossei join the extensor expansion at the level of the proximal portion of the proximal phalanx, while the tendons of the lumbricals join the extensor mechanism further distally at the midportion of the proximal phalanx. Their line of pull is anterior to the axis of rotation at the metacarpophalangeal joint, but dorsal to the axis

Fig. 50.26 The flexor sheath of the left thumb, showing the anular and oblique pulleys. (From Doyle JR, Blythe WF 1977 Anatomy of the flexor tendon sheath and pulleys of the thumb. $J$ Hand Surg 2:149-51. With permission from the American Society for Surgery of the Hand.)

Fig. 50.27 A transverse section through the left wrist at the level of the distal row of the carpus, showing the muscle tendons (in grey) and their synovial sheaths (in green).

Fig. 50.28 The tendons and vincula tendinum of the index finger and the muscles in the first intermetacarpal space of the left hand: lateral aspect.

Fig. 50.29 The extensor mechanism of the finger. A, Dorsal view. B, Lateral view. C, Lateral view in flexion.
of rotation at the proximal interphalangeal joint. The extensor mechanism trifurcates into a central slip and two lateral bands just proximal to the proximal interphalangeal joint. The central slip receives a contribution from the tendons of the lumbricals and interossei via the lateral bands. Similarly, some fibres from the central region pass to each lateral band, producing a criss-cross arrangement of fibres. The central slip attaches to the base of the middle phalanx, while the lateral bands continue distally; they eventually fuse together and insert into the distal phalanx. The tension in the central slip and the lateral bands varies as the finger moves between flexion and extension and plays a crucial role in coordinating synchronous activity between the proximal and distal interphalangeal joints.

The transverse and oblique retinacular ligaments of Landsmeer connect the fibrous flexor sheath to the extensor apparatus. The transverse retinacular ligament passes from the A3 pulley of the fibrous flexor sheath at the level of the proximal interphalangeal joint to the lateral border of the lateral extensor band. The oblique retinacular ligament lies deep to the transverse retinacular ligament. It originates from the lateral aspect of the proximal phalanx and flexor sheath (A2 pulley) and passes volar to the axis of rotation of the proximal interphalangeal joint, but in a dorsal and distal direction, to insert into the terminal extensor tendon.

## INTRINSIC MUSCLES OF THE HAND

The intrinsic muscles of the hand are organized into three groups plus a superficial muscle. The thenar muscles include flexor pollicis brevis, abductor pollicis brevis, opponens pollicis and adductor pollicis. The hypothenar muscles include abductor digiti minimi, flexor digiti minimi brevis and opponens digiti minimi. The interossei and lumbricals act on the fingers. Palmaris brevis is a superficial muscle that lies beneath the ulnar palmar skin.

## Flexor pollicis brevis

Attachments Flexor pollicis brevis lies medial to abductor pollicis brevis (Fig. 50.30). It has superficial and deep parts. The superficial head arises from the distal border of the flexor retinaculum and the distal part of the tubercle of the trapezium, and passes along the radial side of the tendon of flexor pollicis longus. It is attached by a tendon that contains a sesamoid bone to the radial side of the base of the proximal phalanx of the thumb. The deep part arises from the trapezoid and capitate bones and from the palmar ligaments of the distal row of carpal bone, and passes deep to the tendon of flexor pollicis longus. It
unites with the superficial head on the sesamoid bone and base of the first phalanx.

The superficial head is frequently blended with opponens pollicis. The deep head varies considerably in size and may even be absent.

Relations Flexor pollicis brevis lies superficial in the thenar eminence and is distal to abductor pollicis brevis. It is crossed by the motor branch of the median nerve.

Actions Flexor pollicis brevis flexes the metacarpophalangeal joint.
Testing Flexor pollicis brevis is palpated whilst flexing the metacarpophalangeal joint, with the interphalangeal joint fully extended.

## Abductor pollicis brevis

Attachments Abductor pollicis brevis is a thin, subcutaneous muscle in the proximolateral part of the thenar eminence (see Figs 50.25B, 50.30). It arises mainly from the flexor retinaculum, but a few fibres spring from the tubercles of the scaphoid bone and trapezium and from the tendon of abductor pollicis longus. Its medial fibres are attached by a thin, flat tendon to the radial side of the base of the proximal phalanx of the thumb, and its lateral fibres join the dorsal digital expansion of the thumb. The muscle may receive accessory slips from the long and short extensors of the thumb, opponens pollicis, or the styloid process of the radius.

Relations Abductor pollicis brevis lies proximomedial to flexor pollicis brevis in the superficial part of the thenar eminence.

Actions Abductor pollicis brevis draws the thumb ventrally in a plane at right angles to the palm of the hand (abduction).

Testing The patient abducts the thumb at right angles to the palm against resistance; the muscle can be seen and felt.

## Opponens pollicis

Attachments Opponens pollicis lies deep to abductor pollicis brevis (see Fig. 50.30). It arises from the tubercle of the trapezium and the flexor retinaculum, and is attached to the whole length of the lateral border, and the adjoining lateral half of the palmar surface of the metacarpal bone of the thumb.

Relations Opponens pollicis lies deep between the other two muscles of the thenar eminence and is revealed only when they are retracted.

Fig. 50.30 The muscles of the left hand. The deep layer is shown after cutting the flexor retinaculum and partial removal of several superficial muscles: palmar aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Actions Opponens pollicis flexes the metacarpal bone of the thumb.

Testing The patient touches the base of the little finger against resistance.

## Adductor pollicis

Attachments Adductor pollicis arises by oblique and transverse heads (see Figs $50.26,50.28,50.30$ ). The oblique head is attached to the capitate bone, the bases of the second and third metacarpal bones, the palmar ligaments of the carpus, and the sheath of the tendon of flexor carpi radialis. Most of the fibres converge into a tendon (containing a sesamoid bone) that unites with the tendon of the transverse head and is attached to the ulnar side of the base of the proximal phalanx of the thumb. The deepest fibres may pass into the medial side of the dorsal digital expansion of the thumb. On the lateral side of the oblique head, a considerable fasciculus, described as the 'deep head' of flexor pollicis brevis, passes deep to the tendon of flexor pollicis longus to join flexor pollicis brevis. The transverse head is the deepest of the muscles of the thumb; it is triangular and arises from the distal twothirds of the palmar surface of the third metacarpal. The fibres converge to be attached, with the oblique head and the first palmar interosseous, to the base of the proximal phalanx of the thumb. The two parts of the adductor vary in relative size and degree of connection.

Relations The deep palmar arch and the deep branch of the ulnar nerve pass between the two heads of the muscle. Anteriorly, adductor pollicis is crossed by the flexor tendons of the index finger and their sheath, and the first lumbrical, and is overlapped by flexor pollicis brevis. Posteriorly, it abuts against the first dorsal interosseous muscle; together, these muscles form the mass of the first web space of the hand.

Actions Adductor pollicis is the largest and most powerful of the intrinsic muscles and acts to approximate the thumb to the palm of the hand. It acts optimally when the abducted, rotated and flexed thumb is opposed to the fingers in gripping.

Testing The patient adducts the thumb at right angles to the palm against resistance.

## Abductor digiti minimi

Attachments Abductor digiti minimi arises from the pisiform bone, the tendon of flexor carpi ulnaris and the pisohamate ligament (see Figs $50.25 B, 50.30$ ). It ends in a flat tendon that divides into two slips: one is attached to the ulnar side of the base of the proximal phalanx of the little finger, and the other to the ulnar border of the dorsal digital expansion of extensor digiti minimi. The muscle may have two or three slips and may be fused with flexor digiti minimi brevis. An additional slip may arise from the flexor retinaculum, antebrachial fascia, or tendons
of palmaris longus or flexor carpi ulnaris, and may be partly attached to the fifth metacarpal by a slip from the pisiform.

Relations Abductor digiti minimi lies along the ulnar border of flexor digiti minimi brevis and overlies opponens digiti minimi.

Actions Abductor digiti minimi abducts the little finger away from the fourth, e.g. in the habitual spreading of the digits when they are extended. Abduction is also possible when digits 2-4 are tightly adducted in flexion or extension.

## Testing The little finger is abducted against resistance.

## Flexor digiti minimi brevis

Attachments Flexor digiti minimi brevis arises from the convex surface of the hook of the hamate and the palmar surface of the flexor retinaculum, and inserts into the ulnar side of the base of the proximal phalanx of the little finger with abductor digiti minimi (see Fig. 50.30) It may be absent, or fused with the abductor, and it may attach to the distal end of the fifth metacarpal by a muscular slip.

Relations Flexor digiti minimi brevis lies lateral to the abductor. Its origin is separated from that of the abductor by the deep branches of the ulnar artery and nerve.

Actions Flexor digiti minimi brevis produces flexion of the little finger at its metacarpophalangeal joint, together with some lateral rotation.

Testing The subject flexes the metacarpophalangeal joint of the little finger against resistance with the interphalangeal joints in extension.

## Opponens digiti minimi

Attachments Opponens digiti minimi is a triangular muscle lying under cover of the flexor and abductor (see Fig. 50.30). It arises from the convexity of the hook of the hamate and the contiguous portion of the flexor retinaculum, and inserts along the whole length of the ulnar margin of the fifth metacarpal bone and the adjacent palmar surface. The muscle is often divided into two lamellae by the deep branches of the ulnar artery and nerve. It blends to a variable degree with its neighbours.

Relations Opponens digiti minimi lies on the ulnar margin and adjacent palmar surface of the fifth metacarpal, overlapped by, and often partly fused with, the other two muscles of the hypothenar eminence.

Actions Opponens digiti minimi flexes the fifth metacarpal bone, drawing it forwards and rotating it laterally at the carpometacarpal joint; this deepens the hollow of the palm. These actions, together with flexion and some lateral rotation at the metacarpophalangeal and interphalangeal joints, bring the digit into opposition with the thumb.

Testing The patient opposes the tip of the little finger to the tip of the thumb with the interphalangeal joints of the little finger in extension.

## Palmaris brevis

Attachments Palmaris brevis is a thin, quadrilateral muscle lying beneath the skin of the ulnar side of the palm (see Fig. 50.7A). It arises from the flexor retinaculum and the medial border of the central part of the palmar aponeurosis and is attached to the dermis on the ulnar border of the hand.

Relations Palmaris brevis is superficial to the ulnar artery and the superficial terminal branch of the ulnar nerve.

Actions Palmaris brevis wrinkles the skin on the ulnar side of the palm of the hand and deepens the hollow of the palm by accentuating the hypothenar eminence.

Testing The patient opposes the thumb to the little finger; the skin on the ulnar side of the palm is seen to pucker.

## Interossei

The interossei occupy the intervals between the metacarpal bones and are divided into a palmar and a dorsal set.

## Palmar interossei

Attachments Palmar interossei are smaller than dorsal interossei and lie on the palmar surfaces of the metacarpal bones rather than between

Fig. 50.31 The palmar interossei of the left hand: palmar aspect. Note that there is no first palmar interosseous in this specimen. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
them (see Fig. 50.30; Fig. 50.31). The middle finger has no palmar interosseous. The remaining digits have palmar interossei on their aspects that face the middle finger. The first arises from the ulnar side of the palmar surface of the base of the first metacarpal bone and is inserted into a sesamoid bone on the ulnar side of the proximal phalanx; from here, it passes to the phalanx and, usually, also into the dorsal digital expansion. It is often rudimentary. The second arises from the ulnar side of the second metacarpal bone and is inserted into the same side of the digital expansion of the index finger. The third arises from the radial side of the fourth metacarpal bone and is inserted together with the third lumbrical. The fourth arises from the radial side of the fifth metacarpal bone and is attached with the fourth lumbrical and to the base of the proximal phalanx. The attachment of these muscles to the dorsal digital expansions (see Fig. 50.29) stabilizes the extensor tendons on the convex heads of the metacarpal bones during flexion and extension at the metacarpophalangeal joints. The interossei show little variation in their arrangement, although they may, occasionally, be duplicated.

Relations The first palmar interosseous lies anterior to the lateral head of the first dorsal interosseous and is overlapped anteriorly by the oblique head of adductor pollicis, which also crosses anterior to the second palmar interosseous. The third and fourth are overlapped by the long flexor tendons of the ring and little finger, respectively, within their flexor sheaths.

Actions Palmar interossei adduct the fingers towards the longitudinal axis of the middle finger. Interossei have a considerable cross-sectional area and, therefore, contribute strongly to metacarpophalangeal joint flexion and interphalangeal extension. When the interossei are paralysed, the grip strength of the hand is reduced and the arc of finger motion is abnormal, with a tendency for the fingers to claw. Each interosseous has a considerable ability to rotate the digit at the metacarpophalangeal joint. Generally, this is not obvious because interossei act in pairs, but it may occur where one interosseous is deficient as a result of injury or congenital deformity.

Testing The patient adducts the index ring and little fingers against resistance.

## Dorsal interossei

Attachments Dorsal interossei consist of four bipennate muscles, each arising from the adjacent sides of two metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle passes (see Figs 50.29-50.30; Fig. 50.32). They insert on the

Fig. 50.32 The dorsal interossei of the left hand: dorsal aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
bases of the proximal phalanges and separately into the dorsal digital expansions. There is a narrow triangular interval between the double origin of each of these muscles; the radial artery passes through the first of these intervals, and a perforating branch from the deep palmar arch passes through each of the others. The first and largest muscle is sometimes called abductor indicis. It is attached to the radial side of the proximal phalanx of the index finger and to the capsule of the adjoining metacarpophalangeal joint. The second and third are attached to the radial and ulnar sides of the middle finger, respectively. Whereas the second generally reaches the digital expansion and the proximal phalanx, the third usually extends only to the digital expansion. The fourth may be wholly attached to the digital expansion, but it often sends an additional slip to the proximal phalanx.

Relations The first dorsal interosseous abuts anteriorly with adductor pollicis. The other dorsal interossei occupy the spaces between the second and the fifth metacarpal bones.

Actions Dorsal interossei abduct the fingers away from the longitudinal axis of the middle finger. See also the description of the actions of the palmar interossei above.

Testing The patient abducts the index, middle and ring fingers against resistance. The first dorsal interosseous is tested with the subject's fingers and palm flat on the table. The subject tries to abduct the index finger against the examiner's resistance. The muscle belly can be felt and seen.

## Lumbricals

Attachments The four small lumbrical muscles arise from the tendons of flexor digitorum profundus (see Figs 50.29-50.30; Fig. 50.33). The first and second arise from the radial sides and palmar surfaces of the tendons of the index and middle fingers, respectively. The third arises from the adjacent sides of the tendons of the middle and ring fingers, and the fourth from the adjoining sides of the tendons of the ring and little fingers. Each passes to the radial side of the cor-

Fig. 50.33 Lumbricals of the left hand: palmar aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
responding finger and is attached to the lateral margin of the dorsal digital expansion of extensor digitorum covering the dorsal surface of the finger. Variations in the attachments of the lumbricals are common. Any of them may be unipennate or bipennate. When they are bipennate, the two heads arise from adjoining tendons of flexor digitorum profundus, and, in the case of the first lumbrical, from the tendon of flexor pollicis longus. Accessory lumbrical slips may be attached to an adjacent tendon of flexor digitorum superficialis.

Actions Lumbricals arise from flexor tendons and insert into the extensor apparatus. Since both attachments are mobile, they have the potential for producing movement at either. The action on the extensor apparatus extends both interphalangeal joints in a coordinated manner. The mode of action at the metacarpophalangeal joints is disputed, but if there is a flexor action, it is very weak. The effect on the flexor digitorum profundus attachment is to pull the tendon distally. The combined action on both origin and insertion is, therefore, to alter the posture of the finger to allow more interphalangeal extension. Pinching the index finger against the thumb without a lumbrical would result in a nail-to-nail contact; the addition of the lumbrical increases the interphalangeal joint extension and results in pulp-topulp pinch. Lumbricals contain many muscle spindles and have a long fibre length; it is, therefore, reasonable to assume that they play a role in proprioception.

Testing Lumbricals cannot be tested in isolation but only as the lumbrical-interosseous muscle complex. The examiner holds the metacarpophalangeal joint of the index finger in hyperextension and the subject is instructed to extend the proximal interphalangeal joint against resistance. This test is repeated on the other fingers.

## Vascular supply to the intrinsic muscles of the hand

Flexor pollicis brevis is supplied by the superficial palmar branch of the radial artery, and branches from the princeps pollicis artery and radialis indicis artery. Abductor pollicis brevis is supplied by the superficial palmar branch of the radial artery and, often, by an independent branch directly from the radial artery lying on the radial aspect of the thumb. Opponens pollicis is supplied by the superficial palmar branch of the radial artery and by branches from the first palmar metacarpal artery (when present), arteria princeps pollicis, arteria radialis indicis and the deep palmar arch. Adductor pollicis is supplied by the arteria princeps pollicis and arteria radialis indicis (sometimes combined as the first palmar metacarpal artery) and by branches from the deep palmar arch. Abductor digiti minimi and flexor digiti minimi brevis are
supplied by the deep palmar branch of the ulnar artery and branches from the ulnar end of the superficial palmar arch; the medial border of the little finger is supplied by the palmar digital artery. Opponens digiti minimi is supplied by the deep palmar branch of the ulnar artery and branches from the medial end of the deep palmar arch. Palmaris brevis is supplied by branches from the ulnar end of the superficial palmar arch. The palmar interossei are supplied by branches from the deep palmar arch, arteria princeps pollicis, arteria radialis indicis, palmar metacarpal arteries, proximal and distal perforating arteries, and common and proper digital (palmar) arteries. The dorsal interossei are supplied by the dorsal metacarpal arteries (first to fourth), palmar metacarpal arteries (second to fourth), radial artery (first), arteria princeps pollicis, arteria radialis indicis, three perforating branches from the deep palmar arch (proximal perforating arteries) and three distal perforating branches. Their tendons are supplied by branches from the common and proper palmar digital arteries and the dorsal digital arteries.

The first and second lumbricals are supplied by the first and second dorsal metacarpal and dorsal digital arteries. The third and fourth lumbricals are supplied by the second and third common palmar digital arteries, and the third and fourth dorsal digital arteries and their anastomoses with the palmar digital arteries.

## Innervation of the intrinsic muscles of the hand

The superficial head of flexor pollicis brevis is usually innervated by the recurrent motor branch of the median nerve, and the deep head is usually innervated by the deep branch of the ulnar nerve; variation is common. Abductor pollicis brevis is innervated by the recurrent motor branch of the median nerve and is the only thenar muscle that is constantly supplied by the median nerve. Opponens pollicis is innervated by the lateral terminal branch of the median nerve and, commonly, by a branch of the deep terminal branch of the ulnar nerve. Adductor pollicis, abductor digiti minimi, flexor digiti minimi brevis, opponens digiti minimi and all the interossei are innervated by the deep branch of the ulnar nerve; the first dorsal interosseous and adductor pollicis are supplied by its most distal portion. Palmaris brevis is innervated by the superficial branch of the ulnar nerve. The first and second lumbricals are innervated by the median nerve, and the third and fourth lumbricals by the deep terminal branch of the ulnar nerve. The third lumbrical frequently receives a supply from the median nerve. The first and second lumbricals are, occasionally, innervated by the deep terminal branch of the ulnar nerve.

## MOVEMENTS OF THE HAND

The apparently simple human functions of closing the hand to grasp an object, or opening the palm to release it, are, in reality, tasks of considerable mechanical complexity, requiring the simultaneous contraction of many individual muscles. The isolated action of a single muscle may be inferred from the positions of its origin and insertion, and the estimated line of action (usually, the centre line of the muscle) in relation to the axes of all the joints traversed by the muscle and its tendon. The limb can be regarded as a chain of joints crossed by muscles. If it is known which muscles are active, then the reason why one joint moves and others do not is a matter of simple mechanical relationships. For example, flexor pollicis longus is considered to have a major role as a flexor of the interphalangeal joint of the thumb However, the position of its tendon relative to more proximal joints in the limb gives it the potential for producing flexion at the metacarpophalangeal joint and also at the trapeziometacarpal and wrist joints. In the living subject, the actual motion that takes place depends on which other muscle groups are acting, and so the potential for movement must be considered for each joint in the chain in turn. Motion at the wrist is generally balanced by wrist extensors. Motion at the trapeziometacarpal joint is balanced by abductor pollicis longus. Flexor pollicis longus will then have an action as a flexor of the metacarpophalangeal and interphalangeal joints only.

The factor that determines whether one or both of two joints will move is the turning moment at each. The greater the perpendicular distance from the line of muscle or tendon pull to the axis of the joint, the stronger is the turning effect of the muscle at the joint, but the smaller the range of joint motion that can be produced. In the case of flexor pollicis longus, the tendon is situated further from the axis of the metacarpophalangeal joint than from the axis of the interphalangeal joint; it will, therefore, tend to produce flexion preferentially at the metacarpophalangeal joint, unless that joint is restrained by extensor
pollicis brevis. In this way, different postures of the thumb can be produced by the interplay of flexor and extensor forces. These simple guiding principles should provide an understanding of muscle action in the hand that is sufficient for most purposes.

In considering the role of a particular muscle, there is a tendency to concentrate on motion. Indeed, many muscles are named on the basis of the movements that they generate, although others, often those whose actions are the most difficult to interpret, are described according to their morphology or situation. A more important function may be the nature of the force generated. For example, although flexor pollicis longus flexes the thumb (see above), a large range of flexion is actually required in only a few activities, such as certain ripping tasks. In most pinch and manipulative tasks, the role of the thumb is to apply isometric force, which it does with such precision that it is possible to pick up an egg and neither crush nor drop it. Thus, for much of the time, flexor pollicis longus behaves as an extremely sophisticated mechanism for the application of force, in which contraction and proprioception are equally important.

The anatomical position of the hand (palm flat and pointing anteriorly, forearm supinated) is a convenient standard for studying structural relationships. The hand in the relaxed (anaesthetized) position adopts a posture of partial flexion and mid-supination/pronation (the reader can verify this by relaxing completely and observing forearm and hand position).

## Movements of the thumb

The thumb does not easily assume the classical anatomical position. Therefore, the normal descriptive anatomical terms, i.e. anterior, posterior, medial and lateral, do not readily apply. The terms 'palmar', 'dorsal', 'ulnar' and 'radial' have been adopted in clinical practice.

An opposable thumb requires a different system of control from the other digits. Since the metacarpal is much more mobile than in the digits, muscles are needed to control the extra freedom of movement. The basic active movements are flexion-extension, abductionadduction, rotation and circumduction. In the resting position of the first metacarpal, flexion and extension are parallel with the palmar plane, and abduction and adduction occur at right angles to this.

Flexion and extension should be confined to motion at the interphalangeal or metacarpophalangeal joints (see Video 50.1). Palmar abduction (see Video 50.1), in which the first metacarpal moves away from the second at right angles to the plane of the palm, and radial abduction (see Video 50.1), in which the first metacarpal moves away from the second with the thumb in the plane of the palm, occur at the carpometacarpal joint. The opposite of radial abduction is ulnar adduction, or transpalmar adduction, in which the thumb crosses the palm towards its ulnar border. In clinical practice, the term adduction is generally used without qualification. Circumduction describes the angular motion of the first metacarpal, solely at the carpometacarpal joint, from a position of maximal radial abduction in the plane of the palm towards the ulnar border of the hand, maintaining the widest possible angle between the first and second metacarpals (see Video

It is clear that the fingers and palm of the hand flex in gripping, grasping or making a fist, but there are subtle differences in hand posture in these various activities. The basic mechanisms of hand closure will be described before special grips are considered.

As the digits flex, the wrist usually extends (dorsiflexes) at the same time. The involvement of the long digital flexors in this movement will be considered first, followed by an analysis of the role of the wrist.

Flexor digitorum superficialis acts principally to flex the proximal interphalangeal joints, through its insertions into the middle phalanges. However, in each digit, it also has an action on the metacarpophalangeal joint because the tendon passes anterior to that joint. The muscle has the potential to produce flexion at the wrist for the same reason. The fact that each tendon arises from an individual muscle slip allows the clinician to test one finger at a time. The reader can verify this by attempting to flex each digit individually while using the other hand to keep the distal interphalangeal joints of the remaining fingers in extension. This test is frequently used in clinical practice and is useful for the middle and ring fingers, where flexion of one finger alone must be attributed to flexor digitorum superficialis. The index finger, however, has its own profundus musculotendinous unit and may, therefore, move independently under the action of this tendon. Many individuals cannot flex the proximal interphalangeal joint of the little finger alone, usually because of linkage between the tendons of the ring and little finger flexor digitorum superficialis, but occasionally because superficialis is deficient. Most individuals can flex the metacarpophalangeal joint of the little finger using flexor digiti minimi.

Flexor digitorum profundus is the only flexor of the distal interphalangeal joint. It also contributes, together with superficialis, to flexion at the proximal interphalangeal and metacarpophalangeal joints. These two long flexors (sometimes called extrinsic flexors because the muscle bellies are outside the hand) can be considered to act together to flex the finger. However, their action alone would wind up the interphalangeal before the metacarpophalangeal joints and the finger would not move in a normal arc of flexion. This is precisely what happens in an ulnar nerve paralysis, in which the interossei and lumbricals are not functioning. These small (intrinsic) muscles have been described earlier in terms of their individual actions. For their role in coordinated activity, it is sufficient to appreciate that their contribution changes the arc produced by the long flexors, increasing flexion at the metacarpophalangeal joint and reducing flexion at the proximal interphalangeal joint. All three joints are then angulated to the same degree and the fingers form a normal arc of flexion. As the finger flexes, the long extensor tendons (extensor digitorum, extensor indicis and extensor digiti minimi) aid the process by relaxing and allowing the extensor apparatus to glide distally on the dorsum of the phalanges.

As the fingers wind up to make a fist, the wrist tends to extend, particularly when force is applied. This extension has a marked effect on the excursion of the long flexor tendons. On its own, digital flexion would require the long tendons to move proximally in their sheaths and the flexor muscles in the forearm would shorten. Extension of the wrist tends to produce a lengthening of the same muscles, which, in normal use, is almost enough to balance the shortening due to finger flexion; the net effect is a very slight shortening (approximately 1 cm ) of the long flexors in the forearm. The wrist can, therefore, be seen as a mechanism for maximizing force because it allows the fingers to flex while maintaining the resting length of the extrinsic muscles near to the peak of the force-length curve. It is, of course, possible to wind up the fingers with the wrist held in a neutral position but the grip is somewhat weaker. With the wrist in full flexion, it is not possible to flex the fingers fully.

Flexion of the fingers on gripping tends to result in a distal excursion of the long extensors. However, this tendency is counteracted by dorsiflexion of the wrist. The net effect is a very small proximal excursion of the long extensor tendons on gripping, mirroring the effect on the flexor surface. If the movement of the wrist is exaggerated so that the wrist is a little flexed on opening the hand, and fully dorsiflexed on closing it, the net excursion of long flexors and extensors is zero, i.e. this whole movement sequence can be completed with the forearm flexor and extensor muscles contracting isometrically.

The reader can observe the relationship between digits and wrist by performing the following manœuvre. The wrist is held in a relaxed, mid-supinated position, with the elbow flexed at $90^{\circ}$. If the forearm is now rotated into pronation, the wrist will fall into flexion and the fingers will automatically extend. If the forearm is rotated into supination, the wrist will extend and the fingers flex. The finger movements compensate for the wrist movements and are entirely automatic; they are made without the need for any excursion of forearm flexor or extensor tendons. This test, the wrist tenodesis test, is a useful way of examining the limb for tendon injury. The pointing finger (which does not move with wrist motion) 'points to' a tendon injury.

Wrist motion is controlled principally by two wrist flexors (flexor carpi radialis and flexor carpi ulnaris) and three extensors (extensors carpi radialis longus and brevis, and extensor carpi ulnaris). Although the radiocarpal joint has some functional similarity to a ball and socket joint, it is possible to think of the wrist as a variable hinge joint, the axis of which may be set in a number of inclinations. For example, in using a hammer, it is useful to rotate the wrist backwards and forwards about an axis that permits not only wrist flexion but also ulnar deviation. It would be very restricting to have a pure hinge joint with collateral ligaments of fixed length. In this context, the wrist flexors and extensors may be regarded as variable collateral ligaments that allow the joint to be set about a number of different axes.

It is possible to observe and to palpate the muscle groups that are active in making a tight fist. Flexor digitorum profundus and flexor digitorum superficialis are active, and flexor carpi ulnaris contracts strongly, as do the wrist extensors. Palpation of the long digital extensors on the dorsum of the wrist, the first dorsal interosseous in the thumb web, and of the other interossei and the thenar and hypothenar muscles, will confirm that all these muscles are contracting. As a firm fist is swung forwards in anger, brachioradialis stands out; at the moment of impact, virtually every muscle in the limb is active.

The hand is opened from its relaxed balanced posture, e.g. when stretching out to reach an object. This motion is made up of extension of the distal interphalangeal, proximal interphalangeal and metacarpophalangeal joints. The hand is provided with an ingenious mechanism that allows this to happen. The laws of mechanics would suggest that one motor would be required for every joint in a chain, together with some sort of controlling mechanism to ensure that the chain of joints moved together in a coordinated fashion. In the hand, this is achieved through an extensor apparatus that minimizes the number of motors required for movement by allowing the muscles to act on more than one joint, and by linking different levels in the mechanism so that the arc of motion is controlled.

The tendons of extensor digitorum run distally over the metacarpal heads, forming the major component of the extensor apparatus. Extensor digitorum has no insertion into the proximal phalanx and, therefore, exerts its extensor action on the metacarpophalangeal joint indirectly through more distal insertions. The first point of insertion is at the base of the middle phalanx ('central slip', in clinical practice). Acting at this insertion alone, extensor digitorum can extend both metacarpophalangeal and proximal interphalangeal joints together. The interossei are also active in hand opening, since they will tend to increase extension of the proximal interphalangeal joint. There is, therefore, a range of possibilities. At one extreme, with no contribution from the interossei, the long extensor will exert all of its action at the metacarpophalangeal joint; this leads to full extension, and even hyperextension, while the proximal interphalangeal joint remains flexed (the typical 'intrinsic minus', or claw hand, of ulnar nerve paralysis). At the other extreme, when the intrinsics act strongly together with extensor digitorum, the proximal interphalangeal joint will extend completely while the metacarpophalangeal joint remains flexed ('intrinsic plus' hand). Thus, the hand possesses, in the proximal part of the extensor apparatus, a variable mechanism that allows different amounts of relative metacarpophalangeal or proximal interphalangeal joint motion.

In contrast, the more distal part of the extensor apparatus acts as an automatic or fixed mechanism that determines that the two interphalangeal joints, proximal and distal, will move together. The lateral slips of the extensor apparatus arise from extensor digitorum and pass distally on either side of the central slip and thus over the proximal interphalangeal joint; being further lateral, they are nearer the joint axis because the dorsal surface curves away on each side. A helpful analogy that has been suggested for this arrangement is to consider it as two pulleys of different size on one axle. The central slip can be regarded as a cord that passes over the larger wheel, and each lateral slip as a cord that passes over the smaller wheel. Since these latter pulleys are smaller, there is less longitudinal excursion for a given rotation of the wheel, and this allows some of the excursion to be used for another function, namely: extension at the distal joint. There is an additional mechanism by which the lateral slips move laterally during flexion of the proximal interphalangeal joint. The effect of this lateral movement is to reduce further the distance between the lateral slips and the joint axis, thereby reducing the amount of excursion at the proximal interphalangeal joint still more and allowing more excursion at the distal joint. When the hand flexes, this mechanical linkage system allows both interphalangeal joints to flex together in a coordinated way.

The extensor expansion also receives contributions from the interossei and lumbricals, which approach the digits from the webs and join the corresponding expansion in the proximal segment of the digit. These muscles can, therefore, act on the extensor apparatus at two levels: they can extend the proximal interphalangeal joint through fibres that radiate towards the central slip, and they can act on the distal interphalangeal joint through fibres that join the lateral slip.

Apart from the components of the extensor expansion that are concerned with joint function, the whole structure requires additional anchorage. This must be arranged in such a way that it is not displaced from the underlying skeleton, yet it must not restrict longitudinal movement. These difficult requirements are met by transverse retinacular ligaments at the level of the joints, the transverse ligaments running to relatively fixed attachment points in the region of the joint axis. As the expansion glides backwards and forwards, the transverse fibres move like bucket handles. Smooth gliding layers are required under the expansion and retinacular ligaments to allow motion to occur without friction.
50.1). Lateral inclinations of the first phalanx maximize the extent of excursion of the circumduction arc. Opposition is a composite position of the thumb achieved by circumduction of the first metacarpal, internal rotation of the thumb ray, and maximal extension of the metacarpophalangeal and interphalangeal joints (see Video 50.1). Retroposition is the opposite to opposition (see Video 50.1). Flexion and adduction is the position of maximal transpalmar adduction of the first metacarpal; the metacarpophalangeal and interphalangeal joints are flexed and the thumb is in contact with the palm (see Video 50.1).

Rotary movements occur during circumduction. The simple angular movements described above combine with rotation about the long axis of the metacarpal shaft. In opposition, the shaft must rotate medially into pronation. In retroposition, the thumb must rotate laterally into supination. Axial rotation of the thumb metacarpal is produced by muscle activity (which moves the thumb through its arc of circumduction); the geometry of the articular surfaces of the trapeziometacarpal joint; and tensile forces in the ligaments (which combine with forces exerted by the muscles of opposition and retroposition to produce axial rotation). The stability of the first metacarpal is greatest after complete pronation in the position of full opposition, when the tension in the ligaments, muscular contraction and joint congruence combine to maximal effect.

## Position of rest

The hand has a well-recognized position of rest, with the wrist in extension and the digits in some degree of flexion. The precise position of the thumb in the position of rest appears to be rather variable. Typically, it is considered as the midpoint between maximal palmar abduction and maximal retroposition. In this position, the carpometacarpal joint lies within $20^{\circ}$ of radial abduction and $30^{\circ}$ of palmar abduction; from clinical observations, it seems that the metacarpophalangeal joint lies within approximately $40^{\circ}$ of flexion and the interphalangeal joint between extension and $10^{\circ}$ of flexion.

## Grips

From the position of rest, the tip of the thumb can approach the radial aspect of the fingers without incurring axial rotation because the palmar and dorsal trapeziometacarpal ligaments remain relaxed (see below). From different positions of the arc of circumduction, numerous different types of pinch grip are possible (see Video 50.1). In clinical practice, these have been classified into two main types: tip pinch and lateral (or key) pinch. Many forces contribute to these configurations.

The thumb is activated by monoarticular muscles (abductor pollicis longus and opponens pollicis), biarticular muscles (extensor pollicis brevis, adductor pollicis, abductor pollicis brevis and flexor pollicis brevis) and polyarticular muscles (extensor pollicis longus and flexor pollicis longus). It appears, however, that even a monoarticular muscle can change posture in all three joints by altering the overall balance of forces and it is, therefore, very difficult to attribute function to the individual intrinsic muscles. However, the thumb muscles do seem to provide two broad functions. They position the metacarpal, an activity automatically accompanied by rotation, and also control the axial stability of the skeleton of the thumb.

The thumb muscles may be classified into those used for retroposition, opposition and pinch grip.

## Retroposition muscles

The muscles that bring about retroposition are extensor pollicis longus, extensor pollicis brevis and abductor pollicis longus. As the thumb moves into retroposition, automatic axial rotation produces supination of the first metacarpal. This is produced by the off-axis action of two parallel, but oppositely directed, forces: one exerted by extensors pollicis longus and brevis, and the other by abductor pollicis longus and the anterior oblique carpometacarpal ligament.

## Opposition muscles

A succession of activity occurs in the thenar muscles during the movement of opposition. Three subgroups of radial (abductor pollicis longus and extensor pollicis brevis), central (abductor pollicis brevis and opponens pollicis) and ulnar (flexor pollicis brevis) muscles are involved. These forces act simultaneously but with different intensities, depending on the situation of the thumb. As the thumb moves into opposition, there is automatic axial rotation of the first metacarpal shaft to produce pronation. This is produced by the paired action of oppositely directed forces: the opposition muscles provide one force, and the posterior oblique carpometacarpal ligament provides the other.

(A-F, H-K, continued online)

## Pinch grip muscles

The muscles of pinch grip may be divided into lateral, medial and intermediate subgroups. The lateral subgroup (opposition muscles) moves the first metacarpal into palmar abduction. The metacarpal shaft rotates medially into pronation. Radial angulation at the metacarpophalangeal joint increases the span of the hand. The metacarpophalangeal joint is stabilized principally by extensor pollicis brevis and flexor pollicis brevis. Flexion of the proximal and distal phalanges is controlled. Muscles of the medial subgroup (abductor pollicis brevis and first dorsal interosseous) produce an approach of the first metacarpal towards the palm. Since they act with the lateral group, they have a strong controlling effect on the position and rotation of the first metacarpal. The intermediate subgroup consists of flexor pollicis longus, which flexes the interphalangeal or metacarpophalangeal joint. Palpating the thenar eminence during tip and lateral pinch provides some appreciation of the action of the pinch grip muscles.

## The paralysed hand

## VASCULAR SUPPLY

## ARTERIES

Anastomoses occur between the radial and ulnar arteries at the wrist (via the palmar and dorsal carpal arches) and in the hand (via the superficial and deep palmar arches), and between their digital and metacarpal branches (Fig. 50.34; Wong and Higgins 2015).

## Radial artery

At the wrist, the radial artery passes on to the dorsal aspect of the carpus between the lateral carpal ligament and the tendons of abductor pollicis longus and extensor pollicis brevis (Fig. 50.35). It crosses the scaphoid bone and trapezium (in the anatomical snuff-box), where again, its pulsation is obvious; as it passes between the heads of the first dorsal interosseous, it is crossed by the tendon of extensor pollicis longus. Between the thumb extensors, it is crossed by the start of the cephalic vein and the branches of the radial nerve that pass to the thumb and index finger (see Fig. 50.42). Occasionally, it gives off a distal superficial dorsal branch that crosses the radial extensor tendons at the wrist, together with the superficial radial nerve. Branches of the lateral cutaneous nerve of the forearm run along its distal part as it curves round the carpus.

In the hand, the radial artery passes through the first interosseous space between the heads of the first dorsal interosseous and crosses the palm. At first, it lies deep to the oblique head of adductor pollicis and then passes between its oblique and transverse heads or through the transverse head. At the fifth metacarpal base, it anastomoses with the deep branch of the ulnar artery, completing the deep palmar arch (Fig. 50.36).

The wrist and hand may be paralysed by many conditions, the most common of which are spinal cord, brachial plexus and peripheral nerve injury or compression, poliomyelitis, cerebral palsy and leprosy. Each of these will cause different patterns of paralysis and contracture. The main deformities in the cerebral palsied hand are pronation of the forearm, flexion of the wrist and fingers, and flexion-adduction of the thumb. Flexion-adduction deformity of the thumb reflects an imbalance between its intrinsic and extrinsic musculature - principally powered by adductor pollicis, the first dorsal interosseous, flexor pollicis brevis and abductor pollicis brevis - which produces flexion, adduction and lateral rotation of the carpometacarpal joint, flexion and lateral rotation of the metacarpophalangeal joint and flexion of the interphalangeal joint. In an attempt to counteract this, the patient tends to hold the wrist in extreme flexion and ulnar deviation (Matev 1963). In leprosy, the intrinsic muscles of the hand are paralysed. The metacarpophalangeal joints have no primary flexor but retain the powerful extensor digitorum. The interphalangeal joints have no primary extensor and rely on the long flexor to initiate movement. This results in four main disabilities: the fingers cannot be extended fully at the interphalangeal joints; abduction and adduction of the digits are lost; when grasping an object, flexion begins at the terminal joints, closing the fingers on themselves rather than on the palm; and the effective part of the finger becomes the tip and nail rather than the pulp (Brand 1958).

Fig. 50.34 Hand digital subtraction macroangiogram. Predominant phases. A, B arterial phase; C, D, arteriolar phase; E, F capillary phase; H, I venular phase; $\mathrm{J}, \mathrm{K}$ venous phase. A small arterial-venous malformation shown on the index finger is suitable for radiologically guided embolization.

Fig．50．36 The deep palmar arch and its branches．Note that the palmar digital arteries to the thumb have a separate origin from the superficial palmar arch in this specimen（as sometimes occurs）．The arteria princeps pollicis is absent in this specimen．

Palmar carpal branch The palmar carpal branch arises near the distal border of pronator quadratus (see Fig. 49.9B). It crosses the anterior surface of the distal end of the radius, near the palmar carpal surface, and passes medially to anastomose behind the long flexor tendons with the palmar carpal branch of the ulnar artery. This transverse anastomosis is joined by longitudinal branches from the anterior interosseous artery and recurrent branches from the deep palmar arch, forming a cruciate palmar radiocarpal arch that supplies the carpal articulations and bones by descending branches.

Superficial palmar branch The superficial palmar branch arises from the radial artery just before it curves round the carpus. It passes through, and occasionally over, the thenar muscles, which it supplies, and usually anastomoses with the end of the ulnar artery to complete a superficial palmar arch (see Figs 50.35-50.36).

Dorsal carpal branch The dorsal carpal branch arises deep to the tendons of the thumb extensors. It runs medially across the dorsal carpal surface under the tendons and anastomoses with the ulnar dorsal carpal branch, and also with the anterior and posterior interosseous arteries, to form a dorsal radiocarpal arch (see Figs 49.9A, 49.9C). The carpal arches are both close to bone and supply the distal epiphysial parts of the radius and ulna. Three dorsal metacarpal arteries descend from the dorsal intercarpal arch on the second to fourth dorsal interossei, and bifurcate into dorsal digital branches to supply the adjacent sides of all four fingers.

First dorsal metacarpal artery The first dorsal metacarpal artery arises from the radial artery just before it passes between the heads of the first dorsal interosseous. It divides, almost at once, into two branches that supply the adjacent sides of the thumb and index finger as far distally as the proximal interphalangeal joint. The radial side of the thumb receives a branch direct from the radial artery proper. In most cases, the first dorsal metacarpal artery follows a fascial course overlying the first dorsal interosseous and parallel to the second metacarpal bone. Occasionally, it may follow an intramuscular course. Distally, it anastomoses with the dorsal branches of the radiopalmar digital artery of the index finger over the proximal phalanx.

Second, third and fourth dorsal metacarpal arteries The second to fourth dorsal metacarpal arteries arise from the dorsal carpal arch. Near their origins, they anastomose with the deep palmar arch by proximal perforating arteries and, near their bifurcation, with dorsal perforating branches from the palmar metacarpal arteries that pass between the metacarpal necks. They also anastomose distally at the level of the web spaces with dorsal perforating branches from the palmar digital arteries from the superficial palmar arch. The third and fourth dorsal metacarpal arteries are much smaller than the first and second. Cutaneous branches from the dorsal metacarpal arteries supply the dorsal skin as far distally as the proximal interphalangeal joint. At the level of the neck of the second, third and fourth metacarpals, a direct cutaneous branch is given off that passes proximally and supplies an area of skin between the two adjacent metacarpals (Fig. 50.37).

Arteria princeps pollicis The arteria princeps pollicis arises from the radial artery as it turns into the palm to form the deep palmar arch. It descends on the palmar aspect of the first metacarpal under the

Fig. 50.37 Communication between the palmar and dorsal metacarpal arteries and the direct cutaneous branch given off the dorsal metacarpal artery, $0.5-1.0 \mathrm{~cm}$ proximal to the metacarpophalangeal joint: sagittal view.
oblique head of adductor pollicis lateral to the first palmar interosseous. At the base of the proximal phalanx, deep to the tendon of flexor pollicis longus, the artery divides into two branches that appear between the medial and lateral attachments of the oblique head of adductor pollicis and run along both sides of the thumb. On the palmar surface of the distal phalanx, the branches form a pollicial arch that supplies the skin and subcutaneous tissue. The arteria princeps pollicis is the usual nutrient of supply to the first metacarpal bone.

Arteria radialis indicis The arteria radialis indicis is often a proximal branch of the arteria princeps pollicis, or may arise from the superficial arch or from the first dorsal metacarpal artery, or may even combine with the arteria princeps pollicis to form the first palmar metacarpal artery. It descends between the first dorsal interosseous and transverse head of adductor pollicis, and runs along the lateral side of the index finger to its tip (see Fig. 50.35). It anastomoses with the index medial digital artery and with the arteria princeps pollicis and the superficial palmar arch at the distal border of the transverse head of adductor pollicis.

Deep palmar arch The deep palmar arch is formed by anastomosis of the end of the radial artery with the deep palmar branch of the ulnar artery (see Figs 50.36, 50.34G, 49.9B). It crosses the bases of the metacarpal bones and interossei, covered by the oblique head of adductor pollicis, the tendons of the digital flexors and the lumbricals. In its concavity, running laterally, is the deep branch of the ulnar nerve. Rarely, the arch may be incomplete.

Palmar metacarpal artery The three palmar metacarpal arteries run distally from the convexity of the deep palmar arch on the interossei of the second to fourth spaces, and join the common digital branches of the superficial arch at the digital clefts (see Fig. 50.36). They supply nutrient branches to the medial four metacarpals.

Perforating branches Three perforating branches from the deep palmar arch cross the second to fourth interosseous spaces between the heads of the corresponding dorsal interossei and anastomose with the dorsal metacarpal arteries.

Recurrent branches Recurrent branches ascend proximally from the deep palmar arch anterior to the carpus to supply the carpal bones and intercarpal articulations. They end in the palmar carpal arch.

## Ulnar artery

At the wrist, the ulnar artery (see Figs 50.35-50.36) is covered by skin, fasciae and palmaris brevis. It lies between the superficial and main parts of the flexor retinaculum, lateral to the ulnar nerve and pisiform.

Dorsal cutaneous branch A constant dorso-ulnar perforator vessel is given off distally. It arises $2-5 \mathrm{~cm}$ proximal to the pisiform and accompanies the dorsal cutaneous branch of the ulnar nerve. It emerges between flexor carpi ulnaris and extensor carpi ulnaris.

Palmar carpal branch The palmar carpal branch crosses the distal ulna deep to the tendons of flexor digitorum profundus and anastomoses with the palmar carpal branch of the radial artery to make a palmar radiocarpal arch.

Dorsal carpal branch The dorsal carpal branch arises just proximal to the pisiform. It curves deep to the tendon of flexor carpi ulnaris to reach the carpal dorsum, which it crosses laterally beneath the extensor tendons. It anastomoses with the dorsal carpal branch of the radial artery to complete the dorsal carpal arch. Near its origin, it sends a small digital branch along the ulnar side of the fifth metacarpal to supply the medial side of the dorsal surface of the fifth finger.

Deep palmar branch The deep palmar branch is often double. It passes between abductor and flexor digiti minimi, through or deep to opponens digiti minimi, and anastomoses with the radial artery, completing the deep palmar arch. The deep palmar branch accompanies the deep branch of the ulnar nerve.

## Superficial palmar arch

The superficial palmar arch is an anastomosis fed mainly by the ulnar artery (see Figs 50.35-50.36). The latter enters the palm with the ulnar
nerve, anterior to the flexor retinaculum and lateral to the pisiform. It passes medial to the hook of the hamate, then curves laterally to form an arch that is convex distally and level with a transverse line through the distal border of the fully extended base of the thumb. About onethird of superficial palmar arches are formed by the ulnar artery alone, a further third are completed by the superficial palmar branch of the radial artery, and a third by the arteria radialis indicis, or a branch of either arteria princeps pollicis or the median artery. The superficial palmar arch is covered by palmaris brevis and the palmar aponeurosis, and it is superficial to flexor digiti minimi, branches of the median nerve and the tendons of the long flexors and the lumbricals.

Common and proper palmar digital arteries Three common palmar digital arteries arise from the convexity of the superficial palmar arch (see Fig. 50.36). They pass distally on the second to fourth lumbricals, each joined by a corresponding palmar metacarpal artery from the deep palmar arch, and divide into two proper palmar digital arteries. These run along the contiguous sides of all four fingers, dorsal to the digital nerves, between Grayson's and Cleland's ligaments, anastomosing in the subcutaneous tissue of the fingertips and near the interphalangeal joints. Each digital artery has two dorsal branches that anastomose with the dorsal digital arteries and supply the soft parts dorsal to the middle and distal phalanges, including the matrices of the nails. The palmar digital artery for the medial side of the little finger leaves the arch under palmaris brevis. Palmar digital arteries supply the metacarpophalangeal and interphalangeal joints and nutrient rami to the phalanges. They are the main digital supply because the dorsal digital arteries are minute. The origins of the palmar digital arteries of the thumb are quite variable. Both may arise from a single arteria princeps pollicis or they may arise separately from the superficial palmar arch. The ulnar digital artery may arise from the first dorsal metacarpal artery.

The terminal branches of the digital arteries contribute to a number of vascular arcades that provide a rich vascular supply for the distal elements of each digit (see Fig. 50.37; Fig. 50.38). Three distal phalan-

Fig. 50.38 Terminal vascular arcades over the distal phalanx. (With permission from Flint MH 1956 Some observations on the vascular supply of the nail bed and terminal segments of the fingers. BJPS 8:186-95.)
geal dorsal arterial arcades anastomose with each other and with those from the other side of the digit. The superficial arcade occurs at the level of the proximal nail fold and is supplied primarily by a dorsal branch from the palmar digital artery, which is given off at the level of the middle phalanx. The proximal subungual arcade is at the level of the lunula and is supplied by a terminal branch of the digital artery, which passes dorsally. The distal subungual arcade occurs more distally in the nail bed. It is supplied by a dorsal vessel that emerges from the point of confluence of the ' H '-shaped anastomosis between the terminal portions of both digital arteries, and passes from volar to dorsal aspect of the digit under the interosseous ligament connecting the proximal and distal parts of the distal phalanx.

Variations The ulnar and radial arteries to the hand may occasionally be supplemented by a median artery that contributes to, or supplies, the superficial palmar plane and by the anterior interosseous artery, which may make a contribution to the deep palmar plane.

Rodriguez-Niedenführ et al (1999) have confirmed that the median artery may persist in two different forms, palmar and antebrachial. The palmar type arises from the junction of the ulnar artery and its common interosseous trunk; it is long and large, and reaches the palm, usually ending as the first or second common digital artery, or both. The antebrachial type is slender and short, usually arising from the anterior interosseous artery and finishing in the forearm. These variations are seen in about $20 \%$ of individuals and tend to be unilateral.

Kleinert et al (1989) demonstrated by plethysmography that 5\% of hands have ulnar artery dominance in all digits, compared with $28 \%$ with complete radial digital dominance.

Glomus tumours Glomus tumours are very painful tumours of the glomus bodies (small arteriovenous anastomoses involved in the regulation of peripheral skin temperature control (see Fig. 6.16)). They are often tiny and sometimes difficult to identify. These tumours typically occur in the proximal nail fold/subungual regions of the fingertips in association with the dorsal digital arterial arcades, although they can occur anywhere. They are diagnosed by exquisite point tenderness over the swelling, with reduction of tenderness when the finger is exsanguinated.

## VEINS

## Superficial veins of the hand

Dorsal and palmar digital veins Dorsal digital veins pass along the sides of the fingers, joined by oblique branches. They unite from the adjacent sides of the digits into three dorsal metacarpal veins that form a dorsal venous network over the metacarpus (Fig. 50.39). This is joined laterally by a dorsal digital vein from the radial side of the index finger and both dorsal digital veins of the thumb, and is prolonged proximally as the cephalic vein. Medially, a dorsal digital vein from the ulnar side of the little finger joins the network, which ultimately drains proximally into the basilic vein. A vein often connects the central parts of the network to the cephalic vein near the mid-forearm. Palmar digital veins connect to their dorsal counterparts by oblique veins that pass between metacarpal heads. They also drain to a plexus superficial to the palmar aponeurosis, extending over both thenar and hypothenar regions.

Cephalic vein The cephalic vein forms over the anatomical snuff-box from the radial extremity of the dorsal venous plexus and runs proximally over the distal lateral aspect of the radius, where it is easily visible. Its further course is described on pages 858 and 830 .

## Deep veins of the hand

Superior and deep palmar venous arches Superficial and deep palmar venous arches accompany their arterial counterparts and receive the corresponding branches; common palmar digital veins join the superficial arch and palmar metacarpal veins join the deep arch.

Palmar and dorsal metacarpal veins Deep veins accompanying the dorsal metacarpal arteries receive perforating branches from the palmar metacarpal veins. They end in the radial veins and the dorsal venous network over the metacarpus. This network is joined laterally by a dorsal digital vein from the radial side of the index finger and by both digital veins of the thumb, and is prolonged proximally as the cephalic vein.

## INNERVATION

## Median nerve

The median nerve proximal to the flexor retinaculum is lateral to the tendons of flexor digitorum superficialis and lies between the tendons of flexor carpi radialis and palmaris longus (Figs 50.40A-50.41). It passes under the retinaculum in the 'carpal tunnel', where it may be compressed in the carpal tunnel syndrome (see Fig. 46.11). Distal to the retinaculum, the nerve enlarges and flattens, and usually divides into five or six branches; the mode and level of division are variable.

Muscular branch (motor or recurrent branch)
The muscular branch is short and thick, and arises from the lateral side of the nerve; it may be the first palmar branch or a terminal branch that arises level with the digital branches. It runs laterally, just distal to the flexor retinaculum and with a slight recurrent curve beneath the part of the palmar aponeurosis covering the thenar muscles (see Fig. 50.40A). It turns round the distal border of the retinaculum to lie superficial to flexor pollicis brevis, which it usually supplies, and either continues superficial to the muscle or traverses it. It gives a branch to abductor pollicis brevis that enters the medial edge of the muscle, and then passes deep to it to supply opponens pollicis, entering its medial edge. Its terminal part occasionally gives a branch to the first dorsal interosseous, and may be its sole or partial supply. The muscular branch may arise in the carpal tunnel and pierce the flexor retinaculum. Anomalies of the median nerve occur in approximately $10 \%$ of patients undergoing a carpal tunnel release. These branches usually arise from the ulnar side of the nerve and may be motor or sensory.

## Palmar digital branches

The median nerve usually divides into four or five digital branches (see Figs 50.40A, 50.35). It often divides first into a lateral ramus, providing digital branches to the thumb and the radial side of the index finger, and a medial ramus, supplying digital branches to adjacent sides of the index, middle and ring fingers. Other modes of termination can occur.

Digital branches are commonly arranged as follows. They pass distally, deep to the superficial palmar arch and its digital vessels, at first anterior to the tendons of the long flexors. Two proper palmar digital nerves, sometimes from a common stem, pass to the sides of the thumb; the nerve supplying its radial side crosses in front of the tendon of flexor pollicis longus. The proper palmar digital nerve to the lateral side of the index finger also supplies the first lumbrical. Two common palmar digital nerves pass distally between the tendons of the long flexors. The lateral divides in the distal palm into two proper palmar digital nerves that traverse adjacent sides of the index and middle finger. The medial divides into two proper palmar digital nerves that supply adjacent sides of the middle and ring fingers. The lateral common digital nerve supplies the second lumbrical, and the medial receives a communicating twig from the common palmar digital branch of the ulnar nerve and may supply the third lumbrical. In the distal part of the palm, the digital arteries pass deeply between the divisions of the digital nerves; the nerves lie anterior to the arteries on the sides of the digits. The median nerve usually supplies palmar cutaneous digital branches to the radial three and a half digits (thumb, index, middle and the lateral side of the ring); sometimes, the radial side of the ring finger is supplied by the ulnar nerve. Occasionally, there is a communicating branch between the common digital nerve to the middle and ring fingers (derived from the median nerve) and the common digital nerve to the ring and little fingers (derived from the ulnar nerve); this may explain variations in sensory patterns that do not conform to the classic pattern.

The proper palmar digital nerves pass along the medial side of the index finger and both sides of the middle and the lateral side of the ring finger. They enter these digits in fat between slips of the palmar aponeurosis. Together with the lumbricals and palmar digital arteries, they pass dorsal to the superficial transverse metacarpal ligament and ventral to the deep transverse metacarpal ligament. In the digits, the nerves run distally beside the long flexor tendons (outside their fibrous sheaths), level with the anterior phalangeal surfaces and anterior to the digital arteries, between Grayson's and Cleland's ligaments. Each nerve gives off several branches to the skin on the front and sides of the digit and sends branches to the metacarpophalangeal and interphalangeal joints.

The digital nerves supply the fibrous sheaths of the long flexor tendons, blood vessels (vasomotor) and sweat glands (sudomotor). Distal to the base of the distal phalanx, each digital nerve gives off a branch that passes dorsally to the nail bed. The main nerve frequently trifurcates to supply the pulp and skin of the terminal part of the digit. Distal to the base of the proximal phalanx, each proper digital nerve also gives off a dorsal branch to supply the skin over the back of the middle and distal phalanges. The proper palmar digital nerves to the thumb and the lateral side of the index finger emerge with the tendons of the long flexors from under the lateral edge of the palmar aponeurosis. They are arranged in the digits as described above, except that, in the thumb, small distal branches supply the skin on the back of the distal phalanx only.

## Other branches

In addition to the branches of the median nerve described above, variable vasomotor branches supply the radial and ulnar arteries and their branches. Some of the intercarpal, carpometacarpal and

Fig. 50.40 The cutaneous nerves of the hand. A, Palmar aspect. The anular and cruciate pulleys are shown schematically in the ring finger. B, Dorsal aspect.

Fig. 50.41 A transverse section through the supinated left wrist at the level of the distal radio-ulnar joint, showing the muscle tendons (in grey) and their synovial sheaths (in green). (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
intermetacarpal joints are said to be supplied by the median nerve or its anterior interosseous branch; the precise details are uncertain.

## Carpal tunnel syndrome

Carpal tunnel syndrome is the most common entrapment mononeuropathy. It is caused by compression of the median nerve as it passes through the fibro-osseous tunnel beneath the flexor retinaculum (see Fig. 50.28).

## Median nerve division at the wrist

## Available with the Gray's Anatomy e-book

## Ulnar nerve

At the wrist, the ulnar nerve passes under the superficial part of the flexor retinaculum (in Guyon's canal) with the ulnar artery, and divides into superficial and deep terminal branches (see Fig. 50.5).

## Dorsal branch

The dorsal branch arises approximately 5 cm proximal to the wrist (see Fig. 49.23). It passes distally and dorsally, deep to flexor carpi ulnaris, perforates the deep fascia, descends along the medial side of the back of the wrist and hand, and then divides into two, or often three, dorsal digital nerves. The first supplies the medial side of the little finger; the second, the adjacent sides of the little and ring fingers; while the third, when present, supplies adjoining sides of the ring and middle fingers. The latter may be replaced, wholly or partially, by a branch of the radial nerve, which communicates with it on the dorsum of the hand (see Fig. 50.40). In the little finger, the dorsal digital nerves extend only to the base of the distal phalanx; in the ring finger, they extend only to the base of the middle phalanx. The most distal parts of the little finger and of the ulnar side of the ring finger are supplied by dorsal branches of the proper palmar digital branches of the ulnar nerve. The most distal part of the lateral side of the ring finger is supplied by dorsal branches of the proper palmar digital branch of the median nerve.

## Superficial and deep terminal branches

## Superficial terminal branch

The superficial terminal branch supplies palmaris brevis and the medial palmar skin. It divides into two palmar digital nerves, which can be palpated against the hook of the hamate bone. One supplies the medial side of the little finger; the other (a common palmar digital nerve) sends a branch to the median nerve and divides into two proper digital nerves to supply the adjoining sides of little and ring fingers. The proper digital branches are distributed like those derived from the median nerve.

## Deep terminal branch

The deep terminal branch accompanies the deep branch of the ulnar artery as it passes between abductor digiti minimi and flexor digiti minimi, and then perforates opponens digiti minimi to follow the deep palmar arch dorsal to the flexor tendons (see Fig. 50.40A ). At its origin, it supplies the three short muscles of the little finger. As it crosses the hand, it supplies the interossei and the third and fourth lumbricals. It
ends by supplying adductor pollicis, the first dorsal interosseous and, usually, flexor pollicis brevis.

The medial part of flexor digitorum profundus is supplied by the ulnar nerve, as are the third and fourth lumbricals, which are connected with the tendons of this part of the muscle. Similarly, the lateral part of flexor digitorum profundus and the first and second lumbricals are supplied by the median nerve. The third lumbrical is often supplied by both nerves. The deep terminal branch gives branches to some intercarpal, carpometacarpal and intermetacarpal joints; precise details are uncertain. Vasomotor branches, arising in the forearm and hand, supply the ulnar and palmar arteries.

## Ulnar tunnel syndrome

Ulnar tunnel syndrome is an entrapment neuropathy of the ulnar nerve as it passes through Guyon's canal at the wrist.

## Ulnar nerve division at the wrist

Available with the Gray's Anatomy e-book

## Radial nerve

Branches of the superficial branch of the radial nerve reach the hand by curving around the wrist over the tendons of abductor pollicis longus and extensor pollicis brevis, and dividing into dorsal digital nerves (see Fig. 50.40B, Fig. 50.42). They usually communicate with the posterior and lateral cutaneous nerves of the forearm on the dorsum of the hand.

## Dorsal digital nerves

There are usually four or five small dorsal digital nerves. The first supplies the skin of the radial side of the thumb and the adjoining thenar eminence, and communicates with branches of the lateral cutaneous nerve of the forearm. The second supplies the medial side of the thumb; the third, the lateral side of the index finger; the fourth, the adjoining sides of the index and middle fingers. The fifth communicates with a ramus of the dorsal branch of the ulnar nerve and supplies the adjoining sides of the middle and ring fingers, where it is frequently replaced by the dorsal branch of the ulnar nerve. The digital nerves of the thumb reach only to the root of the nail; those in the index finger, midway along the middle phalanx; and those to the middle and the lateral part of the ring finger may reach no further than the proximal interphalangeal joints. The remaining distal dorsal areas of the skin in these digits are typically supplied by palmar digital branches of the median and ulnar nerves. However, the superficial terminal branch of the radial nerve may supply the whole dorsum of the hand.

## SURFACE ANATOMY OF THE WRIST AND HAND

## Available with the Gray's Anatomy e-book

See Video 50.2.

The carpal tunnel may be narrowed by arthritic changes in the wrist joint, particularly from rheumatoid arthritis, and by soft tissue thickening, as may occur in myxoedema and acromegaly; it may also be associated with oedema, obesity or pregnancy. Usually, the condition is idiopathic. Normally, the median nerve slides smoothly in and out of the carpal tunnel during flexion and extension of the wrist, but when the nerve is compressed, additional damage may be produced during these movements. The dominant hand is usually affected first, probably because this hand is used more frequently and more vigorously. Typically, the syndrome produces pain, paraesthesia and numbness in the thumb, index, middle and medial side of the ring fingers, which is worse at night and on gripping objects. The palmar branch of the median nerve is spared because it does not pass through the carpal tunnel. With time, the compression leads to wasting and weakness of abductor pollicis brevis. Treatment is usually surgical decompression of the nerve by dividing the flexor retinaculum, either as an open procedure or with endoscopic assistance. The most common hazards of decompression are: inadequate decompression because of failure to divide the most distal part of the flexor retinaculum; damage to the motor, or palmar cutaneous, or one or more terminal sensory branches; prolapse of the nerve through the gap in the retinaculum; and damage to the superficial palmar arch causing haematoma, compression, pain and, ultimately, fibrosis or even a late false aneurysm (Birch 2011). The distal ulnar nerve and its branches may also be damaged.

Anatomical anomalies of the median nerve occur at the level of the carpal tunnel in up to $12 \%$ of hands. The most common are variations in the course of the recurrent motor branch in relation to the flexor retinaculum: transligamentous (23\%), subligamentous (31\%) or extraligamentous (46\%) (Kretschmer et al 2009). Damage may also occur to the palmar cutaneous branch of the median nerve and to the superficial connections between the median and ulnar nerves (the so-called Berrettini branch), division of which will leave the patient with numbness in the middle and ring fingers. Stancic et al (1999) noted that this connection was present in $81 \%$ of dissected hands and proposed that it should be regarded as a normal anatomical finding.

Median nerve division at the wrist leads to paralysis of the lumbricals to the index and middle fingers and of the thenar muscles (apart from flexor pollicis brevis and adductor pollicis), as well as loss of sensation to the thumb, index, middle and radial half of the ring fingers. The radial half of the hand becomes flattened as a result of wasting of the thenar muscles and the adducted posture of the thumb. Division of the median nerve distal to the origin of its palmar cutaneous branch, which arises somewhere between 3 and 7 cm proximal to the proximal edge of the flexor retinaculum and the distal transverse wrist crease, will leave the branch intact to supply the skin over the thenar eminence and radial side of the proximal part of the hand. Careful clinical examination of the sensibility of the skin in this region should help to clarify the level of the lesion. High division of the nerve (Ch. 49) will, as with compressive lesions at this level, result in weakness of pronation of the forearm, flexion of the wrist and the lateral two fingers.

Causes of compression at this site include a ganglion, trauma, and proximity of aberrant or accessory muscles. The symptoms include pain in the hand or forearm and sensory changes in the palmar aspect of the little and ulnar half of the ring fingers; sensation on the ulnar aspect of the dorsum of the hand is normal. In addition, there may be weakness and wasting of the intrinsic muscles of the hand supplied by the ulnar nerve, with clawing posture in extreme cases.

Surgical treatment involves decompression of the nerve by division of the roof of Guyon's canal and removal of the causative lesion, such as a ganglion. Ulnar tunnel syndrome can be difficult to distinguish from more proximal causes of ulnar nerve compression, of which the most common is entrapment of the nerve in cubital canal at the elbow (Ch. 49). Sensory changes may be present more proximally and, in severe cases, weakness may be noted in flexor carpi ulnaris and the ulnar part of flexor digitorum profundus. In the absence of obvious clinical indicators, local tenderness over the site of compression and nerve conduction studies may aid diagnosis.

Ulnar nerve division at the wrist paralyses all the intrinsic muscles of the hand (apart from the radial two lumbricals, abductor pollicis brevis, and part of flexor pollicis brevis and opponens pollicis). The intrinsic muscle action of flexing the metacarpophalangeal joint and extending the interphalangeal joints is lost. The unopposed action of the long extensors and flexors of the fingers cause clawing, with extension of the metacarpophalangeal joints and flexion of the interphalangeal joints. The clawing is less intense in the index and middle fingers because their lumbricals are supplied by the median nerve. (For a detailed account of the hand posture adopted in ulnar nerve lesions, see Smith (2002).) There is sensory loss over the little finger and the ulnar half of the ring finger. The skin over the ulnar aspect of the dorsum of the hand is spared because the dorsal branch of the ulnar nerve is given off approximately 5 cm proximal to the wrist joint. A combined median and ulnar nerve palsy at the wrist results in a full claw hand with thenar and hypothenar flattening and thumb adduction and flexion (a simian hand).

The superficial cutaneous branches of the radial nerve are at risk of injury from any procedure or injury in their immediate vicinity. Incisions or injections in or around the radial border of the wrist are particularly implicated. The resultant painful neuromata can prove to be resistant to treatment.

## FLEXOR/VOLAR SURFACE

The wrist joint is identified between the distal ends of the radius and ulna, and the proximal carpus, on flexion and extension of the wrist. The line of the wrist joint corresponds to a line, convex superiorly, joining the radial and ulnar styloid processes. Its position is also marked by the proximal of the two transverse anterior wrist creases (see Fig. 46.30A). The radial styloid process normally sits 1 cm distal to the ulnar styloid process. Alteration of this arrangement can indicate fracture.

When the forearm is pronated, the head of the ulna forms a rounded surface elevation on the medial side of the posterior aspect of the wrist (see Figs 46.29C, 46.30B), and the ulnar styloid process projects distally from its posteromedial aspect. The radial styloid process projects inferiorly from the distal radius along the lateral aspect of the wrist. The posterior aspect of the lower end of the radius is partly obscured by the extensor tendons but is palpable. The prominent dorsal radial (Lister's) tubercle is both visible and palpable, and aligns with the web space between digits 2 and 3 (see Fig. 46.30B). The tendon of extensor pollicis longus in extensor compartment 3 sits medial to the tubercle, and the tendons of extensors carpi radialis longus and brevis sit lateral to the tubercle in compartment 2.

Four of the carpal bones are palpable. The pisiform is both visible and palpable on the palmar aspect of the medial wrist at the base of the hypothenar eminence. It is often overlain by the distal wrist crease. It can be moved over the articular surface of the triquetrum when the wrist is passively flexed. The hook of the hamate lies approximately 2.5 cm distal to the pisiform, in line with the ulnar border of the ring finger. It can be felt on deep palpation, and the superficial division of the ulnar nerve can be rolled from side to side over the tip of the hook. The tubercle of the scaphoid is situated at the base of the thenar eminence, in line with the tendon of flexor carpi radialis and, in many individuals, forms a small, visible elevation. Immediately distal to it, but covered by the muscles of the thenar eminence, the tubercle of the trapezium can be identified on deep palpation.

Proximal to the wrist creases, the prominent tendon of flexor carpi radialis can be seen and palpated when the wrist is flexed against resistance (see Fig. 46.30A). The radial artery lies on its lateral side and crosses the anterior margin of the expanded distal end of the radius, where it is palpable. It then passes posteriorly, deep to the tendons of abductor pollicis longus and extensor pollicis brevis, and enters the anatomical snuff-box, where its pulsations are palpable (see Fig. 46.30C).

Palpation lateral to flexor carpi radialis, $3-4 \mathrm{~cm}$ proximal to the wrist crease, reveals the muscle belly of flexor pollicis longus (flexing and extending the thumb will confirm that the examining finger is correctly placed). The area on the ulnar side of flexor carpi radialis tendon is packed with functionally important structures. The median nerve is either covered by, or situated just lateral/radial to, the tendon of palmaris longus. The latter can be identified by gently pinching the tips of the digits together and partially flexing the wrist (see Fig. 46.30A). Near to the wrist, the median nerve lies very close to the skin and can, therefore, be injured by relatively superficial lacerations. When palmaris longus is absent, only a thin covering of subcutaneous fat and deep fascia separate skin and nerve. The four tendons of flexor digitorum superficialis lie deep to the median nerve; the tendons to the middle and ring fingers lie anterior to those for the index and little fingers as they pass deep to the flexor retinaculum, and can be felt and usually seen to move during finger flexion/extension. Deeper still are the tendons of flexor digitorum profundus. The broad tendon of flexor carpi ulnaris is easily palpated passing to the pisiform on the ulnar side of the anterior wrist; the ulnar nerve, artery and venae comitantes lie along its lateral (radial) edge. Any sharp injury that cuts through the tendon usually has enough energy to sever the ulnar neurovascular bundle.

## ANATOMICAL SNUFF-BOX

When the thumb is fully extended, the depression of the anatomical snuff-box is seen on the lateral aspect of the wrist immediately distal to the radial styloid process. The snuff-box is bounded on its anterolateral (radial) side by the tendons of abductor pollicis longus (laterally) and extensor pollicis brevis (immediately medial), and on its posteromedial/ulnar side by the tendon of extensor pollicis longus. Running a finger along extensor pollicis brevis enables palpation of the superficial radial nerve, which can be rolled from side to side on the tendon. The cephalic vein passes through the roof of the snuff-box, where it is visible and palpable, and the pulsation of the radial artery can be palpated deeply on its floor.

Three bones are palpable distal to the radial styloid process along the floor of the anatomical snuff-box: the convex, ovoid proximal articular surface of the scaphoid (best palpated during alternating wrist abduction/adduction), the radial aspect of the trapezium and the expanded base of the first metacarpal. The first carpometacarpal joint forms a palpable depression distal to the trapezium. When wrist stability is clinically assessed throughout its range of movements, the scaphoid may be compressed bidigitally, between index finger and thumb, along its oblique long axis between the tubercle and articular surface. Similarly, the trapezium may be compressed between its tubercle and radial aspect.

## EXTENSOR/DORSAL SURFACE

The tendons located within the six extensor compartments of the wrist are subcutaneous and palpable (see Fig. 46.30B). Compartment 1 (containing abductor pollicis longus and extensor pollicis brevis) sits over the lateral radius. Regional tenderness to palpation occurs in de Quervain's tenosynovitis. Compartments 2 (containing extensors carpi radialis longus and brevis) and 3 (containing extensor pollicis longus) flank the lateral and medial sides of the dorsal radial (Lister's) tubercle, respectively. Compartments 5 (containing extensor digiti minimi) and 6 (containing extensor carpi ulnaris) flank the posterior and medial sides of the ulnar head, respectively. Compartment 4 (containing extensors digitorum and indicis) sits between the ulnar head and compartment 3. The tendons of extensors carpi radialis longus and brevis can be identified on the dorsal carpus when the fist is clenched and relaxed. The tendons of extensor digitorum are visible and palpable on the dorsal hand with the fingers fully extended. The tendon of extensor carpi ulnaris is palpable distal to the ulnar styloid as it crosses the wrist, with the wrist in extension and adduction. The first dorsal interosseous forms a visible fleshy mass on the lateral part of the dorsal hand between the index finger and thumb, especially whilst abducting the

## HAND

The palmar skin is marked by a number of creases but they are of little value as points of reference. Transverse skin creases cross the palmar aspect of the fingers in three places: the most proximal crease sits at the junction of the digit with the palm and lies approximately 2 cm distal to the metacarpophalangeal joint; the intermediate crease sits opposite the proximal interphalangeal joint; and the distal crease sits just proximal to the distal interphalangeal joint.

The first metacarpal is both visible and palpable on the dorsolateral hand; its dorsal aspect forms the lateral border of the hand. The fleshy elevation of the thenar eminence, produced by abductor and flexor pollicis brevis overlying opponens pollicis, is located on the lateral palm (see Fig. 46.48A). The less prominent hypothenar eminence is located on the medial palm and is formed by the comparable muscles of the little finger. The medial aspect of the hypothenar eminence forms the medial border of the hand.

The dorsal aspects of the trapezium and of each of the metacarpal bones are partially palpable around the margins of the corresponding extensor tendons. The heads of the metacarpal bones form the prominences of the knuckles and are most obvious during digit flexion. On the dorsal hand, the metacarpophalangeal joint line forms a palpable depression lateral to the digital extensor tendon, and alternating digit flexion/extension aids identification. The joint can be aspirated/injected from this perspective. Palpation distal to the metacarpal head reveals the flared base of the corresponding proximal phalanx. The interphalangeal joints are palpable on the dorsal aspect of a flexed digit just distal to the prominences formed by the heads of the proximal and middle phalanges.

The flexor retinaculum, and therefore the surface position of the carpal tunnel, can be mapped according to its palpable bony attachments (see Fig. 46.30A). The distal border is concave inferiorly and is marked by a curved line that joins the tubercle of the trapezium to the hook of the hamate. Its proximal border is marked by a curved line, concave superiorly, which joins the tubercle of the scaphoid to the pisiform. Flexion of the wrist produces a number of transverse skin creases (usually two, sometimes three) at the wrist. The dominant, most distal, wrist crease normally sits distal to the lunate and overlies pisiform and the proximal edge of the flexor retinaculum. The carpal tunnel passes distal to this crease for $2.5-3 \mathrm{~cm}$.

The position of the superficial palmar arterial arch is indicated by a horizontal line approximately 4 cm long, drawn at the level of the fully extended and partially abducted thumb (see Fig. 46.30A). A horizontal line, approximately 4 cm long and running from a point just distal to the hook of the hamate, indicates the position of the deep palmar arterial arch. The deep arch is located approximately 1 cm proximal to the superficial arch. The digital neurovascular bundles pass along the medial and lateral sides of the dorsal and volar surfaces of the digits, and can be anaesthetized in these positions via the web space.

# Injuries of the supraclavicular brachial plexus 

Rolfe Birch

The closed traction lesion of the supraclavicular brachial plexus is amongst the worst of all peripheral nerve injuries because of the frequent association with injury to the spinal cord and the usual complication of severe pain. There is one common element: the violent distraction of the forequarter from the head, neck and chest so that the angle between the head and the shoulder is opened. One important physical sign that illustrates this point is the presence of linear abrasions and bruising at the tip of the shoulder (Fig. 6.1.1). These are often injuries of great violence and motor cyclists in high-speed accidents are particularly at risk. Associated injuries to the head, spine, chest, abdomen, pelvis, long bones and subclavian artery are common.

The most common site of nerve lesion lies within the spinal canal, affecting the intradural segments of the spinal nerves. These injuries are called preganglionic because the lesion lies between the dorsal root ganglion and the spinal cord. This concept of pre- and postganglionic injury, introduced by Bonney in 1954, is fundamental to diagnosis and treatment. The preganglionic injury is the most common lesion because the union of the ventral and dorsal roots is the weakest link in the long chain between the central nervous system and the periphery. Postganglionic rupture usually involves the ventral (anterior) primary ramus, distal to the branching of the dorsal (posterior) primary ramus (see Figs $45.1,45.7$ ). In one series of 200 patients operated on between the years 2000 and 2004, 429 spinal nerves sustained preganglionic rupture, 223 were postganglionic ruptures and the remaining 298 spinal nerves were intact or recovering. The fifth and sixth cervical nerves are somewhat protected by proximal branches to such nerves as the phrenic and long thoracic, and also by the transverse radicular ligaments. The vulnerability of C8 and T1 is enhanced by the increasing obliquity of the roots in the spinal canal and the angulated course of T1.

There are two types of preganglionic, intradural, injury: rupture peripheral to the transitional zone and avulsion central to it (Figs 6.1.2, 6.1.3; see also Fig. 3.35). The former is more common (Schenker and Birch 2001). The extent of the displacement of the dorsal root ganglion,

Fig. 6.1.1 Linear abrasions in the neck indicate separation of the forequarter from the trunk. The abrasion at the tip of the shoulder marks the point of impact against a roadside kerb. Rupture of C 5 , preganglionic C6-T1. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. SpringerVerlag, London.)
and the level of rupture of the dura, vary. These patterns are outlined in a classification by Bonney (Birch 2011a) and examples are illustrated in Figures 6.1.4, 6.1.5.

Bonney $(1954,1959)$ showed that the neuronal cell bodies in the dorsal root ganglion in preganglionic injuries remained alive and that conduction within their peripheral axons was maintained, even though the cell body was separated from the spinal cord (Figs 6.1.6, 6.1.7); the axon reflex is probably maintained by the unmyelinated C fibres.

Fig. 6.1.2 A transverse section of the tip of an avulsed dorsal root at C6 4 days after injury, showing a central avulsion. The tissue in the centre of the section is central nervous system (CNS) tissue, in which glial cells show post-traumatic lytic changes. Corpora amylacea are indicated by arrows. Toluidine blue stained resin section $\times 100$. (Courtesy of the Editor Journal of Bone and Joint Surgery (British), from Schenker and Birch (2001).

Fig. 6.1.3 An avulsed ventral root of C6 4 days after injury, showing a peripheral intradural rupture. The nerve tissue at the site of the rupture showed no central nervous system features. The tip is covered by organized blood clot and erythrocytes that interweave with fibrin strands. The myelinated fibres show early signs of Wallerian degeneration. Toluidine blue stained resin section $\times 200$. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 6.1.4 The fifth and sixth cervical nerves avulsed from the spinal cord. The ventral root is easily distinguishable from the dorsal rootlets. Note the dorsal root ganglion, the dural sleeve merging into the epineurium, and the spinal nerve itself. The small pieces of tissue on the proximal ends of the dorsal rootlets (below) are probably portions of the spinal cord. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Bonney and Gilliatt (1958) recorded sensory action potentials from peripheral nerves in cases of preganglionic injury; the measurements of persisting peripheral conduction stimulated a profound and lasting interest in conduction in the central pathways. Intraoperative studies of motor and sensory conduction are essential in emergency or urgent exploration of the brachial plexus. The demonstration that myelinated afferent fibres pass through the ventral root in the human (Schenker and Birch 2000) (Fig. 6.1.8) may be significant in recent successful

Fig. 6.1.5 Ischaemia and conduction. A, A traction lesion of the brachial plexus accompanied by rupture of the subclavian artery; there was a weak pulse. At operation, 54 hours after injury, stimulation of the avulsed ventral roots of C7, 8 and T1 evoked strong contraction in the relevant muscles distally. This showed that there was neither critical ischaemia within the limb nor a second, more distal, lesion. B, Strong somatosensory evoked potentials were recorded through electrodes placed over the scalp, by stimulation of the postganglionic ruptured stumps of C5 and C6 (1). The dorsal root ganglia of C7, 8 and T1 (2) and their ventral roots (3) are shown. An extensive repair was done. C, An arteriogram showing the ruptured subclavian artery. attempts to reattach the ruptured ventral root to the spinal cord (see below).

## Diagnosis

It is important always to search for occult injuries to the head, chest and spine. Once the diagnosis of injury to the brachial plexus has been

Fig. 6.1.6 A dorsal root ganglion 6 months after avulsion from the spinal cord. The cell bodies are healthy and there are numerous myelinated fibres. Solochrome cyanin $\times 960$. Fig. 6.1.9 A-B, Intense, lightning-like pain was felt in the dermatomes of C5, 6 and 7 in this patient on the day of injury; these three nerves were avulsed from the spinal cord. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
made, it should be put to one side while a systematic and systemic examination is made of the whole patient. Analysis, history and precise clinical examination usually permit an accurate diagnosis of the extent and the level of the neurological injury.

History An understanding of the axis of application of force to the injured limb is very important. A description from witnesses or the patient of the shoulder being violently arrested by an object - stone, tree, kerb or vehicle - while the body is flying through the air confirms that there has been violent stretching of the structures in the posterior triangle of the neck.

Pain Severe pain within a paralysed and anaesthetic limb indicates very serious injury to the spinal nerves. It may be constant, described as crushing, burning or intense pins and needles, and is usually felt in the forearm and hand. Two-thirds of conscious patients who developed such pain did so on the day of injury. The superimposed shooting pain coursing into the dermatome of a spinal nerve signifies preganglionic injury to the nerve (Fig. 6.1.9). More than one-half of conscious patients experienced this pain on the day of injury (Birch 2011b).

Inspection Inspection of the limb may reveal linear cuts and abrasions passing from the face to the shoulder, indicating distraction of the limb when injury was sustained. Deep bruising is an important sign of tearing of prevertebral muscle or even of the subclavian artery. Increasing swelling in the posterior triangle indicates a collection of spinal fluid, either from nerves avulsed from the spinal cord or from an expanding haematoma, or both. A Horner (Bernard Horner) sign is a strong indicator of preganglionic injury to C8 and T1 because of interruption of the rami between the spinal nerves and the stellate ganglion (see Figs 46.16 and 16.13).

Sensory loss Sensory loss extending above the clavicle is a sign of preganglionic injury to at least the upper nerves of the brachial plexus (Figs 6.1.10-6.1.13).

Fig. 6.1.10 Sensory loss in a complete preganglionic lesion of C4-T1 in two patients. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 6.1.11 Sensory loss in a preganglionic lesion of C5-T1. C4 innervates the skin of the outer aspect of the shoulder; T2 innervates the skin of the inner aspect of the arm. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Muscle weakness Paralysis of serratus anterior and of the ipsilateral hemidiaphragm shows that the lesion is in the most proximal segments of C4-C7 and that these nerves are likely to have sustained preganglionic injury.

Recognition of postganglionic rupture Tinel's sign is most valuable in the early detection of ruptures. It is important to advise the

Fig. 6.1.12 Sensory loss in a preganglionic lesion of $\mathrm{C} 4,5,6,7$. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
patient that percussion in the posterior triangle of the neck may be painful - at times, extremely so. The patient is asked to indicate the region into which they experience radiation of intense 'pins and needles'. When these extend down the outer arm and proximal forearm, then rupture of C5 is likely. When they extend to the lateral aspect of the forearm and thumb, then a similar lesion of C6 may be anticipated. Percussion over a rupture of C7 evokes sensations into the dorsum of the hand; that over a rupture of the lower trunk evokes sensations in the inner aspect of the forearm and little fingers.

It is difficult to overstate the significance of a strong positive Tinel's sign in detecting rupture of a spinal nerve within the posterior triangle: the stronger the sign, the more likely the chances of finding a robust stump. It should be emphasized that Tinel's sign is detectable, in a conscious patient, on the day of injury.

Investigations Radiological and imaging studies confirm or modify the clinical diagnosis, but they may also confirm or reveal associated injuries to the spinal column, the spinal cord and the chest. Plain radiographs confirm elevation of the ipsilateral hemidiaphragm and may show tilting of the cervical spine away from the side of injury, which is often associated with fracture or dislocation of the first rib. The
condition of roots and evidence of displacement or other abnormalities of the spinal cord are revealed by myelography: more precisely, by computed tomographic (CT) myelography and, increasingly in current practice, by magnetic resonance imaging (MRI).

## Patterns of lesions

A survey of the incidence of these lesions in the UK, conducted through the auspices of the British Orthopaedic Association, uncovered 328 patients admitted with complete or partial lesions in 1987 (Goldie and Coates 1992). The lesion was complete in $26.2 \%$ of patients; the subclavian artery was ruptured in $5.5 \%$; there were other major injuries in $40 \%$, and a wound in the neck in $5.5 \%$. Table 6.1 .1 sets out the patterns of injury in 301 patients operated on in 1989-93. Complete lesions accounted for 141 of the cases; 52 patients sustained preganglionic injury to all five spinal nerves. Over the years, there has been a modest

Fig. 6.1.13 Sensory loss in a preganglionic lesion of C5. The area of sensory loss is usually larger than that seen after rupture of the axillary (circumflex) nerve (see Fig. 48.2). (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
decrease in the severity of injury; the proportion of cases with complete preganglionic injury of C5-T1 was $18.7 \%$ in the series reported by Rosson (1987); $17.3 \%$ in those operated on between 1989 and 1993; and less than $8 \%$ in patients operated on between 2000 and 2004 (Birch 2011a). However, the incidence of injury to the subclavian artery in the operated cases remains steady over this time at about $10 \%$.

## Treatment

The direct object of treatment is rehabilitation. This entails the following steps: provision of accurate diagnosis and prognosis; improvement of prognosis by repair of damaged nerves; relief of pain; palliation of paralysis by custom-made orthoses and by musculotendinous transfers (Fig. 6.1.14); and assistance towards a return to original, appropriately modified or new work or study and to independent living.

Operations should be undertaken as soon as the patient's general condition permits in cases where there is evidently a serious nerve injury (Birch 2011a). There have been important improvements in outcomes over the years. The possibility of reconnection of the avulsed ventral roots to the spinal cord has been realized in a few carefully selected cases (Fig. 6.1.15). The return of fluid and coordinated muscle action, and of the biceps tendon jerk, suggests some regeneration into the deep afferent pathway, perhaps through myelinated afferent fibres in the ventral root.

Pain relief One of the most pleasing aspects of surgical endeavour has been the finding that reinnervation of muscle is regularly successful in improving pain and this is a strong indication for securing reinnervation of a limb, no matter how limited, in even the most severe injuries (Berman et al 1996, Berman et al 1998, Kato et al 2006; see Birch 2011a, Birch 2011b, Birch 2011c).

Table 6.1.1 Patterns of injury in 301 consecutively operated supraclavicular lesions (1989-93)

| Pattern of injury | Number of patients |
| :---: | :---: |
| Complete lesions: pre-and postganglionic injuries | 141 |
| Ruptures of upper nerves C5 (C6, 7) <br> Intradural ruptures of lower nerves (C6, 7, 8) T1 | 83 |
| Ruptures of middle nerves (C6) C7 (C8) Intradural above and below | 5 |
| Ruptures of lower nerves C8, T1 <br> Intradural ruptures of upper nerves C5, 6, 7 | 1 |
| Total intradural ruptures of C5-T1 | 52 |
| Incomplete lesions: some roots intact | 153 |
| Damage C5, 6 (C7) <br> Recovering or intact (C7) C8, T1 | 117 |
| Damage C6, 7, 8 <br> Recovering or intact $\mathrm{C} 5, \mathrm{~T} 1$ | 23 |
| Damage C7, 8, T1 <br> Recovering or intact C5, 6 | 13 |

Fig. 6.1.14 A-B, A woman aged 28 at the time of injury with left-sided rupture of $\mathrm{C} 5, \mathrm{C} 7, \mathrm{C} 8$ and T 1 , preganglionic lesion C 6 . Function is shown at 96 months after repair: wrist extension was regained by transfer of flexor carpi ulnaris to extensor carpi radialis brevis. # Nerves at risk from musculoskeletal injury 

Rolfe Birch

The anatomical arrangements of some of the peripheral nerves make them particularly vulnerable to damage from musculoskeletal injury.

## Fractures and dislocations

In the upper limb, the cords of the brachial plexus and the axillary vessels pass in a space bounded by subscapularis (deep) and pectoralis minor (superficial). Anterior displacement of the humeral head or bone fragments forces the nerves and vessels against the deep surface of pectoralis minor, which acts as a guillotine. Rupture of nerves and vessels is frequent in high-energy transfer injuries in younger adults and is common in many lower-energy transfer injuries in the elderly (Fig. 6.2.1). The proximity to bone of all three main nerves at the elbow renders them vulnerable to skeletal injuries.

In the lower limb, nerve injuries are more common and more serious because of the greater forces involved in serious skeletal injuries. The lumbosacral plexus is at risk in fracture dislocations of the sacroiliac joints, especially when fractures extend into the sacral foramina. The sciatic nerve is damaged by posterior displacement of the femoral head (see Fig. 78.11).

## Tethering of nerves

In the upper limb, the axillary nerve runs in loose fatty tissue in its course anterior to subscapularis. When it turns around that muscle, it enters a quadrilateral tunnel formed by the union of the fasciae of subscapularis cranially, teres major caudally and coracobrachialis laterally, which surrounds the nerve and the posterior circumflex vessels.

Fig. 6.2.1 A leaking aneurysm 20 weeks after fracture of the neck of the humerus in an 83-year-old woman. She made a good recovery after repair of the defect. A, A radiograph on the day of injury. B, A radiograph at 18 weeks. C, A magnetic resonance imaging (MRI) scan at 18 weeks. D, An angiogram on the day of operation. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

The neurovascular bundle curves around the inferior border of the tendon of subscapularis, and passes over the superior border of the tendon of teres major, entering a near-horizontal tube. This arrangement puts the nerve at risk during anterior dislocation of the head of the humerus and the frequent complication of bleeding from the posterior circumflex vessels, which strangles the nerve. The radial nerve is at risk from fractures of the shaft of the humerus between the two relatively fixed points of the nerves to the lateral head of triceps and the tunnel through the lateral intermuscular septum.

In the lower limb, the common fibular nerve, which passes above or through piriformis in as many as $30 \%$ of cases, is tethered above in relation to piriformis and below at the neck of the fibula. The fascia surrounding biceps femoris and its tendon sweeps around to embrace the nerve; in dislocation of the knee, the muscle frequently avulses the tip of the head of the fibula and is displaced anteriorly, pulling the nerve with it. The deep fibular nerve passes rather acutely forwards to enter the anterior compartment of the leg.

Refer to Commentary 9.1 for further information on nerve biomechanics.

## Fascial arrangements

Sleeves of fascia surround main nerves and main vessels in some regions, an arrangement that predisposes the nerves to injury from ischaemia and compression from bleeding. After the ventral primary rami of C7, 8 and T1 enter the posterior triangle of the neck, they are enclosed in quite a rigid space bounded posteriorly by the dorsal part of the first rib, the transverse processes of the cervical vertebrae and the fascia of levator scapulae. The nerves are embraced by scalenus anterior and scalenus medius, both of which are invested in an unyielding fascia (this is one envelope of the prevertebral fascia that also serves to bind the phrenic nerve down to the anterior face of scalenus anterior). The prevertebral fascia is particularly well developed anterior to the vertebral column and at the base of the posterior triangle, where it envelops the ventral primary rami of C7, 8 and T1, the phrenic nerve, the cervical sympathetic chain, and subclavian and vertebral arteries. Infusion of relatively large volumes of fluid, from 10 to 20 ml , deep to the prevertebral fascia, for the purpose of inducing regional block, may cause tamponade of the radicular vessels that enter the spinal canal and contribute to the anterior spinal artery (Fig. 6.2.2, see also Figs 45.11, 45.12).

The medial brachial fascial compartment extends from the axilla to the elbow and is bounded by the tough medial intramuscular septum and the axillary sheath. Bleeding into this compartment is responsible for many infraclavicular plexopathies following regional block or fracture dislocation of the shoulder (Fig. 6.2.3).

## Neurovascular compartments

The anterior interosseous nerve and its accompanying artery may be damaged by compression because of swelling in the deepest part of the

Fig. 6.2.2 The hands of an 11 -year-old boy 7 years after anterior cord infarction caused by interscalene block. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
flexor compartment of the forearm. The ulnar nerve is accompanied by the ulnar artery in a discrete fascial compartment in the distal two-thirds of the forearm. The deep fibular nerve is accompanied by the anterior tibial artery, an end artery, throughout most of the anterior compartment of the leg; occlusion of this artery causes death of the nerves and muscles of the anterior compartment. The femoral nerve is damaged by haematoma where it passes deep to the thick fascia over iliacus, and it is also at risk from bleeding into the femoral triangle (see Fig. 80.32; Fig. 6.2.4). The tibial nerve is accompanied by the posterior tibial artery in the distal half of the leg in a sheath of fascia similar to the arrangements for the ulnar vessels and nerve (Fig. 6.2.5).

## Collateral circulation

The collateral circulation at the elbow depends on vessels that run with the three main nerves. This network may maintain an adequate supply to the hand and the extensor muscles of the forearm after acute loss of flow through the brachial artery if there is no associated fracture dislocation. The situation is much worse if the ulnar or radial nerves, with their accompanying vessels, are displaced into a fracture or compressed by haematoma.

The collateral circulation at the knee is particularly poor. Acute loss of flow through the popliteal artery, unless urgently restored, invariably leads to extensive death of muscle and nerve, and often to amputation.

Fig. 6.2.3 Fracture of left proximal humerus, complicated by expanding haematoma in a 63-year-old man. Two attempts to occlude the torn posterior circumflex artery by interventional radiology failed. He was seen at 8 weeks, by which time he was in right heart failure and in great pain; he had a complete infraclavicular plexopathy on the left side. Six litres of altered blood were removed from the axilla; his pain was relieved. Recovery was particularly poor in the radial and median nerves. A, An MR angiogram before operation. B, The left hand 4 years after operation. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 6.2.4 Recovering femoral palsy from haematoma in the femoral triangle in a 69-year-old farmer who was taking warfarin after aortic valve replacement. Two months previously he had injured his thigh whilst vaulting a gate. He experienced severe pain for 24 hours but this recovered spontaneously. The area of sensory loss is outlined and the site of the Tinel's sign is also marked. Recovery was good but not complete by 6 months. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 6.2.5 A, 'Closed' intramedullary nailing of a fracture of a long bone. The tibial nerve and the posterior tibial artery were involved in the fracture. B, The muscles of the deep flexor compartment were fibrosed, causing severe clawing of the toes. ## Thoracic outlet syndromes

Rolfe Birch

Thoracic outlet syndromes (TOS) are amongst the most confusing and controversial of peripheral nerve disorders. Several different entities are grouped under this one heading but they have little in common beyond the presumed site of the lesion. The lower part of the brachial plexus, and the lower trunk in particular, joined at the first rib by the subclavian vessels, run a regular obstacle course on their way to the lower borders of pectoralis minor. Some of the more important obstacles will be described here.

## Suprapleural membrane (Sibson's fascia)

In its pure form, the suprapleural membrane is a thin, fan-shaped structure attached anteriorly to the internal border of the first rib, and posteriorly to the anterior border of the transverse process of the seventh cervical vertebra. It covers the apical pleura and intervenes between it and the subclavian artery. The deep part of the membrane may be quite tough and aponeurotic (Fig. 6.3.1). The extent of its peripheral attachment varies. Scalenus minimus is the muscle that sometimes replaces the deep or posterior part of the membrane; it may be up to 10 mm in diameter in its widest part but is usually much smaller than that. The posterior border of the membrane forms, with the edge of the first rib, the foramen through which the first thoracic nerve escapes.

## First rib

The broad first rib (see Fig. 53.9A) has a surface that is more horizontal than vertical. It extends over the apical pleura and curves round to the costochondral junction and then to the manubrium (see Fig. 53.8). In the healthy state, the apical pleura is easily separable from the head and neck, and most of the underside of the first rib; anteriorly, it becomes rather adherent to the underside of the rib, in relation to the costochondral junction. Scalenus medius is attached to the upper surface of the rib posteriorly. The upper portion of the nerve to serratus anterior is usually formed in scalenus medius by branches from the ventral primary rami of C4, 5 and 6; it emerges from the lateral surface of the muscle to be joined by a contribution from C7. Anterior to scalenus medius, the surface of the rib is, in the adult, grooved by the passage of the ventral primary ramus of T1 and the lower trunk of the brachial plexus. There is a distinct tubercle at the attachment of scalenus anterior; the subclavian artery lies in a slight depression posterior to the tubercle, and the subclavian vein runs over the upper surface of the rib anterior to the tubercle. The intercostal muscles are attached to the edge of the rib. The lower part of the cervicothoracic (stellate) ganglion lies on the head of the first rib, deep to the proximal part of the vertebral artery as it arises from the first part of the subclavian artery (see Fig. 29.18). The major part of the ventral primary ramus of T 1 is at first below the rib, then medial to its edge. The preganglionic (sympathetic) ramus of T1 connects it to the stellate ganglion; the postganglionic ramus is less noticeable. The size and disposition of scalenus anterior vary: it may bifurcate to include the artery; it may be bulky and its tendon may curve posteriorly round the artery to form a kind of snare. Deep to scalenus anterior, a very thin fascia covers the artery. The phrenic nerve, chiefly derived from the ventral primary ramus of C4, curves round the muscle to run down anterior to it into the thorax, lying, at first, posterior to the internal jugular vein and crossing behind the subclavian vein. The thoracic duct and the right lymphatic duct enter the brachiocephalic (innominate) vein at the subclavian-jugular (triradiate) junction on the left and right, respectively. All of the scalene muscles vary in formation and size. Bridges of muscle and fascia may pass between them, altering and diminishing the space available for the neurovascular bundles.

## Seventh cervical rib

Estimates of incidence range from $0.004 \%$ to $1 \%$. Cervical ribs are asymptomatic in most people. The extent of the rib, which is rarely symmetrical bilaterally, ranges from a prolongation and pointing of the seventh cervical transverse process to a complete rib in all respects like a first thoracic rib. The classification proposed by Sargent (1921) is illustrated in Figure 6.3.2, and is as follows: type 1, prolongation and pointing of the seventh cervical transverse process; type 2, short articulating rib with fibrous prolongation; type 3, jointed rib long enough to carry the eighth cervical nerve; type 4, jointed rib fused at its end with

Fig. 6.3.1 Entrapment of the lower trunk through an anomaly of the suprapleural membrane and scalenus medius. A, The right lower trunk is trapped between the aponeurotic edge of scalenus medius posteriorly and the suprapleural membrane anteriorly. B, A 'scalenus sickle' and an anomalous scalenus anterior. The left lower trunk passes over the edge of the sickle and behind the part of scalenus anterior that passes posterior to the subclavian artery. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 6.3.2 Variations of the seventh cervical rib (purple), ranging from elongation of the seventh cervical transverse process to a virtually complete additional rib (after Sargent 1921). (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. SpringerVerlag, London.)
the first rib or articulating with it; and type 5, a complete seventh cervical rib with cartilaginous union to the first costal cartilage or to the manubrium.

## Arterial thoracic outlet syndrome

Arterial TOS was the first of the syndromes to be recognized and the first to be treated surgically. Astley Cooper wrote, 'I have seen an exostosis arise from the $6^{\text {th }}$ or $7^{\text {th }}$ cervical vertebrae or perhaps from both' (Cooper and Travers 1817). He went on to describe the case of a woman who came into Guy's Hospital with no pulse at the wrist or elbow and with 'venous redness' of the upper limb, which was cold, 'ennumbed' and painful; she also had a projection of the lower cervical vertebrae towards the clavicle, with consequent pressure on the subclavian artery. Coote (1861) reported the removal of a left seventh cervical rib causing aneurysm of the subclavian artery. Two physicians, Lewis and Pickering (1934), pointed to the mechanism of production of the arterial lesion, namely: intimal breakage with local thrombosis and distal embolization. Arterial affection occurs as the subclavian artery crosses a 'normal' first rib or a seventh cervical rib, commonly one with bony union to,
or synchondrosis or synostosis with, a boss on the first rib at about its middle part. The vessel is distorted by the bone and constricted by a leash formed by the tendon of insertion of scalenus anterior. There is commonly dilation of the artery distal to the point of constriction, and the dilation may proceed to the formation of a true aneurysm (Wickham and Martin 1962). Complete obstruction of the main vessel with distal embolization may lead to critical ischaemia. The most dangerous complication is contralateral hemiplegia, doubtless from embolization from a thrombus extending proximally to the carotid vessel (Symonds 1927).

The arterial form of this outlet syndrome is a condition predominantly affecting young women; the occurrence of such symptoms in older individuals must suggest a primary diagnosis of atherosclerosis or other systemic disorder. The symptoms are initially those of a Raynaud's phenomenon with episodic blanching and temperature change, episodic pain with muscular activity, and distal ulceration and necrosis. The extremity may be cooler than the unaffected limb and there is likely to be a pulse difference, even the absence of a pulse. Even if the hands are the same colour at rest and slightly dependent, there is likely to be blanching of the affected hand on elevation. The artery is prominent, displaced upwards and anteriorly by the underlying rib; there is a loud
bruit and there may be a thrill. Doppler ultrasound examination is likely to show an abnormality: principally, a clamped, monophasic velocity signal anywhere over the arterial tree of the upper limb (Parry and Eastcott 1992). Radiographs will, of course, show a seventh cervical rib if one is present. Magnetic resonance angiography and duplex ultrasonography have generally superseded arteriography in this field, as in others, and will confirm the site and extent of the obstruction, the extent of stenosis and aneurysm formation, and the degree of distal occlusion (Fig. 6.3.3).

Operation is required urgently in cases of critical ischaemia, and soon in cases in which ischaemia is threatened. It may be indicated when a cervical rib is present, causing no symptoms but producing deformity of the subclavian artery sufficient to cause a steady bruit over the vessel, which must surely indicate distortion of the vessel that is

Fig. 6.3.3 Arterial thoracic outlet syndrome: angiographic appearances. A, Complete occlusion over a cervical rib. B, Complete occlusion at the thoracic outlet in a 40-year-old woman, a heavy smoker. C, Obstruction of the artery at the thoracic outlet on elevation of the limb. likely, in time, to cause intimal breakage and thrombosis. Arterial TOS is uncommon rather than rare and it is potentially dangerous. The bruit from a prominent subclavian artery associated with an underlying seventh cervical rib cannot be ignored and investigations need to be pursued to define the extent of distortion of the artery.

## Neurogenic thoracic outlet syndrome

Neurogenic TOS is rare. As Gilliatt (1984) pointed out, a number of cases were seen at the National Hospital for Nervous Diseases, Queen Square, London, UK, in the early years of the last century, with wasting of the thenar muscles that were attributed to a cervical rib. In fact, these patients probably had a carpal tunnel syndrome. The confusion was not resolved for more than 40 years until the application of nerve conduction studies defined the much more common disorder. Gilliatt put the annual incidence of cervical rib syndrome with muscle wasting as low as 1 in 1 million in the general population. The patients are usually young to middle-aged women and the abnormalities are usually confined to one upper limb. The symptoms are insidious and often mild; presentation is delayed for some years, and is usually occasioned by the sudden realization that the hand has become wasted. There is pain in the medial aspect of the forearm and there may also be some blunting of sensibility in that area and in the little finger. The latter is frequently shorter than it is in a normal, age-matched hand, suggesting that the affliction of the fibres in the lower trunk commenced before skeletal maturity. There is wasting of the superficial thenar muscles, which sometimes extends to all of the small muscles of the hands (Fig. 6.3.4)

Fig. 6.3.4 The classical neurogenic outlet syndrome; shortening of the little finger is often evident. A, Severe wasting of the intrinsic muscles of the right hand in a 35 -year-old woman. $\mathbf{B}$, The right lower trunk is seen angulated over a 'scalenus sickle' and there is extreme attenuation of the trunk, which, in the photograph, appears to be rather lateral to the sickle. When the nerve was first exposed at operation, the zone of attenuation was, in fact, at the site of angulation. There was slow improvement after decompression. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
and there may be weakness of the flexor muscles of the forearm, most evident in those innervated by the ulnar nerve. There may be a bruit over the subclavian artery. Radiographs of the neck show rudimentary cervical ribs or elongated transverse processes of the seventh cervical vertebrae. The diagnostic electrophysiological findings were characterized by Gilliatt, Le Quesne and Logue in 1970 and include a small or absent sensory response in the ulnar nerve and the medial cutaneous nerve of the forearm; a normal sensory response in the median nerve; an attenuated compound motor action potential amplitude from abductor pollicis brevis; and a low-amplitude ulnar motor response (Smith and Knight 2011). Operation is indicated in these patients in the expectation of alleviation of pain, improvement in sensation and some improvement in strength; recovery of the wasted small muscles of the hand is rare.

## Neural thoracic outlet syndrome without plain motor signs

Neural TOS without plain motor signs is more common and more difficult. Patients present with symptoms and signs consistent with a diagnosis of TOS but studies of blood flow and nerve conduction are normal. It is important to seek causes of the symptoms beyond the apparent diagnosis and to remember that the presence of a cervical rib does not, of itself, permit a diagnosis of TOS. The urge to advise operation should be tempered with knowledge of the possibility of complications and the high rate of recurrence of symptoms as time passes (Birch 2011).

The thorax is the upper part of the trunk. It consists of an external musculoskeletal cage, the thoracic wall, and an internal cavity that contains the heart, lungs, oesophagus, trachea and principal bronchi, thymus, vagus and phrenic nerves, right and left sympathetic trunks, thoracic duct, lymph nodes, and major systemic and pulmonary blood vessels. Inferiorly, the thorax is separated from the abdominal cavity by the diaphragm; superiorly, it communicates with the neck and the upper limbs. The thoracic wall offers protection to some of the abdominal viscera: the greater part of the liver lies under the right dome of the diaphragm; the stomach and spleen lie under the left dome of the diaphragm; and the posterior aspects of the superior poles of the kidneys lie on the diaphragm and are anterior to the twelfth rib on the right, and to the eleventh and twelfth ribs on the left (Fig. 51.1).

Variations in thoracic dimensions and proportions are partly individual and also linked to age, sex and race. At birth, the transverse diameter is relatively less than it is in the adult, but adult proportions develop as walking begins. Thoracic capacity is less in females than it is in males, both absolutely and proportionately: the female sternum is shorter, the thoracic inlet more oblique, and the suprasternal notch is level with the third thoracic vertebra, whereas it is level with the second thoracic vertebra in males. In all individuals, the size of the thoracic cavity changes continuously according to the movements of the ribs and diaphragm during respiration (Ch.55) and the degree of abdominal visceral distension.

Fig. 51.1 The thoracic wall and cavity. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

## MUSCULOSKELETAL FRAMEWORK

## BONES AND JOINTS

The thoracic skeleton consists of twelve thoracic vertebrae and their intervening intervertebral discs (midline, posterior), twelve pairs of ribs and their costal cartilages (predominantly lateral), and the sternum (midline, anterior). When articulated, they form an irregularly shaped osteocartilaginous cylinder, reniform in horizontal section, which is narrow above, broad below, flattened anteroposteriorly and longer behind (see Fig. 53.8). Laterally, the thoracic cage is convex and is formed by the ribs; anteriorly, it is slightly convex and is formed by the sternum and the distal parts of the ribs and their costal cartilages. The first seven pairs of ribs are connected to the sternum by costal cartilages, the costal cartilages of the eighth to tenth ribs usually join the superjacent cartilage, and the eleventh and twelfth ribs are free (floating) at their anterior ends. The posterolateral curvature of the ribs, from their vertebral ends to their angles, produces a deep internal groove, the paravertebral gutter, on either side of the vertebral column. The ribs and costal cartilages are separated by intercostal spaces, which are deeper anteriorly and between the upper ribs. Each space is occupied by three layers of flat muscles and their aponeuroses, neurovascular bundles and lymphatic channels.

The narrow thoracic inlet (superior thoracic aperture) typically measures 5 cm anteroposteriorly and 10 cm transversely. It is bounded by the first thoracic vertebral body posteriorly, the medial border of the first ribs on each side, and the superior border of the manubrium sterni anteriorly. It slopes down and forwards, so that the apex of the lung extends upwards into the neck behind the anterior end of the first rib; structures that pass between the thorax and the upper limb therefore pass over the first rib and the apices of the lungs and the apical pleurae.

The broad thoracic outlet (inferior thoracic aperture) is limited posteriorly by the twelfth thoracic vertebral body, posterolaterally by the twelfth rib and the distal end of the eleventh rib, anterolaterally by the distal cartilaginous ends of the seventh to tenth ribs (which unite and ascend to form the costal margin), and anteriorly by the xiphoid process. It is wider in the transverse plane than in the sagittal plane and slopes obliquely inferiorly and posteriorly, so that the thoracic cavity is deeper posteriorly than anteriorly.

The horizontal sternal plane is traditionally reported to pass through the intervertebral disc between the fourth and fifth thoracic vertebrae posteriorly and the manubriosternal joint (sternal angle or angle of Louis) at the level of the second costal cartilage anteriorly. Recent data place the sternal angle between the fourth thoracic vertebra and the upper half of the fifth thoracic vertebra in the majority of adults (Mirjalili et al 2012a). The sternal plane separates the superior mediastinum from the inferior mediastinum and marks the positions of the superior limits of the pericardium; the bifurcation of the pulmonary trunk; the origin of the arch of the aorta; the level at which the trachea bifurcates into right and left principal bronchi; and the site where the superior vena cava penetrates the pericardium to enter the right atrium.

## MUSCLES

## Intrinsic and extrinsic muscles

The intrinsic muscles of the chest wall are the intercostal muscles, subcostalis, transversus thoracis, levatores costarum and serratus posterior superior and inferior.

The uncommon variants, sternalis and rectus thoracis bifurcalis, are important clinically as they may mimic a focal density in medial breast craniocaudal mammograms and be encountered during reconstructive surgery of the breast and chest wall (p. 942).

The intercostal muscles occupy each of the intercostal spaces and are named according to their surface relations, i.e. external, internal and innermost. All except levatores costarum are innervated by the adjacent intercostal nerves derived from the ventral rami of the thoracic spinal nerves; levatores costarum are innervated by the dorsal rami of the thoracic spinal nerves. The intrinsic muscles can elevate or depress the rib and are particularly active in forced respiration; their primary action is believed to be to stiffen the chest wall, preventing paradoxical movement during inspiration.

The skeletal framework of the thoracic wall provides extensive attachment sites for muscles associated functionally with the neck, abdomen, back and upper limbs. Some of them (scalenes, infrahyoid strap muscles, sternocleidomastoid, serratus anterior, pectoralis major and minor, external and internal obliques, and rectus abdominis) function as accessory muscles of respiration and are usually active only during forced respiration; scalenus medius is active in quiet inspiration. Scalenus anterior, medius and posterior are described in Chapter 29. Trapezius, latissimus dorsi, rhomboid major, rhomboid minor, levator scapulae, pectoralis major and minor, subclavius and serratus anterior are described in Chapter 48. Rectus abdominis, external oblique and internal oblique are described in Chapter 61.

## Diaphragm

The diaphragm, a curved musculotendinous sheet attached to the circumference of the thoracic outlet and to the upper lumbar vertebrae, forms the floor of the thoracic cavity, separating it from the abdominal cavity (Ch. 55). The diaphragm is relatively flat centrally and domed peripherally, rising higher on the right side than on the left, an asymmetry that reflects the relative densities of the underlying liver and gastric fundus, respectively. From its most superior point on each side, the diaphragm slopes inferiorly to its costovertebral attachments; this slope is most marked posteriorly, where the space between the diaphragm and the posterior wall of the thorax is very narrow. The domes are higher in the supine position. During quiet respiration in the erect position, diaphragmatic excursion is about 2 cm in both sexes, increasing to around 7 cm during deep breathing (Boussuges et al 2009); values are greater in men and possibly increase further in the supine position (Takazakura et al 2004).

## Diaphragmatic openings

The inferior vena cava passes through an opening in the central tendon of the diaphragm to enter the right side of the mediastinum at the level of the eighth thoracic vertebra; the oesophagus passes through the muscular part of the diaphragm and enters the abdomen just to the left of the midline at the level of the tenth thoracic vertebra; and the descending thoracic aorta passes posterior to the diaphragm in the midline at the level of the twelfth thoracic vertebra (see Fig. 55.1). Other structures that pass between the thorax and abdomen include the right and left vagi, phrenic and subcostal nerves, thoracic duct, sympathetic trunks, thoracic splanchnic nerves, right and left superior epigastric arteries, and the hemiazygos and accessory hemiazygos veins.

According to a CT study, the inferior vena cava and the oesophagus traverse the diaphragm at the upper and lower borders, respectively, of the eleventh thoracic vertebra; these levels are lower than those based on cadaveric/radiographic studies (eighth and tenth thoracic vertebrae, respectively) (Mirjalili 2012a).

## THORACIC CAVITY

## PLEURAL CAVITIES

The right and left pleural cavities are separate compartments on either side of the mediastinum. Each encloses a lung and its associated bronchial tree, and vessels, nerves and lymphatics (Ch. 54). The walls are formed by a serous membrane, the pleura, arranged as a closed sac. The outer layer of the sac, the parietal pleura, lines the corresponding half of the thoracic wall and covers much of the diaphragm and structures occupying the middle region of the thorax. The inner or visceral layer is more delicate and adheres closely to the pulmonary surface, following the interlobar fissures. The two layers are continuous with each other around the hilar structures, and remain in close, though sliding, contact at all phases of respiration. The potential space between them is the pleural cavity, which is maintained at a negative pressure by the inward elastic recoil of the lung and the outward pull of the chest wall. The lungs do not fill this space in quiet respiration, but move into
recesses such as the costodiaphragmatic recess, which separates the costal and diaphragmatic pleura, in deep breathing.

The left pleural cavity is the smaller of the two pleural cavities because the heart extends further to the left.

## MEDIASTINUM

The mediastinum lies between the right and left pleural sacs in and near the median sagittal plane of the chest (Ch. 56). It extends from the sternum anteriorly to the vertebral column posteriorly. A horizontal plane passing through the manubriosternal joint, and the intervertebral disc between the fourth and fifth thoracic vertebrae separates the mediastinum into superior and inferior portions.

## Superior mediastinum

The superior mediastinum lies between the manubrium sterni anteriorly and the upper thoracic vertebrae posteriorly, and is limited laterally by the pleurae. Its inferior boundary is a slightly oblique plane that passes backwards from the manubriosternal joint to the lower part of the body of the fourth thoracic vertebra. It contains the lower ends of sternohyoid, sternothyroid and longus colli on each side; the aortic arch, brachiocephalic trunk and thoracic portions of the left common carotid and left subclavian arteries; the brachiocephalic veins and upper half of the superior vena cava; the left highest intercostal vein; the vagus, cardiac, phrenic and left recurrent laryngeal nerves; and the trachea, oesophagus, thoracic duct, thymic remnants and lymph nodes.

## Inferior mediastinum

The inferior mediastinum is divided into three parts: anterior, in front of the pericardium; middle, containing the pericardium and its contents (Ch. 57); and posterior, behind the pericardium.

Anterior mediastinum The anterior mediastinum exists only on the left side where the left pleura diverges from the mid-sternal line. It is bounded anteriorly by the sternum, laterally by the pleurae, and posteriorly by the pericardium. It is narrow above but widens a little below. Its anterior wall is formed by the left transversus thoracis and the fifth to seventh left costal cartilages. It contains a quantity of loose areolar tissue, lymphatic vessels that ascend from the convex surface of the liver, two or three anterior mediastinal lymph nodes, and the small mediastinal branches of the internal thoracic artery.

Middle mediastinum The middle mediastinum is the broadest part of the interpleural space; it contains the heart enclosed in the pericardium; the ascending aorta; the lower half of the superior vena cava with the azygos vein opening into it; the bifurcation of the trachea and the right and left principal bronchi; the pulmonary artery dividing into its two branches; the right and left pulmonary veins and phrenic nerves; and some bronchial lymph nodes.

Posterior mediastinum The posterior mediastinum is an irregular triangular space, bounded anteriorly by the pericardium above and the posterior surface of the diaphragm below, posteriorly by the vertebral column from the lower border of the fourth to the twelfth thoracic vertebrae, and laterally by the mediastinal pleura. It contains the thoracic part of the descending aorta, the azygos and hemiazygos veins, the vagus and splanchnic nerves, oesophagus, thoracic duct and lymph nodes.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES

The skin of the thorax is supplied by direct cutaneous vessels and musculocutaneous perforators, which reach the skin primarily via the intercostal muscles, pectoralis major, latissimus dorsi and trapezius. Branches from the thoraco-acromial axis, lateral thoracic, internal thoracic, anterior and posterior intercostal, thoracodorsal, transverse cervical, dorsal scapular and circumflex scapular arteries are the major contributing vessels (see Figs 43.4, 53.1-53.2).

Muscles of the thoracic wall receive their blood supply from the internal thoracic artery (either directly or via the musculophrenic artery), the superior intercostal artery (from the costocervical trunk), superior thoracic artery (from the axillary artery), descending thoracic

Fig. 51.2 Arteries of the thoracic wall and thoracic aorta. (With permission from Drake RL, Vogl AW, Mitchell A, Tibbitts R, Richardson P (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)
aorta, and the subcostal artery (Fig. 51.2). Additional contributions come from vessels that supply the proximal muscles of the upper limb, namely: suprascapular, superficial cervical, thoraco-acromial, lateral thoracic and subscapular arteries.

The detailed arterial supply of the thoracic viscera is described with the viscera.

## VEINS

The intercostal veins accompany the similarly named arteries in the intercostal spaces (Fig. 51.3). The small anterior intercostal veins are tributaries of the internal thoracic and musculophrenic veins; the internal thoracic veins drain into the appropriate brachiocephalic vein. The posterior intercostal veins drain backwards, and most drain directly or indirectly into the azygos vein on the right and the hemiazygos or hemiazygos veins on the left. The azygos veins exhibit great variation in their origin, course, tributaries, anastomoses and termination.

## LYMPHATIC DRAINAGE

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see Fig. 53.22). Lymph vessels from deeper tissues of the thoracic walls drain mainly to the parasternal, intercostal and diaphragmatic lymphatic nodes.

## INNERVATION

## THORACIC SPINAL NERVES

There are twelve pairs of thoracic spinal nerves. The ventral rami, unlike their cervical and lumbar counterparts, have retained a largely segmental distribution to the body wall (see Figs 16.10, 53.3). The upper eleven lie between the ribs (intercostal nerves), and the twelfth lies below the last rib (subcostal nerve). Each is connected with the adjoining ganglion

Fig. 51.3 Veins of the thoracic wall and azygos system. (With permission from Drake RL, Vogl AW, Mitchell A, Tibbitts R, Richardson P (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)
of the sympathetic trunk by pre- and postganglionic branches (white and grey rami communicantes, respectively). Intercostal nerves are distributed primarily to the thoracic and abdominal walls. The greater part of the first thoracic ventral ramus passes into the brachial plexus, together with a variable proportion of the second. The next four ventral supply only the thoracic wall, and the lower five supply both thoracic and abdominal walls. The subcostal nerve is distributed to the abdominal wall and the gluteal skin. Communicating branches link the intercostal nerves posteriorly in the intercostal spaces, and the lower five nerves communicate freely in the abdominal wall. Thoracic dorsal rami divide into medial and lateral branches that supply the intrinsic muscles of the back and the overlying postvertebral skin on a segmental basis (see Fig. 43.3).

The supraclavicular branches of C4 from the cervical plexus innervate the skin over the clavicle and may communicate with the anterior cutaneous branches of the second thoracic ventral ramus (p. 443).

## AUTONOMIC INNERVATION

The autonomic nervous system in the thorax consists of right and left sympathetic trunks and vagus nerves, and the cardiac, oesophageal and pulmonary plexuses.

## Sympathetic trunks

The ganglionated sympathetic trunks lie anterior to the heads of the ribs; the ganglia are arranged segmentally (see Fig. 56.6). Preganglionic sympathetic axons originate from neurones in the lateral grey column of the spinal cord from T1 to L2, and leave the spinal cord with the corresponding ventral roots as white rami communicantes. Their targets vary. Some enter the sympathetic trunk, where they either synapse in their segmental ganglion, or ascend or descend in the trunk to synapse in cervical or lumbar ganglia. Many of the preganglionic axons that
originate in the lower thoracic spinal segments (T5-12) do not synapse locally but enter the abdominal cavity as the thoracic splanchnic nerves; they synapse either in prevertebral ganglia, especially the coeliac ganglion (Ch. 59), or around the medullary chromaffin cells of the suprarenal gland (Ch. 71). Axons destined for the cervical ganglia are derived from preganglionic neurones in T1.

## Vagus nerves in the thorax

Preganglionic parasympathetic fibres arise from neuronal cell bodies in the dorsal motor nucleus of the vagus in the medulla. Those destined for the thoracic viscera travel in the pulmonary, cardiac and oesophageal branches of the vagus and synapse in minute ganglia in the visceral walls. Axons travelling in cardiac branches join the cardiac plexuses and synapse in ganglia distributed over both atria; when stimulated, they slow the cardiac cycle (Ch. 57). Pulmonary branches contain axons that relay in ganglia of the pulmonary plexuses; they are motor (bronchoconstrictor) to the circular non-striated muscle fibres of the bronchi and bronchioles, and secretomotor to the mucous glands of the respiratory epithelium.

## Autonomic plexuses in the thorax

Cardiac plexus The cardiac plexus has a superficial component inferior to the aortic arch, lying between it and the pulmonary trunk, and a deep part between the aortic arch and tracheal bifurcation (Ch. 57). The superficial part is formed by the cardiac branch of the left superior cervical sympathetic ganglion and the lower of the two cervical cardiac branches of the left vagus. The deep part is formed by the cardiac branches of the cervical and upper thoracic sympathetic ganglia and of the vagus and recurrent laryngeal nerves. The only cardiac nerves that do not join it are those that join the superficial part of the plexus. Branches from the cardiac plexuses also form the left and right coronary and atrial plexuses.

Pulmonary plexus The pulmonary plexuses are anterior and posterior to the other structures at the hila of the lungs (Ch. 54). They are formed by cardiac branches from the second to fifth (or sixth) thoracic sympathetic ganglia and from the vagus and cervical sympathetic cardiac nerves. The left plexus also receives branches from the left recurrent laryngeal nerve.

Oesophageal plexus The oesophageal plexus surrounds the oesophagus below the level of the lung roots (Ch. 56). Vagal fibres either pass through the plexus or are given off directly by the vagus in the thorax. All fibres relay in the oesophageal wall and are motor to the smooth muscle in the lower oesophagus and secretomotor to mucous glands in the oesophageal mucosa. Vasomotor sympathetic fibres arise from the upper six thoracic spinal cord segments. Those from the upper segments synapse in cervical ganglia; postganglionic axons innervate the vessels of the cervical and upper thoracic oesophagus. Fibres from the lower segments pass directly to the oesophageal plexus or to the coeliac ganglion, where they synapse; postganglionic axons innervate the vessels of the distal oesophagus.

## SURFACE ANATOMY

In clinical practice, an evidence-based knowledge of thoracic surface anatomy underpins practical procedures such as placing drains or catheters and siting surgical incisions. The accuracy of some older descriptions of clinically important surface landmarks, based on cadaveric or radiographic studies, has been questioned recently (Hale et al 2010). Cross-sectional computed tomography (CT) imaging, undertaken with subjects supine, at end tidal inspiration, and with arms abducted, has emphasized a greater inter-individual variation in some thoracic surface anatomy landmarks than appears in the current anatomical literature (Mirjalili et al 2012a).

## BREAST

In females, the base of the breast is relatively constant in position; it extends vertically from the second or third to the sixth rib, and from the lateral sternal border medially almost to the mid-axillary line laterally. The tail of the breast extends towards the axilla along the inferolateral border of pectoralis major (Ch. 53). In adult females, the site of
the nipple is dependent on the size and shape of the breasts. In adult males, the nipple is usually sited either in the fourth intercostal space or over the fifth rib in the mid-clavicular line, approximately 20 cm from the sternal notch and mid-clavicular point (Beckenstein et al 1996). The pigmented areola surrounding the nipple varies in size.

## SKELETAL LANDMARKS

Anteriorly, the clavicle, sternoclavicular and acromioclavicular joints are both palpable and visible in all but obese individuals (Fig. 51.4). The sternum may be felt throughout its length in the midline, although laterally it may be covered by pectoralis major. The jugular (suprasternal) notch is palpable in the midline at the superior sternal border and typically lies at the level of the junction between the second and third thoracic vertebrae. The cartilaginous rings of the trachea are palpable immediately superior to the notch, using a posteriorly directed finger. The manubriosternal angle is more pronounced in the male than in the female, and is palpable at the junction of the manubrium with the sternal body. It serves as a useful landmark because it indicates the level of the sternal plane and the medial ends of the second costal cartilages, and so offers an accurate point at which to start counting ribs. In the majority of adults, the sternal angle is located between the fourth thoracic vertebra and the upper half of the fifth thoracic vertebra, with a range from the lower half of the second thoracic vertebra to the lower half of the sixth thoracic vertebra, a linear distance of about 8 cm ; the plane lies at a slightly higher vertebral level in women. The xiphisternal joint and xiphoid process are palpable at the inferior end of the sternum; the joint usually lies at the level of the ninth thoracic vertebra. The costal margin is palpable passing inferolaterally from the xiphisternum. Posteriorly, the free ends of the eleventh and twelfth ribs may be

Fig. 51.4 Surface anatomy of the anterior thorax. Key: 1, right acromioclavicular joint; 2, clavicle and mid-clavicular line (dashed black); 3, apex of right lung, located posterior to the medial third of the clavicle; 4, sternal notch of manubrium sterni: the trachea may be located here by posterior palpation; 5, sternoclavicular joint: marks the junction of the internal jugular and subclavian veins to form the brachiocephalic vein; 6, zone of formation of the superior vena cava: from first intercostal space to second costal cartilage level (78\% of subjects, white zone); 7, sternal angle: marks the level of the sternal plane and the second costal cartilage; 8, pectoralis major and the anterior axillary fold; 9 , horizontal fissure; 10, right oblique fissure; 11, lower anterior border of the right lung: typically, either the sixth intercostal space or the seventh rib in the mid-clavicular line; 12, lower anterior border of the left lung: typically, either at the fifth rib or fifth intercostal space in the mid-clavicular line; 13, xiphisternum; 14, costal margin; 15, tenth costal cartilage, forming the lower part of the costal margin. A-D and blue line: conventional surface markings of the heart. A overlies the left second costal cartilage; B overlies the right third costal cartilage; $\mathrm{B}^{*}$, zone of the superior vena cava meeting the right atrium from the fourth to fifth costal cartilage in $71 \%$ of subjects at end tidal inspiration (from CT data); C, right sixth costal cartilage; $D$, zone of location of the cardiac apex: almost always from the level of the fifth to the sixth rib, and a mean of $8.7 \pm 1 \mathrm{~cm}$ from the midline.

Fig. 51.5 Surface anatomy of the posterior thorax. The levels of the spinous processes of the third, ninth and twelfth thoracic vertebrae and the first lumbar vertebra are indicated in the midline. Key: 1, border of the left lung; 2, oblique fissure: passes anteroinferiorly from the spinous process of the third thoracic vertebra to cross the fifth rib in the midaxillary line. The upper lobe sits superiorly and the lower lobe inferiorly; 3 , lower border of the lung: this is often located at level of the twelfth thoracic vertebra but may be lower, at the level of the first lumbar vertebra, adjacent to the vertebral column at end tidal inspiration. Dashed blue lines indicate the range of levels for the lower border of the lung (ninth thoracic vertebra to first lumbar vertebra); 4, twelfth rib: can be traced superomedially to aid identification of the spinous process of the twelfth thoracic vertebra.
palpable. Tracing the twelfth rib superomedially aids identification of the spinous process of the twelfth thoracic vertebra (Fig. 51.5). In thin individuals, it is possible to palpate all the ribs anteriorly, from the first to the costal margin. Posteriorly, the spinous processes of the thoracic vertebrae are palpable; the spinous process of the first thoracic vertebra sits below that of the seventh cervical vertebra (vertebra prominens) and is often more prominent. The angles of the ribs are palpable several centimetres lateral to the spinous processes of the vertebrae.

The surface anatomy of the back is described in Chapter 43.

## MUSCULOTENDINOUS LANDMARKS

In a lean, muscular subject, pectoralis major, the slips of serratus anterior, latissimus dorsi, trapezius, external oblique and rectus abdominis are all easily visible. In females, the breasts may significantly obscure the anterior thoracic wall.

## INTRATHORACIC VISCERA

The sternal plane represents the lower border of the superior mediastinum. At this point, the right and left pleurae are in contact with each other; it is therefore a useful starting point when delineating the surface markings of the parietal pleura (see Fig. 51.7). The sternal plane is conventionally described as lying over the tracheal bifurcation, the concavity of the aortic arch and the point where the azygos vein enters the superior vena cava. CT analysis places these three major surface landmarks typically a little lower, at the level of the fifth or sixth thoracic vertebra rather than in the plane of the sternal angle (between the fourth and fifth thoracic vertebrae) (Mirjalili et al 2012a) (Fig. 51.6; Table 51.1).

## Heart

The cardiac surface projections described below apply to an average adult. They may be modified by age, sex, stature, ventilation, the position of the diaphragm and posture (Macklin 1925). The projection of the cardiac borders on to the anterior thoracic wall forms a trapezoid. The area of cardiac dullness may be mapped out via percussion.

The upper border slopes gently from the second left costal cartilage to the third right costal cartilage (see Fig 51.4). CT analysis places the

Fig. 51.6 Surface anatomy of the great vessels and tracheobronchial tree relative to bony landmarks. Key: 1, internal jugular vein; 2, subclavian vein; 3, formation of the brachiocephalic vein posterior to the sternoclavicular joints; 4, formation of the superior vena cava, posterior to the right second costal cartilage or first intercostal space; 5 , manubriosternal joint, 6, concavity of the aortic arch, typically sitting inferior to the sternal plane, level with the upper half of the fifth thoracic vertebra; 7, azygos vein entering the superior vena cava: typically, it sits inferior to the sternal plane, level with the lower half of the fifth thoracic vertebra; 8, tracheal bifurcation: typically, it sits inferior to the sternal plane, level with the upper half of the sixth thoracic vertebra; 9, bifurcation of the pulmonary trunk, level with the upper half of the sixth thoracic vertebra, approximately 3 cm inferior to the sternal angle. (Redrawn with permission from Mirjalili S, Hale S, Buckenham T, Wilson B, Stringer M. 2012. A reappraisal of adult thoracic surface anatomy. Clin Anat 25:827-34.)

Table 51.1 The level of key thoracic viscera relative to the sternal plane and vertebrae

|  | Mean position relative to sternal plane (Range, cm) | Most common position/level (frequency \% of 153 subjects studied) | Sex differences ( $95 \% \mathrm{Cl}$ ) |
| :---: | :---: | :---: | :---: |
| Tracheal bifurcation | $\begin{aligned} & -3.1 \mathrm{~cm} \\ & (0 \text { to }-7.5) \end{aligned}$ | T6 (46\%) (lower T4 to lower T7) | 1.3 cm higher in females <br> ( $0.8-1.8 \mathrm{~cm}: \mathrm{p}<0.001$ ) |
| Aortic arch concavity | $\begin{aligned} & -1.1 \mathrm{~cm} \\ & (+2.8 \mathrm{to}-4.8) \end{aligned}$ | T5 (55\%) (lower T3 to lower T6) | 0.6 cm higher in females ( $0.1-1.1 \mathrm{~cm}: p=0.01$ ) |
| Azygos vein joining the superior vena cava | $\begin{aligned} & -2 \mathrm{~cm} \\ & (+1.3 \text { to }-6.4) \end{aligned}$ | T5 (49\%) (upper T4 to upper T7) | 0.7 cm higher in females (0.3-1.2 cm: $p=0.001$ ) |
| Pulmonary trunk bifurcation | Not reported | T6 upper (28\%) (T4/5 to T7/8) | No significant effect |

Measurements relative to the sternal plane are shown as + (superior to the plane) and - (inferior to the plane). Adapted from Mirjalili S, Hale S, Buckenham T, Wilson B, Stringer M. 2012. A reappraisal of adult thoracic surface anatomy. Clin Anat. Oct;25(7):827-34.
latter point, as represented by the junction between the superior vena cava and right atrium, most commonly between the fourth and fifth right costal cartilages. The right border is a gently curved line, convex to the right, running from the third to the sixth right costal cartilages, usually $1-2 \mathrm{~cm}$ lateral to the sternal edge. The inferior or acute border runs leftwards from the sixth right costal cartilage to the cardiac apex, located approximately 9 cm lateral to the midline, often in the left fifth intercostal space or level with the fifth or sixth rib. Clinicians vary when locating the mid-clavicular line (Naylor et al 1987); a measurement from the midline is preferable. The most inferolateral point at which a pulsation is visible and palpable is called the cardiac apex beat and is usually palpable near the cardiac apex.

The left ('obtuse') border is convex laterally and extends superomedially from the cardiac apex to meet the second left costal cartilage approximately 1 cm from the left sternal edge. An oblique line joining the sternal end of the third left and sixth right costal cartilages
represents the anterior part of the coronary sulcus/atrioventricular groove, which separates the right atrium from the right ventricle. The projections of the cardiac valves, although in different planes, are also sited along or close to this line (see Fig. 57.19). The orifice of the pulmonary valve is represented by a horizontal line approximately 2.5 cm long that lies over the superior border of the left third costal cartilage and behind the corresponding region of the sternum. The pulmonary trunk is delineated by two parallel lines drawn perpendicular to the ends of the pulmonary valve line, up to the level of the left second intercostal space. The orifice of the aortic valve is located below and to the right of the orifice of the pulmonary valve, and is represented by a line approximately 2.5 cm long running inferolaterally and to the right from the medial end of the left third intercostal space. Two parallel lines, drawn perpendicular to the ends of the valve line and slanting up towards the right half of the manubriosternal joint, outline the location of the ascending aorta.

The orifice of the tricuspid valve is represented by a line approximately 4 cm long that starts near the midline just below the level of the right fourth costal cartilage and passes down and slightly to the right. The centre of this line should be level with the middle of the right fourth intercostal space. The orifice of the mitral valve is level with the left half of the sternum opposite the left fourth costal cartilage and is represented by a line approximately 3 cm long and descending to the right.

The direction of blood flow through a valve carries the valve sound with it and thus the sites of cardiac valve auscultation do not correspond to the surface anatomy of the valves. Convenient sites at which to auscultate using a stethoscope are: the sternal end of the left second intercostal space (pulmonary area); the sternal end of the right second intercostal space (aortic area); near the cardiac apex (mitral area); and over the left lower sternal border, at the level of the fifth intercostal space (tricuspid area) (see Fig. 57.19).

## Great vessels

The aortic arch lies mainly posterior to the manubrium (see Fig. 51.6). The concavity of the arch sits approximately 1 cm inferior to the sternal plane, level with the upper half of the fifth thoracic vertebra (range 2.8 cm superior to 4.8 cm inferior). Starting at the aortic valve (see above), the ascending aorta curves anteriorly, superiorly and to the right, and becomes the aortic arch posterior to the right half of the manubrium at the level of the right second costal cartilage. It continues to ascend to the right side of the manubrium sterni, then arches to the left across or over the sternal plane and descends such that the aortic knuckle protrudes just to the left of the manubrium sterni around the first intercostal space. The brachiocephalic trunk arises approximately posterior to the centre point of the manubrium sterni and ascends to the right sternoclavicular joint. The left and right brachiocephalic veins are formed posterior to the sternoclavicular joints; the right brachiocephalic vein descends almost vertically, whereas the left brachiocephalic vein passes posterior to the superior portion of the manubrium sterni. According to conventional descriptions, the superior vena cava forms posterior to the right first costal cartilage and descends vertically to enter the right atrium at the level of the right third costal cartilage. CT data show that it commonly forms posterior to the right second costal cartilage or first intercostal space and the associated part of the manubrium sterni, and joins the right atrium between the right fourth and fifth costal cartilages; the level at which it forms is higher in females and younger adults. The azygos vein enters the superior vena cava approximately 2 cm inferior to the sternal plane at the level of the lower part of the fifth thoracic vertebra.

## Lungs and pleurae

Anteriorly, the apex of the lung sits posterior to the medial third of the clavicle; posteriorly, it lies level with the seventh cervical vertebra (see Fig. 51.4). The surface markings of both the apex and costovertebral border of the lung correspond to those of the parietal pleura. Conventionally, the surface projection of the lower border of the lung is represented by a curved line that crosses the mid-clavicular line at the sixth rib, the mid-axillary line at the eighth rib and the tenth rib just lateral to the vertebral column. CT data reveal considerable variation, redefining the lower lung border, at the end of tidal inspiration, as lying mainly behind the fifth rib/fifth intercostal space on the left, or the sixth intercostal space/seventh rib on the right in the mid-clavicular line, and adjacent to the twelfth thoracic vertebra posteriorly (ranging from the ninth thoracic to the first lumbar vertebra). In full expiration, the lower margin of the lung may rise 5 cm above the parietal pleural
reflection (the costodiaphragmatic recess) and may retreat from the retrosternal costomediastinal recess.

## Trachea and bronchi

The trachea starts at the level of the inferior border of the cricoid cartilage, which usually sits at the level of the seventh cervical vertebra (range C5 to T1) (Mirjalili et al 2012b). It runs inferiorly in the midline and bifurcates level with the upper half of the sixth thoracic vertebra, i.e. inferior to the sternal angle, and lower than was previously believed (see above). The trachea is palpable immediately superior to the suprasternal notch either by rolling one finger over its convex surface or by defining its lateral extents with two fingers. A shift to one side indicates that the mediastinum has either been pulled over to that side by loss of lung volume, or pushed over by a pneumothorax or pleural effusion. The level at which the trachea bifurcates moves down, on average, by a mean of 3 mm per decade.

## Pulmonary fissures

On either side, the upper and lower lobes of the lung are separated by the oblique fissure. This can be marked by a line that runs anteroinferiorly from the posterior end of the fourth rib (spinous process of the third thoracic vertebra), crosses the fifth rib in the mid-axillary line and continues inferiorly, crossing either the sixth intercostal space/seventh rib on the right or the fifth rib/intercostal space on the left, on both sides at the mid-clavicular line (i.e. $7-8 \mathrm{~cm}$ lateral to the midline). As a convenient approximation, the oblique fissure follows the medial border of the scapula when the upper limb is in full abduction. The left oblique fissure may be slightly more vertical than the right.

The horizontal fissure lies between the upper and middle lobes of the right lung (see Fig. 51.4; Fig. 51.7). It extends from the fourth costal cartilage at the right sternal border to intersect the oblique fissure. The right middle lobe may be projected on to the thoracic wall using three points, namely: the fourth costal cartilage at the right parasternal edge, the fifth rib at the mid-axillary line and the sixth intercostal space/seventh rib at the mid-clavicular line. The upper and middle lobes lie anterior to the oblique fissure and are best examined from in front and to the side. The lower lobes lie posteriorly and should be examined from behind.

## Pleural reflections

Starting in the midline at the sternal angle, the anterior reflections of the parietal pleura may be traced superiorly along a curved line that diverges from the midline and extends up and outwards to the apex of the lung and pleural cavity (see Fig. 51.4). The line lies $3-4 \mathrm{~cm}$ above the anterior end of the first rib; the surface marking is posterior to the

Fig. 51.7 The relation of the pleura and lungs to the chest wall, right lateral aspect.
medial third of the clavicle. The right and left pleurae are in contact retrosternally in the midline from the second to the fourth costal cartilages, at which point they diverge. The pleura on the right descends vertically to the xiphisternum, whereas the pleura on the left deviates laterally by $3-5 \mathrm{~cm}$ and then passes inferiorly to cross the anterior end of the sixth rib. This deviation produces an area between the heart and the sternum that is free of pleura; a needle puncture of the heart may be performed at this site without risk of damaging the pleura.

The costodiaphragmatic reflections of the pleurae may be followed around the chest wall from the sixth rib/costal cartilage anteriorly to the eighth rib in the mid-clavicular line, tenth rib in the mid-axillary line and twelfth rib, or just below, adjacent to the vertebral column. Viewed from behind, the medial edges of the pleurae may be followed along a line joining the transverse processes of the second to the twelfth thoracic vertebrae on either side.

The parietal pleura is fused with the inner aspect of the thoracic cavity and can be followed laterally and inferiorly down the inner aspect of the thoracic wall to the level of the tenth rib in the mid-axillary line
(see Fig. 51.4). The position of the diaphragmatic pleura varies according to the phase of ventilation.

## Diaphragm

The dome of the diaphragm is often located level with the fifth intercostal space on the right and the sixth rib on the left; it ranges widely, from the fourth intercostal space to below the costal margin. Conventionally, the diaphragm is said to be traversed by the inferior vena cava at about the level of the disc between the eighth and ninth thoracic vertebrae, the oesophagus at the level of the tenth thoracic vertebra and the aorta at the level of the lower border of the twelfth thoracic vertebra and the adjacent disc, slightly to the left of the midline. CT assessment reveals that the inferior vena cava and the oesophagus frequently pass through the diaphragm at levels slightly lower than those predicted from chest radiographs, at the level of the eleventh thoracic vertebra (Mirjalili et al 2012a).

## Development of the thorax

## cumber 52

## THORACIC WALL AND DIAPHRAGM

The thorax as an entity is not apparent in embryos until the end of the embryonic stage of development (stage 23). It develops around the early pericardial cavity and the associated pericardioperitoneal canals (Fig. 52.1A; see Fig. 52.3A). The pericardioperitoneal canals give rise to the pleural cavities surrounding the lungs and that part of the peritoneal cavity surrounding the lower end of the foregut, which becomes the distal oesophagus, stomach and proximal duodenum. Later, these portions of peritoneal cavity are sequestered into the abdominal cavity by the development of the diaphragm.

In stage 14 embryos, the heart is at the level of the upper cervical somites and above the upper limb buds. The thoracic somites are opposite the midgut. The putative thoracic region contains the pericardial cavity ventrally and the pericardioperitoneal canals posteriorly, on each side of the foregut. The future pleural cavities are as yet undefined regions of the pericardioperitoneal canals. Below the heart, septum transversum mesenchyme is being invaginated by endodermal epithelial cells from the foregut hepatic primordium.

The heart and pericardial cavity are relatively large in the early embryo (Fig. 52.1B; see Fig. 52.3A). Throughout development, the lungs remain unexpanded and do not achieve their full size within the thorax, reflecting the fact that the placenta, and not the lungs, is the organ of fetal respiration. The lower partition of the thorax, the diaphragm, can be identified in stage 13 embryos; it migrates caudally
in line with the craniocaudal progression of development and the elongation of the neck. The parietal pericardium remains attached to the diaphragm as it descends.

For the lungs to inflate and deflate, they must be surrounded by a complete pleural cavity slightly larger than the capacity of the lungs. The synchronous development of the thoracic cage, diaphragm and pleural cavities is, therefore, of vital importance for the normal development of the lungs and postnatal functioning of the respiratory system. Before birth, fetal breathing movements may be observed using ultrasonography. These can have no respiratory function, but it is thought that these phasic changes lead to the release of growth factors that promote normal lung development. These movements require an intact thoracic and abdominal cavity, so that the diaphragm can descend towards the rigid pelvic bowl, pushing out the abdominal wall. In conditions where this is not the case, e.g. exomphalos, the lungs may be smaller than normal. Other causes of interference with these movements include neuromuscular disorders of antenatal onset, such as severe spinal muscular atrophy and myotonic dystrophy inherited from the mother, and reduced volume of amniotic fluid, e.g. in Potter's syndrome (bilateral renal agenesis, oligohydramnios sequence).

The lung buds are invested by splanchnopleuric mesenchyme derived from the medial walls of the pericardioperitoneal canals, whereas the lateral walls produce somatopleuric mesenchyme, which contributes to the body wall. This latter mesenchyme is penetrated by the developing ribs, which arise from the thoracic sclerotomes. In the midline, the somatopleuric mesenchyme gives rise to the sternum and

Fig. 52.1 A, The arrangement of the epithelial populations in an embryo at about stage 11. The future thoracic region lies caudal to the pharynx and extends to the upper part of the septum transversum. B, The heart is shown in situ within the pericardial cavity. Venous tributaries return blood from the body, yolk sac and placenta, and arterial trunks pass each side of the pharynx. C, The respiratory diverticulum arises in the midline from the lower portion of the pharynx, and lung buds extend dorsally into the pericardioperitoneal canals.

Fig. 52.2 A, A dorsolateral view of the foregut between the pericardioperitoneal canals. The respiratory diverticulum arises from the ventral side of the pharynx and grows caudally. Bilateral lung buds extend dorsally into the pericardioperitoneal canals dorsolaterally. Later changes in position of the common cardinal veins contribute to the formation of the pericardiopleural membranes cranial to the developing lungs, whereas folds of coelomic epithelium, pleuroperitoneal membranes, separate the pleural cavities from the peritoneal cavity. B, Components of the diaphragm.
costal cartilages. The bony and cartilaginous cage provides insertions for the intercostal muscles, which arise from the ventrolateral edge of the epithelial plate of the somites. The somatopleuric coelomic epithelium, after its proliferative phase, contributes to the mesothelium of the parietal layer of pleura.

As the lung buds project into the pericardioperitoneal canals (Figs $52.1 \mathrm{C}, 52.2 \mathrm{~A}$ ), they subdivide them into primary pleural coeloms around the lung buds cranially, and paired peritoneal coeloms caudally, which are contiguous with the wider peritoneal coelom around the mid- and hindguts. The communications with the pericardial and peritoneal coeloms become termed the pleuropericardial and pleuroperitoneal canals, respectively. When separation between these fluid-filled major coelomic regions is advancing towards completion, they are named the pericardial, pleural and peritoneal cavities. In early embryos, the cavities retain substantial volumes of fluid and their walls are separate; they provide the route for a primitive type of circulation until superseded by the blood vascular system. In later fetal and postnatal life, the cavity walls are coapted, so that a mere microscopic film of serous fluid intervenes between them.

A curved elevation of tissue, the pulmonary ridge, develops on the lateral wall of the pleural coelom and partly encircles the pleuropericardial canal. The ridge is continuous with the dorsolateral edge of the septum transversum. The developing lung bud abuts on the ridge, which, as a result, divides into two diverging membranes meeting at the septum transversum. One is cranially placed and termed the pleuropericardial membrane (see Fig. 52.2A); embedded within it are the common cardinal vein and phrenic nerve, which reach the septum transversum by this route. The other membrane, caudally placed, is termed the pleuroperitoneal membrane (see Fig. 52.2A). As the apical part of the lung forms, it invades and splits the body wall, and extends cranially on the lateral aspect of the common cardinal vein, preceded by an extension from the primary pleural coelom to form part of the secondary, definitive, pleural sac. In this way, the common cardinal vein and the phrenic nerve come to lie medially in the mediastinum. The pleuropericardial canal, which lies medial to the vein, is gradually narrowed to a slit, which is soon obliterated by the apposition and fusion of its margins. Closure occurs early and is mainly effected by the growth and expansion of the surrounding viscera (heart and great vessels, lungs, trachea and oesophagus), and not by active growth of the pleuropericardial membrane across the opening to the root of the lung.

In addition to its extension in a cranial direction, the lung and its associated visceral and parietal pleurae also enlarge ventromedially and caudodorsally. With the ventromedial extension, the lungs and pleurae therefore excavate and split the somatopleuric mesenchyme over the pericardium, separating the latter from the ventral and lateral thoracic walls (Fig. 52.3B-D). The ventrolateral fibrous pericardium, parietal serous pericardium and mediastinal parietal pleura, although topographically deep, are, therefore, somatopleuric in origin.

## Congenital anomalies of the chest wall

The dorsal portion of the thorax is derived from somites, the sclerotomal portions of which form the thoracic vertebrae and ribs (Ch. 44). Vertebral anomalies, including formation of hemivertebrae and block vertebrae (where cranial and caudal sclerotomal halves do not separate), may contribute to scoliosis. Five per cent of scoliosis is congenital; it may be associated with multiple other anomalies, e.g. the VACTERL
(vertebral; anorectal; cardiac; tracheal; esophageal; renal; limb) association, or with congenital syndromes such as Marfan's and congenital neurofibromatosis. The diagnosis may be missed at birth. There are a number of syndromes in which the chest wall does not develop properly, and the lungs are consequently hypoplastic. These include Jeune's syndrome (asphyxiating thoracic dystrophy - an autosomal recessive condition that may be associated with short-limb dwarfism and polydactyly). Ribcage abnormalities also occur in thanatrophic dwarfism, achondroplasia, chondroectodermal dysplasia and giant exomphalos. Many of these conditions are fatal soon after birth; milder forms may improve with time, but affected individuals may need prolonged respiratory support.

## DIAPHRAGM

The separation of the pleural and peritoneal cavities is effected by development of the diaphragm, which forms from a portion of the septum transversum mesenchyme above the developing liver (see Fig. 52.2). The septum transversum is a population of mesenchymal cells that arises from the coelomic wall of the caudal part of the pericardial cavity. As the population proliferates, it forms a condensation of mesenchyme, caudal to the pericardial cavity and extending from the ventral and lateral regions of the body wall to the foregut. Dorsal to it, on each side, are the relatively narrow pleuroperitoneal canals. The endodermal hepatic bud grows into the caudal part of the septum transversum, whereas the cranial portion will form the diaphragm.

The oesophagus and stomach are medial to the pleuroperitoneal canals. As development proceeds, the lower portion of the oesophagus inclines ventrally anterior to the descending thoracic aorta. Although the oesophagus has no true ventral or dorsal mesentery, in descriptions of diaphragmatic development, the portion of mesenchyme between the oesophagus and aorta at the level of the forming diaphragm is often homologized with part of a dorsal meso-oesophagus. The pleuroperitoneal membranes, which remain small, are dorsolateral to the canals, and the mesonephric ridges, suprarenal glands and gonads are dorsal. Just as the enlargement of the pleural cavity cranially and ventrally is effected by a process of burrowing into the body wall, so is its caudodorsal enlargement. The expanding pleural cavities extend into the mesenchyme dorsal to the suprarenal glands, the gonads and (degenerating) mesonephric ridges. Thus, somatopleuric mesenchyme is peeled off the dorsal body wall to form a substantial portion of the dorsolumbar part of the diaphragm (see Fig. 52.3C). The pleuroperitoneal canal is closed by the fusion of its edges, which are carried together from posterolaterally to anteromedially by growth of the organs surrounding it: in particular, by growth of the suprarenal gland. The right pleuroperitoneal canal closes earlier than the left, which presumably explains why an abnormal communication persisting between the pleural and peritoneal cavities is more frequently encountered on the left.

While these changes are occurring, the septum transversum undergoes a progressive alteration in relative position. The dorsal border of the septum transversum, which initially lies opposite the second cervical segment, migrates caudally as the embryo grows and the heart enlarges. At first, the ventral border moves more rapidly than the dorsal, but after the embryo has attained a length of 5 mm , the dorsal border

Fig. 52.3 A, A ventral view of the intraembryonic coelom forming early body cavities. B, The parietal pericardium is shown surrounding the developing heart ventrally, with the parietal pleura of the lungs dorsal and lateral on each side. C, A transverse section through the thoracic region, showing the ventral extensions of the pleural sacs on each side of the pericardium that split the body wall mesenchyme. D, An anterior view of the pleural sacs. The position of the pericardium is shown by a dotted line. Dorsolateral growth of the pleural sacs also splits the body wall dorsocaudally, defining the costodiaphragmatic recess.
migrates more rapidly. When the dorsal border of the septum transversum lies opposite the fourth cervical segment, the phrenic nerve (C3, 4 and 5) and portions of the corresponding myotomes grow into it and accompany it in its later migrations. The dorsal border of the septum transversum does not come to lie opposite the last thoracic and first lumbar segments, the final position occupied by some of the dorsal attachments of the diaphragm, until the end of the second month. The main derivatives of the central part of the diaphragm lie at considerably more cranial levels.

The diaphragm is, therefore, composed of the dorsal mesooesophagus and paired pleuroperitoneal membranes (posteriorly); septum transversum mesenchyme (ventrally); and excavated body wall (posteriorly and laterally).

## Diaphragmatic hernias

Diaphragmatic hernias may result from failure of fusion of the component parts or from a primary defect. Posterolateral defects (Bochdalek's hernia) are the most common (85-90\%) and may be bilateral (5\%) or unilateral. Of the unilateral defects, the left side is more commonly affected (80\%). Although these hernias have been attributed to failure of fusion of the pleuroperitoneal membrane, there is increasing evidence that the primary abnormality is lung hypoplasia, and the herniation of the abdominal contents is secondary, which has important implications for treatment (Jesudason 2002). A non-muscular membranous sac, possibly derived from the pleuroperitoneal canal wall, is present in $10-15 \%$ of cases, signifying the early occurrence of this lesion prior to closure of the pleuroperitoneal canal. Hernias between the costal and sternal origins (Morgagni hernias) are rare (1-2\%) (Fig. 52.4). Midline defects in the central tendon arise from septum transversum defects. The incidence of congenital diaphragmatic hernias is about 1:3000 to $1: 5000$ in neonates, with a prenatal incidence of 1:2000.

Diaphragmatic hernias can usually be diagnosed by antenatal ultrasound examination. The presence of bowel in the thorax and mediastinal shift may be seen sonographically and radiographically (Fig. 52.5). The main causes of death in babies with diaphragmatic hernias are pulmonary hypoplasia and hypertension. Pulmonary hypoplasia is related to the abnormal branching of the airways both ipsilaterally and contralaterally, resulting in the formation of reduced numbers of alveoli. Pulmonary hypertension is related to pulmonary hypoplasia, and also to the increased muscularization and reactivity of the pulmonary circulation. There may be associated abnormalities, including trisomy 13 and 18, and diaphragmatic hernia may be part of a number of syndromes, many of which may lead to termination of the pregnancy or to death of the neonate. For a review summarizing the recurrent genetic causes of congenital diaphragmatic hernia, see Wynn et al (2014).

Diaphragmatic eventration is a condition in which an abnormal diaphragmatic silhouette is seen on X-ray with an abnormal medial bulge into the thorax; it is associated with paradoxical motion of the diaphragm during respiratory movements. This may be a benign condition, often a chance finding and requiring no treatment, or it may lead to respiratory symptoms, requiring plication; it is occasionally associated with rib and cardiac abnormalities.

## OESOPHAGUS

The development of the oesophagus is described in Chapter 36. Oesophageal atresia, with or without tracheo-oesophageal fistula, may present antenatally with polyhydramnios due to failure of movement of amniotic fluid into the gut after fetal swallowing (Ch. 9), and choking and inability to swallow saliva in the neonatal period.

## Ultrasound antenatal imaging of the thorax

The overall shape of the fetal chest is best seen on coronal section. A bell-shaped chest is present in pulmonary hypoplasia. In axial section, the thorax is almost circular. Fetal chest size is estimated by measuring the chest circumference on axial section at the level of the four-chamberheart view. Such measurement can confirm or exclude reduced chest volume (Karl and Chaoui 2015). The relative circumference of the thorax and heart remains the same in the second and third trimesters. The diaphragm is best viewed in sagittal view. Diaphragmatic hernias can be diagnosed from about 18 weeks onwards.

A number of differences between the neonatal and adult thorax and diaphragm are significant in early postnatal life, especially in the preterm infant. The full-term neonatal thorax has a rounded circumference, whereas the adult profile is dorsoventrally flattened. The compliance of the adult chest wall and lung is approximately equal, but the neonatal chest wall is up to five times more compliant than the lungs and so is easily deformable; indrawing of the chest wall is an important sign of increased work of breathing in the neonate. The diaphragm is relatively flat at birth and gains its dome shape as the thorax and abdominal viscera grow. The arrangement of the ribs and diaphragm in the neonate means that contraction of the diaphragm pulls the compliant ribs inwards; this does not contribute to inspiration and leads to chest distortion, and may be opposed by the stabilizing action of the expiratory muscles. The neonatal diaphragm exhibits an exaggerated asymmetric movement: the posterior portion shows a considerably greater excursion than the anterior portion.

A neonate undertakes relatively greater work in order to breathe, and is much more vulnerable to developing respiratory muscle fatigue and

Edge of hernial defect showing diaphragmatic muscle

Fig. 52.5 A plain radiograph of the chest and abdomen in a 1-day-old neonate with left posterolateral congenital diaphragmatic hernia. (Courtesy of Mr G Jawaheer, Great North Children's Hospital, Newcastle upon Tyne.)
respiratory muscle failure than an adult. Experimental animal studies suggest that neonates may be especially vulnerable to respiratory muscle failure because of the initial immaturity of synapses. Moreover, myosin isoforms are developmentally regulated in the diaphragm; the reduced power output and work performance of the newborn diaphragm may reflect these molecular differences.

In expiration, there may be active braking of airflow, caused by inspiratory muscle activity and partial constriction of the larynx; this produces grunting on expiration, especially if the lungs are stiff, e.g. in neonatal respiratory distress. A very preterm neonate is difficult to study, but respiration is likely to be even more compromised by the compliant chest wall and lack of reserve than it is in the term newborn (van Vonderen et al 2014).

At all ages, there is a reduction in, if not loss of, tonic intercostal activity during rapid eye movement (REM) sleep. The mechanism is believed to be related to a descending spinal inhibition of the muscle spindle system. In addition, although, during REM sleep, the diaphragm descends further, this inspiratory effort is dissipated in sucking in the ribs and enlarging the abdomen; thus, the ribcage and abdominal ventilatory movements become out of phase. The neonate is at particular risk in this respect because the chest wall is flexible and much of the infant sleep activity is of the REM type. Furthermore, the upper airway musculature may lose tone during REM sleep, so that the soft tissues of the pharynx are sucked in during inspiration, limiting the crosssectional area of the upper airway, and further increasing the work of breathing.

## heart and great vessels

In the last few decades, understanding of the development of the heart and great vessels has been revolutionized by molecular lineage tracing and cell division studies. Cardiac development has traditionally been taught from the standpoint of a formed heart tube, with venous and arterial ends, which folds within an external pericardial cavity. It is now clear that this view is incorrect. The cells contributing to the heart arise sequentially from a range of extracardiac cell populations, and local instructive interactions maintain the developmental progression; cardiomyocyte identity is not fixed but dependent on spatial and temporal signals (Sylva et al 2013). As the changing orientation of the developing heart within three dimensions is particularly difficult to understand conceptually, and considering that the received view of organogenesis is coloured by past explanations and specific pedagogic approaches, it is necessary to maintain some of the older terminology by which heart development was described, as well as considering the most recent findings.

Cardiac differentiation and morphogenesis are intimately related processes, achieved by a highly complicated transcriptional network. The cardiac transcription factor $N k x 2-5$, which has a homogeneous distribution over the embryonic heart tube, is generally important for cardiac-specific gene expression. In the human, mutations in this factor cause atrial septal defects and disturbances of atrioventricular conduction; in Drosophila, the heart will not form in its absence. The recent discovery of the involvement of the role of T-box transcription factors, which are locally expressed, provides some evidence of the further complexity of patterning the heart. Whereas Tbx5 confers caudocranial positional information over the heart tube, thereby determining the regional development of the cardiac chambers along these axes, Tbx2 and 3 prevent regional formation of the cardiac chambers, permitting the myocardium in these regions to differentiate into the conduction system. Tbx18 is involved in the development of the sinus venosus and Tbx1 in the development of the outflow tract of the heart.

A number of terms must be specified before development of the heart and discussion of the cardiac chambers can be described. The inflow tract of the heart starts at the transition of the systemic tributaries (sinus venosus) into the primary heart tube. Within the straight heart tube, forming atrial and ventricular chambers can be discerned, separated by an atrioventricular canal. The inflow tract thus connects the sinus venosus with the forming atrium, whereas the outflow tract connects the ventricles with the aortic sac; a proximal portion (close to the ventricle) and a distal portion can be defined within the outflow tract.

## CELLS THAT GIVE RISE TO THE HEART

The heart is formed from tissues derived from the midline splanchnopleuric coelomic epithelium with later contributions from neural crest mesenchyme. The splanchnopleuric coelomic epithelium gives rise to the myocardium, including the conduction system of the heart, and the

Fig. 52.6 A, The early embryonic disc viewed from a dorsolateral aspect, showing the position of the primary heart-forming field relative to the surface ectoderm of the trilaminar disc. B, The rostral end of the unfolded embryonic disc from a dorsal aspect, showing the position of the mesenchymal populations that will give rise to the primary heart-forming field, septum transversum mesenchyme and second heart-forming field.
endocardium, including its derived cardiac mesenchymal population, which produces the valvular tissues of the heart. Splanchnopleuric coelomic epithelium is also the source of the epicardium, coronary arteries and interstitial fibroblasts.

Primitive cardiac myocytes can first be seen in embryos at stage 8 . During the onset of neurulation and somitogenesis, the intraembryonic coelom forms across the midline, initially above the endoderm, in a horseshoe-shaped area termed the primary heart-forming field (cardiac crescent) (Fig. 52.6). As the head fold emerges, the coelom undergoes a reversal, so that the future pericardial cavity comes to lie ventral to the endodermal foregut (see Fig. 52.1; Fig. 52.7). The splanchnopleuric wall of the pericardial coelom, subjacent to the endoderm, provides a germinal epithelium that produces early cardiac myocytes. It is characterized by the expression of myocardial-specific markers, such as cardiac myosin heavy chain and the cardiac transcription factor Nkx2-5. Later myocardial additions from mesenchyme localized central and peripheral to the cardiac crescent on the embryonic disc are termed the second heart-forming field (see Fig. 52.6). Whether these two myocardial fields represent distinct myocardial lineages, or constitute a single field, which is gradually added to the heart, remains a matter of debate.

The endocardium also develops during stage 8-9 from the coelomic splanchnopleuric epithelium. Cells arise singly close to the ventrolateral edges of the cranial intestinal portal and form an endocardial plexus between the splanchnopleuric coelomic epithelium and the foregut endoderm. These groups of cells are now termed angioblastic mesenchyme; they are amongst the earliest intraembryonic vascular precursors to appear and express markers for the endothelial cell lineage. The cells aggregate to form an epithelium, the endocardium, which encloses small cavities that coalesce in the vicinity of the developing foregut to establish bilateral, hollow, endocardial tubes. The latter fuse across the midline progressively, commencing at the outflow tract, or arterial pole, and extending to the inflow tract, or venous pole (see Fig. 52.7). By stage 10, a single endocardial tube is present and is almost completely surrounded by myocardial cells. This arrangement of an outer myocardial sleeve containing an inner endocardial tube constitutes the primary heart tube. The inner endocardial epithelium induces the myocardial cells to synthesize specific extracellular matrix proteins, which form a fine extracellular reticulum that holds the endocardial tube apart from the developing myocardium. Close to the foregut endoderm, the myocardial cells at the reflections of the pericardial splanchnopleuric epithelium form the dorsal mesocardium, which may stabilize the developing endothelium and promote the fusion of the bilateral endocardial tubes. The dorsal mesocardium encompasses a mesenchymal population specifically referred to as mediastinal mesenchyme, and is contiguous with the splanchnopleuric mesenchyme surrounding the embryonic foregut.

Much later in heart development, neural crest cells, arising from the region between the otic vesicle and the caudal limit of somite three, grow into the outflow tract of the heart. They are believed to play a role

D, A horizontal section through the pericardium and endothelial heart tube shown in C . The position of the dorsal mesocardium, a source of secondary heart field mesenchyme, is indicated.
in the spatio-temporal regulation of the division of the outflow tract into the aortic and pulmonary pathways, and the development of the muscular subpulmonary infundibulum.

The epicardium, sometimes included in descriptions of the myocardium as 'epimyocardium', is not present at the early stages of heart development.

## Endocardial cushions

The extracellular matrix of the heart, historically termed cardiac jelly, promotes occlusion of the endocardial tubular lumen during myocardial contraction, thus providing mechanical assistance for the generation of the flow of blood. It also acts as a site for the deposition of inductive factors from the myocardial cells, which, in turn, modify the differentiation of specific endocardial cells. It has been called a gelatinoreticulum, a myoepicardial reticulum (see Fig. 52.7C-D) and, more recently, the myocardial basement membrane. Here, the term cardiac extracellular matrix will be used. It is composed of hyaluronic acid, hyaluronidase and fibronectin, among other things. Inductive signals originating from the myocardial cells cause a subset of endocardial cells
lining the atrioventricular canal and the proximal outflow tract to transform into mesenchyme (cardiac mesenchyme); the endocardial cells in other regions of the heart tube, such as those in the ventricle, do not undergo such a transition. When activated by myocardial inductive factors, the endocardial cells lose their cell-to-cell associations, and show decreased expression of neural cell adhesion molecule, and increased expression of substrate adhesion molecules such as chondroitin sulphate and fibronectin. They undergo rearrangement of their cytoskeleton necessary for migration, and they express type I procollagen. Uniquely, they retain their expression of endothelial markers. This epithelial to mesenchymal transition may, perhaps, be the only example of a mesenchymal population that is derived from an endothelial lineage.

Formation of cardiac mesenchymal cells at the atrioventricular canal and the proximal myocardial outflow tract is followed by their migration into the cardiac extracellular matrix. These cells proliferate between the endocardium and myocardium, and, with local accumulation of extracellular matrix molecules, produce protrusions, termed endocardial or cardiac cushions, which bulge into the primary heart tube and initially provide the valvular mechanisms required in the atrioventricular canal and outflow tract. Their position corresponds to
the future positions of the definitive cardiac valves. In the distal part of the outflow tract, which initially has myocardial walls, cells that are derived from the neural crest subsequently make significant contributions to the mesenchyme of the endocardial cushions. Although proper migration of these cells from the neural crest is crucial for normal development of the outflow tract and formation of the leaflets and sinuses of the arterial valves, their function is largely obscure. They are no longer found in the leaflets of the arterial valves in the formed heart, or in the muscular subpulmonary infundibulum, which is also derived from the outflow cushions. The endocardial cushions themselves ultimately fuse, forming a wedge of mesenchyme that serves to guide the union of the internal muscular septal structures. At their time of fusion, the atrioventricular endocardial cushions are large, relative to the size of the atrioventricular orifices; they will provide the scaffold for formation of the leaflets of the tricuspid and mitral valves.

## Cardiac myocytes - contraction, conduction and automaticity

Cardiac myocytes share a number of characteristic features that distinguish them from other cells. All cardiac myocytes have sarcomeres and a sarcoplasmic reticulum; in principle, they share the capacity for producing an intrinsic cycle of electrical activity resulting in contraction. This phenomenon is called automaticity, or pacemaker activity. An absolute requirement for effective pacemaking is poor electrical coupling of the cells, which also implies slow conduction. It allows the cells to build up sufficient electrical charge, which is then propagated through the surrounding myocardium. Thus 'a small node can drive a large heart'.

Varying degrees of differentiation are seen in early populations of cardiac myocytes, which can be categorized as forming working, nodal, conducting and primary myocardium (Table 52.1). Cells of the atrial and ventricular working myocardium display virtually no automaticity, but are well coupled and have well-developed sarcomeres and sarcoplasmic reticular structures. The development of the synchronously (fast) contracting working myocardium requires fast conduction of the depolarizing impulse, and so the cells possess well-developed gap junctions. In marked contrast, the cells forming the nodes of the cardiac conduction system have the opposite phenotype, and resemble the myocytes that are found initially in the primary heart tube. The cells of the putative atrioventricular and peripheral ventricular conduction system have an ambiguous phenotype: the cells are well coupled, thus allowing fast conduction of the depolarizing impulse, but otherwise retain an embryonic phenotype. The division does not imply that the cells belonging to one group are identical, but rather that they share distinguishing features developed to variable degrees.

Automaticity and slow conduction are features of the myocardium of the primary heart tube (see Video 52.1). The slow conduction of the depolarizing impulse over the heart tube causes a peristaltic wave of contraction, by means of which the blood is pushed towards the arterial pole. During the waves of contraction, the accumulated cardiac extracellular matrix closes the endocardial tube and prevents the backward flow of blood. Unambiguous morphological markers are often lacking in the early embryonic heart, which means that it is not possible to distinguish the various cells phenotypically; automaticity and the speed of conduction have, therefore, become important functional parameters by which to describe the development of the different parts of the heart.

## HEART TUBE

During the process of embryonic folding, the midline splanchnopleuric coelomic epithelium, which is derived from the primary heart field (cardiac crescent), becomes positioned ventral to the foregut. The coelomic epithelium is highly proliferative and gives rise to mesenchymal populations. The early cardiac myocytes arise from the coelomic wall adjacent to the endoderm of the foregut (see Fig. 52.7). The cells

Table 52.1 Basic phenotypes of cardiac myocytes

| Feature | Type of myocardium |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  | 'Primary' | 'Nodal' | 'Conducting' | 'Working' |
| Automaticity | High | High | High | Low |
| Conduction velocity | Low | Low | High | High |
| Contractility | Low | Low | Low | High |
| Sarcoplasmic <br> reticulum | Low | Low | Low | High |

undergo restriction, differentiate and leave the cell cycle. After folding, the second heart field contributes cells to the heart. It has been suggested that the secondary heart field may contribute cells only to those cardiac components that are required for the pulmonary circulation: namely, the right ventricle and outflow tract at the arterial pole, and the atrial septum and the dorsal atrial wall at the venous pole. To extend this suggestion, the original primary heart-forming field would give rise to those components that are required for the systemic circulation: namely, the systemic venous sinus and its tributaries, the initial atrium, the left ventricle and the arterial conus, as seen in the outflow tract of primitive fishes, although this latter structure has no homologue in mammalian hearts.

During the process of folding, the pericardial cavity and, concomitantly, the myocardium gradually extend around the forming endocardial tube, leaving the dorsal mesocardium, a transient connection that is analogous to the mesentery of the intestines (see Fig. 52.7C-D). The persisting stalk of the dorsal mesocardium connects the venous pole of the heart with the splanchnopleuric mesenchyme around the developing lung buds and with the septum transversum mesenchyme, which will give rise to the liver. The dorsal mesocardium is the site of early mediastinal mesenchyme production. It disappears as a mesenteric entity during the third week of development, when the embryo has from 4 to 12 somites; at the same time, the endocardial heart tube becomes entirely surrounded by the myocardium and enclosed within the pericardial cavity. The breakdown of the dorsal mesocardium establishes a passage across the pericardial cavity, from side to side and dorsal to the heart, which persists as the transverse sinus of the pericardium. After folding and rupture of the dorsal mesocardium, the second heart field contributes cells to both the arterial and the venous poles of the heart.

At this stage, the heart is bilaterally symmetrical and has the form of an inverted ' Y '. The legs of the Y are positioned caudal to each side of the cranial intestinal portal, where they form the venous pole of the heart (Fig. $52.8 \mathrm{~A}-\mathrm{B}$ ). The stem of the Y connects cranially with the great arteries, forming the arterial pole of the heart. From the outset, both poles are connected with the systemic vessels running from the embryo, the yolk sac and the placenta. The pulmonary veins form later, during the fifth week of development, the initial venous primordium becoming evident in the mesenchyme derived from the dorsal mesocardium caudally. Also at this site, mediastinal myocardium continues to be added to the heart, forming the smooth dorsal wall of the left atrium, and providing the site of formation of the primary atrial septum.

Recent genetic fate map studies have shown that the primary heart tube contains cell lines that will contribute to only two compartments. The myocardium of the stem of the inverted Y contains only precursor cells of the left ventricle, and both legs of the inverted $Y$ contain precursor cells of the atrioventricular canal and parts of both atrial chambers. The atrioventricular canal, in turn, provides the precursors for the left ventricular free wall, whereas the cells of the original embryonic left ventricle largely end up in the ventricular septum. The embryonic outflow tract contributes to the right ventricle. There is no evidence to support the previous, traditional, concept of heart development, i.e. that all the putative cardiac segments are already present in the straight heart tube and develop to contribute to the various parts of the definitive cardiac chambers. This hypothesis has now been disproved by elegant experimental studies that have shown that the definitive cardiac chambers are formed by local differentiation and expansion, or 'ballooning', of the myocardial walls of the primary heart tube.

## Looping of the heart tube

Cranial and caudal recruitment of myocardium and endocardium produces considerable lengthening of the primary heart tube. Recent studies of the mechanism of proliferation in the avian, mouse and human heart have shown that cardiac myocytes stop dividing after overt differentiation. The tube continues to elongate, largely as a result of the recruitment of additional myocytes to the tube, as shown by studies of both morphology and molecular lineages, and, to a lesser extent, because of an increase in the size of the myocytes that form the walls of the tube. The lengthening heart tube bends ventrally and rightwards, concomitant with the breakdown of the dorsal mesocardium. The bend is called the ventricular loop, since the left ventricle subsequently balloons and expands at its outer curvature, which is the original ventral side of the straight tube. The inner curvature of this loop was originally its dorsal side.

It is often stated that looping of the tube is the first visual evidence of asymmetry in the embryo, although careful examination reveals that the atrioventricular canal has become asymmetric prior to the start of

Fig. 52.8 Local expansion of the myocardial wall of the early heart tube and heart tube looping. A, A ventral view. B, The ventral wall has been removed to show the inner aspect of the early heart tube. C, A left lateral view. The early heart tube is shaped like an inverted ' $Y$ '. The legs of the $Y$ pass caudal to each side of the cranial intestinal portal. In the early heart tube, the myocardium of the stem of the $Y$ (purple) contains only precursor cells for the left ventricle. The remaining myocardium (grey) contains only precursor cells for the atrioventricular canal and atria. The precursor left ventricular cells expand first. D-G, The later heart tube, showing looping. D, A ventral view. E, The ventral wall has been removed to show the inner aspect of the folding heart tube. $\mathbf{F}, \mathrm{A}$ left lateral view. G, The lateral wall has been removed to show the inner aspect of the heart from the left. In $D$ and $E$, the expansion of the right ventricle can be seen and the heart tube has elongated to the right. The developing atrium can be seen dorsolaterally in D-G.
looping. Although the sense of laterality of the developing organs of the body, including the atrial appendages, develops during gastrulation, the pathway of signalling that governs rightward looping of the heart tube remains unknown. However, it is now well established that signalling pathways, including Pitx2, nodal, lefty and cited-2, determine the formation of the morphologically left-sided or right-sided features seen in organs such as the lungs, bronchial tree, liver and spleen, and atrial appendages.

By the time the primary heart tube has formed its ventricular loop, it is possible to distinguish the atrial and ventricular components of the developing heart (Figs 52.8D-G,52.9), and to recognize an outflow tract connected with the aortic sac and developing pharyngeal arch arteries. The cells that, at this stage, make up the outflow tract, will, at later stages, be found within the right ventricle. At the proximal side of the outflow tract, cells are recruited to the developing right ventricle and, contemporaneously, new cells are recruited to the outflow tract from the second heart-forming field. The atrial and ventricular compo-
nents are separated one from another by the atrioventricular canal, which, at this stage, has significant length. The systemic venous tributaries drain directly to the atrial cavity.

The sinus venosus with right and left sinus horns, which forms at the confluence of the systemic venous tributaries, is a prominent structure in lower vertebrates. In mammals, it does not become recognizable as a morphological entity until the systemic veins have excavated themselves from the mesenchyme of the body and been surrounded by myocardium. It then becomes incorporated into the pericardial cavity so that the sinus horns become part of the heart. All of these processes occur up to the twenty-fifth day of development in humans; only after this stage is it possible to consider development of the definitive atrial and ventricular chambers.

## INFLOW TRACT

The working myocardium of the atrium differentiates locally at the dorsolateral sides of the heart tube (see Fig. 52.8D-G). The developing atrium then expands enormously, in dorsal, lateral and, most prominently, cranial directions. The cranial expansion is seen as pouches, which become the left and right atrial appendages (see Fig. 52.9A-B). The floor of the atrium, including the sinus venosus, and the atrioventricular canal are made of primary myocardium. Less cellular proliferation occurs in these parts than in the expanding atrial chambers; the primary myocardium marks the inflow to, and the outflow from, the initial atrial chambers as 'rings', which are also associated with the formation of the conduction system. The ring at the inflow defines the sinuatrial junction, whilst the atrioventricular canal, which forms the atrial outlet during development, will eventually be incorporated into the definitive right and left atrial chambers as the atrial vestibules. Although it is possible to recognize the forming left and right atrial appendages at this stage, the right being more extensive than the left, the atrium itself has a single cavity and there is no evidence of septum formation. The myocardium of the sinus venosus and the newly forming mediastinal myocardium are smooth-walled, whereas the myocardium of the appendages shows ridges, the pectinate muscles, on the inner surface. The formation of the different appendages is under control of the Pitx2 signalling pathway. The myocardium of the appendages has a chamber phenotype, or is working myocardium; it expresses atrial natriuretic factor and connexin 40 , among other markers.

## Right atrium

The further development of the right atrium is characterized by the incorporation of the sinus venosus into the right part of the primary atrium. This process is under control of the T-box transcription factor Tbx18. At about 4 weeks of development, the sinuatrial junction of the looping primary heart tube is positioned symmetrically in the midline (Fig. 52.10; see also Figs 13.1, 60.9). The left and right common cardinal veins drain directly into the cavity of the primary atrium. The atrial myocardium extends to the margins of the pericardial cavity and, strictly speaking, the sinus venosus is not yet formed because the systemic venous tributaries are embedded within the mesenchyme of the septum transversum.

During subsequent development, the pericardial cavity expands to enclose the terminal segments of the systemic venous tributaries; at the same time, their walls differentiate as myocardium. They can now be termed the left and right horns of the sinus venosus; each horn receives the union of the corresponding umbilical vein, vitelline radicles and common cardinal vein (see Figs 52.10, 60.9). Concomitantly, the constriction between the left horn and the atrium becomes more pronounced. As the dorsal wall of the left atrium is formed from additions of mediastinal myocardium, the left horn becomes incorporated into the developing left atrioventricular junction, its orifice draining to the newly formed right atrium. At the same time, the left-sided venous tributaries diminish in size; the left common cardinal vein forms the oblique vein of the left atrium, and the left sinus horn forms the coronary sinus (see Fig. 52.10C), maintaining its own myocardial wall as it becomes incorporated into the atrioventricular junction.

The right sinus horn increases rapidly in size with growth of the liver (see Figs 60.9-60.10). The vitello-umbilical blood flow enters the right horn through a wide but short hepatocardiac channel, which becomes the cranial end of the inferior vena cava. The right horn also receives the right common cardinal vein, draining the blood from the right side of the body. Later, when transverse connections are established between the cardinal veins, the blood from the left side of the body also reaches the heart via the veins draining the right side (see Fig. 13.4). As these

Developmental Stages in Human Embryos 1987 Carnegie Institution of Washington. Pub 637.)

Fig. 52.10 The changes to the sinus venosus. A, A dorsal view of the early heart tube shown in Figure 52.8D. B, Changes to the circulation bring the venous circulation to the right, causing enlargement of the right horn of the sinus venosus and atrium, and attenuation of the left horn of the sinus venosus. C, The right horn of the sinus venosus becomes absorbed into the atrium. The left horn of the sinus venosus becomes the coronary sinus. D, A dorsal view of the embryonic heart, showing the relative changes to the sinus venosus.
changes take place, the right sinus horn, including the proximal parts of the superior and inferior cardinal veins, becomes incorporated into the right atrium, forming the smooth-walled systemic venous sinus, also known as the sinus venarum.

The right sinus horn opens into the right atrium through its dorsal and caudal walls (see Figs 52.10, 52.14). The sinuatrial orifice becomes elongated and slit-like, guarded by two muscular folds: the left and right sinuatrial (venous) valves. These two valves meet cranially and become continuous with a fold that projects from the atrial roof: the septum spurium. The valves also meet caudally, and merge with the inferior atrioventricular cushion. With ongoing development, the cranial part of the right sinuatrial valve loses its fold-like form, but its position is indicated in the adult heart by the site of the crista terminalis of the right atrium. Its caudal part forms the valve of the coronary sinus, also known as the Thebesian valve, and most of the valve of the inferior vena cava (Eustachian valve). The union of the two valvular remnants then passes through the tissue that separates the orifice of the coronary sinus from the fossa ovalis. This area is known as the 'sinus septum' but, in reality, this 'septum' is no more than a muscular fold in the dorsal wall of the right atrium. The continuation of the venous valves persists as the tendon of Todaro, an important landmark for the location of the atrioventricular node in the definitive heart. The left venous valve blends with the right side of the atrial septum; there is usually no trace of it in the postnatal heart.

## Left atrium

Following the formation of the primary atrium and the left atrial appendage, the left atrium takes shape by the formation and incorporation of mediastinal myocardium. While the tributaries of the sinus venosus approach the atrium caudally, the differentiating pulmonary veins gain their entrance to the atrial cavity through the dorsal mesocardium (see Fig. 52.7). The topographical relationships seen in the postnatal heart are, thus, established as soon as differentiation of the pulmonary venous portal occurs.

Early in the development of the atrium, the pulmonary vein develops as a solitary channel from angiogenic cells derived from the dorsal mesocardium, and establishes continuity with the vascular plexus formed in the mediastinal mesenchyme around the developing lung buds. The solitary pulmonary vein opens into the caudo-dorsal wall of the atrium adjacent to the developing atrioventricular junction, its atrial orifice being flanked by two prominent ridges. The primary atrial septum develops from the right ridge, following incorporation of the left sinus horn into the right side of the primary atrium, thus confining the pulmonary venous orifice to the developing left atrium (see Fig. 52.14 ). The pulmonary vein initially branches within the dorsal mediastinal mesenchyme, its tributaries draining blood from the developing lung. With continuing development, the walls of the venous channels become surrounded by myocardium, this process occurring to the level of the second bifurcation. The veins then expand and are incorporated into the roof of the left atrium, eventually forming the greater part of its cavity. However, all four pulmonary veins do not achieve their separate opening into the atrial roof until well after the completion of atrial septation, and probably not until the tenth or eleventh week of development. Variations in the precise pattern of pulmonary venous drainage are quite common. With these changes, the left half of the primary atrium becomes progressively restricted to the mature appendage. The myocardial sleeves surrounding the pulmonary orifices taper off and become intermingled with fibrous tissue. In later life, it is likely that this intermingling of myocardial and fibrous tissues forms the substrate for some forms of atrial fibrillation. The opening of the solitary pulmonary vein to the left of the right pulmonary ridge is a prerequisite for atrial septation.

## VENTRICLES

The ventricles develop at the ventral side of the looping primary heart tube during the fourth week of development (see Figs 52.8-52.9). The left ventricle develops from the stem of the Y-shaped heart; the right ventricle develops later, downstream relative to the left ventricle, when more myocardium has been added to the cardiac tube. As a result of the looping of the heart tube, the right ventricle is positioned at the right of the left ventricle, which is a prerequisite for the appropriate connection with the expanding atrial component of the heart. Unlike the atrial chambers, the morphological differences between the right and left ventricles are not part of the general asymmetry between the right- and left-sided organs of the body, but rather are under control of

Fig. 52.11 A scanning electron micrograph of a human heart at 42 days' gestation. The right lateral wall of the right atrium, the right ventricle and the outflow tract have been removed. The valve of the sinus venosus ( V ) is prominent. There is no septal cusp of the tricuspid valve guarding the inlet portion of the right ventricle. The parietal cusp has been removed. The atrioventricular cushions are fused. Note the adjacent right lateral tubercles (O). A small interventricular foramen (foramen secundum, p. 915) is indicated (arrowhead). There is a well-developed right ventricular outflow tract (curved arrow). Other abbreviations: E, embryonic trabeculae; P , pulmonary trunk.
the signalling pathways that determine caudocranial differentiation. Retinoic acid and its downstream transcription factor, Tbx5, play a crucial role in this process.

The myocardium at the inner curvature, the original dorsal side of the cardiac tube, remains smooth-walled and maintains its molecular phenotype, whereas the myocardium at the outer curvature of the myocardial tube displays trabeculations in the fifth week of development; the original primary heart tube is represented by an interventricular ring (see Fig. 52.9C). By stage 17, the trabeculations have achieved a typical spatial orientation, giving a sponge-like appearance to the internal aspect of both ventricles (Fig. 52.11). The definitive trabeculations, coarse in the right ventricle but much finer in the left, are first observed around the fortieth day of gestation; they appear initially in the walls of both ventricles at the level of the atrioventricular junction and develop towards the apex of the heart. By the time the fetus is 10 weeks old, the trabeculations are much sparser, and are confined to the apical regions. This process of remodelling is accomplished without the intervention of macrophages or inflammatory cells in the immediate interstitium. The ventricular myocardium, encompassing the trabeculations and exterior wall, possesses a chamber phenotype, the myocytes expressing, among other proteins, the fast-conducting gap-junctional proteins connexin 40 (Cx40) and 43, and atrial natriuretic peptide. This myocardium stops proliferating and differentiates into the fast-conducting peripheral ventricular conduction system, whereas the outer layer becomes highly proliferative and forms the compact layer of the ventricular wall, no longer expressing Cx 40 and atrial natriuretic peptide, but still expressing Cx43.

## OUTFLOW TRACT

Initially, the outflow tract possesses myocardial walls up to the pericardial reflections. It displays a characteristic bend, which has a proximal part arising from the developing right ventricle, and a distal part that becomes continuous with the aortic sac beyond the pericardial reflections. Although this bend is a conspicuous morphological feature, it is highly unlikely that the cells to either side of it retain their position during subsequent development. Instead, it seems probable that cells are recruited from the second heart-forming field, and pass through the outflow tract to contribute to the definitive right ventricle. Subsequently, still more cells are recruited from pharyngeal mesenchyme, passing proximal to the pericardial reflections and forming the intrapericardial components of the arterial trunks. There remains much disagreement as to how best to describe these morphological parts of the outflow tract. Some authors have labelled the proximal myocardial part the conus, calling the distal part the truncus, and the intrapericardial portion of the outflow tract the aortic sac. Others have called the entire
myocardial outflow tract the bulbus, since the myocardial outflow tract of primitive vertebrates, called the conus arteriosus in primitive fish and the bulbus cordis in amphibia, is presumed to develop into the right ventricle in higher vertebrates. Because the terms conus and truncus have been inconsistently used in literature, we prefer simply to describe proximal and distal parts of the myocardial outflow tract, and to describe, when it appears, an intrapericardial arterial portion of the outflow tract, this part interposing between the muscular component and the ventral aorta, the distal junction occurring at the pericardial reflections.

Given that different authors use different terminologies, it is not surprising that formation of the outflow tract remains one of the most confusing areas of cardiac development. The recent finding that the stem of the heart tube contains precursor cells exclusively for the left ventricle makes it essential to adopt descriptions that follow dynamic events, rather than continuing to use static names. Thus, as soon as the primary heart tube bends to produce its ventral ventricular expansion, by definition, the developing ventricle achieves inlet and outlet components, even though these structures are not the definitive ventricular inlets and outlets. Cells that, initially, are found in the ventricular outflow tract subsequently become cells of the right ventricle. Furthermore, working myocytes can easily be distinguished from the primary myocytes of the straight heart tube. The primary myocardium is smoothwalled, whereas the developing myocardium of the ventricles is trabeculated, and expresses specific markers such as atrial natriuretic peptide and Cx40 and Cx43. Thus, that part of the primary heart tube downstream of the developing ventricular loop is termed the outflow tract, irrespective of the fact that, eventually, it will largely become incorporated within the definitive right ventricle (see Figs 52.8-52.9). Moreover, within the inner curvature of the ventricular loop, the walls of the outflow tract and atrioventricular canal fade into one another without a clear boundary. Indeed, ventricular working myocardium never develops at the inner curvature. It is within this ventricular part of the primary heart tube that the cushions of the atrioventricular canal and the outflow tract must achieve appropriate connections with the muscular ventricular septum in order to divide this part of the tube into left and right compartments. The cavity of the tube within which these events take place has been called the 'interventricular foramen'. This is incorrect, since it is, rather, the region between adjacent parts of the primary heart tube. It is, none the less, the remodelling of this inner curvature that sets the scene for the completion of cardiac septation.

## CARDIAC FUNCTION AND THE CONDUCTION SYSTEM

Although only mammalian hearts have a well-defined conduction system, an essentially similar electrocardiogram can be recorded from animals as diverse as fish and humans, indicating that the electrical connections between the cardiac components, along with the underlying gene-regulatory networks, have been conserved during vertebrate evolution. Indeed, the development of the conduction system of the heart is inextricably associated with the development of the basic building plan for the heart. The conduction system is best defined as the system that initiates and conducts the sinus impulse. In mammals, it encompasses the sinuatrial node, the atrioventricular node, the atrioventricular bundle, the bundle branches and their terminal ramifications. The nodes and the atrioventricular bundle can be considered the central conduction system, while the bundle branches and their ramifications represent the peripheral ventricular conduction system. The sinus impulse is generated in the sinus node; from here, it is rapidly propagated through the atrial myocardium towards the atrioventricular node, where propagation is delayed. After an essential period of atrioventricular delay, the impulse travels rapidly through the atrioventricular conduction axis and the peripheral ramifications to reach the ventricular myocardium, which is then rapidly depolarized. Following repolarization, the sequence recurs in endless fashion throughout the life of the individual. The term 'conduction system', as opposed to the working myocardium of the chambers, may suggest that the working myocardium does not conduct, while the conduction system conducts rapidly. In order to produce powerful synchronous contractions, the working myocardium of the chambers must also, of necessity, conduct rapidly, whereas to act as a pacemaker, the cells of the nodes need to be poorly coupled, and hence display slow conduction.

The vertebrate heart is myogenic, implying that all cardiomyocytes have the capacity to generate and conduct the depolarizing impulse. Because cardiac myocytes are electrically coupled, the cells with the highest pacemaking activity take the lead. In the formed normal heart, the leading pacemaker is always within the sinus node. In embryonic
hearts, the leading pacemaker is always found at the venous pole (Fig. 52.12). Thus, it is the most recently recruited cells at the venous pole that always have the highest pacemaking activity. All regions of the early embryonic heart tube possess poorly coupled cells and display intrinsic automaticity, thus permitting slow propagation of the depolarizing impulses along the cardiac tube, and producing matching peristaltic waves of contraction that push the blood in an antegrade direction. The myocytes of a developing heart do not have well-developed sarcomeric structures, and have a poorly developed sarcoplasmic reticulum. This tissue has been called primary myocardium, distinguishing it from the rapidly conducting and well-developed working myocardium of the atrial and ventricular chambers.

As development proceeds, the ventricular chambers develop in the cranial part of the heart tube, by ventral expansion, and the atrial chambers in the caudal part by dorsolateral expansion (see Fig. 52.8). An adult type of electrocardiogram can be recorded from such hearts, showing rapid atrial depolarization, a period of atrioventricular delay, and rapid ventricular depolarization. The electrocardiographic tracings reflect the development of fast-conducting components within a slowly conducting heart tube, i.e. the development of a morphological conduction system. The newly developed working myocardium expresses atrial natriuretic factor, along with the gap junctional proteins Cx40 and Cx43, which permit fast conduction.

Like the early peristaltic heart, flow through the developing chambered heart remains directional because the dominant pacemaking activity is still at the inlet of the heart (see Fig. 52.12). Peristaltic hearts do not need valves, whereas chambered hearts require the presence of one-way valves at the inlets to, and the outlets from, the chambers. The slowly conducting atrioventricular canal, interposed between the atrium and the ventricle, and the outflow tract positioned between the ventricle and the great arteries, are the parts that contain the endocardial cushions. These are able to function as sphincteric valves, as a result of their prolonged duration of contraction. These components retain their function until the definitive leaflets of the one-way valves have been sculpted from the cushions. The primary myocardium of the outflow tract does not regress until the arterial valves have been formed, and does not disappear in its entirety until around the twelfth week of human development. The primary myocardium of the atrioventricular canal is eventually incorporated into the atrial vestibules at the same time as the formation of the atrioventricular valves, becoming sequestrated on the atrial side of the atrioventricular junctions between 6 and 12 weeks of development. An important part of the canal persists dorsally, where it differentiates into the slowly conducting atrioventricular node (see Fig. 52.12).

Considerable progress has been made over recent years in deciphering the pathways involved in establishing the building plan of the heart (Fig. 52.13). The combined action of the transcription factors Tbx5 and Nkx2-5 is required for the formation of the myocardium of the atrial and ventricular chambers. Tbx 5 is expressed in a gradient over the heart tube, decreasing in concentration from caudal to cranial, and may impose positional information. However, its pattern cannot explain the localized formation of the chambers and the conduction system. Localized expression of the transcriptional repressors Tb 2 and Tb 33 in the inflow tract, the floor of the atrium, the atrioventricular canal, the inner curvature of the ventricular region, and the outflow tract prevents the differentiation of primary into working myocardium. Tbx2 and Tbx3 effectively compete for binding to the promoters of the chamberspecific genes, such as atrial natriuretic factor, Cx40 and Cx43. The remaining primary myocardium of these regions initially induces the endocardium to undergo epithelial to mesenchymal transition, by which process the cardiac cushions become filled with mesenchyme. The myocardium also participates in the alignment of the atrial and ventricular chambers (which is essential for proper cardiac septation, and is guided by the fusing cardiac cushions); it forms the conduction system, including the sinus and atrioventricular nodes, the atrioventricular bundle, the floor of the developing right atrium (the internodal region), and the entirety of the atrioventricular canal. In the early chamber-forming heart of the mouse, Tbx3 is expressed in the atrioventricular canal, the floor of the atrium and around the orifices of the systemic venous tributaries, but not in the dorsal mesocardium surrounding the entrance of the pulmonary vein. During subsequent development, the domain of expression of Tbx3 expands from the atrioventricular canal to form a crescent on the crest of the ventricular septum. The dorsal aspect of this crescent develops into the atrioventricular bundle, while the atrioventricular node is formed at the dorsal junction with the atrioventricular canal. The ventral parts subsequently disappear during development.

The fact that the ventricular conducting system originates from a single primary ring provides a solid base for understanding the

Fig. 52.12 Development of the conduction system of the heart. A, At stage 13 with the truncus arteriosus reflected to the right, the interventricular ring marks the region of the primary heart tube. The purple part of the interventricular ring will give rise to the atrioventricular bundle and bundle branches, whereas the yellow part of the interventricular ring will not participate in the formation of the adult conducting system. B, The truncus arteriosus, now divided into the pulmonary trunk and aorta, is presented between the right and left atria, which expand lateral to it. The right atrium is now positioned entirely above the right ventricle, and the outflow tract has expanded to the left; the left ventricle has access to the aorta. C, The position of the original primary heart tube ring indicated in the formed heart. The pulmonary trunk has been removed.

disposition of the conducting system in a number of congenital anomalies. The concept accounts particularly well for the morphology and disposition of the atrioventricular node and bundle in hearts with straddling tricuspid valves, with double inlet left ventricles, and with congenitally corrected transposition.

## SEPTATION OF THE EMBRYONIC CARDIAC COMPARTMENTS

The flow of blood on the right and left sides does not intermingle, even in the developing heart, because flow is laminar, and the pressures are similar at the right and left sides. It is only after birth that the pressures in the 'left' systemic circulation become higher than those in the 'right' pulmonary circulation; therefore, the different flows have to be separated physically in order to prevent admixture of oxygenated and deoxy-
genated blood. Prior to birth, the lungs are not functioning and blood flow to them is small. Even so, normal development of the heart requires that all cardiac compartments receive an adequate amount of blood. To this end, even before birth, the systemic blood of the right atrium is guided to the left atrium so that the left half of the heart and the brain is provided with a normal flow of blood. The right ventricle, in contrast, drains to the dorsal aorta via the ductus arteriosus (see Fig. 36.9B). The walls that separate the right and left sides of the heart are largely formed in the fourth and fifth weeks of development. Some time later, not only the components of the primary heart tube - specifically, the atrioventricular canal and the outflow tract - but also the atrial and ventricular chambers, must be separated physically into right and left halves. However, each compartment is separated in markedly different fashion.

## Septation of the atrial chambers

As a prelude to atrial septation, the right horn of the sinus venosus is incorporated into the right part of the atrium, and the pulmonary vein arises as a midline structure within the dorsal mesocardium. Internal separation into right and left atria is mainly effected by growth of two septa, coupled with remodelling of the venous compartments. At the end of the fourth week of development, a crescentic fold, the primary atrial septum or septum primum, grows by active proliferation from the dorsocranial atrial roof into the direction of the atrioventricular canal, extending downwards just to the right of the entrance of the pulmonary vein (Fig. $52.14 \mathrm{~A}, \mathrm{D}$ ). It is separated from the left sinuatrial valve by the interseptovalvular space. The leading edge of the septum primum is covered by a mesenchymal cap in continuity dorsally with extracardiac mesenchyme (mediastinal mesenchyme) derived from the dorsal mesocardium which forms the vestibular spine, or spina vestibule, also called the dorsal mesenchymal protrusion. The ventral horn of the septum primum reaches the ventral (cranial) atrioventricular cushion, while the dorsal horn reaches the dorsal (caudal) cushion. Thus the primary atrial foramen, the foramen or ostium primum, is entirely surrounded by mesenchyme derived from endocardium. Ventral and caudal to the advancing edge of the septum primum, the developing atrial chambers communicate through the foramen primum (see Fig. 52.14A,D).

As the foramen primum diminishes in size, the upper margin of the septum primum perforates by apoptosis and, thus, right to left shunting of blood continues through a secondary foramen, the foramen or ostium secundum. The latter is formed before the end of the fifth week of development. Initially, it lacks an upper rim, since its upper border is the atrial roof. The foramen primum is finally occluded in the median plane, as the edge of the septum primum merges with the fusing atrioventricular cushions (Fig. 52.14B,E). The foramen secundum then enlarges to permit free passage of blood from the right to the left atrium.

Fig．52．14 Three representative stages in the development of the atrial septum．A－C，Coronal views from the front．D－F，Lateral views from the right side．A and $\mathbf{D}$ ，The septum primum has not yet obliterated the original communication between the two atria（foramen primum）and the atrioventricular endocardial cushions have not yet fused．B and E，The atrioventricular endocardial cushions have fused with each other and with the septum primum， which has broken down in its dorsal part to form the foramen secundum． $\mathbf{C}$ and $\mathbf{F}$ ，The septum secundum is forming on the right side of the foramen secundum from an interatrial fold．Abbreviations：AV，atrioventricular；IVC，inferior vena cava；SVC，superior vena cava．

The solitary opening of the pulmonary vein into the roof of the left atrium，which is originally adjacent to the atrioventricular junction， becomes incorporated into the atrial wall，ultimately forming four sepa－ rate orifices at the corners of the atrial roof．As this development con－ tinues，the muscular atrial roof itself invaginates on the right side of the primary atrial septum（see Fig．52．14B，E），the invaginated fold consti－ tuting the septum secundum．The free edge of the septum secundum overlaps the foramen secundum．When left atrial pressure exceeds right atrial pressure in postnatal life，the septum primum closes against the septum secundum as a flap－valve（Fig．52．14C，F）．The passage taken by blood as it passes from the right atrium－under the crescentic edge of the septum secundum，then obliquely towards and through the foramen secundum to the left atrium－persists throughout intrauterine life as the foramen ovale．At first，the foramen ovale is sited craniodorsally relative to the atrial septum，but with remoulding of the venous com－ ponents，it achieves a cranioventral position．

## Septation and appropriate positioning of the atrioventricular canal

Extracellular matrix accumulates between the endocardium and myo－ cardium of the primary heart tube．However，it mostly disappears in the regions of ballooning of the chamber myocardium of the developing atria and ventricles．The matrix becomes filled with mesenchyme in the persisting regions of the primary heart tube．In conventional accounts
of the process，these regions are called the atrioventricular canal and the outflow tract，or conotruncus．The dorsal or inferior atrioventricular cushion continues into the floor of the atrium，which is made of primary myocardium．As the cushion extends dorsally，it meets the mediastinal mesenchyme in the region initially termed the spina vesti－ buli，where it continues as a mesenchymal cap running along the leading edge of the septum primum until it meets the ventral，or cranial， atrioventricular cushion（see Figs 52．14，52．16）．The dorsal cushion also has a significant ventricular extension in the inner curvature of the heart tube，which comes to lie on top of the developing muscular ventricular septum．The two atrioventricular cushions fuse in the sixth week of development，dividing the atrioventricular canal into its right and left components．The cushions are very large relative to the canal，leaving narrow right and left slits，which increase markedly in size during further development．

At the start of stage 10，the venous pole，the atrioventricular canal， the developing left ventricle and the outflow tract are all positioned symmetrically around the midline（Fig．52．15A）．As a result of the subsequent rapid growth of the cardiac tube，the atrioventricular canal moves in its entirety to the left（Fig．52．15B）as the ventricular part of the heart tube loops to the right，thus placing the developing left ven－ tricle on the left and the forming right ventricle on the right（see Fig． 52．9）．This ventricular loop is conspicuous throughout the fourth and fifth weeks of development，and it is at this stage that a deep interven－ tricular groove appears externally．Over this period，the atrial floor， including the developing systemic venous sinus（sinus venosus）and the
atrioventricular canal, moves to the right (Fig. 52.15C). The developing pulmonary vein remains anchored in the midline and, subsequent to these manœuures, the atrioventricular canal once more becomes positioned in the midline; this process facilitates the appropriate connections of the developing muscular septum with the atrioventricular and outflow cushions. The orifice of the sinus venosus is, by now, positioned to the right. From the outset, the muscular ventricular septum develops in line with the right side of the dorsal (inferior) atrioventricular cushion (Fig. 52.16), so that the separating right atrium always has direct access to the developing right ventricle. The process also ensures that space remains ventrally for incorporation of the subaortic component of the outflow tract into the left ventricle.

## Septation of the ventricles

After the looping of the heart tube, it is easy to gain the impression that the atrioventricular canal communicates exclusively with the developing left ventricle, while the outflow tract is supported exclusively by the developing right ventricle. In the definitive heart, blood entering the

Fig. 52.15 Movements of the atrioventricular canal relative to the midline during development.
right ventricle passes in through the right atrial vestibule and exits through the muscular subpulmonary infundibulum, while blood entering the left ventricle passes in through the left atrial vestibule, and exits through the aortic root. The changes needed to produce the definitive connections between the cardiac components are complex. Three distinct structures contribute to the formation of the postnatal ventricular septum: the muscular ventricular septum, the proximal parts of the outflow cushions and the atrioventricular endocardial cushions. The latter two components separate those parts of the primary heart tube that are committed to the right and left ventricles, as opposed to the ballooned apical ventricular components. Inappropriate formation and connection of the cushions with the muscular ventricular septum underscores deficiencies of the definitive ventricular septum; such lesions account for about two-thirds of all cardiac septal defects.

Separation between the right and left ventricles is initially heralded by the appearance of a caudal crescentic ridge within the ventricular loop. The trabeculated parts of the ventricles contain less extracellular matrix than the walls of the primary heart tube, and it is these parts of the chambers that expand on each side of the ridge that remains between them. The crest of the developing septum, therefore, is its oldest portion. The more apical parts are added concomitant with enlargement of the chambers, as if they were expanding like balloons. The impression can be gained that the dorsal and ventral horns of the ventricular septum grow along the ventricular walls, meeting and fusing with the right extremities of the dorsal and ventral cushions of the atrioventricular canal. In reality, the crest of the septum marks the position of the original primary heart tube and becomes the atrioventricular bundle. The septum has a free, sickle-shaped margin that, together with the fused caudal surface of the endocardial cushions, bounds an ovoid foramen. Previously, this foramen has erroneously been termed the interventricular, or bulboventricular foramen; it is no more than a locus within the cavity of the primary heart tube. The apical trabecular components of the ventricles balloon from the ventral side of the primary heart tube. At the dorsal side, or the inner curvature, there is no chamber myocardium, only the smooth walls of the primary heart tube. Therefore, from the outset of the process, the forming apical parts of the ventricles are separated by a muscular septum. The foramen marked caudally by the crest of the ventricular septum provides the initial inlet to the developing right ventricle, and the outlet for the developing left ventricle. Completion of ventricular septation requires division of this primary foramen, rather than its closure. It also demands appropriate connection between the muscular septum and the divided atrioventricular canal, including its cushions, and with the divided outflow tract, along with its cushions (see Fig. 52.16).

Use of inappropriate terminology means that the entire region upstream relative to the foramen has previously been called the primitive ventricle, the entire downstream region the bulbus, and the junction between them the bulboventricular junction. In the account presented here, the area is termed the primary junction, initially marked by a distinct notch on the outside of the heart, and inside by the corresponding ridge of the developing ventricular septum. The ridge is positioned between the atrioventricular orifice, which is initially a common structure, and the caudal part of the forming right ventricle.

Fig. 52.16 Septation of the ventricles and outflow tract. A, A frontal view of the heart at stage 13, with the outflow tract reflected to the right. Lines show the level of transverse sections of the atrioventricular cushions and outflow tract. Note that blood from both atria passes through the embryonic interventricular foramen at this stage. B, A sagittal section of heart along the dotted line in A, showing the atrioventricular junctional region, seen from the right side. The atrioventricular cushions extend on to the leading edge of the septum primum (although the mesenchymal cap on the atrial septum - see Figure 52.14 - probably has a different developmental origin).

Appropriate connection with the separating atrioventricular and arterial junctions is essential for the development of a four-chambered heart. The serendipitous discovery of the expression of a 'neural' antigen in the primary junctional myocardium, surrounding the so-called primary interventricular foramen, has clarified the complex morphogenic steps involved in the remodelling of this region at the inner curvature and the final position of the original interventricular ring in the fully developed heart (see Fig. 52.12).

## Septation and appropriate positioning of the outflow tract

The length of the myocardial portion of the outflow tract decreases markedly between the fourth and eighth weeks of development. In part, the myocardium becomes incorporated into the ventricles; in part, it disappears by apoptosis. In the definitive heart, there is no distinct myocardial outflow tract present within the left ventricle because the myocardium that initially separated the developing mitral and aortic valves disappears, leaving the fibrous aortic-mitral continuity distinctive for the postnatal heart. In the right ventricle, the proximal myocardial outflow tract persists as the smooth-walled muscular subpulmonary infundibulum. Formation of the part adjacent to the aortic root requires muscularization of the most proximal parts of the outflow cushions to form the greater part of the supraventricular crest, or crista supraventricularis.

Key to separation of the outflow tract is the appearance of the two outflow ridges, or cushions, which spiral one round another as they run from the distal end of the right ventricle, where they are positioned septally and parietally, to the aortic sac (see Fig. 52.16; Fig. 52.17). Within the aortic sac, a transverse wedge of tissue, termed the aortopulmonary septum, separates the origins of the arteries traversing the fourth and sixth pharyngeal arteries. The septum is formed from dorsal mediastinal mesenchyme. Myocardial precursor cells and nonmyocardial cells are added to the outflow tract, the latter forming the intrapericardial components of the arterial trunks. Neural crest cells migrate from the pharyngeal mediastinal myocardium into the outflow cushions. They do not appear to populate the septum itself, but form the larger parts of the walls of the intrapericardial portions of the truncus arteriosus. The precise relationship between the outflow cushions and the newly formed aortic arch arteries, which never possess a septum between them, has still to be assessed.

The spiral outflow ridges start to fuse from the sixth week onwards, initially in the distal part of the outflow tract, and fusions continue gradually into the direction of the ventricular septum (see Fig. 52.17;

Fig. 52.18A). The most proximal parts of the cushions remain unfused when the aorta and pulmonary trunk have gained their separate existence within the pericardial cavity. At this time, the proximal part of the outflow tract, upstream to the intrapericardial arterial trunks, remains encased in a myocardial sleeve. The arterial valves and sinuses then develop within the more distal part of this myocardial outflow tract; the outer myocardial wall does not disappear completely until well after the completion of septation. The most proximal parts of the cushions are the last ones to fuse, and they then muscularize and join the muscular ventricular septum, thereby joining the aorta into the left ventricle. The dorsal atrioventricular cushion maintains its mesenchymal character, becoming the membranous part of the interventricular septum in the formed heart. Formation of its interventricular and atrioventricular components does not become evident until the septal leaflet of the tricuspid valve delaminates from the surface of the ventricular septum.

## NON-MYOCARDIAL COMPONENTS OF THE HEART

The non-myocardial components of the heart are the epicardium, including the coronary vasculature, and the interstitial fibroblasts and the valvular apparatus, which are formed, in their larger part, from endocardially derived mesenchyme. From the outset, the atrioventricular valves, mitral and tricuspid, are formed at the site of the initial atrioventricular canal, whereas the aortic and pulmonary valves are initially developed within the myocardial outflow tract, and only later achieve the semilunar attachments of the leaflets, which cross the anatomical ventriculo-arterial junctions. All of the leaflets form initially as internal endocardial projections that enclose a myocardial basement membrane, matrix and mesenchymal cells. The precise mechanisms involved in the formation of these areas have still to be determined.

## Development of the epicardium and the coronary vasculature

The epicardium, coronary vascular bed and interstitial fibroblasts develop from a mesothelially covered protrusion of mesenchymal cells, the pro-epicardium, which arises from the pericardium in the region of the sinus venosus during week 5 . The base of the pro-epicardium encompasses bi-potential pericardial cells, which are recruited either to the cardiac lineage to form the venous pole of the heart, or else to the epicardial lineage. The entire structure expresses Tbx18. Bone morphogenetic proteins and fibroblast growth factors influence which lineage is followed; the precise mechanism of specification is not yet clear. Cells

Fig. 52.18 A, A scanning electron micrograph (SEM) of a human heart at 32 days (stage 15). The right lateral wall of the right atrium, right ventricle and the outflow tract have been removed. The septum primum (S) and the developing valve of the sinus venosus (white arrow) are at a distance from the unfused ventral ( V ) and dorsal ( D ) atrioventricular cushions. The interventricular foramen (primum) is open (O). Its lower margin is made up by the developing interventricular septum (I). Note the left anterolateral ridge ( R ) and, at the distal margins of the truncus arteriosus, the valve swellings ( ${ }^{*}$ ) of the putative aorta and pulmonary trunk. Other abbreviations: At, atrium; E, embryonic trabeculae; IV, origin of fourth aortic arch; VI, origin of sixth aortic arch. B, The septal aspect of the right ventricle of a human heart at 8 weeks. Delamination of the septal cusp of the tricuspid valve $(T)$ is taking place. A cleft (black arrow) has appeared, marking the posterior margin of the septal cusp. There are no clefts delineating the anterior margins in the region adjacent to the supraventricular crest (C), and the endocardium is continuous. No tension apparatus (chordae tendinae and papillary muscles) is present. Other abbreviations: AV, aortic valve; LA, left atrium; PV, pulmonary valve; RA, right atrium.
detach from the pro-epicardium and spread over the myocardial tube, caudally to cranially and dorsally to ventrally. Thus, in successive stages, the pro-epicardial cells approach the myocardial surface of the developing atria, atrioventricular canal, ventricles and the proximal part of the outflow tract. The distal part of the outflow tract, as it becomes arterialized with regression of the initial myocardial walls, is covered by an outgrowth of the pericardial mesothelium at the site of the initial pericardial reflections. After the formation of the epicardium, a space is formed between the developing epicardium and the outer myocardial layer, which is particularly pronounced at the atrioventricular and outflow regions of the heart tube. This is the subepicardial space, or subepicardium; it is subsequently populated by mesenchymal cells that are largely derived from the epicardium and which play an important role in the formation of the coronary vasculature. The precursors of coronary fibroblasts, smooth muscle cells and endothelium are all derived from these pluripotent cells, which possibly also play roles in the development of non-vascular tissues, including the mesenchyme of the atrioventricular cushions and some myocardial elements. The remnants of the pro-epicardium can be found in the area of the developing systemic venous tributaries up to stage 15 .

The coronary arteries were previously assumed to form by means of angiogenesis, or sprouting from the aortic root. However, recent studies have demonstrated that the vessels develop prior to the formation of the arterial orifices in the aortic sinuses; it is now thought that the vessels arise by vasculogenesis, and that mesenchymal cells in the subepicardial space give rise to primitive vessels that invade the myocardium and spread over the myocardial surface. Sprouts of this plexus approach the base of the outflow tract and connect to the sinuses of the aortic root. Ultimately, only solitary right and left coronary arteries remain, although, in up to one-third of human hearts, small accessory branches of the coronary arteries take origin directly from the coronary sinuses. The vessels that remain acquire a medial wall and an adventitial covering, whereas those that do not form a medial wall are destined to regress. The coronary veins develop by sprouting from the coronary sinus, draining directly to the atrial chambers. The mature coronary vascular pattern is established by remodelling of the capillary plexuses and reduction in the number of arteriovenous anastomoses.

## Atrioventricular valves

Initially, the atrial myocardium is continuous with the ventricular myocardium through the myocardium of the atrioventricular canal. The atrioventricular canal itself is characterized by the tissues of the atrioventricular groove on the epicardial side, and those of the endocardial cushions on the endocardial side. As the atrioventricular valves develop, these tissues fuse at the ventricular margin of the canal, and so disrupt myocardial continuity. Although molecular lineage studies in the mouse have demonstrated that the atrioventricular cushions are initially entirely populated by endocardium-derived mesenchymal cells, they receive a significant epicardial contribution during further development, the fibroblasts making up the valvular leaflets, and their tendinous cords in the formed heart are therefore derived from both the endocardium and the epicardium.

The atrioventricular valves develop as shelf-like projections from the margins of the atrioventricular orifices. They are directed as almost complete conical sheets towards the ventricles, their advancing edges continuing, initially as trabecular ridges, deep into the ventricular cavity. With continued differential growth and excavation on their ventricular aspects, each sheet develops major indentations forming the mitral and tricuspid orifices and defining their principal leaflets. Minor marginal indentations subdivide some leaflets into scallops. Each leaflet develops functionally significant regional variations in surface texture and its core condenses as a collagenous fibrous lamina, supported either by the fibro-fatty tissue of the atrioventricular groove, or by a fibrous anulus. The anterior leaflet of the tricuspid valve and the aortic and mural leaflets of the mitral valve all appear at about the time of fusion of the atrioventricular and outflow cushions. Delamination of the septal leaflet of the tricuspid valve occurs after the completion of ventricular septation, producing the interventricular and atrioventricular components of the membranous septum, and continuing until at least week 11 (Fig. 52.18B).

## Aortic and pulmonary valves

The aortic and pulmonary valves form from endocardial cushions within the distal end of the myocardial outflow tract and become populated by neural crest cells, in addition to endocardial- and pharyngealderived mesenchyme. The fusing outflow cushions divide, providing two rudiments each for the developing aortic and pulmonary valves. The remaining leaflet for each valve is then produced from the newly appearing intercalated cushions (see Fig. 52.17). Each cushion-derived intrusion grows, and is also excavated on its mural aspect to form a semilunar valvular leaflet. Similar events affect the adjacent wall. In this way, the pouches between the valves and the walls of the cushions gradually enlarge, the mural aspect of each cushion forming the valvular sinuses. The core of each leaflet forms a collagenous fibrous lamina, delicate and thin in each crescentic lunule, thick and compact in the central nodule, with marginal radiate and basal bands. The dynamic nature of cardiac development makes it difficult to describe the positions of the leaflets precisely in space; it is, therefore, best to describe the right, left and non-coronary sinuses and leaflets of the aortic valve, and the adjacent and non-adjacent leaflets of the pulmonary valve.

## FETAL CIRCULATION

As the cardiovascular system develops, the embryonic circulation (Ch. 13) is modified into a fetal circulation, which maintains a placental
circulation and is also able to establish the pulmonary circulation at birth. Extensive remodelling of the early aortic arch arteries and (initially bilateral) dorsal aortae occurs (Ch. 36). The dorsal aortae persist on the cranial side of the third aortic arches as continuations of the internal carotid arteries (see Fig. 36.9). The dorsal aorta between the third and fourth aortic arches, the carotid duct, diminishes and finally disappears. From the fourth arch to the origin of the seventh intersegmental artery, the right dorsal aorta becomes part of the right subclavian artery, and caudal to the seventh intersegmental artery, the right dorsal aorta disappears as far as the locus of fusion of the thoracic aortae. After disappearance of the left carotid duct, the remainder persists to form the descending part of the arch of the aorta. The fused right and left embryonic dorsal aortae persist as the definitive descending thoracic and abdominal aorta. A constriction, the aortic isthmus, is sometimes present in the aorta between the final site of origin of the left subclavian artery and the orifice of the arterial duct.

Concomitant changes also occur in the early venous system. The precardinal veins enlarge as the head and brain develop. They are further augmented by the subclavian veins from the upper limb buds, which become the chief tributaries of the common cardinal veins, gradually assuming an almost vertical position as the heart descends into the thorax (see Fig. 13.4). That part of the original precardinal vein rostral to the subclavian vein is now the internal jugular vein, and their confluence is the brachiocephalic vein of each side. The right and left common cardinal veins are originally of the same diameter; by the development of a large oblique transverse connection, the left brachiocephalic vein carries blood across from the left to the right. The part of the original right precardinal vein between the junction of the two brachiocephalic veins and the azygos veins forms the upper part of the superior vena cava. The caudal part of this vessel, below the entrance of the azygos vein, is formed by the right common cardinal vein. The left precardinal and left common cardinal veins caudal to the transverse branching of the left brachiocephalic vein largely atrophy; the precardinal constitutes the terminal part of the left superior intercostal vein, while the common cardinal is represented by the ligament of the left superior vena cava and the oblique vein of the left atrium. The remainder of the left superior intercostal vein is developed from the cranial end of the postcardinal vein and drains the second, third and, on occasion, the fourth intercostal veins. The oblique vein passes downwards across the back of the left atrium to open into the coronary sinus, which represents the persistent left horn of the systemic venous sinus.

The fetal circulation contains a number of relatively large vessels that permit the majority of the blood flow to bypass the liver and lungs. The placenta serves as the organ for fetal nutrition and excretion, receiving deoxygenated fetal blood and returning it oxygenated and detoxified. Fetal blood reaches the placenta via two umbilical arteries and, in early fetal life, returns by two umbilical veins (Fig. 52.19). The right umbilical vein later disappears, whereas the persisting left umbilical vein enters the abdomen at the umbilicus, traverses the edge of the falciform ligament to reach the hepatic surface, and then joins the left branch of the portal vein at the hepatic portal. Opposite the junction, a large vessel, the ductus venosus, arises and ascends posterior to the liver to join the left hepatic vein near its termination in the inferior vena cava. (For a detailed developmental account of the circumhepatic veins, see Figs 60.8-60.11.) The portal vein is small in the fetus compared to the size of the umbilical vein. Parts of the left branch of the umbilical vein, proximal and distal to their junctions, function as branches of the portal vein, carrying oxygenated blood to the right and left parts of the liver. Blood in the left umbilical vein, therefore, reaches the inferior vena cava by three routes: some enters the liver directly and reaches the vena cava via the hepatic veins; a considerable quantity circulates through the liver with portal venous blood before also entering by the hepatic veins; and the remainder is bypassed into the inferior vena cava by the ductus venosus.

The refreshed placental blood passes almost directly to the aorta for distribution to the head and upper limbs. Blood from the ductus venosus and hepatic veins mixes in the inferior vena cava with blood from the lower limbs and abdominal wall, and enters the right atrium. Because right atrial pressure is much greater than left atrial pressure, it forces the flap-like valve of the septum primum to the left, which permits passage of blood from the right to the left atrium. The valve of the inferior vena cava is so placed as to direct $75 \%$ of the richly oxygenated blood from the umbilical vein to the foramen ovale and left atrium, where it mingles with the limited venous return from the pulmonary veins. From the left atrium, blood enters the left ventricle and from there flows to the aorta; from here, it is probably distributed almost entirely to the heart, head and upper limbs, which means that little reaches the descending aorta.

Fig. 52.19 A plan of the fetal circulation. The arrows indicate the direction of blood flow. The placenta is drawn to a greatly reduced scale.

Blood from the head and upper limbs returns to the right atrium via the superior vena cava, flows through the right atrioventricular orifice into the right ventricle (together with the small amount of blood that is returned via the inferior vena cava), and then passes into the pulmonary trunk. However, because the fetal lungs are largely inactive, only a little of the blood from the right ventricle flows through the right and left pulmonary arteries and returns to the left atrium via the pulmonary veins. The greater part of the outflow through the pulmonary trunk is carried by the ductus arteriosus directly to the aorta, where it mixes with the small quantity of blood that passes from the left ventricle into this part of the aorta. The mixture descends in the aorta and most is returned via the umbilical arteries to the placenta; some is distributed to the lower limbs and the organs of the abdomen and pelvis.

## CHANGES IN THE FETAL CIRCULATION AND OCCLUSION OF FETAL VESSELS AFTER BIRTH

At birth, as pulmonary respiration begins, increased amounts of blood from the pulmonary trunk flow through the pulmonary arteries to the lungs and return by the pulmonary veins to the left atrium; pressure therefore increases within the left atrium. A decrease in pressure also occurs in the inferior vena cava as a result of the reduction of venous return concomitant with occlusion of the umbilical vein and ductus venosus. Atrial pressures become equal and the valvular foramen ovale is closed by apposition, and subsequent fusion, of the septum primum to the rims of the foramen. Contraction of the atrial septal muscle, synchronized with that in the superior vena cava, may assist this closure, which occurs after functional closure of the ductus arteriosus. Although the foramen ovale closes functionally after pulmonary respiration is established, it does not become structurally closed until some time later. It is obliterated in fewer than $3 \%$ of infants 2 weeks after birth, and in $87 \%$ by 4 months after birth. Fusion is sometimes incomplete
and a potential atrial communication (atrial septal defect) persists throughout life. Almost always, this has no functional effect because the inequality of atrial pressures and the valve-like arrangement of the opening do not favour passage of blood.

Soon after birth, a number of fetal vessels occlude, although the majority remain patent. This differential constriction suggests that the walls of a population of fetal vessels are different to those of the remaining vessels. Bradykinin, one of the kinin polypeptide hormones that induce contraction or relaxation of smooth muscle, forms in the blood of the umbilical cord when the temperature of the cord decreases at or shortly after birth. It is also formed and released by granular leukocytes in the lungs of the neonate after exposure to adequate oxygen. Bradykinin is a potent constrictor of the umbilical arteries and veins, and of
the ductus arteriosus, and is also a potent inhibitor of contraction of the pulmonary vessels.

## Ductus arteriosus

The ductus arteriosus shunts blood from the pulmonary trunk to the arch of the aorta, bypassing the fetal lungs (see Fig. 52.19; Fig. 52.20). It arises as a direct continuation of the pulmonary trunk at the point where it divides into right and left pulmonary arteries. It is $8-12 \mathrm{~mm}$ long, and joins the aorta at an angle of $30-35^{\circ}$ on the left side, anterolaterally, below the origin of the left subclavian artery. The opening of the ductus arteriosus into the aorta is greatly elongated. Its diameter at

Fig. 52.20 An anterior view of the heart and great vessels in a full-term neonate. The lungs have been displaced to expose the heart, and the epicardium has been dissected off the heart and the roots of the great vessels. Note that, after birth, blood flow reverses through the ductus arteriosus prior to its closure. (After Crelin ES 1969 Anatomy of the Newborn. Philadelphia: Lea and Febiger.)

Fig. 52.21 An anterior view with the heart removed to show the relationship between the left primary bronchus, the aortic arch and the ductus arteriosus in a full-term fetus. (After Crelin ES 1969 Anatomy of the Newborn. Philadelphia: Lea and Febiger.)
its origin from the pulmonary trunk, when distended with blood, is $4-5 \mathrm{~mm}$, which is nearly equal to the diameter of the adjacent ascending aorta $(5-6 \mathrm{~mm})$. Both arteries taper to a smaller diameter as they pass inferiorly and the aorta remains slightly larger ( 4 mm ) (Fig. 52.21). In the neonate, the ductus arteriosus is closely related to the left primary bronchus inferiorly and the thymus gland anteriorly.

The ductus arteriosus differs from the other great vessels that arise from the heart because its tunica media contains smooth muscle rather than layers of elastin. It has been suggested that the relationship between the recurrent laryngeal branch of the vagus nerve and the developing ductus arteriosus is responsible for this histological difference on the grounds that the left recurrent laryngeal nerve (which, in a stage 16 embryo, is very large in relation to the aortic arch system) supports the ductus arteriosus as it enwraps it, thereby permitting the ductus to develop as a muscular, and not an elastic, artery.

It is essential that the ductus arteriosus remains patent during intrauterine life. Prostaglandins appear to have a role in maintaining this patency. Fetal and neonatal ductal tissue can produce prostaglandins $\mathrm{E}_{2}, \mathrm{I}_{2}$ and $\mathrm{F}_{2} \mathrm{a}$, which inhibit the ability of the ductus to contract in response to oxygen.

## Closure of the ductus arteriosus

The ductus arteriosus starts to close immediately after birth, although blood probably continues to flow intermittently through it for a week or so. The flow is reversed relative to that occurring in the fetal circulation, reflecting the increased systemic vascular resistance that follows exclusion of the placental circulation, and the decreased pulmonary resistance that follows expansion of the lungs. Animal studies have shown that reversal of flow occurs rapidly after ventilation begins. Blood flow from the left ventricle travelling via the aorta and ductus arteriosus contributes almost $50 \%$ of total pulmonary blood flow. Initial constriction at birth has been attributed to increased oxygen tension. A neural factor may also be involved; the muscular wall has afferent and efferent nerve endings and responds to adrenaline (epinephrine) and noradrenaline (norepinephrine) within 10 minutes of ventilation onset; this reduces to about $25 \%$ by 2 hours. It is suggested that the turbulence and increased shear-stress of this blood flow releases vasoconstrictive factors from the endothelium (Crossley et al 2009).

The first stage of ductal closure is completed within 10-15 hours and the second stage takes 2-3 weeks. The first stage consists of contraction of the smooth muscle cells and development of subendothelial oedema.

Destruction of the endothelium and proliferation of the intima subsequently occur, and lead to permanent closure. Diverse factors that may promote ductal closure have been identified, and include increased oxygen tension; increased plasma catecholamine concentrations; suppression of prostaglandin $\mathrm{I}_{2}$ production; switching off prostaglandin E receptors; a synergistic role of prostaglandin $\mathrm{F}_{2} \mathrm{a}$ and oxygen concentrations; and a decrease in plasma adenosine concentration. After birth, these interrelated events result in the closure of the ductus arteriosus. It has been proposed that the high oxygen tension of the reversed blood flow through the ductus initiates the synthesis of a hydroperoxy fatty acid that suppresses prostacyclin production, thus exposing the ductus to the contractile effects of prostaglandin endoperoxide. After closure, the duct becomes the ligamentum arteriosum, which connects the left pulmonary artery (near its origin) with the aortic arch.

## FETAL AND NEONATAL HEART

At full term, the heart is situated midway between the crown of the head and the lower level of the buttocks (see Fig. 14.6). The anterior surface is formed mainly by the right atrium and right ventricle, as it is in the adult. This surface is usually covered by the thymus, which may extend over the base of the right ventricle. The heart is relatively large at birth, weighing around 20 g . The cardiac output is around 550 ml per minute and the blood pressure is $80 / 46 \mathrm{mmHg}$. The heart rate during fetal life, as term approaches, is around 150 beats per minute (bpm). It increases at birth to around 180 bpm , decreases over the first 10 minutes after birth to 170 bpm , and reaches $120-140 \mathrm{bpm}$ from 15 minutes to 1 hour after birth. Any signs of fetal distress will increase this general basic level. The heart rate decreases further with increasing age: it is normally $113-127 \mathrm{bpm}$ from 6 months to 1 year, and settles to around 100 bpm by the end of the first year.

Considered relative to the thoracic landmarks, the foramen ovale lies at the level of the third intercostal space, with its long axis in the median plane. It is $4-6 \mathrm{~mm}$ in vertical length and $3-4 \mathrm{~mm}$ wide (see Fig. 14.6). It is almost exactly in the coronal plane of the body, so that blood passes from the anterior, or ventral, right atrium posteriorly and upwards to reach the upper and posterior part of the left atrium. After birth, the intra-atrial pressures are equalized, and the free edge of the flap valve formed by the primary atrial septum is kept in contact with the left side of the rims of the fossa, promoting subsequent anatomical fusion, despite the fact that the foramen remains probe-patent in up to onethird of all individuals. The initially free crescentic margin of the infolded superior interatrial fold forms the border of the fossa after fusion; the flap valve formed by the primary septum accounts for its floor in the adult heart.

Functionally, the ventricular septum is often considered to be part of the left ventricle; while this is certainly true in terms of the orientation of the myocardial aggregates that make up the ventricular walls, it is not correct from a cellular lineage perspective. The ratio of cardiac weight is usually expressed as the weight of the right ventricle relative to that of the left ventricle and the septum. Calculated in this fashion, the left ventricle at birth weighs about $25 \%$ more than the right ventricle. However, the right ventricle has been working against the systemic pressure in the fetus, the pulmonary circulation not yet being active, and there is a preponderance of right ventricular function in the first 2 or 3 months after birth. With the establishment of the pulmonary circulation, the work of the right side of the heart decreases, and the left side of the heart, particularly the ventricle, grows rapidly to meet the demands of the active neonate. By the end of the second year, the left side weighs twice as much as the right, a ratio that continues to middle age. At birth, the average thicknesses of the lateral walls of the ventricles are approximately equal ( 5 mm ). By the end of the third postnatal month, the left ventricle has already become thicker than the right; it becomes twice as thick by the second year, and three times as thick by puberty.

## CONGENITAL HEART DEFECTS

Defects of cardiac development may not come to light until after birth, although many, if not most, can now be observed on fetal ultrasonic examination. They may affect any part of the developing heart, and include more complex forms with inappropriate connections of cardiac components. They include anomalies such as double inlet ventricle; absence of one atrioventricular connection, commonly described as tricuspid or mitral atresia; and discordant atrioventricular and ventriculo-arterial connections, also known as congenitally corrected transposition.

A

Fig. 52.22 A, Location of the defects that produce an interatrial communication. Only defects within the fossa ovalis are true atrial septal defects. B, Shunting across an atrioventricular septal defect. This can be atrial (left), ventricular (right) or at both levels (middle), depending on the attachment of the bridging cusps. C, Ventricular septal defects. Depending on the structure of the anatomical borders seen from the right ventricle, these defects can be placed into perimembranous, muscular or doubly committed groups. (B and C, Courtesy of Professor RH Anderson, Institute of Child Health, University College, London.)

Congenital cardiac anomalies are often multiple, and probably occur more frequently in siblings and in children of consanguineous marriages; there is a low correlation among monozygotic twins. Ventricular septal defects are the most common lesions, making up around onefifth of all cases, followed by persistent patency of the ductus arteriosus, coarctation, pulmonary stenosis, Fallot's tetralogy, transposition, aortic stenosis, and hypoplasia of the left heart.

## Atrial septal defects

A persistent communication between the atrial chambers within the fossa ovale is common, and results from the failure of the flap valve of the primary atrial septum to fuse with the infolded muscular rims of the fossa. When the flap valve is still able to overlap the rims, the communication is of no functional significance as long as left atrial pressure is greater than right, which is usually the case. However, when the flap valve is smaller than the fossa ovale, or when it is perforate, there is a true atrial septal defect (Fig. 52.22A).

In normal development, the free leading edge of the septum primum merges with the atrioventricular endocardial cushions, permitting subsequent formation of the atrioventricular septum. When this does not happen, there is a common atrioventricular junction and an atrioventricular septal defect. This can occur when the leaflets of the atrioventricular valves are fused to the crest of the ventricular septum (see Fig. 52.22 A ), producing an interatrial communication at the expected site of the atrioventricular septum. This is the so-called ostium primum defect; in reality, it is an atrioventricular septal defect permitting exclusive atrial shunting. Other interatrial communications can be formed in the mouths of the vena cavae, most frequently the superior vena cava, and are usually associated with drainage of the right pulmonary veins into the cavo-atrial junction. Known as sinus venosus defects (see Fig. 52.22 A ), their essential feature is a bi-atrial connection of the involved caval vein. An interatrial communication can also occur through the mouth of the coronary sinus when there is a deficiency or absence of the walls that usually separate the sinus from the left atrium.

Atrioventricular septal defects result from failure of fusion of the endocardial atrioventricular cushions, producing a common atrioventricular orifice and deficiencies of the adjacent septal structures (Fig. 52.22 B ). The common orifice is guarded by a basically common valve, with superior and inferior leaflets bridging the scooped-out ventricular septum and tethered in both right and left ventricles. Although the left component of the valve thus formed is often interpreted as a 'cleft mitral valve', it bears no resemblance to the normally structured mitral valve, in reality, because it has three leaflets; the 'cleft' forms the zone of apposition between the left ventricular components of the bridging
leaflets. Two major subgroups are identified. The more frequent pattern has a common atrioventricular orifice, and the potential for shunting through the septal defect at both atrial and ventricular levels (see Fig. 52.22 B ). The less common form has separate right and left atrioventricular orifices, and shunting occurs only at atrial level. Occasionally, when the bridging leaflets are attached to the underside of the atrial septum, shunting is confined at ventricular level and is typically small.

## Ventricular septal defects

The most common defect of the ventricular septum occurs around the expected site of the membranous septum in the right wall of the aortic vestibule, below the zone of apposition between the non-coronary and right coronary leaflets of the aortic valve (Fig. 52.22C). The defect is closely related to the septal leaflet of the tricuspid valve, but can extend to open into the ventricular outlet beneath the supraventricular crest. It occurs because the ventricular septum is incompletely closed by its membranous component, and it is often associated with overriding of the crest of the muscular septum by the aortic orifice, together with pulmonary stenosis or atresia and hypertrophy of the right ventricle (this latter combination is known as Fallot's tetralogy). Rarely, the pulmonary trunk can be normal or even dilated with this combination of abnormalities (Eisenmenger complex). Perimembranous defects, which retain the remnant of the membranous septum as part of their perimeter, can also occur with abnormal ventriculo-arterial connections, e.g. the pulmonary trunk may override the muscular septum (the TaussigBing anomaly). In perimembranous ventricular septal defects, the atrioventricular bundle and its right and left branches are always found along the posteroinferior margin of the defect.

Less commonly, a septal defect can be found in the ventricular outflow tracts roofed by the conjoined facing leaflets of the aortic and pulmonary valves. Such juxta-arterial defects are doubly committed, in that they open beneath the orifices of both aortic and pulmonary valves. They are the result of the failure of formation of the free-standing subpulmonary muscular infundibulum, but with appropriate septation of the ventriculo-arterial junctions. They usually have a muscular posteroinferior rim, which protects the atrioventricular bundle, but can extend to become perimembranous.

The third type of ventricular septal defect occurs within the musculature of the septum; defects may affect all parts of the septum and can be multiple, producing a so-called 'Swiss cheese' septum.

Defects within the inlet part of the septum are important because the atrioventricular bundle passes in their upper border. Perimembranous defects open into the inlet of the right ventricle, where the atrioventricular bundle is posteroinferiorly located.

Fig. 52.23 This heart possesses a common arterial trunk, with a common truncal valve overriding a juxtaarterial deficiency of the ventricular septum, the result of failure of septation of the arterial pole of the developing heart. (Courtesy of Professor RH Anderson, Institute of Child Health, University College, London. Specimen prepared by Dr Leon M Gerlis.)

## ANOMALIES OF THE GREAT ARTERIES AND VEINS

A number of outflow anomalies may occur if the outflow cushions either fail to develop or fuse in inappropriate fashion. When the spiral septum cushions fail to fuse, the result is a common arterial trunk, represented by an undivided arterial channel, guarded by a common arterial valve, positioned above and astride the free margin of the muscular ventricular septum (Fig. 52.23). There is, therefore, a coexisting juxta-arterial deficiency of the ventricular septum. The right and left pulmonary arteries usually arise via a confluent segment but can take independent origin from the common arterial trunk, which continues as the ascending aorta. The common valve usually has three leaflets but may have two, four or more. The lesion is almost certainly linked to abnormal migration of cells into the heart from the neural crest.

Transposition of the arterial trunks (also referred to as transposition of the great vessels) is the condition in which the aorta arises from the right ventricle and the pulmonary trunk from the left. Better described as having discordant ventriculo-arterial connections, such hearts can coexist with deficiencies of cardiac septation. They can also be found with discordant connections at the atrioventricular junctions, producing congenitally corrected transposition. The developmental history of discordant connections remains unknown.

Double outlet ventricle exists when the greater parts of both arterial valves are attached within the same ventricle, almost always the right. For the circulation to continue, it is then necessary for the ventricular septum to be deficient, although the septal defect can rarely close as a secondary event. The position of the septal defect serves for subclassification. It is usually beneath the aorta or the pulmonary trunk, but can be doubly committed or even non-committed.

Either the systemic or pulmonary veins can be anomalously connected. Right and left superior vena cavae are present in some animals and occasionally persist in mankind. The most common systemic anomaly is a persistent left superior vena cava draining into the right atrium through the enlarged orifice of the coronary sinus. More rarely, the persisting left-sided vena cava may connect directly with the superior aspect of the left atrium, usually associated with so-called 'unroofing' of the coronary sinus, so that the orifice of the sinus functions as an interatrial communication. The most common lesion of the inferior vena cava is when its abdominal course is interrupted, with drainage to the heart via the azygos or hemiazygos venous system. This lesion is found most frequently with isomerism of the left atrial appendages. The pulmonary veins can be connected to an anomalous site individually or in combination. Totally anomalous connection is of most significance. Usually, the veins form a confluence behind the left atrium, which then connects to the superior vena cava, the coronary sinus or the portal venous system after traversing the diaphragm.

A right aortic arch is found most frequently with Fallot's tetralogy or with a common arterial trunk. It can also exist, together with a left arch, in various combinations known as arterial rings, which compress the
oesophagus, giving so-called dysphagia lusoria. Persistent patency of the ductus arteriosus must be distinguished from delayed closure. The persistently patent ductus can be an obligatory part of the circulation when associated with aortic or pulmonary atresia. Coarctation of the aorta can be found as an isolated lesion when the ductus arteriosus is closed, or with an open duct, when it is more likely to be associated with additional lesions within the heart.

In the adult, the right subclavian artery occasionally arises from the arch of the aorta distal to the origin of the left subclavian artery, and then passes upwards and to the right, behind the trachea and oesophagus. This condition is possibly explained by the persistence of the embryonic right dorsal aorta and the obliteration of the fourth aortic arch of the right side.

## Ultrasound antenatal imaging of the heart and vessels

In a four-chamber view of the fetal heart, up to about 28 weeks' gestation, the heart occupies about one-third of the thorax in the anterior left quadrant of the chest. The two atria are of equal size, as are the two ventricles, which have an intact interventricular septum between them; the apex of the heart points to the left anterior thorax. In moving images, the ventricles show equal contraction, the two atrioventricular canals open equally, and the foramen ovale flap valve can be seen flickering in the left atrium (see Video 14.1). The blood flow through the heart can be demonstrated with colour flow (Fig. 52.24). After 28 weeks' gestation, the right ventricle may look dilated compared with the left.

Ultrasound evaluation of the fetal heart checks that the fetal heart and stomach are both on the left and that the liver is on the right. Within the four-chamber view, the function and rhythm of the heart and the origin of the great vessels from their respective ventricles can be observed. The great vessels can be assessed in transverse section and the aorta can also be assessed longitudinally (see Fig. 14.4); it normally arises in the centre of the thorax, and the vessels to the head and neck can be seen arising from the curve of the aortic arch. For further details of ultrasound findings, consult Coady and Bower (2015).

## NEONATAL ARTERIAL AND VENOUS VESSELS

In the neonate, the blood vessels of the trunk and their associated visceral branches are relatively larger than the vessels in the limbs, an arrangement that favours central pooling of blood. Neonatal peripheral vessels are nearly microscopic; consequently, their cannulation poses much more of a problem than is the case with their adult counterparts. Large vessels are in the same relative positions as in the adult but may correspond to different vertebral levels. Thus, although the bifurcation of the common carotid artery into internal and external carotid arteries occurs at the level of the upper border of the thyroid cartilage, in both neonate and adult, the thyroid cartilage is relatively higher in the neonatal neck than it is in the adult. The renal arteries also arise higher in the neonate, often between T12 and L1, whereas they arise at the upper border of L2 in the adult. The abdominal aorta bifurcates into common iliac arteries at the upper border of L4, rather than at the lower border of L4, as occurs in the adult.

## Central venous catheterization

Small-bore catheters can be fed into large central veins or into the right atrium via needles or catheters inserted in the peripheral veins. Typically, the median cubital or basilic veins are used in the upper limb, the long saphenous vein at the medial malleolus in the lower limb and the superficial temporal vein in the scalp. The tip of the catheter is sited at the entrance to the right atrium. The required catheter length is assessed from direct measurement of the distance between the point of surface entry in the limb to the right atrium, estimated at mid-sternal level. For details of umbilical catheterization, see Chapter 60.

## RESPIRATORY TREE

The development of the respiratory system can be conceptualized as the growth of six intertwined trees: the bronchial tree of conducting airways and terminal gas-exchanging sacs; the systemic arterial and venous trees that perfuse and drain the airways, respectively; the pulmonary arterial and venous trees that supply and drain the alveolar membrane, respectively, and anastomose with the systemic and venous trees (and are

Fig. 52.24 A, A normal four-chamber view at 22 weeks' gestation.

Abbreviations: LA, left atrium; LV, left ventricle; MV, mitral valve; RA, right atrium; RV, right ventricle; TV, tricuspid valve. (Courtesy of Gurleen Sharland, Evelina London Children's Hospital.)
pivotal to the provision of blood oxygenation and carbon dioxide excretion after birth); and the lymphatic tree. Development of each tree is related to the other and all proceed in proximal to distal growth and expansion. Uniquely, the lung develops while not fulfilling its postnatal function, and must function efficiently immediately after birth or else the baby will require respiratory support and may die of respiratory failure. Current knowledge of the molecular basis of lung development is based on growth in vitro of human and animal explants (usually mouse and rat), and studies using knockout and transgenic mice (Herriges et al 2012). Anomalies of lung development make an important contribution to the development of airway diseases such as asthma and chronic obstructive pulmonary disease (COPD) (Bush 2008). The reader is referred to recent studies of lung developmental biology for more information (Roth-Kleiner and Post 2005, Kimura and Deutsch 2007, Maeda et al 2007, Bhaskaran et al 2009, Kho et al 2010, Morrisey and Hogan 2010, Sgantzis et al 2011, Ornitz and Yin 2012).

The development of the respiratory diverticulum can first be seen at stage 12 (approximately 26 days), when there is a sharp onset of epithelial proliferation within the foregut at regions of the endoderm tube destined to become the lungs, stomach, liver and dorsal pancreas. The specialist respiratory epithelium forms from the endoderm, whereas the other elements of the airway wall are of mesenchymal origin. The future respiratory epithelium bulges ventrally into the investing splanchnopleuric mesenchyme, then grows caudally as a bulb-shaped tube (Fig. 52.25; see Figs 52.1C, 60.3, 60.5). By stage 13, the caudal end of the tube has divided asymmetrically to form the future primary bronchi; with growth, the right primary bronchus becomes orientated more caudally, whereas the left extends more transversely. The trachea is clearly recognizable at stage 14 . From this time, the origin of the trachea remains close to its site of evagination from the future oesophagus; however, longitudinal growth of the trachea causes the region of the future carina to descend, ultimately to lie within the thorax. Failure of complete separation between trachea and oesophagus will result in the baby being born with one of the variants of tracheo-oesophageal fistula (see below).

There is a sexual dimorphism in lung development. Androgens delay fetal lung maturation while stimulating fetal lung growth; in males, type II cells are less mature than in females, as they develop during the canalicular phase, perhaps because androgens block the effects of cortisol on fibroblast-pneumocyte factor concentrations. It is possible that, in male fetuses, surfactant production is delayed. The clinical counterpart is the observation that preterm males may have worse respiratory distress than females after control for other risk factors, such as degree of prematurity.

## TRACHEA

The trachea starts to develop at stage 12, as a ventral outgrowth from the endodermal foregut into the mesenchyme that surrounds the sinus venosus and inflow tract of the heart (see Figs 52.1C, 60.3, 60.5). The point at which the original respiratory diverticulum buds from the foregut, the laryngotracheal groove, remains at a constant level during the embryonic period, and the trachea lengthens distally as the bifurcation point descends. The respiratory diverticulum generally becomes surrounded by angiogenic mesenchyme that connects to the developing sixth aortic arch artery and is essential for airway branching. By stage 17, the mesenchyme around the trachea is beginning to condense to form cartilage.

Initially, the tracheal mesenchyme is continuous with that surrounding the ventral wall of the oesophagus (see Fig. 52.3). Progressive lengthening and continued division of the tracheal bud, together with deviation of the lung buds dorsally, isolates the oesophagus and trachea within tissue-specific mesenchyme and facilitates regional differentiation, not only between trachea and lungs, but also within the lungs themselves, i.e. the number of lobes, or the degree of growth and maturity of a particular lung. Each lung develops by a process of dichotomous branching. For branching to occur, a cleft must develop in the tip (or side) of the epithelial tube. The epithelium then evaginates each side of the cleft, forming new branches that lengthen, and the process is then repeated (see Fig. 11.3). At the tips of the developing epithelial buds, the mesenchyme is flattened and densely packed, whereas it forms an ordered row of cuboidal cells along the side of the bud and in the clefts. Cells in both arrangements send processes towards the epithelial basal lamina, which is thicker in the clefts, but so attenuated as to be almost indistinguishable on the tips of the buds where the epithelium and mesenchymal cells form intimate contacts. Tenascin, an extracellular matrix molecule, is present in the budding and distal tip regions, but absent in the clefts. Conversely, fibronectin, an extracellular

Fig. 52.25 Development of the respiratory tree and diaphragm. A-C, Development of the endodermal respiratory tree. D, Major epithelial populations in the early embryo from a left dorsolateral view. The lung buds are bulging into the laterally placed pericardioperitoneal canals.
matrix molecule found commonly in basal laminae, is found in the clefts and along the sides of the developing bronchi, but not on the budding and distal tips. It is likely that, after the first generation, branching morphogenesis is not rigidly prespecified, but adapts to the space available within the mesenchyme (Blanc et al 2012).

The control of the branching pattern of the respiratory tree resides with the splanchnopleuric mesenchyme. Experimental recombination of tracheal mesenchyme with bronchial respiratory endoderm results in inhibition of bronchial branching, whereas recombination of bronchial mesenchyme with tracheal epithelium will induce bronchial outgrowths from the trachea. Experimental exposure of rat fetal airway to chick mesenchyme produces a chick airway branching pattern. Broadly, receptor tyrosine kinases and their ligands positively modulate growth and branching morphogenesis, while transforming growth factor beta (TGF- $\beta$ ) family members have an inhibitory effect.

Interestingly, even at this early stage, airway smooth muscle is innervated and contractile (Tollet et al 2002). Phasic contraction and relaxation of airways is important in growth factor release. Smooth muscle and nerves are found outside the airways at this developmental stage. Glial-derived neurotrophic factor (GDNF) is important in this process.

In the normal neonate, the trachea is relatively small in relation to the larynx (see Fig. 14.6B). The walls of the trachea are relatively thick
and the tracheal cartilages are relatively closer together than in the adult. The trachea begins at the upper border of the sixth cervical vertebra, a relationship that is conserved with growth, and it bifurcates at the level of the third or fourth thoracic vertebra.

## Endotracheal intubation in the neonate

The insertion of an endotracheal tube is a procedure that may be required to resuscitate the newborn at birth and, subsequently, to enable artificial ventilation. Initially, the tube is usually introduced orally and it is then guided through the vocal cords under direct vision using a laryngoscope. The length of the trachea in the neonate can be as short as 3 cm in premature infants, and the distance from T1 to carina ranges from 1.4 cm in babies weighing $500-1000 \mathrm{~g}$ to 1.8 cm in those weighing 3001-3500 g. Once in place, the tip of the tube should be in the mid-trachea, well above the carina

The required length of the tube can be estimated according to birth weight. If a shouldered tube is used, only the distal, tapered portion of the tube is inserted beyond the vocal cords, and the shoulders should prevent the tube being advanced too far. Confirmation of correct positioning of the endotracheal tube is obtained from a chest X-ray. The anatomical reference points used for the X-ray to assess the position of the endotracheal tube are the clavicles, the bodies of the vertebrae and the carina (although the last of these is not always visible on X-ray) Previously, it was advised that the tip of the endotracheal tube should be placed just below the clavicles, at the level of the first rib or 1-2 cm above the carina. Recently, this has been revised because positioning of the clavicles can vary according to angulation and placement of the baby, and the carina cannot always be identified. It is now suggested that the body of the first thoracic vertebra (T1) is a more stable reference point as the target for the tip of the endotracheal tube.

## LUNGS

Branching of the conducting airways is generally complete by week 16 Airways subsequently increase in size but not in number. Alveolar development is largely (but not completely) a postnatal phenomenon. The development of pre-acinar blood vessels follows the conducting airway development, the airways acting as a template for blood vessel development by de novo vasculogenesis driven by epithelial-derived vascular endothelial growth factor (VEGF), whereas development of intra-acinar blood vessels follows the development of the alveolar ducts and alveolar sacs. Lung development is described histologically as progressing through embryonic, pseudoglandular, canalicular, saccular and alveolar phases. (For further details, see Bush (2005).)

## Embryonic phase (0-7 weeks: appearance of lung buds and main pulmonary arteries)

The lung buds grow dorsally, passing each side of the relatively smaller oesophagus, and bulge into the medial walls of the laterally situated pericardioperitoneal canals (see Figs 52.25, 60.5A). The investing splanchnopleuric mesenchyme surrounding the lung buds contains a mixed population of cells. Further mesenchymal cells will differentiate into the smooth muscle cells that surround both the respiratory tubes and the blood vessels. In stage 13 embryos, proliferation of the adjacent splanchnopleuric coelomic epithelium (of the primary pleural cavities) is especially evident. The proliferative activity decreases in stage 14, and the mesenchyme becomes arranged in zones around the developing endoderm. Key molecules in airway branching include the fibroblast growth factors (FGFs), especially FGF-10, and their four receptors. There is almost certainly redundancy in the system, since mice null for either FGF-1 or FGF-7 exhibit normal lung development, despite the potent in vitro effects of these mediators. The key receptor appears to be FGFR2IIIb, and those ligands that bind it. Sonic hedgehog is important in lung development; it is tightly regulated and over-expression leads to the formation of excessive lung mesenchyme. The three members of the gli family of transcription factors are implicated in Sonic hedgehog signalling. Sonic hedgehog produced in distal epithelial cells appears to act on mesenchymal cells to suppress FGF-10 to limit budding. Other signals interacting with this process include bone morphogenetic protein 4 and TGF- $\beta 1$

At stage 15, angiogenetic mesenchyme is apparent around the primary bronchi. It forms an extensive capillary network around each lung bud, receiving blood from the developing sixth aortic arch artery and draining it into an anastomosis connected to the dorsal surface of the left atrium in the mediastinal mesenchyme. The pulmonary arteries
arise from the sixth aortic arch arteries, and the pulmonary veins develop from a solitary channel derived from the dorsal mesocardium, which, by branching morphogenesis, establishes continuity with the vascular plexus formed in the mediastinal mesenchyme. The pulmonary veins become surrounded by myocardium to the level of the second bifurcation. The veins themselves expand and are incorporated into the roof of the left atrium; cardiac muscle is, therefore, found in the central branches of the pulmonary venous tree (Hislop 2005)

The lung buds on each side of the oesophagus project dorsally into the pericardioperitoneal canals at stage 15. After this stage, the coelomic epithelium at the perimeter of the lung surface follows a differentiation pathway to form the visceral pleura. Lobar or secondary bronchi can be seen at stage 16, and the bronchopulmonary segments are present at stage 17 (see Fig. 60.3). Later stages of respiratory development involve the repeated division of the bronchial tree to form the subsegmental bronchi.

## Pseudoglandular phase (5-17 weeks: development of airways and blood vessels to level of acinus)

By stage 17 (late sixth to early seventh week), the separation of the lungs from the digestive system is complete and the pseudoglandular phase of pulmonary development, which includes the development of the lower conducting airways and the appearance of the acinar structures, can be identified. During this period, virtually the complete branching structure of the future bronchial tree is laid down, giving rise to 20 generations.

The growth and branching of the endoderm epithelium is controlled by the local investing splanchnopleuric mesenchyme. The airways begin to differentiate during this stage. Primitive ciliated cells appear at about week 7, initially in the region of the membranous trachea, and in the cartilaginous region by week 12. Ciliary biology and ciliopathy are an increasing focus of study (Bush and Hogg 2012). There are three known types of cilia. Best known are motile cilia, which propel mucus along epithelial surfaces, or are responsible for motility of unicellular organisms, but also probably have some cell signalling role; these are abnormal in primary ciliary dyskinesia (PCD, Kartagener's syndrome). Nodal cilia are also motile and are responsible for determining organ situs in the developing embryo (Nonaka et al 2002). Primary cilia are nonmotile, are ubiquitous throughout the body, and have a wide range of signalling functions during development (Goetz and Anderson 2010). The exact in utero function of these early ciliated cells in the trachea is obscure. It is unclear whether airway ciliated cells develop from an undifferentiated precursor or through the further development of a population of secretory cells. The epithelium differentiates into ciliated and goblet cells. The proximal airways develop basal cells from week 11, and ciliogenesis is complete at birth in humans. Mucous glands develop by 12 weeks and enlarge in the submucosa; secretory activity has been identified in the trachea at 14 weeks. The splanchnopleuric mesenchyme condenses around the epithelium and differentiates into connective tissue cell types and smooth muscle, which differentiates proximal to the tips of the developing airways as they develop, from week 6 onwards. Smooth muscle cells are innervated from as early as week 8 (see below). First-trimester human tracheal smooth muscle cells have a fluctuating resting membrane potential that is associated with the spontaneous development of tone and peristalsis-like contractions of the airway of a myogenic nature, probably modified by neurohumoral factors. These contractions are important in moving fluid from distal to proximal within the airways, which is essential for normal lung development and may also stimulate mediator release. Clara cells develop in the peripheral airways during the pseudoglandular period. They produce a 10 kDa protein (CC10) with immunomodulatory and anti-inflammatory activities, as well as producing a surfactant apoprotein. Cartilage also develops during this period, and is found in the airways in an adult distribution by 24 weeks. By the end of this period, the airway branching and the pre-acinar vascular patterns are fully mature. A normal airway 'template' is essential for normal alveolar formation; in conditions characterized by an abnormal airway branching pattern (e.g. both ipsilateral and contralateral to a diaphragmatic hernia), a degree of pulmonary alveolar hypoplasia is inevitable.

Endothelial development is also seen in the pseudoglandular phase when capillary networks form around the developing lung buds. These networks will become capillary anastomoses around the future alveoli. The mesenchyme produces both the endothelium and the smooth muscle cells of the tunica media of the vessels. Vimentin occurs in the cells around developing vessels in the pseudoglandular stage, but is replaced by desmin in the saccular phase.

## Canalicular phase (17-27 weeks: formation of respiratory airways and thinning of bloodgas barrier)

During the canalicular phase, about two to three generations of branching take place, after which the amount of mesenchyme around the branching tips of the dividing respiratory tree decreases and the distal airspaces widen. At 23 weeks, longitudinal sections of the future distal regions show a sawtooth margin, which may indicate the site of further acini. Peripheral growth is accompanied by an increase in the capillary network around the distal airspaces. In many places, the capillaries are in close contact with the respiratory cuboidal epithelium. The primitive cuboidal cells, which hitherto predominated in this part of the lung, differentiate into type 2 epithelial cells (pneumocytes), containing lamellar bodies that form the intracellular storage bodies of surfactant, and type 1 epithelial cells (pneumocytes). Type II pneumocytes are believed to be the stem cells of the alveolar epithelium. Apposition of the capillary networks to the thin pneumocytes (type 1), and reduction of the interstitial tissue of the lung, are prerequisites for future effective gas exchange. By 24 weeks of gestation, the histological characteristics of the airways, including cartilage distribution, are the same as in the adult.

## Saccular/alveolar phase ( 28 weeks to term: first appearance of alveoli in humans)

#### Abstract

Thin-walled terminal saccules are apparent at the saccular stage and will become alveolar ducts as development proceeds. The expansion of the prospective respiratory airspaces that occurs during this period is accompanied by a further decrease in the amount of interstitial tissue, and the capillary networks become ever more closely opposed to the pneumocyte epithelium. Invaginations (secondary crests) develop from the saccule walls. As a crest protrudes into a saccule, part of the capillary network becomes drawn into it. After the later expansion of the saccules on each side of the crest, a double capillary layer becomes annexed between what are now alveolar walls. During the saccular stage, elastin is deposited beneath the epithelium (an important step for future alveolar formation), and surfactant production from type 2 pneumocytes (essential for the survival of a preterm neonate) matures.

Maturation of the blood-gas barrier is an essential part of normal human development but the molecular basis of this is little understood. Mechanical stretch drives type 2 to type 1 cell differentiation. VEGF is a key mediator; it is upregulated by hypoxia, in late gestation, by cyclic stretch and by the transcription factor HIF2 $\alpha$. Type 2 cell maturation and capillary development fail in HIF2 $\alpha^{-} /{ }^{-}$mice. VEGF also drives surfactant production from glycogen in type 2 cells.

## Alveolar phase

Exactly when the saccular structure of the lung can be termed alveolar is not yet clear: estimates range from 28 to 32 weeks. The distal airspaces expand during late gestation and continue to do so after birth. The number of alveoli present at birth (variously estimated as between none and $5 \times 10^{7}$ ) is controversial but the numbers probably increase particularly rapidly over the first 6 months of life. This process is accompanied by fusion of adjacent capillary nets, so that, shortly after birth, there is an extensive double capillary net. Fusion of these layers is apparent at 28 days postnatally, extensive at 1.5 years and probably complete by 5 years. The alveolar stage is now considered to continue beyond infancy and to last throughout childhood (see below). Interestingly, in rats and mice, formation of alveoli is entirely postnatal.

The formation of millions of alveoli is accomplished by a complex process of folding and division. Existing walls of distal airspaces become thinner as pneumocyte epithelial cells flatten, and some cells undergo apoptosis. Ridges subsequently grow out from the sides of the saccule walls, forming primitive alveoli. The secondary septa contain a double capillary layer and further new alveoli form by the infolding of one of these layers, further subdividing the airspaces. The double capillary networks then undergo remodelling to form the familiar single capillary sheet around each alveolus. Conducting airways also undergo profound postnatal changes and exhibit increased smooth muscle and bronchoconstrictor responsiveness. The precise molecular signalling for these processes has yet to be established. However, they are clearly tightly regulated developmentally; hyperoxia or dexamethasone treatment of rats during the alveolarization period permanently abrogates alveolar development. This experimental finding implies that iatrogenic damage to the developing alveoli when ventilating a preterm baby with oxygen-
enriched mixtures is probably irreversible and, indeed, may be the basis of 'new' bronchopulmonary dysplasia.

Elastin gene expression, possibly modulated through retinoic acid, appears to be of pivotal importance in alveolar budding. Retinoic acid treatment of rats increases alveolarization, and salvages some alveoli in an experimental model, whereas mice with a deletion in the retinoic acid receptor $\gamma$ have impaired alveolarization. Retinoic acid regulates the expression of a number of growth signalling molecules, homeobox genes and lung epithelial genes; other gene groups involved in alveolarization probably include TGF- $\beta$, platelet-derived and fibroblast growth factors. (For further reading on the control of alveogenesis, see Galambos and DeMello (2008) and Hind et al (2009).)

## Development of the intrapulmonary vasculature and lymphatics

In an adult lung, the pulmonary arteries accompany the airways. The pulmonary veins have a similar number of branches but are separated from the airways by the alveoli; they have a different embryological origin, being derived from the mediastinal mesenchyme proximally rather than from the splanchnopleuric mesenchyme around the bifurcating respiratory tree. New vessels are formed by either vasculogenesis (the formation in situ of new blood vessels) or angiogenesis (outsprouting from existing vessels). Failure of separation of pulmonary veins from the arterial-airway bundle is a feature of the alveolarcapillary dysplasia spectrum (alveolar-capillary dysplasia with misalignment of the pulmonary veins), and may be caused by FOXF1 or STRA6 mutations (Bishop et al 2011). The mesenchyme around the single lung bud contains a number of cells that stain positively for the endothelial cell markers CD34 and CD31. The earliest pulmonary vessels form in the mesenchyme by vasculogenesis; the capillaries coalesce to form small blood vessels alongside the airways. By 34 days of gestation, blood circulates from the aortic sac via pulmonary arteries into a capillary plexus around the two lung buds and drains to the developing atrium. As each new airway forms in the mesenchyme, a new plexus forms as a halo around it and coalesces with the vessels already alongside the previous airway. In this way, addition of the newly formed tubules to the existing vessels is sustained; the airways act as a template for the development of blood vessels. Vessel formation occurs at least until the end of the pseudoglandular stage and is probably controlled by production of VEGF from the epithelial cells of the peripheral lung buds. As the arteries increase in size, they acquire a muscular wall. Initially, this arterial tunica media is derived from the bronchial smooth muscle of the adjacent airways, but as the vessels progressively enlarge, cells derived from the splanchnopleuric mesenchyme differentiate around the wall to form layers of smooth muscle cells. The muscular wall is thick relative to the lumen and this, in part, increases resistance to blood flow, although only $10 \%$ of blood flow goes through the pulmonary circulation of the lung during intrauterine life. None the less, this small blood flow is important in normal lung development (see below). At 20 weeks, the structure of the pulmonary vessels is the same as it is in the adult. Vascular innervation follows muscularization; the vasoactive peptides in the nerves are predominantly vasoconstrictor.

As the pulmonary veins enlarge, they become separated from the airways by lymphatic vessels lying within connective tissue. At around week 12, the peripheral veins develop a single layer of smooth muscle cells in their walls. This layer is derived only from the splanchnopleuric mesenchyme and not from bronchial smooth muscle (as occurs in the arteries). The lumen of each vein is relatively large and the wall is relatively thin at all levels. Arteries and veins continue to develop in the canalicular phase, probably by angiogenesis; dividing cells are seen in the peripheral capillaries. The epithelium of the most peripheral conducting airways flattens when the developing capillaries come to lie immediately subjacent to it during this phase. (For a review of the development of the pulmonary circulation, see Hislop (2005).)

Lymphatic capillaries and vessels run within bronchovascular bundles. Lymphatic channels develop from outgrowths of vascular endothelial cells; the molecular trigger for lymphatic sprouting is VEGF-C and D, acting through the VEGF receptor 3 (Janér et al 2006). (See Kulkarni et al (2011) for a review of lymphatic development in the lung.)

As well as developing a pulmonary circulation, the lung also develops a bronchial supply from the systemic circulation. Two or three bronchial arteries grow from the descending aorta from week 8 onwards, entering the lung at the hilum. These arteries extend down the intrapulmonary airways, eventually forming subepithelial and adventitial plexuses, which, by birth, have reached the distal portions of the bronchioli.

The bronchial veins from the periphery of the lungs drain into the pulmonary veins. Bronchial arteries also supply the pleura near the hilum, and form vasa vasorum in the adventitia of the large arteries and veins. Postnatally, inflammatory lung conditions, such as asthma, cystic fibrosis and bronchiectasis, cause hypertrophy of the bronchial circulation and these vessels may bleed, sometimes giving rise to massive haemoptysis (see McCullagh et al (2010)).

## Intrauterine maturation of the lungs

There are more than 30 different cell types within the adult lung that mature during development. Only a few important changes relevant to human disease will be highlighted here.

Pulmonary surfactant is produced by type 2 alveolar epithelial cells and stored in lamellar bodies. Surfactant proteins (Sp) B and C are surface-active, whereas A and D are part of the collectin family of pattern recognition receptors. Surfactant is crucial for maintaining the functional integrity of alveoli; the main morbidity of extreme prematurity reflects surfactant deficiency causing neonatal respiratory distress (treatment of these babies has been transformed by the availability of exogenous surfactant). Mutations in the genes encoding $S p B$ and $S p C$, $A B C A 3$ (responsible for surfactant processing) and the transcription factor TTF-1 (controlling $S p B, S p C$ and $A B C A 3$ expression) can all present in the newborn period in term babies with relentlessly progressive respiratory distress, with diffuse ground-glass shadowing on imaging studies (Bush and Nicholson 2008, Galambos et al 2010). Fetal breathing movements appear to be important in surfactant synthesis: the functional maturation of the surfactant system can be accelerated therapeutically by the administration of steroids to the mother.

Normal lung development requires sufficient intrathoracic space, normal fetal breathing movements and sufficient amniotic fluid. There is evidence that perturbation of fetal lung blood flow also affects lung growth, even though most of the right ventricular output of the heart is shunted away from the lungs through the ductus arteriosus; pulmonary valve stenosis is associated with pulmonary hypoplasia.

Although many fetal organs are able to grow to normal proportions even if they are in abnormal locations, this is not the case for the lungs. Lung growth becomes impaired by restricted expansion, and distension of the developing lung may provide a major stimulus to growth during normal development. Absence or impairment of fetal breathing movements, and anomalies affecting diaphragmatic activity, are all associated with pulmonary hypoplasia. It is believed that normal fetal breathing movements increase the lung volume and stimulate growth of the distal airspaces. These movements involve rhythmic activation of the diaphragm and the muscles of the upper respiratory tract; even though they are necessarily very small compared with those seen after birth (because the fetal airways are filled with lung fluid), there is evidence that these phasic movements are important in the release of growth factors. (The role of fetal breathing movements has been reviewed in Inanlou et al (2005).)

During development, the mucous glands of the trachea and bronchi secrete a chloride-rich fluid, which usually passes up the respiratory tract to mix with the amniotic fluid. The relationship between lung fluid and amniotic fluid is far more complex than was previously believed. Pulmonary hypoplasia at birth may be associated with severe congenital urinary obstruction and oligohydramnios (Potter's syndrome). In renal agenesis, reduced bronchial branching occurs as early as 12-14 weeks of gestation (i.e. at a time before amniotic fluid is produced by the kidneys), which suggests that a direct renal factor supports lung development. Later, the presence of amniotic fluid is necessary for normal fetal lung development. The fetal lung is a net fluid secretor, the output of fluid reaching as high as $5 \mathrm{ml} / \mathrm{kg}$ shortly before birth (see p. 179). Most of the fluid produced within the lungs remains there because of the mechanical effect exerted by amniotic fluid pressure and, normally, only a small amount of this fluid contributes to the amniotic fluid. The normal functioning of the kidneys regulates the volume and pressure of the lung airway fluid and may, in turn, provide the pressure needed for expansion and enlargement of the bronchial and pulmonary systems. Interestingly, obstruction to the fetal airway causes accelerated maturation of alveoli; this approach has been used therapeutically in congenital diaphragmatic hernia, where intermittent inflation and deflation of an intratracheal balloon in a lamb model resulted in better lung growth and maturation (Nelson et al 2005).

Two other cell types that are part of normal lung development, neuroendocrine cells and glycogen-containing cells, are implicated in postnatal paediatric interstitial lung disease, with early onset of respiratory distress. Neuroendocrine cells are found in the normal developing airway. Neuroendocrine cell hyperplasia of infancy (NEHI) is character-
ized by persistence of bombesin-positive neuroendocrine cells. Persistence of glycogen-containing cells results in pulmonary interstitial glycogenosis (PIG), which is not related to any of the systemic glycogen storage diseases. Both conditions tend to remit over time, and in neither case is it known whether the abnormal cells are of pathophysiological significance or are merely markers of another process.

## Adverse effects on intrauterine lung development

There is increasing evidence from epidemiological studies that antenatal factors have effects on lung development that are long-lasting. The earliest major effect is congenital diaphragmatic hernia, which leads to both ipsilateral and contralateral anomalies in branching pattern in the first 16 weeks of gestation that cannot be corrected subsequently, even by intrauterine tracheal balloon occlusion. Inevitably, abnormal branching leads to abnormal alveolarization in this condition. The most important later influence is maternal smoking but there is evidence that maternal exposure to pollution is also important (Latzin et al 2009). Animal studies have confirmed that antenatal nicotine exposure leads to structural changes in the fetal lung (Elliot et al 2001, Sekhon et al 2002, Fu et al 2011). Other factors that may be important include maternal hypertension in pregnancy, and maternal antibiotic and paracetamol usage.

## Ultrasound antenatal imaging of the lungs

Pulmonary hypoplasia, an absolute decrease in lung volume and weight for gestational age, may be identified but cannot be confirmed. It is normally associated with oligohydramnios and renal agenesis. Unilateral hypoplasia may be suggested by rotation and displacement of the heart on ultrasound examination. In bilateral pulmonary hypoplasia, the heart appears relatively large with reduced chest volume. However, intrauterine growth retardation may also cause similar findings. Increased echogenicity of the lungs indicates conditions that prevent the normal circulation of lung fluid (for further details, consult Coady and Bower (2015)). Details of prenatal lung anomalies and their detection are given in Epelman et al (2013).

## FUNCTIONAL CHANGES IN THE LUNG AROUND THE TIME OF BIRTH

Just prior to birth, the placenta is the organ of respiration. Virtually all the venous return to the right heart is shunted away from the lungs through the foramen ovale and the ductus arteriosus. Pulmonary vascular resistance (PVR) is maintained at a very high level by the muscular precapillary pulmonary vessels. At birth, the umbilical cord is tied and cut; within seconds, the lungs must take over all respiratory function in order to maintain life. They also must convert from secreting fluid to absorbing it. The mechanisms that mediate these dramatic changes are obscure. However, it is clear that the first breath results in vasodilation by at least two mechanisms. First, there is the mechanical effect of traction on the vasculature: as the chest wall expands, it pulls open the pulmonary vessels. Second, oxygen entering the lungs for the first time produces pulmonary vasodilation. The experimental demonstration that PVR falls, even if the fetus is delivered into an atmosphere of pure nitrogen, implies that other mediators, including cyclo-oxygenase metabolites, are important. The gene for cyclo-oxygenase 1 (but not 2) in endothelium and vascular smooth muscle shows enhanced expression in late fetal and early postnatal life. Endothelin receptor expression increases around the time of birth, implying a role for this system in postnatal adaptation (Levy et al 2005). The role of nitric oxide in postnatal adaptation is controversial and there are likely to be important species differences. Nitric oxide synthase (NOS) is more abundant in young compared with mature animals, and smooth muscle sensitivity to nitric oxide may be greater at birth than in older animals. The effects of mediators may differ ante- and postnatally, e.g. endothelin (ET)-1 causes vasodilation in fetal sheep, but vasoconstriction postnatally in lambs. Immediately after birth, and before structural remodelling has taken place, PVR may rise steeply if the baby becomes even minimally hypoxic or acidaemic. The fetal shunts (foramen ovale and ductus arteriosus) reopen and right to left shunting causes profound hypoxaemia and 'persistent fetal circulation'.

To summarize, at birth, the lung volume is small but related to body weight; all airways are present and differentiated (cartilage, glands, muscle, nerves); the one-third to one-half of the adult complement of alveoli present at birth give sufficient surface area for gas exchange; the
morphology of the blood-gas barrier is the same as in adults; and most arteries and veins are present.

## POSTNATAL LUNG DEVELOPMENT

The amount and type of connective tissue in the lung change after birth. The neonatal lung has abundant type III and type IV collagen, but little type I collagen. Types III and IV collagen are not mechanically strong, suggesting that the neonatal lung has a phenotype that facilitates the changes in cell shape and orientation that characterize adaptation to extrauterine life. It is probable that the rapid deposition of type I collagen postnatally contributes structural stiffness to the blood vessel walls.

Lung volume increases most rapidly during the first year of life and also increases more rapidly than airway calibre during this time, a finding consistent with the concept of dysanaptic lung growth, i.e. a dissociation between the growth of the lung parenchyma and the airways. Until recently, it was thought that most of the alveoli were formed by 2 years of age, and that subsequent lung growth primarily resulted from an increase in the size of individual alveoli. However, recent work measuring alveolar size throughout childhood and adolescence using hyperpolarized helium has shown that neo-alveolarization, as well as increase in alveolar size, continues through childhood and adolescence (Narayanan et al 2012). This has important implications for diseases characterized by neonatal arrest of alveolarization, e.g. after ventilation of the extreme preterm baby. Forced vital capacity is reported to be the same in male and female infants and very young children (Jones et al 2000), which is consistent with postmortem morphometric measurements. By the second year of life, the rate of increase in forced vital capacity is similar to that reported in older children.

During childhood, lung volumes and flow rates increase linearly with height, with a greater intercept and more positive slope in boys compared to girls (Stanojevic et al 2008). The linearity of these changes is interrupted by puberty (Rosenthal et al 1993a, 1993b, Rosenthal and Bush 2002), when important shape changes occur in the thorax, particularly in boys; these are mirrored by changes in the size of the underlying lung (and, in particular, the alveoli), as manifested by an abrupt increase in vital capacity, forced expired volume in 1 second, and total lung capacity. Thereafter, the change in lung size again proceeds in a linear fashion. High-resolution computed tomographic scanning has been used to measure airway dimensions (de Jong et al 2006), although this technique should be used with caution because of the radiation exposure.

There is little in the way of structural data to set alongside epidemiology. The reticular basement membrane (lamina reticularis) is first detected at about 30 weeks' gestation, thickens throughout childhood and adolescence, and plateaus, or possibly declines, in thickness with age (Tsartsali et al 2011). In terms of airway smooth muscle, autopsy data suggest that it increases over the first 2 years of life; limited data from endobronchial biopsies suggested that it did not change from age 3 years throughout childhood (O'Reilly et al 2013). Goblet cells also increase over the same timeframe (Hislop and Haworth 1989).

## Normal postnatal pulmonary arterial development

Immediately after birth, dramatic remodelling of the pulmonary vasculature occurs, to effect an abrupt reduction of pulmonary vascular resistance. This process continues at a rapid rate throughout the first 1-2 months, while the lungs adapt to extrauterine life, and then more slowly throughout childhood. Failure to remodel in the presence of an anatomically normal heart leads to persistent pulmonary hypertension. Normal postnatal pulmonary arterial development in the full-term neonate can be divided into three stages.

Stage one This lasts from birth to about postnatal day 4 and concerns the immediate adaptation to extrauterine life. At birth, the endothelial cells of the precapillary arteries are squat and have narrow bases on the subendothelium, a low surface to volume ratio and many surface projections. Five minutes after birth, the endothelial cells are thinner and gradually show less cell overlap, the surface to volume ratio increases, few cell projections are seen, the vessel wall becomes thinner and the luminal diameter increases (Fig. 52.26). The smooth muscle cells show a significant reduction in diameter during this time.

Stage two This lasts from around day 4 to 3-4 weeks and is the time when the cells deposit matrix around themselves to fix their new

Fig. 52.26 En face views (left) and transverse sections (right) showing the changes in the endothelial and smooth muscle cells of small muscular pulmonary arteries accompanying terminal bronchi from the neonatal period to 3 weeks after birth. (With permission from Haworth SG 1992 Pathophysiological and metabolic manifestations of pulmonary vascular disease in children. Herz 17(40:254-261).)
positions. At birth, the internal elastic lamina of the small muscular arteries consists only of amorphous elastin in a basal lamina-like matrix. By 3 weeks of age, a definitive elastic lamina is evident, although it is heavily fenestrated, permitting contact between the endothelial cells and the smooth muscle cells.

Stage three This continues into adulthood. The intrapulmonary arteries increase in size and their walls increase in thickness. However, the maturation of all of the pulmonary vascular smooth muscle cells, from the hilum to the precapillary bed, is not advanced until 2 years. As the distal airspaces expand, the capillary nets fuse from one alveolus to another, forming, for a period, an extensive double capillary net; this process can be seen from postnatal day 28, becomes more extensive by 1.5 years, and is believed to be complete by 5 years.

## Adverse effects on postnatal lung development

The long-term effects of preterm birth and its treatment are changing over the years. Current extremely premature babies, who are treated with surfactant and ventilated using low pressure, high-risk strategies, have arrest of alveolar development and pulmonary hypoplasia. Survivors from the pre-surfactant era have disease dominated by airflow obstruction. Importantly, even so-called 'late pre-term' babies (born at 33-34 weeks' gestation) have persistent airflow obstruction (Kotecha et al 2012). Postnatal lung development is also impaired by exposure to tobacco smoke, and there is increasing evidence that air pollution (Schultz et al 2012) and early sensitization to aeroallergens (Illi et al 2006) also have an adverse impact on normal lung growth. The first 4-6 years of life seem to be a key time window, after which there is no catch-up growth in lung function (Oswald et al 1997, Morgan et al 2005, Stern et al 2007); early effects on lung growth have lifelong implications.

## CONGENITAL MALFORMATIONS OF THE TRACHEA, BRONCHI AND LUNGS

This is an enormous topic and only a small number of anomalies can be mentioned here (for further information, see Abel et al (2012)). The concept of the lung as six 'trees' has been mentioned earlier; all but the
systemic venous tree may contribute to a congenital thoracic malformation (CTM) (Bush 2009). In addition, congenital anomalies of the heart and great vessels, and of the chest and abdominal walls, including neuromuscular disease, may impact on lung development. It is somewhat artificial to describe airway malformations in isolation, and the possibility of associated vascular anomalies must always be considered. Moreover, descriptions of what is seen clinically should be kept separate from speculations about the embryological origins of the anomaly.

## Tracheomalacia and bronchomalacia

Anomalies in cartilage development lead to the affected airways being 'floppy' and collapsing during inspiration or expiration, depending on whether they are outside or inside the bony thorax, respectively; these anomalies are termed tracheomalacia when the trachea is affected, and bronchomalacia when the bronchi are involved. The anomaly may involve a small, localized area or may be more generalized (e.g. Williams-Campbell syndrome, a congenital deficiency of the airway cartilage, in which there is diffuse bronchomalacia from the second to the seventh generation of bronchi). Tracheobronchomalacia usually presents in early infancy with cough, tachypnoea, stridor and wheeze; it may also be associated with cardiac or respiratory anomalies, such as absent pulmonary valve syndrome, or tracheo-oesophageal fistula, respectively. Patients with significant obstruction and apnoea may be treated by the insertion of airway stents if the disease is localized, although there is only limited long-term experience in children with stents; generalized disease may mandate respiratory support, either with non-invasive mask ventilation during sleep, or via a tracheostomy, depending on severity. Surgical treatment by aortopexy is controversial.

## Tracheo-oesophageal fistulae

Tracheo-oesophageal fistulae are the most common anomalies of the lower respiratory tract and occur in about 1 in 3000 births. They usually present in the newborn with recurrent respiratory distress and choking spells, although late presentation in adult life has been described and may be associated with oesophageal atresia. Normally, the oesophagus lengthens with the rapid elongation of the embryo up to 7 weeks. The rapid proliferation of the oesophageal lumen partially obliterates the mucosa and recanalization is not complete until 8 weeks. The cellular processes that lead to separation of the trachea and oesophagus occasionally produce oesophageal atresia. Tracheo-oesophageal atresia is rare, with an incidence of 1 in 3000 to 1 in 4500 births. Five types of tracheo-oesophageal fistulae may be recognized (Fig. 52.27). In almost all cases, the oesophagus ends blindly and the stomach is connected to the lower end of the trachea. Because of this connection, the abdomen becomes rapidly distended with air once the baby is delivered and starts breathing. Prenatally, polyhydramnios may be a clinical feature but may not be apparent until the third trimester. In two of the five types of tracheo-oesophageal fistulae, there is no communication between the stomach and the upper gut. Such cases are identifiable on ultrasound because the stomach should always be visible at a 20 -week examination; its absence on ultrasound should prompt further evaluation.

Tracheo-oesophageal fistula is commonly associated with other congenital anomalies, including cardiovascular defects (30\%), anorectal anomalies (15\%) and genitourinary anomalies (15\%). These defects may be combined in the VATER, VACTER and VACTERL associations, which involve varying combinations of vertebral defects, anorectal atresia, cardiac anomalies, tracheo-oesophageal fistula and oesophageal atresia, together with radial aplasia and other limb anomalies, renal anomalies and the presence of a single umbilical artery.

## Complete cartilage rings

The normal large-airway cartilages are horseshoe-shaped, and the ends of the horseshoes are bridged by the membranous part of the trachea. Complete cartilage rings may develop in the trachea and large airways, and the posterior, membranous, part of the airway may be absent in a single cartilage or in long segments of the airway. This anomaly may be associated with vascular anomalies such as pulmonary artery sling (where the left pulmonary artery originates from the right pulmonary artery and not from the main pulmonary trunk). Extensive severe disease may present with neonatal respiratory distress; later presentations include apparently steroid-resistant asthma. Tracheal transplantation has been used to treat long-segment tracheal stenosis. Tracheal cartilage shape is abnormal in cystic fibrosis in both human infants and the experimental pig model, but the cartilages are not continuous rings in this condition (Meyerholz et al 2010).

## Agenesis and aplasia of the lungs

Agenesis and aplasia of the lungs are extremely rare congenital anomalies, in which there may be unilateral or bilateral absence of the lung. In agenesis, the airway stump is absent, i.e. the trachea is absent in bilateral disease, or the primary bronchus is absent in unilateral disease. In aplasia, there is a rudimentary airway stump but no distal lung; the contralateral lung is enlarged, with a greater number of alveoli, but has a normal bronchial branching pattern. Individuals with aplasia may present with recurrent infection, dyspnoea and reduced exercise capacity, and there may be pooling of bronchial secretions, with secondary infection and overspill of infected secretions into the contralateral normal lung.

## Bronchogenic and other cysts

Cysts of various types, by order of frequency, may be found in the carinal (51\%), right paratracheal (19\%), para-oesophageal (14\%), hilar (9\%) and pericardial, retrosternal and paravertebral (7\%) regions. Clinically, they are part of the spectrum of congenital thoracic anomalies, and can only be classified in more detail pathologically when the wall of the cyst is examined; they may have a systemic blood supply and venous drainage. Multicystic anomalies, described as various types of congenital cystic adenomatous malformations (CCAM) and sequestrations (intra- and extrapulmonary), are best considered generically as a CTM spectrum, at least until examined pathologically; even then, features of CCAM and sequestration may be found in the same anomaly, rendering classification difficult. Presentation may involve a range of problems, from intractable newborn respiratory distress to a chance finding in adult life. If the infant is symptomatic, then surgical resection is indicated. Treatment of the asymptomatic anomaly is controversial; some centres would operate electively on all but the tiniest malformations, whereas others would manage even large, asymptomatic, cystic malformations conservatively. Evidence is summarized in a recent meta-analysis (Stanton et al 2009).

Fig. 52.27 Examples of tracheo-oesophageal fistulae and oesophageal atresia.

## Bronchial atresia

Bronchial atresia is a congenital condition in which a major bronchus or segmental airway ends blindly or with a thin membrane. Pulmonary development normally occurs distally and, over time, this tissue becomes distended with debris and mucus (bronchocele), with adjacent over-inflated lung tissue. Typically, bronchial atresia affects the left upper lobe ( $64 \%$ of cases); the chest radiographic findings are of a perihilar ovoid density with strands projecting into a localized area of hyperlucent lung. The left lower lobe is affected in $14 \%$ of cases and the right lower and right middle lobes in $8 \%$ of cases. The majority of
cases are asymptomatic and are revealed as incidental findings on chest radiographs. However, many eventually become the seat of recurrent infection and require operative removal. Some infants may show a congenital large hyperlucent pulmonary lobe (CLHL). This condition is termed 'congenital lobar emphysema', although it has nothing to do with adult emphysema. Presentation in severe cases is with newborn respiratory distress; in this case, early surgery is required. Otherwise, it may be a chance radiographic finding later in life; in this case, no action is needed.

## Chest wall and breast

The chest wall surrounds the thoracic cavity. The skin and soft tissue cover a musculoskeletal frame consisting of twelve pairs of ribs, which articulate with twelve thoracic vertebrae posteriorly and (except for the last two pairs of ribs) with the sternum anteriorly, via their costal cartilages; intrinsic muscles and muscles that connect the chest wall with the upper limb and the vertebral column; and numerous blood and lymphatic vessels and nerves that supply the components of the musculoskeletal frame and the overlying skin and breast tissue.

## SKIN AND SOFT TISSUE

## SKIN

## Vascular supply

## Arteries

The skin of the thorax is supplied by a combination of direct cutaneous vessels and musculocutaneous perforators that reach the skin primarily via the intercostal muscles, pectoralis major, latissimus dorsi and trapezius. The major contributing vessels are branches from the thoracoacromial axis, lateral and internal thoracic, anterior and posterior intercostal, thoracodorsal, transverse cervical, dorsal scapular and circumflex scapular arteries (Figs 53.1-53.2; see Fig. 43.4).

The anterior aspect of the thoracic skin is supplied by the thoracoacromial axis, the internal thoracic arteries, perforating branches from the intercostal arteries and branches from the lateral thoracic and superficial thoracic arteries. The thoraco-acromial axis supplies the skin primarily via musculocutaneous perforators from its pectoral branch; they reach the skin through pectoralis major. In addition, direct cutaneous branches arise from the acromial and deltoid branches. The internal thoracic artery sends direct perforating branches to the skin of the upper six intercostal spaces, accompanied by the cutaneous branches of the anterior intercostal nerves. The branches reach the skin after passing through pectoralis major and travelling laterally in the subcutaneous fat as direct cutaneous vessels. The second intercostal perforator is usually the largest. The lateral aspect of the thoracic skin is supplied by the lateral thoracic and superficial thoracic arteries and by lateral cutaneous branches of the intercostal arteries. The lateral thoracic artery gives off direct cutaneous branches to the lateral chest wall in addition to musculocutaneous branches that pass through pectoralis major. The posterior aspect of the thoracic skin is supplied by the medial and lateral dorsal cutaneous branches of the posterior intercostal arteries (via erector spinae and latissimus dorsi); musculocutaneous perforating branches from the superficial cervical, transverse cervical and dorsal scapular arteries (via trapezius); musculocutaneous perforating branches from the thoracodorsal artery and the intercostal arteries (via latissimus dorsi); and direct cutaneous branches from the circumflex scapular artery.

## Veins

The intercostal veins accompany the similarly named arteries in the intercostal spaces (see Fig. 51.3). The small anterior intercostal veins are tributaries of the musculophrenic and internal thoracic veins, the latter draining into the appropriate brachiocephalic vein. The posterior intercostal veins drain backwards directly or indirectly into the azygos vein on the right and the hemiazygos or accessory hemiazygos veins on the left. The azygos veins exhibit great variation in their origin, course, tributaries, anastomoses and termination (Ch. 56).

## Lymphatic drainage

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (p. 834; see Figs 53.22, 53.24, 48.45). Lymph vessels from the deeper tissues of the thoracic walls drain mainly to the parasternal, intercostal and diaphragmatic lymph nodes.

## Innervation

The skin of the thorax is supplied by cutaneous branches of cervical and thoracic nerves in consecutive, curved zones; the upper zones are almost horizontal and the lower are oblique. On the upper anterior aspect of the thorax, the areas innervated by the third and fourth cervical nerves adjoin those innervated by the first and second thoracic nerves because the intervening nerves provide the sensory and motor supply to the upper limb (Ladak et al 2014) (Fig. 53.3). There is a similar, but less extensive, posterior 'gap': most of the skin covering the posterior aspect of the thorax is supplied by the dorsal rami of the thoracic nerves (see Fig. 45.8). The subcostal margin is supplied by the seventh thoracic nerve.

The ventral rami of the first to the eleventh thoracic nerves pass into the appropriate intercostal space, giving off a lateral cutaneous branch that arises beyond the angle of the rib and divides into anterior and posterior branches, terminating near the sternum as an anterior cutaneous branch (see Fig. 53.21).

Branches of the supraclavicular nerve, which originates from the third and fourth cervical nerve roots, supply the skin in the upper pectoral region. Most of the first thoracic nerve joins the brachial plexus, apart from a small inferior branch that becomes the first intercostal nerve. The lateral cutaneous branch of the second intercostal nerve supplies the skin of the axilla as the intercostobrachial nerve. The costal margin is supplied by a branch from the seventh thoracic nerve. The seventh to eleventh thoracic nerves supply the skin of the thoracic wall as they pass anteriorly and inferiorly; they continue beyond the costal cartilages to supply the skin and subcutaneous tissues of the abdominal wall. The skin of the abdomen at the level of the umbilicus is supplied by the tenth thoracic nerve. The subcostal nerve follows the inferior border of the twelfth rib and supplies the skin of the lower abdominal wall (see Fig. 61.5).

## SOFT TISSUE

## Superficial fascia

The superficial fascia consists primarily of fat and is only loosely attached to the skin, an arrangement that allows some movement of the underlying structures. Small blood vessels and nerves perforate the superficial fascia to supply the skin. The breast lies within the superficial fascia, apart from a superolateral extension that pierces the deep fascia to form the axillary tail in the female. It is described later in this chapter.

## Deep fascia

## Clavipectoral fascia

The clavipectoral fascia is the cranial continuation of the deep lamina of the pectoral fascia and the medial continuation of the parietal layer of the subscapular bursal fascia. It extends between the clavicle and pectoralis minor, surrounds subclavius and extends medially to the first rib. It is described in detail on page 799.

## BONE AND CARTILAGE

The twelve thoracic vertebrae and their associated intervertebral discs are described in detail in Chapter 43.

## STERNUM

The sternum is an elongated, flattened bone that forms the middle portion of the anterior wall of the thorax. It articulates with the clavicles

Fig. 53.1 Anatomical territories of cutaneous blood vessels on the anterior trunk. (With permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd ed. Edinburgh: Churchill Livingstone.)
at the sternoclavicular joints (p. 808) and with the cartilages of the first seven pairs of ribs. The sternum consists of a cranial manubrium, an intermediate body (mesosternum, gladiolus) and a caudal xiphoid process (Figs 53.4-53.5). Until puberty, the body consists of four sternebrae, which are intersegmental. The average length of the adult sternum is 17 cm ; the ratio between manubrial and mesosternal lengths differs between the sexes. Growth may continue beyond the third decade and possibly throughout life.

In natural stance, the sternum slopes down and slightly forwards. The bone is anteriorly convex and posteriorly concave, and broadest at the junction with the first costal cartilages. It narrows at the manubriosternal joint, widens to its articulation with the fifth costal cartilages, and then narrows again. The sternum contains highly vascular trabecular bone enclosed by a compact layer that is thickest in the manubrium between the clavicular notches. Centrally, the bone is lightly constructed whereas, laterally, the trabeculae are thicker and wider. The medulla contains haemopoietic bone marrow.

4 Cutaneous branches from thoracodorsal and lateral thoracic arteries
Fig. 53.2 Anatomical territories of cutaneous blood vessels on the lateral trunk. (With permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd ed. Edinburgh: Churchill Livingstone.)

## Manubrium

The manubrium is level with the third and fourth thoracic vertebrae. It has a somewhat quadrangular form, being broad and thick above and narrowing to its junction with the body. The anterior surface is smooth, transversely convex and vertically concave, and the posterior surface is concave and smooth. The superior border is thick and contains a central jugular (suprasternal) notch between two oval fossae, the clavicular notches, that are directed up and posterolaterally for articulation with the sternal ends of the clavicles. Fibres of the interclavicular ligament are attached to the jugular notch. The inferior border, oval and rough, carries a thin layer of cartilage for articulation with the body. The lateral borders are marked above by a depression for the first costal cartilage and below by a small articular demifacet, which articulates with part of the second costal cartilage. The narrow curved edge descends medially between these facets. There is very little accessory movement at the manubriosternal joint, although pressure on either the body or the manubrium close to the joint will produce slight angling of the two sections.

Unlike all the other sternocostal joints, the joint between the manubrium and the first costal cartilage is a fibrous synarthrosis. It lies 1 cm below and 1 cm lateral to the medial end of the clavicle and is difficult to palpate.

Fig. 53.3 The approximate segmental distribution of the cutaneous nerves on the anterior trunk. The contribution from the first thoracic spinal nerve is not shown and the considerable overlap that occurs between adjacent segments is not indicated.

## Body

The body is level with the fifth to ninth thoracic vertebrae. It is longer, narrower and thinner than the manubrium, and is broadest near its lower end. The anterior surface, being nearly flat and facing slightly upwards, usually bears three variable transverse ridges that mark the levels of fusion of its four sternebrae. A sternal foramen, of varying size and form, may occur between the third and fourth sternebrae. The posterior surface, slightly concave, also displays three less distinct transverse lines. The oval upper end articulates with the manubrium at the level of the sternal angle (manubriosternal joint, angle of Louis), which lies opposite the inferior border of the fourth vertebral body and is marked by a posterior transverse groove.

Named after the French surgeon, Antoine Louis (1723-1792), the Latin name, angulus Ludovici, is not infrequently mistranslated into English as 'the angle of Ludwig'.

The lower end of the body is narrow and continuous with the xiphoid process. On each lateral border, at its superior angle, a small notch articulates with part of the second costal cartilage (see Figs 53.4, 53.5). Below this, four costal notches articulate with the third to sixth costal cartilages. The inferior angle bears a small facet, which, together with the xiphoid process, articulates with the seventh costal cartilage. Between these articular depressions, a series of curved edges diminish in length downwards and form the anterior limits of the intercostal spaces.

## Xiphoid process (xiphisternum)

The xiphoid process is in the epigastrium. It is the smallest and most variable sternal element, and may be broad and thin, pointed, bifid, perforated, curved or deflected. When elongated and curved forwards, it may be mistaken for an epigastric mass. The xiphoid is cartilaginous in youth but more or less ossified in adults. It is continuous with the lower end of the body at the xiphisternal joint. Demifacets that articulate with parts of the seventh costal cartilages occur anterior to its superolateral angles (see Fig. 53.5).

B, Posterior aspect. Key: 1, jugular notch; 2, attachment for sternohyoid; 3, attachment for sternothyroid; 4, edge of area covered by left pleura; 5, edge of area covered by right pleura; 6, attachment for transversus thoracis; 7, area in contact with pericardium; 8, attachment for transversus thoracis; 9, clavicular notch; 10, first costal notch; 11, manubrium; 12, second costal notch; 13, sternal angle and manubriosternal joint; 14, third costal notch; 15 , body of sternum; 16, fourth costal notch; 17, fifth costal notch; 18, seventh costal notch.

Muscle attachments The sternal ends of pectoralis major and sternocleidomastoid are attached to the anterior surface of the manubrium. Sternothyroid is attached to the posterior surface, opposite the first costal cartilage, and the most medial fibres of sternohyoid are attached above sternothyroid. The articular capsules of the sternocostal joints and sternal fibres of pectoralis major are attached to the anterior surface of the body. Transversus thoracis (sternocostalis) is attached to its posterior surface. The external intercostal membranes are attached to the borders of the body between the costal facets. The most medial fibres of rectus abdominis and the aponeuroses of external and internal oblique are attached to the anterior surface of the xiphoid. The linea alba is attached to its lower end, and the aponeuroses of internal oblique and transversus abdominis are attached to its borders. Slips of the diaphragm are attached to its posterior aspect, and the sternum is here related to the liver.

Vascular supply The internal thoracic artery provides the main blood supply for the sternum via anterior and posterior networks of perforating arteries that directly penetrate the sternum at the level of each intercostal space. These networks are particularly well developed posteriorly and at the level of the fourth and fifth intercostal spaces.

The venous network is less developed. It is formed mainly by an inframedullary network of sinuses in the bone that drain via transcortical veins either into the peripheral sternal networks or the internal thoracic vein.

Innervation The manubrium is supplied by the anterior branch of the supraclavicular nerve and the anterior cutaneous branch of the first intercostal nerve, whereas the body of the sternum is supplied largely by anterior branches of the intercostal nerves. The anterior branch of the phrenic nerve runs anteromedially from the diaphragm and supplies the lower portion of the sternum.

Fig. 53.5 The sternum, left lateral aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer, 2013.)

Fig. 53.6 The ossification of the sternum. A, Before birth. B, After birth.

Ossification The sternum is formed by fusion of two cartilaginous sternal plates flanking the median plane. The arrangement and number of centres of ossification vary according to the level of completeness and time of fusion of the sternal plates, and according to the width of the adult bone. Incomplete fusion leaves a sternal foramen. The manubrium is ossified from one to three centres appearing in the fifth fetal month. The first and second sternebrae usually ossify from single centres that appear at about the same time (Fig. 53.6A). Centres in the third and fourth sternebrae are commonly paired, and appear in the fifth and sixth months, respectively; one of either pair may be delayed until the seventh or even eighth month, and the fourth sternebral centre may be absent. The xiphoid process begins to ossify in the third year or later. In some sterna, all centres are single and median; in others, the manubrial centre is single and the sternebral centres are all paired, symmetric or asymmetric. Union between mesosternal centres begins at puberty and proceeds from below upwards; by the age of 25 years, they are all united (Fig. 53.6B).

Suprasternal ossicles, paired or single, sometimes occur. They may fuse to the manubrium or articulate posteriorly at the lateral border of the jugular notch. When well formed, they are pyramidal, and their base is articular. The ossicles are cartilaginous at birth and ossify during adolescence.

Pectus excavatum Pectus excavatum is the most common congenital deformity of the anterior chest, and is a depression of the sternum and costal cartilage that is sometimes referred to as cobbler's chest, sunken chest, the crevasse or funnel chest. The lower costal cartilages and the body of the sternum are depressed and there is some asymmetric curving of the ribs posteriorly. There is often an abnormal posture with dorsal lordosis, sometimes with developing scoliosis. The deformity is found either at birth (1 in 500 live births) or early in life; in the majority of cases, the condition is manifest by 1 year but may not develop until puberty. The aetiology is unknown but some cases are associated with connective tissues diseases, such as Marfan's syndrome.

Pectus carinatum Pectus carinatum, often called 'pigeon chest', is an overgrowth of cartilage that causes the sternum to protrude forwards. It is less common than pectus excavatum and a quarter of cases are familial. The condition may occur as a solitary congenital abnormality or in association with other genetic disorders. Although present in early childhood, pectus carinatum usually progresses during adolescence and then remains unchanged throughout adulthood.

## CLAVICLE

The clavicle is described in Chapter 48.

## RIBS

The ribs are 12 pairs of elastic arches (Fig. 53.8), each consisting of highly vascular trabecular bone containing large amounts of red marrow, enclosed in a thin layer of compact bone.

The ribs articulate posteriorly with the vertebral column and form the greater part of the thoracic skeleton. Their number may be increased by cervical or lumbar ribs or reduced by the absence of the twelfth pair. The first seven 'true' ribs connect to the sternum by costal cartilages, whilst the remaining lower five 'false' ribs either join the superjacent costal cartilage (8-10) or 'float' free at their anterior ends as relatively small and delicate structures tipped with cartilage (11-12). The tenth rib may also float: the incidence varies from $35 \%$ to $70 \%$, depending on ancestry.

The ribs are separated by the intercostal spaces, which are deeper in front and between the upper ribs. The latter are less oblique than the lower ribs; obliquity is maximal at the ninth rib. Ribs increase in length up to the seventh and thereafter diminish. They decrease in breadth downwards; in the upper ten the greatest breadth is anterior. The first two and the last three ribs present special features, whereas the remainder conform to a common plan.

## Typical rib

A typical rib has a shaft with anterior and posterior ends (Fig. 53.9). The anterior costal end has a small concave depression for the lateral end of its cartilage. The shaft has an external convexity and is grooved internally near its lower border, which is sharp, whereas its upper border is rounded. The posterior vertebral end has a head, neck and tubercle. The head presents two facets, separated by a transverse crest. The lower and larger facet articulates with the body of the corresponding vertebra, its crest attaching to the intervertebral disc above it. The neck is the flat part beyond the head, anterior to the corresponding transverse process. It is oblique and faces anterosuperiorly. Its posteroinferior surface is rough and pierced by foramina. Its upper border is the sharp crest of the neck, its lower border rounded. The tubercle, which is more prominent in upper ribs, is posteroexternal at the junction of the neck and shaft, and is divided into medial articular and lateral non-articular areas. The articular part bears a small, oval facet for the transverse process of the corresponding vertebra. The non-articular area is roughened by ligaments. The shaft is thin and flat, and has external and internal surfaces, and superior and inferior borders. It is curved, bent at the posterior angle ( $5-6 \mathrm{~cm}$ from the tubercle), and twisted about its long axis. The part behind the angle inclines superomedially and so its external surface is posteroinferior. In front of the angle, the rib faces slightly up. It is convex and smooth, and, near the

The clinical significance of pectus excavatum may vary considerably (Fig. 53.7). Severe defects can lead to cardiopulmonary dysfunction, whilst almost all patients will have some degree of cosmetic concern. Back and chest pain may occur. Evaluation of the deformity demands careful symptom assessment in addition to baseline radiological investigations (chest radiograph and computed tomography (CT)). Where there are physiological restrictions, lung function tests, electrocardiograms (ECGs) and echocardiograms form part of the assessment before specialist clinicians can determine the safety of any surgical intervention. A classification system based on morphology using CT scanning has been proposed (Park et al 2004) and is useful for standardizing the results of surgical correction of the different subtypes.

Mild defects causing aesthetic concerns may be improved with customized silicone implants (Masson et al 1970) or with soft tissue reconstructive procedures (Raab et al 2009), to camouflage the concavity. More severe defects often require correction of the underlying skeletal deformity. Several techniques have been described. Open resection procedures were pioneered by Ravitch; however, more recently, minimally invasive techniques have gained in popularity (Ravitch 1955, Nuss et al 1988).

Pectus carinatum occurs in three different ways, most commonly in the 11-14-year-old pubertal male undergoing a growth spurt. Some parents report that their child's pectus seemingly popped up 'overnight'. The second most common occurrence is from birth, when it is evident in newborns as a rounded chest, becoming more prominent as the child reaches 2 or 3 years old. The least common occurrence is as an acquired condition after open heart surgery, when healing has been aberrant. Pectus carinatum may be associated with Turner's, Marfan's, Ehlers-Danlos, Morquio's, Noonan's, Sly's or multiple lentigines syndromes, trisomies 18 or 21, homocystinuria, osteogenesis imperfecta or scoliosis.

Fig. 53.7 Pectus excavatum.

Fig. 53.8 The skeleton of the thorax, anterior aspect, showing muscle attachments.
tubercle, is crossed by a rough line, directed inferolaterally, towards the posterior angle. The smooth internal surface is marked by a costal groove, bounded below by the inferior border. The superior border of the groove continues behind the lower border of the neck, but terminates anteriorly at the junction of the middle and anterior thirds of the shaft, anterior to which the groove is absent.

Attachments and relations A radiate ligament is attached along the anterior border of the head and an intra-articular ligament is attached along its crest. The anterior surface of the head is related to costal pleura and, in the more inferior ribs, to the sympathetic trunk. The anterior surface of the neck is divided by a faint transverse ridge for the internal intercostal membrane and is continuous with the inner lip of the superior border of the shaft. The area above the ridge, which is more or less triangular, is separated from the membrane by fatty tissue whilst the inferior smooth area is covered by costal pleura. The posterior surface of the neck gives attachment to the costotransverse ligament and is pierced by vascular foramina. The superior costotransverse ligament is attached to the crest of the neck, which extends laterally into the outer lip of the superior border of the shaft. The rounded inferior border of the neck continues laterally into the upper border of the costal groove, and gives attachment to the internal intercostal membrane. The articular area of the tubercle in the upper six ribs is convex and faces posteromedially. In the succeeding three or four ribs it is almost flat, and faces down, back and slightly medially. The lateral costotransverse ligament is attached to the non-articular area.

The ridge on the external surface of the shaft (near its posterior angle) gives attachment to an upward continuation of the thoracolumbar fascia and lateral fibres of iliocostalis thoracis. From the second to the tenth ribs, the distance between angle and tubercle increases. Medial to the angle, the external surface gives attachment to levator costae and is covered by erector spinae. Near the sternal end of this surface, an indistinct oblique line, the anterior 'angle', separates the attachments
of external oblique and serratus anterior (or latissimus dorsi, in the case of the ninth and tenth ribs). The internal intercostal muscle is attached to the costal groove on the internal surface, and separates the bone and the intercostal neurovascular bundle. At its vertebral end, the groove faces down, its borders in the same plane. The shaft broadens near the posterior angle, and the groove reaches its internal surface. The innermost intercostal is attached to the superior rim of the groove, and this attachment occasionally extends to the anterior quarter of the rib. Posteriorly, the superior rim meets the lower border of the neck. The external intercostal muscle is attached to the sharp inferior costal border. The superior border has two lips posteriorly: an inner and an outer lip. The internal intercostal muscles and the innermost intercostal muscles are attached to the inner lip. The external intercostal muscle is attached to the outer lip.

Vascular supply and innervation Typical ribs receive their blood supply anteriorly via branches from the internal thoracic artery (first six intercostal spaces) or musculophrenic artery (subsequent spaces), and posteriorly from intercostal arteries derived directly from the aorta. Venous drainage is into the corresponding intercostal vein and thence into the azygos system. Typical ribs are innervated segmentally by branches from their corresponding intercostal nerves.

## Cervical rib

A cervical rib, the costal element of the seventh cervical vertebra, may be a mere epiphysis on its transverse process but more often it has a head, neck and tubercle. When a shaft is present, it is of variable length and extends anterolaterally into the posterior triangle of the neck, where it may end freely or join the first rib, its costal cartilage or even the sternum. A cervical rib may be partly fibrous but its effects are not related to the size of its osseous part. If it is long enough, its relations are those of a first thoracic rib; the brachial plexus (usually lower trunk)

and subclavian vessels are superior and apt to suffer compression in a narrow angle between the rib and scalenus anterior. Hence, cervical ribs may first be revealed by neurovascular symptoms, particularly those caused by pressure on the eighth cervical and first thoracic spinal nerves.

A cervical rib (pleurapophysis) may show synostosis or diarthrosis with either the anterior (parapophysial) or posterior (diapophysial) 'roots' of the so-called seventh cervical transverse process or, more usually, with both.

## First rib

Most acutely curved and usually shortest, the first rib is broad and flat, its surfaces are superior and inferior, and its borders are internal and external (see Fig. 53.9A). It slopes obliquely down and forwards to its sternal end. The obliquity of the first rib accounts for the ingress of the pulmonary and pleural apices into the neck.

The head of the first rib is small and round, and bears an almost circular facet that articulates with the body of the first thoracic vertebra. The neck is rounded and ascends posterolaterally, and the tubercle, wide and prominent, is directed up and backwards. Medially, an oval facet articulates with the transverse process of the first thoracic vertebra. At the tubercle, the rib is bent, its head turned slightly down, and so the angle and tubercle coincide. The superior surface of the flattened shaft is crossed obliquely by two shallow grooves, separated by a slight ridge, which usually ends at the internal border as a small pointed projection, the scalene tubercle, to which scalenus anterior is attached.

The groove anterior to the scalene tubercle forms a bed for the subclavian vein, and the rough area between this and the first costal cartilage gives attachment to the costoclavicular ligament and, more anteriorly, to subclavius. The subclavian artery and (usually) the lower trunk of the brachial plexus pass in the groove behind the tubercle. Behind this, scalenus medius is attached as far as the costal tubercle.

The external border is convex, thick posteriorly and thin anteriorly. It is covered behind by scalenus posterior descending to the second rib. The first digitation of serratus anterior is, in part, attached to it, behind the subclavian (arterial) groove. The internal border is concave and thin, and the scalene tubercle is near its midpoint. The suprapleural membrane, which covers the cervical dome of the pleura, is attached to the internal border. The inferior surface is smooth and the anterior end is larger than in any other rib.

Vascular supply and innervation The first rib is supplied by the internal thoracic and superior intercostal arteries, drained by the intercostal vein and innervated by the first intercostal nerve.

Ossification The first rib has a primary centre for the shaft, and secondary ossification centres for the head of the rib and the tubercle.

## Second rib

The second rib is twice the length of the first and has a similar curvature. The non-articular area of its tubercle is small. The angle is slight and
near the tubercle. The shaft is not twisted but at the tubercle is convex upwards, as in the first rib but less so. The external surface of the shaft is convex and superolaterally is marked centrally by a rough, muscular impression that continues posteromedially towards the tubercle as a narrow, roughened ridge. The internal surface, smooth and concave, faces inferomedially and there is a short costal groove posteriorly.

The lower parts of the first two digitations of serratus anterior are attached to a rough prominence that extends from just behind the midpoint of the external surface (see Fig. 53.9B). The distinct lips of the upper border are widely separated behind; scalenus posterior and serratus posterior superior are attached to the outer lip in front of the angle.

Vascular supply and innervation The blood supply of the second rib is via the internal thoracic and superior intercostal arteries. Venous drainage is via the superior intercostal vein, which drains into the brachiocephalic vein, and the anterior intercostal veins, which drain into the internal thoracic vein. The bone is innervated by branches of the first intercostal nerve.

Ossification The second rib is ossified from a primary centre for the shaft, which appears near the angle late in the second month. The secondary centres for the head and articular and non-articular parts of the tubercle appear about puberty, uniting to the shaft soon after the age of 20 years.

## Tenth, eleventh and twelfth ribs

The tenth rib has a single facet on its head that may articulate with the intervertebral disc above, in addition to the upper border of the tenth thoracic vertebra near its pedicle. The ninth and tenth ribs are usually united anteriorly by a fibrous joint. However, the tenth rib may be free in 35-70\% (depending on ancestry), in which case it is pointed like the eleventh and twelfth ribs.

The eleventh and twelfth ribs each have one large articular facet on the head but no neck or tubercle. Their pointed anterior ends are tipped with cartilage. The eleventh rib has a slight angle and shallow costal groove. The twelfth rib has neither, is much shorter and slopes cranially at its vertebral end. The internal surfaces of both ribs face slightly upwards, more so in the twelfth.

Numerous muscles and ligaments are attached to the twelfth rib (Fig. 53.10). Quadratus lumborum and its anterior covering layer of thoracolumbar fascia are attached to the lower part of its anterior surface in its medial one-half to two-thirds; the upper part is related to the costodiaphragmatic pleural recess. The internal intercostal muscle (medially) and the diaphragm (laterally) are attached at or near the upper border. The lower border gives attachment to the middle lamella of the thoracolumbar fascia and, lateral to quadratus lumborum, to the lateral arcuate ligament and posterior lamella of the thoracolumbar fascia. The lumbocostal ligament is attached posteriorly, close to the head, connecting it to the first lumbar transverse process. The lowest
levator costae, longissimus thoracis and iliocostalis are attached to the medial half of the external surface, and serratus posterior inferior, latissimus dorsi and external oblique are attached to its lateral half. The external intercostal muscle is attached along the upper border. These attachments vary: those of the internal intercostal, levator costae and erector spinae merge and those of latissimus dorsi, diaphragm and external oblique may reach the costal cartilage. The lower limit of the pleural sac crosses in front of the rib, approximately at the point where it is crossed by the lateral border of iliocostalis. Its lateral end is usually below the line of costodiaphragmatic pleural reflection and is therefore not covered by pleura.

Vascular supply and innervation The tenth and eleventh ribs are supplied by the posterior intercostal artery and branches from the musculophrenic artery. The twelfth rib is supplied by the subcostal artery. Venous drainage is via the posterior intercostal and subcostal veins, which in turn drain into the azygos system. There is additional drainage via the anterior intercostal veins (branches of the musculophrenic vein). The tenth and eleventh ribs are innervated by the corresponding intercostal nerve, and the twelfth rib is innervated by the subcostal nerve.

Ossification The tenth rib ossifies from a primary centre in the shaft and secondary centres for the head and articular parts of the tubercle. The eleventh and twelfth ribs, without tubercles, have two centres each.

## Costal cartilages

Costal cartilages are the persistent, ossified anterior parts of the cartilaginous models in which the ribs develop. They are flat bars of hyaline cartilage that extend from the anterior ends of the ribs, and contribute greatly to thoracic mobility and elasticity (see Fig. 53.8). The upper seven pairs join the sternum; the eighth to tenth articulate with the lower border of the cartilage above; and the lowest two have free, pointed ends in the abdominal wall. They increase in length from the first to the seventh, and then decrease to the twelfth. They diminish in breadth from first to last, like the intercostal spaces. The costal cartilages are broad at their costal continuity and taper as they pass forwards. The first and second are of even breadth and the sixth to eighth enlarge where their margins are in contact. The first descends a little, the second is horizontal and the third ascends slightly; the others are angulated and incline up towards the sternum or cartilage above, a little anterior to their ribs.

Each costal cartilage has two surfaces, borders and ends. The anterior surface is convex, facing anterosuperiorly. The sternoclavicular articular disc, costoclavicular ligament and subclavius are attached to the first costal cartilage. Pectoralis major is attached to the medial aspect of the first six cartilages and the others are covered by the partial attachments of the anterior abdominal muscles. The posterior surface is concave and, really, posteroinferior. Sternothyroid is attached to the first cartilage, transversus thoracis is attached to the second to sixth, and transversus

Fig. 53.10 The twelfth rib, left side. A, Anterior aspect. B, Posterior aspect. Key: 1, attachment of latissimus dorsi; 2, attachment of external oblique; 3 , attachment of serratus posterior inferior; 4, attachment of external intercostal muscle; 5, attachment of levator costae; 6, head; 7, attachment of erector spinae.
abdominis is attached to the lower six. The internal intercostal muscles and external intercostal membranes are attached to the concave superior and convex inferior borders. The inferior borders of the fifth (sometimes) and sixth to ninth cartilages project at points of greatest convexity. Oblong facets on these projections articulate with facets on slight projections from the superior borders of subjacent cartilages. The lateral end of each cartilage is continuous with its rib. The medial end of the first is continuous with the sternum; those of the six succeeding cartilages are round and articulate with shallow costal notches on the lateral margins of the sternum; those of the eighth to tenth are pointed, each connected with the cartilage above; and those of the eleventh and twelfth are pointed and free. With the exception of the fibrous synarthrosis between the first rib and sternum, all these articulations are synovial.

## Costal cartilage ossification forensic radiology

Available with the Gray's Anatomy e-book

## Rib fractures

Elastic recoil of the ribs that suspend the sternum may explain the rarity of sternal fractures. Despite their pliability, the ribs are much more frequently broken, the middle ribs being the most vulnerable. Because traumatic stress is often the result of compression of the thorax, the usual site of fracture is just in front of the angle, which is the weakest point of the rib. Direct impact may fracture a rib at any point; the ends of the broken bone may be driven inwards and potentially may injure thoracic or upper abdominal viscera.

## JOINTS

## MANUBRIOSTERNAL JOINT

The manubriosternal joint lies between the manubrium and sternal body; it is usually a symphysis but it may be synovial, synchondrotic or synostotic. It lies approximately 7 cm below the upper border of the manubrium. The bony surfaces are covered by hyaline cartilage and connected by a fibrocartilage, which may ossify in the aged. Sometimes, the central part of the disc is absorbed and the joint appears synovial. The manubriosternal joint is connected by a fibrous membrane enveloping the entire bone. In occasional individuals over the age of 30 years, the manubrium is joined to the sternal body by bone but the intervening cartilage may be only superficially ossified; ossification becomes complete only in the aged. Early synostosis has been attributed to a persistent synchondrosis in place of a symphysis. In the newborn, union is by collagenous and elastic fibres, without chondrocytes.

Movements There is a small range of angulation between the longitudinal axes of the manubrium and body of the sternum, and limited anteroposterior displacement. The powerful ligamentous attachments in this region mean that dislocation of the manubriosternal joint is rare, although it may be associated with high-energy trauma. Dislocation is most common when the joint is synovial, whereas synchondral and synosteal types typically fracture through the manubrium.

## XIPHISTERNAL JOINT

The joint between the xiphoid process and the body of the sternum process is a symphysis. It is usually transformed to a synostosis by the fortieth year but sometimes remains unchanged, even in old age.

## STERNOCLAVICULAR JOINT

The sternoclavicular joint is described in Chapter 48.

## COSTOVERTEBRAL, STERNOCOSTAL AND INTERCHONDRAL JOINTS

The heads of the ribs articulate with vertebral bodies (costocorporeal joints); their necks and tubercles articulate with transverse processes (costotransverse joints).

Fig. 53.11 Ligaments of the vertebral column and costovertebral joints, left lateral aspect. The lateral parts of the anterior longitudinal ligament have been removed. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer, 2013.)

## Joints of costal heads

Heads of typical ribs articulate with facets (often termed demifacets) on the margins of adjacent thoracic vertebral bodies and with the intervertebral discs between them (Fig. 53.11). The first and tenth to twelfth ribs articulate with a single vertebra by a simple synovial joint. In the others, an intra-articular ligament bisects the joint, producing a double synovial compartment, so the joint is classified as both compound and complex. Often inaccurately described as plane, their articular surfaces are slightly ovoid and the upper and lower synovial articulations are obtusely angled to each other. The ligaments are capsular, radiate and intra-articular.

Fibrous capsules The fibrous capsule connects the costal head to the circumference of the articular surface formed by an intervertebral disc and the demifacets of two adjacent vertebrae. Some of the upper fibres traverse their intervertebral foramina to blend with the posterior aspects of the intervertebral discs. The posterior fibres are continuous with the costotransverse ligaments

Radiate ligaments Radiate ligaments connect the anterior parts of each costal head to the bodies of two vertebrae and their intervening intervertebral disc. Each is attached to the head just beyond its articular surface. Superior fibres ascend to the vertebral body above, inferior to the body below. Intermediate fibres, shortest and least distinct, are horizontal and attached to the disc. The radiate ligament associated with the first rib is attached to the seventh cervical and first thoracic vertebrae. In the joints of the tenth to twelfth ribs, which articulate with single vertebrae, the radiate ligament is attached to the numbered vertebra and the one above.

Intra-articular ligament The intra-articular ligament is a short flat band attached laterally to the crest between the costal articular facets and medially to the intervertebral disc, dividing the joint. The ligament is absent from the first and tenth to twelfth joints.

## Costotransverse joints

The facet of a costal tubercle articulates reciprocally with the transverse process of its corresponding vertebra (Fig. 53.12). The eleventh and twelfth ribs lack this articulation. In the upper five or six joints, articular

When present, marginal and central subperichondrial ossification patterns seen on X-ray afford a relatively simple, rapid, inexpensive and accurate means of identifying sex in completely or partially skeletonized and unidentified human material, providing the subject is over 20 years of age. The predictive ability of this technique lies in a range of $80-90 \%$. In males, the predictive ability of the marginal subperichondrial ossification pattern is $75-80 \%$. In females, the predictive ability for a central subperichondrial ossification pattern is greater than $90 \%$.

Fig. 53.12 Costovertebral joints, superior aspect.

Fig. 53.13 A section through the third to the ninth costotransverse joints. Contrast the concave facets on the upper transverse processes with the less curved facets on the lower transverse processes.
surfaces are reciprocally curved but below this they are flatter (Fig. 53.13). Their ligaments are capsular, costotransverse, superior and lateral costotransverse, and accessory.

Fibrous capsule The fibrous capsule is thin and attached to articular peripheries; it has a synovial lining.

Costotransverse ligament The costotransverse ligament fills the costotransverse foramen between the neck of the rib and its adjacent corresponding transverse process. Its numerous short fibres extend back from the posterior rough surface on the neck to the anterior surface of the transverse process. A costotransverse ligament is rudimentary or absent in the eleventh and twelfth ribs.

Superior costotransverse ligament The superior costotransverse ligament has anterior and posterior layers. The anterior layer is attached between the crest of the costal neck and lower aspect of the transverse process above, and blends laterally with the internal intercostal membrane; it is crossed by the intercostal vessels and nerve. The posterior layer is attached posteriorly on the costal neck, ascending posteromedially to the transverse process above, and blends laterally with the external intercostal muscle. The first rib has no such ligament. The shaft of the twelfth rib, near its head, is connected to the base of the first lumbar
transverse process by a lumbocostal ligament in series with the superior costotransverse ligaments.

Accessory ligament An accessory ligament is usually present. It lies medial to the superior costotransverse ligament, and is separated from it by the dorsal ramus of a thoracic spinal nerve and accompanying vessels. These bands are variable in their attachments, but usually pass from a depression medial to a costal tubercle to the inferior articular process immediately above. Some fibres also pass to the base of the transverse process.

Lateral costotransverse ligament The lateral costotransverse ligament is short, thick and strong, and passes obliquely from the apex of the transverse process to the rough non-articular part of the adjacent costal tubercle. The ligaments of upper ribs ascend from their transverse processes, and are shorter and more oblique than those of the lower ribs, which descend.

Movements Costal heads are so firmly tied to vertebral bodies by radiate and intra-articular ligaments that only slight gliding can occur. Strong ligaments binding costal necks and tubercles to transverse processes also limit movements at costotransverse joints to slight gliding, guided by the shape and direction of the articular surfaces (see Fig. 53.13). The facets on the tubercles of the upper six ribs are oval and vertically convex, and fit corresponding concavities on the anterior surfaces of transverse processes; consequently, up and down movements of tubercles involve rotation of costal necks about their long axes. The facets on the seventh to tenth tubercles are almost flat and face down, medially and backwards; their opposing surfaces are on the upper aspects of transverse processes and so, when these tubercles ascend, they also move posteromedially. Both sets of joints move simultaneously and in the same directions; the costal neck therefore moves as if at a single joint in which the two articulations form its ends.

In the upper six ribs, the neck moves slightly up and down but its chief movement is one of rotation about its long axis, which means that downward rotation of its anterior aspect is associated with depression, and upward rotation with elevation, of the shaft and anterior end of the rib. In the seventh to tenth ribs, the neck ascends posteromedially or descends anterolaterally, increasing or diminishing the infrasternal angle, respectively; slight rotation accompanies these movements.

## Sternocostal joints

Costal cartilages articulate with small concavities on the lateral sternal borders (chondrosternal articulations) (Fig. 53.14). Perichondrium and periosteum are continuous. The first sternocostal joint is an unusual variety of synarthrosis (fibrous) and is often inaccurately called a synchondrosis. The second to seventh costal cartilages articulate by synovial joints, although articular cavities are often absent, particularly in the lower joints. Fibrocartilage covers the articular surfaces and also unites the costal cartilages and the sternum in those joints where cavities are absent. The seventh costosternal joint may be synovial or 'symphysial'. Ligaments involved are capsular, radiate sternocostal, intra-articular and costoxiphoid.

Fig. 53.14 Sternocostal and interchondral joints, anterior aspect.

Fibrous capsules Fibrous capsules surround the second to seventh sternocostal joints. They are thin, blended with the sternocostal ligaments, and strengthened above and below by fibres that connect the costal cartilages to the sternum.

Radiate sternocostal ligaments The radiate sternocostal ligaments are broad, thin bands that radiate from the anterior and posterior surfaces of the sternal ends of the costal cartilages of the true ribs to the corresponding sternal surfaces. Their superficial fibres intermingle with adjacent ligaments above and below, with those of the opposite side and with tendinous fibres of pectoralis major. Collectively, these tissues form a thick fibrous membrane around the sternum that is more marked inferiorly

Intra-articular ligaments Intra-articular ligaments are constant only between the second costal cartilages and sternum. The ligament associated with the second costal cartilage extends from the costal cartilage to the fibrocartilage uniting the manubrium and sternal body, and is therefore intra-articular. Occasionally, the third sternal cartilage is connected with the first and second sternal segments by a similar ligament. Fibrocartilaginous strands may occur in the third and lower joints. Articular cavities may be absent at any age.

Costoxiphoid ligaments Costoxiphoid ligaments connect the anterior and posterior surfaces of the seventh (and sometimes sixth) costal cartilage to the same surfaces of the xiphoid process. They vary in length and breadth, and the posterior is less distinct.

Movements Slight gliding movements, sufficient for ventilation, occur at sternocostal joints.

## Interchondral joints

Contiguous borders of the sixth to ninth costal cartilages articulate by apposition of small oblong facets. Each articulation is enclosed in a thin fibrous capsule, lined by synovial membrane with lateral and medial interchondral ligaments. Sometimes the fifth cartilage, and less commonly the ninth cartilage, articulate at their inferior borders with adjoining cartilages; this connection is usually effected by ligamentous fibres. Articulation between the ninth and tenth cartilages is never synovial and sometimes absent.

Fig. 53.15 The left transversus thoracis, exposed and viewed from its posterior aspect. The lower border of transversus thoracis is in contact with the upper border of transversus abdominis in the interval between the sternal and costal origins of the diaphragm. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer, 2013.)

## Costochondral junctions

Artificially separated from its rib, a costal cartilage has a rounded end that fits a reciprocal depression in the rib. Periosteum and perichondrium are continuous across the costochondral junctions and the collagen of the osseous and cartilaginous matrices blend. No movement occurs at costochondral junctions.

## MUSCLES

The intrinsic muscles of the chest wall are the intercostals, subcostales, transversus thoracis, levatores costarum, serratus posterior and, occasionally, sternalis. Scapular muscles and muscles connecting the upper limb, chest wall and vertebrae, i.e. trapezius, latissimus dorsi, rhomboids major and minor, levator scapulae, pectorales major and minor, subclavius, supra- and infraspinatus, teres major and teres minor, are described in detail in Chapter 48.

## INTRINSIC CHEST WALL MUSCLES

## Intercostal muscles

The intercostal muscles are thin multiple layers of muscular and tendinous fibres that occupy the intercostal spaces; their names are derived from their spatial relationship, i.e. the external, internal and innermost intercostals (Fig. 53.15).

## External intercostals

Eleven pairs of external intercostals extend from the tubercles of the ribs, where they blend with the posterior fibres of the superior costotransverse ligaments, almost to the costal cartilages, where each continues forwards to the sternum as an aponeurotic layer, the external intercostal membrane. Each muscle passes from the lower border of one rib to the upper border of the rib below; their fibres are directed obliquely downwards and laterally at the back of the thorax, and downwards, forwards and medially at the front. In the upper two or three spaces, they do not quite reach the ends of the rib, and in the lower two spaces, they extend to the free ends of the costal cartilages. The external intercostals are thicker than the internal intercostals.

Innervation External intercostals are supplied by the adjacent intercostal nerves.

Action External intercostals are believed to act with the internal intercostals (Ch. 55).

## Internal intercostals

Eleven pairs of internal intercostals begin anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and at the anterior extremities of the cartilages of the 'false' ribs. Their greatest thickness lies in this intercartilaginous or parasternal part. They continue back as far as the posterior costal angles, where each is replaced by an aponeurotic layer, the internal intercostal membrane, that is continuous posteriorly with the anterior fibres of a superior costotransverse ligament, and anteriorly with the fascia between the internal and external intercostal muscles. Each muscle descends from the floor of a costal groove and adjacent costal cartilage, and inserts into the upper border of the rib below; their fibres are directed obliquely, nearly at right angles to those of the external intercostal muscles.

Innervation Internal intercostals are supplied by the adjacent intercostal nerves.

Action Internal intercostals are believed to act with the external intercostals (p. 974).

## Innermost intercostals

The innermost intercostals were once regarded as internal laminae of the internal intercostal muscles, and fibres in the two layers do coincide in direction. Each muscle is attached to the internal aspects of two adjoining ribs. They are insignificant, and sometimes absent, at the highest thoracic levels but become progressively more substantial below this, typically extending through the middle two quarters of the lower intercostal spaces. Posteriorly, the innermost intercostals, in those spaces where they are well developed, may come together with the corresponding subcostales. The innermost intercostals are related internally to the endothoracic fascia and parietal pleura, and externally to the intercostal nerves and vessels.

Innervation Innermost intercostals are supplied by the adjacent intercostal nerves.

Action Innermost intercostals are believed to act with the internal intercostals (Ch. 55).

## Subcostales

Subcostales consist of muscular and aponeurotic fasciculi and are usually well developed only in the lower part of the thorax. Each descends from the internal surface of one rib, near its angle, to the internal surface of the second or third rib below. Their fibres run parallel to those of the internal intercostals and, like the innermost intercostals, they lie between the intercostal vessels and nerves and the pleura.

Innervation Subcostales are supplied by the adjacent intercostal nerves.

Action Subcostales depress the ribs.

## Transversus thoracis

Transversus thoracis (triangularis sternae, sternocostalis) spreads over the internal surface of the anterior thoracic wall (see Fig. 53.15). It arises from the lower third of the posterior surface of the sternum, the xiphoid process and the costal cartilages of the lower three or four true ribs near their sternal ends. The fibres diverge and ascend laterally as slips that pass into the lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth and sixth ribs. The lowest fibres are horizontal and are contiguous with the highest fibres of transversus abdominis; the intermediate fibres are oblique; and the highest are almost vertical. Transversus thoracis varies in its attachments, not only between individuals but even on opposite sides of the same individual. Like the innermost intercostals and subcostales, transversus thoracis separates the intercostal nerves from the pleura.

Innervation Transversus thoracis is supplied by the adjacent intercostal nerves.

Action Transversus thoracis draws down the costal cartilages to which it is attached.

## Levatores costarum

Levatores costarum are strong bundles, 12 on each side, which arise from the tips of the transverse processes of the seventh cervical and first to eleventh thoracic vertebrae. They pass obliquely downwards and laterally, parallel with the posterior borders of the external intercostals. Each is attached to the upper edge and external surface of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle (levatores costarum breves). Each of the four lower muscles divides into two fasciculi; one is attached as already described, and the other descends to the second rib below its origin (levatores costarum longi).

Innervation Levatores costarum are supplied by the lateral branches of the dorsal rami of the corresponding thoracic spinal nerves.

Action Levatores costarum elevate the ribs but their importance in ventilation is disputed. They are also said to act from their costal attachments as rotators and lateral flexors of the vertebral column.

## Serratus posterior superior

Serratus posterior superior (Fig. 53.16) is a thin quadrilateral muscle, external to the upper posterior part of the thorax. It arises by a thin aponeurosis from the lower part of the nuchal ligament, the spines of the seventh cervical and upper two or three thoracic vertebrae, and their supraspinous ligaments. It descends laterally and ends in four digitations attached to the upper borders and external surfaces of the second, third, fourth and fifth ribs, just lateral to their angles. It is superficial to the thoracic part of the thoracolumbar fascia and deep to the rhomboids. The number of digitations can vary from three to six, and the muscle may even be absent.

Innervation Serratus posterior superior is innervated by the second, third, fourth and fifth intercostal nerves.

Action The attachments of serratus posterior superior clearly indicate that it could elevate the ribs; its role in humans is uncertain.

Fig. 53.16 Superficial (extrinsic) muscles of the back.

## Serratus posterior inferior

Serratus posterior inferior (Fig. 53.16) is a thin, irregularly quadrilateral muscle at the junction of the thoracic and lumbar regions. It arises from the spines of the lower two thoracic and upper two or three lumbar vertebrae and their supraspinous ligaments by a thin aponeurosis that blends with the lumbar part of the thoracolumbar fascia. It ascends laterally and its four digitations pass into the inferior borders and outer surfaces of the lower four ribs, a little lateral to their angles. There may be fewer digitations and, in rare cases, the entire muscle may be absent.

Innervation Serratus posterior inferior is innervated by ventral rami of the ninth, tenth, eleventh and twelfth thoracic spinal nerves.

Action Serratus posterior inferior draws the lower ribs downwards and backwards, although possibly not in ventilation.

## Sternalis

Sternalis is an anatomical variation well known to anatomists but relatively unknown to clinicians and surgeons (Snosek et al 2014). The muscle appears as a parasternal mass deep to the superficial fascia of the anterior thoracic wall and superficial to the pectoral fascia overlying pectoralis major. It may be a cord-like, flat band or irregular and flame-like in shape, is almost twice as commonly unilateral, and occurs more often on the right side. Various attachment sites have been described in an extensive anatomical literature, including the sternum, inferior border of the clavicle, sternocleidomastoid fascia, pectoralis major, and the upper ribs and their costal cartilages, all superiorly, and the lower ribs and their costal cartilages, pectoralis major, the rectus sheath and the external abdominal oblique aponeurosis, all inferiorly The muscle occurs occasionally in the general population, but there is great variation both within and between different geographic populations. Its superficial location makes it an ideal candidate for utilization as a muscular flap in plastic reconstruction of the head and neck region.

The aetiology is unknown; sternalis may be an example of a much larger group of variations, including pectoralis minimus, pectoralis tertius, infraclavicularis and chondroepitrochlearis, that are thought to be caused by a disturbance of the normal processes of pectoral muscle development.

The relationship of sternalis to pectoralis major may cause a diagnostic dilemma during breast surgery, mammography, computed tomography and magnetic resonance imaging scans because its appearance mimics tumour pathology of the region.

## Mechanism of thoracic cage movement

Breathing involves changing the thoracic volume by altering the vertical, transverse and anteroposterior dimensions of the thorax (p. 974). The diaphragm is the key muscle in this process. Its muscle fibres descend from their relatively 'high' anterior sternocostal attachments steeply to the central tendon and obliquely to their complex 'low' posterior attachments (see Fig. 55.1). The central tendon is fixed: when the diaphragm contracts, it allows the lower ribcage to move inferiorly and anteriorly without any change to the curvature of the diaphragm. The intercostal muscles maintain the rigidity of the chest wall. The external and internal intercostals, transversus thoracis, subcostales, levatores costarum, serratus posterior superior and serratus posterior inferior can elevate or depress the ribs, and hence can act as accessory muscles of ventilation.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE CHEST WALL

## ARTERIES

Muscles of the thoracic wall receive their blood supply from the internal thoracic artery, either directly or via the musculophrenic artery, the superior intercostal artery, descending thoracic aorta, and the subcostal and superior thoracic arteries. Additional contributions come from vessels that supply the proximal muscles of the upper limb: namely, the suprascapular, superficial cervical, thoraco-acromial, lateral thoracic and subscapular arteries.

## Internal thoracic artery

The internal thoracic artery (internal mammary artery) arises inferiorly from the first part of the subclavian artery, approximately 2 cm above
the sternal end of the clavicle and opposite the root of the thyrocervical trunk (see Fig. 51.2). It descends behind the first six costal cartilages, 1 cm from the lateral sternal border and divides at the level of the sixth intercostal space into musculophrenic and superior epigastric branches. The superior epigastric artery is described in Chapter 61.

Relations At first, the internal thoracic artery descends anteromedially behind the sternal end of the clavicle, the internal jugular and brachiocephalic veins, and the first costal cartilage. As it enters the thorax, the phrenic nerve crosses it obliquely from its lateral side, usually in front. The artery then descends almost vertically to its bifurcation, lying behind pectoralis major, the first six costal cartilages, external intercostal membranes, internal intercostals and terminations of the upper six intercostal nerves. It is separated from the pleura, down to the second or third cartilage, by a strong layer of fascia, and below this by transversus thoracis. The artery is accompanied by a chain of lymph nodes and by venae comitantes that unite at about the third costal cartilage into a single vein medial to the artery. Its intermediate branches are sternal, anterior intercostal and perforating.

Sternal branches Sternal branches are distributed to transversus thoracis, the periosteum of the posterior sternal surface and the sternal red bone marrow. These branches, together with small branches of the pericardiacophrenic artery, anastomose with branches of the posterior intercostal and bronchial arteries to form a subpleural mediastinal plexus.

Anterior intercostal branches Anterior intercostal arteries are distributed to the upper six intercostal spaces. They pass laterally along the borders of the space and anastomose with the posterior intercostal arteries and their collateral branches (see Fig. 53.19). The anterior intercostals usually arise from the internal thoracic artery as single vessels that promptly divide into two branches, one passing superiorly, the other inferiorly within each intercostal space. Occasionally, one branch passes to the space above and one to the space below. (The anterior intercostals may sometimes arise as two separate branches from the internal thoracic artery.) The arteries lie at first between the pleura and the internal intercostals, then between the innermost and the internal intercostals (Fig. 53.18). They supply the intercostal muscles and send branches through them to the pectoral muscles, breast and skin.

Perforating branches Perforating branches traverse the upper five or six intercostal spaces with the anterior cutaneous branches of the corresponding intercostal nerves. They pierce and supply pectoralis major, and then curve laterally to become direct cutaneous vessels that supply the skin. These cutaneous vessels provide the anatomical basis for surgically raising the deltopectoral skin flap that is used for reconstructing areas of missing tissue in the head and neck. The second to fourth branches supply the breast and become enlarged during lactation.

Fig. 53.18 Dissection of part of an intercostal space, external aspect, showing the position of the intercostal vessels and nerve and their collateral branches relative to the intercostal muscles.

The mammographic appearance of sternalis muscle is variable. Typically visible in the medial aspect of the breast on a craniocaudal (CC) mammogram, it appears as a small soft tissue density/mass abutting the chest wall. Its margins and shape are variable. Sternalis is not usually seen on standard mediolateral oblique or mediolateral views.

Musculophrenic artery The musculophrenic artery passes inferolaterally behind the seventh to ninth costal cartilages, traverses the diaphragm near the ninth, and ends near the last intercostal space. It anastomoses with the inferior phrenic and lower two posterior intercostal arteries and ascending branches of the deep circumflex iliac arteries. Two anterior intercostal arteries branch from it for each of the seventh to ninth intercostal spaces, and are distributed similarly to their counterparts in the higher spaces. The musculophrenic artery also supplies the lower part of the pericardium and the abdominal muscles.

## Clinical significance of the internal thoracic artery

Available with the Gray's Anatomy e-book

## Superior intercostal artery

The superior intercostal artery arises from the costocervical trunk. It descends between the pleura and the necks of the first and second ribs, and anastomoses with the third posterior intercostal artery. Crossing the neck of the first rib, it lies medial to the ventral branch of the first thoracic spinal nerve, which it crosses at a lower level, and lateral to the stellate ganglion. In the first space, it gives off the first posterior intercostal artery, which has a similar distribution to the lower posterior intercostal arteries. It descends to become the second posterior intercostal artery, usually joining a branch from the third. The artery is not constant, and is more common on the right; when absent, it is replaced by a direct branch from the aorta.

## Posterior intercostal arteries

There are usually nine pairs of posterior intercostal arteries. They arise from the posterior aspect of the descending thoracic aorta and are distributed to the lower nine intercostal spaces. Right posterior intercostal arteries are longer because the aorta deviates to the left (Fig. 53.19); they cross the vertebral bodies behind the oesophagus, thoracic duct and azygos vein, right lung and pleura. Left posterior intercostal arteries turn backwards on the vertebral bodies in contact with the left lung and pleura; the upper two are crossed by the left superior intercostal vein, and the lower by the hemiazygos and accessory hemiazygos veins. The further course of the arteries is the same on both sides. The sympathetic trunk lies anterior to all of the arteries, and the splanchnic nerves descend in front of the lower arteries.

Fig. 53.19 A schematic transverse section through a lower intercostal space to show the branches of a typical intercostal artery. The usual branching arrangement of the dorsal cutaneous branch is shown to the right of the spine and a common variant is shown to the left. (With permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd ed. Edinburgh: Churchill Livingstone.)

Each artery crosses its intercostal space obliquely towards the angle of the rib above and continues forwards in its costal groove. At first between the pleura and internal intercostal membrane as far as the costal angle, it passes between the internal intercostal and innermost intercostal muscles (see Fig. 53.18), anastomosing with an anterior intercostal branch from either the internal thoracic or musculophrenic artery. Each artery has a vein above and a nerve below, except in the upper spaces, where the nerve at first lies above the artery. The third posterior intercostal artery anastomoses with the superior intercostal artery and may provide the major supply to the second space. The lower two arteries continue anteriorly into the abdominal wall, where they anastomose with the subcostal, superior epigastric and lumbar arteries. Each posterior intercostal artery has dorsal, collateral, muscular and cutaneous branches.

Dorsal branch Each dorsal branch runs dorsally between the necks of adjoining ribs; a vertebral body and superior costotransverse ligament lie medial and lateral, respectively. Each dorsal branch gives off a spinal branch that enters the vertebral canal via the intervertebral foramen and supplies the vertebra, spinal cord and meninges, anastomosing with the spinal arteries above and below and with its contralateral fellow. It then divides into a medial and a lateral dorsal musculocutaneous branch (occasionally, these arise separately from the posterior intercostal artery rather than from a common trunk). The medial branch crosses a transverse process with the medial dorsal branch of a thoracic spinal nerve to supply spinalis, longissimus thoracis and an area of overlying skin. The lateral branch supplies longissimus thoracis and iliocostalis, and the medial aspects of latissimus dorsi and trapezius, in addition to an area of overlying skin.

Collateral intercostal branch A collateral intercostal branch arises near the costal angle and descends to the upper border of the subjacent rib, along which it courses to anastomose with an anterior intercostal branch of the internal thoracic or musculophrenic artery.

Muscular branches Muscular branches supply the intercostal and pectoral muscles and serratus anterior, anastomosing with the superior and lateral thoracic branches of the axillary artery. Lateral cutaneous branches accompany the same branches of the thoracic spinal nerves. Mammary branches from the vessels in the second to fourth spaces supply the pectoral muscles, breast tissue and skin; they enlarge during lactation.

Lateral cutaneous branch The lateral cutaneous branch is given off in the posterior part of the intercostal space and travels anteriorly for a few centimetres with an accompanying vein and the lateral cutaneous branch of the equivalent intercostal nerve. This neurovascular bundle pierces the intercostal muscles and emerges lower down between the interdigitations of serratus anterior and external oblique. It divides into anterior and posterior rami, which contribute to the blood supply of the skin of the lateral trunk; these vessels are less significant in the upper three intercostal spaces.

Unnamed branches Other unnamed branches supply tissues of the thoracic wall, e.g. costal periosteum, bone and bone marrow of the ribs, tissues of synovial and synarthrodial joints, and the parietal pleura.

## Clinical significance of the posterior intercostal arteries

## Available with the Gray's Anatomy e-book

## VEINS

## Internal thoracic veins

The internal thoracic veins are venae comitantes of the inferior half of the internal thoracic artery. Near the third costal cartilages, the veins unite and ascend medial to the artery to end in their appropriate brachiocephalic vein. Tributaries correspond to branches of the artery and include a pericardiacophrenic vein. The internal thoracic veins have several valves.

## Left superior intercostal vein

The left superior intercostal vein drains the second and third (sometimes fourth) left posterior intercostal veins. It ascends obliquely forwards across the left aspect of the aortic arch, lateral to the left vagus

Fig. 53.17 The internal thoracic vessels prepared for micro-anastomosis beneath the third costal cartilage. The dissected internal thoracic artery (red arrow) and vein (blue arrow) are shown after removal of the right third costal cartilage. These vessels are divided to provide recipient blood supply for a free tissue transfer.

The internal thoracic artery has a number of clinical uses but perhaps most significantly is the vessel of choice for coronary artery bypass grafting (Fig. 53.17). It has become a popular recipient vessel for free flap transfers to the chest wall, principally for breast reconstruction (Ninković et al 1995), and has largely superseded the thoracodorsal vessels for this purpose. It is routinely accessed by removing a portion of the third costal cartilage, although some surgeons prefer to dissect the vessels between the ribs, with a rib-sparing approach (Parrett et al 2008, Malata et al 2011) or even utilizing the anterior perforating branches as they pierce pectoralis major (Park et al 2003, Munhoz et al 2004). The anterior perforating branches form the vascular pedicles for fasciocutaneous flaps raised from the chest wall that have been used for many decades in head and neck reconstruction (Bakamjian et al 1971, Neligan et al 2007). The superior epigastric artery is the main vascular pedicle for the superiorly based rectus abdominis flap, a muscle or myocutaneous flap useful in breast, sternal and chest wall reconstruction (Hartrampf et al 1982). During CT-guided lung and mediastinal biopsies, the internal thoracic vessels must be avoided: exsanguination has been reported with Trucut needle trauma. The approach must be at least 2 cm lateral to the sternal margin. The vessels are not seen easily on non-contrast fluoroscopic CT images.

Catheter embolization is an interventional radiology technique that can be used to block branches of the posterior intercostal arteries when they are bleeding, e.g. secondary to blunt trauma usually associated with rib fractures, or when there is an abnormality of the vertebrae supplied by the dorsal branch of the posterior intercostal artery. In such cases, the posterior intercostal artery may be accessed by placing a catheter in the thoracic aorta, usually by puncturing the femoral artery in the groin. A smaller catheter (referred to as a superselective catheter) may then be placed in the posterior intercostal artery and embolic material (which can be metallic coils or glue) injected to block the artery. This can cause cessation of bleeding in cases of trauma and provide pain relief when the vertebral body is infiltrated with tumour (Fig. 53.20).

Fig. 53.20 A,B, Pre- and post-embolization images after selective catherization of the right eleventh posterior intercostal artery.
and medial to the left phrenic nerve, to open into the left brachiocephalic vein. It usually receives the left bronchial veins, sometimes the left pericardiacophrenic vein, and connects inferiorly with the accessory hemiazygos vein. It may be seen on a chest X-ray as the 'aortic nipple', not to be confused with a small lung nodule.

## Posterior intercostal veins

The posterior intercostal veins accompany their arteries in 11 pairs Approaching the vertebral column, each vein receives a posterior tributary that returns blood from the dorsal muscles and skin and the vertebral venous plexuses. On both sides, the first posterior intercostal vein ascends anterior to the neck of the first rib, arching forwards above the pleural dome to end in the ipsilateral brachiocephalic or vertebral vein. On the right side, the second, third and often the fourth veins form a right superior intercostal vein that joins the arch of the azygos vein. The lower spaces drain directly into the azygos vein. On the left side, the second, third and sometimes the fourth veins form a left superior intercostal vein. Veins from the fourth or fifth to eighth intercostal spaces end in the accessory hemiazygos vein, and veins from the ninth to the eleventh intercostal spaces drain into the hemiazygos vein.

Posterior intercostal veins are so called to distinguish them from small anterior intercostal veins, which are tributaries of the internal thoracic and musculophrenic veins.

## LYMPHATIC DRAINAGE

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see Fig. 53.22). Those superficial to trapezius and latissimus dorsi unite to form 10 or 12 trunks, which end in the subscapular nodes. Those in the pectoral region, including vessels from the skin covering the periphery of the breast and its subareolar plexus, run back, collecting those superficial to serratus anterior, to reach the pectoral nodes. Vessels near the lateral sternal margin pass between the costal cartilages to the parasternal nodes and anastomose across the sternum, providing a route for contralateral nodal spread in medially located breast carcinoma. A few vessels from the upper pectoral region ascend over the clavicle to the inferior deep cervical nodes. Lymph from the deeper tissues of the thoracic walls drains mainly to the parasternal, intercostal or diaphragmatic nodes.

## Parasternal (internal thoracic) nodes

There are four or five parasternal nodes along each internal thoracic artery at the anterior ends of the intercostal spaces. They drain afferents from the breast, deeper structures of the supra-umbilical anterior abdominal wall, the superior hepatic surface (through a small group of nodes behind the xiphoid process) and deeper parts of the anterior thoracic wall. Their efferents usually unite with those from the tracheobronchial and brachiocephalic nodes to form the bronchomediastinal trunk. The latter may open on either side, directly into the jugulosubclavian junction, into either great vein near the junction, the right subclavian trunk or lymphatic duct, or the thoracic duct on the left.

## Intercostal nodes

Intercostal nodes occupy the intercostal spaces near the heads and necks of the ribs. They receive deep lymph vessels from the posterolateral aspects of the chest wall and breast, some of which are interrupted by small lateral intercostal nodes. Efferents of nodes in the lower 4-7 spaces unite into a trunk that descends to the abdominal confluence of lymph trunks or to the start of the thoracic duct. Efferents of nodes in the left upper spaces end in the thoracic duct; those of the right upper spaces end in one of the right lymph trunks.

## Diaphragmatic nodes

Located on the thoracic surface of the diaphragm, these nodes are arranged in anterior, right and left lateral, and posterior groups.

Anterior group The anterior group consists of two or three small nodes behind the base of the xiphoid process, draining the convex hepatic surface, and one or two nodes on each side near the junction of the seventh rib and cartilage, which receive anterior lymph vessels from the diaphragm. The anterior group drains to the parasternal nodes.

Lateral groups The lateral groups each contain two or three nodes, and lie close to the point where the phrenic nerves enter the diaphragm. On the right, some nodes lie within the fibrous pericardium anterior to the intrathoracic end of the inferior vena cava. Their afferents drain the central diaphragm; those on the right also drain the convex surface of the liver, and their efferents pass to the posterior mediastinal, parasternal and brachiocephalic nodes.

Posterior group The posterior group consists of a few nodes that lie on the posterior aspect of the crura and connect with the lateral aortic and posterior mediastinal nodes.

## Lymphatic drainage of deeper tissues

Collecting vessels of the deeper thoracic tissues include lymphatics that drain the muscles attached to the ribs. Most end in axillary nodes but some from pectoralis major also drain to the parasternal nodes. Intercostal vessels drain the intercostal muscles and parietal pleura; those from the anterior thoracic wall and pleura end in the parasternal nodes, and their posterior counterparts drain to intercostal nodes.

Vessels from the diaphragm form two plexuses, thoracic and abdominal, which anastomose freely, especially in areas covered by pleura and peritoneum, respectively. The thoracic plexus unites with lymph vessels draining the costal and mediastinal pleura. Its efferents are anterior, draining to the anterior diaphragmatic nodes near the junctions of the seventh rib and cartilage; middle, draining to nodes on the oesophagus and around the end of the inferior vena cava; and posterior, draining to nodes around the aorta at the point where it leaves the thorax. The abdominal plexus anastomoses with the hepatic lymphatics and peripherally with those of the subperitoneal tissue. Efferents from its right half end in a group of nodes on the inferior phrenic artery, or in the right lateral aortic nodes. Those from the left half of the abdominal diaphragmatic plexus pass to the pre-aortic, lateral aortic and terminal oesophageal nodes.

## INNERVATION OF THE CHEST WALL

## THORACIC VENTRAL SPINAL RAMI

There are 12 pairs of thoracic ventral rami. The upper 11 lie between the ribs (intercostal nerves) and the twelfth lies below the last rib (subcostal nerve). Each is connected with the adjoining ganglion of the sympathetic trunk by grey and white rami communicantes; the grey ramus joins the nerve proximal to the point at which the white ramus leaves it (Fig. 53.21). Intercostal nerves are distributed primarily to the thoracic and abdominal walls. The first two nerves supply fibres to the

Fig. 53.21 The course of a typical intercostal nerve. The muscular and the collateral branches are not shown.
upper limb in addition to their thoracic branches, the next four supply only the thoracic wall, and the lower five supply both thoracic and abdominal walls. The subcostal nerve is distributed to the abdominal wall and the gluteal skin. Communicating branches link the intercostal nerves posteriorly in the intercostal spaces, and the lower five nerves communicate freely in the abdominal wall.

## First to sixth thoracic ventral rami

The first thoracic ventral ramus divides unequally: a large branch ascends across the neck of the first rib, lateral to the superior intercostal artery, to enter the brachial plexus, and a smaller branch (the first intercostal nerve) runs in the first intercostal space and terminates as the first anterior cutaneous nerve of the thorax. A lateral cutaneous branch pierces the chest wall anterior to serratus anterior and supplies the axillary skin; it may communicate with the intercostobrachial nerve and sometimes joins the medial cutaneous nerve of the arm. The first thoracic ramus often receives a connecting ramus from the second, which ascends in front of the neck of the second rib.

The second to sixth thoracic ventral rami pass forwards in their intercostal spaces below the intercostal vessels. Posteriorly, they lie between the pleura and external intercostal membranes, but they run mainly between the internal intercostals and the subcostales/innermost intercostals. Near the sternum, they cross anterior to the internal thoracic vessels and transversus thoracis, pierce the internal intercostals, the external intercostal membranes and pectoralis major, and terminate as the anterior cutaneous nerves of the thorax. The second anterior cutaneous nerve may be connected to the medial supraclavicular nerves of the cervical plexus, and twigs from the sixth intercostal nerve supply abdominal skin in the upper part of the infrasternal angle.

Branches Numerous slender muscular filaments supply the intercostals, serratus posterior superior and transversus thoracis. Anteriorly, some cross the costal cartilages from one intercostal space to another. Each intercostal nerve gives off a collateral and a lateral cutaneous branch before it reaches the angle of the adjoining ribs (see Fig. 53.21). The collateral branch follows the inferior border of its space in the same intermuscular plane as the main nerve, which it may rejoin before it is distributed as an additional anterior cutaneous nerve. The lateral cutaneous branch accompanies the main nerve a little way and then pierces the intercostal muscles obliquely. With the exception of the lateral cutaneous branches of the first and second intercostal nerves, each divides into anterior and posterior rami that subsequently pierce serratus anterior. Anterior branches run forwards over the border of pectoralis major to supply the overlying skin; those of the fifth and sixth also supply twigs to a variable number of upper digitations of external oblique. Posterior branches run backwards and supply the skin over the scapula and latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is the intercostobrachial nerve (see Fig. 48.34). It crosses the axilla to gain the medial side of the arm and joins a branch of the medial cutaneous nerve of the arm. It then pierces the deep fascia of the arm, and supplies the skin of the upper half of the posterior and medial parts of the arm, communicating with the posterior cutaneous branch of the radial nerve. Its size is in inverse proportion to the size of the medial cutaneous nerve. A second intercostobrachial nerve often branches off from the anterior part of the third lateral cutaneous nerve and sends filaments to the axilla and the medial side of the arm.

## Seventh to eleventh thoracic ventral rami

The ventral rami of the seventh to eleventh thoracic nerves are continued anteriorly from the intercostal spaces into the abdominal wall; their further course is described in Chapter 61.

## Lesions of the intercostal nerves

Subluxation of the interchondral joints between the lower costal cartilages may trap the intercostal nerves, causing referred abdominal pain. The dorsal cutaneous branch of an intercostal nerve can become entrapped as it penetrates the fascia of erector spinae. This produces an area of numbness, usually with painful paraesthesia, which extends approximately 10 cm from the midline laterally and 10 cm in length (notalgia paraesthetica); the area between the medial edge of the scapula and the spine is commonly affected. The anterior cutaneous branches of the intercostal nerves can also become entrapped as they penetrate the fascia of rectus abdominis, and this produces an area of numbness on the abdomen, usually with painful paraesthesia, which
extends from the midline laterally for 10 or 12 cm (rectus abdominis syndrome).

## Twelfth thoracic ventral ramus (subcostal nerve)

The ventral ramus of the twelfth thoracic nerve (subcostal nerve) is larger than the others and gives a communicating branch to the first lumbar ventral ramus (sometimes termed the dorsolumbar nerve). Like the intercostal nerves, it soon gives off a collateral branch and then accompanies the subcostal vessels along the inferior border of the twelfth rib, passing behind the lateral arcuate ligament and kidney, and in front of the upper part of quadratus lumborum. It perforates the aponeurosis of the origin of transversus abdominis and passes forwards between that muscle and internal oblique, to be distributed in the same manner as the lower intercostal nerves. The subcostal nerve connects with the iliohypogastric nerve of the lumbar plexus and sends a branch to pyramidalis. Its lateral cutaneous branch pierces the internal and external oblique muscles and supplies the lowest slip of the latter. It usually descends over the iliac crest 5 cm behind the anterior superior iliac spine (see Fig. 61.5) and is distributed to the anterior gluteal skin; some filaments reach as low as the greater trochanter of the femur.

## THORACIC DORSAL SPINAL RAMI

Thoracic dorsal rami pass backwards close to the vertebral zygapophysial (facet) joints and divide into medial and lateral branches. The medial branch emerges between the joint and the medial edge of the superior costotransverse ligament and intertransverse muscle. The lateral branch runs in the interval between the ligament and the muscle before inclining posteriorly on the medial side of levator costae.

Medial branches of the upper six thoracic dorsal rami pass between and supply semispinalis thoracis and multifidus; they then pierce the rhomboids and trapezius and reach the skin near the vertebral spines (see Fig. 45.8). Medial branches of the lower six thoracic dorsal rami are distributed mainly to multifidus and longissimus thoracis; occasionally, they give filaments to the skin in the median region. Lateral branches increase in size from above downwards. They run through or deep to longissimus thoracis to the interval between it and iliocostalis cervicis, supplying these muscles and levatores costarum; the lower five or six also give off cutaneous branches, which pierce serratus posterior inferior and latissimus dorsi in line with the costal angles. The lateral branches of a variable number of the upper thoracic rami also supply the skin. The lateral branch of the twelfth dorsal ramus sends a filament medially along the iliac crest and then passes inferiorly to innervate the skin of the anterior part of the gluteal region.

Medial cutaneous branches of the thoracic dorsal rami descend for some distance close to the vertebral spines before reaching the skin. Lateral branches descend for a considerable distance, which may be as much as the breadth of four ribs, before they become superficial, e.g. the branch of the twelfth thoracic ramus reaches the skin only a little way above the iliac crest.

## BREAST

The breasts form a secondary sexual feature of females and are a source of nutrition for the neonate. In young adult females, each breast is a rounded eminence largely lying within the superficial fascia anterior to the upper thorax but spreading laterally to a variable extent (Figs 53.22, 53.23A). Breast shape and size depend on genetic, racial and dietary factors and on the age, parity and menopausal status of the individual. Breasts may be hemispherical, conical, variably pendulous, piriform or thin and flattened. In the adult female, the base of the breast, i.e. its attached surface, extends vertically from the second or third to the sixth rib, and in the transverse plane from the sternal edge medially almost to the mid-axillary line laterally. The superolateral quadrant is prolonged towards the axilla along the inferolateral edge of pectoralis major, from which it projects a little, and may extend through the deep fascia up to the apex of the axilla (the axillary tail of Spence). The trunk superficial fascial system splits to enclose the breast to form the anterior and posterior lamellae. Posterior extensions of the superficial fascial system connect the breast to the pectoralis fascia, part of the deep fascial system. The inframammary crease is a zone of adherence of the superficial fascial system to the underlying chest wall at the inferior crescent of the breast.

The breast lies on the deep pectoral fascia, which in turn overlies pectoralis major and serratus anterior superiorly and external oblique

Fig. 53.22 The relations of the breast. (With permission from Drake, RL, Vogl, AW, Mitchell, A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
and its aponeurosis inferiorly, as the latter forms the anterior wall of the rectus sheath. Between the breast and the deep fascia, the loose connective tissue in the 'submammary space' allows the breast some degree of movement on the deep pectoral fascia. Advanced mammary carcinoma may cause tethering or fixation of the breast to the underlying musculature. Occasionally, small projections of glandular tissue may pass through the deep fascia into the underlying muscle in normal subjects.

## NIPPLE AND AREOLA

The nipple projects from the centre of the breast anteriorly (Fig. $53.23 \mathrm{~A}-\mathrm{C}$ ). It may be cylindrical and rounded, hemispherical or flattened, depending on the effects of developmental, nervous or hormonal factors and external temperature on the erectile properties of the subareolar muscle of the nipple. The level of the nipple varies widely. In females, its site is dependent on the size and shape of the breasts; it overlies the fourth intercostal space in most young women. In the male, the nipple is usually sited in the fourth intercostal space in the midclavicular line. In the young adult of either sex, the nipples are usually positioned $20-23 \mathrm{~cm}$ from the suprasternal notch in the mid-clavicular line and $20-23 \mathrm{~cm}$ apart in the horizontal plane. With increasing age and parity, female breasts adopt a more ptotic shape and the position of the nipple drops to the level of the inframammary crease or below. In the nulliparous, the nipple is pink, light brown or darker, depending on the general melanization of the body. Occasionally, the nipple may not evert during prenatal development and it remains permanently retracted (see below).

The skin covering the nipple and the surrounding areola (the disc of skin that circles the base of the nipple) has a convoluted surface. It contains numerous sweat and sebaceous glands that open directly on to the skin surface. The oily secretion of these specialized sebaceous glands acts as a protective lubricant and facilitates latching of the neonate during lactation; the glands are often visible in parous women, arranged circumferentially as small elevations, Montgomery's tubercles, around the areola close to the margin. Other areolar glands, intermediate in structure between mammary and sweat glands, become enlarged in pregnancy and lactation as subcutaneous tubercles. The sebaceous glands of the areola are not usually associated with hair follicles. The skin of the nipple and areola is rich in melanocytes and is therefore typically darker than the skin covering the remainder of the breast; further darkening occurs during the second month of pregnancy, and subsequently persists to a variable degree.

## SOFT TISSUE

The breasts are composed of lobes that contain a network of glandular tissue consisting of branching ducts and terminal secretory lobules in a connective tissue stroma (see Fig. 53.30). The terminal duct lobular unit is the functional milk secretory component of the breast; pathologically, it gives rise to primary malignant lesions within the breast. Although the lobes are usually described as discrete territories, they intertwine in three dimensions and merge at their edges; they cannot be distinguished during surgery. The connective tissue stroma that surrounds the lobules is dense and fibrocollagenous, whereas intralobular connective tissue has a loose texture that allows the rapid expansion of

Fig. 53.23 A, The structure of the breast. B, Changes in the breast during lactation. C, A section of the nipple. D, A cross-section of the nipple. There is a corrugated layer of stratified squamous keratinized epithelium over the nipple surface; 20 or more lactiferous ducts (L) open on to the surface; sebaceous glands (S) are deep to the epidermis. (D, With permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby.)
secretory tissue during pregnancy (see Fig. 53.30B). Fibrous strands or sheets consisting of condensations of connective tissue extend between the layer of deep fascia that covers the muscles of the anterior chest wall and the dermis. These suspensory ligaments (of Astley Cooper) are often well developed in the upper part of the breast and support the breast tissue, helping to maintain its non-ptotic form. Elsewhere in the normal breast, fibrous tissue surrounds the glandular components and extends to the skin and nipple, assisting the mechanical coherence of the gland. The interlobar stroma contains variable amounts of adipose tissue, which is responsible for much of the increase in breast size at puberty.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The breasts are supplied by branches of the axillary, internal thoracic and some intercostal arteries. The axillary artery supplies blood via the superior thoracic artery, the pectoral branches of the thoraco-acromial artery, the lateral thoracic artery (via branches that curve around the
lateral border of pectoralis major to supply the lateral aspect of the breast) and the subscapular artery. The internal thoracic artery supplies perforating branches to the anteromedial part of the breast. The second to fourth anterior intercostal arteries supply perforating branches more laterally in the anterior thorax. The second perforating artery is usually the largest and supplies the upper region of the breast, the nipple, areola and adjacent breast tissue.

## Veins

Blood drains from the circular venous plexus around the areola and from the glandular tissue of the breast into the axillary, internal thoracic and intercostal veins via veins that accompany the corresponding arteries. Individual variation is common.

## Lymphatic drainage

The lymphatic flow of the breast is of great clinical significance because metastatic dissemination occurs principally by the lymphatic routes
(the breasts are the site of malignant change in as many as 1 in 8 women). The dominant lymphatic drainage of the breast is derived from the dermal network. The breast lymphatics branch extensively and do not contain valves; lymphatic blockage through tumour occlusion may therefore result in reverse blood flow through the lymphatic channels. The direction of lymphatic flow within the breast parallels the major venous tributaries and enters the regional lymph nodes via the extensive periductal and perilobular network of lymphatic channels. Most of these lymphatics drain into the axillary group of regional lymph nodes either directly or through the retro-areolar lymphatic plexus (see Fig. 48.48). Dermal lymphatics also penetrate pectoralis major to join channels that drain the deeper parenchymal tissues, and then follow the vascular channels to terminate in the subclavicular lymph nodes.

Lymphatics from the left breast ultimately terminate in the thoracic duct and, subsequently, the left subclavian vein. On the right, the lymphatics ultimately drain into the right subclavian vein near its junction with the internal jugular vein. Part of the medial side of the right breast drains towards the internal thoracic group of lymph nodes. The internal thoracic chain may drain inferiorly via the superior and inferior epigastric lymphatic routes to the groin. Connecting lymphatics across the midline may provide access of lymphatic flow to the opposite axilla.

Axillary nodes receive more than $75 \%$ of the lymph from the breast (Fig. 53.24). There are 20-40 nodes, grouped artificially as pectoral (anterior), subscapular (posterior), central and apical. Surgically, the nodes are described in relation to pectoralis minor. Those lying below pectoralis minor are the low nodes (level 1), those behind the muscle are the middle group (level 2), while the nodes between the upper border of pectoralis minor and the lower border of the clavicle are the upper or apical nodes (level 3). There may be one or two other nodes between pectoralis minor and major; this interpectoral group of nodes are also known as Rotter's nodes. Efferent vessels directly from the breast pass round the anterior axillary border through the axillary fascia to the pectoral lymph nodes; some may pass directly to the subscapular nodes. A few vessels pass from the superior part of the breast to the

Fig. 53.24 Lymph vessels of the breast and the draining axillary and supraclavicular nodal groups.
apical axillary nodes, sometimes interrupted by the infraclavicular nodes or by small, inconstant, interpectoral nodes. Most of the remainder drain to parasternal nodes from the medial and lateral parts of the breast; they accompany perforating branches of the internal thoracic artery. Lymphatic vessels occasionally follow lateral cutaneous branches of the posterior intercostal arteries to the intercostal nodes.

## Axillary surgery in breast cancer

Axillary lymph node dissection may be performed because the presence of metastases within axillary lymph nodes has strong prognostic significance and might influence decisions on adjuvant therapy. However, axillary lymph node dissection can lead to chronic postoperative problems such as pain, seroma formation, reduced mobility of the arm, impaired sensation and lymphoedema. The vessels and nerves have to be carefully identified at surgery as anatomical landmarks.

## Lymphatic drainage in breast cancer and role of sentinel lymph node biopsy

Lymphatic mapping with sentinel lymph node biopsy has become an important technique in the staging of patients with early breast cancer. A radiolabelled colloid is injected into either the subareolar tissue of the index quadrant of the breast or the peritumoral and intradermal tissue overlying the primary breast cancer. At the time of surgery, a vital blue dye is injected after general anaesthesia is established. The combination of radioisotope and dye provides the most accurate means of localizing the sentinel node (Tanis et al 2001). The latter represents the first draining node of the axilla and is surgically removed for careful histopathological analysis to detect the presence of metastases.

## INNERVATION

The breast is innervated by anterior and lateral branches of the fourth to sixth intercostal nerves, which carry sensory and sympathetic efferent fibres. The nipple is supplied from the anterior branch of the lateral cutaneous branch of T4, which forms an extensive plexus within the nipple; its sensory fibres terminate close to the epithelium as free endings, Meissner corpuscles and Merkel disc endings. These are essential in signalling suckling to the central nervous system. Secretory activities of the gland are largely controlled by ovarian and hypophysial hormones rather than by efferent motor fibres. The areola has fewer sensory endings.

## MICROSTRUCTURE

The microstructure of breast tissue varies with age, time in the menstrual cycle, pregnancy and lactation. The following description relates to the mature, resting breast. For most of their lengths, the ducts are lined by columnar epithelium (Fig. 53.25A). In the larger ducts, this is two cells thick but, in the smaller ones, only a single layer of columnar or cuboidal cells is present. The bases of these cells are in close contact with numerous myoepithelial cells of ectodermal origin, similar to those of certain other glandular epithelia (see Figs 2.3, 2.4, 53.30A). Myoepithelial cells are so numerous that they form a distinct layer surrounding the ducts and presumptive alveoli, and give the epithelium a bilayered appearance.

Lactiferous ducts draining each lobe of the breast pass through the nipple and open on to its tip as 15-20 orifices. Near its orifice, each of these ducts is slightly expanded as a lactiferous sinus, which, in the lactating breast, is further dilated by the presence of milk. Each lactiferous duct is therefore connected to a system of ducts and lobules, surrounded by connective tissue stroma, collectively forming a lobe of the breast. Lobules consist of the portions of the glands that have secretory potential. Their structure varies according to hormonal status. In the mature resting breast, each lobule consists of a cluster of blind-ended, branched ductules (Fig. 53.25B), whose termini lack mature terminal alveoli (acini), which are the sites of milk secretion in the lactating breast (see Fig. 53.30B). The stratified cuboidal lining is replaced by keratinized stratified squamous epithelium, continuous with the epidermis, close to the openings of the lactiferous ducts on the nipple. Shed squames may sometimes block the duct apertures in the nonpregnant breast.

Internally, the nipple is composed mostly of collagenous dense connective tissue and contains numerous elastic fibres that wrinkle the overlying skin. Deep to the nipple and areola, bundles of smooth muscle cells are arranged radially and circumferentially within the connective tissue and are thought to be remnants of the panniculus carnosus. Their contraction, induced by cold or tactile stimuli (e.g. in

If the histopathological results prove negative, the morbidity associated with axillary dissection can be avoided. In women who are found to have metastases to the axillary nodal group, axillary completion dissection or radiotherapy is offered. The majority of sentinel nodes are found in the low axilla (level 1). Higher-level 'skip' nodes are involved in $5-10 \%$ of cases. Occasionally, the sentinel node is identified in an extra-axillary position, either within the breast parenchyma as an intramammary lymph node, or as an internal thoracic lymph node or in the supraclavicular fossa.

suckling), causes erection of the nipple and wrinkling of the surrounding areola.

## BREAST CANCER

Available with the Gray's Anatomy e-book

## DEVELOPMENT

The epithelial/mesenchymal interactions that will give rise to the glandular tissue of the breast in both sexes can first be seen at about the fifth or sixth week, when two ventral bands of thickened ectoderm, the mammary ridges or milk lines, extend from the axilla to the inguinal region. Usually, invagination of the thoracic mammary bud occurs by day 49, and the remaining mammary line involutes.

The thoracic ectodermal ingrowths branch into 15-20 solid buds of ectoderm that will become the lactiferous ducts and their associated lobes of alveoli in the fully formed gland. They are surrounded by somatopleuric mesenchyme that forms the connective tissue, fat and vasculature that is invaded by the mammary nerves. Continued cell proliferation, elongation and further branching produce the alveoli and define the duct system. Nipple formation begins at day 56, primitive ducts (mammary sprouts) develop at 84 days, and canalization occurs at about the 150th day. During the last 2 months of gestation, the ducts become canalized and the epidermis at the point of original development of the gland forms a small mammary pit, into which the lactiferous tubules open (Fig. 53.27). Perinatally, the nipple is formed by mesenchymal proliferation. Should this process fail, the ducts open into shallow pits. Rarely, the nipple may not develop (athelia), a phenomenon that occurs more commonly in accessory breast tissue.

At birth, the breasts have reached a similar developmental stage in both sexes, and the combination of fetal prolactin and maternal oestrogen may give rise to transient hyperplasia and secretion of 'witch's milk'. In males, the breasts normally remain undeveloped whereas in females at puberty, in late pregnancy and during the period of lactation, they undergo further, hormone-dependent developmental changes. The female breast is a unique organ in that it remains in a rudimentary (i.e. fetal) form until puberty, at which time its development continues under the influence of sex hormones. The adult form is reached in late adolescence, i.e. the breast is then able to function as a milk-producing organ. At menopause, the breast involutes into a predominantly fatty organ with minimal glandular parenchyma.

## Accessory breast tissue and nipples

Polymastia (supernumerary breasts) and polythelia (supernumerary nipples) may develop in males and females anywhere along the length of the mammary ridges (milk lines; Fig. 53.28). Conversely, breast tissue may not develop at all (amastia), or there may be nipple development but no breast tissue (amazia). Supernumerary breast development

Breast cancer is a common disease, particularly in postmenopausal women (see Fentiman 1993). Each year, in the United Kingdom, there are approximately 40,000 new cases diagnosed and 14,000 deaths. Male breast cancers constitute up to $1 \%$ of all mammary malignancies and may include tissue beyond the areolar boundary.

Breast cancers arise within the epithelia of lobules or ducts. As they increase in size and infiltrate the stroma, they often lead to a fibrous tissue reaction. Breast lumps may be classified as benign or malignant masses. Malignant breast lumps may have the clinical signs of infiltrating adjacent structures, leading to a hard and irregular mass with skintethering, muscle fixation, skin infiltration or oedema of the overlying skin (peau d'orange). Standard radiological imaging investigations of the breast include mammography and ultrasonography. Mammography is useful in detecting the presence of malignant masses as a stellate opacity with architectural distortion of the surrounding parenchyma. Early stages of preinvasive breast cancer, ductal cancer in situ, may appear as microcalcification on the mammogram. An ultrasound scan of the breast is helpful to distinguish solid from cystic (or fluid-filled) masses, and can also aid in the distinction of breast cancer from benign lumps by the different attenuation characteristics of the ultrasound waves and blood-flow patterns. Wrinkles caused by contraction of muscular fibres in the areola described above may create critical angle shadowing in breast ultrasound.

Magnetic resonance imaging (MRI) is also useful in diagnosis, particularly in women with younger, denser breasts, achieving higher sensitivity of breast cancer detection but with lower specificity. A cytological diagnosis of a breast lump can be achieved using fine needle aspiration (FNA) to evaluate the cellular component of a lump. FNA is also useful to drain symptomatic breast cysts. A wide-bore needle biopsy is a procedure performed under local anaesthetic to obtain several pieces of specimen for a histological diagnosis with the tissue architecture maintained. This permits distinction between in situ and invasive cancer, and provides an indication of tumour subtype by evaluation of the pathological characteristics. Vacuum-assisted mammotome biopsies based on the wide-bore needle enable some benign and indeterminate lesions to be excised for full histological analysis and, in some patients, can avoid the need for conventional open surgery.

If a breast lump has to be surgically removed, the incision should be based, whenever possible, in the relaxed skin tension lines, for the best cosmetic results. In women with sizeable malignant lesions in whom breast conservation surgery is to be attempted, the skin incision should be planned with consideration of the possible requirement for a subsequent mastectomy if the margins of excision are incompletely excised by pathological criteria (Swanson et al 2002). Most women with single breast cancers of up to 4 cm in diameter are treated by breast conservation rather than mastectomy. This is a combination of surgery (tumour excision and sentinel node biopsy or clearance) together with external beam radiotherapy. Patients with larger tumours are treated by modified radical mastectomy with axillary lymph node clearance. During axillary dissection to clear the axillary lymph nodes, the nerve to serratus anterior, the thoracodorsal vessels, the nerve to latissimus dorsi, and the medial and lateral pectoral nerves are all identified and carefully preserved. The boundaries of the axillary dissection are the nerve to serratus anterior medially, the thoracodorsal pedicle laterally and the axillary vein superiorly. The posterior limit of the dissection is the ventral surface of subscapularis. The superomedial limit of a level 1 axillary dissection extends to the lateral border of pectoralis minor at the apex of the axilla; a level 2 dissection extends to the medial border of pectoralis minor; and a level 3 dissection extends beyond the medial border until it reaches the point where the axilla is limited by the first rib (the latter is easily distinguished by its flat lateral surface, easily palpable at surgery). Failure to preserve the nerve to serratus anterior will result in winging of the scapula. The intercostobrachial nerve is often sacrificed in an axillary lymph node clearance operation, and this may result in anaesthesia of a narrow strip of sensation in the upper medial border of the arm.

## Reconstructive surgery for breast cancer disease

Breast reconstruction may be performed at the time of mastectomy for breast cancer, or at a later stage (Serletti and Moran 2000). During a mastectomy where an immediate breast reconstruction is planned, the glandular breast tissue is removed either through a conventional mastectomy skin incision or in association with preservation of the native breast skin, a form of mastectomy termed a skin-sparing mastectomy. Patient selection is important to minimize risks of breast cancer recurrence in the skin of the reconstructed breast mound or associated lymph
nodes. In an implant-based immediate breast reconstruction, a tissue expander is placed beneath the musculofascial plane consisting of pectoralis major, in continuity laterally under serratus anterior with the intervening fascia, and the abdominal fascia inferiorly. The lower fibres of the attachment of pectoralis major to the sixth rib need to be detached; otherwise, the implant will be placed too high on the chest wall. The tissue expander has to stretch the potential space below this musculofascial plane to match the space created by the removed breast beneath the subcutaneous plane and the deep fascia overlying pectoralis major. The tissue expander is subsequently replaced by a silicone or saline breast implant.

The skin and volume component of the breast can also be replaced by the latissimus dorsi musculocutaneous flap, with or without an underlying silicone or saline breast implant. Latissimus dorsi and an overlying paddle of skin are raised on its dominant vascular pedicle: namely, the thoracodorsal vessels, which enter the muscle on its deep surface and send perforating branches through the muscle to the overlying skin. The flap is transferred in an arc from the back to the front of the chest and fashioned to make a new breast. An implant may be required to provide additional volume replacement, in which case it is placed beneath the flap. The donor defect on the back is directly sutured. In selected cases, this flap can be raised with additional superficial fascia and fat, to avoid the need for a silicone implant. This is known as the extended or autologous latissimus dorsi flap.

Women with a suitable abdominal panniculus may have breast reconstruction utilizing this excess tissue. Historically, this was achieved with a pedicled transverse rectus abdominis musculocutaneous (TRAM) flap based on the superior epigastric artery, where the skin and fat of the lower abdomen, attached to the rectus muscle, are transposed into the breast defect and shaped into a breast reconstruction.

The development of microvascular techniques over the last 30 years has seen an increase in the popularity of free tissue transfers, based on the deep inferior epigastric vessels, including muscle-sparing (MS-) TRAM flaps and deep inferior epigastric artery perforator (DIEP) flaps. These flaps require dissection of the blood vessels within rectus abdominis, rather than sacrifice of the entire muscle, and this aims to reduce donor site morbidity, including hernias and bulging. Radiological investigations (CT angiograms, MRI and duplex) are used to determine the calibre and position of perforators within these flaps to improve the accuracy of dissection and enhance surgical outcomes (Fig. 53.26). Free TRAM and DIEP flap vessels are anastomosed to recipient vessels in the chest; the internal thoracic or the thoracodorsal artery is used most frequently for this purpose.

Breast reconstruction using an autologous method, such as the extended latissimus dorsi, free MS-TRAM and DIEP flap, avoids the need for a silicone implant and has advantages in terms of producing a more natural appearance and achieving greater longevity of results. Free tissue transfers for breast reconstruction are also performed using buttock tissue (superior and inferior gluteal artery perforator flaps) and thigh tissue (transverse upper gracilis and anterolateral thigh flaps).

Fig. 53.26 A CT angiogram showing the deep inferior epigastric artery (red arrow) and a perforator (yellow arrow) emerging from the rectus sheath for MS-TRAM and DIEP flap reconstruction.

## Breast reconstruction using <br> autologous tissue

One of the earliest recorded breast reconstructions using latissimus dorsi, based on the thoracodorsal pedicle, was published in 1906 (Tansini 1906). The flap incorporated superficial fascia and a skin paddle attached to the muscle, and was used to replace part of the breast skin envelope that had been removed during the mastectomy. This form of breast reconstruction inexplicably fell out of regular use until the 1970s, when there was renewed interest in the latissimus dorsi musculocutaneous flap combined with silicone breast implants (Schneider et al 1978, Bostwick 1977) and improved definitions of the vascular supply and territory of the flap (McCraw et al 1977, Maxwell et al 1979).

Later in the twentieth century, further developments of this most versatile flap meant that breast reconstruction could be performed without a silicone implant. The so-called 'extended' flap (Hokin and Silfverskiold 1987) used autologous tissues exclusively; it was designed to satisfy an increasing demand for breast reconstruction in an era when silicone implants were under scrutiny because of safety fears and proposed links with autoimmune diseases. Further developments to maximize the volume available for autologous reconstructions of small to medium-sized breasts included harvesting larger skin paddles from the back and burying them beneath the breast skin envelope after de-epithelializing their surface (Papp et al 1988), and inclusion of additional fat pads in the back to increase flap volume (Delay et al 1998).

Despite the enhancements to the latissimus dorsi flap, the lower abdominal region provides a plentiful and more reliable source of tissue for reconstructive surgeons and also avoids the sometimes troublesome and often unsightly dorsal donor site wound. DIEP or MS-TRAM flaps are generally considered the first choice for breast reconstruction when the tissues are adequate.

The first description of lower abdominal tissues being used as a free flap appeared in 1979 (Holmstrom 1979), although at this time the pedicled TRAM flap was a far more popular choice for reconstruction. This was mainly because microvascular techniques were still in development and the required instruments and microscopes were not widely available. However, over the years, it became possible to achieve excellent, reliable results without the problems of fat necrosis and abdominal wall weakness associated with the pedicled version (Schusterman 1994, Grotting 1989, Arnez et al 1991). The TRAM flap particularly lends itself to microsurgical transfer on account of the characteristics of the supplying vessels (deep inferior epigastric artery is $2.5-3 \mathrm{~mm}$ in diameter and its venae comitantes are 3 mm in diameter); the length of the pedicle (frequently up to 15 cm ); and the large surface area of skin supplied by these vessels (from the midline to a point lateral to the anterior superior iliac spine below the level of the umbilicus).

Further developments in dissection techniques, combined with a desire to reduce donor site morbidity, led to the first description of a 'perforator' flap based on the same vessels (Allen and Treece 1994). This is the DIEP flap, which captures the same soft tissue area of the abdomen for reconstruction, but attempts to avoid injury to rectus abdominis by dissecting the perforating vessels through the muscle rather than by sacrificing it. Some authors have identified fewer donor site bulges and herniae with DIEP flaps compared with TRAM flaps (Blondeel et al 1997), and it is for this reason that DIEP flaps are the preferred choice, if possible. However, the perforating vessels are not always anatomically favourable for allowing safe harvest of the flap. Many clinicians have adopted radiological studies (CT angiogram, duplex or MR angiogram) to determine the calibre and position of the vessels preoperatively for more accurate surgical planning (see Fig. 53.26).

Fig. 53.28 Milk lines.
occurs in most cases in the thoracic region, just inferior to the normal breast ( $90 \%$ ), but may also occur in the axillary (5\%) and abdominal regions (5\%) and even on to the medial thigh. Polythelia occurs along the same mammary line but no underlying glandular tissue develops. This condition is rare in the female population but it is more common in males, in whom the accessory nipple may be mistaken for a mole.

## Congenital inversion of nipple

Congenital inversion of the nipples occurs rarely in the female population and is almost always bilateral. The majority of the cases are umbilicated, i.e. the nipple can be easily pulled forwards from its depressed position underneath the areolar surface. The condition is thought to be due to failure of proliferation of the mesenchymal tissue, which fails to push the nipple out. The remaining cases are due to invagination of the nipple. Apart from psychological implications, inversion of the nipple may cause recurrent mastitis and difficulty with breast feeding. The abnormality may be corrected surgically.

## AGE-RELATED CHANGES

## Prepuberty

The neonatal breast contains lactiferous ducts but no alveoli. Until puberty, little branching of the ducts occurs, and any slight mammary enlargement reflects the growth of fibrous stroma and fat.

## Puberty

In the postpubertal female, the ducts become branched on stimulation by ovarian oestrogens. The ends of the branches form solid, spheroidal masses of granular polyhedral cells: the potential alveoli. Oestrogens also promote adipocyte differentiation from mesenchymal cells in the interlobar stroma. Breast enlargement at puberty is mainly a consequence of lipid accumulation by these adipocytes.

From puberty onwards, externally recognizable breast development (thelarche) can be divided into five separate phases (Fig. 53.29): elevation of the breast bud (phase I); glandular subareolar tissue is present and both nipple and breast project from the chest wall as a single mass (phase II); the areola increases in diameter and becomes pigmented, and there is proliferation of palpable breast tissue (phase III); further pigmentation and enlargement occur in the areola, so that the nipple and areola form a secondary mass anterior to the main part of the breast (phase IV); and a smooth contour to the breast develops (phase V).

## Changes during the menstrual cycle

Changes occur in the breast tissues in the menstrual cycle. In the follicular phase (days 3-14), the stroma becomes less dense. Various changes, including luminal expansion, take place in the ducts; there are occasional mitoses but no secretion. In the luteal phase (days 15-28), there is a progressive increase in stromal density and the ducts have an open lumen that contains secretion, associated with flattening of the epithelial cells. Cell proliferation is maximal on day 26 and thereafter the ductal system undergoes reduction; epithelial cell apoptosis is greatest on day 28 of the cycle. There are also changes in blood flow, which are greatest at mid-cycle, and an increase in the water content of the stroma in the second half of the menstrual cycle.

## Postmenopausal

Progressive atrophy of lobules and ducts occurs after the menopause, and there is fatty replacement of glandular breast tissue. A few ducts may remain. The stroma becomes much less cellular and collagenous fibres decrease. The amount of adipose tissue varies widely between individuals, and the breast may return to a condition similar to the prepubertal state.

## CHANGES ASSOCIATED WITH PREGNANCY AND LACTATION

## Pregnancy

As the output of oestrogen and progesterone, produced first by the corpus luteum and later by the placenta, rises during pregnancy, the intralobular ductal epithelium proliferates and the cells increase in size; the number and length of the ductal branches therefore increase. Alveoli develop at their termini and expand as their cells and lumina fill with newly synthesized and secreted milk. The myoepithelial cells, which are initially spindle-shaped, become highly branched stellate cells, especially around the alveoli. Adjacent myoepithelial cells intermesh to form a basket-like network around the alveoli and ducts, interposed between the basal lamina and the luminal cells (see Fig. 2.3). Their cytoplasm contains actin and myosin filaments, and they are contractile (see Fig. 2.4). There is a concomitant reduction in adipose tissue in the stroma. The numbers of lymphocytes, including plasma cells, and eosinophils increase greatly. Blood flow through the breast increases.

Secretory activity in the alveolar cells rises progressively in the latter half of pregnancy. In late pregnancy, and for a few days after parturition, their product is different from later milk and is known as colostrum, characteristically low in lipid but rich in protein and immunoglobulins. Proliferation of the glandular breast parenchyma results in an overall increase in breast size through gestation.

## Lactation

True milk secretion begins a few days after parturition as a result of a reduction in circulating oestrogen and progesterone, a change that appears to stimulate production of prolactin by the anterior hypophysis. Milk distends the alveoli so that the cells flatten as secretion increases (see Fig. 53.23B; Fig. 53.30). The alveolar cell cytoplasm accumulates membrane-bound granules of casein and other milk proteins, and these are released from the apical plasma membrane by membrane fusion (merocrine secretion; see Fig. 2.6). Lipid vacuoles are formed directly in the apical cytoplasm as small lipid droplets that fuse with each other to create large 'milk vacuoles' up to $10 \mu \mathrm{~m}$ across. These are released as intact lipid droplets with a thin surround of apical plasma membrane and adjacent cytoplasm (apocrine secretion; see Fig. 2.6). On hormonal stimulation by oxytocin, myoepithelial cells contract to expel alveolar secretions into the ductal system in readiness for suckling.

After the onset of lactation, there is a gradual reduction in the numbers of lymphocytes and eosinophils in the stroma, although plasma cells continue to synthesize immunoglobulin A (IgA) for secretion into the milk. Alveolar cells take up IgA synthesized by adjacent plasma cells by endocytosis at their basal surfaces and secrete it apically, as dimers complexed to the epithelial secretory component.

## Post lactation

When lactation ceases, which may be after as long as $31 / 2$ years, the secretory tissue undergoes some involution but the ducts and alveoli never return completely to the pre-pregnant state. Two major processes

Fig. 53.29 Pre- and postpubertal development and structure of the female breast, demonstrating changes in the contour of the breast.
are responsible for the regression of the alveolar-ductal system: a reduction in epithelial cell size and a reduction in cell numbers mediated via apoptosis (p. 26). Gradually, the breast tissue reverts to its resting state. If another pregnancy occurs, the resting glandular tissue is reactivated and the process outlined above recurs. Up to the age of 50 years, increasing amounts of elastic tissue tend to be laid down around vessels and ducts (elastosis), and also in the stroma. Elastosis does not normally continue into later life.

Mammary stem cells Mammary stem cells (MaSCs) and distinct luminal progenitor cell types have been prospectively isolated from adult mouse and human mammary tissue, implying the existence of an epithelial differentiation hierarchy in the mammary gland. For further reading on the role that MaSCs may play in the postnatal mammary gland, see Rios et al (2014).

## MALE BREAST

The male breast remains rudimentary throughout life. It is formed of small ducts (without lobules or alveoli) or solid cellular cords and a little supporting fibroadipose tissue (Ellis et al 1993). Slight temporary enlargement may occur in the newborn, reflecting the influence of maternal hormones, and again at puberty. The areola is well developed, although limited in area, and the nipple is relatively small. It is usually stated that the ducts do not extend beyond the areola in a male breast but glandular tissue can be more extensive.

## Gynaecomastia

Gynaecomastia is a benign proliferation of subareolar breast tissue in the male. It may be unilateral or bilateral and of varying severity (Simon
et al 1973) and symptomatology. Pain or tenderness, thought to be due to accumulation of fluid in the glandular ducts, may be a presenting feature. Histological changes are fibrosis and subsequent hyalinization. The aetiology in the majority of cases is idiopathic. Broadly speaking, causes may be either physiological, reflecting imbalances of sex hormones in neonates, at puberty and in senescence, or pathological, reflecting hypogonadal or hyperoestrogenic states. Acquired causes include metabolic imbalances, endocrine and neoplastic conditions, and drug-induced gynaecomastia. In the adult male, unilateral gynaecomastia should be investigated to exclude male breast cancer.

## INTERVENTIONAL ACCESS TO THORACIC VISCERA

Thoracocentesis (pleural aspiration) Thoracocentesis or pleural aspiration is an essential step in the assessment of pleural effusions. A chest radiograph will confirm the location and extent of the effusion and clinical examination will identify the best position for aspiration, the posterior mid-scapular line being a common site. The skin of the desired interspace is cleaned and anaesthetized, and the aspiration needle is inserted at the lower margin of the interspace because the posterior intercostal vessels run mid-interspace. After appropriate local analgesia has been applied, the needle is carefully advanced in a perpendicular direction in the lower portion of the interspace until it enters the pleural space. More complex or small effusions should be aspirated under ultrasound guidance.

Needle thoracocentesis Needle thoracocentesis is performed when a life-threatening tension pneumothorax is suspected. A needle is inserted into the second intercostal space in the mid-clavicular line on the side of the tension pneumothorax, with the patient in an erect

Fig. 53.30 The microstructure of breast epithelium. A, Note that the myoepithelial process is actually about half the relative size of that shown in the lower diagram. B, The peripheral part of a lactating breast lobule enclosed by a connective tissue septum (left). The alveoli are distended by milk secretion. Milk protein appears as eosinophilic material in the lumen and milk fat as pale cytoplasmic vacuoles in the flattened alveolar epithelium. Intralobular connective tissue between the alveoli contains a prominent lymphocytic infiltration, including plasma cells secreting $\lg A$.
position. A sudden escape of air is heard when the needle enters the parietal pleura. A chest tube must be inserted after this procedure.

Chest drain insertion The insertion site for a chest drain is usually the fifth intercostal space, just anterior to the mid-axillary line on the affected side. A 2 cm horizontal incision is followed by blunt dissection through the subcutaneous tissues to the top of the rib. The parietal pleura is punctured with the tip of a clamp, and a gloved finger is inserted into the pleural space to free up any adhesions. The chest drain (thoracostomy tube) is then inserted into the pleural space and attached to an underwater sealed container placed below the level of the lungs; the water level rises and falls in the tube with ventilation.

Pericardiocentesis Pericardiocentesis is performed to aspirate a pericardial effusion or, in an emergency, to decompress a cardiac tamponade, where pressure from blood in the pericardial space prevents the heart chambers from filling during the cardiac cycle, seriously impairing cardiac output.

Pericardial puncture can be performed in either the fifth or sixth left intercostal space near the sternum (to avoid the internal thoracic artery) or at the left costoxiphoid angle. The needle is passed $1-2 \mathrm{~cm}$ to the left of the costoxiphoid angle at $45^{\circ}$ to the skin, and then up and backwards towards the tip of the scapula until it enters the pericardial sac.

The 12-lead ECG provides three-dimensional information on the electrical activity of the heart. The limb leads provide information about the electrical activity in the frontal plane. They are placed on the left and right wrists and the left foot; the right foot acts as a neutral grounding point. The chest leads provide information about the electrical activity in the horizontal plane and are placed as follows: V1, right fourth intercostal space, parasternal position; V2, left fourth intercostal space, parasternal position; V3, midpoint of V2 and V4 on the left; V4, fifth intercostal space, mid-clavicular line on the left; V5, fifth intercostal space, anterior axillary line on the left; and V6, fifth intercostal space, mid-axillary line on the left.

Thoracotomy incisions may be posterolateral or anterolateral, or involve a transverse thoracosternotomy.

Posterolateral incision A posterolateral incision is most commonly used in thoracic surgery for unilateral pulmonary resections, bullectomy, unilateral lung volume reduction surgery, chest wall resection and oesophageal surgery (Fry 2000). The patient is placed in a lateral decubitus position with adequate support of the elbow, axilla and knee with padding. The standard approach is via an incision from the anterior axillary line, which curves about 4 cm below the tip of the scapula and then vertically between the posterior midline and medial edge of the scapula. The incision is usually extended to the level of the spine of the scapula. Overall, the incision forms an S-shape in the fifth intercostal space. The sixth or seventh intercostal space is used in oesophageal surgery.

The lower portions of trapezius and latissimus dorsi are divided. Serratus anterior is retracted, and may be divided in a high thoracotomy. The costal muscle and pleura are dissected along the inferior margin of the intercostal space to avoid damaging the neurovascular bundle. A small section of rib is removed at the costovertebral angle to reduce the risk of fracture, particularly in patients older than 40 years. This technique provides good access to the thoracic contents; the main problem is postoperative pain as a consequence of intraoperative musculoskeletal traction.

Anterolateral incision The patient is placed in the supine position, with the arms by the sides. A roll is placed vertically under the back and hips in order to raise the operative side by approximately $45^{\circ}$. The incision is from the mid-axillary line over the fifth intercostal space along the inframammary fold, and curves upwards parasternally. The pectoral
muscles are divided, and subsequent access to the thorax is similar to that used in the posterolateral approach. However, access is limited, and may be improved by dividing costal cartilages.
'Clam shell' The transverse thoracosternotomy is known as the 'clam shell' incision. It provides excellent exposure to both sides of the chest and is therefore used in bilateral lung transplantation and in lung volume reduction surgery with bilateral lung resections. The patient is placed in the supine position with a roll vertically along the upper thoracic spine. Bilateral anterolateral incisions are made in the inframammary fold, and the sternum is transected. This allows the upper portion of the thorax to be displaced upwards with a rib-spreader; hence the name 'clam shell'. The main disadvantage of the clam shell procedure is the need to transect the sternum; even after careful repair with sternal wires, there is a risk of sternal instability.

Sternotomy is commonly needed in cardiac surgery. The patient is placed in the supine position with both arms extended by the side. A vertical incision is made in the midline from the suprasternal notch to a point just below the xiphoid process; the tissues around the manubrium and the xiphoid process are mobilized; and the pectoral fascia in the midline is incised. The sternum is split and its two edges retracted; it is subsequently closed using interosseous wire sutures.

The patient is placed in the lateral decubitus position, with arms abducted at $90^{\circ}$ and supported on an arm rest. The incision is based along the desired intercostal space; for upper thoracic lesions, this is the second or third space. Latissimus dorsi is elevated and retracted, whereas serratus anterior is divided in the direction of its fibres. The anterior aspect of serratus anterior is divided to expose the intercostal muscles, which are divided in turn. The overall size of the incision is limited and it provides good access to the upper thorax. Postoperative pain is less than with some other approaches, but the long thoracic nerve (nerve of Bell) may be damaged if serratus anterior is divided too posteriorly.

Occasionally, video-assisted thoracoscopic surgery is required to assess the mediastinum. The thoracoscope is usually introduced via the fifth intercostal space in the mid-clavicular line, with additional ports at the third and sixth intercostal spaces to assess the anterior mediastinum. To assess the posterior mediastinum, the thoracoscope is inserted into the seventh intercostal space in the mid-clavicular line.

## Pleura, lungs, trachea and bronchi

The lungs are the essential organs of respiration and are responsible for the uptake of oxygen into the blood and the removal of carbon dioxide. The functional design of the thorax facilitates this complex process. Acting together, the muscles of respiration and the diaphragm increase the intrathoracic volume, creating a negative pressure within the pleural space that causes lung expansion. The resultant reduction in intra-alveolar pressure prompts the conduction of air through the upper respiratory tract, trachea, bronchi and bronchioles, and finally into the alveoli, where gaseous exchange occurs. The respiratory movements do not clear the lung of its gas with each breath; the presence of a large residual volume of gas minimizes the degree to which each new breath can affect the composition of gas in diffusion exchange with the blood (Lambertsen 1980). Besides efficient oxygen diffusion from alveolar air to blood, the lungs must also provide an inefficient carbon dioxide transfer, thus maintaining a stable carbon dioxide blood and tissue pressure, grossly higher (about 40 mmHg ) than that in the atmosphere. Maintenance of critical homeostasis for carbon dioxide pressure is of greater importance than precise control of oxygen because so many essential electrical and metabolic functions depend on the hydrogen ion concentration $\left[\mathrm{H}^{+}\right]$of the fluids in which these functions are carried out.

The process of breathing exposes the lung to noxious agents, including gases, dust particles, bacteria and viruses, and to dehydration and freezing. The mucous barrier (including its cellular and immunoglobulin factors), the mucociliary escalator, branching pattern of the airways and the cough reflex are all anatomical defences against these insults. Studies of trends of particle deposition in children and young adults have shown that pulmonary deposition fractions are highest in infants who are at greatest risk from exposure to airborne particulate matter (Asgharian et al 2004). Respiratory function may be compromised either by anatomical defects such as chest wall abnormalities or by paralysis of respiratory muscles. Similarly, ultrastructural abnormalities, such as ciliary dysfunction (as seen in Kartagener's syndrome), lead to recurrent respiratory infections and airway damage.

## PLEURA

Each lung is covered by pleura, a serous membrane arranged as a closed invaginated sac. The visceral (pulmonary) pleura adheres closely to the lung surface and follows the interlobar fissures, eventually ensheathing each pulmonary lobe. The visceral pleura continues over the hila as the parietal pleura, covering the mediastinal organs, most of the diaphragm and the corresponding half of the thoracic wall.

The pleural cavity represents the potential space between the two pleura and incorporates an intervening pellicle of fluid that allows close sliding contact between the two layers during all phases of respiration. This liquid pellicle has a high daily turnover: fluid is produced at $0.01-$ $0.02 \mathrm{ml} / \mathrm{kg} / \mathrm{h}$ and is continuously absorbed to maintain a pleural fluid level of $0.1-0.2 \mathrm{ml} / \mathrm{kg}$. Fluid movement and absorption are supported by a balance between plasmatic and pleural (hydrostatic and oncotic) pressures and thoracic lymphatic drainage. Pleural effusions occur when the mechanisms that normally resorb the fluid pellicle are destabilized.

The negative pressure developed in the pleural cavity is the result of the opposing outward pull of the chest wall and the inward elastic recoil of the lung. Any change in the elasticity of these structures or accumulation of fluid or air will alter respiratory activity either regionally or globally. Inter-regional disparities in ventilation normally exist as a result of local differences in thoracic expansion and position-related, gravity-dependent gradients in pleural pressure, and are reflected as regional inequalities in gas exchange.

The right and left pleural sacs constitute separate compartments and are contiguous only posterior to the upper half of the sternal body. They come close to each other posterior to the oesophagus at the midthoracic level and are widely separate between, where they enclose the
mediastinal space. Cardiac asymmetry dictates that the left pleural cavity is smaller, although it may extend more inferiorly in the midaxillary line in response to left hemidiaphragmatic disposition. Transudates accumulate earlier within, and have a preference for, the larger right pleural cavity.

The folded portions of the pleura at its reflection sites (retrosternal, interlobar fissures and the azygo-oesophageal recess) are the only aspects of normal pleura that can be visualized radiologically. Demonstration of significant pleural shadowing in any other region usually implies pathological pleural abnormality. At direct inspection of the pleural cavity, either during surgery or thoracoscopy, both parietal and visceral pleura appear translucent; the underlying thoracic muscles and blood vessels are visible beneath the parietal pleura, and the lung and subpleural vascular network are visible beneath the visceral pleura, rendering the latter grey and variegated.

## PARIETAL PLEURA

Although it is a continuous structure, different regions of parietal pleura are customarily distinguished by name. Thus the costovertebral pleura lines the internal surface of the thoracic wall and the vertebral bodies, the diaphragmatic pleura lies on the thoracic muscular surface of the diaphragm, the cervical pleura (pleural dome) covers the pulmonary apices, and the mediastinal pleura is applied to the structures between the lungs.

## Costovertebral pleura

The costovertebral pleura lines the sternum, ribs, transversus thoracis, intercostal muscles and the sides of the vertebral bodies; normally, it is easily separated from these structures. External to the pleura is a thin layer of loose connective tissue, the endothoracic fascia, analogous to the transversalis fascia of the abdominal wall. Anteriorly, the costal pleura begins posterior to the sternum, where it is continuous with the mediastinal pleura along a line extending from posterior to the sternoclavicular joint inferomedially to the midline posterior to the sternal angle. From here, the right and left costal pleurae descend in contact with each other to the level of the fourth costal cartilages and then diverge. On the right side, the line descends to reach the posterior aspect of the xiphisternal joint, while on the left the line diverges laterally and descends at a distance of 2-2.5 mm from the sternal margin to the sixth costal cartilage, forming the cardiac notch. On each side, the costal pleura sweeps laterally, lining the internal surfaces of the costal cartilages, ribs, transversus thoracis and intercostal muscles. Posteriorly, it passes over the sympathetic trunk and its branches to reach the sides of the vertebral bodies, where it is again continuous with the mediastinal pleura. Superior to the first rib, the costovertebral pleura is continuous with the cervical pleura; inferiorly, it becomes continuous with the diaphragmatic pleura along a line that differs slightly on the two sides. On the right, this line of costodiaphragmatic reflection begins posterior to the xiphoid process, passes posterior to the seventh costal cartilage to reach the eighth rib in the mid-clavicular line and the tenth rib in the mid-axillary line, then ascends slightly to cross the twelfth rib level with the upper border of the twelfth thoracic spine. On the left, the line initially follows the ascending part of the sixth costal cartilage but then follows a course similar to that on the right, although it may be slightly lower.

## Diaphragmatic pleura

The diaphragmatic pleura is a thin, tightly adherent layer that covers most of the superior surface of the diaphragm. It is continuous with the costal pleura and medially with the mediastinal pleura along the line of attachment of the pericardium to the diaphragm.

Fig. 54.1 Structures related to the cervical pleura, as seen from below.

## Cervical pleura

The cervical pleura is the continuation of the costovertebral pleura over the pulmonary apex, looking as if it is moulded by the latter (see Fig. 51.1). It ascends medially from the internal border of the first rib to the apex of the lung, as high as the inferior edge of the neck of the first rib, and then descends lateral to the trachea to become the mediastinal pleura. As a result of the obliquity of the first rib, the cervical pleura extends $3-4 \mathrm{~cm}$ superior to the first costal cartilage, but not superior to the neck of the first rib. The cervical pleura is strengthened by a fascial suprapleural membrane that is attached anteriorly to the internal border of the first rib and posteriorly to the anterior border of the transverse process of the seventh cervical vertebra. It contains a few muscular fibres, which spread from the scaleni. Scalenus minimus extends from the anterior border of the transverse process of the seventh cervical vertebra to the inner border of the first rib behind its subclavian groove, and also spreads into the pleural dome, which it therefore tenses; it has been suggested that the suprapleural membrane is the tendon of scalenus medius. The cervical pleura and the pulmonary apex reach the level of the seventh cervical spine approximately 2.5 cm from the midline. Their surface projection is a curved line from the sternoclavicular joint to the junction of the medial and middle thirds of the clavicle, its summit being 2.5 cm superior to the clavicle (see Fig. 51.4). The subclavian artery ascends laterally in a furrow posterior to the summit of the cervical pleura (Fig. 54.1). The dome is related to the supraclavicular part of the brachial plexus, the stellate ganglion and the vertebral vessels.

## Mediastinal pleura

The mediastinal pleura represents the lateral boundary of the mediastinum and forms a continuous coat above the hilum of the lung from the sternum to the vertebral column. On the right, it covers the right brachiocephalic vein, upper part of the superior vena cava, terminal part of the azygos vein, right phrenic and vagus nerves, trachea and oesophagus. On the left, it covers the aortic arch, left phrenic and vagus nerves, left brachiocephalic and superior intercostal veins, left common carotid and subclavian arteries, thoracic duct and oesophagus. At the hilum of the lung, it turns laterally to form a tube that encloses the hilar structures and is continuous with the pulmonary pleura.

## VISCERAL PLEURA

The pulmonary pleura is inseparably adherent to the lung over all its surfaces, including those in the fissures, except at the root or hilum of
the lung and along a line descending from this, which marks the attachment of the pulmonary ligament (Figs 54.2-54.3).

## INFERIOR PULMONARY LIGAMENTS

The mediastinal pleura extends as a double layer, the pulmonary ligament, inferior to the hilum, from the lateral surface of the oesophagus to the mediastinal surface of the lung, where it is continuous with the visceral pleura (see Figs 54.2B-54.3B). It is continuous superiorly with the pleura around the hilar structures, and inferiorly it ends in a free sickle-shaped contour.

## PLEURAL RECESSES

The pleura extends considerably beyond the inferior border of the lung but not as far as the attachment of the diaphragm; therefore, the diaphragm is in contact with the costal cartilages and intercostal muscles below the line of pleural reflection from the thoracic wall to the diaphragm. In quiet inspiration, the inferior margin of the lung does not reach this reflection and the costal and diaphragmatic pleurae are separated merely by a narrow slit, the costodiaphragmatic recess; the lower limit of the lung is normally 5 cm above the lower pleural limit. A similar costomediastinal recess exists posterior to the sternum and the costal cartilages, where the thin anterior margin of the lung falls short of the line of pleural reflection. The extent of this recess, the anterior costomediastinal line of pleural reflection, and the position of the anterior margin of the lung all exhibit individual variation.

The pleural recesses allow the proportionate inspiratory expansion of the lungs, admitting the supplementary volume with minimal friction. The same pellicle of fluid within the recesses separates the parietal costal and diaphragmatic pleura during expiration, or the parietal pleura from the intervening visceral pleura during inspiration. Pleural adhesions and air or fluid accumulation limit this mechanism to a variable degree.

The inferior border of the costodiaphragmatic recess is an important consideration in the surgical posterior approach to the kidney. Usually, the pleura crosses the twelfth rib at the lateral border of erector spinae, so that the medial region of the kidney is above the pleural reflection. The eleventh rib may be mistaken for the twelfth in palpation (sometimes the latter does not project beyond muscle) and an incision prolonged to this level will open the pleura. Whether the lowest palpable rib is the eleventh or twelfth can be ascertained by counting from the second rib (identified at its junction with the sternal angle) or by ultrasound.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The parietal and visceral pleurae are developed from somatopleural and splanchnopleural layers of the lateral plate mesoderm, respectively; consequently, the parietal pleura has a somatic arterial supply. The costovertebral pleura is supplied by branches of the intercostal and internal thoracic arteries; the mediastinal pleura by branches from the bronchial, upper diaphragmatic, internal thoracic and mediastinal arteries; the cervical pleura by branches from the subclavian artery; and the diaphragmatic pleura by the superficial part of the diaphragmatic microcirculation. The veins join the thoracic wall veins, eventually draining into the superior vena cava. Lymph from the costovertebral pleura drains into the internal thoracic chain anteriorly
and intercostal chains posteriorly, while that from the diaphragmatic pleura drains into the mediastinal, retrosternal and coeliac axis nodes.

The visceral pleura forms an integral part of the lung and, accordingly, its arterial supply and venous drainage are provided by the bronchial vessels. The bronchial arteries at the hilum form a circle, surrounding the principal bronchus; pleural branches from this anulus supply the visceral pleura facing the mediastinum, the interlobar and apical surfaces, and part of the diaphragmatic surface. The visceral pleura is drained by pulmonary veins, apart from an area around the hilum that drains into bronchial veins. The lymphatic drainage of the visceral pleura is to the deep pulmonary plexus within the interlobar and peribronchial spaces.

## INNERVATION

The costal and peripheral diaphragmatic parietal pleurae are innervated by intercostal nerves. The mediastinal and central diaphragmatic parietal pleurae are innervated by the phrenic nerves. Irritation of the former results in pain that is referred to the appropriate part of the thoracic or abdominal wall, whereas irritation of the central diaphragmatic pleura causes pain that is referred to the lower neck and shoulder tip, i.e. to the C3 and 4 dermatomes. Visceral afferents travel along the bronchial vessels with the autonomic fibres.

## PNEUMOTHORAX

Any breach of the chest wall and parietal pleura or visceral pleura leads to the accumulation of air within the pleural cavity (pneumothorax). Fluid (hydrothorax), blood (haemothorax) and, rarely, lymph (chylothorax) can also accumulate in this space. Pneumothoraces may occur spontaneously (rupture of emphysematous bullae, or subpleural 'blebs' typically in tall, asthenic males) or following rib or penetrating trauma. Significant air in the pleural space is visible on a chest radiograph because this condition leads to various degrees of pulmonary collapse; there is separation of the parietal and visceral pleurae and an absence of peripheral pulmonary vascular markings in the corresponding area. Occasionally, a valve-like effect occurs, so that air enters the pleural space during inspiration but cannot escape in expiration. This may result in a 'tension pneumothorax', which can be life-threatening and should be suspected whenever there are unilateral decreased breath sounds and hyper-resonance on percussion (due to collapse of the lung), hypotension, jugular venous distension and contralateral tracheal deviation (due to mediastinal shift). A tension pneumothorax requires immediate decompression with intercostal drainage, preceded by, if in extremis, a wide-bore needle in the second intercostal space anteriorly in the mid-clavicular line. Fluid collection in the pleural space may be due to congestive cardiac failure, hypoalbuminaemia or inflammatory, infective or neoplastic conditions. An incipient pleural effusion causes obliteration of the costophrenic angle, where a lateral fluid meniscus is often visible from a non-loculated effusion on a frontal chest radiograph. Drainage of the fluid and subsequent analysis are required for diagnostic purposes. Where there is a collection of pus (empyema) or blood, pleural drainage is essential for therapeutic purposes. Ultrasonography is useful in assessing the size and characteristics of an effusion, such as the presence of loculation and debris. It may even demonstrate underlying consolidated lung. Computed tomography (CT) is utilized to assess the underlying lung parenchyma, endobronchium and mediastinal lymph nodes.

## miCROSTRUCTURE

The moist, smooth pleural surface consists of a single layer of flat mesothelial (serosal) cells separated from an underlying lamina propria of loose connective tissue by a basal lamina. Ultrastructurally, pleural and peritoneal mesothelial cells are similar in having a highly folded basal plasma membrane, in that their adjacent cell surfaces interdigitate and are joined by desmosomes, and in that their luminal surfaces bear numerous microvilli and some cilia. Cytoplasmic pinocytotic vesicles are common. The connective tissue covers the entire pulmonary surface; it extends from the hilum along the conducting tubes and blood vessels within the substance of the lung and divides the lung into numerous small polyhedral lobules, each of which receives a terminal bronchiole and arteriole, venules, lymphatics and nerves. Lobules vary in size; the superficial ones are the largest, visible as polygonal areas $5-15 \mathrm{~mm}$ across.

## LUNGS

The lungs are the essential organs of respiration. They are situated on either side of the heart and other mediastinal structures, and occupy most of the thoracic cavity. Each lung is free in its pleural cavity, except at the hilum and pulmonary ligament, where it is attached to the mediastinum. When removed from the thorax, a fresh normal lung is spongy, can float in water, and crepitates when handled because of the air within its alveoli. It is also highly elastic and so retracts on removal from the thorax. Its surface is smooth and shiny, and is divided by fine, dark lines into numerous small polyhedral domains, each crossed by numerous finer lines, indicating the areas of contact between its most peripheral lobules and the pleural surface.

The adult right lung usually weighs 625 g , and the left 565 g , but the range of wet weights is considerable, not least because it reflects the amount of blood or serous fluid contained within the lungs when weighed. In proportion to body stature, the lungs are heavier in men than in women, and boys have bigger lungs than girls (Thurlbeck 1982). Lung volumes in children vary significantly according to race (Sylvester et al 2005), and lung volume, air volume and pulmonary tissue volume all increase linearly with body length (Rao et al 2010). Pulmonary agenesis is a rare congenital abnormality in which pulmonary vessels, bronchi and lung parenchyma are undeveloped; it is associated with congenital heart disease (Nabati et al 2013).

## Pulmonary surface features

Each lung has an apex, base, three borders and two surfaces, roughly resembling a halved cone (see Figs 54.2-54.3).

## Apex

The apex, the rounded upper extremity, extends above the superior thoracic aperture where it contacts the cervical pleura, and is covered in turn by the suprapleural membrane. As a consequence of the obliquity of the aperture, the apex rises $3-4 \mathrm{~cm}$ above the level of the first costal cartilage. The summit of the apex is level posteriorly with the neck of the first rib and lies 2.5 cm above the junction of the mid and medial thirds of the clavicle, therefore within the root of the neck (see Fig. 29.18). It has been claimed that, because the apex does not rise above the neck of the first rib, it is really intrathoracic, and that it is the anterior surface that ascends highest in inspiration. The subclavian artery arches superolaterally over the suprapleural membrane and grooves the anterior surface of the apex near its summit, separating it from scalenus anterior. The cervicothoracic (stellate) sympathetic ganglion, ventral ramus of the first thoracic spinal nerve and superior intercostal artery all lie posterior to the apex. Scalenus medius is lateral and the brachiocephalic trunk, right brachiocephalic vein and trachea are adjacent to the medial surface of the apex of the right lung. The left subclavian artery and left brachiocephalic vein are adjacent to the medial surface of the apex of the left lung.

## Base

The basal surface is semilunar and concave, moulded on the superior surface of the diaphragm, which separates each lung from the corresponding lobe of the liver, and the left lung from the gastric fundus and spleen. Since the diaphragm extends higher on the right than on the left, the concavity is deeper on the base of the right lung. Posterolaterally, the base has a sharp margin that projects a little into the costodiaphragmatic recess.

## Costal surface

The costal surface of the lung is smooth and convex, and its shape is adapted to that of the thoracic wall, which is vertically deeper posteriorly. It is in contact with the costal pleura; in specimens that have been preserved in situ, this surface exhibits grooves that correspond with the overlying ribs, a situation similar to the hyperinflated lungs of asthma patients.

## Medial surface

The medial surface has posterior vertebral and anterior mediastinal parts. The vertebral part lies in contact with the sides of the thoracic vertebrae and intervertebral discs, posterior intercostal vessels and splanchnic nerves. The mediastinal area is deeply concave because it is adapted to the heart at the cardiac impression, which is much larger and deeper on the left lung where the heart projects more to the left of the median plane. Posterosuperior to this concavity is the somewhat triangular hilum, where various structures enter or leave the lung, collectively surrounded by a sleeve of pleura that also extends below the hilum and behind the cardiac impression as the pulmonary ligament.

## Other impressions on the lung surface

In addition to these pulmonary features, cadaveric lungs that have been preserved in situ can show a number of other impressions that indicate their relations with surrounding structures (see Figs 54.2B-54.3B). All these impressions reflect the intimate relationships of the lungs with the adjacent mediastinal structures and offer a good perspective on surgical approaches, either from the anterior or posterior aspect of the corresponding pleural cavity.

On the right lung, the cardiac impression is related to the anterior surface of the right auricle, the anterolateral surface of the right atrium and partially to the anterior surface of the right ventricle. The
impression ascends anterior to the hilum as a wide groove for the superior vena cava and the terminal portion of the right brachiocephalic vein. Posteriorly, this groove is joined by a deep sulcus that arches forwards above the hilum and is occupied by the azygos vein. The right side of the oesophagus makes a shallow vertical groove behind the hilum and the pulmonary ligament. Towards the diaphragm it inclines left and leaves the right lung, and therefore does not reach the lower limit of this surface. Posteroinferiorly, the cardiac impression is confluent with a short, wide groove adapted to the inferior vena cava. Between the apex and the azygos groove, the trachea and right vagus are close to the lung but do not mark it.

On the left lung, the cardiac impression is related to the anterolateral surface of the left ventricle and auricle (see Fig. 54.3B). The anterior infundibular surface and adjoining part of the right ventricle are related to the lung as it ascends in front of the hilum to accommodate the pulmonary trunk. A large groove arches over the hilum, and descends behind it and the pulmonary ligament, corresponding to the aortic arch and descending aorta. From its summit, a narrower groove ascends to the apex for the left subclavian artery. Posterior to this, and superior to the aortic groove, the lung is in contact with the thoracic duct and oesophagus. Anterior to the subclavian groove there is a faint linear depression for the left brachiocephalic vein. Inferiorly, the oesophagus may mould the surface anterior to the lower end of the pulmonary ligament.

## Pulmonary borders

The inferior border is thin and sharp where it separates the base from the costal surface and extends into the costodiaphragmatic recess, and more rounded medially where it divides the base from the mediastinal surface. It corresponds, in quiet respiration, to a line drawn from the most inferior point of the anterior border that passes to the sixth rib at about the mid-clavicular line, then to the eighth rib in the mid-axillary line (usually 10 cm above the costal margin), and then continues posteromedially and slightly superiorly to a point 2 cm lateral to the tenth thoracic spine (see Fig. 51.5). The diaphragm rises more superiorly on the right to accommodate the liver, and so the right lung is vertically shorter (by approximately 2.5 cm ) than the left. However, cardiac asymmetry means that the right lung is broader, and has a greater capacity and weight than the left. The posterior border separates the costal surface from the mediastinal surface, and corresponds to the heads of the ribs. It has no recognizable markings and is really a rounded junction of costal and vertebral (medial) surfaces. The thin, sharp, anterior border overlaps the pericardium. On the right, it corresponds closely to the costomediastinal line of pleural reflection, and is almost vertical. On the left it approaches the same line above the fourth costal cartilage; below this point, it shows a variable cardiac notch, the edge of which passes laterally for 3.5 cm before curving inferomedially to the sixth costal cartilage 4 cm from the midline. It therefore does not reach the line of pleural reflection here (see Fig. 51.4) and so the pericardium is covered only by a double layer of pleura (area of superficial cardiac dullness). Surgical experience suggests that the line of pleural reflection, the anterior pulmonary margin and the costomediastinal pleural recess are all variable.

## PULMONARY FISSURES AND LOBES

## Right lung

The right lung is divided into superior, middle and inferior lobes by its oblique (major) and horizontal (minor) fissures (see Fig. 54.2). The superior, lengthier oblique fissure separates the inferior from the superior and middle lobes, and corresponds closely to the left oblique fissure, although it is less vertical, crossing the inferior border of the lung approximately 7.5 cm behind its anterior end. On the posterior border, it is either level with the spine of the fourth thoracic vertebra or slightly lower. It descends across the fifth intercostal space and follows the sixth rib to the sixth costochondral junction. The shorter horizontal fissure separates the superior and middle lobes. It passes from the oblique fissure, near the mid-axillary line, horizontally forwards to the anterior border of the lung, level with the sternal end of the fourth costal cartilage, then passes posteriorly to the hilum on the mediastinal surface. The horizontal fissure is usually visible on a frontal chest radiograph. The oblique fissure is usually visible on a lateral radiograph and on a high-resolution CT scan as a curvilinear band from the lateral aspect to the hilum (Fig. 54.4). The smaller middle lobe is wedged between the superior and inferior lobes, and includes some
of the costal surface, the inferior part of the anterior border and the anterior part of the base of the lung. The azygos vein may sometimes course in a more lateral position, within a four-layered pleural septum within the superior lobe, creating an 'azygos lobe'. This is not a true lobe, but a separated portion of the superior lobe that lacks its own bronchi, arteries or veins. The condition represents an incidental finding on chest radiographs or CT scans, with no associated morbidity; it may be confused with a pulmonary nodule, and loculated effusions in the fissure may appear. Accessory fissures may separate either the medial basal segment (Twining's line) or the superior segment from the remainder of the inferior lobe. Incomplete separation of the lobes and identification of the completeness of the fissures are important prior to lobectomy because individuals with incomplete fissures are more prone to develop postoperative air leaks and may require further procedures, such as stapling and pericardial sleeves.

## Left lung

The left lung is divided into superior and inferior lobes by its oblique fissure, which extends from the costal to the medial pulmonary surfaces, superior and inferior to the hilum (see Fig. 54.3). Superficially, this fissure begins on the medial surface at the posterosuperior part of the hilum, ascends obliquely and posteriorly to cross the posterior border of the lung 6 cm below the apex, then descends anteriorly across the costal surface, to reach the inferior border almost at its anterior end. It finally ascends on the medial surface to the inferior part of the hilum. At the posterior border of the lung, the fissure usually lies opposite a surface point 2 cm lateral to the midline between the spines of the third and fourth thoracic vertebrae, but it may be superior or inferior to this level. Traced around the chest, the fissure reaches the fifth intercostal space (at or near the mid-axillary line) and follows this to intersect the inferior border of the lung, close or just inferior to the sixth costochondral junction ( 7.5 cm from the midline). The left oblique fissure is usually more vertical than the right, and is indicated approximately by the medial border of the scapula with the fully abducted arm. A left horizontal fissure is a normal, occasional variant.

The superior lobe lies anterosuperior to the oblique fissure and includes the apex, anterior border, much of the costal and most of the medial surfaces of the lung. A small process, the lingula, is usually present at the lower end of the cardiac notch. The larger inferior lobe lies behind and below the fissure, and contributes almost the whole of the base, much of the costal surface and most of the posterior border of the left lung.

Lung lobation, and the morphology of the tracheobronchial tree, can predict the atrial situs.

In situs solitus, the right principal bronchus is short and eparterial (its branch for the right upper lobe lies over the second branch of the right pulmonary artery) and the left principal bronchus is longer and hyparterial (it courses underneath the left pulmonary artery). A bilobed left lung and a trilobed right lung are typical in situs solitus. In situs inversus, there is a mirror imaging of the disposition seen in situs solitus. In situs ambiguus, the bronchi and lungs can display either a bilateral right morphology with bilateral trilobed lungs and bilateral eparterial bronchi (heterotaxy syndrome: incomplete or inappropriate lateralization of the thoracic and abdominal viscera, and asplenia) or a bilateral left morphology with bilateral bilobed lungs and bilateral hyparterial bronchi (heterotaxy syndrome and polysplenia) (Van Praagh et al 1992).

## Bronchopulmonary segments

Each of the principal bronchi divides into lobar bronchi. Primary branches of the right and left lobar bronchi are termed segmental bronchi because each ramifies in a structurally separate, functionally independent, unit of lung tissue called a bronchopulmonary segment (Figs 54.5-54.7).

The main segments are named and numbered as shown in Table 54.1.

Each segment is surrounded by connective tissue that is continuous with the visceral pleura, and is a separate respiratory unit. The vascular and lymphatic arrangements of the segments are described on page 959.

## PULMONARY HILA

The pulmonary root connects the medial surface of the lung to the heart and trachea, and is formed by a group of structures that enter or leave

Fig. 54.4 A, An axial section through the lungs below the carina, demonstrating the left and right oblique fissures. The circular avascular area anterior to the right oblique fissure and surrounded by a halo of white (arrow) is due to the horizontal fissure. In this individual, the fissure is slightly domed and passes through the plane of the section. B, An axial section through the lungs at the mid left atrial level, demonstrating the left and right oblique fissures (arrows) as they pass more anteriorly and separate the lower lobes from the lingula and middle lobes. C, A sagittal section through the right lung, demonstrating the oblique (down-pointing arrow) and horizontal fissures (horizontal arrow). D, A sagittal section through the left lung, demonstrating the oblique fissure (arrow).

Table 54.1 Bronchopulmonary segments

|  | Right lung | Left lung |
| :--- | :--- | :--- |
| Superior lobe | I, apical; II, posterior; III, anterior | I, apical; II, posterior; III, anterior; |
|  |  | IV, superior lingular; V, inferior lingular |
| Middle lobe | IV, lateral; V, medial | - |
| Inferior lobe | VI, superior (apical); VII, medial | VI, superior (apical); VII, medial basal; |
|  | basal; VIII, anterior basal; IX, | VIII, anterior basal; IX, lateral basal; |
|  | lateral basal; X, posterior basal | X, posterior basal |

the hilum (see Figs 54.2B-54.3B, 54.6C,D). These are the principal bronchus, pulmonary artery, two pulmonary veins, bronchial vessels, a pulmonary autonomic plexus, lymph vessels, bronchopulmonary lymph nodes and loose connective tissue, all enveloped by a pleural sleeve. The pulmonary roots, or pedicles, lie opposite the bodies of the fifth to seventh thoracic vertebrae. The phrenic nerve, pericardiacophrenic vessels and anterior pulmonary plexus are common anterior relations of both hila. The vagus nerve and posterior pulmonary plexus are common posterior relations and the pulmonary ligament is a common inferior relation. The major structures in both roots are similarly arranged: the superior of the two pulmonary veins is anterior, the pulmonary artery and principal bronchus are more posterior, and the bronchial vessels are most posterior. The arrangement of bronchopulmonary segments and the pulmonary hila permit the resection of abscesses and localized primary lung malignancy.

## Right hilum

The right root is situated behind the superior vena cava and right atrium, inferior to the terminal part of the azygos vein. The usual sequence of hilar structures, from superior to inferior, is superior lobar (eparterial) bronchus, pulmonary artery, principal bronchus and inferior pulmonary vein (see Fig. 54.2B).

## Left hilum

The left root lies inferior to the aortic arch and anterior to the descending thoracic aorta. The usual vertical sequence of structures at the left hilum is pulmonary artery, principal (hyparterial) bronchus and inferior pulmonary vein (see Fig. 54.3B). The pulmonary artery is longer on the left side, and each of its branches from the hilum to the oblique fissure must be identified in pulmonary resections.

## SECONDARY PULMONARY LOBULES

Each segmental bronchus supplies a bronchopulmonary segment. Progressive subdivisions of the bronchi occur within each segment, and the bronchi become increasingly narrow. All intrapulmonary bronchi are kept patent by cartilaginous plates that decline in size and number, and finally disappear when bronchi become bronchioles (less than 1 mm in diameter). The secondary lobule is the smallest macroscopic subsection of the peripheral lung, bounded by connective tissue septa of

Fig. 54.5 Lungs and bronchi: anterior aspect. The lobar and segmental bronchi are projected on to the lung in different colours (compare with Fig. 54.6). (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
uneven size and shape. It consists of approximately six terminal bronchioles, the latter being the most peripheral bronchioles not to have alveoli in their walls. Distal to each terminal bronchiole is an acinus, the functional unit of the lung for gas exchange, which consists of 3-4 orders of respiratory bronchioles, each leading to 3-8 orders of alveolar ducts. The walls of these ducts consist of alveolar sacs or the mouths of alveoli. The primary lobule is the lung distal to the respiratory bronchiole.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The lungs have two functionally distinct circulatory pathways. The pulmonary vessels convey systemic deoxygenated blood to the alveolar walls and drain oxygenated blood back to the left atrium for systemic distribution by the left ventricle. The much smaller bronchial vessels, which are derived from the systemic circulation, provide oxygenated blood to lung tissues that do not have close access to atmospheric oxygen, i.e. those of the bronchi and larger bronchioles.

The pulmonary trunk bifurcates into right and left pulmonary arteries that approach the hila of the lungs. Each artery divides into branches that accompany the segmental and subsegmental bronchi, mostly in a posterolateral position. The pulmonary capillaries form single-layered and exceedingly thin-walled plexuses immediately outside the epithelium in the walls and septa of the alveoli and alveolar sacs. Pulmonary veins, two from each lung, drain the pulmonary capillaries; their rootlets coalesce into larger and more freely communicating veins that traverse the lung, for the most part independently of the pulmonary arteries and bronchi. At the hilum, the pulmonary vessels accompany the main bronchial divisions; the veins are anteromedial and the arteries posterolateral to the bronchi. This is not the case in the bronchopulmonary segments, where a segmental bronchus, its branches and associated arteries occupy a central position but the many tributaries of the pulmonary veins run between segments, serving adjacent segments (which therefore drain into more than one vein). Some veins also lie beneath the visceral pleura, including the pleura in the interlobar fissures. It follows from this that a bronchopulmonary segment is not a complete vascular unit with an individual bronchus, artery and vein. During resection of segments, it is obvious that the planes between them are not avascular but are crossed by pulmonary veins and sometimes by branches of arteries. This pattern of bronchi, arteries and veins exhibits considerable variation; veins are the most variable, and arteries are more variable than bronchi.

## Pulmonary arteries

The right pulmonary artery divides into two large branches as it emerges behind the superior vena cava (Fig. 54.8). This intimate relationship facilitates the cavopulmonary anastomosis (the Glenn shunt) conceived to bypass the defective right heart chambers in various congenital cardiac disorders. A lymph node usually lies adjacent to the bifurcation. The smaller branch to the superior lobe usually divides again, supplying the majority of that lobe. The inferior branch descends anterior to the bronchus intermedius (see below) and posterior to the superior pulmonary vein. It provides a small recurrent branch to the superior lobe, and then, at the point where the horizontal fissure meets the oblique fissure, it gives off the branch to the middle lobe anteriorly, and a branch to the superior segment of the inferior lobe posteriorly. It then continues a short distance before dividing to supply the rest of the inferior lobe segments.

The left pulmonary artery emerges from within the concavity of the aortic arch and descends anterior to the descending aorta to enter the oblique fissure (see Fig. 54.8). The ligamentum arteriosum skirts between the superior aspect of the left pulmonary artery and the proximal descending aorta. The left recurrent laryngeal nerve winds around the aorta, to the left of the ligament; the aorta is relatively fixed by the ligament, and so may be ruptured in cases of major trauma associated with rapid deceleration. The branches of the left pulmonary artery are extremely variable. The first and largest branch is usually given off to the anterior segment of the left superior lobe. Before reaching the oblique fissure, the artery gives off a variable number of other branches to the superior lobe, and, as it enters the fissure, it usually supplies a large branch to the superior segment of the inferior lobe. Lingular branches arise within the fissure, and the rest of the lower lobe is supplied by many varied branching patterns. It was a surgical aphorism of the late Lord Brock that when performing a left upper lobectomy, 'there was always one more branch of the pulmonary artery than you thought!'

## Pulmonary sequestration

When a portion of lung exists without the appropriate bronchovascular connections, it is usually supplied by the systemic vasculature (thoracoabdominal aorta or branches) and drains into either atrium, superior vena cava or azygos veins (Clements 1999) (Figs 54.9-54.10). Extralobar pulmonary sequestration segments are covered by visceral pleura and usually found below the left inferior lobe, whereas intralobar abnormalities are usually embedded in normal lung: classically, the posterior basal segment of the left inferior lobe. Extralobar pulmonary

Unilateral absence of a pulmonary artery is a rare congenital abnormality characterized by normal lung volume and anatomy at birth. Revascularization before the age of 6 months avoids the development of lung hypoplasia (Alison et al 2011). The left pulmonary artery sling is a congenital abnormality characterized by the left pulmonary artery arising from the right pulmonary artery, coursing over the right principal bronchus and heading posteriorly between the trachea and oesophagus. This abnormality is associated with significant tracheobronchial stenosis (Zhong et al 2010).

Fig. 54.6 Bronchopulmonary segments of the right and left lungs, coloured to indicate the different territories. A, Right lung, lateral aspect. B, Left lung, lateral aspect. C, Right lung, medial aspect. D, Left lung, medial aspect. *Usually, this segment is not a separate unit but is fused with the anterior basal segment. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
sequestration per se is asymptomatic but is often associated with other congenital abnormalities: pulmonary hypoplasia, congenital diaphragmatic hernia, congenital cystic adenomatoid malformation and congenital heart disorders (Stocker et al 1978, Kravitz 1994). A fistula with the oesophagus may also develop (Ch. 52). Consideration of differential diagnosis with mediastinal or pulmonary tumours is mandatory.

## Pulmonary embolism and arteriography

Available with the Gray's Anatomy e-book

## Pulmonary veins

There are usually four pulmonary veins, two from each lung. They originate from capillary networks in the alveolar walls and return oxygenated blood to the left atrium. All the main tributaries of the pulmonary veins receive smaller tributaries, both intra- and intersegmental; by serial
junctions, tributary veins finally form a single lobar trunk, i.e. three in the right lung, two in the left. The right middle and superior lobar veins usually unite and so two veins, superior and inferior, leave each lung.

At the pulmonary hilum, the usual distribution of veins is as follows. The superior pulmonary vein is anteroinferior to the pulmonary artery, and the inferior pulmonary vein is the most inferior hilar structure and also slightly posterior. On the right, the union of apical, anterior and posterior veins (draining the upper lobe) with a middle lobar vein formed by lateral and medial tributaries constitutes the right superior pulmonary vein. The right inferior pulmonary vein is formed by the hilar union of superior (apical) and common basal veins from the lower lobe. The union of superior and inferior basal tributaries forms the common basal vein. Occasionally, the three right lobar veins remain separate. The right superior pulmonary vein passes posterior to the superior vena cava, the inferior behind the right atrium.

The superior left pulmonary vein is formed by the union of apicoposterior, anterior and lingular veins. The left inferior pulmonary vein is formed from the union of the superior (apical) and common basal

A thrombus that has developed in the deep veins (usually leg or pelvic) may embolize and travel in the right side of the circulation through the right atrium and ventricle, lodging in the pulmonary vasculature. The clinical abnormalities observed depend on the size of the embolus and on the number and frequency of embolic episodes. Large emboli may lodge in the main pulmonary artery branches and cause right ventricular dysfunction and hypoxia, representing a medical emergency. Smaller emboli may lodge in segmental pulmonary arteries and cause pleuritic chest pain, shortness of breath and haemoptysis but the clinical picture is rarely pathognomonic. Pulmonary emboli cause a ventilation/perfusion mismatch that can have serious physiological implications leading to a significant reduction in the oxygenation of

Fig. 54.9 A lung window axial view showing an intralobar sequestration in the left lower lobe of the lung in a 15-month-old girl. (Courtesy of Mr Hany Gabra \& Mr Jonathan Goring, Great North Children's Hospital, Newcastle upon Tyne, UK.)
blood. Ventilation/perfusion scans with radiolabelled xenon and technetium usually demonstrate segmental abnormalities in perfusion with normal ventilation in the corresponding regions. Pulmonary emboli may also be evaluated by contrast-enhanced spiral CT or pulmonary angiograms and appear as filling defects. Repetitive embolization may eventually lead to a dramatic reduction of the pulmonary vascular bed and chronic cor pulmonale. Thrombolysis, anticoagulation or inferior vena caval filters prevent progression or recurrence of embolism. A clot may also traverse a patent foramen ovale and lodge in the arterial system (paradoxical embolism), most severely in the cerebral circulation, causing a stroke (Kent and Thaler 2011).

veins, the latter formed by the union of a superior and an inferior basal vein. Both left superior and inferior pulmonary veins pass anterior to the descending thoracic aorta. Sometimes, the two left pulmonary veins form a single trunk, or they may be augmented by an accessory lobar vein from each lobe, which unite to form a third left pulmonary vein.

The right and left pulmonary veins perforate the fibrous pericardium and open separately in the posterosuperior aspect of the left atrium (see Figs 57.3, 57.4B). Their terminations are separated medially by the oblique pericardial sinus, and laterally by smaller and variable pulmonary venous pericardial recesses that are directed superomedially. The pulmonary veins are devoid of valves.

The variable incorporation of the primitive pulmonary vein into the left atrium means that the number of main pulmonary veins may differ. The left atrium is the heart chamber most posterior and median in position, and so the length of the left and right pulmonary veins is equal, unlike the arteries and bronchi, where there are conspicuous left-right differences in length. The terminal parts of the pulmonary veins are surrounded by atrial myocardium; these areas represent potential accessory re-entrant circuits responsible for the initiation or maintenance of supraventricular tachycardias or atrial fibrillation and may be percutaneously ablated. Pulmonary vein atresia is a rare congenital abnormality (Kozak et al 2011).

## Lymphatic drainage

The pulmonary lymphatics originate in superficial and deep plexuses. The superficial plexus lies deep to the visceral pleura; its efferents turn around the margins of the lung and its fissures, eventually reaching the bronchopulmonary nodes. The alveoli have no lymph vessels. The deep lymphatics originate at bronchiolar level and follow the bronchovascular divisions to the hilum, ending in the same nodes. No free anastomoses exist between the two systems, except at the hilum and peripherally, where small but dilatable channels connect superficial and
deep lymphatic vessels; these connections direct lymph from the deep to the superficial channels when outflow from deep vessels is obstructed by pulmonary disease. There is a tendency for vessels from the superior lobes to pass to the superior tracheobronchial nodes, and those from the inferior lobes to pass to the inferior tracheobronchial group. However, lymphatic vessels of adjoining lobes connect deep in the fissures and so these connections are not exclusive. At the level of pulmonary lobation, the arrangement of lymphatic vessels follows the central artery of a lobule and its peripheral veins. Lymphoid aggregations, nonfollicular in appearance, occur in peribronchial sites and in 'placoid' formations deep to the pulmonary pleura.

## INNERVATION

The autonomic nervous system controls many aspects of airway function, including regulation of airway smooth muscle tone, mucus secretion from submucosal glands and surface epithelial goblet cells, vascular permeability and blood flow (Belvisi 2002).

## Pulmonary plexuses

The pulmonary plexuses lie anterior and posterior to the other hilar structures of the lungs (see Figs 56.7, 57.61). The anterior plexus is small and is formed by rami from vagal and sympathetic cervical cardiac nerves via connections with the superficial cardiac plexus. The posterior pulmonary plexus is formed by the rami of vagal and sympathetic cardiac branches from the second to fifth or sixth thoracic sympathetic ganglia. The left plexus also receives branches from the left recurrent laryngeal nerve. Further details of the pulmonary plexuses are given in the description of the cardiac plexuses on page 1021. The sympathetic nervous system (noradrenaline (norepinephrine)) acting on $\beta$-receptors produces bronchodilation; the parasympathetic nervous system (acetylcholine) acting on muscarinic M3 receptors maintains

Fig. 54.8 The relationship between the central airways and the pulmonary vessels. The numbers in the lower figure denote the numbers of the bronchopulmonary segments.
the resting tone of the bronchiolar smooth muscle. Prostaglandins have various effects: $\mathrm{PGI}_{2}$ produces bronchodilation (acting on IP receptors) or bronchoconstriction (acting on $\mathrm{EP}_{1}$ receptors); $\mathrm{PGF}_{2 \alpha}$ produces bronchoconstriction.

## MICROSTRUCTURE OF RESPIRATORY SURFACES

Thin-walled respiratory surfaces (alveoli) are distributed as isolated patches within the walls of respiratory bronchioles and as tube-like alveolar ducts and balloon-like alveolar sacs that contain groups of adjacent alveoli.

#### Abstract

Alveolar area Both human lungs contain 300-500 million alveoli, giving a total surface area of $70-100 \mathrm{~m}^{2}$. These values vary considerably between normal young individuals; the differences become even more marked with age and as a consequence of degenerative changes. The number of alveoli increases from approximately 10 million at birth to the adult value, mainly in the first 8 years; thereafter, the increase in lung volume is achieved through augmentation of alveolar volume (Narayanan et al 2013). Their inflated diameter varies with lung position, and is greater in the superior regions than in the inferior because of the increased gravitational pressure at the lung base. Although the lung enlarges in all directions during inspiration, most of the change in volume appears to be due to the lengthening and expansion of the alveolar ducts and increase in the size of the openings into the air sacs; the inspiratory change in the volume of the gas-conducting system is insignificant. The combined alveolar and capillary surface area for gas exchange is

$60-80 \mathrm{~m}^{2}$ surface. The capillary blood transit time at rest is 0.75 s , halving with exercise.

## Alveolar structure

The alveoli are thin-walled pouches that provide the respiratory surface for gaseous exchange (Figs 54.11-54.13). Their walls contain two types of epithelial cell (pneumocytes) and cover a delicate connective tissue within which a network of capillaries ramifies. Since the walls are extremely thin, they present a minimal barrier to gaseous exchange between the atmosphere and the blood in the capillaries. Adjacent alveoli are frequently in close contact; the intervening connective tissue forms the central part of the interalveolar septum. Alveolar macrophages are present within the alveolar lumen and migrate over the epithelial surface.

## Interalveolar septum

The alveolar lining epithelium varies in thickness, but extensive areas of it are as little as $0.05 \mu \mathrm{~m}$ thick (see Fig. 54.13). The epithelium lies on a basal lamina that is fused with the basal lamina that surrounds the adjacent capillaries in the thin portions of a septum. The total barrier to diffusion between air and blood in these thin portions may be as little as $0.2 \mu \mathrm{~m}$. The thick portions of a septum contain connective tissue elements, including elastic and collagen type III fibres, resident and migratory cells (see Fig. 54.12).

## Alveolar epithelial cells (pneumocytes)

The alveolar epithelium is a mosaic of type I and II pneumocytes. Type I pneumocytes are simple squamous epithelial cells and form over $90 \%$ of the alveolar area. Their basal laminae fuse with that of the adjacent

Fig. 54.11 The respiratory tree and its arterial blood supply, venous and lymphatic drainage, and nerve supply. The distribution of the different epithelial cells is shown. Blue is used for vessels that contain deoxygenated blood, and red for vessels that contain oxygenated blood.
capillary endothelium to form the thin portions of interalveolar septa. Their thin cytoplasm ( $0.05-0.2 \mu \mathrm{~m}$ ) facilitates gaseous diffusion between the lumen of the alveolus and its capillaries. The edges of adjacent cells overlap; they are joined by tight junctions, creating a strict diffusion barrier between the alveolar surface and underlying tissues.

Together with a similar endothelial barrier, this arrangement limits the movement of fluid from blood and interstitial spaces into the alveolar lumen (the blood-air barrier). If damaged, type I cells, which do not divide, are replaced by type II cells, which proliferate and differentiate into type I pneumocytes.

Fig. 54.12 The respiratory portion of the lung and its cell types.

The smaller type II cells are often more numerous than type I cells, but they contribute less than $10 \%$ of the alveolar surface area. They are rounded and protrude from the alveolar surface, particularly at the angles between alveolar profiles. In the human lung, they are often associated with interalveolar pores of Kohn. Their cytoplasm contains numerous characteristic secretory lamellar bodies consisting of concentric whorls of phospholipid-rich membrane, the precursors of alveolar surfactant, which they can recycle (see Fig. 54.13C).

## Interalveolar pores of Kohn

Interalveolar pores of Kohn are small pores lined by epithelium (usually type II alveolar cells), which cross interalveolar septa to link adjacent alveolar airspaces. Humans have up to seven pores per alveolus, ranging in size from 2 to $13 \mu \mathrm{~m}$. These small passages may sustain the flow of air in the event of blockage of one of the alveolar ducts and also provide routes of migration for alveolar macrophages, bacteria and viruses.

## Alveolar macrophages

Alveolar macrophages are derived from circulating monocyte precursors (see Fig. 4.12). They originate in haemopoietic tissue in the bone marrow, migrate into the alveolar lumen from adjacent blood vessels and connective tissue, and wander about on the epithelial surfaces. They
clear the respiratory spaces of inhaled particles that are small enough to reach the alveoli (hence their alternative name of 'dust cells'; see Fig. 4.13). Most of them migrate with their phagocytosed load to the bronchioles, where they are swept into the mucociliary rejection current and removed from the lung. Others migrate through the epithelium of the alveoli into the lymphatics that drain the connective tissue of the lung, and so pass into lymphoid tissue around the pulmonary lobules. Under normal conditions, alveolar macrophages have a granular cytoplasm because they contain phagocytosed particles; in smokers, the particles have a characteristic appearance and are called 'tar bodies'. When actively phagocytic, macrophages release proteases: if antiproteases (e.g. $\alpha_{1}$-antitrypsin) that are normally present in the alveolar lining are deficient, macrophage activity may damage the lung. Alveolar macrophages are involved in the turnover of surfactant.

Alveolar macrophages can be recovered from sputum and are of diagnostic importance if they appear abnormal. For instance, whenever erythrocytes leak from pulmonary capillaries, the macrophages that engulf the extravasated cells become brick-red and are detectable in 'rusty' sputum. They are typical of congestive heart failure and often termed 'heart-failure cells'. Macrophages that migrate back into the connective tissue of the lung settle in patches that are visible beneath the visceral pleura, e.g. carbon-filled cells give the lungs a mottled

Fig. 54.13 A, An electron micrograph showing the septum between three adjacent alveoli (A). The septum contains two capillaries $\left(C_{1}\right.$ and $\left.C_{2}\right)$ in section; the lower one is cut obliquely through the nucleus of an endothelial cell $(E)$. Type I pneumocytes $\left(P_{1}\right)$ line the alveolar airspaces except where a type II pneumocyte $\left(\mathrm{P}_{2}\right)$, with cytoplasmic lamellar bodies $(\mathrm{L})$, intervenes. $\mathbf{B}$, The thin portion of an interalveolar septum. Part of an erythrocyte (Er) is shown in the capillary lumen, lined by endothelium (E). The alveolar airspace (right) is lined by a type I pneumocyte ( $\mathrm{P}_{1}$ ). The two cells share a basal lamina (BL). C, Cytoplasmic lamellar bodies in a type II pneumocyte are composed mainly of phospholipids that contribute to the surfactant secreted by these pneumocytes and by Clara cells of the respiratory bronchioles. (With permission from Young B, Heath JW 2000 Wheater's Functional Histology. Edinburgh: Churchill Livingstone.)
appearance. However, if the inhaled particles are abrasive or chemically active, they may elude macrophage removal and damage the respiratory surface, producing fibrosis and a concomitant reduction in the respiratory area. This occurs in many industrial diseases, e.g. pneumoconiosis caused by coal dust, or asbestosis, where the long thin fibres of asbestos can cause considerable damage and may trigger fatal mesothelioma in the pleural lining.

## Alveolar surfactant

The alveolar surface is normally covered by a film of pulmonary surfactant, which is a complex mixture mainly of phospholipids (particularly dipalmitoylphosphatidylcholine and phosphatidylglycerol), with some protein and neutral lipid. Surfactant is stored in lamellar bodies and secreted in the form of tubular myelin (unrelated to myelin of the nervous system) by type II pneumocytes. It is recycled by type II pneumocytes, or cleared (i.e. phagocytosed) by alveolar macrophages. Clara cells of the bronchiolar epithelium are believed to secrete surfactant of a different composition.

Surface tension at the alveolar surface is very high because the alveoli are minute and spherical; these features oppose expansion during inspiration, and tend to collapse the alveoli in expiration. The detergent-like properties of pulmonary surfactant greatly reduce the surface tension and make ventilation of the alveoli much more efficient. As the volume of an alveolus alternatively increases and decreases, so does its surface area. With a fixed amount of surfactant in the alveolar film, the relative concentration of surfactant increases on exhalation. The fortunate result is a decrease in collapsing tendency as the alveolar volume decreases, stabilizing the alveolus and overcoming the tendency of small gas spaces to obliterate.

## TRACHEA AND BRONCHI

## TRACHEA

The trachea is a $10-11 \mathrm{~cm}$ long tube formed of cartilage and fibromuscular membrane, and lined internally by mucosa. It descends from the larynx at the level of the sixth cervical vertebra and divides into right and left principal bronchi typically inferior to the sternal plane, level with the upper half of the sixth thoracic vertebra (see Fig. 51.6). It lies approximately in the sagittal plane but its point of bifurcation is usually a little to the right. The trachea is mobile and can rapidly alter in length, such that the bifurcation reaches the level of the sixth thoracic vertebra during deep inspiration. In children with full neck extension, the length of the trachea increases by $0.95 \pm 0.43 \mathrm{~cm}$; this elongation is insufficient to prevent displacement of the tip of an endotracheal tube towards the vocal cords in intubated children (Jin-Hee et al 2005).

The anterolateral portion of the trachea consists of 16-20 superimposed incomplete rings of hyaline cartilage and intervening fibroelastic tissue (the latter allows tracheal inspiratory elongation). The posterior aspect is a flat, fibromuscular wall. The trachea is funnel-shaped in neonates, when the upper end is wider than the lower end, and gradually becomes cylindrical with increasing age. The external transverse diameter is typically 2 cm in adult males and 1.5 cm in adult females. In the first postnatal year, the tracheal diameter does not exceed 4 mm . Mean transverse diameter is greater than anteroposterior diameter up to the age of 6 years and, after that, the two diameters are nearly equal (Griscom and Wohl 1986); during later childhood, tracheal diameter in millimetres is approximately equal to age in years. The lumen is about 12 mm in diameter in live adults but increases as a result of relaxation of the smooth muscle post mortem. The transverse shape of
the lumen is variable, especially in the later decades of life, and it may be round, lunate or flattened. At bronchoscopy, the posterior wall of the trachea bulges into the lumen and this is exaggerated in expiration and coughing. The distal end of the trachea is visible as a concave spur. A tracheal bronchus may occasionally arise, mainly from the right aspect of the trachea, as either a supernumerary or a displaced superior lobe bronchus (porcine bronchus). A tracheal bronchus was noted in $2.4 \%$ of children undergoing bronchoscopy for respiratory symptoms (Wong et al 1999). The variable position of the trachea in children makes it unreliable as an indicator of the presence of a right-sided aortic arch on a chest radiograph. In children with a right-sided aortic arch, the trachea is on the right in $47 \%$ of cases, in the midline in $33 \%$ and on the left in $7 \%$ (Strife et al 1989). Tracheal agenesis is a rare and usually lethal congenital abnormality.

## Relations of the cervical part of the trachea

## Anterior relations

The cervical trachea is covered anteriorly by skin and by the superficial and deep cervical fasciae. It is crossed by the jugular arch and overlapped by sternohyoid and sternothyroid. The second to fourth tracheal cartilages are crossed by the isthmus of the thyroid gland, above which an anastomosis connects the two superior thyroid arteries; anteroinferiorly are the pretracheal fascia, inferior thyroid veins, thymic remnants and the thyroid ima artery (when present). In children, the brachiocephalic trunk crosses obliquely in front of the trachea at, or a little above, the upper border of the manubrium; the left brachiocephalic vein may also rise a little above this level. An enlarged thyroid gland may cover the cervical trachea and reach the superior mediastinum, usually anterior to the left brachiocephalic vein.

Obstruction of the upper airways, craniofacial trauma and neck cancers (especially laryngeal), in either the acute or the chronic setting, require a tracheostomy: the creation of a hole (stoma) in the anterior aspect of the trachea that can serve independently or as a site for a dedicated tube allowing the spontaneous or mechanical ventilation of the patient. This manœuvre usually involves the second and third cartilages; in particular cases, the lumen of the larynx can be approached (laryngotomy or cricothyroidotomy). Tracheostomy may be performed surgically or percutaneously (Ciaglia et al 1985, Griggs et al 1990).

## Posterior relations

The oesophagus is a posterior relation of the cervical trachea, separating it from the vertebral column and the prevertebral fascia.

## Lateral relations

The paired lobes of the thyroid gland, which descend to the fifth or sixth tracheal cartilage, and the common carotid and inferior thyroid arteries are lateral relations. The recurrent laryngeal nerves ascend on each side, in or near the grooves between the sides of the trachea and the oesophagus.

## Relations of the thoracic part of the trachea

## Anterior relations

As it descends through the superior mediastinum, the thoracic trachea lies behind the manubrium sterni, the origins of sternohyoid and sternothyroid, the thymic remnants and the inferior thyroid veins. The brachiocephalic and left common carotid arteries come to lie on the right and left of the trachea, respectively, as they diverge upwards into the neck. At a lower level, the aortic arch, brachiocephalic trunk, left common carotid artery, left brachiocephalic vein, deep cardiac plexus and lymph nodes are all anterior to the trachea.

## Posterior relations

The oesophagus is posterior to the trachea and separates it from the vertebral column.

## Lateral relations

Laterally and on the right are the right lung and pleura, right vagus nerve, right brachiocephalic vein, superior vena cava and azygos vein. On the left are the arch of the aorta, left common carotid and subclavian arteries. The left recurrent laryngeal nerve is at first situated between the trachea and aortic arch, and then lies within or just anterior to the tracheo-oesophageal groove.

The trachea and oesophagus can be compressed (or even eroded) by vascular rings resulting from abnormal formation of the aorta and its
branches, such as: double aortic arch, right aortic arch, aberrant right subclavian artery, double ductus arteriosus or persistence of the fifth aortic arch.

## RIGHT PRINCIPAL BRONCHUS

The right principal bronchus is approximately 2.5 cm long, and is wider, shorter and more vertical than the left (see Fig. 54.7; Fig. 54.14A). These differences explain why inhaled foreign bodies enter the right principal bronchus more often than the left (more common in children who may present with breathlessness, unilateral wheeze or recurrent aspirations; a chest radiograph may show air trapping in the affected lobe). The right principal bronchus gives rise to its first branch, the superior lobar bronchus, then enters the right lung opposite the fifth thoracic vertebra. The azygos vein arches over it, and the right pulmonary artery lies at first inferior, then anterior to it (the eparterial bronchus). After giving off the superior lobar bronchus, which arises posterosuperior to the right pulmonary artery, the right principal bronchus crosses the posterior aspect of the artery, enters the pulmonary hilum posteroinferiorly, and divides into middle and inferior lobar bronchi.

## Right superior lobar bronchus

The right superior lobar bronchus arises from the lateral aspect of the parent bronchus and runs superolaterally to enter the hilum; 1 cm from its origin it divides into three segmental bronchi.

## Segmental anatomy

The apical segmental bronchus continues superolaterally towards the apex of the lung, which it supplies, and divides near its origin into apical and anterior branches. The posterior segmental bronchus serves the posteroinferior part of the superior lobe, passes posterolaterally and slightly superiorly, and soon divides into a lateral and a posterior branch. The anterior segmental bronchus runs anteroinferiorly to supply the rest of the superior lobe, and divides near its origin into a lateral and an anterior branch of equal size (see Fig. 54.7).

## Bronchus intermedius

The bronchus intermedius is the continuation of the right principal bronchus distal to the right upper lobe bifurcation, coursing in the same direction as the former but with a slight rightward deviation. It is slightly flattened, 10 mm wide and 2.5 cm long. It begins at the base of the right upper lobe bronchus and gives rise to the common middle lobe and lower lobe bronchi, and sometimes to an additional variant subsuperior segmental bronchus (see below).

## Right middle lobar bronchus

The right middle lobar bronchus usually starts 2 cm below the superior lobar bronchus and descends anterolaterally.

## Segmental anatomy

The right middle lobar bronchus soon divides into a lateral and a medial segmental bronchus distributed to the homonymous segments of the middle lobe (see Fig. 54.7).

## Right inferior lobar bronchus

The right inferior lobar bronchus is the continuation of the bronchus intermedius beyond the origin of the common middle lobar bronchus.

## Segmental anatomy

At or a little below its origin from the principal bronchus, the right inferior lobar bronchus gives off a large superior (apical) segmental bronchus posteriorly. This runs posteriorly to the upper part of the inferior lobe, and then divides into medial, superior and lateral branches; the first two usually arise from a common stem. After giving off the superior segmental branch, the right inferior lobar bronchus descends posterolaterally. The medial basal segmental bronchus branches from its anteromedial aspect, and runs inferomedially to serve a small region below the hilum. The inferior lobar bronchus continues downwards and divides into an anterior basal segmental bronchus, which descends anteriorly, and a trunk that soon divides into a lateral basal segmental bronchus, which descends laterally, and a posterior

Normal variants in the bronchial anatomy are occasionally seen and consist of either displaced or supernumerary airways (Ghaye et al 2001). Abnormalities include a common origin of the right upper and middle lobe bronchi; an accessory cardiac bronchus; a right lower lobe bronchus that may arise from the left main stem bronchus; and an oesophageal bronchus. These anatomical variants are largely asymptomatic, occasionally causing haemoptysis, recurrent infection and bronchiectasis. Congenital bronchial atresia is associated with a bronchocele and emphysematous changes in the peripheral lung fields (Wang et al 2012). Left bronchial isomerism, characterized by two hyparterial bronchi and two bilobed lungs, and right bronchial isomerism, characterized by two eparterial bronchi and two trilobed lungs, may be features of the heterotaxy syndrome, which may include congenital cardiac, liver, stomach, intestinal and splenic abnormalities.

Fig. 54.14 A, A bronchogram showing the branching pattern of the trachea and bronchi of the right lung, in a slightly oblique, anteroposterior view. In this procedure, a radiopaque contrast medium has been introduced into the respiratory tract to coat the walls of the respiratory passages. For identification of the major branches, compare with Figures 54.5B-E and 54.6. B-E, CT images demonstrating branching of lobar and segmental bronchi. These axial images correspond to level T4 (carina) to T6 (bifurcation right middle lobe bronchus), respectively.
basal segmental bronchus, which descends posteriorly. In more than half of all right lungs, a subsuperior (subapical) segmental bronchus arises posteriorly from the bronchus intermedius or right inferior lobar bronchus $1-3 \mathrm{~cm}$ below the superior segmental bronchus, and is distributed to the region of lung between the superior and posterior basal segments (see Fig. 54.7).

## LEFT PRINCIPAL BRONCHUS

The left principal bronchus is narrower, less vertical and twice as long ( 5 cm ) as the right principal bronchus. Passing to the left, inferior to the aortic arch, it crosses anterior to the oesophagus, thoracic duct and descending aorta; the left pulmonary artery is at first anterior and then superior to it (the hyparterial bronchus). It enters the hilum of the left lung at the level of the sixth thoracic vertebra and divides into superior and inferior lobar bronchi.

## Left superior lobar bronchus

The left superior lobar bronchus arises from the anterolateral aspect of its parent stem, curves laterally, and soon divides into two bronchi that correspond to the branches of the right principal bronchus as it supplies the right superior and middle lobes, except that, on the left side, both are distributed to the left superior lobe because there is no separate middle lobe.

## Segmental anatomy

The superior division of the left superior lobar bronchus ascends 1 cm , gives off an anterior segmental bronchus, continues a further 1 cm as the apicoposterior segmental bronchus, and then divides into apical and posterior branches. The apical, posterior and anterior segmental bronchi are largely distributed as they are in the right superior lobe. The inferior division descends anterolaterally to the anteroinferior part of the left superior lobe (the lingula) and forms the common lingular bronchus, which divides into superior and inferior lingular segmental bronchi. This is different from the pattern in the right middle lobe, where the corresponding distribution is lateral and medial (see Fig. 54.7).

## Left inferior lobar bronchus

The left inferior bronchus descends posterolaterally and divides to supply territories of the lung that are distributed in essentially the same manner as they are in the right lung.

## Segmental anatomy

The superior (apical) segmental bronchus arises from the inferior lobar bronchus posteriorly, 1 cm from its origin. After a further $1-2 \mathrm{~cm}$, the inferior lobar bronchus divides into anteromedial and posterolateral stems. The latter divides into lateral and posterior basal segmental bronchi. The anterior basal segmental bronchus is an occasional independent branch of the inferior lobar bronchus, and a subsuperior (subapical) segmental bronchus occasionally arises posteriorly from the left inferior lobar bronchus (see Fig. 54.7).

## ASPIRATION PNEUMONIA

Penetration of foreign substances into the bronchial tree, usually oral or gastric contents, produces aspiration pneumonia. Chemical (gastric acid) injury or bacterial infection complicates the clinical picture. The location depends on the position of the patient, since it is gravitydependent; right middle and inferior lobes are the most common sites because of the larger and more vertical corresponding bronchi. Aspiration while standing leads to bilateral inferior lobar infiltrates. Patients lying down will aspirate in the right superior lobe (e.g. alcoholics).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Trachea

The trachea is supplied mainly by branches of the inferior thyroid arteries, which anastomose with ascending branches of the bronchial arteries. Veins draining the trachea end in the inferior thyroid venous plexus. The lymph vessels pass to the pretracheal and paratracheal lymph nodes.

## Bronchi

## Bronchial arteries

The bronchial arteries supply oxygenated blood and nutrition to the bronchi and connective tissue of the lungs. Each bronchial artery also has a branch that supplies the oesophagus. They are derived from the descending thoracic aorta either directly or indirectly, travel and branch with the bronchi, and terminate around the level of the respiratory bronchioles. They anastomose with the branches of the pulmonary arteries, and together supply the visceral pleura of the lung. Much of the blood supplied by the bronchial arteries is returned via the pulmonary veins rather than the bronchial veins (see below).

The single right bronchial artery has a variable origin, usually arising from the thoracic aorta as a common trunk with the right third posterior intercostal artery, sometimes from the superior left bronchial artery or any number of the right intercostal arteries, mostly the third right posterior. There are normally two left bronchial arteries (superior and inferior) that branch separately from the thoracic aorta.

The bronchial arteries accompany the bronchial tree and supply bronchial glands, the walls of the bronchi and larger pulmonary vessels. The bronchial branches form a capillary plexus in the muscular tunic of the air passages that supports a second mucosal plexus, which communicates with branches of the pulmonary artery and drains into the pulmonary veins. Other arterial branches ramify in interlobular loose connective tissue and most end in either deep or superficial bronchial veins; some also ramify on the surface of the lung, forming subpleural capillary plexuses. The bronchopulmonary arterial anastomoses in the walls of the smaller bronchi and in the visceral pleura may be more numerous in the neonate and are subsequently obliterated to a marked degree.

In addition to the three main bronchial arteries, smaller bronchial branches arise from the descending thoracic aorta; some may course through the pulmonary ligament and bleed during inferior lobectomy. The bronchial arteries are typically enlarged and tortuous in chronic pulmonary thromboembolic hypertension. They are not usually reconnected following lung transplantation. Aneurysms of a bronchial artery may mimic aortic aneurysms.

Some degree of mixing of blood between bronchial and pulmonary circulations and through Thebesian veins (venae cordis minimae) draining into the left ventricle normally occurs. A small degree of shunt, i.e. perfusion without ventilation, appears as normal and is usually $2-$ 4\%. Cardiac malformations with right-to-left flow, pulmonary arteriovenous malformations, congenital diaphragmatic herniae or pulmonary embolism cause more important shunting, which is refractory to administration of pure oxygen.

## Bronchial veins

Usually two on each side, the bronchial veins drain blood from larger bronchi and hilar structures. They form two distinct systems. Deep bronchial veins commence as intrapulmonary bronchiolar plexuses that communicate freely with the pulmonary veins and eventually join a single trunk that ends in a main pulmonary vein or in the left atrium. Superficial bronchial veins drain extrapulmonary bronchi, visceral pleura and the hilar lymph nodes. They also communicate with the pulmonary veins and end in the azygos vein on the right, and in the left superior intercostal or the accessory hemiazygos vein on the left. Bronchial veins do not receive all the blood conveyed by bronchial arteries; some enters the pulmonary veins. The main bronchial arteries and veins run on the dorsal aspect of the extrapulmonary bronchi.

## Lymphatic drainage

The deep lymphatic plexus reaches the hilum by travelling along the pulmonary vessels and bronchi. In larger bronchi, the deep plexus has submucosal and peribronchial parts, but in smaller bronchi there is only a single plexus that extends to the bronchioles. The walls of the alveoli have no lymphatic vessels.

## INNERVATION

The anterior and posterior pulmonary plexuses innervate the trachea and bronchi. The two plexuses are interconnected. The trachea is innervated by branches of the vagi, recurrent laryngeal nerves and sympathetic trunks; the nerves enter the lung as networks that travel along branches of the bronchi and pulmonary and bronchial vessels as far as
the visceral pleura. Efferent vagal preganglionic axons synapse on small ganglia within the walls of the tracheobronchial tree, likely acting as sites of integration and/or modulation of the input from extrinsic nerves, or permitting local control of aspects of airway function by local reflex mechanisms.

## MICROSTRUCTURE OF THE CONDUCTING AIRWAYS

The conducting airways are lined internally by a mucosa (see Fig. 2.16), and the epithelium lies on a thin connective tissue lamina propria. External to this is a submucosa, also composed of connective tissue, in which are embedded airway smooth muscle, glands, cartilage plates (depending on the level in the respiratory tree), vessels, lymphoid tissue and nerves. Cartilage is present from the trachea to the smallest bronchi, but is absent (by definition) from bronchioles.

## Cartilaginous support

The trachea and extrapulmonary bronchi contain a framework of incomplete rings of hyaline cartilage, which are united by fibrous tissue and smooth muscle (see Fig. 54.16). Intrapulmonary bronchi contain discontinuous plates or islands of hyaline cartilage in their walls.

## Tracheal cartilages

Each of the 16-20 tracheal cartilages measures about 4 mm in height and 1 mm in thickness, appearing thicker in the middle part; their external surface is flat while the internal aspect is slightly convex. The cartilaginous 'rings' encompass the anterior two-thirds of the trachea, the ring being completed in the posterior third by fibroelastic and muscular tissue. Cartilage loses elasticity and calcifies in older age, and adjacent cartilages may variously fuse. The first and the last two cartilages are more conspicuous, the first being the thickest (see Fig. 54.7). The last tracheal ring merges into the incomplete rings at the origin of each principal bronchus; the bifurcation is marked by a cartilaginous spur, the carina (see Fig. 54.11).

## Bronchial cartilages

Cartilaginous plates mainly surround the dorsal aspect of the lobar bronchi. They become more irregular and form progressively less of the bronchial walls in intrapulmonary bronchi, and disappear in the bronchioles.

## PULMONARY DEFENSIVE MECHANISMS

The respiratory tract presents a huge surface area that is vulnerable to desiccation, freezing, microbial invasion and the mechanical and chemical effects of inhaled particles. Inhaled air is humidified chiefly in the upper respiratory tract, where it passes, with some turbulence, over the nasal and buccopharyngeal mucosae. The secretions of the various glands of the bronchial tree also help to prevent desiccation. Goblet cells secrete sulphated acid mucosubstances; cells in mucous glands beneath the epithelial surface contain mainly carboxylated mucosubstances, particularly those associated with sialic acid, although sulphated groups also occur; cells of serous glands contain neutral mucosubstances. Goblet cells respond mainly to local irritation, while tubular glands, both mucous and serous, are mainly under neural and hormonal control. Excessive or altered secretions may obstruct the flow of air. Antibacterial and antiviral substances, e.g. lysozyme, IgA antibodies and possibly interferon, also appear in the secreted fluid.

Inhaled particles may be removed via the mucociliary rejection current. Cilia sweep the fluid overlying the surfaces of bronchioles, bronchi and trachea upwards at $1 \mathrm{~cm} / \mathrm{min}$, and much of the inhaled matter trapped in the viscous fluid may be removed in this way. Particles small enough to reach the alveoli may be removed by alveolar phagocytes. Alveolar epithelium has limited powers of regeneration but normally is continually replaced. The lifespan of alveolar squamous cells is approximately 3 weeks, and that of alveolar phagocytes is 4 days. Inhaled particles may also be cleared by the cough reflex.

Numerous lymphoid nodules occur in the bronchial lining, providing foci for the production of lymphocytes and giving local immunological protection against infection both by cell-mediated (T-cell) activities, and by the production of immunoglobulins (mainly $\operatorname{Ig} A$ ) from B cells, which are passed on to gland cells for secretion to the epithelial surface.

The predominant contractile innervation of airway smooth muscle is parasympathetic and cholinergic in nature, while the primary relaxant innervation of the airways is non-cholinergic (parasympathetic nerves containing nitric oxide synthase and vasoactive intestinal peptide). These parasympathetic nerves are anatomically and physiologically distinct from one another and differentially regulated by reflexes. Sympathetic-adrenergic nerves play little, if any, role in directly regulating smooth muscle tone in the human airways. Activation of airway afferent nerves (rapidly adapting receptors, C fibres) can evoke increases in airway smooth muscle parasympathetic nerve activity, or decreases in parasympathetic nerve activity (via activation of slowly adapting receptors). Extrapulmonary afferents may modulate neurally mediated regulation of airway smooth muscle tone (Canning 2001a).

Stimulation of cholinergic nerves causes not only bronchoconstriction but also mucus secretion and bronchial vasodilation. Sympathetic nerves may control tracheobronchial blood vessels.

## Epithelium

The epithelia of the trachea, bronchi and bronchioles are, in general, similar to each other, with graded variations in the numbers of different cell types. The extrapulmonary and larger intrapulmonary passages are lined with respiratory epithelium (see Fig. 2.2D), which is pseudostratified and predominantly ciliated, and contains interspersed mucussecreting goblet cells. There are fewer cilia in terminal and respiratory bronchioles, and the cells are reduced in height to low columnar or cuboidal. The epithelium of smaller bronchi and bronchioles is folded into conspicuous longitudinal ridges, which allow for changes in luminal diameter (see Fig. 54.11). The epithelium in the respiratory bronchioles progressively reduces in height towards the alveoli, and is eventually composed of cuboidal, non-ciliated cells. Respiratory bronchioles have lateral pouches in their walls, which are lined with squamous cells, so providing an accessory respiratory surface.

Six distinct types of cell have been described in the conducting airways, namely: ciliated columnar, goblet, Clara, basal, brush and neuroendocrine (see Fig. 54.11). Lymphocytes and mast cells migrate into the epithelium from the underlying connective tissue.

## Ciliated columnar cells

Ciliated columnar cells are the driving force of the mucociliary rejection current (escalator) in the bronchial tree. They vary from low to tall columnar, and each has up to 300 cilia (Ch. 1, see Fig. 1.17) projecting from the apical surface. The cilia extend into a watery fluid secreted by serous cells of the submucosal glands, but their tips are in contact with a more superficial layer of thicker mucus secreted by surface goblet cells and mucous cells in the submucosal glands. The rate of ciliary beating is usually $12-16$ per second; mechanical stimulation of the epithelial surface and inflammatory mediators increase the rate. In addition to tight junctions, which seal the apical intercellular space from the airway lumen, the ciliated cells are coupled by gap junctions, which allow a change in rate of beating to spread from stimulated cells to their neighbours (probably via calcium signalling) so that their metachronal coordination remains intact. Primary ciliary dyskinesia is a ciliary abnormality inherited as an autosomal recessive disorder and may be a feature of Kartagener's syndrome, which is a combination of bronchiectasis, sinusitis and situs inversus.

## Goblet cells

Goblet cells are present from the trachea (6000-7000 per mm²) distal to the smaller bronchi, but are normally absent from bronchioles. They contain an apical region full of large secretory vacuoles filled with mucinogen. When the epithelium is irritated, e.g. by tobacco smoke, there is an overall increase in the number of goblet cells, and they also extend into the bronchioles.

## Clara cells

Clara cells are cuboidal, non-ciliated cells with apices that bulge into the lumen. They contain numerous electron-dense secretory granules and many lysosomes. Clara cells produce surfactant lipoprotein and thus share functional similarities with the type II alveolar cell of pulmonary alveoli, although their secretory granules differ in structure and composition. They may also regulate ion transport.

## Basal cells

Basal cells are small, rounded cells that occur in parts of the airway lined by pseudostratified respiratory epithelium; they are mitotic stem cells for other epithelial cell types. Basal cells contact the basal lamina and are most frequent in the larger conducting passages.

## Brush cells

Brush cells are slender, non-ciliated cells with characteristically long, stiff apical microvilli, from which they derive their name. Although infrequent, they are present throughout all parts of the conducting airway passages, including the respiratory epithelium of the nasopharynx. They are in contact with afferent nerve fibres basally and are presumed to have a sensory receptor function.

## Neuroendocrine cells

Neuroendocrine cells, also termed dense-core or small granule (Kulchitsky) cells, are found mainly in the basal part of the epithelium. They have a rounded shape and the cytoplasm basal to their nuclei contains numerous small, dense-cored vesicles, approximately 150 nm in diameter. They form part of the dispersed neuroendocrine system of amine precursor uptake and decarboxylation (APUD) cells. Neuroendocrine cells are most numerous in fetal lungs and their number decreases dramatically after birth. There appears to be little further change in their frequency during adult life, although they may proliferate in certain pulmonary diseases.

## Lymphocytes

T lymphocytes, derived from mucosa-associated lymphoid tissue (MALT) in the walls of the passages, occur within the epithelium throughout the conducting airway tissues, particularly in the extrapulmonary portion. They are concerned with the immune surveillance of the epithelium. Clusters of lymphocytes sometimes lie beneath nonciliated epithelial cells of the microfold (M-cell) type.

## Mast cells

Mast cells are present within the basal regions of the epithelium. They resemble connective tissue mast cells, and their cytoplasmic histaminecontaining granules are released in response to irritants, including inhaled allergens.

## Submucosal glands

Tubuloacinar, seromucous glands are present in the submucosa of the trachea and bronchi and, to a lesser extent, in the larger bronchioles. They contain separate mucous and serous cells and are an important source of the mucus at the surface of the ciliated respiratory epithelium. Their secretions include mucins; bacteriostatic substances such as lysozyme and lactoferrin; secretory antibodies (immunoglobulin A (IgA)) produced by plasma cells in the submucosal connective tissue; and protease inhibitors (e.g. $\alpha_{1}$-antitrypsin), important for neutralizing leukocyte-derived proteases in the respiratory tract, particularly elastase. Deficiency of $\alpha_{1}$-antitrypsin causes chronic obstructive pulmonary disease, by inducing panacinar emphysema and bronchiectasis. The secretory acini and tubules are surrounded by myoepithelial cells, which are innervated by autonomic fibres (see above).

## Connective tissue and muscle

Broad, longitudinal bands of elastin within the submucosa (Fig. 54.15) follow the course of the respiratory tree and connect with the elastin networks of the interalveolar septa (see Fig. 54.11). This elastic framework is a vital mechanical element of the lung and is responsible for elastic recoil during expiration.

In the trachea and extrapulmonary bronchi, the smooth muscle is mainly confined to the posterior, non-cartilaginous part of the tracheal tube (Fig. 54.16). Along the entire intrapulmonary bronchial tree, smooth muscle forms two opposed helical tracts, which become thinner and finally disappear at the level of the alveoli. The tone of these muscle fibres is under nervous and hormonal control; groups of muscle cells are coupled by gap junctions to spread excitation within fascicles.

Muscle cell contraction narrows the airway, while relaxation permits bronchodilation. Some tone normally exists in the muscular bands, which relax slightly during inspiration and contract during expiration, thereby assisting the tidal flow of air. Abnormal contraction may be caused by circulating smooth muscle stimulants or by local release of excitants such as 5-HT (5-hydroxytryptamine, serotonin), histamine and leukotrienes, which produces bronchospasm. Numerous mast cells are present in the connective tissue of the respiratory tree, especially towards the bronchioles.

## Anatomy of coughing

Coughing is an important defensive reflex．It enhances clearance of secretions and particulates from the airways and protects from aspiration of foreign materials（occurring as a consequence of aspira－ tion or inhalation of particulate matter，pathogens，accumulated secretions，postnasal drip，inflammation and mediators associated with inflammation）．

Under normal conditions，cough serves an important protective role in the airways and lungs，but in some conditions it may become exces－ sive，non－productive and potentially harmful to the airway mucosa．

The mechanical events of a cough can be divided into three phases． An initial deep inhalation generates the volume necessary for an effec－ tive cough and is followed by a compression phase，when forceful contraction of the muscles of the chest wall，diaphragm and abdominal wall against a closed glottis results in a rapid rise in intrathoracic pres－ sure．Subsequent glottal opening causes a rapid peak expiratory airflow that dislodges and expels mucus from the airways；forceful airway com－ pression produces the coughing sound．

## BRONCHOSCOPY

Bronchoscopy allows the direct visualization of the vocal cords，trachea and major airways as far as the first division of the subsegmental airway． Occasionally，bronchoscopy can also provide some information about structures adjacent to the airways，e．g．significant subcarinal lymphaden－ opathy may cause splaying or widening of the carina．Bronchoscopy enables the acquisition of samples（e．g．bronchial lavage，bronchial brushings，bronchial and transbronchial biopsies）；provides informa－ tion about staging in lung cancer；and facilitates therapeutic procedures （e．g．foreign body removal，ablation of tumours and insertion of airway stents）．The information obtained by volume CT scanning can be recon－ structed to provide three－dimensional images that can be used to create endobronchial views（virtual bronchoscopy，Fig．54．17）or to demon－ strate the pulmonary arteries．

Coughing is initiated when mechanically and chemically sensitive vagal afferents innervating the airways from the upper respiratory tract to the terminal bronchioles and lung parenchyma are activated (Morice and Gepetti 2004). Data from experimental studies suggest that the receptors innervated by these afferents may be broadly divided into three groups: namely, slowly (SAR) and rapidly (RAR) adapting stretch receptors and bronchopulmonary unmyelinated C fibres. The vagal afferents terminate centrally in largely non-overlapping regions of the caudal half of the nucleus tractus solitarius. Second-order neurones from this nucleus terminate on respiratory-related regions of the pons, medulla and spinal cord. Efferent impulses travel via the vagus, phrenic and spinal motor nerves to the inspiratory and expiratory muscles, larynx, diaphragm and abdominal wall muscles. Airway receptors in the external auditory canals, eardrums, paranasal sinuses, pharynx, diaphragm, pleura, pericardium and stomach are probably mechanoreceptors, stimulated by triggers such as touch or displacement (Polverino et al 2012).

Rapidly adapting receptors (RAR) RARs are dynamic receptors that respond to changes in airway mechanical properties (e.g. diameter, length and interstitial pressures). Functional studies of RARs suggest that they terminate within or beneath the epithelium mainly of the intrapulmonary airway (Widdicombe 2003). They may be differentiated from other airway afferents by their rapid adaptation (in 1-2 seconds) to sustained lung inflation (Schelegle and Green 2001). RARs are sporadically active throughout the respiratory cycle, activated by the dynamic mechanical forces that accompany lung inflation and deflation, and become more active as the rate and volume of lung inflation increase. Their activation initiates reflex bronchospasm and mucus secretion through parasympathetic pathways.

Slowly adapting stretch receptors (SARs) SARs are highly sensitive to the mechanical forces that act on the lung during breathing. Their activity increases during inspiration and peaks just prior to the initiation of expiration. They are thus thought to be the afferent fibres involved in the Hering-Breuer reflex, which terminates inspiration and initiates expiration when the lungs are adequately inflated. SARs appear to terminate primarily in the intrapulmonary airways. SAR activation results in the central inhibition of respiration and the inhibition of the cholinergic drive to the airways, leading to decreased phrenic nerve activity and decreased airway smooth muscle tone (Canning et al 2001b); most of these SARs are associated with alveoli or bronchioles.

C fibres The majority of afferent nerves innervating the airways and lungs are unmyelinated C fibres, similar to the unmyelinated somatic sensory nerves that innervate the skin, skeletal muscle, joints and bones and that respond to noxious chemical and mechanical stimuli. In addition to their slow conduction velocity ( $<2 \mathrm{~m} / \mathrm{s}$ ), airway vagal afferent C fibres are distinguished from RARs and SARs by their relative insensitivity to mechanical stimulation and lung inflation. They are generally quiescent throughout the respiratory cycle (Lee and Pisarri 2001).

The specific pattern of the cough depends on the site and type of stimulation. Mechanical laryngeal stimulation results in immediate
expiratory stimulation (sometimes termed the expiratory reflex), protecting the airway from aspiration; stimulation distal to the larynx causes a more prominent inspiratory phase to generate the airflow necessary to remove the stimulus.

During vigorous coughing, intrathoracic pressures may reach 300 mmHg (with an abrupt rise in pleural pressure from 6.5 to 13 kPa ) and expiratory velocities approach 500 miles per hour (Ford et al 2007). While these pressures and velocities are responsible for the beneficial effects of cough on mucus clearance, they are also the cause of many of the complications of cough, including exhaustion, selfconsciousness, insomnia, headache, dizziness, musculoskeletal pain, hoarseness, excessive perspiration, urinary incontinence and coughinduced multiple rib fractures.

Lesions that compress the upper airway, including arteriovenous malformations and retrotracheal masses, may present with chronic cough. Cough can also be a symptom of tracheobronchomalacia, which results from the loss of rigid support of the large airways and inspiratory collapse, usually seen in conjunction with obstructive lung disease in patients with a history of cigarette smoking.

Chronic dry cough may be caused by irritation of the external auditory canal by impacted foreign bodies or cerumen (Jegoux et al 2002). The aetiology of the 'ear-cough' (otorespiratory reflex) is related to stimulation of the auricular branch of the vagus nerve (Arnold's nerve) (Feldman and Woodworth 1993). Holmes-Adie syndrome is a rare cause of coughing when autonomic dysfunction affects the vagus nerve. Patients present with anisocoria, abnormal deep tendon reflexes and patchy areas of hyperhidrosis or anhidrosis (Kimber et al 1998).

Differences among several sites from which cough stimuli can originate may result in variations in the sounds and patterns of coughing. Laryngeal stimulation produces a choking type of cough without a preceding inspiration. Inadequate mucociliary clearance mechanisms (as in bronchiectasis or cystic fibrosis) may produce a pattern of coughing with less violent acceleration of air and a sequence of interrupted expirations without any intervening inspiration.

Since cough is an important defensive reflex required to maintain the health of the lungs, people who do not cough effectively are at risk of atelectasis, recurrent pneumonia and chronic airways disease from aspiration and retention of secretions. Many disorders can impair the ability to cough effectively, which may result in persistent cough. The elderly, the newborn, lung transplant recipients and patients with paralysis or neuromuscular disorders have a poorly developed and/or compromised cough reflex, and are rendered highly susceptible to infective and aspiration pneumonia (Polverino et al 2012). Patients with paralysis or neuromuscular disorders (including rib fractures) and chest wall deformities may not generate the flows necessary for effective clearance of secretions due to defective 'pump' mechanisms. Individuals with reduced function of the abdominal wall musculature are particularly at risk of ineffective cough. Patients with tracheobronchomalacia ('floppy' airways) or with obstructive airways diseases often do not generate the high flow rates needed for effective clearance of secretions. Individuals with laryngeal disorders, including those with tracheostomies, may not achieve sufficient laryngeal closure to generate the increased intrathoracic pressures necessary for an effective cough.

## Diaphragm and phrenic nerves

The diaphragm is a domed musculofibrous sheet that separates the thoracic and abdominopelvic cavities (Fig. 55.1). Its mainly convex superior surface faces the thorax, and its concave inferior surface is directed towards the abdomen. The positions of the domes or cupulae of the diaphragm are extremely variable; they are influenced by body build (often higher in the short and obese compared to the tall and asthenic), position and ventilatory phase. Conditions resulting in lung over-inflation, e.g. emphysema, cause marked diaphragmatic depression. Usually, after forced expiration, the right cupula is level anteriorly with the fourth costal cartilage and the right nipple, whereas the left cupula lies approximately one rib lower. On full inspiration, the cupula will descend by as much as 10 cm , and on a plain chest radiograph the right dome coincides with the anterior end of the sixth rib. The diaphragm lies more superiorly in the supine compared to the erect position, and the dependent half of the diaphragm will be considerably higher than the uppermost one in the decubitus position.

## ATTACHMENTS AND COMPONENTS

The muscle fibres of the diaphragm arise from the highly oblique circumference of the thoracic outlet; the attachments are low posterolaterally and high anteriorly (Fig. 55.2). Although it is a continuous sheet, the muscle can be considered in three parts: sternal, costal and lumbar. The sternal part arises by two fleshy slips from the posterior aspect of the xiphoid process. The attachment varies; it may be a broad, continuous band but is not always present (Loukas et al 2015a). On each
side, the costal part arises from the internal surfaces of the lower six costal cartilages and their adjoining ribs, interdigitating with transversus abdominis (see Fig. 53.15).

The lumbar part arises from two aponeurotic arches - the medial and lateral arcuate ligaments (sometimes termed lumbocostal arches) - and asymmetrically from the upper lumbar vertebral bodies via two pillars or crura. The lateral arcuate ligament covers quadratus lumborum, arching across the upper part of that muscle, and attaching medially to the anterior aspect of the transverse process of the first lumbar vertebra, and laterally to the inferior margin of the midpoint of the twelfth rib. The medial arcuate ligament covers the upper part of psoas major. Medially, it is continuous with the lateral tendinous margin of the corresponding crus, and is thus attached to the side of the body of the first or second lumbar vertebra. Laterally, it is fixed to the anterior aspect of the transverse process of the first lumbar vertebra.

The crura are tendinous at their attachments and blend with the anterior longitudinal ligament. The broader and longer right crus arises from the anterolateral surfaces of the bodies and intervertebral discs of the upper three lumbar vertebrae. The left crus arises from the corresponding parts of the upper two lumbar vertebrae. The medial tendinous margins of the crura meet in the midline to form an often poorly defined arch, the median arcuate ligament, which crosses anterior to the aorta at the level of the intervertebral T12/L1 disc. The crura vary greatly in length, thickness and ratio of muscle to tendon (Loukas et al 2015a).

From these circumferential attachments, the muscle fibres of the diaphragm converge into a central tendon. Fibres from the xiphoid

Fig. 55.1 The abdominal aspect of the diaphragm. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Fig. 55.2 A coronal CT scan depicting the diaphragmatic domes (arrows) superior to the liver and spleen. Notice the attachment of the diaphragm at the lumbar vertebrae. (Courtesy of Professor Loukas.)
process are short, run almost horizontally and are occasionally aponeurotic. Fibres originating from the medial and lateral arcuate ligaments, and particularly the osteochondral surfaces of the ribs, are much longer. They arise almost vertically at first and then curve towards their central attachment. Fibres from the crura diverge, the most lateral becoming even more lateral as they ascend to the central tendon. Medial fibres of the right crus embrace the oesophagus where it passes through the diaphragm, the more superficial fibres ascend on the left, and deeper fibres cover the right margin. Sometimes, a fleshy fasciculus from the medial side of the left crus crosses the aorta and runs obliquely through the fibres of the right crus towards the caval opening; this fasciculus does not continue upwards around the oesophageal hiatus on the right side.

The central tendon of the diaphragm is a thin but strong aponeurosis of closely interwoven fibres situated near the centre of the muscle, but closer to the anterior wall of the thorax, so that the posterior muscular fibres are longer (Fig. 55.3). In the centre, it lies immediately inferior to the pericardium, with which it is partially blended. It is trifoliate in shape. The middle folium, which projects anteriorly, has the form of an equilateral triangle with the apex directed towards the xiphoid process. The right and left folia are tongue-shaped and curve posterolaterally, the left being a little narrower.

The central area of the tendon consists of four well-marked diagonal bands that fan out from a thick central node where compressed tendinous strands decussate anterior to the oesophagus and to the left of the inferior vena cava. Although always present, their morphology varies; in some individuals, the right leaflet of the central tendon is smaller than the left or the anterior leaflets. The ratio between muscle and tendon varies disproportionately, such that larger diaphragms may have a small central tendon, while smaller diaphragms may have only a small amount of muscle contributing to their overall size (Loukas et al 2015a).

## PROFILE AND RELATIONS

The superior surface of the diaphragm is related to three serous membranes. On each side, the pleura separates it from the base of the corresponding lung, and the pericardium is interposed between the middle folium of the central tendon and the heart. The middle folium, the 'cardiac plateau', is almost flat and extends more to the left than the right. In anteroposterior view, the superior profile of the diaphragm rises on either side of the cardiac plateau to a smooth convex dome or cupula. The right cupula is higher and slightly broader than the left. Most of the inferior surface is covered by peritoneum. The right side is moulded over the convex surface of the right lobe of the liver, right kidney and suprarenal gland. The left side conforms to the left lobe of the liver, gastric fundus, spleen, left kidney and suprarenal gland. In view of these differences in the profile and anatomical relationships of the right and left sides of the diaphragm, the side should always be

Fig. 55.3 Two diaphragms removed from the thoracic cavity to show the central tendon and muscular components. Note the different proportions of the central tendon and the muscular portions between A and B. (With permission from Loukas M, du Plessis M, Shah S, Tubbs RS, Raffi E, Polo L, Shoja MM. The clinical anatomy of the musculotendinous part of the diaphragm. Surgical and Radiologic Anatomy, in press, 2015a.)
specified in clinical descriptions. The right hemidiaphragm is found at the anterior end of the sixth rib on a properly inspired posteroanterior chest radiograph, the left hemidiaphragm $1.5-2.5 \mathrm{~cm}$ lower (see Fig. 56.16). Unilateral paralysis may be seen as a raised hemidiaphragm on a chest radiograph, but this sign should not be relied on uncritically in clinical practice.

Ultrasound imaging The posterolateral aspects of the diaphragm may be visualized using ultrasound. It is typically identified by its curved morphology, deep location and specific echotexture. It can be visualized as a thin, muscular hypoechoic line wedged between two hyperechoic layers consisting of peritoneum and pleura. During inspiration, the hypoechoic line thickens as the muscle contracts, making it more visible. This change can be used diagnostically to identify an atrophic diaphragm, when the size of the hypoechoic line does not change. Ultrasound investigation of the diaphragm is best done with the patient in the supine position, limiting veiling by other organs, as well as the risk of misdiagnosis attributable to underlying pulmonary pathologies. The left side poses more of a challenge in visualization (Sarwal et al 2013).

## APERTURES

A number of structures pass between the thorax and abdomen via apertures in the diaphragm. There are three large openings, for the aorta, oesophagus and inferior vena cava, and a number of smaller ones (see Fig. 55.1).

The aortic hiatus is the most posteroinferior of the large openings, and is found at the level of the lower border of the twelfth thoracic vertebra and the adjacent intervertebral disc, slightly to the left of the midline. It is actually an osseo-aponeurotic opening defined by the diaphragmatic crura laterally, the vertebral column posteriorly and the median arcuate ligament anteriorly; the aorta therefore passes posterior to the diaphragmatic musculature and is not affected by its contraction
(Nason et al 2012). Occasionally, some tendinous fibres from the medial parts of the crura also pass posterior to the aorta, converting the osseo-aponeurotic opening into a fibrous ring. The aortic hiatus transmits the aorta, thoracic duct, lymphatic trunks from the lower posterior thoracic wall and, sometimes, the azygos and hemiazygos veins.

The oesophageal hiatus is located at the level of the tenth thoracic vertebra, anterosuperior to, and a little to the left of, the aortic hiatus It transmits the oesophagus, vagal trunks and gastric nerves, oesophageal branches of the left gastric vessels and some lymphatic vessels. The elliptical opening has a slightly oblique long axis, and is bounded by muscle fibres that originate from the medial part of the right crus and cross the midline, forming a 'chimney' approximately 2.5 cm long, that accommodates the terminal part of the oesophagus. The outermost fibres run in a craniocaudal direction, and the innermost fibres are arranged circumferentially. There is no direct continuity between the oesophageal wall and the muscle around the oesophageal hiatus. The fascia on the inferior surface of the diaphragm, rich in elastic fibres, is continuous with the transversalis fascia and extends superiorly into the opening as a flattened cone to blend with the oesophageal wall $2-3 \mathrm{~cm}$ superior to the gastro-oesophageal (squamocolumnar) junction. Some of its elastic fibres penetrate to the submucosa of the oesophagus. This peri-oesophageal areolar tissue, the phreno-oesophageal ligament, connects the oesophagus flexibly to the diaphragm, thus permitting freedom of movement during swallowing and ventilation while synchronously limiting superior oesophageal displacement.

The caval opening, the most superior of the three large openings lies at about the level of the intervertebral disc between the eighth and ninth thoracic vertebrae. It is quadrilateral, with aponeurotic margins, located at the junction of the right leaf with the central area of the tendon. It is traversed by the inferior vena cava, which adheres to the margin of the opening, and by some branches of the right phrenic nerve. During inspiration, dilation of the caval hiatus, combined with increased intra-abdominal pressure, increases cardiac venous return (Nason et al 2012).

There are two lesser apertures within each crus; one transmits the greater, and the other, the lesser, splanchnic nerve. The ganglionated sympathetic trunks usually enter the abdominal cavity posterior to the diaphragm, deep to the medial arcuate ligaments. Openings for minute veins frequently occur in the central tendon.

On each side of the diaphragm, there are small areas where the muscle fibres are replaced by areolar tissue. One, between the sternal and costal parts, contains the superior epigastric branch of the internal thoracic artery and some lymph vessels from the abdominal wall and convex surface of the liver. The other, between the costal part and the fibres that spring from the lateral arcuate ligament, is less constant; when it is present, the posterosuperior surface of the kidney is separated from the pleura only by areolar tissue. Additional, smaller fascial spaces may also be found throughout the lateral aspects of the diaphragmatic domes without evidence of vascular penetration. Although these spaces are found on both left and right sides, they appear to be more numerous on the left (Loukas et al 2015a).

Oesophageal reflux Reflux of gastric contents into the oesophagus, with risk of pulmonary aspiration, is normally prevented by a physiological antireflux barrier located at the gastro-oesophageal junction. The major components of this barrier consist of the specialized smooth muscle of the inferior oesophageal wall and the encircling crural fibres. The diaphragm acts as a 'physiological' sphincter to prevent gastrooesophageal reflux by constricting during inspiration (Nason et al 2012) (see also Ch. 64).

Hiatus hernia The diaphragm lends additional power to all expulsive efforts: sneezing, coughing, laughing, crying, urination, defecation and uterine fetal expulsion are all preceded by a deep inspiration. Similarly, a deep inspiration followed by closure of the glottis is a common preliminary to powerful recruitment of the trunk muscles in lifting heavy objects because the increased intra-abdominopelvic pressure pneumatically braces the vertebral column.

Repeated stress may eventually compromise the integrity of the hiatus with widening of the muscular hiatal tunnel. Concomitant laxity of the phreno-oesophageal ligament allows the gastro-oesophageal junction to migrate into the thorax; this is usually termed a sliding, or type I, hiatus hernia. Sliding hernias are typically acquired, commonly occur in the fifth decade of life, and are found in more than $50 \%$ of patients with gastro-oesophageal reflux. The latter induces tonic contraction of the longitudinal oesophageal muscle and this further exacerbates the hiatus hernia. When the stomach herniates into the thorax adjacent to the oesophagus, it is termed a para-oesophageal, or type II, hiatus hernia.

Congenital hernia Congenital diaphragmatic defects may cause abdominal organs, usually the stomach and/or the small bowel, colon, liver and spleen, to herniate through the diaphragm into the thorax; they are described on page 907.

Eventration Eventration is a focal bulge, usually in the anteromedial segment of the muscular portion of the diaphragm, that is caused by congenital thinning.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES

The profuse arterial supply of the diaphragm is derived from anastomoses between the lower five intercostal and subcostal arteries, the superior and inferior phrenic arteries, and the pericardiacophrenic and musculophrenic arteries.

## Intercostal and subcostal arteries

The lower five intercostal and subcostal arteries supply the costal margins of the diaphragm (Ch. 53).

## Inferior phrenic arteries

The major arterial supply to the diaphragm is derived from the right and left inferior phrenic arteries (Fig. 55.4). Most commonly, the right inferior phrenic artery arises from the coeliac trunk or separately from the aorta, less commonly it arises from the right renal artery, and occasionally it arises from the left gastric artery or the hepatic artery proper. The left inferior phrenic artery usually arises from the coeliac trunk or separately from the aorta; occasionally, it may arise from the left renal artery, left gastric artery or the hepatic artery proper (Loukas et al 2008).

Each artery ascends anterolateral to the diaphragmatic crus, near the medial border of the suprarenal gland. The left passes posterior to the oesophagus and then runs anteriorly on the left side of its diaphragmatic opening. The right inferior phrenic artery passes posterior to the inferior vena cava, and then along the right side of its opening. Each phrenic artery divides into medial and lateral branches near the posterior border of the central tendon. The medial branch curves anteriorly to anastomose with its contralateral fellow anterior to the central tendon and with the musculophrenic and pericardiacophrenic arteries. The lateral branch approaches the thoracic wall and anastomoses with the inferior posterior intercostal and musculophrenic arteries. The lateral branch of the right inferior phrenic artery supplies the inferior vena cava. The left sends ascending branches to the oesophagus.

## Superior phrenic arteries

The superior phrenic arteries supply the superior portion of the diaphragm (Figs 55.5-55.6). The right superior phrenic artery most commonly arises from either the thoracic aorta, the proximal (pre-intercostal space) segment of the tenth intercostal artery or its distal segment. The left superior phrenic artery most commonly arises from the thoracic aorta or the proximal segment of the tenth intercostal artery; occasionally, it arises from the distal segment of the tenth intercostal artery (Loukas et al 2005).

## VEINS

## Phrenic veins

The superior surface of the diaphragm is drained by tributaries of the musculophrenic and pericardiacophrenic veins that run alongside the corresponding arteries. The inferior surface of the diaphragm is drained by tributaries of the right and left inferior phrenic veins. The right inferior phrenic vein drains into the inferior vena cava - almost always inferior, but occasionally superior, to the diaphragm - or to the right

On imaging, it appears as a sharp transition between adjoining parts and may be mistaken for a diaphragmatic hernia. It is identified and becomes more pronounced with increased abdominal pressure and has been linked to obesity. Eventration is typically found on the left; the affected part shows diminished or paradoxical movement during fluoroscopic sniff testing while the posterior aspect of the ipsilateral dome acts normally (Nason et al 2012).

Closed or penetrating thoraco-abdominal injuries may result in rupture or laceration of the diaphragm. With closed injuries and diaphragmatic rupture, there may be subsequent herniation of the abdominal contents into the thorax. Spiral CT with planar reformation should be the primary investigation (Shanmuganathan et al 2000). Magnetic resonance imaging (MRI) is usually performed when other imaging modalities have produced equivocal findings. Early operative repair is recommended because untreated cases may develop gastrointestinal obstruction or perforation. Patients with penetrating injuries may require additional assessment by thoracoscopy (Lowdermilk and Naunheim 2000).

In up to a quarter of individuals, the median arcuate ligament lies significantly inferiorly, positioning itself anterior to the coeliac axis. This may cause compression and downward arching of the coeliac artery, leading to mesenteric angina and pancreaticoduodenal aneurysms as a consequence of resulting collateral flow. Most patients will present with postprandial pain, nausea and often vomiting, and many will avoid eating, resulting in major weight loss. During expiration, concurrent movement of the abdominal aorta and the median arcuate ligament compresses the coeliac artery; the position, angle and level of the coeliac artery are also major aetiological factors. Diagnosis is based mainly on exclusion of other causes, e.g. compression of the vessel as a result of fibrotic or neoplastic changes in the sympathetic plexus and coeliac ganglion, as well as atherosclerotic changes in the vessel itself. Definitive diagnosis can only be made with multiple imaging modalities.

Fig. 55.4 A posterior cadaveric dissection showing the origin and course of the right (RIPA) and left (LIPA) inferior phrenic arteries. The right inferior phrenic artery arises from the superior mesenteric artery (SMA), and the left inferior phrenic artery arises from the coeliac trunk. Fig. 55.6 A lateral view of the left superior phrenic artery arising from the aorta. (With permission. Loukas M, Louis RG Jr, Wartmann CT, Tubbs RS, Esmaeili E, Bagenholm AC, Merbs W, Curry B, Jordan R. Superior phrenic artery: an anatomic study. Surg Radiol Anat. 2007;29(1):97-102.)
hepatic vein. The left inferior phrenic vein drains into the inferior vena cava - commonly inferior, or rarely superior, to the diaphragm. It may also drain into the left suprarenal vein, the left renal vein, the left hepatic vein or, rarely, the left suprarenal renal vein and the inferior vena cava (Loukas et al 2005).

## LYMPHATIC DRAINAGE

The diaphragm is drained by anterior, middle and posterior groups of lymph nodes that lie on its superior surface; they also drain the superior portion of the liver, the gastro-oesophageal junction and the abdominal surface of the diaphragm. In addition, lymph drains anterosuperiorly to parasternal and anterior mediastinal nodes, and posterosuperiorly to posterior mediastinal and brachiocephalic nodes.

Hepatocellular carcinoma

## INNERVATION

The diaphragm receives its motor supply via the phrenic nerves (Fig. 55.7). Sensory fibres are distributed to the peripheral part of the muscle by the lower six or seven intercostal nerves. The fibres of the right crus of the diaphragm divide to the right and left of the oesophagus and are innervated by both right and left phrenic nerves. There is some evidence that the crural fibres contract slightly before the costal part, and this may be functionally significant for non-respiratory tasks.

## Phrenic nerve

The phrenic is a mixed nerve that provides the sole motor supply to its hemidiaphragm. Derived mostly from the fourth cervical ramus, it also receives contributions from the third and fifth cervical ventral rami (see Figs 29.17, 29.18). The course of the cervical part of the phrenic nerve is described on page 464. Within the thorax, the phrenic nerve descends anterior to the pulmonary hilum between the fibrous pericardium and mediastinal pleura, accompanied by the pericardiacophrenic vessels. In its thoracic course, each phrenic nerve supplies sensory branches to the mediastinal pleura, fibrous pericardium and parietal serous pericardium. The right and left phrenic nerves differ in their intrathoracic relationships (Rajanna 1947).

Fig. 55.7 The distribution of the right and left phrenic nerves. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

## Right phrenic nerve

The right phrenic nerve is shorter and more vertical than the left. Separated at the root of the neck from the second part of the right subclavian artery by scalenus anterior, the nerve then descends lateral to the right brachiocephalic vein, the superior vena cava and the fibrous pericardium covering the right surface of the right atrium and inferior vena cava, and divides just superior to or at the level of the diaphragm.

## Left phrenic nerve

At the root of the neck, the left phrenic nerve commonly leaves the medial edge of scalenus anterior and passes anterior to the first part of the left subclavian artery and posterior to the thoracic duct. However, sometimes the right and left nerves are symmetrical in their cervical course, in which case the left phrenic nerve may cross anterior to the second part of the left subclavian artery, from which it is separated by scalenus anterior, at the level of the thoracic inlet. Thereafter, the left phrenic nerve crosses anterior to the left internal thoracic artery and descends across the medial aspect of the apex of the left lung and its pleura to the first part of the subclavian artery, which it crosses obliquely to reach a groove between the left common carotid and subclavian arteries. It passes anteromedially, superficial to the left vagus nerve just superior to the aortic arch and posterior to the left brachiocephalic vein, then descends superficial to the aortic arch and the left superior intercostal vein, anterior to the left pulmonary hilum, to lie between the fibrous pericardium covering the surface of the left ventricle and the mediastinal pleura (see Fig. 57.3).

Diaphragmatic relationships The right phrenic nerve passes through the central tendon of the diaphragm, either by the caval hiatus or just lateral to it. The left phrenic nerve passes through the muscular part of the diaphragm anterior to the central tendon, just lateral to the left cardiac surface and more anterior than the right phrenic nerve (see Fig. 55.7). At the diaphragm or slightly superior to it, each phrenic nerve supplies fine branches to the parietal pleura above the central diaphragm, and the parietal peritoneum below. Typically, the trunk of each nerve then divides into three branches as it passes through the diaphragm. With some variation, these constitute an anterior (sternal) branch, which runs anteromedially towards the sternum and connects with its fellow; an anterolateral branch, which runs to the lateral leaf of the central tendon; and a short posterior branch. The latter divides into a posterolateral ramus that courses posterior to the lateral leaf and a posterior ramus that supplies the crural fibres. Posterolateral and posterior crural rami may arise as separate branches from the phrenic nerve.

These main branches may be submerged in diaphragmatic muscle or lie inferior to it. They supply motor fibres to the muscle and sensory fibres to the peritoneum and pleura related to the central part of the diaphragm. They also relay proprioceptive fibres from the musculature. The right phrenic nerve supplies the part of the right crus that lies to the right of the oesophagus, and the left phrenic nerve supplies the left crus and the part of the right crus that lies on the left of the oesophagus.

Phrenic ganglia The right phrenic nerve continues its course inferior to the diaphragm and frequently connects to the right phrenic ganglion. An additional, smaller, right accessory phrenic ganglion is sometimes located proximally along the phrenic nerve, closer to its caval foraminal exit. The right phrenic ganglion exhibits plexiform communications with the coeliac and aorticorenal ganglia and with the right suprarenal gland (Fig. 55.8). The left phrenic nerve usually continues its course inferior to the diaphragm. A left phrenic ganglion is less common than its right counterpart; when present, it exhibits plexiform communications to several autonomic ganglia. Both phrenic nerves and ganglia are closely related to the diaphragmatic crura; sutures for crural approximation in repair of hiatal hernia must be placed superior to the ganglia in order to avoid iatrogenic injuries to the autonomic supply of the diaphragm and abdomen (Loukas et al 2015b).

Lesions of the phrenic nerve An appreciation of the location of the main branches of the phrenic nerves is important to avoid iatrogenic surgical damage. Radial incisions in the diaphragm from the costal margin to the oesophageal hiatus lead to diaphragmatic paralysis, whereas thoraco-abdominal incisions in a circumferential manner in the periphery of the diaphragm do not involve any significant branches of the phrenic nerves and preserve diaphragmatic function. Similarly, incisions of the central tendon are safe.

Division of the phrenic nerve in the neck completely paralyses the corresponding half of the diaphragm, which atrophies. If an accessory phrenic nerve exists, section or crushing of the main nerve as it lies on

Successful control of hepatocellular carcinoma often requires chemoembolization of the hepatic artery, as well as any extrahepatic collaterals; the right inferior phrenic artery is often found to be associated with hepatocellular carcinoma as a major collateral pathway. Transcatheter oily chemoembolization regresses the tumour with increased survival rates. The inferior phrenic vein is one of the major sources of collateral venous drainage in hepatocellular carcinoma (and in retroperitoneal malignant disease). As well as conventional angiography, the use of 64+ slice computed tomography (CT) scanners enables clear visualization of the right and left inferior phrenic arteries, making CT a reliable method of diagnosing thrombosis and aneurysm of these vessels (Loukas et al 2008).

Fig. 55.8 A cadaveric dissection showing a right phrenic ganglion close to the right inferior phrenic artery and right diaphragmatic crus with plexiform communications to the coeliac ganglion, aorticorenal ganglion and suprarenal gland (arrows). (With permission from Loukas M, Joseph S, Louis RG Jr., Wartmann CT, Tubbs RS. The surgical anatomy of the subdiaphragmatic phrenic nerve and phrenic ganglia. Clinical Anatomy, in press, 2015b.)
scalenus anterior will not produce complete paralysis. The phrenic nerve may be involved in traumatic lesions of the upper brachial plexus. Historically, it was deliberately injured in order to collapse, and hence rest, the lung in patients with pulmonary tuberculosis. Cardiac surgery is one of the most common iatrogenic causes of phrenic nerve injury, especially as a result of the instillation of saline slush for myocardial preservation. Surgery for tumours of the lung or mediastinum may also cause damage, as well as infections such as poliomyelitis, obstetric injury during traumatic childbirth, and radiation therapy (Nason et al 2012). Respiratory muscle weakness of rapid onset is a feature of Guillain-Barré syndrome.

Phrenic nerve damage leads to paradoxical movement of the diaphragm that is best observed fluoroscopically, with the patient first in the upright position (diaphragm unloaded), and then supine with a small weight on the abdomen (diaphragm loaded). Diaphragmatic paralysis can also be assessed by ultrasound examination with a sniff manœuvre. The 'gold standard' for assessment of the phrenic nerve/ diaphragm unit is electrical or magnetic stimulation of the phrenic nerve with recording of the compound muscle action potential and/ or the transdiaphragmatic pressure. Electrical stimulation of the diaphragm, by 'pacing' of one or both phrenic nerves, has been used with some success in infants with central alveolar hypoventilatory syndrome ('Ondine's curse') and in patients with high cervical lesions of the spinal cord, in whom the diaphragm is paralysed but the lower motor neurones are intact. Electrodes are placed adjacent to the nerves, sometimes in the neck but more usually in the chest, and a ventilatory rhythm is established by trains of stimuli delivered by an implanted device. As this is a non-physiological way of recruiting the muscle, the fibres must be 'conditioned' during the initial period of stimulation, so that they acquire the necessary resistance to fatigue.

Referred pain Diaphragmatic pain is frequently felt at the tip of the shoulder, reflecting common nerve root origins in the neck. It usually occurs when there is inflammation of the diaphragmatic pleura, e.g. in basal pneumonia, pleural effusions or malignant disease, or with irritation of the peritoneal pleura, as with subphrenic abscess, where involuntary diaphragmatic contraction (hiccups) may also occur.

## Accessory phrenic nerve

The accessory phrenic nerve is described on page 464

## ANATOMY OF BREATHING

Breathing is a highly coordinated abdominal and thoracic process. The diaphragm is the major muscle of inspiration, responsible for approximately two-thirds of quiet breathing in healthy humans. The external intercostal muscles are most active in inspiration, and the less strong internal intercostals in expiration. Increasing the vertical, transverse and anteroposterior dimensions of the chest increases the volume of the pleural space, and the resulting decrease in intrapleural pressure draws air into the lungs. During expiration, the diaphragm relaxes and moves superiorly. Air is expelled from the lungs and the elastic recoil of the lung creates a subatmospheric pressure that returns the lateral and anteroposterior dimensions of the thorax to normal (De Troyer and Estenne 1988, Celli 1998). During inspiration, the most inferior ribs are fixed and contraction of the diaphragm draws the central tendon inferiorly, scarcely altering diaphragmatic curvature. The cupulae move inferiorly and a little anteriorly, almost parallel to their original positions. The associated inferior displacement of the abdominal viscera is permitted by the extensibility of the abdominal wall, but the limit of this extensibility is soon reached. The central tendon, its motion arrested by the abdominal viscera, then becomes a fixed point from which the fibres of the diaphragm continue to contract. This causes the second to tenth ribs to be elevated and the inferior portions of the ribs are turned outwards as a result of direct transmission of pressure through the zone of apposition (Fig. 55.9). The medial aspect of the rib is elevated and this increases the transverse dimension of the chest in the same manner as a bucket handle swinging outwards; this effect is most evident in the inferior seventh to tenth ribs. Movements at the costovertebral joints cause elevation of the anterior ends of the ribs that push the body of the sternum and the upper ribs anteriorly in a 'pump handle' movement; this effect is most evident in the superior second to sixth ribs, and increases the anteroposterior dimension of the thorax. The right cupula of the diaphragm, which lies on the liver, has a greater resistance to overcome than the left, which lies over the stomach, and so the right crus and the fibres of the right side are more substantial

Fig. 55.9 Inspiratory movements: pressure changes during inspiration. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
than those of the left. The balance between descent of the diaphragm, protrusion of the abdominal wall ('abdominal breathing'), and elevation of the ribs ('thoracic breathing') varies in different individuals and with the phase and depth of ventilation, the degree of distension of the stomach and intestines, and the size of the liver. The thoracic element is usually more marked in females, but increases in both sexes during deep inspiration.

Radiographs show that the height of the diaphragm within the thorax also varies considerably with posture. It is highest when the body is supine, when it performs the greatest ventilatory excursions with normal breathing. When the body is erect, the diaphragm is lower and its ventilatory movements become smaller. The diaphragmatic profile is still lower in the sitting posture and ventilatory excursions are smallest under these conditions. When the body is horizontal and on one side, the two halves of the diaphragm do not behave in the same way. The uppermost half sinks to a lower level than that seen when sitting, and moves little with ventilation. The lower half rises higher in the thorax than it does even in the supine position, and its ventilatory excursions are considerably greater. Changes in the level of the diaphragm with alterations in posture explain why patients with severe dyspnoea are most comfortable, and least short of breath, when sitting up.

Diaphragmatic excursion is typically 1.5 cm in quiet breathing. During deep ventilation, the maximum movement ranges from 6 to 10 cm . After a forced inspiration, e.g. when breathing is partially obstructed, the right cupula of the diaphragm may descend to about the level of the eleventh thoracic vertebra, while the left cupula may reach the level of the body of the twelfth thoracic vertebra. After forced expiration, the right cupula of the diaphragm is level anteriorly with the fourth costal cartilage, laterally with the fifth, sixth and seventh ribs, and posteriorly with the eighth rib; the left cupula is a little lower.

The role of the abdomen in breathing is often underestimated. If, for example, the anterolateral wall were made of steel and linked the pelvic rim rigidly to the costal margins, inspiration would be impossible; the diaphragm could not descend (because the abdominal contents are incompressible), and the ribs could not rise (because the links to the pelvis would be inextensible). During normal breathing, the abdomen relaxes as the diaphragm contracts. It is possible to oppose this motion by tensing the abdomen, as in the 'beach posture' adopted to exaggerate the size of the chest. In this case, the abdominal contents fix the central tendon of the diaphragm, so that it raises the ribcage as it contracts, but it is a condition of that manœuvre that the gap between the ribs and the pelvic rim widens.

The ventilatory muscles must also work during sleep, when the pharyngeal muscles relax and upper airway resistance increases. It is now appreciated that in some people, particularly the obese, this relaxation can lead to periodic apnoea and marked hypoxia during sleep, implying that the pharyngeal muscles play an important ventilatory role
in waking life. It is also clear that although ventilatory muscles rarely tire in normal life, they do fatigue when placed under abnormal loads, e.g. in chronic obstructive pulmonary disease.

The different pulmonary regions do not all move equally in ventilation. In quiet ventilation, the juxtahilar part of the lung scarcely moves and the middle region moves only slightly. The superficial parts of the lung expand the most, and the mediastinal surface, posterior border and apex move less because they are related to less movable
structures. The diaphragmatic and costomediastinal regions expand most of all. Most of the volumetric change during ventilation occurs in the alveoli.

The primary role of the intercostal muscles is to stiffen the chest wall, preventing paradoxical motion during inspiratory diaphragmatic descent. This becomes most obvious immediately after high spinal injury, when there is flaccid paralysis of the entire trunk and only the diaphragm remains functional.

In a healthy adult with a vital capacity of 4.5 litres, some 3 litres is accounted for by diaphragmatic excursion. Immediately after high spinal injury, the vital capacity decreases to about 300 ml , even though the diaphragm is moving maximally, because some 2.7 litres is lost by paradoxical incursion of the flaccid chest wall as the diaphragm descends. Usually after several weeks, the paralysis becomes spastic, stiffening the chest wall, and the vital capacity increases towards its phrenic limit of about 3 litres. In the same way, high spinal injury reveals the role of the abdomen in inspiration and expiration. The abdominal musculature plays a major role in active expiration in humans. During the flaccid stage of high spinal paralysis, the only mechanisms available for returning the relaxed diaphragm into the thorax on expiration are passive recoil of the lungs and chest wall, and the weight of the abdominal viscera. The latter is the most important and operates only when patients are lying down. If they are sat up or raised upright, they are unable to exhale; trussing the abdomen with an elastic binder can be helpful. Conversely, when paralysis becomes spastic, the stiff abdominal wall opposes inspiration.

## Mediastinum

Strictly speaking, the mediastinum is the visceral compartment between the two lungs and includes the mediastinal pleura. However, it is commonly defined as the region between the two pleural sacs, bounded anteriorly by the sternum and posteriorly by the thoracic vertebral column, and extending vertically from the thoracic inlet to the diaphragm. It communicates with the neck via the superior thoracic aperture and with the extraperitoneal, extrapleural and epidural spaces. Beyond each pulmonary hilum, the mediastinum merges into the lung interstitium, incorporating the bronchial tree with its accompanying neurovascular bundles and the pulmonary vasculature.

The posterior mediastinal boundary is longer as a result of the oblique disposition of the superior thoracic aperture and the diaphragmatic curvature posteroinferiorly. With respect to the median sagittal plane, the mediastinum appears asymmetrical.

The mediastinum is divided into superior and inferior mediastina by a plane that crosses the manubriosternal joint and the lower surface of the fourth thoracic vertebra (Fig. 56.1). The inferior mediastinum is subdivided into anterior, middle and posterior parts.

Detailed accounts of mediastinal contents are included with descriptions of the respiratory organs (Ch. 54) and the heart (Ch. 57).

## SUBDIVISIONS OF THE MEDIASTINUM

## SUPERIOR MEDIASTINUM

The superior mediastinum lies between the manubrium sterni anteriorly and the upper four thoracic vertebrae posteriorly, and is bounded laterally by the mediastinal pleurae (see Fig. 56.1). The reflection of the costomediastinal pleurae follows a line that passes from the sternoclavicular joints in an inferomedial direction, to join the midline on the posterior aspect of the sternal angle. The resultant triangular space is occupied by the thymus or its remnants. The superior mediastinum accommodates the trachea, oesophagus, aortic arch, brachiocephalic

Fig. 56.1 The mediastinal divisions
trunk, left common carotid and subclavian arteries (the vertebral artery sometimes arises from the aortic arch between them), the internal thoracic arteries, the left superior intercostal, hemiazygos, internal thoracic and inferior thyroid veins, and numerous lymph nodes, including those from the tracheobronchial, paratracheal and brachiocephalic groups. Laterally, the superior mediastinal structures have the appearance of being 'shrink-wrapped' by the tightly applied pleura. The superior mediastinum transmits the sympathetic and parasympathetic cardiac nerves, the phrenic nerve laterally, the vagus nerves medially and the left recurrent laryngeal nerve. The terminal part of the thoracic duct emerges from the posterior aspect of the aorta and oesophagus, ascending between the left subclavian and carotid arteries. The left and right brachiocephalic veins form the superior vena cava. The superior (extrapericardial) half of the superior vena cava and its major tributaries are situated on a more superficial plane posterior to the manubrium and the origins of sternothyroid inferiorly, and sternohyoid superiorly. An enlarged thyroid gland may extend inferiorly between the sternum and the brachiocephalic veins; its surgical excision requires due diligence from possible venous adherence. The origins of longus colli (inferior oblique and vertical intermediate portions) are the deepest elements of the superior mediastinum.

## INFERIOR MEDIASTINUM

## Anterior mediastinum

The anterior mediastinum lies between the sternal body and pericardium (see Fig. 56.1). It narrows above the fourth costal cartilages where the pleural sacs converge, and contains loose connective tissue, the sternopericardial ligaments, a few lymph nodes, the mediastinal branches of the internal thoracic artery, and sometimes part of the thymus gland or its degenerated remains. The paired intervals between the sternal and costal muscular slips of the diaphragm are filled with areolar tissue and are crossed by the superior epigastric vessels and by some lymph vessels from the abdominal wall and liver; they are rare sites of abdominal herniation. The pericardium and the heart are routinely approached by either a complete median or partial sternotomy. The sternopericardial ligaments and the pleural reflections are easily separated by blunt dissection. In case of pericardial tamponade, the pericardial cavity can be easily drained through a subxyphoid approach, either surgically or via needle pericardiocentesis.

## Middle mediastinum

The middle mediastinum is the broadest part of the inferior mediastinum (see Fig. 56.1) and contains the pericardium, heart and ascending aorta, the inferior, intrapericardial half of the superior vena cava (receiving the azygos venous arch posteriorly), the tracheal bifurcation and main bronchi, the pulmonary trunk, right and left pulmonary vasculature, phrenic nerves, the deep part of the cardiac plexus and the tracheobronchial lymph nodes. The short thoracic part of the inferior vena cava, both extra- and intrapericardial segments, extends between the vena caval aperture of the diaphragm and its termination in the right atrium. The structures forming the pulmonary root converge at the level of the hilum. The mediastinal pleura is continuous with the visceral pleura at the level of the hilum, which is where the lateral boundary of the middle mediastinum is conventionally located. The fibrous pericardium lies on, and is fused with, the anterior two-thirds of the central tendon of the diaphragm.

## Posterior mediastinum

The posterior mediastinum is the lengthiest and narrowest portion of the inferior mediastinum (see Fig. 56.1). It is bounded anteriorly by the
tracheal bifurcation, pericardium and pulmonary vessels, and posteriorly by the bodies of the fifth to the twelfth thoracic vertebrae. There is no strict demarcation with the superior mediastinum; numerous structures travel through both regions. The arched posterior third of the central portion of the diaphragm constitutes the anteroinferior limit of the posterior mediastinum laterally as the mediastinal pleurae come close together. Two pleural recesses, the interaortico-oesophageal and interazygo-oesophageal recesses, intercalate from the left and right sides between the aorta and oesophagus and the azygos vein and oesophagus, respectively.

The posterior mediastinum contains the descending thoracic aorta (on the left side of the spine), the oesophagus (median, but positioned anterior to the aorta inferiorly) and, more posteriorly, the azygos and hemiazygos venous systems, the thoracic duct, lymph nodes, right and left sympathetic chains and thoracic splanchnic nerves. The vagal trunks course adjacent to the oesophagus; the anterior trunk is constituted mainly from the left vagus nerve and the posterior mainly from the right vagus nerve. The descending thoracic aorta gives off the intercostal arteries and the largest anterior segmental medullary artery, the 'great radicular artery of Adamkiewicz' (Yoshioka et al 2003) (p. 770).

There are a number of communications between the posterior mediastinum and the abdomen. These are: the oesophageal aperture (also transmits the vagal trunks) at the level of the tenth thoracic vertebra; the aortic aperture (also transmits the thoracic duct and occasionally the azygos vein) at the level of the twelfth thoracic vertebra; apertures within the diaphragmatic crura that transmit the thoracic splanchnic nerves; apertures deep to the medial lumbosacral arches for the sympathetic chains; and minute openings in the central tendon of the diaphragm that transmit small veins. All openings represent potential communication sites for suppurative or neoplastic processes.

## MEDIASTINAL COMMUNICATIONS WITH THE NECK

Anatomical pathways exist between the oral cavity and the thorax via the parapharyngeal space and along other fascial planes of the neck. The former is more likely to be infected than any of the other potential tissue spaces in the head and neck, communicating with the retropharyngeal and pretracheal spaces, so reaching the superior mediastinum and then the anterior part of the inferior mediastinum (see Chs 29 and 31). The plane between the buccopharyngeal and prevertebral fasciae is a highway for spread of air and gastric contents between the neck and mediastinum after oesophageal injury (Wind and Valentine 2013). The carotid sheath, containing the carotid arteries, jugular veins and vagus nerves, represents another potential route of communication.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The mediastinum contains the great vessels (ascending aorta, aortic arch and its branches, descending thoracic aorta, superior vena cava and the terminal part of the inferior vena cava), the pulmonary arteries and veins, the internal thoracic and posterior intercostal arteries and veins, the azygos and hemiazygos venous systems, and the thoracic duct.

## Great vessels of the superior mediastinum

The aortic arch, descending thoracic aorta, pulmonary trunk and superior vena cava are described in Chapter 57.

## Azygos venous system

## Azygos vein

The azygos vein has a variable origin from the azygos lumbar vein or from the posterior aspect of the inferior vena cava at or below the level of the renal veins (Figs 56.2-56.3; see Fig. 56.14B). When present, the azygos lumbar vein ascends anterior to the upper lumbar vertebral bodies and passes either posterior to or through the right diaphragmatic crus or traverses the aortic hiatus to the right of the cisterna chyli. Anterior to the twelfth thoracic vertebra, it is joined by a venous trunk, formed by the union of the right ascending lumbar and subcostal veins, to form the azygos vein. In the absence of a lumbar azygos vein, this common trunk may continue as the azygos vein proper. The azygos vein passes to the right, posterior to the right crus of the diaphragm, and ascends in the posterior mediastinum to the level of the fourth thoracic vertebra, where it arches anteriorly, superior to the right pulmonary hilum, and joins the posterior aspect of the superior vena cava, just superior to its pericardial incorporation.

Fig. 56.2 A common course followed by the intrathoracic azygos, hemiazygos and accessory azygos veins. Outlines of the root of the right lung and ascending thoracic aorta are included.

Fig. 56.3 The most common topography of the azygos venous system.

In its course, the azygos vein lies anterior to the bodies of the lower eight thoracic vertebrae, anterior longitudinal ligament and right posterior intercostal arteries. Right lateral relations are the right sympathetic chain, the right greater splanchnic nerve, lung and pleura. Left lateral relations are the thoracic duct, aorta and, where the vein arches anteriorly, the oesophagus, trachea and right vagus. Aortic pulsations
may assist venous return in the azygos and hemiazygos veins, although only a small and variable number of imperfect valves are present. Inferiorly, the azygos vein lies posterior to the oesophagus, from which it is separated by a pleural recess, the azygo-oesophageal recess. There are differences in the appearance of the contour of this recess on computed tomography (CT) between children and adults. The recess is dextroconvex below the age of 6 years, non-concave (equally divided between straight and convex) between 6 and 12 years and concave, as in adults, after the age of 12 years (Miller et al 1993). Its major tributaries are the right intercostal veins (the first drains into the right brachiocephalic vein and the second, third and fourth form a common trunk, the superior intercostal vein), the right ascending lumbar and subcostal veins, mediastinal, oesophageal, pericardial and right bronchial veins, and the hemiazygos and accessory hemiazygos veins.

Numerous anastomoses exist between the tributaries and the main trunks of the azygos, hemiazygos and accessory hemiazygos veins, the inferior vena cava and the vertebral venous plexuses. These allow for alternate drainage pathways in case of segmental agenesis ('interruption') or thrombosis of the inferior vena cava (see also below for the variations of the azygos vein).

## Hemiazygos vein

The hemiazygos vein represents the left-sided equivalent of the more inferior part of the azygos vein. It originates in a similar fashion (from the union of the left lumbar ascending and subcostal veins) but exhibits more variability; it may also connect with the left renal vein via the equivalent of the lumbar azygos vein. The hemiazygos vein crosses posterior to the aorta and oesophagus, and either anterior or posterior to the thoracic duct, and usually terminates in the azygos vein at the level of the eighth thoracic vertebra (see Fig. 56.2). It receives the lower three left posterior intercostal, mediastinal and oesophageal veins.

## Accessory hemiazygos vein

The accessory hemiazygos vein functions as the left-sided mirror image of the superior portion of the azygos vein. It drains the fifth to eighth posterior intercostal veins and occasionally the left bronchial veins, and usually terminates in the azygos vein after crossing the seventh thoracic vertebra. The first posterior intercostal vein drains directly into the left brachiocephalic vein, while the second to the fourth drain indirectly to the accessory hemiazygos vein via the left superior intercostal vein. The accessory hemiazygos vein may also join the hemiazygos vein. One or more prevertebral transversal anastomoses may be present.

## Variations of the azygos venous system

The origin, course, tributaries, anastomoses and termination of the azygos system of veins are all highly variable. The arrangement shown in Figure 56.2 represents the most common pattern with a right sided azygos vein. The left channel may be absent or underdeveloped, allowing direct drainage of the left intercostal veins into the azygos and/or the termination of the accessory hemiazygos into the left brachiocephalic vein. In such cases, the azygos vein is in median position.

## Internal thoracic arteries and veins

The internal thoracic vessels are described on pages 942 and 943 .

## Pulmonary arteries and veins

The pulmonary vessels are described on pages 959 and 960 .

## Posterior intercostal arteries and veins

The posterior intercostal veins accompany their arteries in eleven pairs; they are described on page 944

## Mediastinal lymph nodes

For the purposes of staging lung cancer, thoracic surgeons classify the mediastinal lymph nodes into regional lymph node stations, which are defined as shown in Table 56.1 and Figure 56.4.

These groups are not sharply demarcated. Pulmonary nodes become continuous with the bronchopulmonary nodes, and these, in turn, merge with the inferior and superior tracheobronchial nodes, which are continuous with the paratracheal group. The tracheobronchial nodes drain the lungs, bronchi, the thoracic part of the trachea, and heart, and also receive efferents from the posterior mediastinal nodes. Their efferent vessels ascend on the trachea to unite with efferents of the paraster-

nal and brachiocephalic nodes as the right and left bronchomediastinal trunks. The right trunk may occasionally join a right lymphatic duct or another right-sided lymph trunk, and the left trunk may join the thoracic duct, but usually they open independently in or near the ipsilateral jugulosubclavian junction (see Fig. 29.16).

In congenital interruption of the inferior vena cava or acquired thrombosis, the azygos system provides an alternative pathway for venous drainage. A higher than usual azygos arch may travel within an accessory azygos fissure (four pleural layers) and isolate a portion of the right upper lobe of the lung medially: the 'azygos lobe', which may rarely be radiopaque on a chest radiograph. An azygos lobe is rarely present and is rarely seen on chest radiographs. The azygos fissure often presents a nestled azygos vein as a lung 'pseudo-nodule' on a chest radiograph; it is typically comma-shaped and should not to be confused with a more rounded early lung carcinoma or metastasis.

Metastatic involvement of these lymph nodes has important prognostic implications and influences the choice of treatment (Mountain and Dresler 1997). The staging system for lung cancer classifies involvement of ipsilateral hilar lymph nodes as N1, ipsilateral mediastinal lymph nodes as N2, contralateral mediastinal or hilar nodes as N3 and supraclavicular/scalene nodes as M1 (distant metastases).

## Mediastinoscopy

The decision to proceed with mediastinoscopic biopsy depends on whether suitable nodal stations seem involved on CT scanning and whether there is a history of prior neck and mediastinal surgical procedures.

## THORACIC DUCT

The thoracic duct conveys the lymph from the entire body, except the right part of the head, neck and heart, right upper limb, right lung and part of the convex surface of the liver, back to the venous circulation. It usually originates anterior to the first or second lumbar vertebrae, where the intestinal and two lumbar lymph trunks join to form the cisterna chyli. (Both the thoracic duct and the cisterna chyli are variable in their origin, course and length; the latter is even more variable in width and shape than the thoracic duct.) From the superior aspect of the cisterna chyli, the thoracic duct passes through the aortic hiatus and enters the posterior mediastinum, lying to the right between the aorta and the azygos vein up to the level of the fifth thoracic vertebra, where it typically crosses over the vertebral column posterior to the oesophagus (see Fig. 56.7B). It continues upwards, first posterior to the aortic arch adjacent to the left side of the oesophagus, then posterior to the left subclavian artery in the superior mediastinum. It next arches over the subclavian artery and descends anteriorly to empty into the venous circulation in the region of the left jugular and subclavian veins, either at their very confluence or in proximity, sometimes in the left brachiocephalic vein (Fig. 56.5, p. 462). In the space between longus colli, the anterior scalene muscles and the pleural dome, the duct usually arches

Fig. 56.5 The thoracic and right lymphatic ducts. Note that the accessory hemiazygos vein is crossing the median plane lower and the hemiazygos higher than typically found.

3 or 4 cm superior to the clavicle, crossing anterior to the vertebral vessels, the left sympathetic trunk, the vertebral ganglion, the thyrocervical trunk and the left phrenic nerve.

In some patients, two thoracic ducts exist within the mediastinum, and occasionally a single thoracic duct may empty into rightsided venous structures, the latter disposition being more frequent in individuals with an aberrant right subclavian artery (the latter originating from the distal aortic arch ascending posterior to the oesophagus).

When present as a single channel, the thoracic duct is 5 mm in diameter at its origin, narrows to $2-3 \mathrm{~mm}$ at mid-thoracic level and then widens again at its termination. Alternatively, it may divide into two or three branches that eventually reunite or drain into both the left and right venous systems. The duct appears sinuous and has valves throughout its length; a bicuspid valve at its termination may prevent the backflow of blood. As it passes through the mediastinum, the thoracic duct also receives non-chylous lymph from tributaries that drain regions of the pulmonary parenchyma and parietal pleura. The sum of these sources accounts for a total lymphatic flow through the thoracic duct of 1500-2400 ml per day in proportion to the dietary intake of fat, particularly long-chain triglycerides.

The anatomy of the thoracic duct determines the location of the effusion seen with duct injury or obstruction.

## Tributaries of the thoracic duct

Some tributaries of the thoracic duct may terminate directly in the venous system. Numerous anastomoses exist between visceral, parietal, limb and mammary lymphatics, an arrangement that is manifest in observed multiple patterns of dissemination of cancer cells. Besides the cisterna chyli and its tributaries, bilateral ascending lumbar lymph trunks from the upper lateral aortic nodes pierce the corresponding diaphragmatic crus and eventually join the thoracic duct in the posterior mediastinum. The inferior six or seven intercostal lymph trunks from the corresponding bilateral intercostal nodes descend to terminate in the duct, either directly or by variable common trunks. The left upper intercostal lymphatics may join the cervical portion of the duct or the subclavian trunk. The left subclavian trunk usually joins the thoracic duct but may open independently into the left subclavian vein. These mediastinal trunks provide lymph drainage paths to the thoracic duct from the convex diaphragmatic aspect of the liver, the diaphragm, the pericardium, heart and oesophagus, and many possess terminal bicuspid valves. The left bronchomediastinal trunk occasionally joins the thoracic duct but usually has an independent venous termination. The left jugular trunk usually joins the thoracic duct but may open independently into the left internal jugular vein.

## Injury during oesophageal surgery

The variable origin, course and length of the thoracic duct, coupled with failure to identify it at surgery, may lead to its inadvertent incision or transection, particularly during trans-hiatal and thoracoscopic oesophageal surgery, with an incidence between 0.2 and 3\% (Wemyss-Holden et al 2001). Thoracic duct laceration is a potentially life-threatening complication; mortality rates are higher with conservative management but still elevated even after surgical ligation. Rupture of the thoracic duct leads to leakage of chyle, which is rich in lipid, protein, T lymphocytes (ranging from 400 to 6800 cells $/ \mu$ l), immunoglobulins and fat-soluble vitamins, and hence a progressive nutritional and immune deficit develops. Postoperative chylous effusions are usually the result of damage to ductal tributaries rather than to the duct itself, and are usually self-limiting. The greater incidence of injury with trans-hiatal resection may be attributable to shear forces during the mobilization of the distal oesophagus, whereas the limited field of view probably contributes to the greater incidence of thoracic duct injury during thoracoscopic surgery. Injury should be suspected in the postoperative period if there is either an enlarging mediastinal silhouette on serial chest radiographs or a significant milky drainage from the chest or abdominal drains. An electrophoretic confirmation of the presence of chylomicrons in the pleural fluid is diagnostic, amongst other tests. The thoracic duct may be injured during the left cervical approach for the exposure of the vertebral and subclavian arteries or the cervicothoracic (stellate) sympathetic ganglion. However, deliberate ligature of the duct at this level represents an accepted surgical manœuvre with no particular consequences.

## RIGHT LYMPHATIC TRUNK

The right lymphatic trunk has an inconstant anatomy (see Fig. 56.5). Its three main tributaries - the right jugular, subclavian and

Mediastinoscopy can be performed with video-assisted or direct optic visualization. A transverse incision is made in the suprasternal notch through the deep lamina of the deep cervical fascia after retraction of sternohyoid and sternothyroid within its superficial lamina. The pretracheal plane is dissected and a space is created between the anterior aspect of the trachea and the brachiocephalic trunk inferior to the carina and along both sides of the trachea and main bronchi. This space facilitates biopsy of the upper paratracheal $2 R / L$ stations, the right paratracheal 4R station and higher nodes from the left paratracheal 4L station superior to the aortic arch. Anterior subcarinal station 7 and bilateral hilar stations 10R/L may be accessible but are technically challenging. Nodes can be sampled or removed entirely for histological evaluation.

The anterior part of the superior mediastinum is more difficult to assess by mediastinoscopy and usually requires an anterior mediastinotomy (Chamberlain procedure). This is performed to biopsy nodes from the more inferior aspect of the left paratracheal 4 L station, subaortic station 5, para-aortic station 6 and subcarinal station 7, and also facilitates anterior mediastinal mass biopsy.

Complications of mediastinoscopy include haemorrhage, injury to the trachea or left recurrent laryngeal nerve, and pneumothorax.

Endobronchial ultrasound can be performed to biopsy lymph nodes in stations $1-4,7$ and $10-12$, using fine needle aspiration through the tracheal or bronchial walls. In a similar way, transoesophageal ultrasound may biopsy subcarinal station 7, para-oesophageal station 8 and pulmonary ligament station 9 nodes.

Because the thoracic duct crosses the mediastinum at, or at about, the level of the fifth thoracic vertebral body, lymphatic injury or obstruction above or below this level results in a left- or right-sided pleural effusion, respectively (Doerr et al 2001). Anomalies and sites of injury to the duct are identified by lymphangiography, with or without postprocedure CT scanning, or lymphoscintigraphy. Lymphangiography is performed using bilateral localization of pedal lymphatics with a subcutaneous injection of methylene blue, followed by a minor surgical procedure to cannulate the lymphatic vessel, and injection of Lipiodol contrast agent. Conventional plain films and CT images (without intravenous contrast) are then obtained. Lymphangiography can identify areas of chyle leakage and lymphangiectasia in the majority of patients (Deso et al 2012).
bronchomediastinal trunks - often terminate separately at the jugular and subclavian veins (see Fig. 29.16). In up to one-fifth of individuals, they may aggregate to form the right lymphatic trunk, usually $0.5-1 \mathrm{~cm}$ in length. The terminal portions of the right lymphatic trunk and of the thoracic duct are concealed by the scalene fat pad, which renders them more vulnerable during surgery.

## AUTONOMIC NERVOUS SYSTEM

The thoracic autonomic nervous system consists of the right and left ganglionated sympathetic chains and vagi, and the cardiac, pulmonary and oesophageal plexuses. The cardiac plexus is described on page 1021, the pulmonary plexus on page 961, and the oesophageal plexus is described below.

## THORACIC SYMPATHETIC TRUNK

The thoracic sympathetic trunk contains ganglia that are almost equal in number to those of the thoracic spinal nerves (usually 11, occasionally 12 , rarely 10 or 13 ) (Figs 56.6-56.7). Almost always, the first thoracic ganglion is fused with the inferior cervical ganglion, forming the cervicothoracic (stellate) ganglion; occasionally, the second thoracic ganglion is included in this fusion. The succeeding ganglia are counted in order to make them correspond numerically with the correlative segmental structures. Except for the second and lowest two or three, the thoracic ganglia lie against the costal heads, posterior to the costal pleura. The second thoracic sympathetic ganglion is commonly located in the second intercostal space, and the lowest two or three ganglia lie lateral to the bodies of the corresponding vertebrae. Inferiorly, the thoracic sympathetic trunk passes posterior to the medial arcuate ligament
or through the diaphragmatic crus to become the lumbar sympathetic trunk.

The ganglia are small and interconnected by intervening segments of the trunk. Unlike other mammalian species, including primates, each sympathetic ganglion in humans is connected to two consecutive spinal nerves: the corresponding and succeeding nerves. The classic description is that two or more rami communicantes, named white (myelinated, preganglionic) and grey (unmyelinated, postganglionic), connect each ganglion with its corresponding spinal nerve, the white rami joining the nerve distal to the grey.

Variation in this pattern is common, especially at the upper thoracic levels, but symmetry is rarely seen. Additional ascending and descending rami issue from the second ( $54 \%$ and $46 \%$, respectively), third ( $6 \%$ and $25 \%$ ) and fourth ganglia ( $5 \%$ and $8 \%$ ) (Cho 2005). Occasionally, a grey and a white ramus fuse to form a 'mixed' ramus. An inconstant intrathoracic ramus may join the second intercostal nerve to the ventral ramus of the first thoracic nerve proximal to the point where the latter issues a large branch to the brachial plexus (Kuntz 1927). This intrathoracic nerve of Kuntz is considered to carry sympathetic fibres to the brachial plexus without passing through the sympathetic trunk and has been held responsible for the recurrence of symptoms following sympathectomy. The anatomical variation exhibited by the communicating rami and the location of the second sympathetic ganglion may also contribute to surgical failure and symptom recurrence.

The medial branches from the upper five ganglia are very small, and may supply filaments in a retrograde manner to the thoracic aorta and its branches, as they pass to the cardiac plexuses (Kawashima 2011). Some fibres form a fine thoracic aortic plexus with filaments from the greater splanchnic and vagus nerves. Rami of the second to fifth or sixth ganglia enter the posterior pulmonary plexus. Small branches of these pulmonary and cardiac nerves pass to the oesophagus and trachea.

Fig. 56.6 The thoracic autonomic nervous system. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Fig. 56.7 The mediastinum. A, Right lateral aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Continued

The larger medial branches from the lower seven ganglia supply the aorta and then unite to form the greater, lesser and least splanchnic nerves (see below for variability).

The greater splanchnic nerve consists mainly of myelinated preganglionic efferent and visceral afferent fibres, and is formed by branches from the fifth to ninth or tenth thoracic ganglia; fibres in the upper branches may be traced to the first or second thoracic ganglia. Its roots vary from one to eight, four being the most usual number. It descends obliquely on the vertebral bodies, supplies branches to the descending thoracic aorta, and perforates the ipsilateral diaphragmatic crus to end mainly in the coeliac but partly in the aorticorenal ganglion and suprarenal (adrenal) gland. A splanchnic ganglion exists on the nerve opposite the eleventh or twelfth thoracic vertebra in a majority of individuals.

The lesser splanchnic nerve, formed by rami of the ninth and tenth (sometimes the tenth and eleventh) thoracic ganglia and the trunk between them, pierces the diaphragm with the greater splanchnic nerve and joins the aorticorenal ganglion.

The lowest (least) splanchnic nerve (or renal nerve) from the lowest thoracic ganglion enters the abdomen with the sympathetic trunk to end in the renal plexus.

The greater splanchnic nerve is always present, the lesser is usually present, and the least is often absent. A fourth (accessory) splanchnic nerve has been described.

## Thoracic sympathectomy

Endoscopic thoracic sympathectomy (ETS) is a surgical procedure used to relieve the symptoms of craniofacial, palmar or axillary hyperhidrosis, facial blushing, Raynaud's disease with digital ulcers, and reflex sympathetic dystrophy (shoulder-hand syndrome).

## VAGUS NERVE IN THE MEDIASTINUM

The vagus nerve contains preganglionic parasympathetic fibres that arise in its dorsal nucleus and travel in the nerve and in its pulmonary, cardiac, oesophageal, gastric and intestinal branches (see Fig. 56.6). Vagal fibres that originate from neurones in the nucleus ambiguus are distributed to the constrictor muscles of the pharynx and the intrinsic muscles of the larynx. The proportion of efferent parasympathetic fibres in the vagus varies at different levels but is small relative to its sensory and sensorimotor content. Efferent fibres relay in minute ganglia in the visceral walls.

Cardiac branches join the cardiac plexuses and relay in ganglia that are distributed freely over both atria in the subepicardial tissue. The terminal fibres are distributed to the atria and the atrioventricular bundle; they are concentrated around the sinu-atrial and, to a lesser

ETS may be beneficial to ameliorate cerebral vascularization in patients with moyamoya disease and to treat migraine, hyperactive bronchial states, long QT syndrome, causalgic pain, erythromelalgia, Buerger's disease, Prinzmetal's angina, and chronic non-infectious rhinitis. ETS is also effective in frostbite injury, especially if performed within 36-72 hours of cold exposure.

The operation involves making tiny incisions posterior to the pectoral fold in the axilla, and insufflating a small amount of carbon dioxide into the thoracic cavity to allow access with a modified thoracoscope. In the treatment of facial blushing, it is sufficient to divide the fibres that run superiorly from the second thoracic ganglion over the neck of the second rib, leaving the second ganglion almost intact. Treatment of palmar hyperhidrosis requires ablation thermocoagulation of the sympathetic trunk over the necks of the third and fourth ribs, taking care to avoid any spreading of thermal energy along the trunk in order to avoid damaging the more superior stellate ganglion (see 'Horner's syndrome' below). The risk of compensatory sweating is greatly reduced, though not completely excluded, by limiting the number of ganglia treated to an absolute minimum. As an additional procedure, dividing the inconstant sympathetic pathways (nerve of Kuntz, ascending or descending additional rami communicantes) on the second, third and fourth ribs may improve surgical outcomes.

The effect is immediately evident: the patient awakes from anaesthesia with dry, warm hands. In many cases, even hyperhidrosis of the feet improves, but the underlying anatomical/physiological mechanisms are not yet properly understood (Gofeld and Faclier 2006). Surgical complications are very rare; Horner's syndrome is the most feared, and is caused by damage to the stellate ganglion and interruption of the sympathetic fibres from C8-T1, which ascend around the arteries supplying the head and neck (see pp. 468, 469 and Fig. 29.18). Side-effects include compensatory sweating (ranging from barely noticeable to quite disturbing) in other locations of the body on exercise or from exposure to high temperatures in up to $70 \%$ of patients. Severe in $5 \%$ of patients, it may be more frequent in those with axillary hyperhidrosis (when two more inferior ganglia have to be divided); some surgeons do not now consider isolated axillary hyperhidrosis as an indication for this procedure. Gustatory or olfactory sweating may also occur in up to one-third of patients but is rarely considered a problem. Other documented side-effects are the inability to raise the heart rate when working out physically; in some cases, this has led to decreased ability to perform work and daily activities. Some patients also experience an uncomfortable sensation of not being able to control their body temperature.

Fig. 56.7, cont'd The mediastinum. B, Left lateral aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
extent, the atrioventricular nodes (Ch. 57). Cardiac branches slow the heart rate and diminish the force of contraction. It has been claimed that the vagi indirectly influence ventricular muscle via their effect on the atrioventricular node, the postganglionic parasympathetic innervation of the ventricles being sparse. The smaller branches of the coronary arteries are innervated mainly via the vagus, whereas the larger arteries are mainly supplied by sympathetic fibres. Regional patterns of innervations may explain some particular forms of cardiomyopathies such as apical ballooning (Takotsubo cardiomyopathy). Pulmonary branches are motor to the circular smooth muscle fibres of the bronchi and bronchioles, and are therefore bronchoconstrictor; synaptic relays occur in the ganglia of the pulmonary plexuses.

The distribution of the vagi to the abdominal viscera is described in the relevant chapters.

## Right vagus

The right vagus nerve descends posterior to the internal jugular vein in the neck (p. 466) and crosses the first part of the subclavian artery to enter the thorax; the ansa subclavia is lateral, and the phrenic nerve is further lateral. It then descends through the superior mediastinum, at first posterior to the right brachiocephalic vein, and then to the right of the trachea and posteromedial to the superior vena cava. Superiorly, the right pleura and lung are lateral; inferiorly, the azygos vein and its arching terminal portion separate the right vagus from the lung and pleura (see Fig. 56.7A). The nerve next passes posterior to the right main
bronchus and lies on the posterior aspect of the right pulmonary hilum. Here, it gives off posterior bronchial branches that unite with rami from the second to fifth or sixth thoracic sympathetic ganglia to form the right posterior pulmonary plexus. Two or three branches descend from the inferior part of this plexus on the posterior aspect of the oesophagus to join a left vagal branch and form the posterior oesophageal plexus. A vagal trunk containing fibres from both vagi leaves the plexus and runs inferiorly on the posterior surface of the oesophagus, entering the abdomen by passing through the diaphragmatic oesophageal aperture.

## Left vagus

The left vagus enters the thorax posterior to the left brachiocephalic vein, between the left common carotid (anterior) and the subclavian arteries (posterior). It descends through the superior mediastinum and crosses the left side of the aortic arch, passing posterior to the left pulmonary hilum (see Fig. 56.7B). Superior to the aortic arch, it is crossed anterolaterally by the left phrenic nerve; on the arch, it is crossed by the left superior intercostal vein. Posterior to the left hilum, it divides into the posterior bronchial branches, which unite with rami of the second to fourth thoracic sympathetic ganglia to form the left posterior pulmonary plexus. Two or three branches descend anteriorly on the oesophagus and join with a ramus from the right posterior pulmonary plexus to form the anterior oesophageal plexus. A trunk containing fibres from both vagi descends anterior to the oesophagus and enters the abdomen
through the oesophageal diaphragmatic aperture. Numerous branches from the anterior vagal and left sympathetic trunks are distributed to the descending thoracic aorta. This pathway transmits the typical intense, excruciating pain of an intramural aortic haematoma from dissection or laceration.

## THYMUS

The thymus and the bone marrow are the two primary lymphoid organs. The thymus is an encapsulated soft, bilobed organ; the two parts are joined in the midline by connective tissue that merges with the capsule of each lobe (Figs 56.8-56.9). Capsular tissue may have adhesions to the fibrous pericardium, which is thinner superiorly and may either easily tear or require a limited pericardotomy during thymectomy. The thymus is visible on CT and magnetic resonance imaging (MRI) just anterior to the ascending aorta and inferior to the left brachiocephalic vein. CT attenuation in younger individuals is homogeneous, greater than that of the chest wall and cardiac muscles below the age of 1 year, and similar to that of these muscles after the age of 1 year (Sklair-Levy et al 2000); the signal intensity with MRI on $\mathrm{T}_{2}$-weighted images is similar to or greater than that of fat. The decline in CT attenuation with age is secondary to fatty infiltration.

## Relations

The thymus is largest in the early part of life, particularly around puberty, and persists actively into old age despite considerable fibrofatty degeneration that sometimes hides the existence of persistent thymic tissue. The greater part of the thymus lies in the superior and anterior mediastina; the inferior aspect of the thymus reaches the level of the fourth costal cartilages. In some children, the thymus has been described

Fig. 56.8 The neonatal thymus.

Fig. 56.9 A thymus from a 9 -year-old female (left) and one from an 80-year-old male (right). Note the fibrofatty infiltration of the older thymus. (Courtesy of Professor M Kendall.)
as encircling the left innominate vein (Han et al 1989). Superiorly, extensions into the neck are common, reflecting its bilateral embryonic origins from the third pharyngeal pouch (p. 619, see Fig. 36.18). Its superior poles join at, and extend above, the level of the suprasternal notch; the left usually extends higher and is seen first behind the strap muscles during the initial stages of transcervical thymectomy. It sometimes reaches the inferior poles of the thyroid gland or even higher, and is connected to the thyroid gland by the thyrothymic ligament. Its shape is largely moulded by adjacent structures. Inferiorly, the right lobe commonly lies between the right side of the ascending aorta and the right lung, anterior to the superior cava. Anteriorly, from superior to inferior, lie sternohyoid and sternothyroid, cervical fascia, the manubrium sterni, internal thoracic vessels and upper three costal cartilages. The pleurae lie laterally and the phrenic nerves are anterolateral and inferior; both structures may be injured during thymectomy. Posteriorly, the thymus is in contact with the vessels of the superior mediastinum (the left brachiocephalic vein and the inferior thyroid veins are usually partly embedded in the gland), the superior part of the thoracic trachea and the anterior cardiac surface (right atrium and ventricle). Thoracic surgeons performing thymectomy must be aware of the anatomical variation in which the upper poles may lie posterior to the left brachiocephalic vein.

Separated thymic tissue is often found scattered around the gland, and ectopic thymic rests are sometimes discovered in unusual mediastinal locations. Small accessory nodules may occur in the neck, representing separated portions, detached during embryological descent, and sometimes reaching more superiorly than the thyroid cartilage. Ectopic intrathyroidal thymi have been reported in children (Segni et al 2011).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

Thymic branches originating from the internal thoracic, inferior and sometimes superior thyroid arteries supply the thymus and the surrounding mediastinal connective tissue. As no definite hilum exists, the arterial branches either travel along the interlobar septa before entering the thymus at the junction of the cortex and medulla, or they reach the thymic tissue directly through the capsule.

## Veins

Thymic veins drain to the left brachiocephalic, internal thoracic and inferior thyroid veins, and occasionally directly into the superior vena cava. One or more veins often emerge medially from each lobe of the thymus to form a common trunk opening into the left brachiocephalic vein and require careful ligation during thymectomy.

## Lymphatic drainage

The thymus has no afferent lymphatics. Efferent lymphatics arise from the medulla and corticomedullary junction, drain through the extravascular spaces, accompany the supplying arteries and veins, and end in the brachiocephalic, tracheobronchial and parasternal nodes.

## INNERVATION

The thymus is innervated from the sympathetic chains via the cervicothoracic (stellate) ganglia or ansa subclavia and from the vagi. Branches from the phrenic and descending cervical nerves (inferior roots of the ansa cervicalis) are distributed mainly to the capsule. The two lobes are innervated separately through their dorsal, lateral and medial aspects. During development and before its descent into the thorax, the thymus is innervated by the vagi in the neck. After its descent, the thymus receives a sympathetic innervation via fibres that travel along the vessels; postganglionic sympathetic terminations branch radially and form a plexus with the vagal fibres at the corticomedullary junction.

## MICROSTRUCTURE

The thymus is responsible for the provision of thymus-processed (T) lymphocytes to the entire body, and provides a unique microenvironment in which thymocytes (T-cell precursors) undergo development, differentiation and clonal expansion to deliver the exquisitely specific

The roles of the nervous system and other neuroendocrine elements in the overall biology of the thymus are little understood. Many of the autonomic nerves are doubtless vasomotor, but other terminal branches (at least in rodents) ramify among the cells of the thymus, particularly the medulla, suggesting that they may have other roles. Innervation is complete by the onset of thymic function. The medulla contains a number of different types of non-lymphoid cells, including cells positive for vasoactive intestinal polypeptide and acetylcholinesterase; large non-myoid cells; and cells containing oxytocin, vasopressin and neurophysin, of possible neural crest origin.

Fig. 56.10 Thymic structure and cellular organization, showing an interlobular septum, the cortical circulation and thymocytes within an epithelial framework.

T-cell response, simultaneously acquiring immune tolerance to the body's own components. These steps involve intimate interactions between thymocytes, mainly epithelial and antigen-presenting cells and chemical factors in the thymic environment. The thymus is also part of the neuroimmunological and neuroendocrine axes of the body, influenced by and influencing the products of these axes. Its activity therefore varies throughout life under the influence of different physiological states, disease conditions and chemical insults, such as hormones, drugs and pollutants. The thymus appears to be most active between the ages of 3 and 6 months, when the highest number of total thymocytes are present (Weerkamp et al 2005).

## General architecture

It is useful to consider the embryological origins of the thymus in order to understand its cellular organization. It is derived from a number of sources, including epithelial derivatives of the pharyngeal pouches, mesenchyme, haemolymphoid cells and vascular tissue. In section, the thymus can be seen to consist of an outer cortex of densely packed thymocytes (T-cell precursors) and an inner medulla with fewer lymphoid cells (Fig. 56.10). Both thymic lobes have a loose, fibrous connective tissue capsule, from which septa penetrate to the junction of the cortex and medulla, and partially separate the irregular lobules, which are each $0.5-2.0 \mathrm{~mm}$ in diameter (see Fig. 56.12). The connective tissue septa form a route of entry and exit for blood vessels and nerves, and carry efferent lymphatics. Most migrant cells enter or leave the thymus by this route. In each lobule, the cortex is composed of a superficial subcapsular cortex (a narrow band of cells immediately beneath the capsule) and a more extensive main cortex. The central medulla of both thymic lobes is continuous from one lobule to the next.

## Epithelial framework

Unlike other lymphoid structures, in which the supportive framework is chiefly collagenous reticular tissue, the thymus contains a network of interconnected epithelial cells (see Fig. 56.10) that create an appropriate microenvironment, by cell-to-cell contact and the release of paracrine factors, in which thymic lymphocytes ( T cells) develop and mature. Although differing in morphology, all the epithelial cells of the thymus share a common origin from pharyngeal endoderm. They vary in size and shape, according to their positions within the thymus. Typically, they have pale, oval nuclei, a rather eosinophilic cytoplasm and intercellular desmosomal attachments. Intermediate filament bundles of cytokeratin lie within their cytoplasm. The subcapsular cells form a continuous external lining to the thymus, following its lobulated profile, ensheathing the penetrating vessels, and contributing to the blood-thymus barrier. Other cortical epithelial cells form a loose mesh

Fig. 56.11 The medulla of a neonatal thymus, showing three concentric Hassall's corpuscles of varying degrees of maturity, surrounded by closely packed lymphocytes and a few epithelial cells with larger nuclei.
of long cytoplasmic processes, whereas medullary epithelial cells tend to form more solid cords and Hassall's corpuscles. Lymphocytes lie within the interstices of the mesh or between the cords. Large epithelial 'nurse' cells may be associated with around 50 or more thymocytes.

Hassall's corpuscles are whorls of flattened, concentrically layered cells, $30-100 \mu \mathrm{~m}$ in diameter, that characterize the thymic medulla (see Fig. 56.10; Fig. 56.11). Originating prenatally, and increasing in number throughout life, they perhaps remove dying thymocytes because their centres are eosinophilic and partly keratinized, and often contain cellular debris. Corpuscles with a similar appearance have been described in the palatine tonsil. (For further reading, see Raica et al (2006), Asghar et al (2012).)

## Other non-lymphocytic thymic cells

The thymus also contains cells of the myeloid, fibroblastic and myoid lineages. Myeloid lineage cells include monocytes at the corticomedullary junction, mature macrophages throughout but particularly in the cortex, and interdigitating dendritic (antigen-presenting) cells at the corticomedullary junction and in the medulla. Some dendritic cells are of lymphoid rather than myeloid origin (see Fig. 4.12). Fibroblasts are found in the capsule, perivascular spaces and medulla but are infrequent in the cortex, except in the involute thymus. Myoid cells, which are relatively rare, are situated mainly in the medulla and at the corticomedullary junction. They are large, rounded cells possessing a central nucleus surrounded by irregularly arranged bundles of myofilaments with unknown function, although it has been suggested that their contractions might aid the movement of lymphoid cells across or out of the thymus.

## Thymocytes

The cortex is densely packed with small thymocytes (thymic lymphocytes, presumptive T cells; see Ch. 4). They occupy the interstices of the epithelial reticulum, which they largely obscure in histological sections, and form $90 \%$ of the total weight of the neonatal thymus. A distinct subcapsular zone houses the thymic stem cells and lymphoblasts undergoing mitotic division. The first stem cells to enter the thymus in the embryo come from the yolk sac and liver during their haemopoietic phases. During later developmental periods, it is probable that all thymic lymphocytes originate in the bone marrow before passing in the blood stream to the thymus.

Thymocytes undergo mitosis in all cortical zones as the differentiating T cells mature, gradually moving deeper into the cortex (Fig. 56.12). The processes of thymocyte development and maturation to generate $T$ cells depend on the microenvironment provided by epithelial cells, dendritic cells, macrophages and fibroblasts. T cells that either fail to recognize self-MHC (histocompatibility) molecules or that recognize self-antigens die by apoptosis, in order to achieve functional immune reactivity and maintain self-tolerance, respectively. Over 95\% of cortical thymocytes die within the thymus; the surviving T cells migrate through the walls of venules and efferent lymphatics to enter the circulation and populate secondary lymphoid tissues (for further details of thymocyte development, see p. 76).

Fig. 56.12 The microscopic organization of the thymus at various stages of life and under different conditions. Abbreviations: APC, antigen-presenting cell; $\mathrm{T}_{3}$, tri-iodothyronine hormone.

## Microcirculation

## Cortex

The pattern of blood flow differs in the cortex and medulla. Major blood vessels enter the gland at the corticomedullary junction and pass within each lobe, giving off small capillaries to the cortex and larger vessels to the medulla. Most cortical capillaries loop around at different depths in the cortex and join venules at the corticomedullary junction; some continue through the cortex and join larger venules running in the capsule that leave the thymus. Sheaths of thymic epithelial cells of the blood-thymus barrier lie between the narrow perivascular space of the smaller cortical capillaries and cortical thymocytes (Henry et al 1992). This perivascular space sometimes contains pericytes and, rarely, neurones.

## Medulla

Medullary blood vessels are not as well protected by epithelial cells, and those of the corticomedullary junction are only partially ensheathed, usually on their cortical aspect. Medullary vessels are very variable in size; some have short lengths of cuboidal endothelium similar to those in lymph nodes and mucosa-associated lymphoid tissue (MALT; p. 75).

## DEVELOPMENT

The embryology and prenatal development of the thymus are described on page 619 .

## Thymic changes during postnatal life

At birth, the thymus is most often bilobar and is $4-6 \mathrm{~cm}$ long, $2.5-5 \mathrm{~cm}$ wide and 1 cm thick. The bulkiest part of the gland at this age is immediately above the base of the heart where it covers the phrenic nerves laterally; the protection of these nerves is mandatory during paediatric cardiac surgery procedures. The left lobe is longer and thicker than the right lobe in full-term neonates (Varga et al 2011); during childhood, the thymus narrows and lengthens, and the cervical portion becomes less noticeable. Imaging studies of the thorax in normal children reveal that the right lobe of the thymus typically measures 9 mm in thickness and the left 11 mm . After the age of 20 years, it decreases to $5-6 \mathrm{~mm}$ in thickness (see Fig. 56.12).

The thymus is largest relative to body mass at birth, weighing $10-15 \mathrm{~g}$. It is typically larger in boys than girls at 6 months of age (Garly et al 2008). Studies of thymic mass after sudden death have recorded a wide variation at all ages, but the general pattern is that, after increasing in the first year of life, the mean mass remains fairly constant at 20 g until the sixth decade, when a reduction occurs. At birth, individual adipocytes are present in connective tissue septa, and increased numbers are found within the cortex in the second and third decades. Fatty infiltration is usually complete by the fourth decade, when only the medulla and small patches of associated cortex are spared. This process is independent of body mass index (BMI).

In children, the gland is more pyramidal in shape and firmer than in later life, when the amount of lymphoid tissue is greatly reduced. In the fresh state, it is deep red, reflecting its hypervascularity (see Fig. 56.9). With age, it becomes thinner, greyer and increasingly infiltrated by yellow adipose tissue. Each of the two lobes is partially divided by the ingrowth of shallow septa, so that, superficially, the gland appears lobulated. As fatty atrophy proceeds, this lobulation becomes more distinct. The older thymus may be distinguished from the surrounding mediastinal fat only by the presence of its capsule. However, even greatly atrophied glands usually contain perivascular areas of persistent lymphoid tissue. Thymocyte production and differentiation persist throughout life, and thymic T cells continue to populate peripheral lymphoid tissue, blood and lymph.

## Congenital anomalies of the thymus

Undescended thymus, accessory thymic bodies and rare cysts of the third branchial pouch are usually of no clinical significance in isolation. Patients with thymic agenesis, aplasia and hypoplasia, as in severe combined immune deficiency disease (SCID), have reduced lymphocyte numbers, and early death from infection is common. Most cases are familial, with autosomal recessive genes. In young children, a large normal thymus may press on the trachea, causing attacks of ventilatory stridor. This condition must be differentiated from other congenital conditions such as vascular rings and slings that require surgical correction.

## THYMECTOMY

The thymus is essential for the normal development of lymphoid tissues during neonatal and early postnatal life. Thymectomy during
this period results in hypoplasia of the peripheral lymphoid organs, wasting and an inability to mount an effective immune response; it is ultimately fatal. By the onset of puberty, when the main lymphoid tissues are fully developed, thymectomy is less debilitating, but effective responses to novel antigens are reduced.

Thymectomy is commonly performed for myasthenia gravis, usually after referral from a neurologist. The most beneficial effects of thymectomy are seen in myasthenic females who present with systemic muscular weakness; controversial operative groups include the elderly and those with isolated ocular symptoms.

## Thymoma and myasthenia gravis

## OESOPHAGUS

The oesophagus is a muscular tube, 25 cm long in the adult, that connects the pharynx to the stomach (see Figs 56.4, 56.6; Figs 56.1356.14). Beginning in the neck, level with the lower border of the cricoid cartilage and the sixth cervical vertebra, it descends largely anterior to the vertebral column through the superior and posterior mediastina, passes through the diaphragm, level with the tenth thoracic vertebra,
and ends at the gastric cardiac orifice, level with the eleventh thoracic vertebra.

Generally vertical in its course, the oesophagus normally displays two shallow curves. Starting in the median plane, it inclines to the left as far as the root of the neck, gradually returns to the median plane near the fifth thoracic vertebra, then deviates leftwards again at the seventh thoracic vertebra before piercing the diaphragm. The oesophagus also deviates sagittally as it follows the cervicothoracic vertebral lordosis. Further inferiorly, it is pushed slightly to the right by the aorta before resuming its leftward course towards the oesophageal hiatus. It is the second narrowest part of the alimentary tract (the narrowest is the vermiform appendix) and is constricted at its start ( 15 cm from the incisor teeth, as measured during oesophagoscopy); where it is crossed anteriorly by the aortic arch ( 23 cm from the incisor teeth, as measured during oesophagoscopy) and by the left principal bronchus ( 28 cm from the incisor teeth, as measured during oesophagoscopy); and as it passes through the diaphragm ( 40 cm from the incisor teeth, as measured during oesophagoscopy). In children, the length of the oesophagus correlates best with height (Yang et al 2005).

## CERVICAL OESOPHAGUS

The cervical portion of the oesophagus is posterior to the trachea and attached to it by loose connective tissue. The recurrent laryngeal

Fig. 56.13 The oesophagus. A, Anterior view. B, Posterior view. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Thymectomy is performed through a transcervical approach or a sternotomy，the choice of approach depending on the size and disposi－ tion of the diseased gland．The cervical approach involves a lower transverse incision that includes the sternal heads of both sternocleido－ mastoids，permitting an improved access to the substernal plane．Ster－ nothyroid and sternohyoid are separated and the superior poles of the thymus are identified immediately underneath these muscles．A safe pre－thymic plane is created by blunt dissection just posterior to the sternum，facilitating subsequent mobilization of the gland．The media－ stinal great vessels and the thymic vessels must be carefully identified． The thymic veins are selectively ligated and divided，especially those draining directly into the superior vena cava or the left brachiocephalic vein．The smaller arterial branches from the internal thoracic arteries are usually dealt with using electrocautery，care being taken to avoid injury to the phrenic nerves（patients are generally not given a paralytic agent during anaesthesia，in order for the phrenic nerves to be identified intraoperatively）．The thymus generally remains completely encapsu－ lated and is separated without difficulty from the pericardium（occa－ sionally，adhesions necessitate a limited pericardiectomy）．Further inferiorly，a gentle push on the great vessels allows direct visualization into the aortopulmonary window for complete removal of the thymus in this vicinity．

In most cases，the thymus gland is removed completely with both upper and lower poles intact．Careful inspection of the remaining tissue in the mediastinum is performed to identify any possible anatomical anomalies that might result in retained thymic tissue after the opera－ tion．The most common anomaly is the unanticipated location of the upper poles of the thymus behind the left brachiocephalic vein．The aortopulmonary window is also a common location for thymic tissue and this area is sometimes difficult to expose with a transcervical approach．Any suspicious foci of fat in the mediastinum are removed， and，if necessary，sent for frozen section to ascertain whether or not they contain thymic tissue．

Thymic tumours may compress the trachea，oesophagus and large veins in the neck，causing hoarseness，cough，dysphagia and venous engorge－ ment of the head and neck．Thymomas tend to have a heterogeneous signal intensity on MRI，often developing in one lobe of the thymus without affecting the other．Many affected patients also have myasthe－ nia gravis and other autoimmune conditions．Myasthenia gravis，a chronic autoimmune disease of adults，presents as a diminution in power of repetitive contraction in certain voluntary muscles．Although there may be more than one condition with these signs，myasthenia gravis is essentially an autoimmune disease in which acetylcholine receptor proteins of neuromuscular junctions are attacked by autoanti－ bodies．Muscles commonly involved are levator palpebrae superioris， leading to ptosis，and the extraocular muscles，leading to diplopia． Other muscles in the face，jaws，neck and limbs may be involved，and in severe cases，the ventilatory muscles are compromised．Occasional Caucasian individuals with myasthenia gravis have a thymoma and some have medullary follicular hyperplasia；the latter are predomi－ nantly females younger than 40 years of age with strong expression of HLA－B8－DR3，in whom thymectomy often results in symptomatic improvement．In the absence of a thymoma，the onset of myasthenia gravis occurs after 40 years of age in patients with an HLA－B7－DR2 phenotype，except for a group in whom weaknesses are restricted to eye and eyelid movements．

Fig. 56.14 The oesophagus, anterior view. A, Arterial blood supply. B, Venous drainage. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
nerves ascend on each side in or near the tracheo-oesophageal groove. Posteriorly are the vertebral column, longus colli and the prevertebral layer of deep cervical fascia. Laterally, on each side, are the common carotid arteries and the posterior part of the thyroid gland. In the lower neck, where the oesophagus deviates to the left, it is closer to the left carotid sheath and thyroid gland than it is on the right. The thoracic duct ascends for a short distance along its left side (see Figs 56.5, 56.7B).

## THORACIC OESOPHAGUS

The thoracic oesophagus (see Figs 56.13-56.14) is situated a little to the left in the superior mediastinum between the trachea and the vertebral column. It passes behind and to the right of the aortic arch to descend in the posterior mediastinum along the right side of the descending thoracic aorta. Below, as it inclines left, it crosses anterior to the aorta and enters the abdomen through the diaphragm at the level of the tenth thoracic vertebra. From above downwards, the trachea, right pulmonary artery, left principal bronchus, pericardium (separating it from the left atrium) and the diaphragm are anterior. The vertebral column, longus colli, right posterior intercostal arteries, thoracic duct, azygos vein and the terminal parts of the hemiazygos and accessory hemiazygos veins, and, near the diaphragm, the aorta are posterior. A long recess of the right pleural sac lies between the oesophagus anteriorly and the azygos vein and vertebral column posteriorly in the posterior mediastinum (the azygo-oesophageal recess).

In the superior mediastinum, the terminal part of the aortic arch, left subclavian artery, thoracic duct, left pleura and the recurrent laryngeal nerve are left lateral relations. In the posterior mediastinum, the oesophagus is related to the descending thoracic aorta and left pleura. The right pleura and the azygos vein, as it arches forwards above the right main bronchus to join the superior vena cava, are right lateral relations. Below the pulmonary roots, the vagus nerves descend in contact with the oesophagus, the right mainly behind and the left in front; the vagi subsequently unite to form a plexus around the oesophagus. Low in the posterior mediastinum, the thoracic duct is posterior and to the right of the oesophagus; at higher levels, the duct is posterior, crossing to the left of the oesophagus at about the level of the fifth thoracic vertebra, then ascending on the left.

On the right of the oesophagus, just above the diaphragm, a small, serous infracardiac bursa may occur, representing the detached apex of the right pneumatoenteric recess.

The close relationship between the oesophagus, the heart and the aorta constitutes the anatomical basis of transoesophageal cardiovascular ultrasonography. Aortic dissection may be seen in the descending thoracic aorta in cases of equivocal CT and MRI.

## ABDOMINAL OESOPHAGUS

The abdominal oesophagus is described in Chapter 64.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The cervical oesophagus is supplied by the inferior thyroid artery (see Fig. 56.14, p. 458). The thoracic oesophagus is supplied by bronchial and oesophageal branches of the thoracic aorta (see Fig. 56.14A). Four or five oesophageal branches arise from the anterior surface of the aorta and descend obliquely to the oesophagus, where they form a vascular chain that anastomoses above with the oesophageal branches of the inferior thyroid arteries, and below with ascending branches from the left phrenic and left gastric arteries. Extensive devascularization of the oesophagus may lead to acute oesophageal necrosis as in aortic dissection (van der Wal-Visscher et al 2011).

## Veins

Blood from the oesophagus drains into a submucous plexus and thence into a peri-oesophageal venous plexus, from which the oesophageal veins arise. Those from the thoracic oesophagus drain predominantly into the azygos veins and, to a lesser extent, the hemiazygos, intercostal and bronchial veins (see Fig. 56.14B). Those from the cervical oesophagus drain into the inferior thyroid vein. The left gastric vein meets the lower oesophageal veins at the oesophageal opening in the lesser curvature, one of the sites of porto-caval venous anastomoses where variceal transformation can occur in portal hypertension (see below).

## Oesophageal varices

Cirrhosis or fibrosis of the liver affects the vascular tree within the liver, resulting in a decrease of hepatic vascular compliance, and a likely increased vascular tone reflecting a reduction in endothelial vasodilators such as nitric oxide. The portal resistance increases, leading to the formation of a collateral circulation, and there is a concomitant increase in the systemic and splanchnic blood flow. Porto-systemic shunting of blood occurs between the short gastric coronary veins and the oesophageal veins, largely as the result of the dilation of pre-existing embryonic channels.

## Lymphatic drainage

The oesophagus has an extensive, longitudinally continuous submucosal lymphatic system, which presumably explains remote paraoesophageal lymphadenopathy in oesophageal carcinoma. Efferent vessels from the cervical oesophagus drain to the deep cervical nodes either directly or through the paratracheal nodes. Vessels from the thoracic oesophagus drain to the posterior mediastinal nodes and those from the abdominal oesophagus drain to the left gastric lymph nodes. Some may pass directly to the thoracic duct.

## INNERVATION

The upper oesophagus is supplied by the branches of the recurrent laryngeal nerve and by postganglionic sympathetic fibres that reach it by travelling along the inferior thyroid arteries. The lower oesophagus is supplied by the oesophageal plexus, a wide-meshed autonomic network that surrounds the oesophagus below the level of the lung roots, and contains a mixture of parasympathetic and sympathetic fibres (see Fig. 56.6).

Motor fibres to the striated and smooth muscle of the oesophageal wall travel in the vagus. Axons derived from neuronal cell bodies in the nucleus ambiguus travel via the recurrent laryngeal nerve and supply cricopharyngeus and the striated muscle of the upper third of the oesophagus. Axons with cell bodies in the dorsal nucleus of the vagus pass through the oesophageal plexus and supply the smooth muscle that makes up the lower two-thirds of the oesophagus, after local relay in the oesophageal wall. Other branches are given off by the vagus as it travels through the mediastinum, and pass directly to the oesophagus. The vagus also carries secretomotor fibres to mucous glands in the oesophageal mucosa, and visceral afferent (sensory) fibres to cell bodies in its inferior ganglion.

Vasomotor sympathetic fibres destined for the oesophagus arise from the upper 4-6 thoracic spinal cord segments. Those from the upper ganglia pass to the middle and inferior cervical ganglia, where they synapse on postganglionic neurones that give rise to axons that innervate the vessels of the cervical and upper thoracic oesophagus. Those from the lower ganglia pass either directly to the oesophageal plexus or to the coeliac ganglion (via the greater splanchnic nerve), where they synapse; postganglionic axons innervate the distal oesophagus. Afferent visceral pain fibres travel via the sympathetic fibres to the first four segments of the thoracic spinal cord. Because these segments also receive cardiac afferents, it is sometimes difficult to distinguish between oesophageal and cardiac pain.

## MICROSTRUCTURE

The tissues forming the thoracic oesophageal wall, from the lumen outwards, are the mucosa (consisting of epithelium, lamina propria and muscularis mucosae), submucosa, muscularis externa and adventitia (Fig. 56.15).

## Mucosa

The mucosa is thick. At the gastro-oesophageal junction, a jagged boundary line separates the greyish-pink smooth oesophageal mucosa from the reddish-pink gastric mucosa, the latter covered by minute bulges and depressions. Throughout its length, the oesophageal lumen is marked by deep longitudinal grooves and ridges, which disappear when the lumen is distended, otherwise obliterating it.

## Epithelium

The epithelium is non-keratinized, stratified squamous, and is continuous with that of the oropharynx. In humans, this protective layer is quite thick $(300-500 \mu \mathrm{~m})$ and is not affected by oesophageal disten-

Fig. 56.15 The wall of the oesophagus. A stratified squamous, nonkeratinizing epithelium lines the lumen (right). Submucosal glands (G) in the submucosa (SM) secrete mucus that lubricates the passage of food. (With permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby.)
sion. The boundary between the oesophageal epithelium and its lamina propria is distinct but markedly uneven due to tall connective tissue papillae invaginating the epithelial base, assisting in the anchorage of the epithelium to underlying tissues (see Fig. 56.15). These papillae are permanent structures, also unaffected by oesophageal distension, and they are rich in blood vessels and nerve fibres. At the base of the epithelium, there is a basal lamina, to which epithelial cells are attached by hemidesmosomes, as occurs in the oral mucosa.

Oesophageal epithelium is similar to other stratified squamous epithelia. It can be divided into a basal, proliferative layer, a parabasal layer of cells undergoing terminal differentiation and a flattened layer of superficial cells or squames that retain their nuclei. The most superficial strata of cells contain a few keratohyalin granules, in addition to keratin filaments. The epithelial cell population is constantly renewed by mitosis in the cuboidal basal and deepest parabasal cells; as they migrate towards the lumen, they become progressively polygonal and then more flattened, eventually desquamated at the epithelial surface. This sequence of events normally takes $2-3$ weeks, and is markedly slower than in the stomach and intestine.

The epithelium is an effective protection against mechanical injury during swallowing because of its thickness and the presence of mucus at its surface. However, protection is limited by repeated exposure to the strongly acidic, protease-rich secretions of the stomach, as occurs abnormally during reflux. Failure of the lower oesophageal sphincter allowing reflux results in ulceration and fibrosis, accompanied by dysphagia/odynophagia, with possible epithelial metaplasia to a gastric-like mucosa (Barrett's mucosa), or to more overt neoplastic changes.

Langerhans cells Langerhans cells are present in the oesophageal epithelium. They are immature dendritic cells and resemble those found in the epidermis. They perform similar antigen-processing and antigen-presenting roles, which are important in immunostimulation of naïve T cells and mucosal defence.

## Lamina propria

The oesophageal lamina propria contains scattered groups of mucosaassociated lymphoid tissue (MALT), especially prominent near the gastro-oesophageal junction. Small tubular mucous glands occur in this region and also at the oesophago-pharyngeal junction.

Varices in the distal oesophagus are easily visible at endoscopy because they are situated superficially in the lamina propria．The blood from the superficial veins drains into a superficial venous plexus，then into a deeper intrinsic venous plexus and finally into the peri－ oesophageal veins via perforating veins．Bidirectional flow is normally possible in this region，a phenomenon that permits pressure changes during breathing and Valsalva manœuvres．However，in portal hyper－ tension，the valves within the perforating vessels become incompetent and blood flow is retrograde，causing dilation of the deep intrinsic veins．The greater pressure within this region predisposes the varices to brisk and life－threatening bleeding．Treatment is directed towards con－ trolling the formation of a collateral circulation and the obliteration of varices that are susceptible to bleeding，and is achieved by paravariceal endoscopic injection of a sclerosant，which causes obliteration of the varices as a result of thrombus formation．Fibrosis is also induced within the mucosa，which reduces the formation of new collateral vessels．Alternatively，rubber bands may be applied in an attempt to ligate the varices．Bleeding from varices is associated with a mortality rate of $25 \%$ ，reflecting the problems of rebleeding and underlying comorbidity．

## Muscularis mucosae

The muscularis mucosae is composed mainly of longitudinal smooth muscle and forms a thin sheet near the epithelium, the contours of which it follows closely. At the pharyngeal end of the oesophagus, it may be absent or represented only by sparse, scattered bundles; below this, it becomes progressively thicker. The longitudinal orientation of its cells changes to a more plexiform arrangement near the gastrooesophageal junction. The ducts of the oesophageal glands pierce the muscularis mucosae.

## Submucosa

The submucosa loosely connects the mucosa and the muscularis externa, penetrating the longitudinal ridges of the oesophageal lumen. It contains larger blood vessels, nerves and mucous glands. Its elastic fibres aid closure of the oesophageal lumen after peristaltic dilation.

## Oesophageal glands

Groups of small tubule-acinar oesophageal glands mainly lie in the submucosa, each sending a single long duct through the intervening layers into the lumen. They are composed mostly of mucous cells, with some serous cells that secrete lysozyme. Close to the pharynx and stomach, the glands are simpler in form and restricted to the lamina propria of the mucosa (not submucosa). The mucosal mucous glands of the abdominal oesophagus closely resemble the gastric cardiac glands, and are therefore named oesophageal cardiac glands.

## Muscularis externa

The muscularis externa is up to $300 \mu \mathrm{~m}$ thick, and consists of the outer longitudinal and inner circular layers typical of the intestine. The thicker longitudinal layer exists as a continuous coat of fibres that extends almost the entire length of the oesophagus, except posterosuperiorly, $3-4 \mathrm{~cm}$ inferior to the cricoid cartilage, where it diverges as two fascicles that ascend obliquely and anteriorly, passing deep to the lower border of the inferior constrictor, and ending in a tendon that attaches superiorly to the posterior ridge of the cricoid lamina. The V-shaped space between these fascicles is filled by the circular oesophageal muscle fibres, thinly covered inferiorly by decussating longitudinal fibres and superiorly by the inferior constrictor, predisposing to the oesophageal diverticulum (Zencker).

Accessory slips of smooth muscle sometimes pass between the oesophagus and left pleura or the root of the left principal bronchus, trachea, pericardium or aorta. Some consider these slips to fix the oesophagus to these structures, but they actually equilibrate the normal physiological changes in position, shape and dimensions of the various organs between which they extend. Superiorly, the circular fibres blend posteriorly with the inferior pharyngeal constrictor, and anteriorly, the uppermost fibres attach to the lateral margins of the tendon of the two longitudinal fasciculi of the oesophagus. Inferiorly, the circular muscle is continuous with the oblique layer of muscle fibres in the stomach wall.

In the upper third of the oesophagus, the muscularis externa is formed by skeletal muscle; in the middle third, smooth muscle fascicles intermingle with striated muscle; and this increases distally such that the lower third contains only smooth muscle. This is also reflected by the innervation pattern of the oesophagus (see above).

## DEVELOPMENT

The development of the oesophagus is described on page 1048.

## Tracheo-oesophageal fistula

Tracheo-oesophageal fistula is described on page 930.

## OESOPHAGEAL SPHINCTERIC MECHANISMS

Radiological studies show that swallowed food stops momentarily in the gastric end of the oesophagus, before entering the stomach (see Fig. $56.18)$, suggesting the presence of a sphincter at this point. In the past, there was much controversy surrounding the reason for this behaviour because only slight thickening of the muscle coat has been found in humans. There is now ample physiological and clinical evidence that closure depends on two major mechanisms. The more important of these is the lower oesophageal sphincter, a specialized zone of circular smooth muscle surrounding the oesophagus at its transit through the diaphragm and for much of its short abdominal course. This region of the oesophagus is maintained under tonic contraction, except during swallowing, when it relaxes briefly to admit ingesta to the stomach, and during vomiting. Intramural plexuses of the enteric nervous system and the neural release of nitric oxide contribute to its relaxation. The second mechanism is a functional external sphincter provided by the right crus of the diaphragm, which encircles the oesophagus as it passes into the abdomen and is attached to it by the phreno-oesophageal ligament. Fluoroscopy, electromyography and manometry have shown that its muscular fibres contract around the oesophagus during inspiration and when intra-abdominal pressure is increased, thus helping to prevent gastro-oesophageal reflux, even when the lower oesophageal sphincter is inhibited experimentally with atropine. The relative importance of these two agents in the prevention of oesophageal reflux is still a matter for debate. Clinically, there is a good correlation between this condition and lower oesophageal sphincter dysfunction in some cases, whereas in others, failure of the diaphragmatic component, as seen in hiatus hernia, appears to be a major factor. The anatomical configuration of the gastro-oesophageal orifice may also play some part in these processes.

## Swallowing

The oesophageal phase of swallowing is described on page 584.

## Vomiting

In the initial phase of vomiting, the lower oesophageal sphincter and peri-oesophageal crural fibres simultaneously relax and rapid diaphragmatic and abdominal muscular contraction commences, increasing intra-abdominal pressure.

## OESOPHAGEAL DYSMOTILITY

Oesophageal dysmotility encompasses disorders of the upper and lower oesophageal sphincters (discussed in detail in the section on gastro-oesophageal reflux), congenital anomalies such as atresia, and achalasia. Upper oesophageal sphincter dysfunction is usually neurological, often brainstem disease impairing relaxation of cricopharyngeus with resultant dysphagia and aspiration as demonstrated by videofluoroscopy.

Achalasia of the cardia is a primary motor disorder of the oesophagus in which there is failure of relaxation of the cardial-oesophageal sphincter and loss of peristalsis in the oesophageal body from degeneration of myenteric plexus neurones. Dysphagia, regurgitation of undigested food and retrosternal chest pain result and a posteroanterior chest radiograph may show dilation of the oesophagus and retention of food products as a mottled, double-contoured mediastinal widening. Barium swallow shows a classic 'bird-beak' appearance as a result of failure of relaxation of the lower oesophageal sphincter and an absence of peristalsis. Oesophageal pressure manometry demonstrates absent or impaired relaxation of the lower oesophageal sphincter. Treatment options are endoscopic pneumatic balloon dilation or laparoscopic cardiomyotomy (Heller's myotomy). Alternatively, intrasphincteric injection of botulinum toxin may be offered in frail patients and confers lower morbidity and mortality.

Diffuse oesophageal spasm may present with dysphagia and chest pain. It is characterized by abnormal oesophageal contractions on barium swallow, and produces simultaneous segmental contractions that obliterate the oesophageal lumen to produce a 'corkscrew oesophagus'. Manometry also demonstrates these tetanic contractions. Non-specific oesophageal motility disorder occurs with ageing (presbyoesophagus) and is characterized by a decreased incidence of normal or even absent peristalsis after swallowing, often accompanied by repetitive tertiary contractions and failure of relaxation of the lower oesophageal sphincter. Oesophageal dysmotility is also seen in scleroderma and

Oesophagoscopy, a component of superior digestive endoscopic examination, may be indicated in patients with persistent non-cardiac chest pain, dysphagia, odynophagia (painful swallowing) or symptoms of reflux that include nocturnal cough. The endoscope is passed orally under direct vision with the patient in a lateral decubitus position, with or without sedation, and manœuvred into the oesophageal inlet when the patient is asked to swallow; once through, the endoscope is advanced slowly under direct vision. The mucosa normally appears whitish pink, changing to red at the squamocolumnar junction ( Z line) near the diaphragmatic hiatus. Cranial displacement of the Z line by more than 2 cm is indicative of a hiatus hernia. There may be slight extrinsic compression by the aorta and the left principal bronchus.

Endoscopic transoesophageal ultrasound permits assessment of the oesophageal wall and para-oesophageal structures, such as lymph nodes and the heart and aorta. Numerous surgical and percutaneous cardiovascular procedures are guided by transoesophageal echography. The technique is more sensitive than CT in detecting mediastinal nodal metastases, allowing those less than 10 mm in size to be assessed. Normal lymph nodes cannot be identified easily by endoscopic ultrasound because they have the same echogenicity characteristics as surrounding tissue; a hypoechoic or inhomogeneous echo portrayal on ultrasound is considered more suspicious of malignancy. Endoscopic ultrasound-guided fine needle aspiration allows accurate diagnosis for para-oesophageal nodes. Transbronchial fine needle aspiration is an alternative approach for sampling mediastinal nodes, guided by CT or positron emission tomography (PET) CT findings.

## Oesophageal rupture

The majority of oesophageal ruptures are iatrogenic, and occur during the instrumentation of the oesophagus during simple endoscopy, endoscopic intervention including dilation, and nasogastric tube placement. Other causes are barotrauma, foreign bodies and oesophageal carcinoma. Barotrauma occurs with intense retching and vomiting that usually cause longitudinal tearing in the posterior wall of the thoracic oesophagus (Boerhaave's syndrome). Overall, locations of oesophageal perforation are $60 \%$ thoracic, $25 \%$ cervical and $15 \%$ abdominal. Perforation in the cervical oesophagus occurs in the posterior wall, where
it is at its thinnest, often corresponding to an area of mucosa with no muscular covering bordered by the pharyngeal inferior constrictor and cricopharyngeus. Mortality from oesophageal perforations is $20 \%$ and results from mediastinitis and necrotizing infection. Presenting symptoms include thoracic pain, odynophagia, haematemesis, subacute surgical emphysema, tachycardia, breathlessness and, in advanced cases, septic shock. Diagnosis and repair within 24 hours is associated with a better prognosis and a mortality rate of between $10 \%$ and $15 \%$, whereas late diagnosis has a much greater mortality rate. For a perforation in the upper two-thirds of the thoracic oesophagus, a right thoracotomy in the fifth and sixth intercostal space is performed. The lower third of the oesophagus is approached through a left thoracotomy in the sixth and seventh intercostal space. The perforation is closed in layers after any necrotic tissue has been debrided.

A double-contrast barium swallow with fluoroscopy enables anatomical and functional assessment of the oesophagus (see Fig. 56.18). A standard examination involves the patient swallowing a barium solution and gas granules, and images are taken in the erect, supine and prone recumbent positions. The upright posture fully dilates the oesophagus and is useful in evaluating any constrictions. (The narrow tubular lumen of the oesophagus is normally indented slightly by the aortic arch and the left principal bronchus.) The supine view allows better evaluation of any motor dysfunction and varices, and moving into the prone position provokes underlying gastro-oesophageal reflux. Both repeating single digital images and cine loops of fluoroscopy can be obtained. The fluoroscopic images demonstrate defective opening of the pharyngeal oesophageal sphincter and the nature of the contractions in the body of the oesophagus. The cardio-oesophageal sphincter can be assessed in achalasia. Other abnormalities, such as hiatus hernia and areas of narrowing or dilation of the oesophagus, may be demonstrated. Mucosal relief images are obtained once the bulk of the contrast media has passed into the stomach, and this provides fine mucosal detail. Cross-sectional imaging is usually used for the preoperative planning and staging of oesophageal tumours, and is of value in radiotherapy planning.
other connective tissue diseases where atrophic smooth muscle is replaced by fibrous tissue in the submucosa and lamina propria.

## GASTRO-OESOPHAGEAL REFLUX

Gastro-oesophageal reflux is described in Chapter 64.

## HIATUS HERNIA

Hiatus hernia is described in Chapter 55.

## MEDIASTINAL IMAGING

Mediastinal structures may be viewed using X-rays, CT and MRI (see Commentary 7.1).

## NORMAL MEDIASTINAL CONTOURS ON A FRONTAL CHEST RADIOGRAPH

In the posteroanterior (PA) chest radiograph, the X-ray beam enters the back and exits the anterior chest wall during a full inspiratory breathhold. The patient stands and elevates and abducts the arms over the radiographic detector; this protracts the scapulae and depresses the medial ends of the clavicles to clear the peripheral lung fields and apices, respectively. In this view, the heart and large blood vessels appear as the 'mediastinal silhouette' (Fig. 56.16). Forming its left border, superior to inferior, are the aortic arch ('aortic knuckle', sometimes with the left superior intercostal vein visible - the 'aortic nipple'), left pulmonary artery and left ventricle. The descending aorta is projected as a continuous left paravertebral border to the diaphragm. The right border is delineated by structures containing deoxygenated blood: superior to inferior, the right brachiocephalic vein, superior vena cava, right atrium and thoracic inferior vena cava. The right paratracheal stripe (up to 3 mm ) is seen with the oval silhouette of the azygos arch at its lower margin.

Dilation or displacement of any of these structures accentuates the normal bulges on the borders of the mediastinal silhouette; thus an enlarged left auricle is seen between the left principal pulmonary artery and left ventricle as in mitral valve stenosis. Pulmonary vessels associated with the lung roots form the hilar contours. Sometimes seen are the anterior junctional line, representing supracardiac lung apposition (projects up into the neck because of the obliquity of the superior thoracic aperture), and inferiorly, the posterior junctional line, representing pleural apposition posterior to the oesophagus. The azygooesophageal line is sometimes seen, representing the medial border of the right lung in the azygo-oesophageal recess. The paraspinal lines are also visible parallel to the right and left margins of the thoracic spine.

Fig. 56.16 A posteroanterior (PA) radiograph of the adult female chest. Key: 1, trachea; 2, azygos vein; 3, right atrial border; 4, aortic arch; 5, left ventricular border.

## NORMAL MEDIASTINAL CONTOURS ON A LATERAL CHEST RADIOGRAPH

On a lateral view, the cardiac silhouette is seen above the anterior, horizontal part of the diaphragm (Fig. 56.17). Due to the nomenclature of the cardiac chambers reflecting their prerotational embryonic state, the right ventricle and left atrium form the anterior and posterior cardiac contours, respectively. Posteriorly, both the descending thoracic aorta and the oesophagus in the posterior mediastinum may be seen; the oesophagus can be visualized with swallowed air or barium on a chest radiograph or fluoroscopically in the barium swallow examination (Fig. 56.18). The compressive effect on the oesophagus of a dilated left atrium will be readily identified during barium swallow. Superiorly, the less dense trachea and main bronchi are recognizable, the left principal bronchus appearing almost circular, seen end-on due to its more

Fig. 56.17 A lateral radiograph of the adult female chest. Key: 1, retrosternal line (fat); 2, posterior tracheal line; 3, right principal bronchus; 4, bronchus intermedius.

Fig. 56.18 An oblique radiograph of the thorax during barium swallow. Key: 1, indentation from aortic arch; 2, indentation from left principal bronchus.

An accessory lung fissure, the azygos fissure, is rarely present and seen in $0.5 \%$ of PA chest radiographs, extending from the lung apex to the right tracheobronchial angle. The azygos arch width should be no more than 5 mm , but may measure up to 10 mm in the third trimester of pregnancy as a result of a physiological blood volume increase and the fact that flow through the inferior vena cava may be diminished as a result of compression by the uterus, with compensatory drainage through the azygos system. Similarly, congenital inferior vena cava interruption at the diaphragm or acquired inferior vena cava thrombosis enlarges the azygos vein.
horizontal lie. The oesophagus is directly posterior to the trachea, and the adjacent anterior oesophageal and posterior tracheal walls appear as the posterior paratracheal line, seen in the majority of lateral radiographs (normally less than 5 mm ).

The aortic arch and its main branches, anterior to the trachea, produce faint shadows in the superior mediastinum. The brachiocephalic veins are visible as an extrapleural bulge directly posterior to the manubrium. Retrosternal lung should always be seen; if it is absent, this raises a strong suspicion of a superior mediastinal tumour or
lymphadenopathy. The thoracic inferior vena cava is visible in the majority of patients as it drains into the right atrium.

## CT AND MRI OF THE MEDIASTINAL SPACES

CT provides excellent mediastinal delineation (Figs 56.19-56.20) with intravenous contrast enhancement more readily distinguishing normal anatomy from pathological lymph nodes and tumours. The hilar,

Fig. 56.20 Serial coronal thoracic CT sections. A, Key: 1, right brachiocephalic vein; 2, left brachiocephalic vein; 3, pulmonary trunk; 4, ascending aorta 5 , left ventricle; 6 , right atrium. B, As A, but with lung window settings; horizontal (minor) fissure arrowed. C, Key: 1, brachiocephalic trunk; 2, left common carotid artery; 3, aortic arch; 4, superior vena cava; 5 , pulmonary trunk; 6 , left ventricle; 7, abdominal aorta. D, Key: 1, right subclavian artery; 2, trachea; 3, aortic arch; 4, left main pulmonary artery; 5, right main pulmonary artery; 6 , left superior pulmonary vein; 7, left atrium; 8, descending thoracic aorta. E, Key: 1, left subclavian artery; 2, trachea; 3, posterior aortic arch; 4, left main pulmonary artery; 5, left atrium; 6 , descending thoracic aorta. F, As E, but with lung window settings.
pretracheal, subcarinal, right paratracheal, posterior tracheal and aortopulmonary window stations are common sites of lymph node metastases in lung cancer.

The pretracheal space, as seen on CT, is bordered by the trachea posteriorly, the superior vena cava and right brachiocephalic vein anteriorly, and the descending aorta and superior pericardial sinus to the left. The aortopulmonary window is located between the aortic arch superiorly and the left pulmonary artery inferiorly; the trachea forms its medial border and the left lung its lateral border. The right paratracheal space lies between the right lung and the trachea on its anterolateral aspect; the posterior tracheal space between the lung and the posterolateral aspect of the trachea; and the subcarinal space inferior to the carina bounded by the principal bronchi. On the right, the azygo-oesophageal recess is located posterior to the subcarinal space
and on the left side is the oesophagus. All these areas are in direct continuity with each other and are inspected during transcervical mediastinoscopy.

The junctional areas are where the two lungs approach each other. The anterior junction lies between the great vessels, posterior margin of the chest wall and the lungs where the left brachiocephalic vein, highest mediastinal nodes, thymus and phrenic nerves are located. The posterior junction is an area posterior to the trachea and is where the lungs appose. The paraspinal area lies between the lateral margins of the spine and the lungs where the intercostal vessels, the ganglionated sympathetic chain and small lymph nodes are located. The retrocrural space, between the diaphragmatic crura and vertebral bodies, is traversed by the aorta, azygos venous system, thoracic duct, intercostal arteries, sympathetic chains and splanchnic nerves.

## PERICARDIUM

The pericardium contains the heart and the juxtacardiac parts of its great vessels. It consists of two components - the fibrous and the serous pericardia - with a normal combined thickness of $1-2 \mathrm{~mm}$, as frequently seen on cross-sectional imaging (Figs 57.1-57.2). The fibrous pericardium is a sac made of tough connective tissue, completely surrounding and unattached to the heart. It develops through a sequential process of cavitation of the embryonic body wall by expansion of the secondary pleural cavity; its lateral walls are thus clothed by parietal mediastinal pleura. The serous pericardium consists of two layers, one inside the other; the inner (visceral) serosal layer adheres to the heart and forms its outer covering, known as the epicardium, whereas the outer (parietal) serosal layer adheres to the internal surface of the fibrous pericardium. These two serosal surfaces are apposed and separated by a film of fluid, which allows independent movement of the inner membrane and its adherent heart, constituting two parietovisceral lines of serosal reflection. The separation of the two membranes of the serous pericardium creates a narrow pericardial cavity that provides complete cleavage between the heart and its surroundings, allowing freedom of cardiac motion and shape change.

The multifunctionality of the pericardium has been suggested to include facilitation of secure intrathoracic cardiac stability (via the sternopericardial ligaments and from the fusion of fibrous pericardium with the central diaphragmatic tendon and great vessel adventitia; see below); friction reduction between the heart and the mediastinal structures; limitation of cardiac distension and chamber dilation with prevention of hypertrophy; uniform cardiac distribution of pericardial cavity hydrostatic pressure, preventing ventriculoatrial regurgitations

Fig. 57.1 The effect of section thickness on visualization of normal pericardium. Multidetector CT image of the chest obtained from a dual-source scanner (Somatom Definition Flash; Siemens, Erlangen, Germany) with 1.0 mm collimation. Non-ionic contrast material ( 120 ml ) was injected at a rate of $5 \mathrm{ml} / \mathrm{sec}$. In this image with a section thickness of 10 mm , the pericardium appears as a thin, curvilinear structure (arrows). The pericardium is typically best visualized along the right side of the heart because of surrounding fat. With increasing section thickness, maximal pericardial thickness (measured along the right ventricle) increases from 0.9 mm to 1.0 and 1.6 mm by using section thicknesses of 3 mm and 10 mm , respectively. (With permission from Bogaert J, Francone M. 2013. Pericardial disease: value of CT and MR imaging. Radiology 267:340-356.)
under increased ventricular end-diastolic pressure; formation of a barrier to spread of infection; facilitation of atrial filling by promoting negative pericardial pressure during ventricular systole; and, in association with the pleural fluid, the formation of a system that automatically applies compensating hydrostatic pressures to the cardiac periphery when accelerating forces act.

## FIBROUS AND SEROUS PERICARDIUM

## Fibrous pericardium

The fibrous pericardium is a roughly conical, compact, collagenous cardiac cloak composed mainly of three collagen layers, cross-woven at $120^{\circ}$ to each other, which limits stretch and ensures a physical barrier to disease.

A three-point 'cardiac seat belt' anchors the pericardium securely, maintaining the intrathoracic cardiac disposition. Pericardial anchoring is obtained by superior continuity with the great vessel adventitia and pretracheal fascia, inferior attachment to the central diaphragmatic tendon and a small adjacent muscular area to its left, together with anterior attachment to the posterior sternal surface via the superior and inferior sternopericardial ligaments (the extent of these 'ligaments' is very variable; the superior is often undetectable).

Anteriorly, the fibrous pericardium is separated from the thoracic wall by the lungs and pleural coverings. However, in a small area behind the lower left half of the body of the sternum and the sternal ends of left fourth and fifth costal cartilages, the pericardium is in direct contact with the thoracic wall. Until it regresses, the lower end of the thymus is also anterior to the upper pericardium. The principal bronchi, oesophagus, descending thoracic aorta and posterior parts of the mediastinal surface of both lungs are all posterior relations. Laterally are the pleural coverings of the mediastinal surface of the lungs. The phrenic neurovascular bundle descends bilaterally between the fibrous pericardium and mediastinal pleura. Inferiorly, the pericardium is separated

Fig. 57.2 Normal pericardium. T1-weighted fast spin-echo magnetic resonance image (MRI) ( $1.4 \times 2.0 \mathrm{~mm}$ resolution) in horizontal long-axis plane, in which the pericardium appears as a thin, curvilinear hypointense structure (arrows), best visible when surrounded by fatty tissue. (With permission from: Bogaert J, Francone M. 2013. Pericardial disease: value of CT and MR imaging. Radiology 267:340-356.)
from the liver and gastric fundus by the diaphragm. The aorta, superior vena cava and the pulmonary arteries and veins all receive extensions of the fibrous pericardium but the inferior vena cava traversing the central tendon has no such covering.

## Serous pericardium

The serous pericardium is a closed sac within the fibrous pericardium and has visceral and parietal layers. The parietal layer forms the internal surface of the fibrous pericardium. The visceral layer, or epicardium, covers the heart and great vessels, and is reflected into the parietal layer, which lines the internal surface of the fibrous pericardium. The visceral layer of the serous pericardium is a single layer composed of ciliated mesothelial cells on a thin subserosal layer of connective tissue abundant in elastic fibres, blending with the fibrous pericardium at the parietal membrane and with the interstitial myocardial tissue at the visceral membrane. The serosal cilia increase the surface area for fluid production and resorption, in addition to reducing friction between the opposing pericardial layers. The cardiac subserosal layer contains fat, especially along the ventricular side of the atrioventricular and interventricular grooves and the inferior cardiac border. The main coronary vessels and their larger branches are embedded in this fat; the amount is related to the general extent of body fat and gradually increases with age. The amount of epicardial adipose tissue may be a cardiometabolic risk factor, with increasing thickness linked to metabolic syndrome and diabetes mellitus. A significant correlation has been demonstrated
between the thickness of this fat layer and obesity in children (Ozdemir et al 2010).

Pericardial reflections The reflections of the serosal layer are arranged as two complex 'tubes'; the aorta and pulmonary trunk are enclosed in one, and the venae cavae and four pulmonary veins lie in the other. The perivenous tube is an inverted J; the cul-de-sac within its curve posterior to the left atrium is termed the oblique sinus. The transverse sinus is a passage between the two pericardial 'tubes' (Fig. 57.3); the aorta and pulmonary trunk are anterior (Fig. 57.4A,C), and the atria and their great veins are posterior (Fig. 57.4B,D).

Pericardial space and fluid The pericardial cavity is the space formed between the parietal and visceral layers of the serous pericardium. The pericardial cavity covers the proximal part of the great vessels and the vast majority of the heart, extending between the left atrium and the descending thoracic aorta; the left pleural space extends posterior to the descending aorta. The pericardial cavity normally contains approximately $15-20 \mathrm{ml}$ of serous plasma ultrafiltrate.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Approximately $80 \%$ of the pericardial blood supply is derived from the right and left internal thoracic arteries by way of their pericardiacophrenic branches. Inferiorly, the pericardium is supplied by small

Fig. 57.3 Interior of the serosal pericardial sac after section of the large vessels at their cardiac origin and removal of the heart, anterior view. Refer to the text for additional named recesses of the general serous pericardial cavity and its transverse sinus. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The arrangement of the oblique and transverse sinuses, along with that of the main 'principal' cavity, is further affected by the development of complex three-dimensional pericardial recesses between adjacent structures, grouped according to the siting of their orifices or 'mouths'. From the principal pericardial cavity, the postcaval recess projects towards the left, behind the atrial termination of the superior vena cava, limited superiorly by the right pulmonary artery and inferiorly by the superior right pulmonary vein, with its mouth opening superolaterally to the right. The right and left pulmonary venous recesses each project superomedially on the posterior surface of the left atrium between the superior and inferior pulmonary veins on each side, indenting the side walls of the oblique sinus. The superior aortic recess extends from the transverse sinus; via its inferior mouth, it ascends posterior to, then to the right of, the ascending aorta and ends at the level of the sternal angle. The inferior aortic recess, also extending from the transverse sinus, is a diverticulum that descends from a superiorly located mouth to run between the inferior ascending part of the aorta and the right atrium. The left pulmonary recess, with its mouth under the vena caval fold, passes to the left between the inferior aspect of the left pulmonary artery and the superior border of the superior left pulmonary vein. The right pulmonary recess lies between the inferior surface of the proximal part of the right pulmonary artery and the superior border of the left atrium.

A triangular fold of serous pericardium is reflected from the left pulmonary artery to the subjacent superior left pulmonary vein as the fold of the left superior vena cava. It contains a fibrous ligament, a remnant of the obliterated left common cardinal vein (left duct of Cuvier), which descends anterior to the left pulmonary hilum from the superior part of the left superior intercostal vein to the posterior surface of the left atrium, where it is continuous with the oblique vein of the left atrium. The left common cardinal vein may persist as a left superior vena cava, which then replaces the oblique vein of the left atrium and empties into the coronary sinus. When both common cardinal veins persist as a double superior vena cava, the transverse anastomosis between them, which normally forms the left brachiocephalic vein, may be small or absent. When there is a left superior vena cava, it is joined by the left superior intercostal vein. Knowledge of these recesses and sinuses is important in the avoidance of misdiagnosis as lymphadenopathy or aortic dissection and in surgical control of the great vessels.

Fig. 57.4 The heart and great vessels. A, Anterior view. B, Posteroinferior view. C,D, Corresponding three-dimensional reconstructions from multislice computed tomography (CT) scanning. branches from the intercostal and superior phrenic arteries. The posterior portion of the pericardium is supplied from small mediastinal branches that are derived either directly from the descending aorta or from its oesophageal or bronchial branches. The veins are tributaries of the azygos system, internal thoracic and superior phrenic veins.

Most lymph drainage of the pericardium is to the thoracic and the right lymphatic ducts; bilateral upper mediastinal and parasternal internal thoracic lymph nodal groups also receive efferents. Overall, a double layer of pericardial lymphatic vasculature exists: one contacting and surrounding the parietal pericardium, the other present in the fat and loose areolar tissue. The sternocostal pericardium either drains laterally towards the phrenic nerves as they enter the diaphragm, or travels along the ventral border of the pericardium to enter the prepericardial nodes located at the pericardio-diaphragmatic junction. Drainage from the lateral pericardium is more variable. Inferiorly, it drains towards the phrenic nerves and the pericardiacophrenic vessels as they reach the diaphragm; superiorly, it drains into the tracheobronchial and paratracheal lymph nodes. The posterior pericardium, including the posterior aspect of the cupula and extending as far as the pulmonary veins, drains superiorly to the superior and inferior tracheobronchial lymph nodes. The portion of the pericardium that adheres to the diaphragm drains via short channels to the lymph nodes at the right border of the inferior vena caval opening in the central diaphragmatic tendon.

## INNERVATION

Pain from parietal pericardium is mainly transmitted by the phrenic nerves, while pain from serous pericardium is mediated via sympathetic fibres that arise from the cervical, upper thoracic and stellate ganglia and travel to the aortic and cardiac plexuses. The pericardium also receives vagal fibres via the oesophageal plexus and left recurrent laryngeal nerve (see Fig. 57.61). Pericardial pain is typically sharp, severe and substernal, typically exacerbated by lying back or on the left side and relieved by leaning forwards, occasionally radiating to the superior border of trapezius.

## HEART

The heart has a complicated, spiral, three-dimensional organization that is markedly skewed when compared with the planes of the body. Established anatomical orientation terms have been historically applied to the heart based on early embryological development before axial rotation of the cardiovascular tube. This, together with the traditional study of isolated whole or dissected hearts outside the body, hinders intuitive understanding of the descriptive relations of in vivo and surface cardiac anatomy. The following description emphasizes such difficulties in order to circumvent certain misconceptions, before proceeding to an account of more detailed structure. The oblique position of the heart in the thorax may be conceptualized by comparing it to a rather deformed pyramid, with the base facing posteriorly and to the right, and the apex anteriorly and to the left. A line from the apex to the approximate centre of the base projected posterolaterally emerges near the right mid-scapular line. Some surfaces of the cardiac 'pyramid' are flat and others more or less convex, these aspects merging along rather ill-defined 'borders'. Precise definitions of surfaces and intervening 'borders' are therefore difficult. In the account that follows, the official Terminologia Anatomica (2011) and more generally used terms from clinical practice are given as alternatives.

The heart is described as having a base and apex; its surfaces are designated as sternocostal (anterior), diaphragmatic (inferior), and right and left (pulmonary) (Fig. 57.9). Its borders are termed upper, inferior ('acute' margin or border) and left ('obtuse' margin or border). The right surface is sometimes called a 'border', despite its extent. Although the heart is placed obliquely in the thorax, the atrial and ventricular septal

Fig. 57.9 A cadaveric heart, removed from the body and placed in an attitudinally appropriate position, then viewed from the apex of the left ventricle. The ventricular mass takes the form of a squashed cone with anterior, inferior and posterior borders. The labels show the location of these borders relative to the thoracic structures, and illustrate the acute and obtuse angles between the borders. (With permission from Anderson R, Loukas M. 2009. The importance of attitudinally appropriate description of cardiac anatomy. Clin Anat 22:47-51.)
structures are virtually in line, but inclined forwards and to the left at $45^{\circ}$ to the sagittal plane. The planes of the mitral and tricuspid valves are vertical and not precisely co-planar; they are broadly at right angles to the septal plane. The right atrium, therefore, is not only to the right, but also anterior and inferior to the left atrium, and it is partly anterior to the left ventricle. The right ventricle forms most of the anterior aspect of the ventricular mass (see Fig. 57.12); only its inferior end is to the right of the left ventricle, while its upper left extremity (pulmonary orifice) is to the left and superior relative to the aortic valve. The left atrium forms most of the posterior aspect of the heart, whereas the left ventricle is only prominent inferiorly, running along the left margin to reach the apex. The atria are essentially right of and posterior to their respective ventricles. These general dispositions are of the greatest importance in planning or interpreting radiographs, CT and MRI studies, cardiac angiograms and echocardiograms (Fig. 57.10).

The right heart, while forming the right aspect or 'border', follows a gentle curve and covers most of the anterior aspect of the left heart (except for a left-sided strip including the apex). Thus the right heart forms the largest part of the anterior surface, its outflow tract ascending until it terminates on the left side of the outflow tract from the left ventricle. The sites of the tricuspid and pulmonary valves are widely separated and on different planes, and the sectionally crescentic flat cavity of the right ventricle splays out between them. Conversely, the left heart (except the left-sided strip mentioned above) is largely posterior in position and, when viewed from the front, is obscured by the chambers of the right heart. The inlet to the left ventricle, which contains the mitral valve, is very close to its outlet (the aortic valve), the two being embraced by the wide tract linking inlet and outlet components of the right ventricle. The planes of the left ventricular orifices, although relatively inclined, are more nearly co-planar than those of the right. The left ventricular cavity is narrow and conical, and its tip occupies the cardiac apex.

## GENERAL ORGANIZATION

The heart is a fused pair of valved muscular pumps circulating blood in series through systemic ('left' heart) and pulmonary ('right' heart) circulations (see Fig. 57.4). The fibromuscular framework and conduction tissues of these physiologically separate pumps are structurally interwoven. Despite the functional disposition in series, the two pumps are topographically described in parallel. Of the four cardiac chambers, the two atria receive venous blood as weakly contractile reservoirs for final filling of the two ventricles, which then provide the

Cardiac tamponade is external compression of the heart, usually caused by accumulation of fluid in the pericardial space (pericardial effusion) (Fig. 57.5). This causes compression of the right atrium, reducing venous return and therefore cardiac output. It may be secondary to trauma, proximal extension from a dissecting aortic aneurysm, cardiac surgery or central venous catheter insertion. Patients develop hypotension, chest tightness, dyspnoea and possibly eventual shock. The typical signs of a cardiac tamponade include three elements (Beck's triad): a small quiet heart (due to fluid within the pericardial cavity), falling atrial pressure (decreased stroke volume) and rising jugular venous pressure (impaired cardiac venous return). Emergency treatment involves first relieving the tamponade by percutaneous pericardial aspiration (pericardiocentesis; see below), possibly followed by surgery to address the underlying cause. The volume of fluid may not be proportional to the degree of physiological circulatory impairment. Echocardiography is an important tool in diagnosis and is also useful in guiding percutaneous pericardial aspiration. Surgery is via a subxiphoid incision or a left anterior thoracotomy.

## Pericardiocentesis

Pericardiocentesis is the aspiration of fluid from the pericardial cavity in cases of cardiac tamponade and for relief of symptomatic pericardial effusion. In addition, this technique can be used for the diagnosis of neoplastic effusions and purulent pericarditis, and for introducing cytolytic agents into the pericardial space. Ultrasound-guided parasternal pericardiocentesis has become the preferred elective procedure. With acute traumatic cardiac tamponade, the subxiphoid approach is used and aspiration of as little as $10-20 \mathrm{ml}$ of blood may greatly improve cardiac output. A complete and controlled parasternal drainage avoids the diaphragm and phrenic nerve. Apical and abdominal approaches may also be used (Fig. 57.6).

Congenital anomalies of the pericardium include pericardial cysts and diverticula, and absence of the pericardium.

## Pericardial cysts and diverticula

A pericardial cyst is a congenitally encapsulated cyst with no pericardial communication, which forms when a portion of pericardium is pinched off during early development. Pericardial cysts are most often incidental and are located at the right cardiophrenic angle or sulcus, where they present as a well-defined ovoid expansion of the right inferolateral cardiac border on a chest film, usually round or elliptical, thin-walled and sharply defined with fluid attenuation on CT or homogenously high signal on fluid-sensitive MR sequences.

A pericardial diverticulum is a rare condition that corresponds to a herniation through a defect in the parietal pericardium that communicates with the pericardial cavity. It typically occurs at the same place as a pericardial cyst and should be suspected when a complete wall cannot be identified in all parts of the lesion (Fig. 57.7).

## Congenital absence of the pericardium

Congenital absence of the pericardium is rare. The condition encompasses defects ranging from a small foramen to absence of the entire pericardium. The majority of defects occur on the left side but they can

Fig. 57.5 Acute cardiac tamponade due to ruptured aortic dissection. An axial CT image acquired 60 seconds after contrast agent administration shows a large, high-attenuation pericardial effusion corresponding to massive haemopericardium. Weakening of the aortic wall with subsequent rupture has led to massive extravasation of contrast agent into the pericardial sac. (Image courtesy of GF Gualdi MD, and C Valentini MD, DEA Policlinico Umberto I, Rome, Italy, with permission from Bogaert J, Francone M 2013 Pericardial disease: value of CT and MR imaging. Radiology 267:340-356.)
be located anywhere in the pericardium, and are three times more common in males. It has been suggested that failure of pericardial development results from premature atrophy of the cardinal vein and hence poor nourishment of the left pleuropericardial membrane. The most common defect is complete absence of the left side of the pericardium. When this occurs, lung tissue is interposed between the main pulmonary artery and aorta. Bulging of the left atrial appendage through the defect will cause ischaemic necrosis and compression of the left coronary artery, and the heart rotates to the left. Complete absence of the pericardium is usually asymptomatic. Partial defects may cause complications such as herniation of cardiac structures (Fig. 57.8).

Congenital pericardial defects are associated with other congenital abnormalities such as bronchogenic cysts, ventricular and atrial septal defects, patent ductus arteriosus, mitral stenosis, bicuspid aortic valve, pulmonary arteriovenous malformations, diaphragmatic hernia, midline closure defects or bronchopulmonary sequestration (Hutchison 2009). Pentalogy of Cantrell is a rare congenital abnormality consisting of absence of the diaphragmatic portion of the pericardium; midline closure defects, including sternal and abdominal wall defects; anterior diaphragmatic defect; and congenital heart defects.

The basic rules of cardiac anatomy dictate that structures within the heart should be described relative to the bodily coordinates rather than to the heart itself. In other words, the structures within the heart should be described as the rest of the body when viewed in the anatomical position. An important concept to apply is recognition of the diaphragmatic surface as being inferior, and the left atrium as being posterior. A typical example of not applying this concept is the posterior interventricular artery. In cardiological and older anatomical texts, this artery is described as being posterior and descending, whereas in reality it is neither, since it is interventricular and inferior. Moreover, blockage of the artery is well recognized as producing inferior myocardial infarc-
tion. Another example is the papillary muscles that support the leaflets of the mitral valve. These were conventionally described as being anterolateral and posteroseptal, reflecting the fact that the heart was placed on its apex in order to describe its component parts. However, examination in left anterior oblique orientation, as for the inferior interventricular artery, shows that, in reality, the so-called posteroseptal muscle is anterior to its partner, despite the fact that the latter is currently described as being anterolateral. Similarly, the posterior interventricular sulcus is situated inferiorly rather than posteriorly (Fig. 57.11; see Figs 57.9, 57,10).

Fig. 57.11 The fundamental differences between describing the heart according to the conventional (A) or the attitudinally correct (B) orientation. (With permission from Anderson R, Spicer D, Hlavacek A, Hill A, Loukas M. 2013. Describing the cardiac components-attitudinally appropriate nomenclature. J Cardiovasc Transl Res. 6:118-123.)

Fig. 57.10 A cast of the so-called right and left chambers of the heart, cast in blue and red, respectively. A, The cast superimposed on a chest radiograph from a normal individual. The broken line indicates the midline of the body. The long axis of the heart extends from the right shoulder towards the left hypochondrium. The adult heart is usually positioned within the mediastinum such that one-third is to the right of the midline and two-thirds to the left. B, The cast enlarged to show the chambers that form the various borders of the frontal cardiac silhouette. (With permission from: Anderson R, Loukas M. 2009. The importance of attitudinally appropriate description of cardiac anatomy. Clin Anat 22:47-51.)
powerful expulsive contraction that forces blood into the main arterial trunks.

The 'right heart' starts at the right atrium, which receives the superior and inferior venae cavae and the main myocardial venous inflow via the coronary sinus. This systemic venous blood traverses the right atrioventricular orifice, guarded by the tricuspid valve, to enter the inlet component of the right ventricle. Contraction of the ventricle particularly its apical trabecular component, closes the tricuspid valve and, with increasing pressure, ejects the blood through the muscular right ventricular outflow tract into the pulmonary trunk and then through the relatively low-resistance pulmonary vascular bed. Changes in pressure, time relations and valvular events are described below Many structural features of the 'right heart', including its overall geometry, myocardial architecture, and the construction and relative strengths of the tricuspid and pulmonary valves, accord with this low resistance, being associated with comparatively low changes in pressure.

The 'left heart' starts at the left atrium, which receives all the pulmonary inflow of oxygenated blood and some coronary venous inflow. It contracts to fill the left ventricle through the left atrioventricular orifice, guarded by its mitral valve. Left ventricular contraction rapidly increases the pressure in the apical trabecular component, closing the mitral valve and opening the aortic valve, enabling the ventricle to eject via the left ventricular outflow tract into the aortic sinuses and the ascending aorta, and thence to the entire systemic arterial tree, including the coronary arteries. This vast vascular bed presents a high peripheral resistance that, with large metabolic demands (especially the sustained requirements of the cerebral tissues), explains the more massive structural organization of the 'left heart'. The ejection phase of the left ventricle is shorter than that of the right but its fluctuations in pressure are very much greater.

The heart is therefore, by necessity, a functionally and structurally markedly asymmetrical pair of combined pumps, with both ventricles designed to deliver the same volume with each contraction into two very different resistive series circulations.

## Cardiac size, shape and external features

The heart is a hollow, fibromuscular organ of a somewhat conical or pyramidal form, with a base, apex and a series of surfaces and 'borders'. Enclosed in the pericardium, it occupies the middle mediastinum between the lungs and their pleural coverings (see Fig. 57.3). It is placed obliquely behind the body of the sternum, adjoining costal cartilages and ribs. Approximately one-third of the mass lies to the right of the midline. An average adult heart is 12 cm from base to apex, $8-9 \mathrm{~cm}$ at its broadest transverse diameter and 6 cm anteroposteriorly. Its weight varies from 280 to 340 g (average 300 g ) in males and from 230 to 280 g (average 250 g ) in females. Cardiac weight is $0.45 \%$ of body weight in males and $0.40 \%$ in females. The difference in weight between males and females appears after the age of 12 years (Kortelainen 1997). Adult weight is achieved between the ages of 17 and 20 years. The heart reaches $50 \%$ of its adult dimensions at birth, $75 \%$ by 5 years and $90 \%$ by 12 years (Nidorf et al 1992).

## Grooves on the cardiac surface

The division of the heart into four chambers produces boundaries that are visible externally as grooves (sulci). Some are deep and obvious, and contain prominent structures. Others are less distinct, even barely perceptible, and are sometimes obscured, in part, by the major structures that cross them.

The extensive interatrial groove (of Waterston) separates the two atria. The lateral limits are defined by the borders of the atria. The atrioventricular (coronary) groove separates the atria from the ventricles and contains the main trunks of the coronary arteries. It descends obliquely to the right on the sternocostal surface, separating the right atrium (and its auricle or appendage) from the oblique right margin of the right ventricle and its infundibulum. Superiorly, its left part is obliterated by the crossing of the pulmonary trunk, and posterior to this, the aorta from which the coronary arteries originate. Continuing to the left, the groove curves around the 'obtuse' margin and descends to the right, separating the atrial base from the diaphragmatic surface of the ventricles (see Fig. 57.4). This diaphragmatic part of the atrioventricular groove then curves around the 'acute' margin at its lower right end to become confluent with the sternocostal part. Thus, the groove passes from superior on the left to inferior on the right, with the diaphragmatic part being a little to the left of the sternocostal. A section that includes the atrioventricular groove is at $45^{\circ}$ to the sagittal plane and at a greater but variable angle to the transverse and coronal planes. It approximately traverses the lines of attachment of the atrioventricular valves and, even less precisely, those of the aortic and pulmonary valves. A line at right angles to the centre of this plane will descend anteriorly and leftwards to the cardiac apex. Internally, the ventricles are separated by the septum; its mural margins correspond to the anterior and inferior (diaphragmatic) interventricular grooves. The anterior groove, seen on the sternocostal cardiac surface, is near and almost parallel to the left ventricular obtuse margin. On the diaphragmatic surface, the groove is closer to the midpoint of the ventricular mass. The interventricular grooves extend from the atrioventricular groove to the apical notch on the acute margin, the latter a little to the right of the true cardiac apex.

## Cardiac base, apex, surfaces and borders

Posterior aspect of the heart The true cardiac base is somewhat quadrilateral, with curved lateral extensions. It faces posteriorly and to
the right, separated from the thoracic vertebrae (fifth to eighth in the recumbent, sixth to ninth in the erect posture) by the pericardium, right pulmonary veins, oesophagus and aorta. It is formed mainly by the left atrium, and only partly by the posterior part of the right atrium (see Fig. 57.4B,D). It extends superiorly to the bifurcation of the pulmonary trunk and inferiorly to the posterior part of the atrioventricular groove, which contains the coronary sinus and coronary arterial branches. It is limited to the right and left by the rounded surfaces of the corresponding atria, separated by the shallow interatrial groove. The point of junction of the atrioventricular, interatrial and posterior (inferior) interventricular grooves is termed the cardiac crux. Two pulmonary veins on each side open into the left atrial part of the base, whereas the superior and the inferior venae cavae open into the upper and lower parts of the right atrial basal region. The area of the left atrium between the openings of right and left pulmonary veins forms the anterior wall of the oblique pericardial sinus (see Fig. 57.3). This description of the anatomical base reflects the usual position of the heart in the thorax. Some confusion is produced by other current usages of the term 'base', often applied to the segment of the atrioventricular and ventriculoarterial junctions seen after dissections through the atrioventricular groove. This area is better termed the base of the ventricles. In clinical practice, auscultation in or near the parasternal parts of the second intercostal spaces is often described as occurring at the 'clinical base', to make the contrast with the 'clinical apex'. Such descriptions, while less than perfect anatomically, will almost certainly persist.

Anatomical apex of the heart This is the apex of the conical left ventricle, which is directed anteroinferiorly and to the left. It is overlapped by the left lung and pleura. The apex is located most commonly behind the fifth left intercostal space, near or a little medial to the midclavicular line.

Anterior, sternocostal surface of the heart Facing forwards and upwards, the anterior surface has an acute right and a more gradual left convexity (Fig. 57.12). It consists of an atrial area superior and to the right, and a ventricular part inferior and to the left of the atrioventricular groove. The atrial area is occupied almost entirely by the right
atrium. The left atrium is largely hidden by the ascending aorta and pulmonary trunk. Only a small part of the left atrial appendage projects forwards to the left of the pulmonary trunk. Of the ventricular region, about one-third is made up by the left and two-thirds by the right ventricle. The site of the septum between them is indicated by the anterior interventricular groove. The sternocostal surface is separated by the pericardium from the body of the sternum, the sternocostal muscles and the third to sixth costal cartilages. Because of the bulge of the heart to the left, more of this surface is behind the left costal cartilages than the right. It is also covered by the pleural membranes and the thin anterior edges of the lungs, except for a triangular area at the cardiac incisure of the left lung. The lungs and their pleural coverings are variable in their degree of cardiac overlap.

Inferior, diaphragmatic surface of the heart Largely horizontal, the inferior surface of the heart gently slopes anteroinferiorly towards the apex (see Fig. 57.4B,D). It is formed by the ventricles (chiefly the left) and rests mainly on the central tendon but also, apically, on a small area of the left muscular part of the diaphragm. It is separated from the anatomical base by the atrioventricular groove, and is traversed obliquely by the posterior (inferior) interventricular groove.

Left surface of the heart Facing posterosuperiorly to the left, the left surface consists almost entirely of the obtuse margin of the left ventricle, but a small part of the left atrium and its left atrial appendage contribute superiorly. Convex and widest superiorly, where it is crossed by the atrioventricular groove, it narrows to the cardiac apex. It is separated by the pericardium from the left phrenic neurovascular bundle, and by the left pleura from the deep concavity of the left lung.

Right surface of the heart The right surface is rounded and formed by the right atrial wall. It is separated from the mediastinal aspect of the right lung by the pericardium and pleural coverings. Its convexity merges inferiorly into the short intrathoracic part of the inferior vena cava and above into the superior vena cava. The sulcus terminalis is a prominent landmark separating the systemic atrial venous sinus from

Fig. 57.12 The heart, great vessels and the lungs in situ. The manubrium sterni has been retracted cranially, the thymus has been completely removed and the pericardium has been partially removed. The hilum of the lung has been dissected to expose the tracheobronchial lymph nodes. the appendage; it curves approximately along the junction of the sternocostal and right surfaces, corresponding to the position of the terminal crest.

Upper border of the heart This is atrial (mainly the left atrium). Anterior to it are the ascending aorta and the pulmonary trunk (see Fig. 57.3). At its extremity, the superior vena cava enters the right atrium.

Right border of the heart Corresponding to the right atrium, the profile of the right border is slightly convex to the right as it approaches the vertical.

Inferior border of the heart Also known as the acute margin of the heart, the inferior border is sharp, thin and nearly horizontal. It extends from the lower limit of the right border to the apex and is formed mainly by the right ventricle, with a small contribution from the left ventricle near the apex.

Left border of the heart Also known as the obtuse margin, the left border separates the sternocostal and left surfaces. It is round and mainly formed by the left ventricle but, to a slight extent superiorly, is formed by the left atrial appendage. It descends obliquely, convex to the left, from the appendage to the cardiac apex.

## Right atrium

## General and external features

The right atrium is both anterior and to the right of the left atrium (see Fig. 57.4), and extends inferior to it. Its walls form the right superior sternocostal surface, the convex right (pulmonary) surface and a little of the right side of the anatomical base. The superior vena cava opens
into its dome, and the inferior vena cava into its inferoposterior part (see Fig. $57.4 \mathrm{~A}, \mathrm{~B}$ ). An extensive muscular pouch, the appendage, projects anteriorly to overlap the right side of the ascending aorta; it is a broad, triangular, pyramidal structure and has a wide junction with the venous component of the atrium (see Fig. 57.4A,C). The junction between the venous part (sinus venosus) and the atrium proper is marked externally by a shallow groove, the sulcus terminalis, extending between the right sides of the openings of the two venae cavae. The sulcus terminalis corresponds, internally, to the terminal crest (crista terminalis), which is the site of origin of the extensive pectinate muscles that arise serially at right angles from the crest. Posteriorly, the vertical interatrial groove descends to the crux. Anteriorly, the right atrium is related to the anterior part of the mediastinal surface of the right lung, from which it is separated by pleura and pericardium. Laterally, the atrium is also related to the mediastinal surface of the right lung, but anterior to its hilum and separated from it by the pleura, right phrenic nerve and pericardiacophrenic vessels and pericardium. Posteriorly and to the left, the interatrial septum and the surrounding infolded atrial walls separate the atria (the mural infolding is indicated by an extensive interatrial groove). Posteriorly and to the right are the right pulmonary veins. Medially are the ascending aorta and, to a limited extent, the pulmonary trunk and its bifurcation.

## Internal features

The interior surface of the right atrium can be divided into three regions: the smooth-walled venous component located posteriorly leads anteriorly to the vestibule of the tricuspid valve and to the appendage (Figs 57.13-57.14). The wall of the vestibule is smooth but its junction with the appendage is ridged all around the atrioventricular junction by pectinate muscles. The smooth-walled systemic venous sinus receives the openings of the venae cavae and coronary sinus; it originates from the sinus venosus of the embryonic heart. The trabeculated appendage is derived from the embryonic atrium proper. The superior and inferior

Fig. 57.13 A, The interior of the heart, revealed by incising it along its right, and part of the lower, surfaces. The rest of the heart has been turned over to the left. B, The triangle of Koch, defined by the tendon of Todaro, orifice of the coronary sinus and the septal leaflet of the tricuspid valve. Fig. 57.14 The internal features of the right atrium. The superior and inferior venae cavae have been dissected, exposing the venous component of the right atrium and the fossa ovalis. The dotted line indicates the triangle of Koch, demarcated by the orifice of the coronary sinus (CS) and its valve, the Thebesian valve; the anterior extension of the Eustachian valve, the tendon of Todaro, to the central fibrous body (CFB); and the septal leaflet of the tricuspid valve. (Courtesy of M Loukas MD, PhD.)
venae cavae, together with the coronary sinus, open into the venous component.

The superior vena cava returns blood from head, neck and upper limb through an orifice that faces anteroinferiorly and has no valve; it also receives blood from the chest wall and the oesophagus via the azygos system.

The inferior vena cava is larger than its superior counterpart. It drains blood from all structures below and including the diaphragm into the lowest part of the atrium near the septum. Anterior to its orifice, and found along its lateral or right margin, is the flap-like Eustachian valve, a fold of endocardium that encloses a few muscular fibres and is of varying size (see Fig. 57.13; Fig. 57.15). When traced inferiorly, it forms the Eustachian ridge, which runs into the sinus septum (see below), continuous with the valve of the coronary sinus. The lateral part of the valve becomes continuous with the lower end of the terminal crest. The Eustachian valve is large during fetal life, when it serves to direct richly oxygenated blood (from the placenta) from the right atrium through the foramen ovale of the interatrial septum into the left atrium. The valve varies markedly in size in postnatal life; it is sometimes cribriform or filamentous but often absent.

The coronary sinus opens into the venous atrial component between the orifice of the inferior vena cava, the fossa ovalis and the vestibule of the atrioventricular opening (see Fig. 57.13). It is often guarded by a thin, semicircular Thebesian valve that covers the lower part of the orifice. The upper limb of this valve joins the Eustachian valve and its muscular extension, the Eustachian ridge. It also joins a tendinous structure, the tendon of Todaro, running from this commissure into the sinus septum, which is the septum between the coronary sinus and the fossa ovalis. The tendon of Todaro runs forwards to insert into the central fibrous body and is one of the landmarks of the triangle of Koch (see below). The ostium of the coronary sinus forms a prominent landmark in the right atrium. The sinus itself lies within the left atrioventricular groove (see Fig. 57.4B,D) and is the conduit for return of most of the venous blood from the heart, although some veins drain directly to the atrial chambers. The coronary sinus starts at the confluence of the oblique vein of the left atrium and the great cardiac vein, and receives the middle and small cardiac veins close to its junction with the right atrium. Several small venous ostia, draining the minimal atrial veins, are found scattered around the atrial walls. They return a small fraction of blood from the heart, and are most numerous on the septal aspect. The anterior cardiac veins and, sometimes, the right marginal vein may enter the atrium through larger ostia.

The right atrium and its appendage are separated from the venous sinus by the crista terminalis, a smooth, C-shaped muscular ridge that originates from the upper part of the septal surface and, passing anterior to the orifice of the superior vena cava, skirts its right margin to reach the right side of the orifice of the inferior vena cava. It marks the site of the right venous valve of the embryonic heart, corresponding externally to the terminal groove. The sinu-atrial (sinus) node is located in the superior part of the groove, inferolateral to the orifice of the superior vena cava (see Fig. 57.13). The mean length of the crest is $51 \pm 9 \mathrm{~mm}$ and its thickness from epicardium to endocardium at the junction of the superior vena cava with the posterior atrial wall is $5.5 \pm 1.3 \mathrm{~mm}$. The pectinate muscles (musculi pectinati) are almost parallel muscular ridges that extend anterolaterally from the terminal crest, reaching into the appendage where they form several trabeculations. The largest and most prominent pectinate muscle, forming the bridge of the sulcus terminalis internally, is the taenia sagittalis (second crest or septum spurium). The septal wall presents the fossa ovalis, an oval depression superior and to the left of the orifice of the inferior vena cava. Its floor is the primary atrial septum (septum primum). The rim of the fossa (limbus) is prominent. Often said to represent the edge of the so-called septum secundum, in reality the muscular borders of the fossa are no more than infoldings of the atrial walls, incorporating extracardiac adipose tissue. It is most distinct anterosuperiorly to the fossa, usually deficient inferiorly. Some hearts display an excessive amount of extracardiac adipose tissue within the fold, raising a marked elevation of the superior rim of the fossa (intervenous tubercle of Lower). A small slit is sometimes found at the upper margin of the fossa, ascending beneath the rim to communicate with the left atrium. This represents failure of obliteration of the fetal foramen ovale, which remains patent in up to one-third of all normal hearts. Anteroinferior in the right atrium is the large, oval vestibule leading to the orifice of the tricuspid valve. A triangular zone (of Koch) is defined between the attachment of the septal leaflet of the tricuspid valve, the anteromedial margin of the ostium of the coronary sinus, and the palpable round, collagenous subendocardial tendon of Todaro (see Figs 57.13-57.14). Koch's triangle is a landmark of particular surgical importance, indicating the site of the atrioventricular node and its atrial connections. Anterosuperior to the insertion of the tendon of Todaro, the septal wall is formed by the atrioventricular component of the membranous septum, intervening between the right atrium and subaortic outlet of the left ventricle (Fig. 57.17). The bulging atrial wall anterosuperior to the membranous septum, the aortic mound (torus aorticus), marks the location of the non-coronary aortic sinus with its enclosed valvular leaflet.

## Right ventricle

The right ventricle extends from the right atrioventricular (tricuspid) orifice nearly to the cardiac apex. It then ascends to the left to become the infundibulum, or conus arteriosus, reaching the pulmonary orifice and supporting the leaflets of the pulmonary valve. Topographically, the ventricle possesses an inlet component that supports and surrounds the tricuspid valve; a coarsely trabeculated apical component; and a muscular outlet or infundibulum that surrounds the attachments of the pulmonary valve leaflets.

## External features

The convex anterosuperior surface of the right ventricle makes up a large part of the sternocostal aspect of the heart, and is separated from the thoracic wall only by the pericardium (see Fig. 57.1). The left pleura and, to a lesser extent, the anterior margin of the left lung are interposed above and to the left. The inferior surface is flat and is related mainly, with the interposition of the pericardium, to the central tendon and a small adjoining muscular part of the diaphragm. The left and posterior wall is the ventricular septum, slightly curved and bulging into the right ventricle so that, in sections across the cardiac axis, the outline of the right ventricle is crescentic. The wall of the right ventricle is relatively thin $(3-5 \mathrm{~mm})$, the ratio of the thickness of the two ventricular walls usually being 1:3.

## Internal features

The inlet and outlet components of the ventricle, supporting and surrounding the leaflets of the tricuspid and pulmonary valves, respectively, are separated in the roof of the ventricle by the prominent supraventricular crest (crista supraventricularis) (see Fig. 57.13A; Fig. 57.18). The crest is made up predominantly by the inner heart curvature, bounded on the epicardial aspect by the rightward margin of the transverse sinus. The crest is a thick, muscular, highly arched structure, extending obliquely anteriorly and to the right from a septal limb high on the interventricular septal wall to a mural or parietal limb on the

Fig. 57.15 An inferior view of a cadaveric heart, demonstrating an exaggerated Eustachian valve occupying a significant portion of the lumen of the inferior vena cava. (With permission from Loukas M, Sullivan A, Tubbs R, Weinhaus A, Derderian T, Hanna M. 2010. Chiari's network: review of the literature. Surg Radiol Anat. 32:895-901.)

Occasionally, a reticulated network, Chiari's network, originates from the Eustachian valve and connects to different parts of the right atrium, including the coronary sinus. It results from incomplete resorption of the right valve of the embryonic sinus venosus (Fig. 57.16). Often clinically insignificant, Chiari's network has been associated with the pathogenesis of thromboembolic disease, endocarditis, arrhythmias, cardiac flow obstructions, heart murmurs, infective endocarditis, cardiac tumours and entrapment of catheters on percutaneous intervention.

The prominent sub-Thebesian recess is located posterior to the Eustachian valve and posteroinferior to the ostium of the coronary sinus. The area between the Eustachian and tricuspid valves inferior to the ostium of the coronary sinus (the cavotricuspid isthmus) is the target of catheter-directed ablation procedures, the treatment of choice for atrial flutter (Sánchez-Quintana et al 2013).

Fig. 57.16 Chiari's network. There are multiple attachment sites around the opening of the inferior vena cava and inferiorly towards the coronary sinus (the reflected part of the right atrium covers the distal attachment to the coronary sinus). Fig. 57.18 A 'window dissection' of a cadaveric heart, prepared by removing the anterosuperior wall of the right atrium and ventricle, to expose their internal features. The Eustachian valve separates the inferior vena cava from the sub-Thebesian recess. The Thebesian valve guards the entry into the coronary sinus. The smooth circumferential area of atrial wall that surrounds the orifice of the tricuspid valve is the vestibule. Note the location of the supraventricular crest and septomarginal trabeculation. The body of the septomarginal trabeculation continues as an important muscular strand, the moderator band, to the anterior papillary muscle and the parietal wall of the right ventricle. (Specimen courtesy of M Loukas MD, PhD.)
anterolateral right ventricular wall. The posterolateral aspect of the crest provides a principal attachment for the anterosuperior leaflet of the tricuspid valve. The septal limb of the crest may be continuous with, or embraced by, the septal limbs of the septomarginal trabeculation. The inlet and outlet regions extend apically into and from the prominent coarsely trabeculated component of the ventricle. The inlet component itself is also trabeculated, whereas the outlet component (infundibulum) has predominantly smooth walls. The trabeculated appearance is
caused by a myriad of endocardial, lined, irregular muscular ridges and protrusions collectively known as trabeculae carneae. These protrusions and intervening grooves impart great variation in wall thickness; the protrusions vary in extent from mere ridges to trabeculations, fixed at both ends but otherwise free. Other conspicuous protrusions are the papillary muscles, which are inserted at one end on to the ventricular wall and are continuous at the other end with collagenous cords, the chordae tendineae (tendinous cords), inserted on the free edge of the
atrioventricular valves. One protrusion in the right ventricle, the septomarginal trabeculation or septal band, is particularly prominent, reinforcing the septal surface where, at the base, it divides into limbs that embrace the supraventricular crest. Towards the apex, it supports the anterior papillary muscle of the tricuspid valve and, from this point, crosses to the parietal wall of the ventricle as the moderator band (the name reflects an earlier idea that septomarginal trabeculation prevented overdistension of the ventricle). The role of the moderator band as part of the conduction system of the heart involves the right atrioventricular bundle, as conduction cardiomyocytes move towards the apex of the ventricle before entering the anterior papillary muscle. The moderator band may be short/thick, long/thick, short/thin, long/thin: it is occasionally absent. A further series of prominent trabeculations, the septoparietal trabeculations, extend from its anterior surface and run on to the parietal ventricular wall. The smooth-walled outflow tract, or infundibulum, ascends to the left, superior to the septoparietal trabeculations and inferior to the arch of the supraventricular crest to the pulmonary orifice (Spicer and Anderson 2013).

## Tricuspid valve

The atrioventricular valvular complex, in both ventricles, consists of the orifice and its associated anulus, the leaflets, the supporting chordae tendineae of various types and the papillary muscles. Harmonious interplay of all of these, together with the myocardial mass, depends on the conduction tissues and mechanical cohesion provided by the cardiac skeleton. All parts change substantially in position, shape, angulation and dimensions during the cardiac cycle (see Fig. 57.20).

## Tricuspid valvular orifice

The tricuspid valve orifice is best seen from the atrial aspect. It measures, on average, 11.4 cm in circumference in males and 10.8 cm in females. There is a clear line of transition from the atrial wall or septum to the lines of attachment of the valvular leaflets. Its margins are not precisely in a single plane. It is almost vertical but at $45^{\circ}$ to the sagittal plane and slightly inclined to the vertical, such that it 'faces' (on its ventricular aspect) anterolaterally to the left and somewhat inferiorly (Fig. 57.19). Roughly triangular, its margins are described as anterosuperior, inferior and septal, corresponding to the lines of attachment of the valvular

Fig. 57.19 The relation of the sternocostal surface and valves of the heart to the thoracic cage. The right heart is blue, the arrow denoting the inflow and outflow channels of the right ventricle; the left heart is treated similarly in red. The positions, planes and relative sizes of the cardiac valves are shown. The position of the letters $A, P, T$ and $M$ indicate the aortic, pulmonary, tricuspid and mitral auscultation areas of clinical practice, respectively. Note that, for the purpose of illustration, the orifices of the aortic, mitral and tricuspid valves are shown with some separation between them, whereas, in reality, the leaflets of the three valves are in fibrous continuity (see Fig. 57.24).
leaflets. The connective tissues around the orifice of the atrioventricular valves separate the atrial and ventricular myocardial masses completely, except at the point of penetration of the atrioventricular bundle; they vary in density and disposition around the valvular circumference. Extending from the right fibrous trigone component of the central fibrous body is a pair of curved, tapered, subendocardial tendons, or 'prongs' (fila coronaria), which partly encircle the circumference. The latter is completed by more tenuous, deformable fibroblastic sulcal areolar tissue. Although the extent of fibrous tissue varies with sex and age, the tissue within the atrioventricular junction around the tricuspid orifice is always less robust than similar elements found at the attachments of the mitral valve. The topographical 'attachment' of the free valvular leaflets in the tricuspid valve does not wholly correspond to the internal level of attachment of the fibrous core of the valve to the junctional atrioventricular connective tissue. The line of attachment of the leaflet is best appreciated in the heart when examined grossly, this feature being more readily discerned clinically.

## Tricuspid valve leaflets

When they are closed, it is usually possible to distinguish the three leaflets in the tricuspid valve on the basis of the zones of apposition between them: hence the name. The leaflets are located anterosuperiorly, septally and inferiorly, corresponding to the marginal sectors of the atrioventricular orifice named in conjunction. The inferior leaflet is often described as being posterior, but when assessed in the attitudinally correct anatomical position, the leaflet is positioned inferiorly (Anderson and Loukas 2009). Each leaflet is a reduplication of endocardium enclosing a collagenous core, continuous marginally and on its ventricular aspect with diverging fascicles of chordae tendineae (see below) and basally confluent with the anular connective tissue. In passing from the free margin to the inserted margin, all leaflets of the atrioventricular valves display rough, clear and basal zones. The rough zone is relatively thick, opaque and uneven on its ventricular aspect where most chordae tendineae are attached; its atrial aspect makes contact with the comparable surface of the adjacent leaflets during full valve closure. The clear zone is smooth and translucent, receives few chordae tendineae and has a thinner, fibrous core. The basal zone, extending $2-3 \mathrm{~mm}$ from the circumferential attachment of the leaflets, is thicker from increased connective tissue, vascularized and innervated. It contains the insertions of the atrial myocardium. The anterosuperior leaflet is the largest component of the tricuspid valve, attached chiefly to the atrioventricular junction on the posterolateral aspect of the supraventricular crest, and extending along its septal limb to the membranous septum ending at the anteroseptal commissure. One or more notches often indent its free margin. The attachment of the septal leaflet passes from the inferoseptal commissure on the inferior ventricular wall across the muscular septum, then angling across the membranous septum to the anteroseptal commissure. The septal leaflet defines one of the borders of the triangle of Koch, thereby aiding location of the atrioventricular node at the apex of this triangle, and ensuring avoidance during tricuspid valve surgery (see Figs 57.13, 57.17). The inferior leaflet is wholly mural in attachment and guards the diaphragmatic surface of the atrioventricular junction, its limits being the inferoseptal and anteroinferior commissures. The zone of apposition between the inferior and the anterosuperior leaflets is supported by the septal papillary muscle of the conus.

## Opening of the tricuspid valve

Despite its name, the tricuspid valve acts more like a bicuspid valve because its smallest septal leaflet is fixed between the atrial and ventricular septa. The remainder of the tricuspid anulus is muscular. During diastole, the anulus dilates with right ventricular relaxation and the large anterior and posterior leaflets move away from the plane of the anulus into the right ventricle. During systole, the anulus constricts as the right ventricle contracts and the two major leaflets move like sails about a relatively immobile septal leaflet and the septum itself (Fig. 57.20).

## Chordae tendineae (tendinous cords)

The chordae tendineae are fibrous collagenous structures that support the leaflets of the atrioventricular valves. Sometimes, false chordae connect the papillary muscles to each other or to the ventricular wall or septum, or pass directly between points on the wall or septum, or both. Their numbers and dimensions vary in the right ventricle; approximately $40 \%$ of these false cords contain conduction cardiomyocytes.

The true chordae usually arise from small projections on the tips or margins of the apical third of papillary muscles, although they sometimes arise from the papillary muscle bases or directly from the ventricular walls and septum. They attach to various parts of the ventricular
aspects or the free margins of the leaflets. True chordae are classified into first-, second- and third-order types, according to the distance of the attachment from the margins of the leaflets; the scheme has little functional or morphological merit. Fan-shaped chordae have a short stem from which branches radiate to attach to the margins (or the

Fig. 57.20 A summary of some of the principal events that occur in the cardiac cycle and that are mentioned at various points throughout this chapter. Systole begins at the onset of the first heart sound (see phonocardiogram) and ends at the onset of the second heart sound, when diastole begins, and this cycle repeats itself.
ventricular aspect) of the zones of apposition between leaflets and to the ends of adjacent leaflets. Rough-zone chordae arise from a single stem that usually splits into three components that attach to the free margin, the ventricular aspect of the rough zone and to some intermediate point on the leaflet, respectively. Free-edge chordae are single, thread-like and often long, passing from either the apex or the base of a papillary muscle into a marginal attachment, usually near the midpoint of a leaflet or one of its scallops. Deep chordae pass beyond the margins and, branching to various extents, reach the more peripheral rough zone or even the clear zone. Basal chordae are round or ribbonlike, long and slender, or short and muscular; they arise from the smooth or trabeculated ventricular wall and attach to the basal component of a leaflet.

## Papillary muscles

The two major papillary muscles in the right ventricle are located in anterior and inferior positions. A third, smaller muscle lies medially, together with several smaller, variable muscles attached to the ventricular septum. The anterior papillary muscle is the largest, its base arising from the right anterolateral ventricular wall inferior to the anteroinferior commissure of the inferior leaflet, also blending with the right end of the septomarginal trabecula. The inferior, papillary muscle, often bifid or trifid, arises from the myocardium inferior to the inferoseptal commissure. The septal (medial) papillary muscle of the conus, the muscle of Lancisi, is almost always present and is the most superior and largest of the small septal papillary muscles. It arises from the posterior septal limb of the septomarginal trabeculation and locates the right bundle branch within the right ventricle. All the major papillary muscles supply chordae to adjacent components of the leaflets they support (see Figs $57.17,57.18$ ). A feature of the right ventricle is that the septal leaflet is tethered by individual chordae tendineae directly to the ventricular septum; such septal insertions are never seen in the left ventricle. When closed, the three leaflets fit snugly together, the pattern of the zones of apposition confirming the trifoliate arrangement of the tricuspid valve.

## Pulmonary valve

The pulmonary valve, guarding the outflow from the right ventricle, surmounts the infundibulum and is situated at some distance from the other three cardiac valves (Figs 57.21, 57.23). Its general plane faces superiorly to the left and slightly posteriorly. It has three semilunar leaflets, attached by convex edges partly to the infundibular wall of the right ventricle and partly to the origin of the pulmonary trunk. The line of attachments is curved, rising at the periphery of each leaflet near their zones of apposition (the commissures) and reaching the sinutubular ridge of the pulmonary trunk (Fig. 57.24). Removal of the leaflets reveals that the fibrous semilunar attachments enclose three crescents of infundibular musculature within the pulmonary sinuses, whereas three roughly triangular segments of arterial wall are incorporated within the ventricular outflow tract beneath the apex of each commissural attachment. Thus there is no proper circular 'anulus' supporting the leaflets of the valve, and the fibrous semilunar attachment is an

Fig. 57.21 The base of the ventricles, after removal of the atria and the pericardium, exposing the coronary arteries and cardiac veins. Contrast the planes and positions of the aortic and pulmonary valves, and with Figure 57.23. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
essential requisite for snug closure of the nodules and lunules of the leaflets during ventricular diastole (see below).

It is difficult to name the leaflets and corresponding sinuses of the pulmonary valve and trunk precisely according to the coordinates of the body because the valvular orifice is obliquely positioned. Terminologia Anatomica (2011) refers to anterior, posterior and septal leaflets on the basis of their fetal position but this changes with development, becoming anterior, right and left, respectively, in the adult. Each leaflet is an endocardial fold with a variably developed intervening substantial fibrous core that traverses both the free edge and the semilunar attached border. The latter is particularly thickened at its deepest central part (nadir) of the base of each leaflet, and therefore never forms a simple complete fibrous ring. The free margin of each leaflet contains a central localized collagenous thickening, the nodule of Arantius. Perforations within the leaflets close to the free margin and near the commissures are frequently present and are of no functional significance. Each semilunar leaflet is contained within one of the three sinuses of the pulmonary trunk.

## Opening of the pulmonary valve

During diastole, all three leaflets of the pulmonary valve are tightly apposed. The pulmonary valve is difficult to visualize at echocardiography and usually only the posterior leaflet is visible when the valve is closed; atrial systole may cause a slight posterior movement of the valve leaflets. The pulmonary valve opens passively during ventricular systole and then closes rapidly at the end of systole (see Fig. 57.20).

## Left atrium

## General, external and internal features

Although smaller in volume than the right, the left atrium has thicker walls ( 3 mm on average). It possesses a venous component that receives the right and left superior and inferior pulmonary veins, a vestibule and an appendage. Its cavity and walls are formed largely by the proximal parts of the pulmonary veins that are incorporated into the atrium during development. Its extensive body is a remnant of the initial atrial component of the primary heart tube. The left atrium is roughly cuboidal, extending posterior to the right atrium and separated from it by the obliquely positioned septum. The right atrium is therefore anterolateral to the right part of the left atrium. The left part is concealed anteriorly by the initial segments of the pulmonary trunk and aorta: part of the transverse pericardial sinus lies between it and these arterial trunks. Anteroinferiorly, and to the left, it adjoins the base of the left ventricle at the orifice of the mitral valve. Its posterior aspect forms most
of the anatomical base of the heart and is approximately quadrangular, receiving the terminations of (usually) two pulmonary veins from each lung, forming the anterior wall of the oblique pericardial sinus (see Fig. 57.3). This surface ends at the shallow vertical interatrial groove that descends to the cardiac crux.

The left atrial appendage is characteristically longer, narrower and more hooked than the right, and is a finger-like extension with more deeply indented margins. It is constricted at its atrial junction and all its contained pectinate muscles are much smaller than their right counterparts. The left atrium lacks a crista terminalis, and the muscle bundles in the appendage are arranged in a whorl-like fashion rather than being in an array. The tip of the appendage has a variable position lying over the pulmonary trunk and anterior interventricular artery, pointing posteriorly towards the aorta (Fig. 57.22). Its narrow morphology renders the left atrial appendage a potential site for deposition of thrombi.

The four pulmonary veins open into the superior posterolateral surfaces of the left atrium, two on each side (see Figs 57.3, 57.4B). This typical arrangement is present in $20-60 \%$ of the population. A common variation includes the presence of a short or long left common venous trunk and multiple pulmonary veins on the right (Fig. 57.25). The right pulmonary veins travel posterior to their respective venae cavae. Their orifices are smooth and oval, the left pair frequently opening via a common channel. Interpulmonary ridges are usually found between ipsilateral orifices; the most prominent is located between the openings of the left atrial appendage and left superior pulmonary vein. The ridges are infoldings of the left atrial wall and contain adipose tissue, atrial arteries and nerve bundles. At the site of the pericardial reflection, the atrial musculature extends into the pulmonary veins, forming myocardial sleeves that are thickest in the inferior wall of the superior pulmonary veins and the superior walls of the inferior pulmonary veins. They lie external to the venous tunica media and internal to the epicardium/ adventitia and are often the site of focal electrical activity that initiates atrial fibrillation. Atrial myocardial bridges and crossing strands are often present, connecting the left superior and inferior pulmonary veins.

Several epicardial fat pads on the pulmonary venous component house the superior left, posterolateral, left inferior and posteromedial ganglionated cardiac intrinsic nerve plexuses (typically four). Minimal cardiac veins (venae cordis minimae) return blood directly from the myocardium to the left atrial cavity. The left atrial aspect of the septum has a characteristically rough appearance, bounded by a crescentic, superiorly concave ridge that marks the site of the foramen ovale. The smooth circumferential area of atrial wall that surrounds the orifice of the mitral valve is the vestibule (see Fig. 57.25A, Fig. 57.26). The musculature between the ostium of the inferior pulmonary vein and the

Fig. 57.23 Principal elements of the fibrous skeleton of the heart. For clarity, the view is from the right posterosuperior aspect. Perspective causes the pulmonary anulus to appear smaller than the aortic anulus, whereas, in fact, the reverse is the case. Consult the text for an extended discussion. anulus of the mitral valve is the left atrial or mitral isthmus, and is an area where the vestibule of the left atrium directly opposes the wall of the great cardiac vein, coronary sinus and circumflex coronary artery.

## Left ventricle

## General and external features

The left ventricle is constructed in accordance with its role as a powerful pump for the high-pressured systemic arterial circulation. Variously described as half-ellipsoid or cone-shaped, it is longer and narrower than the right ventricle, extending from its base in the plane of the atrioventricular groove to the cardiac apex. Its long axis descends anteriorly and to the left. In transverse section, at right angles to the axis, its cavity is oval or nearly circular, with walls three times thicker ( $8-12 \mathrm{~mm}$ ) than those of the right ventricle (Fig. 57.27). It forms part of the sternocostal, left and inferior (diaphragmatic) cardiac surfaces. Except where obscured by the aorta and pulmonary trunk, the base of the ventricular cone is superficially separated from the left atrium by part of the atrioventricular groove with the coronary sinus within in its posterior aspect (see Fig. 57.4B,D). The anterior and posterior (inferior) interventricular grooves indicate the lines of mural attachment of the ventricular septum and the limits of the ventricular territories. The sternocostal surface of the ventricle curves bluntly into its left surface at the obtuse margin.

The shape of the left ventricle changes from elliptical in the neonatal period to the round adult shape later in infancy (Azancot et al 1983).

The effect of obesity on the heart is apparent as early as the second year of life. Obese children aged 2 years have a greater left ventricular mass compared with normal weight controls (de Jonge et al 2011).

## Internal features

The left ventricle has an inlet region guarded by the mitral valve (ostium venosum), an outlet region guarded by the aortic valve (ostium arteriosum) and an apical trabecular component. The left atrioventricular orifice admits atrial blood during diastole, the flow being directed towards the cardiac apex (Fig. 57.28). After closure of the mitral leaflets and throughout the ejection phase of systole, blood is expelled from the apex through the aortic orifice. In contrast to the orifices within the right ventricle, those of the left ventricle are in close contact with fibrous continuity between the leaflets of the aortic and mitral valves (the 'subaortic curtain') (Fig. 57.29); the inlet and outlet turn sharply round this fibrous curtain. The anterolateral wall is the muscular ventricular septum, the convexity of which completes the circular outline of the left ventricle (see Fig. 57.27). Towards the aortic orifice, the septum becomes the thin and collagenous interventricular component of the membranous septum, an oval or round area below and confluent with the fibrous triangle separating the right and the non-coronary leaflets of the aortic valve. Between the inferior limits of the free margins of the leaflets of the mitral valve and the ventricular apex, the muscular walls exhibit deeper, finer and more intricate trabeculae carneae than those of the right ventricle, characteristically more developed nearer the apex, and becoming smoother as the superior septal surface is reached.

Fig. 57.24 A, The structure of the aortic root is best conceptualized in terms of a three-pronged coronet; there are at least three rings within this coronet but none supports the entirety of the attachments of the valvular leaflets (compare with C). B, The leaflets have been resected at their attachment to the aortic wall. Note the relationship of the leaflet insertions and the ventriculoarterial junction. C, The root of the aorta has been cut open and distended, in order to show the insertion of the semilunar leaflets. Note the zone of fibrous continuity between the leaflets of the aortic and mitral valves and their relationship to the fibrous trigones, and the semilunar attachment of the leaflets (compare with B). (Redrawn with permission, courtesy of Professor RH Anderson, Institute of Child Health, University College, London.)

Fig. 57.25 Sagittal sections showing the left side of the left atrium in a cadaveric heart. A, The oesophagus (O) passing behind the posterior left atrial wall and a broad left-lateral ridge (double-headed arrow). The left upper (LUPV) and left lower (LLPV) pulmonary veins enter the left atrium via a short common stem. Other abbreviations: LAA, left atrial appendage; MV, mitral valve. B, The section passes through the os of the left atrial appendage and the infolding of the ridge. The triangle indicates the carina or interpulmonary ridge between the upper and lower pulmonary veins. The great cardiac vein (GCV) runs underneath the left atrial wall. ## Hypertrophy of heart muscle

Available with the Gray's Anatomy e-book

## Mitral valve

The general comments already made for the tricuspid valve also apply to the mitral valve. Thus it has an orifice with a supporting anulus, leaflets and a variety of chordae tendineae and papillary muscles.

## Mitral valvular orifice

The mitral orifice is a well-defined transitional zone between the atrial wall and the leaflet bases, being smaller than the tricuspid orifice (mean circumference is 9.0 cm in males and 7.2 cm in females). The approximately circular orifice is almost vertical and at $45^{\circ}$ to the sagittal plane in diastole, but with a slight anterior tilt. Its ventricular aspect faces anterolaterally to the left and a little inferiorly towards the left ventricular apex. It is almost co-planar with the tricuspid orifice but posterosuperior to it, whereas it is posteroinferior and slightly to the left of the aortic orifice. The mitral, tricuspid and aortic orifices are intimately connected at their central fibrous body. When the mitral valve leaflets close, they form a single zone of coaptation, termed the commissure. The anulus of the valve is not a simple fibrous ring but is made up of fibrocollagenous elements of varying consistency, from which the fibrous leaflet cores take origin; the variable consistency is essential to allow the major changes in anular shape and dimensions during the cardiac cycle that are needed for optimal valvular efficiency. The area of

Hypertrophic cardiomyopathy is characterized by myocardial wall thickening, particularly a disproportionate thickening of the interventricular septum in comparison with the posterior wall. Echocardiography accurately assesses the degree of thickening and its effect on systolic function, such as dynamic left ventricular outflow obstruction, systolic anterior motion of the aortic mitral valve leaflet and mid-systolic closure of the aortic valve. There may also be a degree of diastolic dysfunction. Serial short-axis gradient echo MRI allows accurate measurement of wall thickness and is particularly useful in assessing apically confined hypertrophy. A number of histological changes are observed, including cardiomyocytic disarray with replacement fibrosis and collagenous component expansion. Treatment is usually medical, except for refractory cases and those in whom the left ventricular outflow tract obstruction has a gradient of greater than 50 mmHg . Ventricular septal myotomy and myectomy are performed in such cases. Catheter alcohol septal ablation has been introduced as a non-surgical alternative. A number of patients may also require implantation of cardiac defibrillators to prevent sudden cardiac death.

An athlete's heart may physiologically hypertrophy but in a uniform fashion; the left ventricle cavity is usually less than 55 mm in size, and thickness decreases on deconditioning. In contrast, hypertrophic cardiomyopathy reveals asymmetric patterns of left ventricular hypertrophy, often with sharp segmental transitions, left atrial enlargement and bizarre electrocardiographic patterns. Furthermore, there is an autosomal dominant inheritance pattern of abnormalities in genes coding for myocardial proteins associated with hypertrophic cardiomyopathy. Individuals with mutations of the $\beta$-MHC (major histocompatibility complex) gene usually develop the classic form of hypertrophy, whereas those with cardiac troponin T gene mutations generally have only mild or clinically undetectable hypertrophy. Rare forms of hypertrophy include localized left ventricular apical hypertrophy as a result of cardiac troponin I mutations, and isolated midcavity hypertrophy caused by cardiac actin and MLC (myosin light chain) gene mutations.

Fig. 57.26 The posterior wall of the left atrium close to the posterior interatrial groove in a cadaveric heart. The smooth-walled venous component of the left atrium is the most extensive component. The septal aspect of the left atrium shows the crescentic line of the free edge of the flap valve against the rim of the fossa ovalis. The orifices of the right superior and inferior pulmonary veins are adjacent to the plane of the septal aspect of the left atrium. (Specimen courtesy of M Loukas MD, PhD.)

Fig. 57.27 Left and right ventricles: cross-section perpendicular to the axis of the heart, superior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
the anulus increases linearly with body surface area in children and young adults (Poutanen et al 2006). The anulus is strongest at the internal aspects of the left and right fibrous trigones. Extending from these structures, the anterior and posterior coronary prongs (tapering, fibrous, subendocardial tendons) partly encircle the orifice at the atrioventricular junction (see Fig. 57.23). Between the prong tips, the atrial and ventricular myocardial masses are separated by a more tenuous sheet of deformable fibroelastic connective tissue. Spanning anteriorly between the trigones, the fibrous core of the central part of the aortic leaflet of the mitral valve is a continuation of the fibrous subaortic curtain that descends from the adjacent halves of the left and adjacent (non-coronary) valve leaflets (see Fig. 57.29).

## Mitral valve leaflets

The mitral valvular leaflets have long been described as paired structures. (The name 'bicuspid valve' is explicit but erroneous because the leaflets are not cuspid, or 'peaked', in form). Small accessory leaflets are almost always found between the two major leaflets and so the mitral valve should be described as a continuous veil that is attached around the entire circumference of the mitral orifice. Its free edge bears several indentations, of which two are sufficiently deep and regular to be nominated as the ends of a solitary and oblique zone of apposition or
commissure. These anteromedial (inferoseptal) and posterolateral (superoposterior) extremities may be regarded as two independent commissures, each positionally named as indicated in brackets. Although simple, the official names for these leaflets - anterior and posterior, respectively - are somewhat misleading because of the obliquity of the valve.

When the valve is laid open, the anterior leaflet (aortic, septal, 'greater' or anteromedial) is seen to guard one-third of the circumference of the orifice and to be semicircular or triangular, with few or no marginal indentations. Its fibrous core (lamina fibrosa) is continuous on the outflow aspect, beyond the margins of the fibrous subaortic curtain, with the right and left fibrous trigones (see Figs 57.17, 57.21, 57.24 C ). Between the trigones, it is continuous with the fibrous curtain itself and, beyond the trigones, with the roots of the anular fibrous prongs (see Fig. 57.23). The leaflet has a deep crescentic rough zone that receives various chordae tendineae. The ridge limiting the outer margin of the rough zone indicates the maximal extent of surface contact with the mural leaflet in full closure. A clear zone is seen between the rough zone and the valvular anulus; it is devoid of attachments of chordae, although its fibrous core carries extensions from chordae attached in the rough zone. The anterior leaflet has no basal zone and continues into the valvular curtain. Hinging on its anular

Fig. 57.28 A dissection of the left ventricle in a cadaveric heart, exposing the papillary muscles of the ventricle. Notice the thick wall of the left ventricle and the chordae tendineae of the mitral valve attaching to the papillary muscles. (Specimen courtesy of M Loukas MD, PhD.)

Fig. 57.29 The aortic orifice opened from the front to show the leaflets of the aortic valves, their nodules, lunules, commissures and the triple-scalloped line of their anular attachment. Also shown are the continuity of the subaortic curtain with the mitral aortic leaflet (i.e. 'aortic baffle') and the coronary ostia, and the spatial relationship of the aortic orifice to the pulmonary orifice and to the left ventricle. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
attachment, and continuous with the subaortic curtain, it is critically placed between the inlet and the outlet of the ventricle. During passive ventricular filling and atrial systole, its smooth atrial surface is important in directing a smooth flow of blood towards the body and apex of the ventricle. After the onset of ventricular systole and closure of the mitral valve, the ventricular aspect of its clear zone merges into the smooth surface of the subaortic curtain, which, with the remaining fibrous walls of the subvalvular aortic vestibule, forms the smooth boundaries of the ventricular outlet.

The posterior leaflet (mural, ventricular, 'smaller' or posterolateral) usually has two or more minor indentations. Lack of definition of the major intervalvular commissures has led to disagreement and confusion concerning the territorial extent of this leaflet and the possible existence of accessory scallops. Examination of the valve in the closed position reveals that the posterior leaflet may conveniently be regarded as comprising all the valvular tissue posterior to the anterolateral (inferoseptal) and posteromedial (superoposterior) ends of the major zone of apposition with the aortic leaflet. Thus defined, it has a wider attachment to the anulus than does the anterior leaflet, guarding twothirds of the circumferential attachments. Further indentations usually divide the mural leaflet into a relatively large middle scallop and smaller lateral and septal commissural scallops. Each scallop has a crescentic opaque rough zone, receiving on its ventricular aspect the attachments of the chordae that define the area of valvular apposition in full closure. From the rough zone to within $2-3 \mathrm{~mm}$ of its anular attachment, there is a membranous clear zone devoid of chordae. The basal $2-3 \mathrm{~mm}$ is thick and vascular, and receives basal chordae. The ratio of rough to clear zone in the anterior leaflet is 0.6 and in the middle scallop of the posterior leaflet is 1.4. Much more of the mural leaflet is in apposition with the aortic leaflet during closure of the mitral valve.

## Opening of the mitral valve

At the onset of diastole, opening is passive but rapid, the leaflets parting and projecting into the ventricle as left atrial pressure exceeds left ventricular diastolic pressure. Passive ventricular filling proceeds as atrial blood pours to the apex, directed by the pendant aortic valvular leaflet. The leaflets begin to float passively together, hinging on their anular attachments and partially occluding the ventricular inlet. Atrial systole now occurs, jetting blood apically and causing re-opening of the leaflets. As maximal filling is achieved, the leaflets again float rapidly together. Closure is followed by ventricular systole, which starts in the papillary muscles and continues rapidly as a general contraction of the walls and septum. Coordinated contraction of the papillary muscles increases the tension in the chordae and promotes joining of the corresponding points on opposing leaflets, preventing their eversion. With general mural and septal excitation and contraction, left ventricular pressure increases rapidly (see Fig. 57.20). The leaflets 'balloon' towards
the atrial cavity, and the atrial aspects of the rough zones come into maximal contact. Precise papillary contraction, and increasing tension in the chordae, continue to prevent valvular eversion and maintain valvular competence. The orifices and the leaflets of both atrioventricular valves undergo considerable changes in position, form and area during a cardiac cycle. Both valves move anteriorly and to the left during systole, and reverse their motion in diastole. The mitral valve reduces its orificial (anular) area by as much as $40 \%$ in systole; its shape changes from circular to crescentic at the height of systole, the anular attachment of its aortic leaflet being the concavity of the crescent. The attachment of its mural leaflet, although remaining convex, contracts towards the anterior cardiac wall. The smooth left ventricular outflow tract (aortic vestibule) terminates at the aortic valve leaflets. Although stronger in construction, the aortic valve resembles the pulmonary valve (see Figs 57.21, $57.24,57.29$ ) in possessing three semilunar leaflets, supported within the three aortic sinuses of Valsalva. Although the aortic valve, like the pulmonary valve, is often described as possessing an anulus in continuity with the fibrous skeleton, there is no complete collagenous ring that supports the attachments of the leaflets. As with the pulmonary valve, the anatomy of the aortic valve is dominated by the fibrous semilunar leaflet attachment (see Fig. 57.24C).

## Mitral chordae tendineae

Mitral chordae tendineae resemble those supporting the tricuspid valve. False chordae are also irregularly distributed as in the right ventricle. They are single or multiple, thin, fibrous or fibromuscular structures that traverse the cavity of the left ventricle and have no connection with the valvular leaflets (Fig. 57.30). They occur commonly in human left ventricles and often cross the subaortic outflow. Histologically, false chordae sometimes contain extensions from the ventricular conducting tissues; these left ventricular bands are often identified on echocardiography. It has been suggested that false chordae produce premature ventricular contractions and be the possible cause of functional heart murmurs or innocent murmurs in children and young adults.

True mitral valve chordae may be divided into four types: interleaflet (commissural), rough zone (including the special strut chordae), 'cleft' and basal chordae. Most true chordae divide into branches from a single stem soon after their origin from the apical third of a papillary muscle, or proceed as single chordae that divide into several branches near their attachment. Basal chordae, in contrast, are solitary structures passing from the ventricular wall to the mural leaflet. There is such marked variation between the arrangement of the chordae that any detailed classification loses much of its clinical significance. Suffice it to say that, in the majority of hearts, the chordae support the entire free edges of the valvular leaflets, together with varying degrees of their ventricular aspects and bases, and there is some evidence to suggest that those valves with unsupported free edges become prone to prolapse in later life.

Fig. 57.30 The aorta has been transected at the level of the sinutubular junction in this cadaveric heart in order to reveal the closed leaflets of the aortic valve. Note how the supporting sinuses may be described as left coronary, right coronary and non-adjacent, according to the origin of the coronary arteries. However, this terminology could be ambiguous if the coronary arteries arise in variable locations, whereas the terminology of right, left and non-facing aortic sinus, respectively, is not ambiguous. Note the inter-leaflet triangles, membranous septum, and fibrous continuity between the aorta and mitral valve. (Specimen courtesy of M Loukas MD, PhD.)

## Papillary muscles

The two muscles supporting the leaflets of the mitral valve vary in length and breadth, and may be bifid. The anterolateral (superolateral) muscle arises from the sternocostal mural myocardium, and the posteromedial (inferoseptal) from the diaphragmatic region (see Fig. 57.27). Chordae tendineae arise mostly from the tip and apical third of each muscle but sometimes take origin near their base. The chordae from each papillary muscle diverge and are attached to corresponding areas of closure on both valvular leaflets.

## Aortic root

The aortic root, the anatomical bridge between the left ventricle and the ascending aorta, consists of the aortic valvular leaflets (supported by the aortic sinuses of Valsalva) and the inter-leaflet triangles interposed between their basal attachments (see Fig. 57.24). As such, it possesses significant length, but because of the semilunar attachment of the leaflets, it has no discrete proximal border. It is limited distally by the sinutubular junction (see Fig. 57.30). The essential feature is the semilunar attachments of the valve leaflets; their hinge lines cross the anatomical ventriculoarterial junction, marking a transition from the myocardium of the left ventricle to the fibroelastic tissue of the valve sinuses (Fig. 57.31). The muscular portion of the aortic root is roughly two-thirds of its widest circumference. Descriptions of the aortic root over the years have been bedevilled by accounts of a valve anulus. Although echocardiographers used to describe this proximal border in terms of an 'anulus', examination of cross-sections of the left ventricular outflow tract has never found any circular anatomical boundary or a distinct boundary of any kind (Loukas et al 2014a). There are at least two rings within the root; neither serves to support the valve leaflets, which are attached in semilunar fashion from the sinutubular junction to a basal ventricular attachment. Two leaflets are supported by muscle, and the third has an exclusively fibrous attachment. The root acts as a bridging structure not only anatomically, separating the myocardial and arterial components of the left ventricular pathway, but also functionally because its proximal and distal components can withstand considerable changes in ventricular and arterial pressures.

## Aortic valve leaflets

The aortic valve leaflets are attached in part to the aortic wall and in part to the supporting ventricular structures. The situation is more complicated than in the pulmonary valve because parts of the leaflets also take origin from the fibrous subaortic curtain, and are continuous with the aortic leaflet of the mitral valve (see Fig. 57.29). This area of continuity is thickened at its two ends to form the right and left fibrous trigones (see Fig. 57.21). As with the pulmonary valve, the semilunar attachments incorporate segments of ventricular tissue within the bases of two of the aortic sinuses. The sinuses and leaflets are conveniently named as right, left and non-coronary, according to the origins of the coronary arteries (see Fig. 57.24C). However, the so-called non-coronary leaflet is better termed the non-adjacent leaflet because it rarely gives rise to a coronary artery.

The semilunar attachments incorporate three triangular areas (trigones) of aortic wall within the apex of the left ventricular outflow tract. They are interposed between the bulbous aortic sinuses and separate the cavity of the left ventricle from the pericardial space. Removal of the trigones in an otherwise intact heart is instructive in demonstrating the relationships of the aortic valve, which, justifiably, may be considered as the keystone of the heart. The first triangle, between the non-coronary and left coronary leaflets, has a base continuous inferiorly with the fibrous aortic-mitral curtain. The second triangle, between right and non-coronary leaflets, has the membranous components of the interventricular septum as its base and thus 'faces' the right ventricle, whereas its apex 'points' towards the transverse pericardial space behind the origin of the right coronary artery. The third triangle, between the two coronary leaflets, has its base on the muscular interventricular septum and its apex 'points' to the plane of space found between the aortic wall and the free-standing sleeve of right ventricular infundibular musculature that supports the leaflets of the pulmonary valve. Although the basal attachments of each aortic valvular leaflet are thickened and collagenous at their ventricular origins, the leaflets lack a continuous collagenous circular skeletal support; valvular function depends primarily upon the semilunar attachments of the leaflets.

The leaflets are endocardial folds with a central fibrous core. With the valve half-open, each equals slightly more than a quarter of a sphere, an approximate hemisphere being completed by the corresponding sinus. Each leaflet has a thick basal border, deeply concave on its aortic aspect, and a horizontal free margin that is only slightly thickened,
except at its midpoint, where there is an aggregation of fibrous tissue, the valvular nodule of the semilunar leaflet. The fibrous core that flanks each nodule is tenuous, forming the lunules of translucent and occasionally fenestrated valvular tissue; fenestrations are of no functional significance. The aortic surface of each leaflet is rougher than its ventricular aspect.

Confusingly, three sets of names are used to describe the aortic leaflets. Posterior, right and left refer to their fetal positions before full cardiac rotation has occurred (Ch. 52). Corresponding terms based on their approximate positions in maturity are anterior, left and right posterior. Widespread clinical terminology, which links both leaflets and sinuses to the origins of the coronary arteries, has replaced anterior, left and right leaflets with right and left coronary and non-adjacent (and, usually, non-coronary) leaflets, respectively; these clinical terms are preferable in the normal heart because they are simple and unambiguous.

## Aortic sinuses (of Valsalva)

The aortic sinuses are more prominent than those in the pulmonary trunk. The upper limit of each sinus reaches considerably beyond the level of the free border of the leaflet and forms a well-defined circumferential sinutubular ridge on the aortic inner surface, just above the aortic valvular leaflets (see Fig. 57.24C). Coronary arteries usually open near this ridge within the upper part of the sinus but are markedly variable in their origin. The walls of the sinuses are largely collagenous near the attachment of the leaflets but the amount of lamellated elastic tissue increases with distance from the zone of attachment. At the midlevel of each sinus, its wall is about half the thickness of the supravalvular aortic wall and less than one-quarter of the thickness of the sinutubular ridge. At this level, the mean luminal diameter at the commencement of the aortic root is much larger than that of the ascending aorta; these details are functionally significant in the mechanism of valvular motion. A linear relationship between the diameter of the aortic sinus and the square root of body surface area has been described in children (Kaiser et al 2008).

## Opening of the aortic valve

During diastole, the closed aortic valve supports an aortic column of blood at high but slowly diminishing pressure (see Fig. 57.20). Each sinus and its leaflet form a hemispherical chamber. The three nodules are apposed and the margins and lunular parts of adjacent leaflets are tightly apposed on their ventricular aspects. From the aortic aspect, the closed valve is triradiate, three pairs of closely compressed lunules radiating from their nodules to their peripheral commissural attachments at the sinutubular junction (see Fig. 57.21). As ventricular systolic pressure increases, it exceeds aortic pressure and the valve is passively opened.

The fibrous wall of the sinuses nearest the aortic vestibule is almost inextensible but, more superiorly, the wall is fibroelastic. Under left ventricular ejection pressure, the radius here increases $16 \%$ in systole, as the commissures move apart to form a fully open triangular orifice. The free margins of the leaflets then become almost straight lines between peripheral attachments. However, they do not flatten against the sinus walls, even at maximal systolic pressure, which is probably an important factor in their subsequent closure. During ejection, most blood enters the ascending aorta but some enters the sinuses, forming vortices that help to maintain the triangular 'mid position' of the leaflet during ventricular systole and also probably initiate their approximation at the end of systole. Tight and full closure ensues with the rapid decrease in ventricular pressure in diastole. Commissures narrow, nodules aggregate and the valve reassumes its triradiate form. Experiments indicate that $4 \%$ of ejected blood regurgitates through a valve with normal sinuses, whereas $23 \%$ regurgitates through a valve without them. The normal structure of the aortic sinuses also promotes nonturbulent flow into the coronary arteries.

## Echocardiography

Echocardiography allows a detailed assessment of the functional anatomy of the heart. The gross anatomy of the heart can be evaluated by two-dimensional echocardiography in the parasternal, apical, suprasternal and subcostal positions (Fig. 57.32). The standardized planes used are long-axis, short-axis and four-chamber. The long-axis view is obtained by placing the ultrasound transducer in the left apicosternal position and provides detailed images of the left ventricle, aorta, left atrium, and mitral and aortic valves (Fig. 57.32C). Angling the beam towards the right also allows assessment of the right atrium, right ventricle and tricuspid valves. Rotating the transducer by $90^{\circ}$ in the

Fig. 57.31 A histological section through one of the coronary aortic sinuses to demonstrate the way in which ventricular muscle supports the transition from the fibroelastic wall of the sinus to the tissues of the leaflet. The transitional area is anchored to the ventricular muscle. The hinge of the leaflet is well below the level of the ventriculoarterial junction. Importantly, there is no ring-like structure in the form of an 'anulus' supporting the hinge of the leaflet within the ventricle. The muscular tissue of the ventricle is stained pink; fibrous tissue, which would show up as a characteristic light colour with this stain, is absent. Haematoxylin and eosin stain. (Courtesy of Diane E Spicer.)

Fig. 57.32 Cardiac anatomy shown by transthoracic echocardiography and CT. A, Four-chamber view. B, Short-axis view at aortic valve level. Note three aortic leaflets - right, left and non-adjacent - and the central position of the aorta. C, Parasternal long-axis view. D-F, Corresponding images by CT. Note the different orientation compared with transthoracic echocardiography (looked at from below, foot to head). Abbreviations: A, anterior; AV, aortic valve; F, foot; H, head; L, left; LA, left atrium; LV, left ventricle; MV; mitral valve; NC, non-adjacent; P, posterior; PV, pulmonary valve; R, right; RA, right atrium; RV, right ventricle; TV, tricuspid valve. (Images courtesy of Dr Konstantinos Dimopoulos, Royal Brompton and Chelsea and Westminster Hospitals, London.)
clockwise direction produces the short-axis view, which allows assessment of the left ventricle, papillary muscles, chordae tendineae and mitral valves (Fig. 57.32B). The four-chamber view demonstrates the ventricles, atria, and mitral and tricuspid valves (Fig. 57.32A). Rotation of the transducer allows two-chamber views of the heart and more detailed assessment of the aorta and aortic valves. Cardiac MRI and CT provide similar information on cardiac structure and function (see Figs $57.2,57.35 \mathrm{~A}, \mathrm{~B}$ ), together with complementary information on great vessels (Fig. 57.32D-F) and other extracardiac intrathoracic structures.

## CONNECTIVE TISSUE AND FIBROUS SKELETON OF THE HEART

From epicardium to endocardium and from the orifices of the great veins to the roots of the arterial trunks, the intercellular spaces between contractile and conduction elements are permeated by connective tissue; the amount, arrangement and texture vary greatly with location. Over much of the heart, a fine layer of areolar tissue is found beneath the mesothelium of the serous (visceral) epicardium that accumulates subepicardial fat, concentrated along the acute margin, the atrioventricular and interventricular grooves, and their side channels. The coronary vessels and their main branches are embedded in this fat; the amount increases with age. The endocardium also lies on a fine areolar tissue rich in elastic fibres. Fibrocellular components of these subepicardial and subendocardial layers blend on their mural aspects with the endomysial and perimysial connective tissue on the myocardium. Each cardiac myocyte is invested by a delicate endomysium composed of fine reticular, collagen and elastin fibres embedded in ground substance. This matrix is lacking only at desmosomal and gap junctional contacts of intercalated discs. Similar arrangements apply to ventricular conduction myocytes and their extensive working myocardial contacts. The
connective tissue matrix itself is interconnected laterally to form bundles, strands or sheets of macroscopic proportions showing a complex geometric pattern. Surrounding and attaching to larger myocardial bundles are stronger perimysial condensations. The overall pattern is described in terms of struts and weaves. Despite its importance, the myocardial matrix cannot be grossly dissected.

Running at the ventricular base is a complex framework of dense collagen with membranous, tendinous and fibroareolar extensions, intimately related to atrioventricular valves and the aortic orifice. The whole is sufficiently distinct to be termed the fibrous skeleton of the heart, but although it is often stated that all four valves are contained within this skeleton, this is not the case. The leaflets of the pulmonary valve are supported on a free-standing sleeve of right ventricular infundibulum that can easily be removed from the heart without disturbing either the fibrous skeleton or the left ventricle. Another point of confusion is the idea that the 'skeleton' provides the support for the cardiac valves. In reality, it is the overall structure of the atrioventricular junctions that supports the mitral and tricuspid valves, whereas the arterial valves are hinged within the valvular sinuses. The fibrous skeleton is strongest at the junction of the aortic, mitral and tricuspid valves, the so-called central fibrous body (see below) (see Figs 57.21, 57.23). Two pairs of curved, tapering, collagenous prongs, fila coronaria, extend from the central fibrous body. They are stronger on the left, where they pass partially around the mitral and tricuspid orifices. These orifices are almost co-planar and incline to face the cardiac apex. In contrast, the aortic valve faces superiorly, lying anterosuperior and to the right of the mitral orifice. Two of the leaflets of the aortic valve are in fibrous continuity with the aortic leaflet of the mitral valve; this subaortic curtain is also an integral part of the fibrous skeleton (see Figs 57.21, 57.24C). The two ends of the curtain are strengthened as the right and left fibrous trigones, which are the strongest parts of the skeleton. The right trigone, together with the membranous septum, constitutes the central fibrous
body, which is penetrated by the atrioventricular bundle of His (see below). The membranous septum is crossed on its right aspect by the attachment of the tricuspid valve, dividing the septum into atrioventricular and interventricular components.

The aortic root is central within the fibrous skeleton and is often described in terms of an 'anulus' integrated within the fibrous skeleton (Anderson et al 2013b). However, as with the pulmonary valve, the structure of the aortic root corresponds to the triple fibrous semilunar attachments of its leaflets. Within this complex circumferential zone are three crucially important triangular areas that separate, on the ventricular aspect, the aortic bulbous sinuses that house the valvular leaflets. As a whole, three triangles, known as the subaortic spans, can be conceptualized in terms of a three-pointed coronet; their triangular apices correspond to the tips of the valvular commissures and their walls, significantly thinner than those of the sinuses, consist variously of collagen or admixed muscle strands and fibroelastic tissue. They form the subvalvular extensions of the aortic vestibule. The first span is the interval between the non-coronary and left coronary sinuses that is filled with the deformable subaortic curtain. The second span between the non-coronary and right coronary sinuses is continuous with the anterior surface of the membranous septum. The third span, between the two coronary aortic sinuses, is filled with loose fibroelastic tissue and separates the extension of the subaortic root from the wall of the free-standing subpulmonary infundibulum. Previously, this was thought to be the location of the tendon of the infundibulum (conal (conus) ligament) (Loukas et al 2007); research using mouse hearts has shown that the ligament is found at the level of the sinutubular junctions at the site of initial fusion of the distal outflow cushions. The line of proximal fusion is the longitudinal raphe sometimes seen in the muscular subpulmonary infundibulum.

Similar fibrous triangles are found separating the sinuses of the pulmonary trunk but these are significantly less robust. Use of the terms mitral and tricuspid 'anuli' implies that the atrioventricular valves are supported by discrete circular fibrous rings, when, in reality, they are D-shaped structures integrally attached to the fibrous cardiac skeleton. It is therefore inaccurate to consider these valvular orifices as circular. Rather, the straight edge of the ' $D$ '-shaped mitral valve represents a fibrous continuity between the anterior leaflet and the aortic root, and the remainder supports the mural leaflet. The straight edge of the tricuspid valve represents the attachment of the septal leaflet, marking the inferior border of the triangle of Koch, and the remainder supports the anterosuperior and inferior leaflets. The valvular attachments of the atrioventricular valves are not simple, rigid collagenous structures but dynamic, deformable lines that vary greatly at different peripheral points and change considerably with each phase of the cardiac cycle and with increasing age. The tricuspid attachments are even less robust than those of the mitral valve. At several sites, only fibroareolar tissue separates the atrial and ventricular muscular masses.

The fibrous skeleton ensures electrophysiological discontinuity between the atrial and ventricular myocardial masses (except at the site of penetration of the conduction tissue). It also provides direct attachment for the myocardium and for fibrous tissue throughout the heart as a support matrix for a three-dimensional meshwork of cardiomyocytes.

Arrangement of cardiomyocytes The microstructure of cardiac muscle is described in detail in Chapter 6. Ventricular myocytes form a three-dimensional mesh in a supporting fibrous matrix. One population is aligned so that the long axis of the aggregated cells is tangential to the epicardial and endocardial borders, albeit with marked variation in the angulation relative to the ventricular equator. Correlation with measurements taken using force probes shows that these myocytes produce the major unloading of the blood during ventricular systole. A second population is aligned at angles of up to $40^{\circ}$ from the epicardium towards the endocardium and produces auxotonic forces during the cardiac cycle. The three-dimensional arrangement of the mesh as demonstrated in MRI of the porcine heart also mediates the realignment of cardiomyocytes that must take place during ventricular contraction and accounts for the extent of systolic mural thickening (Fig. 57.33).

The finding that the number of cardiomyocytes in the left ventricle increases between the first and the twentieth year of life suggests that children may be able to regenerate myocardium (Mollova et al 2013).

## CONGENITAL CARDIAC MALFORMATIONS

Congenital malformations of the heart are common and amount to about one-quarter of all developmental anomalies. Their incidence is

Fig. 57.33 A reconstruction of a porcine heart made following diffusion tensor MRI of an autopsied heart. The tracks are created from the first eigenvectors and represent the alignment of the aggregated myocytes. This technique enables the identification of reproducible tracks, or pathways, through the myocardium that connect remote end and epicardial regions by means of simultaneous changes in helical and intrusion angles. (With permission from Anderson R, Smerup M, SanchezQuintana D, Loukas M, Lunkenheimer P. 2009. The three-dimensional arrangement of the myocytes in the ventricular walls. Clin Anat 22:64-76.)
estimated at 8 per 1000 live births but they are found in up to $2 \%$ of stillbirths. Only a small proportion of the anomalies are directly attributable to genetic or environmental factors and the majority are the result of multifactorial events.

## CONDUCTION TISSUES

The cells of cardiac muscle differ from those of skeletal muscle in having the inherent ability to contract and relax spontaneously. This myogenic rhythm is shown by small pieces of cardiac tissue, and even isolated myocytes. Ventricular cells contract and relax at a lower frequency than atrial cells, but in the intact heart, both are synchronized to a more rapid rhythm, generated by pacemaker tissue in the sinus and atrioventricular nodes and conveyed by a system of specialist conduction fibres in the atrioventricular conduction axis and the ventricular conducting pathways (Purkinje cells). For an account of excitation-contraction coupling in cardiac muscle, see page 138.

The anatomical arrangement of these tissues is described in the context of the heart. Here, consideration is restricted to the cells that make up the impulse-generating and conduction system. All are modified cardiac cells. Three types within a continuum of morphology may be distinguished from normal working cells, namely: nodal cells, transitional cells and Purkinje cardiomyocytes.

## Overview of the conduction system

Of all the cells in the heart, those of the sinu-atrial node generate the most rapid rhythm, and therefore function as the cardiac pacemaker. The impulse, believed to be generated in the nodal cells, is transmitted

The most severe abnormality of position is an extrathoracic heart (ectopia cordis), where the heart usually projects to the surface through the lower thoracic and upper abdominal wall, remaining covered, in most instances, by the fibrous pericardium, and usually accompanied by herniation of the abdominal contents. A mirror image, i.e. reversal in cardiac shape and position, occurs predominantly in the right hemithorax (dextroposition). The apex of the heart may be directed to the right instead of the left (dextrocardia). This arrangement may be part of 'situs inversus totalis', where the heart, great vessels and abdominal organs all occupy mirror-imaged positions. The heart may also be right-sided in Kartagener's syndrome (a subgroup of ciliary dyskinesias).

More usually, an abnormal location of the heart occurs in cases of isomerism, in which both sides of the thorax, including the main bronchi and the atrial appendages, retain features of either morphological right- or left-sidedness. Isomerism is also commonly associated with the anomalous arrangement of the abdominal organs: right isomerism with absence of the spleen (asplenia) and left isomerism with multiple spleens (polysplenia). Intracardiac anatomy in cases of isomerism is almost universally abnormal, and there is a range of heart defects (usually more simple in left and more complex in right isomerism).

These intrathoracic abnormal arrangements, with or without abdominal abnormalities, often first manifest themselves incidentally following chest radiography. Reversal of normal anatomy has obvious clinical implications, a typical example being a patient with mirror-image arrangements and appendicitis, who presents with an acute left lower quadrant pain.

Most congenital heart abnormalities can be detected during antenatal ultrasound screening (Fig. 57.34). Neonates with severe congenital heart disease may present with tachypnoea, difficulty in feeding, cyanosis and/or cardiovascular collapse, and there may be audible murmurs on auscultation. The vast majority of abnormalities may be detected by postnatal echocardiography; in a very few cases, cardiac catheterization and direct measurements of pressure, oxygen saturations and angiography may be required.

Acyanotic cardiac defects are the result of either left-to-right cardiac shunting through heart defects (intra- or extracardiac) or of obstruction. Left-to-right shunting leads to an increased workload and stress on the heart and the lungs as a consequence of increased pulmonary blood flow and increased pulmonary venous return. Depending on the location of the shunt and the magnitude of left-to-right shunting, patients are at risk of developing pulmonary arterial hypertension unless timely heart surgery is undertaken. Examples of defects leading to left-to-right shunting are simple septal defects such as atrial or ventricular septal defects or patent ductus arteriosus, or more complex atrioventricular septal defects, and/or a combination of any of these defects with abnormal atrioventricular or ventriculoarterial connections (e.g. a double-outlet right ventricle, where more than $50 \%$ of both the aorta and the pulmonary artery originate from the right ventricle) (Ch. 52). Obstructive lesions may involve the atrioventricular or arterial valves (mitral, aortic or pulmonary valve stenosis), or narrow vessels (e.g. coarctation of the aorta or interrupted aortic arch). Depending on the level and severity of the obstruction, patients may have a range of

Fig. 57.34 A, Tricuspid atresia at 21 weeks' gestation. A four-chamber view showing a large left ventricle and a hypoplastic right ventricle. The mitral valve is seen; no tricuspid valve is identified. There is an associated ventricular septal defect. B, An atrioventricular septal defect at 20 weeks' gestation. A common atrioventricular valve (arrow) is associated with a defect in the atrioventricular septum. C, Hypoplastic left heart syndrome at 32 weeks' gestation. This four-chamber view shows a large right atrium, right ventricle and tricuspid valve. There is a hypoplastic left ventricle; no mitral valve is identified. D, Hypoplastic left heart syndrome at 32 weeks' gestation. This four-chamber view shows colour flow from right atrium to right ventricle across the tricuspid valve; no mitral valve is identified and there is no flow in the left side of the heart. E, Tetralogy of Fallot at 33 weeks' gestation. The aorta arises astride a ventricular septal defect. F, Transposition of the great arteries at 21 weeks' gestation. The aorta and pulmonary artery arise in parallel orientation. The aorta arises from the right ventricle and the pulmonary artery from the left ventricle. Fig. 57.35 A, Cardiac magnetic resonance angiography in a patient with a normal heart. Note the criss-cross relationship of the great arteries; the aorta arises from the left ventricle and runs to the right and posteriorly to the pulmonary trunk (at its origin) and towards the head. The pulmonary artery arises from the right and anterior right ventricle, crosses over and then runs to the left of the aorta and towards the back (where it bifurcates into the right and left pulmonary arteries at the underside of the aortic arch). B, A cardiac magnetic resonance angiogram from a patient with transposition of the great arteries. Note the parallel or side-by-side relationship of the great vessels and loss of their normal criss-cross relationship. The aorta runs anteriorly and comes off the right ventricle. The hypertrophied right ventricle supports the systemic circulation, and the ventricular septum bows from right to left Abbreviations: Ao, aorta; LV, left ventricle; PT, pulmonary trunk; RV, right ventricle. (Courtesy of Dr Philip Kilner, Royal Brompton Hospital, London.)
clinical presentations from an asymptomatic heart murmur (common) to cardiovascular collapse (uncommon). Treatment in all cases is directed towards normalizing heart workload, systemic and pulmonary blood flow, and cardiac output, and may be surgical and/or catheterbased.

Cyanotic cardiac defects may be attributable to a right-to-left intra- or extracardiac shunt or to a severe reduction in pulmonary blood flow. They may be caused by simple lesions such as severe pulmonary stenosis with an atrial septal defect and right-to-left shunting; moderate lesions, including Fallot's tetralogy, in which there is a ventricular septal defect, right ventricular outflow obstruction, right ventricular hypertrophy and an overriding aorta; or more complex lesions, including trans-
position of the great arteries (Fig. 57.35; p. 924) and tricuspid and pulmonary atresia (often in the setting of hypoplastic right ventricle and functionally univentricular physiology). Neonates with severe cyanotic congenital heart defects may be dependent on the patency of the ductus arteriosus; early diagnosis, treatment with intravenous prostaglandin infusion and timely transfer to a tertiary centre for more definitive therapy is key to survival and good long-term outcomes.

Major advances in the diagnosis and management of infants with congenital cardiac malformations in recent years have resulted in an increased number of adolescents and adults with palliated or repaired, but not cured, congenital heart disease. This is an area that poses multiple challenges to both cardiovascular and other medical disciplines.
over preferentially conducting pathways to right and left atria, and to the atrioventricular node. At the atrioventricular node, the impulse is delayed by 40 ms , allowing the atria to eject their contents fully before commencement of ventricular contraction, and also placing an upper limit on the frequency of signals that can be transmitted to the ventricles. The transitional cells interpose between the atrial cardiomyocytes and the nodal cells. There is no transition in humans between the node and the penetrating bundle, and the cells are virtually identical. Here, they become continuous with the more distinctively appearing Purkinje cells. Conduction of the impulse is rapid in the bundle and its branches $(2-3 \mathrm{~m} / \mathrm{sec}$, as opposed to $0.6 \mathrm{~m} / \mathrm{sec}$ in normal myocardium). The cardiac impulse therefore arrives at the apex of the heart before spreading through the ventricular walls, producing a properly coordinated ventricular ejection. The human heart beats ceaselessly at 70 cycles every minute for many decades, maintaining perfusion of pulmonary and systemic tissues. The rate and stroke volume fluctuate in response to prevailing physiological demands. The principal events in a cardiac cycle are summarized in Figure 57.20, including the electrical events recorded in the electrocardiogram; the mechanical sequences of diastole, atrial systole, volumetric contraction, ejection and isovolumetric relaxation in ventricular systole; the acoustic phenomena recorded in the phonocardiogram; the pressure profiles of right and left hearts and arterial trunks; and the sequences of valvular events.

Cardiac efficiency depends on precise timing of the operation in interdependent structures. Passive diastolic filling of the atria and ventricles is followed by atrial systole, stimulated by discharge from the sinu-atrial node, which completes ventricular filling. Excitation and contraction of the atria must be synchronous and finish before ventricular contraction; this is effected by a delay in the conduction of excitation from atria to ventricles. Thereafter, ventricular contraction proceeds in a precise manner. The atrioventricular valves are closed by ventricular systole, which must occur prior to closure; ventricular activation must therefore precede valvular closure, which spreads from the ventricular apices towards the outflow tracts and orifices.

Cardiac contraction originates unequivocally in specialized cardiomyocytes, but neural influences are important in adapting the intrinsic cardiac rhythm to functional demands from the entire body. All cardiomyocytes are excitable. They display autonomous rhythmic depolarization and repolarization of their cell membranes, conduction of waves of excitation via gap junctions to adjacent cardiomyocytes, and excitation-contraction coupling to their actomyosin complexes. These properties are developed to different degrees in different sites and in different types of cardiomyocyte (Ch. 6). The rate of depolarization and repolarization is slowest in the ventricular myocardium, intermediate in the atrial muscle, and fastest in the myocytes of the sinu-atrial node. The latter override those generating slower rhythms and, in the normal heart, are the locus for the rhythmic initiation of cardiac cycles. Conversely, conduction velocity is slow in nodal myocytes, intermediate in general 'working' cardiac myocytes, and fastest in the myocytes of the ventricular conduction system.

The nodes and networks of the so-called specialized myocardial cells constitute the cardiac conduction system (Figs 57.36-57.37). The components of this system are the sinus and atrioventricular nodes, the atrioventricular bundle with its left and right bundle branches, and the subendocardial plexus of ventricular conduction cells (Purkinje cells). The main pacemaker rhythm of the heart (sinus rhythm) is generated within the system but is influenced by nerves. It is transmitted specifically from atria to ventricles via the atrioventricular node and bundle. The spread of excitation is very rapid but not instantaneous. Different parts of the ventricles are excited at slightly different times, with important functional consequences. Failure of the conduction system will not block cardiac contraction but the system will become poorly coordinated. The rhythm will be slower because it originates from a spontaneous (myogenic) activity in the working cardiac myocytes or in a subsidiary pacemaker in a more distal part of the diseased or disrupted conduction system. There are no specialized internodal and interatrial conduction pathways; the excitation emanating from the sinu-atrial node spreads to the atrial musculature and to the atrioventricular node through ordinary atrial working myocardium. The geometric arrangement of fibres along well-organized atrial muscle bundles, e.g. the terminal crest, the rims of the fossa ovalis and Bachmann's bundle, ensures that conduction is marginally more rapid than elsewhere within the atrium.

## Sinu-atrial node

In the majority of hearts, the sinu-atrial node is a crescent-shaped structure, between 8 and 25 mm long, located at the embryonic junction between the venous part (sinus venosus) and the atrium proper derived
parts of the right atrium (see Figs 57.13A, 57.37). In hearts over 65 years of age, a layer of connective or fatty tissue between the subendocardium and the body of the node may sometimes render it visible to the naked eye. Extending on the right from the crest of the right appendage, the node typically courses posteroinferiorly into the upper part of the terminal groove; in about 1 in 10 hearts it extends in horseshoe fashion across the crest of the appendage. Nodal tissue does not occupy the full thickness of the right atrial wall from epicardium to endocardium but sits as a wedge of specialized subepicardial tissue within the terminal groove. Its location is consistently marked by a large central artery, which originates from either the proximal part of the right coronary or circumflex arteries in equal proportion. Nodal cells are grouped circumferentially around the sinu-atrial nodal artery, packed within a dense matrix of connective tissue as interlacing strands of myocytes. They are smaller, paler and more empty-looking than working atrial myocardial fibres, being $5-10 \mu \mathrm{~m}$ in their greatest diameter, with a large central nucleus. Their pale appearance is attributable to the sparsity of organelles; myofibrils are few and irregularly arranged, and there is no proper sarcotubular system with little glycogen.

The sinu-atrial node is described as having a head, body and tail, from which 5-8 short digitations of nodal tissue radiate towards the superior vena cava, subepicardium and crista terminalis, penetrating the working atrial myocardium (Figs 57.38-57.39). At the nodal periphery, nodal cells intermingle with slender, fusiform, transitional 'linking' cells that are part of a heterogeneous cellular group intermediate in appearance between nodal cells and normal working atrial myocytes. (For further reading on the use of molecular markers to map the extent of nodal tissue, see Monfredi et al (2010).) There are no autonomic ganglion cells within the node, although many border it anteriorly and posteriorly. Nerve fibres are present but do not appear to contact the nodal myocytes.

## Paranodal area

A paranodal area within the terminal crest, between the cells of the sinu-atrial node and the working atrial cardiomyocytes, and possessing properties of both nodal and atrial tissues, has been identified (Molenaar et al 2011). Its precise function remains to be determined, but computer simulations suggest that it is an integral part of normal atrial activation and may play a role in pacemaking.

## Internodal atrial myocardium

Specialized pathways have been alleged to connect the sinus and atrioventricular nodes, but there is no evidence that tracts insulated from the working myocardium, as occurs in the ventricular conduction pathways, exist within the atrial walls. The impulse generated by the sinuatrial node is conducted more rapidly via the long axis of the atrial muscle bundles than it is transversely. The main pathways for conduction towards the atrioventricular node are the terminal crest and the margins of the oval fossa. Conduction to the left atrium is preferentially through Bachmann's bundle; additional pathways occur through the margins of the oval fossa and through the muscular connections between the walls of the coronary sinus and left atrium. During development, the walls of the systemic venous sinus are exclusively composed of primary myocardium. Although pathways within these walls may be identified in prenatal stages, primary myocardium is slowly conducting, which means that these pathways do not represent areas of preferentially rapid conduction.

## Atrioventricular node

The atrioventricular node is an oblique, half-oval atrial structure, located within the atrial component of the muscular atrioventricular septum and separated from the ventricular musculature by the insulating tissues of the atrioventricular groove (see Fig. 57.37). Its anatomical landmarks are the boundaries of the triangle of Koch, i.e. the attachment of the septal leaflet of the tricuspid valve inferiorly, the ostium of the coronary sinus basally and the tendon of Todaro superiorly (see Fig. 57.13). The atrial aspect of the node is convex and overlain by atrial myocardium. Its left margin is concave and abuts on to the superior aspect of the central fibrous body. The basal end projects into the atrial muscle and the anteroinferior end enters the central fibrous body to become the penetrating atrioventricular bundle.

The node consists of two zones, compact and transitional, pervaded by an irregular collagenous reticulum that enmeshes the myocytes (Fig. 57.40). The compact zone consists of frequently stratified, interlocking nodal cells. Cells from the right and left atrial walls and the atrial septum feed directly into the compact zone. The transitional zone envelops the compact portion of the node and consists of elongated 'transitional cells', intermediate in morphology and function between compact nodal cells and working atrial cardiomyocytes.

Fig. 57.36 The conduction tissue of the heart. A, Right aspect. B, Left aspect. The elements of the conduction system are shown in purple. Conduction tissue accompanies fine trabeculae carneae and false chordae. In reality, the radiation of the left bundle branch is directly related to the leaflets of the aortic valve.

Extensions of nodal cardiomyocytes run in the direction of the coronary sinus along the tricuspid anulus (the putative 'slow pathway'); in the anterior portion of the triangle of Koch near the compact portion of the atrioventricular node (the putative 'fast pathway'); and in the direction of the mitral anulus (the left atrial extension) (Mani and Pavri 2014). In both sinus and atrioventricular nodes, the intercellular contacts between nodal cells, and between nodal and transitional cells, are much less specialized than the intercalated discs between normal cardiac cells (p. 137). A sparsity of gap junctions is consistent with the absence from these areas of connexin-43 (a major protein component of mammalian gap junctions), and probably accounts for the observed difficulty in exciting these cells from adjacent cells. The atrioventricular delay may owe much to this relative non-excitability, which appears to disturb the spread of potential, delaying propagation; the narrow diameter of the transitional cells may also contribute to conduction delay.

The arterial supply to the atrioventricular node is from a characteristic vessel that originates from the dominant coronary artery at the cardiac crux. Autonomic ganglia are present between the node and the coronary sinus.

## Atrioventricular bundle

The atrioventricular bundle (of His) is the direct continuation of the atrioventricular node. It becomes oval, quadrangular or triangular in transverse sectional profile as it enters the central fibrous body. It traverses the fibrous body and branches on the crest of the muscular interventricular septum; the branching tract is sandwiched between the muscular and the membranous components of the septum.

The right branch of the bundle (crus dextrum) is a narrow, discrete, rounded group of fascicles that courses at first within the myocardium and then subendocardially towards the ventricular apex, entering the septomarginal trabecula to reach the anterior papillary muscle. Its branches to the ventricular walls are few in its septal course. At the origin of the anterior papillary muscle, it divides profusely into fine subendocardial fascicles that diverge, first embracing the papillary muscle, then recurving subendocardially for distribution to the remaining ventricular walls.

The left branch (crus sinistrum) arises as numerous fine, intermingling fascicles that leave the left margin of the branching bundle through

Fig. 57.37 The basic structure of the conduction system and its relationship with the electrocardiogram. Note the foramen ovale allowing for communication between the right atrium (RA) and the left atrium (LA) Other abbreviations: SCV, superior vena cava. (Redrawn by courtesy of Professor RH Anderson, Institute of Child Health, University College, London.)
most of its course along the crest of the muscular ventricular septum (see Fig. 57.36). These fascicles form a flattened sheet down the smooth left ventricular septal surface that diverges apically and subendocardially across the left aspect of the ventricular septum, trifurcating into anterior, septal and posterior divisions. Fine branches leave the sheets, forming subendocardial networks, which first surround the papillary muscles and then curve back subendocardially to be distributed to all parts of the ventricle. The principal branches of the bundle are insulated from the surrounding myocardium by sheaths of connective tissue.

Functional contacts between ventricular conduction and working myocytes become numerous only in the subendocardial terminal ramifications. Hence, papillary muscles contract first, followed by a wave of excitation and ensuing contraction that travels from the apex of the ventricle to the arterial outflow tract. Because the Purkinje network is subendocardial, muscular excitation proceeds from endocardium to epicardium.

In the developing heart, the bundle responsible for atrioventricular conduction is a much more extensive structure. Immunohistochemical analysis has revealed that the precursor of the system is a ring of cells that surrounds the inlet and outlet components of the developing ventricular loop (Ch. 52).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Coronary arteries

The right coronary artery arises from the anterior ('right coronary') sinus and the left coronary artery from the left posterior ('left coronary') sinus of the ascending aorta (see Figs 57.21-57.22; Fig. 57.41); ostia levels vary. The two arteries, as indicated by their generic name, form an
oblique inverted crown within the atrioventricular groove. They also form a variable and often insignificant anastomosis (in the nonpathological state) via marginal and interventricular (descending) loops that intersect at the cardiac apex. The main arteries and major branches are usually subepicardial, but those in the atrioventricular and interventricular grooves are often deeply sited, and occasionally hidden by overlapping myocardium or embedded in it (myocardial bridging). The term 'dominant' is used to refer to the coronary artery giving off the posterior interventricular (posterior descending or inferior interventricular) branch, which supplies the posterior (inferior) part of the ventricular septum and often part of the posterolateral (inferolateral) wall of the left ventricle. The right artery is the dominant artery in $60 \%$ of hearts. Anastomoses between right and left coronary arteries are abundant in the fetus but are much reduced by the end of the first year of life. Anastomoses providing collateral circulation may become prominent in conditions of chronic hypoxia and in coronary artery disease. An additional collateral circulation is provided by small branches from mediastinal, pericardial and bronchial vessels.

Coronary arterial original calibre, based on arterial casts or angiogram measurements, ranges between 1.5 and 5.5 mm . The calibre of the left origin exceeds the right in $60 \%$ of hearts, the right being larger in $17 \%$, and both vessels being of approximately equal calibre in $23 \%$. The external diameter of the left coronary artery increases from 2.1 mm at the age of 1 year to 3.3 mm at the age of 15 years (Pesonen et al 1991) and the diameters of the coronary arteries may increase up to the 30th year. A significant association has been found between the diameters of the right and left coronary arteries at birth and at 1 and 6 months of age and birth weight, height and body surface area (Karagol et al 2012).

## Right coronary artery

The right coronary artery arises from the anterior ('right coronary') aortic sinus; its ostium is usually below the sinutubular junction. The artery is usually single but as many as four right ostia have been observed, reflecting the independent origins of the conal, sinu-atrial node and ventricular arteries (Figs 57.42-57.43). The right coronary artery passes at first anteriorly and slightly to the right between the right atrial appendage and pulmonary trunk, where the sinus usually bulges. On reaching the atrioventricular groove, it descends almost vertically to the right (acute) cardiac border, curving around it into the posterior (inferior) part of the groove, where the latter approaches its junction with both interatrial and interventricular grooves, the appropriately termed cardiac crux. The artery ends a little to the left of the crux, often by anastomosing with the circumflex branch of the left coronary artery. The right coronary artery may end near the right cardiac border, between this and the crux, or more often it reaches the left border, replacing the more distal part of the circumflex artery. Its branches supply the right and variable parts of the left chambers and atrioventricular septum. Usually, the first branch is the right conal artery (conus artery, artery of the conus, arteria coni arteriosi; Loukas et al 2014b). (This vessel arises independently from the anterior aortic sinus in approximately onethird of hearts and is therefore sometimes termed the 'third coronary artery'; a similarly named vessel arises from the left coronary circulation and so this title is inappropriate.) The right conal artery ramifies anteroinferiorly over the pulmonary conus and over the superior aspect of the right ventricle, sometimes anastomosing with a similar branch from the left interventricular (anterior descending) artery to form the anulus of Vieussens, a tenuous anastomosis around the right ventricular outflow tract (Figs 57.44-57.45) (Loukas et al 2009).

The first segment of the right coronary artery (between its origin and the right cardiac margin) gives off anterior atrial and ventricular branches that diverge widely, approaching a right angle in the case of the ventricular arteries, an arrangement that is in marked contrast to the more acute origins of the left coronary ventricular branches. The anterior ventricular branches, usually two or three, ramify towards the cardiac apex, which they rarely reach (unless the right marginal artery is included within this group of branches, as it is by some authors). The right marginal artery is greater in calibre than the other anterior ventricular arteries and long enough to reach the apex in most hearts. When it is very large, there may be only one other remaining anterior ventricular branch, or even no other branches. Up to three small posterior (inferior) ventricular branches, most often two, arise from the second segment of the right coronary artery between the right border and crux to supply the right ventricular diaphragmatic aspect. Their size is inversely proportional to that of the right marginal artery, which usually extends to the cardiac diaphragmatic surface. On approaching the crux, the right coronary artery normally produces up to three posterior (inferior) interventricular branches (occasionally none). The posterior (inferior) interventricular artery itself, lying within the interventricular groove, may therefore be flanked, either to the right or to the left, or on

This ring is in continuity with the atrioventricular bundle, itself part of an interventricular ring of specialized cardiomyocytes. The segment of the interventricular ring that encircles the developing left ventricular outflow tract subsequently breaks down. The segment that persists within the ventricles extends along the septum beyond the branching atrioventricular bundle and forms a dead-end tract. The dorsal component of the interventricular ring is part of the definitive atrioventricular node, continuous with the atrioventricular bundle. The rightward component of the atrioventricular ring system, emerging inferiorly from the atrioventricular node, is part of the slow nodal pathway. The cardiomyocytes that formed the ring initially possessed a primary phenotype, i.e. they would have conducted slowly.

Wolff-Parkinson-White syndrome is caused by abnormal small strands of otherwise unremarkable ventricular myocardium that run through the fibroareolar tissue of the atrioventricular groove, connecting the atrial and ventricular myocardial masses at some point around the atrioventricular junctions.

Temporary pacing wires are usually inserted by cannulation of either the internal jugular or subclavian veins; the latter approach carries a slightly greater risk of a pneumothorax because of the proximity of the pleural cavity. Other potential risks are brachial plexus injury if the entry site is too posterior, and thoracic duct injury if the left subclavian vein is cannulated. The most common location for permanent pacemaker devices is subcutaneously on the anterior chest wall. Access to the chambers and endocardium of the right heart is gained via the cephalic vein within the deltopectoral groove.

Intracardiac electrocardiography and electrophysiology are used to assess cardiac conduction and rhythm abnormalities. A catheter is inserted via the femoral, subclavian or internal jugular veins using a guidewire technique. Fluoroscopy, echocardiography and, more recently, cardiac magnetic resonance are used to guide accurate placement of the catheters to the appropriate position. The sites of study are the high right atrium (for assessing the atrioventricular bundle and right bundle branch) and the coronary sinus (for evaluating atrioventricular junctional arrhythmias and accessory pathways). The multipolar electrodes provide detailed electro-anatomical mapping of the sequence of excitation from the atria, atrioventricular junction and ventricles. The origin of supraventricular arrhythmias, ventricular tachycardias, accessory conduction pathways and re-entrant pathways can be identified and used to guide radiofrequency ablation.

In the past, there was an anatomical basis for the majority of presenting congenital conduction abnormalities: they were the product of either accessory pathways or conduction tissue dysgenesis at any point from the atrioventricular node to the atrioventricular bundle. Today, conduction abnormalities are increasingly likely to relate to long-standing haemodynamic problems and/or the effects of previous surgery for patients with congenital heart defects. This reflects the fact that, although surgery for most of these defects has been available for the past four decades, surgery itself has not been curative; more often than not, patients develop conduction abnormalities and arrhythmia from surgical scars that cause haemodynamic problems such as chamber dilation and/or hypertrophy. Occasionally, conduction abnormalities are caused by tumours such as multifocal Purkinje cell tumours, or benign congenital polycystic tumours of the atrioventricular node.

Congenital abnormalities of the coronary arteries are found rarely in children. The two most common abnormalities are coronary arteriovenous fistula and anomalous left coronary artery arising from the pulmonary artery (Uysal et al 2014). Other congenital abnormalities include ectopic origin of left circumflex artery from right coronary artery, single coronary artery arising from right sinus of Valsalva, and ectopic right coronary artery arising from the left sinus of Valsalva (Clemente et al 2010).

(With permission from Loukas M, Sharma A, Blaak C, Sorenson E, Mian A. 2013. The clinical anatomy of the coronary arteries. J Cardiovasc Transl Res. 6:197-207.)

Fig. 57.44 A variation of the anulus of Vieussens (*). This corrosion cast specimen shows the right conal artery, a branch of the right coronary artery, anastomosing with a proximal ventricular branch of the anterior interventricular artery. A second anastomosis (**) occurs between the ventricular branches of the right coronary and anterior interventricular arteries. Close to the apex, a third anastomosis ( ${ }^{(* * *)}$ appears between the distal part of the anterior interventricular artery and branches of the acute marginal artery. (With permission from Loukas M, Bilinsky S, Bilinsky E, Matusz P, Anderson RH. 2009. The clinical anatomy of the coronary collateral circulation. Clin Anat. 22:146-160.)

Fig. 57.41 Anterior views of the coronary arterial system, with the principal variations. The right coronary arterial tree is shown in purple, the left in red. In both cases, posterior distribution is shown in a paler shade. A, The most common arrangement. B, A common variation in the origin of the sinu-atrial nodal artery. C, An example of left 'dominance' by the left coronary artery, also showing an uncommon origin of the sinu-atrial nodal artery. Posteroinferior views of the coronary arterial system. The right coronary arterial tree is shown in purple, the left in red. D, An example of the more normal distribution in right 'dominance'. E, A less common form of left 'dominance'. In these 'posterior' views, the diaphragmatic (inferior) surface of the ventricular part of the heart has been artificially displaced and foreshortening ignored, to clarify the details of the so-called posterior (inferior) distribution of the coronary arteries.

Fig. 57.45 A coronary angiogram demonstrating three collateral arterial anastomoses. At the area of the subpulmonary infundibulum, the right conal artery, a branch of the right coronary artery, anastomoses with the left conal artery, a branch of the anterior interventricular artery, to form the anulus (arterial circle or vascular ring) of Vieussens (*). Ventricular branches of the right coronary artery anastomose with the proximal (**) and distal portions $\left(^{* * *}\right)$ of the anterior interventricular artery, forming two collateral pathways. As a result, there is contrast medium in the anterior interventricular artery. (With permission from Loukas M, Bilinsky S, Bilinsky E, Matusz P, Anderson RH. 2009. The clinical anatomy of the coronary collateral circulation. Clin Anat. 22:146-160.)
both sides, by these parallel branches. When these flanking vessels exist, branches of the posterior (inferior) interventricular artery are small and sparse. The posterior (inferior) interventricular artery is occasionally replaced by a left coronary branch. Although the atrial branches of the right coronary artery are sometimes described as part of anterior, lateral (right or marginal) and posterior groups, they are usually small single vessels, 1 mm in diameter (Figs 57.46-57.48). The right anterior and
lateral branches - occasionally double, and very rarely triple - mainly supply the right atrium. The posterior branch is usually single and supplies both atria.

The artery of the sinu-atrial node is an atrial branch, distributed largely to right atrial myocardium. Its origin is variable: most commonly, it arises from the anterior atrial branch of the right coronary artery, less often from its right lateral part, and least often from its posterior atrioventricular part. This 'nodal' artery thus usually passes posteriorly in the groove between the right atrial appendage and aorta. It may originate from the circumflex branch of the left coronary artery. Whatever its origin, it usually branches around the base of the superior vena cava, typically as an arterial loop from which small branches supply the right atrium. A large branch, the ramus cristae terminalis, traverses the sinuatrial node; it would seem more appropriate to name this branch the 'nodal artery', on the grounds that the vessel that currently bears this name actually supplies the atria and serves as the 'main atrial branch'.

Septal perforating branches of the right coronary artery are relatively short, and leave the posterior (inferior) interventricular branch to supply the posterior interventricular septum. They are numerous but do not usually reach the septal apex. The largest posterior septal perforating artery, usually the first, commonly arises from the inverted loop said to characterize the right coronary artery at the crux; it almost always supplies the atrioventricular node. Small, recurrent atrioventricular branches originate from the ventricular branches of the right coronary artery as they cross the atrioventricular groove, and supply adjacent atrial myocardium.

## Left coronary artery

The left coronary artery is usually larger in calibre than the right. It supplies a greater volume of myocardium, including almost all of the left ventricle and atrium, and most of the interventricular septum (see Fig. 57.42; Figs 57.49-57.51). In hearts with 'right dominance', the right coronary artery supplies a variable posterior region of the left ventricle (see Fig. $57.41 \mathrm{~A}-\mathrm{C}$ ).

The left coronary artery arises from the left posterior (left coronary) aortic sinus; the ostium sometimes lies inferior to the margin of the leaflets and may be double, leading into major initial branches, usually the circumflex and anterior interventricular (descending) arteries. Its initial portion, between its ostium and its first branches, varies in length from a few millimetres to a few centimetres. The artery lies between the pulmonary trunk and the left atrial appendage, emerging into the atrioventricular groove, where it turns left. This part is loosely embedded in subepicardial fat and usually has no branches, but may give off a small

Fig. 57.46 Normal ECG-gated CT anatomy of the right coronary artery and its branches. This oblique volume-rendered image of the superior aspect of the heart shows the right coronary artery (arrow) arising from the right sinus of Valsalva and coursing in the right atrioventricular groove towards the posterior interventricular septum. Abbreviations: A, aorta; PA, pulmonary artery. The conal artery and the sinu-atrial nodal artery were too small to be seen in this case. (With permission from Kim SY, Seo JB, Do KH, et al 2006. Coronary artery anomalies: classification and ECG-gated multi-detector row CT findings with angiographic correlation. Radiographics. 26:317-33.)

Fig. 57.48 Normal ECG-gated multidetector row CT anatomy of the right coronary artery and its branches. This posterior oblique volume-rendered image shows that the distal right coronary artery divides into the posterior (inferior) interventricular artery (long black arrow) and posterior left ventricular branches (short black arrows). The posterior (inferior) interventricular artery courses in the posterior (inferior) interventricular groove, parallel to the middle cardiac vein (white arrow). (With permission from Kim SY, Seo JB, Do KH, et al. 2006. Coronary artery anomalies: classification and ECG-gated multi-detector row CT findings with angiographic correlation. Radiographics. 26:317-33.)

Fig. 57.47 Normal ECG-gated multidetector row CT anatomy of the right coronary artery and its branches. This lateral oblique volume-rendered image shows the caudal course of the proximal right coronary artery (long arrow), which gives off an acute marginal branch (short arrows) to the right ventricle. (With permission from Kim SY, Seo JB, Do KH, et al. 2006. Coronary artery anomalies: classification and ECG-gated multi-detector row CT findings with angiographic correlation. Radiographics. 26:317-33.)

Fig. 57.49 Normal ECG-gated multidetector row CT anatomy of the left coronary artery and its branches. This oblique volume-rendered image of the top of the heart shows the left coronary artery (long white arrow) arising from the left sinus of Valsalva and trifurcating into the left anterior interventricular artery (thick black arrow), the left circumflex artery (thin black arrow), and the ramus intermedius (short white arrow), which takes a course similar to that of the usual first diagonal branch. The left anterior interventricular artery then gives rise to diagonal branches (short black arrows) to the anterior free wall of the left ventricle. Abbreviations: A, aorta; PA, pulmonary artery. (With permission from Kim SY, Seo JB, Do KH, et al. 2006. Coronary artery anomalies: classification and ECG-gated multi-detector row CT findings with angiographic correlation. Radiographics. 26:317-33.)

Fig. 57.50 An anterior oblique volume-rendered image showing the left anterior ventricular artery (thin black arrows) coursing along the anterior interventricular groove, and the left circumflex artery (thick black arrow) coursing in the left atrioventricular groove. Obtuse marginal branches (short white arrow) and diagonal branches (short black arrows) are also shown. Abbreviations: A, aorta; PA, pulmonary artery. (With permission from Kim SY, Seo JB, Do KH, et al. 2006. Coronary artery anomalies: classification and ECG-gated multi-detector row CT findings with angiographic correlation. Radiographics. 26:317-33.)

Fig. 57.51 A posterior oblique volume-rendered image showing the left anterior ventricular artery (long white arrows) coursing along the anterior interventricular groove, and the left circumflex artery (thick black arrow) coursing in the left atrioventricular groove. Obtuse marginal branches (short white arrows) and a diagonal branch (short black arrow) are also shown. (With permission from Kim SY, Seo JB, Do KH, et al 2006. Coronary artery anomalies: classification and ECG-gated multi-detector row CT findings with angiographic correlation. Radiographics. 26:317-33.)

Fig. 57.52 A dissection of a cadaveric heart revealing the course of the left coronary artery and its branches. (With permission from Loukas M, Sharma A, Blaak C, Sorenson E, Mian A. 2013. The clinical anatomy of the coronary arteries. J Cardiovasc Transl Res. 6:197-207.)
atrial ramus and, rarely, the sinu-atrial nodal artery. Reaching the atrioventricular groove, the left coronary artery divides into its main branches: namely, the circumflex and anterior interventricular arteries.

The anterior interventricular artery is commonly described as the continuation of the left coronary artery. It descends obliquely forwards and to the left in the interventricular groove (Fig. 57.52), sometimes deeply embedded in or crossed by bridges of myocardial tissue (myocardial bridges), and by the great cardiac vein and its tributaries.

Almost invariably, the anterior interventricular artery reaches the apex, where it terminates in one-third of hearts. More frequently, it turns round the apex into the posterior interventricular groove and passes one-third to one-half of the way along its length, meeting the terminal twigs of the posterior (inferior) interventricular branches of the right coronary artery (see above).

The anterior interventricular artery gives off right and left anterior ventricular and anterior septal branches, and a variable number of corresponding posterior branches. Anterior right ventricular branches are small and rarely number more than one or two; the right ventricle is supplied almost entirely by the right coronary artery. Up to nine large left anterior ventricular arteries branch at acute angles from the anterior interventricular artery, crossing the anterior aspect of the left ventricle diagonally, with the largest reaching the rounded (obtuse) left cardiac border. One often dominates, sometimes arising separately from the left coronary trunk, which then ends by trifurcation. This left diagonal artery, reported to exist in at least 33-50\% of hearts, may be doubled (20\%). A small left conal artery frequently leaves the anterior interventricular artery near its origin, and anastomoses on the conus with its counterpart from the right coronary artery and with the vasa vasorum of the pulmonary artery and aorta. The anterior septal perforating branches leave the anterior interventricular artery almost perpendicularly, and pass posteroinferiorly within the septum, usually supplying its ventral two-thirds. The first septal perforator artery usually supplies the atrioventricular bundle at the point of its division. Small posterior septal branches from the same source supply the posterior third of the septum for a variable distance from the cardiac apex (Loukas et al 2009).

The circumflex artery, comparable to the anterior interventricular artery in calibre, curves left in the atrioventricular groove, and continues round the left cardiac border into the posterior part of the groove, terminating left of the crux in most hearts, although sometimes continuing as the posterior (inferior) interventricular artery. Proximally, the left atrial appendage usually overlaps it. A large ventricular branch, the left marginal artery, normally arises perpendicularly from the circumflex artery and ramifies over the rounded 'obtuse' margin, supplying much of the adjacent left ventricle, typically to its apex. Smaller anterior and
posterior branches of the circumflex artery also supply the left ventricle. Anterior ventricular branches (from one to five, commonly two or three) course parallel to the diagonal artery when it is present, and replace it when it is absent. Posterior ventricular branches are smaller and fewer because the left ventricle is partly supplied by the posterior (inferior) interventricular artery. When this artery is small or absent, it is accompanied or replaced by often doubled or tripled interventricular continuations of the circumflex artery.

The artery to the sinu-atrial node is often derived from the anterior circumflex segment (less often from the circum-marginal segment). It passes over and supplies the left atrium, encircles the superior vena cava (like a right coronary nodal branch) and sends a large branch through the node; despite its name, it is predominantly atrial in distribution. The artery to the atrioventricular node, sometimes the terminal branch of the circumflex artery (20\%), arises near the crux. When this occurs, the circumflex artery usually gives off the posterior interventricular artery, an example of so-called 'left dominance'.

## Coronary arterial distribution

Details of coronary arterial distribution require integration into a concept of total cardiac supply. Most commonly, the right coronary artery supplies all of the right ventricle (except a small region to the right of the anterior interventricular groove); a variable part of the diaphragmatic aspect of the left ventricle; the posteroinferior third of the interventricular septum; the right atrium and part of the left atrium; and the conduction system as far as the proximal parts of the right and left crura. Left coronary distribution is reciprocal and includes most of the left ventricle; a narrow strip of right ventricle; the anterior two-thirds of the interventricular septum; and most of the left atrium. As noted previously (see Fig. 57.41), variations in the coronary arterial system mainly affect the diaphragmatic aspect of the ventricles and reflect the relative 'dominance' of coronary arterial supply. The term is misleading because the left artery almost always supplies a greater volume of tissue than the right. In 'right dominance', the posterior (inferior) interventricular artery is derived from the right coronary artery; in 'left dominance', it is derived from the left coronary artery. In the so-called 'balanced' pattern, branches of both arteries run in or near the posterior (inferior) interventricular groove.

Less is known about variations in atrial supply because the small vessels involved are not easily preserved in the corrosion casts that are used for analysis. In more than $50 \%$ of individuals, the right atrium is supplied only by the right coronary artery, and in the remainder the supply is dual. More than $62 \%$ of left atria are supplied mainly by the left coronary artery, $27 \%$ by the right coronary artery (in each group a small accessory supply from the other coronary artery exists), and $11 \%$

Fig．57．53 A dissection of a cadaveric heart in which a large part of the anterior interventricular artery is covered by a myocardial bridge．

Myocardial bridges are reported to have a frequency varying from 0.5 to $40 \%$ when identified clinically and from 15 to $85 \%$ when found at autopsy（Fig．57．53）．The wide variation in frequency indicates that many bridges may be asymptomatic during life．The major clinical conditions produced by a myocardial bridge are cardiac ischaemia， atherosclerosis and sudden cardiac death．The incidence of atheroscle－ rosis is increased when the right coronary artery is bridged．Although a relationship between myocardial bridges and sudden cardiac death has not been established，autopsy series have shown histological evidence of otherwise unexplained ischaemia in individuals with myocardial bridges；many died during exercise and had no other risk factors for coronary arterial disease．
are supplied almost equally by both arteries. Arterial supply to the sinuatrial and atrioventricular nodes also varies: the sinu-atrial node is supplied more often by the right coronary artery; fewer than $10 \%$ of sinu-atrial nodes receive a bilateral supply. The atrioventricular node is usually supplied by the right coronary artery.

## ( Coronary anastomoses

The cardiac collateral circulation represents a native system for coronary arterial bypass. The first few centimetres of the arterial main stems are devoid of anastomotic branches, but further distally, collateral channels are abundant, exhibit variable calibres and occupy numerous locations, allowing for bidirectional flow between most native arteries. Approximately 30 different sites of collateral extramural vessels have been described, the most frequent being at the apex; the anterior aspect of the right ventricle; the posterior aspect of the left ventricle; the crux; the interatrial and interventricular grooves; and between the sinu-atrial nodal and other atrial vessels (see Figs 57.44, 57.45). Anastomoses between branches of the coronary arteries, both subepicardial and myocardial, and between these arteries and extracardiac vessels, are of prime medical importance. Clinical studies suggest that anastomoses cannot rapidly provide collateral routes sufficient to circumvent sudden coronary obstruction (see Figs 57.44, 57.45, 57.54). Nevertheless, it has long been established that anastomoses do occur, particularly between fine subepicardial branches, and they may increase during individual life by mechanisms of angiogenesis and arteriogenesis. The anulus of Vieussens is a collateral vessel that crosses the subpulmonary infundibulum, providing an anastomosis between the conal branch of the right coronary artery and the anterior interventricular artery. The artery to the sinu-atrial node commonly provides a communication between the proximal parts of the coronary arteries. The apical collateral artery joins the interventricular arteries. The frequent enlargement of the first septal branch of the anterior interventricular artery, Kugel's anastomotic artery (arteria anastomotica auricularis magna), has been described as running between the proximal parts of the coronary arteries along the anterosuperior margin of the oval fossa to anastomose with the distal part of the right coronary artery.

## Extracardiac anastomoses

Extracardiac anastomoses connect various coronary branches with other thoracic vessels, most commonly involving the bronchial and internal thoracic arteries (Fig. 57.54). To a much lesser degree, anastomoses between coronary arteries and pericardiacophrenic branches of the internal thoracic, anterior mediastinal, intercostal and oesophageal arteries also exist. The posterior pericardium also receives a direct supply from the bronchial arteries; extracardiac coronary anastomoses involving bronchial arteries are typically found at the pericardial reflections, such as the points of entry of the venae cavae. The most common anastomoses are with the circumflex branch of the left coronary artery via the posterior pericardial reflections and reflect the close proximity of the bronchial arteries within the pulmonary hila. In pathological conditions, notably those resulting in pericardial adhesions, it is also possible for extracardiac anastomoses to develop through transpericardial vascularization.

Extracardiac communications also exist with coronary atrial branches, especially the sinu-atrial nodal artery. The effectiveness of any of these connections as collateral routes in coronary occlusion is not well quantified. Coronary arteriovenous anastomoses and numerous connections between the coronary circulation and cardiac cavities, producing so-called 'myocardial sinusoids' and 'arterioluminal vessels', have been reported, but their importance in coronary disease remains uncertain.

## Coronary angiography

Available with the Gray's Anatomy e-book

## Coronary revascularization

Available with the Gray's Anatomy e-book

## Coronary artery fistula

A coronary artery fistula is an abnormal connection that directly links one or more coronary arteries to a heart chamber or to major thoracic vessels without an interposed capillary bed.

Coronary artery fistulae are rare (Fig. 57.58); those that arise from a coronary artery and then terminate in a chamber of the heart are known as coronary cameral fistulae, while those terminating into a vein are coronary arteriovenous fistulae. Fistulae may be congenital or may
develop later in life. Congenital fistulae are more common and account for $50 \%$ of paediatric coronary vascular aberrations; they are believed to be derived from Thebesian vessels. Acquired coronary artery fistulae are most commonly iatrogenic in aetiology but may also occur after traumatic injury; these most commonly are of the coronary cameral type, from the right coronary artery into the right side of the heart.

## Cardiac veins

The cardiac venous system is divided into two major parts. The greater system consists of large vessels that lie within the subepicardial myocardium and drain most of the outer myocardium. These veins extend over the myocardial surface and do not adhere to topographical borders, although the larger collecting vessels lie within the interventricular grooves before draining into the coronary sinus. The intercommunicating parts of this system are the coronary sinus and its tributaries, the anterior cardiac venous system, and the ventricular septal and atrial veins. The coronary sinus and its tributaries return blood to the right atrium from the entire heart (including its septa), except for the anterior region of the right ventricle and small, variable parts of both atria and the left ventricle. The anterior cardiac veins drain an anterior region of the right ventricle, expanding to include a region around the right cardiac border when the right marginal vein joins this group.

The smaller system functions primarily to return venous blood from the inner myocardial walls into the right atrium and ventricle and, to a lesser extent, into the left atrium and sometimes the left ventricle. It contains the smallest cardiac veins (Thebesian veins) that drain the subendocardial myocardium either directly, via connecting intramural arteries and veins, or indirectly, via subendocardial sinusoidal spaces.

Variation in cardiac veins Attempts to categorize variations in cardiac venous circulation into 'types' have not produced any accepted pattern. The coronary sinus may receive all the cardiac veins other than the Thebesian veins, including the anterior cardiac veins, which may be reduced by diversion into the small cardiac vein and then to the coronary sinus.

## Coronary sinus

Most cardiac veins drain into the wide coronary sinus, 2 or 3 cm long, lying in the posterior atrioventricular groove between the left atrium and ventricle (see Fig. 57.4B; Fig. 57.59). The sinus opens into the right atrium between the opening of the inferior vena cava and the right atrioventricular orifice. The opening may be guarded by an endocardial fold (semilunar valve of the coronary sinus, Thebesian valve; see Fig. 57.13 A ); the fold may be absent or may cover the ostium of the sinus completely. The tributaries of the coronary sinus are the great, small and middle cardiac veins, the posterior vein of the left ventricle and the oblique vein (of Marshall) of the left atrium; all except the oblique vein have orificial valves. Isolated absence of the coronary sinus has been reported, with coronary venous drainage into the pulmonary trunk (Ogawa et al 2013).

Fig. 57.59 The principal veins of the heart.

Table 57.1 Patterns of cardiac collateral arteries

| Grade | Description |
| :--- | :--- |
| 0 | Total absence of any collateral arteries <br> 1 |
| Poorly developed collateral arteries with no prominent distal channel visualized by <br> angiography |  |
| 3 | Presence of moderate collateral arteries providing faint but delayed opacification of <br> a prominent distal channel <br> Good collateral arteries giving clear opacification of a prominent distal channel <br> 4 |
| Excellent collateralization giving full and brisk opacification of prominent distal <br> vessels |  |

Clinical imaging (catheter angiography and colour Doppler ultrasound) has led to the development of a grading system to describe the overall pattern of cardiac collateral arteries (Table 57.1).

Coronary angiography may be performed by introducing a catheter through the femoral, radial or brachial arteries. The femoral artery is punctured with a needle 3 cm below the inguinal ligament while the leg is held adducted and slightly externally rotated. The exact position is guided by palpation of the femoral arterial pulse, and the needle is inserted at an angle of $45^{\circ}$. After arterial puncture, a fine guidewire is inserted through the needle and fed into the artery. The catheter is then inserted over the guidewire and manipulated via the iliac artery into the aorta, up the aortic arch and into the ascending aorta. The brachial or radial artery may be used for percutaneous access to the circulation. Once the catheter is located in the ascending aorta, a variety of guidewires may be used to enter the coronary vessels for selective arteriography and interventions. Angiography is performed with standard high-osmolality contrast medium with cineangiography. In selected patients, new-generation, low-osmolality contrast medium may also be used. All the coronary arteries are catheterized and evaluated in a variety of views to obtain a full evaluation of their anatomy and to determine the location and degree of any stenoses (Figs 57.55-57.56). The ostium of the left coronary artery arises from the left aortic sinus and is best viewed in the direct frontal and left anterior oblique projections. The right anterior oblique view is useful in demonstrating the diagonal branches and anterior interventricular (descending) coronary artery. The right coronary artery originates from the right sinus of Valsalva and is usually visualized in the right anterior oblique view. Pressure and oxygen saturations can be measured via the catheter; changes in pressure across valves allow the degree of stenosis to be measured. Coronary blood flow and relative flow reserve can also be calculated. Significant stenosis may be treated initially by balloon angioplasty followed by stent insertion. The balloon exerts pressure against the plaque in the arterial wall, fracturing and splitting the plaque. The splinting effect of the plaque and elastic recoil are reduced, resulting in an increase in the arterial lumen. Stent insertion reduces the re-stenosis rate.

Fig. 57.54 A left coronary angiogram in left lateral projection, showing a large, tortuous vessel (arrow) arising from the proximal circumflex branch of the left coronary artery and anastomosing with the bronchial artery, which goes on to supply the lower lobe of the left lung. Abbreviations: AIA, anterior interventricular artery; Dg, diagonal branch; LCx, left circumflex artery. (Courtesy of M Loukas MD, PhD.)

Atherosclerosis causing more than $60 \%$ stenosis of the terminal diameter of the coronary arteries is likely to cause significant reduction in myocardial perfusion. Patients with high-grade lesions, left main stem coronary artery or triple-vessel disease with impaired left ventricular function are usually considered for coronary artery bypass grafting. The common grafts that are used are the internal thoracic (mammary) and radial arteries. The left internal thoracic artery and radial artery grafts have a greater patency rate than saphenous vein grafts. Approximately $15 \%$ of saphenous vein grafts occlude in 1 year and, from then on, at an annual rate of $1-2 \%$ in the first 6 years and $4 \%$ thereafter; between $40 \%$ and $50 \%$ of saphenous vein grafts have occluded by 10 years, whereas only about $10 \%$ of left internal thoracic or radial artery grafts have occluded over this time. The common surgical approach is via a midline sternotomy. If the internal thoracic artery is used as a donor graft, it is divided distally (maintaining its proximal origin from the subclavian artery) and anastomosed to the coronary artery distal to the stenosis. If radial artery grafts are used, they must be anastomosed both proximal and distal to the coronary artery, to bridge the site of the stenosis. In selected cases, minimally invasive direct coronary artery bypass grafting is performed, but the approach is dependent on the vessel being grafted. The anterior approach is via mini-thoracotomy over the fourth intercostal space underneath the nipple for grafting the mid-left anterior interventricular (descending) and diagonal branches. The anterolateral approach is via an incision in the third intercostal space from the mid-clavicular to anterior axillary lines and is used for grafting early marginal branches of the circumflex system. The lateral approach allows grafting of the circumflex vessels via a lateral thoracotomy measuring only 10 cm in size through the fifth or sixth intercostal spaces. Extrathoracic approaches that are occasionally used include the subxiphoid approach for the distal right coronary artery and posterior interventricular (descending) artery. Port access surgery allows for full revascularization with cardiopulmonary bypass but obviates the need for midline sternotomy. However, the vast majority of patients are treated with stent placement (Fig. 57.57).

Fig. 57.58 A coronary artery fistula in a 54-year-old woman with palpitations. A, A CT image showing a tortuous left circumflex artery (white arrows) that is dilated in comparison with the anterior interventricular artery (black arrow). B, A volume-rendered CT image shows the markedly tortuous left circumflex artery (arrows). (With permission from Shriki JE, Shinbane JS, Rashid MA, Hindoyan A, Withey JG, DeFrance A, Cunningham M, Oliveira GR, Warren BH, Wilcox A. 2012. Identifying, characterizing, and classifying congenital anomalies of the coronary arteries. Radiographics 32:453-468.)

Great cardiac vein The great cardiac vein begins at the cardiac apex, and ascends in the anterior interventricular groove to the atrioventricular groove, which it follows, passing to the left and posteriorly to enter the coronary sinus at its origin (see Fig. 57.59). It receives tributaries from the left atrium and both ventricles, including the large left marginal vein that ascends the left aspect (obtuse border) of the heart. It usually courses superior to the arterial branches. The valve of Vieussens normally guards the orifice of the great cardiac vein at its junction with the oblique vein; smaller diminutive valves may occur.

Small cardiac vein The small cardiac vein lies in the posterior atrioventricular groove between the right atrium and ventricle, receiving blood from their posterior parts and opening into the atrial end of the coronary sinus (see Fig. 57.59). The right marginal vein passes right, along the inferior cardiac margin (acute border), and sometimes joins the small cardiac vein in the atrioventricular groove, typically opening directly into the right atrium.

Middle cardiac vein The middle cardiac vein begins at the cardiac apex and runs posteriorly in the inferior interventricular groove to end in the coronary sinus near its atrial end (see Fig. 57.59). The vein is also described as meeting the great cardiac vein at the apex, so forming, together with the coronary sinus, a full venous circle.

Inferior vein of the left ventricle The inferior vein of the left ventricle (previously named as the posterior vein of the left ventricle) lies on the diaphragmatic surface of the left ventricle, a little to the left of the middle cardiac vein, and usually opens into the middle of the coronary sinus, sometimes into the great cardiac vein (see Fig. 57.59). Rarely, the inferior vein of the left ventricle is absent, in which case the left marginal vein drains most of the left ventricular wall.

Oblique vein of the left atrium The diminutive oblique vein of the left atrium descends obliquely on the posterior aspect of the left atrium to join the coronary sinus (see Fig. 57.59). It is continuous above with the ligament of the left vena cava; both structures are remnants of the left common cardinal vein.

## Left marginal vein

The left (obtuse) marginal vein courses over the left oblique marginal surface of the heart, draining much of the left ventricular myocardium. It runs superficial to the marginal branch of the left coronary artery and usually drains into the great cardiac vein, although may sometimes drain directly into the coronary sinus.

## Anterior cardiac veins

The anterior cardiac veins drain the anterior part of the right ventricle. Usually two or three, sometimes even five, they ascend in subepicardial tissue to cross the right part of the atrioventricular groove, passing deep or superficial to the right coronary artery. They end in the right atrium, near the atrioventricular groove, separately or in variable combinations. A subendocardial collecting channel, into which all may open, has been described.

## Right marginal vein

The right marginal vein courses along the inferior (acute) cardiac margin, draining adjacent parts of the right ventricle, and usually opens separately into the right atrium, although it may join the anterior cardiac veins or, less often, the coronary sinus. It is often grouped with the small cardiac veins but it is larger in calibre, comparable to the anterior cardiac veins or even wider.

## Small cardiac veins

The existence of small cardiac (venae cordis minimae; Thebesian) veins, opening into all cardiac cavities, has been confirmed but they are difficult to demonstrate. Their numbers and size are highly variable: vessels up to 2 mm in diameter open into the right atrium and ones as small as 0.5 mm in diameter open into the right ventricle, all with valveless orifices. Numerous small cardiac veins have been identified in the right atrium and ventricle but they are rarely found in the left side. Four types of Thebesian veins have been described: venoluminal veins drain directly into the cardiac chambers; venosinusoidal veins drain into subendocardial sinusoids (which, in turn, drain into the cardiac chambers); arterioluminal veins connect small arteries and arterioles directly with the cardiac chambers; and arteriosinusoidal veins connect thin arteries or arterioles with subendocardial sinusoidal spaces.

## Cardiac venous anastomoses

Widespread anastomoses occur at all levels of the cardiac venous circulation, on a scale exceeding that of the arteries and amounting to a
veritable venous plexus. Not only are adjacent veins often connected, but connections also exist between tributaries of the coronary sinus and those of the anterior cardiac veins. Abundant anastomoses occur at the apex and its anterior and posterior aspects. Like the coronary arteries, cardiac veins connect with extracardiac vessels, particularly the vasa vasorum of the large vessels that are continuous with the heart.

## Lymphatic drainage of the heart

Cardiac lymphatic vessels form subendocardial, myocardial and subepicardial plexuses. Efferents from the subepicardial plexuses form the left and right cardiac collecting trunks; two or three left-sided trunks ascend the anterior interventricular groove, receiving vessels from both ventricles. On reaching the atrioventricular groove, they are joined by a large vessel from the diaphragmatic surface of the left ventricle, which first ascends in the posterior interventricular groove and then turns left along the atrioventricular groove. The vessel formed by this union ascends between the pulmonary artery and the left atrium, and usually ends in an inferior tracheobronchial node. The right trunk receives afferents from the right atrium and the right border and diaphragmatic surface of the right ventricle. It ascends in the atrioventricular groove, near the right coronary artery, and then anterior to the ascending aorta, and ends in a brachiocephalic node, usually on the left (Fig. 57.60). (For further reading, see Loukas et al (2011).)

## INNERVATION

Initiation of the cardiac cycle is myogenic, originating in the sinu-atrial node. It is harmonized in rate, force and output by autonomic nerves that operate on the nodal tissues and their prolongations, on coronary vessels and on the working atrial and ventricular musculature. All the cardiac branches of the vagus (parasympathetic) and all the sympathetic branches (other than the cardiac branch of the superior cervical sympathetic ganglion) contain both afferent and efferent fibres; the cardiac branch of the superior cervical sympathetic ganglion is entirely efferent. Sympathetic fibres accelerate the heart and dilate the coronary arteries when stimulated, whereas vagal fibres slow the heart and cause coronary arterial constriction.

Preganglionic cardiac sympathetic axons arise from neurones in the intermediolateral column of the upper four or five thoracic spinal segments. Some synapse in the corresponding upper thoracic sympathetic ganglia, while others ascend to synapse in the cervical ganglia; postganglionic fibres from these ganglia form the sympathetic cardiac nerves. Preganglionic cardiac parasympathetic axons arise from neurones either in the dorsal vagal nucleus or near the nucleus ambiguus, and run in vagal cardiac branches to synapse in the cardiac plexuses and atrial walls. In humans (like most mammals), intrinsic cardiac neurones are limited to the atria and interatrial septum, and are most numerous in the subepicardial connective tissue near the sinus and atrioventricular nodes. The intrinsic ganglia are thought not to be simple nicotinic relays, but may act as sites for the integration of extrinsic nervous inputs and form complex circuits for the local neuronal control of the heart, and perhaps even local reflexes.

## Cardiac plexus

Nearing the heart, the autonomic nerves form a mixed cardiac plexus, usually described in terms of a superficial component inferior to the aortic arch, lying between it and the pulmonary trunk, and a deep part between the aortic arch and tracheal bifurcation. The cardiac plexus is also described by regional names for its coronary, pulmonary, atrial and aortic extensions (Fig. 57.61). Ganglion cells are largely confined to the atrial tissues, with a preponderance adjacent to the sinu-atrial node, but some may also be found within the heart along the branches of the plexuses. Their axons are considered to be largely, if not exclusively, postganglionic parasympathetic. Cholinergic and adrenergic fibres, arising in or passing through the cardiac plexus, are distributed most profusely to the sinus and atrioventricular nodes; the supply to the atrial and ventricular myocardium is much less dense. Adrenergic fibres supply the coronary arteries and cardiac veins. Rich plexuses of nerves containing cholinesterase, adrenergic transmitters and other peptides, e.g. neuropeptide $Y$, are found in the subendocardial regions of all chambers and within the valvular leaflets.

Superficial (ventral) part of the cardiac plexus The superficial (ventral) part of the cardiac plexus lies inferior to the aortic arch and anterior to the right pulmonary artery. It is formed by the cardiac branch

Fig. 57.61 The cardiac plexus: its source from the cervical parts of the vagus nerves and sympathetic trunks and its extensions, the pulmonary, atrial and coronary plexuses. Note the numerous junctions between sympathetic and parasympathetic (vagal) branches that form the plexus.

of the left superior cervical sympathetic ganglion and the lower of the two cervical cardiac branches of the left vagus. A small cardiac ganglion is usually present in this plexus immediately below the aortic arch, to the right of the ligamentum arteriosum. This part of the cardiac plexus connects with the deep part, the right coronary plexus and the left anterior pulmonary plexus.

Deep (dorsal) part of the cardiac plexus The deep (dorsal) part of the cardiac plexus lies anterior to the tracheal bifurcation, superior to the point of division of the pulmonary trunk and posterior to the aortic arch. It is formed by the cardiac branches of the cervical and upper thoracic sympathetic ganglia, the vagus and recurrent laryngeal nerves. The only cardiac nerves that do not join it are those that join the superficial part of the plexus. The deep plexus consists of right and left halves; the right typically surrounds the brachiocephalic trunk, and the left surrounds the aortic arch. The more dorsal (deep) aspect is larger than its more ventral (superficial) aspect on both sides. Branches from the right half of the deep part of the cardiac plexus pass both anterior and posterior to the right pulmonary artery. Fibres passing anterior to the pulmonary artery are more numerous; they supply a few filaments to the right anterior pulmonary plexus before continuing
onwards to form part of the right coronary plexus. Fibres passing posterior to the pulmonary artery supply a few filaments to the right atrium and then continue into the left coronary plexus. The left half of the deep part of the cardiac plexus is connected to the superficial part; it supplies filaments to the left atrium and left anterior pulmonary plexus, and forms much of the left coronary plexus.

Left coronary plexus The left coronary plexus is larger than the right and is formed mainly by the prolongation of the left half of the deep part of the cardiac plexus and a few fibres from the right half. It accompanies the left coronary artery to supply the left atrium and ventricle.

Right coronary plexus The right coronary plexus is formed from both superficial and deep parts of the cardiac plexus. It accompanies the right coronary artery to supply the right atrium and ventricle.

Atrial plexuses The atrial plexuses are derivatives of the right and left continuations of the cardiac plexus along the coronary arteries. Their fibres are distributed to the corresponding atria, overlapping those from the coronary plexuses.

## Great vessels

## MAJOR BLOOD VESSELS

The major blood vessels are the pulmonary trunk, the thoracic aorta and its branches, and the superior and inferior venae cavae and their tributaries.

## ARTERIES

## Pulmonary trunk

The pulmonary trunk, or pulmonary artery, conveys deoxygenated blood from the right ventricle to the lungs. About 5 cm in length and 3 cm in diameter, it is the most anterior of the cardiac vessels and arises from the pulmonary anulus surrounding the subpulmonary infundibulum at the base of the right ventricle, superior and to the left of the supraventricular crest. It slopes posterosuperiorly, at first anterior to the ascending aorta and then to its left; at the level of the fifth thoracic vertebra, inferior to the aortic arch at the left of the midline, it divides into right and left pulmonary arteries, of almost equal size. The bifurcation of the pulmonary trunk lies anteroinferior and to the left of the tracheal bifurcation and its associated inferior tracheobronchial lymph nodes and deep cardiac plexus. In the fetus, at the level of the bifurcation, the pulmonary artery is connected to the aortic arch by the ductus arteriosus.

Relations The pulmonary artery is entirely within the pericardium, enclosed with the ascending aorta in a common tube of visceral pericardium. The fibrous pericardium gradually disappears within the adventitia of the pulmonary arteries. Anteriorly, it is separated from the sternal end of the left second intercostal space by the pleura, left lung and pericardium. Posterior relations are the ascending aorta and left coronary artery initially, then the left atrium. The ascending aorta ultimately lies on its right. The appendage and coronary artery lie on each side of its origin. The superficial cardiac plexus lies between the pulmonary bifurcation and the aortic arch. The tracheal bifurcation, lymph nodes and nerves are superior, bilateral and to the right.

Variations and congenital conditions The pulmonary trunk is a relatively constant structure and there are minimal variations in healthy individuals. Congenital anomalies include pulmonary atresia and truncus arteriosus.

The coronary arteries usually originate from within the aortic sinuses, but occasionally may arise from ectopic locations. Most commonly, an ectopic left coronary artery arises from the pulmonary trunk or one of its branches (Bland-White-Garland syndrome). This potentially fatal condition requires urgent surgical correction because the myocardium is supplied with pulmonary blood instead of systemic blood (Loukas et al 2009). Infantile symptoms include pallor, fatigue, irritability, weak cry, cough, dyspnoea, and signs of ischaemia and cardiac failure precipitated by feeding, bowel movements or crying. The electrocardiogram may reveal deep narrow $Q$ waves, left ventricular hypertrophy and left axis deviation. Radiologically, cardiomegaly is present with left ventricular and left atrial enlargement. Colour flow imaging can identify the anomalous origin of the left coronary artery. The pulmonary trunk may also give rise to the right coronary artery, the left interventricular (anterior descending) coronary artery, or even both coronary arteries. Typically, there is a large development of collateral vessels in the heart (Figs 58.1-58.2).

Pulmonary atresia is caused by a complete obstruction of pulmonary outflow and may be due to an absence or defect of the pulmonary valvular leaflets. It is associated with a blind-ending pulmonary trunk that causes right ventricular hypoplasia. Reduced flow may render the
pulmonary trunk atretic, small or even normal in size, making diagnosis challenging. A diminished pulmonary flow is supplied through a patent ductus arteriosus (Smith and McKay 2004), and a concomitant ventricular septal defect may permit outflow from the right ventricle. Surgical repair is necessary to allow adequate oxygenation throughout the body.

In truncus arteriosus, a single arterial trunk exits the heart and subsequently divides into the pulmonary trunk and the aorta. Early neonatal life is possible because there is usually a coexisting ventricular septal defect; expedited surgical repair is necessary to avoid congestive heart failure, failure to thrive and death.

## Right and left pulmonary arteries

The pulmonary arteries are described on page 959.

## Thoracic aorta

## Ascending aorta

The ascending aorta is typically 5 cm long. It originates at the base of the left ventricle, level with the inferior border of the third left costal cartilage, and ascends obliquely, curving anteriorly and to the right, and passing from posterior to the left half of the sternum to the level of the superior border of the second left costal cartilage. In children, the diameter of the thoracic aorta correlates most closely with body surface area (Kervancioglu et al 2006, Kaiser et al 2008).

Relations The ascending aorta lies within the fibrous pericardium, enclosed in a tube of serous pericardium together with the pulmonary trunk (see Figs 57.3, 57.4A-C). The infundibulum, initial segment of the pulmonary trunk and right appendage are anterior to its lower part. Superiorly, it is separated from the sternum by the pericardium, right pleura, anterior margin of the right lung, loose areolar tissue and the thymus or its remnants. The left atrium, right pulmonary artery and principal bronchus are posterior. The superior vena cava and right atrium, the former partly posterior, are to the right. The left atrium and, more superiorly, the pulmonary trunk are to the left. At least two aorticopulmonary bodies lie between the ascending aorta and the pulmonary trunk. The inferior aorticopulmonary body is near the heart and anterior to the aorta, and the middle aorticopulmonary body is near the right side of the ascending aorta.

The aortopulmonary window is a space between the pulmonary artery and aortic arch, bordered by the ascending aorta anteriorly, the descending aorta posteriorly, the mediastinal pleura laterally and the left principal bronchus medially (Deutsch and Savides 2005) (Fig. 58.3). It contains lymph nodes, fatty tissue, the ligamentum arteriosum and the left recurrent laryngeal nerve.

## Aortic arch

The aortic arch continues from the ascending aorta (see Figs 57.3, $57.4 \mathrm{~A}-\mathrm{C}$ ). Its origin, slightly to the right, is level with the superior border of the right second sternocostal joint. The arch first ascends diagonally and posteriorly to the left over the anterior surface of the trachea, then posteriorly across its left side, finally descending to the left of the fourth thoracic vertebral body, continuing as the descending thoracic aorta. It terminates level with the sternal end of the left second costal cartilage and so lies wholly within the superior mediastinum. It curves around the hilum of the left lung, and extends superiorly to the midlevel of the manubrium of the sternum.

The shadow of the arch is easily identified in frontal chest radiographs; its left profile is sometimes called the aortic 'knuckle' or 'knob' (see Fig. 56.16). There may also be an 'aortic nipple' (the shadow of the adjacent left superior intercostal vein crossing posteroanteriorly to its left). The aortic arch is best visualized in left anterior oblique views

Fig. 58.1 A case of a left anterior interventricular artery arising from the pulmonary trunk. (Courtesy of Professor Loukas. With permission from Loukas M, Groat C, Khangura R, Owens DG, Anderson R. The normal and abnormal anatomy of the coronary arteries. Clinical Anatomy. 2009; 22: 114-128.)

Fig. 58.2 Bland-White-Garland syndrome in a 29 -year-old woman. A, A preoperative anterior oblique volume-rendered (VR) image shows a dilated right coronary artery (arrow) and the anterior interventricular artery with multiple collateral vessels at the right ventricular wall (arrowheads). B-C, Preoperative VR images (cardiac chambers removed with manual editing) clearly demonstrate the anomalous origin of the left coronary artery (long arrow) from the pulmonary trunk, along with multiple collateral vessels within the interventricular septum (short arrows in B) and the dilated right coronary artery (short arrow in C). D-E, Postoperative VR images, obtained after ligation of the original os of the left coronary artery from the pulmonary trunk and creation of an anastomosis between the left internal thoracic artery (short white arrows) and the left coronary artery (long white arrow), demonstrate a decrease in the size of the right coronary artery (black arrow) and markedly diminished collateral vessels in the interventricular septum and right ventricular wall ( ${ }^{*}$. Abbreviations: A, aorta; PA, pulmonary artery. (With permission from Kim SY, Seo JB, Do KH, et al 2006 Coronary artery anomalies: classification and ECG-gated multi detector row CT findings with angiographic correlation. Radiographics 26:317-33; discussion 333-4.)

Fig. 58.3 The aortopulmonary (AP) window. A, A posteroanterior (PA) chest radiograph. B, A coronal computed tomography (CT) scan reconstruction
on angiography and with equivalent computed tomography (CT) reconstruction planes; the pulmonary trunk and its left branch may be discerned nestling inferiorly in its concavity. The diameter of the arch initially matches that of the ascending aorta but is significantly reduced distal to the origin of the great vascular branches. The aortic isthmus, a small stricture at the border with the descending thoracic aorta, may be followed by a dilation; in the fetus, the isthmus lies between the origin of the left subclavian artery and the opening of the ductus arteriosus.

Relations The left mediastinal pleura is anterior and to the left of the arch. Deep to the pleura, the arch is crossed, in anteroposterior order, by the left phrenic nerve, left lower cervical cardiac branch of the vagus nerve, left superior cervical cardiac branch of the sympathetic trunk and the left vagus nerve (see Figs 57.3, 57.61). As the left vagus nerve crosses the arch, its recurrent laryngeal branch hooks below the vessel, to the left and behind the ligamentum arteriosum, then ascends on the right of the arch. The left superior intercostal vein ascends obliquely anteriorly on the arch, superficial to the left vagus nerve, deep to the left phrenic nerve. The left lung and pleura separate all these from the thoracic wall. Posterior and to the right are the trachea and the deep cardiac plexus, the left recurrent laryngeal nerve, oesophagus, thoracic duct and vertebral column. Superiorly, the brachiocephalic trunk, left common carotid and subclavian arteries arise from its convexity, and are crossed anteriorly near their origins by the left brachiocephalic vein. The pulmonary bifurcation, left principal bronchus, ligamentum arteriosum, superficial cardiac plexus and the left recurrent laryngeal nerve are all inferior. The concavity of the aortic arch, best viewed from the left, is the upper curved limit through which structures gain access to, or leave, the hilum of the left lung.

## Pneumomediastinum and aortic nipple

Available with the Gray's Anatomy e-book

Variations of the arch The summit of the arch is usually about 2.5 cm inferior to the sternal notch but may diverge from this. In the infant, it is closer to the superior border of the sternum; the same is often the case in senescence as a result of vascular ectasia/unfolding.

In a right-sided aortic arch, the aorta curves over the right pulmonary hilum and descends to the right of the vertebral column; this is usually associated with transposition of the thoraco-abdominal viscera. Less often, after arching over the right hilum, the aorta may pass posterior to the oesophagus to gain its position (this is not accompanied by visceral transposition). The presence of a right-sided arch is of relevance to the paediatric surgeon who is planning repair of oesophageal atresia in neonates.

The aorta may divide into ascending and descending trunks, the former dividing into three branches to supply the head and upper limbs. It may divide near its origin, producing a double aortic arch; the two branches soon reunite and the oesophagus and trachea usually pass through the interval between them. If the aorta, ductus arteriosus or descending aorta entraps the oesophagus and/or trachea, this is referred to as a vascular ring.

Branches and variations Three branches arise from the convex aspect of the arch: the brachiocephalic trunk, left common carotid and left subclavian arteries (see Figs 57.3-57.4). They may branch from the beginning of the arch or the superior part of the ascending aorta. The distance between these origins varies, the most frequent being approximation of the left common carotid artery to the brachiocephalic trunk. Other branches may arise from the aortic arch, including the inferior thyroid, thyroidea ima, thymic, left coronary and bronchial arteries (Bergman et al 1988).

Coarctation of the aorta The aortic lumen is occasionally partly or completely obliterated, either above (preductal or infantile type), opposite or just beyond (postductal or adult type), the entry of the ductus arteriosus. In the preductal type, the length of coarctation is variable, aortic arch hypoplasia is common, and the left subclavian and even the brachiocephalic trunk may be involved. Severe forms of infantile coarctation and its extreme form (aortic interruption) may be patent ductus arteriosus-dependent, as there is no time for effective collateral circulation to develop. Prostaglandin infusion prior to transfer, and surgery at a tertiary centre often provide a very good mid- to long-term outlook for such infants.

The postductal type of coarctation has been attributed to abnormal extension of the ductal tissue into the aortic wall, stenosing both vessels as the duct contracts after birth. This form may permit years of normal life, allowing the development of an extensive collateral circulation to the aorta distal to the stenosis (Figs 58.6-58.7). High vascularity of the thoracic wall is important and clinically characteristic; many arteries arising indirectly from the aorta proximal to the coarctation segment anastomose with vessels connected with it distal to the block, and all of these vessels become greatly enlarged. Thus, in the anterior thoracic wall, the thoraco-acromial, lateral thoracic and subscapular arteries (from the axillary artery), the suprascapular artery (from the subclavian artery) and the first and second posterior intercostal arteries (from the costocervical trunk) anastomose with other posterior intercostal arteries, and the internal thoracic artery and its terminal branches anastomose with the lower posterior intercostal and inferior epigastric arteries.

Posterior intercostal arteries are always involved, and enlargement of their dorsal branches may eventually groove ('notch') the inferior margins of the ribs. The radiographic shadow of the enlarged left subclavian artery is also increased. Enlargement of the scapular vessels and anastomoses may lead to widespread interscapular pulsation (easily appreciated with the palm of the hand, and sometimes heard on auscultation).

Aortic aneurysm formation Degeneration of the aortic tunica media and intimal dissection play a major role in the pathogenesis of aneurysms affecting the ascending aorta and arch. Smooth muscle cells are lost and elastic fibres degenerate, producing cystic spaces in the media, which then fill with mucoid material. The loss of these structural cells leads to weakening of the wall with progressive dilation. Ageing and hypertension are major predisposing factors to cystic medial degeneration and there is a strong link with cigarette smoking. Thoracic aortic aneurysms are categorized by their location. A particular pattern of

Pneumomediastinum is an encompassing term that describes the presence of air in the mediastinum. It may arise from a wide range of pathological conditions or physiological states, e.g. penetrating trauma, ruptured major airways or oesophagus, hyperventilation or distressed ventilation such as acute asthma, periparturition or diabetic ketoacidosis. The 'aortic nipple' is the radiographic term used to describe a lateral nipple-like projection from the aortic knuckle seen in a small number of individuals that corresponds to the end-on appearance of the left superior intercostal vein coursing anteriorly. It may be mistaken radiologically for lymphadenopathy or an intrapulmonary nodule/neoplasm. Despite their relative independence, the aortic nipple is defined by new contours in cases of pneumomediastinum, taking on an 'inverted aortic nipple' appearance (Fig. 58.4). In this position, the inverted aortic nipple may facilitate radiographic discrimination of pneumomediastinum from similar conditions. An aortic nipple has been shown to precede pathological conditions such as venous obstruction in the superior and inferior vena cavae or left brachiocephalic vein, and has been identified in conditions where venous flow through the left superior intercostal vein is increased (e.g. portal hypertension and certain congenital venous anomalies).

There are several variants of this arrangement, of which the most common are as follows: a right-sided aortic arch and upper portion of the descending aorta pass anterior to the oesophagus and trachea, and the ductus arteriosus passes posterior to the oesophagus into an aortic diverticulum; a right-sided aortic arch and the upper portion of the descending aorta pass anteriorly, and the ductus arteriosus is inserted into the left subclavian artery, which arises as a fourth branch from the aortic arch; a left-sided descending aorta is attached to a left-sided ductus arteriosus anterior to the oesophagus, and a right-sided arch passes posteriorly; the right superior portion of the descending aorta wraps around the oesophagus and the ductus arteriosus is right-sided; or the right upper portion of the aorta wraps around the oesophagus and the ductus arteriosus is left-sided (Bergman et al 1988).

The right common carotid and subclavian arteries may arise separately, in which case the latter often branches from the left end of the arch distal to the left subclavian artery, and usually passes posterior to the oesophagus as an aberrant right subclavian artery. When this artery arises from a dilated portion of the descending aorta, the diverticulum of Kommerell, it is known as the lusoria artery (Fig. 58.5). It may become aneurysmal and cause fatal haemorrhage during endoscopy. It may form a vascular ring around the oesophagus and trachea, presenting in the neonate as a feeding disorder with failure to thrive.

The left vertebral artery may arise between the left common carotid and the subclavian arteries.

A rare avian form has been reported in which the right common carotid and subclavian arteries arise from the aortic arch, and the left common carotid and subclavian arteries arise from the descending aorta (Bergman et al 1988). Another rare avian form with two brachiocephalic trunks, the right trunk originating both common carotid arteries, and the left trunk originating both subclavian arteries, has been reported. Another rare order of the aortic branches is (in order from right to left): the right subclavian artery, left subclavian artery, followed by the right common carotid, and left common carotid arteries close together - almost forming a common carotid trunk.

The aortic arch may also curve behind the oesophagus and trachea, instead of in front, with variations in the aortic branches as well. Another rare avian form reported is with both carotid arteries originating from the same stem, and a left subclavian artery originating from the arch, while the right subclavian artery arises from the descending aorta. One or more of the ductus arteriosi may remain patent.

Very rarely, external and internal carotid arteries arise separately, the common carotid artery being absent on one or both sides, or both carotid arteries and one or both vertebral arteries may be separate branches. When a 'right aorta' occurs, the arrangement of its three branches is reversed and the common carotid arteries may have a single trunk. Other arteries may branch from it: most commonly, one or both bronchial arteries and the thyroidea ima artery.

Associations also exist between thoracic aortic aneurysm and other connective tissue diseases such as homocysteinuria and Ehlers-Danlos syndrome. A genetic relation is seen in familial thoracic aortic aneurysm syndrome (Baliga et al 2007). Rarely, aneurysms may occur as a result of Takayasu's arteritis, or infections within the aortic wall.

Fig. 58.4 A PA chest radiograph, anteroposterior view, showing the classic 'aortic nipple' in a patient with pneumomediastinum. A label is added on the left to delineate the nipple-like appearance of the left superior intercostal vein more clearly. (Courtesy of Professor Loukas. With permission from Walters A, Cassidy L, Muhleman M, Peterson A, Blaak C, Loukas M. Pneumomediastinum and the aortic nipple: the clinical relevance of the left superior intercostal vein. Clinical Anatomy 2013; 27:757-63.)

(Courtesy of Professor Loukas with permission from Loukas M, Louis RG Jr, Gaspard J, Fudalej M, Tubbs RS, Merbs W. A retrotracheal right subclavian artery in association with a vertebral artery and thyroidea ima. Folia Morphol (Warsz). 2006 Aug;65(3):236-41.)

Fig. 58.6 A cardiac magnetic resonance (MR) angiograph showing three-dimensional reconstruction of a native aortic coarctation (arrow) in an adult with extensive collateral flow. Note the marked dilation of the left subclavian artery, supplying most of the collateral vessels, and mild aortic arch hypoplasia. (Courtesy of Dr Raad Mohiaddin, Royal Brompton Hospital, London.)

Fig. 58.7 The collateral circulation at MR angiography and phase-contrast velocity-encoded cine MRI. The MR angiogram shows the intercostal (short arrows) and internal thoracic (medium arrow) arteries, obtained in a patient with a haemodynamically significant aortic coarctation (long arrow). Note that the arteries appear enlarged. (With permission from Hom JJ, Ordovas K, Reddy GP. Velocity-encoded cine MR imaging in aortic coarctation: functional assessment of hemodynamic events. Radiographics 2008 Mar-Apr;28(2):407-16.)
aortic root involvement is seen in those with Marfan's syndrome, known as anulo-aortic ectasia (Baliga et al 2007). Descending aortic aneurysms are generally caused by atherosclerosis (90\%); the remainder result from mycotic disease or trauma.

Some aortic aneurysms are incidental findings on chest films or CT studies. Symptomatic cases present with breathlessness, unbearable chest and back pain, hoarse voice, cough and haemoptysis. Early diastolic murmurs caused by aortic regurgitation may be audible. Repair is carried out in patients with symptoms or fusiform dilation measuring more than 5 cm in diameter.

Aneurysms may also occur in an aberrant right subclavian artery and may or may not involve the diverticulum of Kommerell, leading to dysphagia and even tracheal compression. Inadvertent rupture may occur during endoscopy because of its retro-oesophageal position.

## Aortic dissection

## Available with the Gray's Anatomy e-book

## Aortopulmonary paraganglia

Aortopulmonary paraganglia (aortic bodies) belong to the branchiomeric category of paraganglia. They are chemoreceptors and respond to changes in arterial gas concentrations such as lowered $\mathrm{pO}_{2}$, increased $\mathrm{pCO}_{2}$ and increased hydrogen ion concentration. These microscopic structures occur in several locations within the thorax: coronary paraganglia lie between the ascending aorta and pulmonary trunk, either anteriorly or posteriorly, adjacent to the aortic root; pulmonary paraganglia lie in the groove between the ductus arteriosus and the pulmonary artery; and subclavian-supra-aortic paraganglia lie between either the right subclavian and right common carotid arteries or the left subclavian and left common carotid arteries, or caudal to the left subclavian artery, adjacent to the aortic arch.

## Brachiocephalic trunk (artery)

The brachiocephalic (innominate) artery (trunk), the largest branch of the aortic arch, is $4-5 \mathrm{~cm}$ in length (see Fig. $57.4 \mathrm{~A}, \mathrm{~B}$ ). It arises from the convexity of the arch posterior to the centre of the manubrium of the sternum, and ascends posterolaterally to the right, at first anterior to the trachea, then on its right. The brachiocephalic and left common carotid arteries often share a common origin (Osborn 1998). It divides into the right common carotid and subclavian arteries level with the upper border of the right sternoclavicular joint.

Relations Sternohyoid and sternothyroid, thymic remnants, left brachiocephalic and right inferior thyroid veins, crossing its root, and sometimes the right cardiac branches of the vagus nerve, all separate the brachiocephalic trunk from the manubrium. Posterior are the trachea (superiorly) and the right pleura (inferiorly). The right vagus nerve is posterolateral before passing lateral to the trachea. On its right side are the right brachiocephalic vein and the upper part of the superior vena cava and pleura, and on its left side are thymic remains, the origin of the left common carotid artery, the inferior thyroid veins and the trachea.

Branches The brachiocephalic trunk usually has only terminal branches, the right common carotid and subclavian arteries. Occasionally, a thymic or bronchial branch, or a thyroidea ima artery arise from it. The thyroidea ima artery is a small and inconstant artery that may arise from the aorta, right common carotid, subclavian or internal thoracic arteries; it ascends on the trachea to the thyroid isthmus, where it terminates.

## Descending thoracic aorta

The descending aorta is the segment of the thoracic aorta that is confined to the posterior mediastinum (see Figs 56.1-56.2, 56.6-56.7B, 56.13-56.14A, 56.19D,E). It begins level with the lower border of the fourth thoracic vertebra, continuous with the aortic arch, and ends anterior to the lower border of the twelfth thoracic vertebra in the aortic hiatus. At its origin, it is left of the vertebral column; as it descends, it reaches and terminates in the midline.

Relations Anterior to the descending thoracic aorta, from superior to inferior, are the left pulmonary hilum, the pericardium separating it from the left atrium, oesophagus and the vertebral portion of the
diaphragm. The vertebral column and hemiazygos veins are posterior. Posterior to the right are the azygos vein and thoracic duct, and inferiorly, the right pleura and lung; the pleura and lung are to the left. The oesophagus with its plexus of nerves is located laterally and to the right in the upper thorax, anteriorly in the lower thorax and descends to a left anterolateral position when it reaches the diaphragm. To a limited degree, the descending aorta and oesophagus are mutually spiralized. Occasionally, the aorta enters the diaphragm to the left and behind the oesophagus (Berdjas and Turina 2011).

Surface anatomy The descending thoracic aorta may be projected as a 2.5 cm broad band from the sternal end of the second left costal cartilage to a median position 2 cm above the transpyloric plane at the first lumbar vertebra.

## Branches

The thoracic aorta provides visceral branches to the pericardium, lungs, bronchi and oesophagus, and parietal branches to the thoracic wall.

Pericardial branches A few small vessels are distributed to the posterior aspect of the pericardium.

Bronchial arteries Bronchial arteries vary in number, size and origin. There is usually only one right bronchial artery; it arises from either the third posterior intercostal or the upper left bronchial artery, and runs posteriorly on the right principal bronchus. Its branches supply these structures, the pulmonary areolar tissue and the bronchopulmonary lymph nodes, pericardium and oesophagus. The left bronchial arteries, usually two, arise from the thoracic aorta - the upper near the fifth thoracic vertebra, the lower below the left principal bronchus - and run posterior to the left main bronchus; their branches are distributed as on the right.

Oesophageal branches Two or three bronchial arteries supply the thoracic portion of the oesophagus. In addition, two or three oesophageal arteries that arise either anteriorly or from the right side of the aorta supply the distal oesophagus (Norton et al 2008).

Mediastinal branches Numerous small vessels supply lymph nodes and areolar tissue in the posterior mediastinum.

Phrenic branches Superior phrenic arteries arise from the lower thoracic aorta and are distributed posteriorly to the superior diaphragmatic surface, anastomosing with the musculophrenic and pericardiacophrenic arteries.

Posterior intercostal arteries The posterior intercostal arteries and their branches are described on page 943.

Subcostal arteries Subcostal arteries are the last paired branches of the thoracic aorta, in series with the posterior intercostal arteries and inferior to the twelfth ribs. Each runs laterally anterior to the twelfth thoracic vertebral body and posterior to the splanchnic nerves, sympathetic trunk, pleura and diaphragm. The right subcostal artery is also posterior to the thoracic duct and azygos vein, while the left is posterior to the accessory hemiazygos vein. Each artery enters the abdomen at the lower border of the twelfth rib, accompanied by the twelfth thoracic (subcostal) nerve, lying posterior to the lateral arcuate ligament and kidney, and anterior to quadratus lumborum. The right artery courses posterior to the ascending colon, and the left courses posterior to the descending colon. Piercing the aponeurosis of transversus abdominis, each subcostal artery proceeds between this and internal oblique, and anastomoses with the superior epigastric, lower posterior intercostal and lumbar arteries. Each has a dorsal branch, distributed like those of the posterior intercostal arteries.

Aberrant artery A small artery sometimes leaves the descending thoracic aorta on its right near the right bronchial artery origin. It ascends to the right behind the trachea and oesophagus, and may anastomose with the right superior intercostal artery. It is a vestige of the right dorsal aorta and, occasionally, it is enlarged as the first part of a right subclavian artery.

Aortic rupture in trauma Rupture of the ascending aorta is usually associated with a high immediate mortality (Baliga et al 2007). Blunt aortic rupture commonly occurs in road traffic accidents and has a $20 \%$ survival rate. There is usually a transverse tear involving the tunica intima and tunica media of the aortic wall; systemic circulatory pressure

Aortic dissection occurs as a result of degeneration of the tunica media of the aortic wall and is associated with senescence, persistent hypertension or collagen vascular diseases such as Marfan's syndrome. Many patients with aortic dissection have a pre-existing aneurysm. Other associations include aortic coarctation, Turner's syndrome, cocaine abuse ( $<1 \%$ ) and trauma during surgical procedures. There is a higher prevalence in men than women; after the age of 75 , however, there is no sex difference (Baliga et al 2007). In a classic aortic dissection, an intimal tear may occur, producing a split into the tunica media that creates a false lumen (Fig. 58.8). If another tear occurs, connection can be made once again with the true lumen (the double-barrel aorta). Additional aetiopathologies include penetrating atherosclerotic ulceration, where an atherosclerotic plaque ruptures into the aortic tunica media, and aortic intramural haematoma, where the vasa vasorum haemorrhage into the wall of the aorta (Baliga et al 2007).

Aortic dissections are classified as types I, II, IIIa and IIIb (De Bakey classification), or types A and B (Stanford classification). Dissections that are proximal to the left subclavian artery, with or without distal extension, are classified as type I, II or A. Type I may involve the entire aorta, whereas type II involves the ascending aorta only. Dissections that are distal to the left subclavian artery are classified as type IIIa (involve the distal aorta up to the diaphragm), IIIb (extend below the diaphragm) or B. These cases present acutely with severe retrosternal, neck or interscapular chest pain. Depending on the extent of the dissection, they may be associated with neurological signs, diarrhoea or leg weakness. Extension into the pericardium causes cardiac tamponade and circulatory collapse. Diagnosis is established by echocardiography and on contrast-enhanced CT or magnetic resonance imaging (MRI). Medical management is possible for descending aortic dissections, while surgical repair is essential for ascending aortic or aortic arch dissection.

Multidetector CT of Aortic Dissection: A Pictorial Review. Radiographics. 2010 Mar;30(2):445-60.)
may cause the formation of a false aneurysm. Rupture of the isthmus region of the descending aorta is more common probably because it marks the junction between the mobile and fixed portions of the aorta. Other sites include the ascending aorta proximal to the origin of the brachiocephalic trunk, the aortic arch and the abdominal aorta. Rupture is likely to be the result of a number of factors, including torsion, shear and stretching forces, possibly compounded by hydrostatic pressure.

Aortic atherosclerosis or calcification Echocardiography, particularly trans-oesophageal, allows very detailed assessment of proximal aortic atherosclerosis implicated in systemic embolic events and strokes. The extent of turbulent flow may be documented. MRI may also allow an accurate assessment of the composition and size of atherosclerotic plaques and flow dynamics, permitting assessment of the risk of plaque rupture and thrombus formation.

## Subclavian arteries

## Right subclavian artery

The right subclavian artery arises from the brachiocephalic trunk, originating posterior to the upper border of the right sternoclavicular joint (see Fig. 51.2). It ascends superomedial to the clavicle and posterior to scalenus anterior, then descends laterally to the outer border of the first rib, where it becomes the axillary artery.

## Left subclavian artery

In the majority of individuals, the left subclavian artery originates independently from the aortic arch after the origins of the brachiocephalic and left common carotid arteries (see Fig. 57.4). It rises into the neck lateral to the medial border of scalenus anterior, crosses posterior to this muscle and then descends towards the outer border of the first rib, where it becomes the left axillary artery. A common origin occasionally exists between the left subclavian and vertebral arteries. Rarely, there are bilateral brachiocephalic trunks, which subsequently divide on both sides into common carotid and subclavian arteries.

Relations In the thorax, the left subclavian artery is related anteriorly to the left common carotid artery and left brachiocephalic vein, from which it is separated by the left vagus, cardiac and phrenic nerves. More superficially, the anterior pulmonary margin, pleura, sternothyroid and sternohyoid lie between the vessel and the upper left area of the manubrium of the sternum. On the left side of the oesophagus, the thoracic duct and longus colli are posterior. The left subclavian artery is in contact posterolaterally with the left lung and pleura. The trachea, left recurrent laryngeal nerve, oesophagus and thoracic duct are medial. Laterally, the artery grooves the mediastinal surface of the left lung and pleura, which also encroach on its anterior and posterior aspects.

## Common carotid arteries

The right and left common carotid arteries differ in their length and origin. The right is exclusively cervical and arises from the brachiocephalic trunk posterior to the right sternoclavicular joint. The left originates directly from the aortic arch immediately posterolateral to the brachiocephalic trunk and therefore has both thoracic and cervical parts.

## Right common carotid artery

The right common carotid artery and its relations are described in Chapter 29.

## Left common carotid artery

The left common carotid artery (see Figs 57.4, 29.7) ascends until level with the left sternoclavicular joint, where it enters the neck. Its thoracic portion is $20-25 \mathrm{~mm}$ long and it lies first anterior to the trachea, then inclines to the left. The further course of the artery is described in Chapter 29.

Relations Sternohyoid and sternothyroid, the anterior parts of the left pleura and lung, the left brachiocephalic vein and the thymic remnants are anterior and separate the left common carotid artery from the manubrium. The trachea, left subclavian artery, left border of the oesophagus, left recurrent laryngeal nerve and thoracic duct are posterior. To the right are the brachiocephalic trunk (inferior) and the trachea, inferior thyroid veins and thymic remains (superior). To the left are the left vagus and phrenic nerves, left pleura and lung.

## VEINS

## Brachiocephalic veins

The right and left brachiocephalic veins join to form the superior vena cava.

## Right brachiocephalic vein

The right brachiocephalic vein is about 2.5 cm long. It arises posterior to the sternal end of the right clavicle and descends almost vertically to join the left brachiocephalic vein, forming the superior vena cava posterior to the inferior border of the first right costal cartilage, near the right sternal border. It is anterolateral to the brachiocephalic trunk and right vagus nerve; the right pleura, phrenic nerve and internal thoracic artery are initially posterosuperior, becoming lateral inferiorly (see Fig. 29.14). Its tributaries are the right vertebral, internal thoracic and inferior thyroid veins, and sometimes the first right posterior intercostal veins.

## Left brachiocephalic vein

The left brachiocephalic vein is about 6 cm long, over twice the length of the right. It arises posterior to the sternal end of the left clavicle, anterior to the cervical pleura, and descends obliquely to the right, posterior to the superior half of the manubrium sterni, reaching the sternal end of the first right costal cartilage where it joins the right brachiocephalic vein to form the superior vena cava (see Fig. 29.14). It is separated from the left sternoclavicular joint and manubrium by sternohyoid and sternothyroid, the thymus or its remnants, and areolar tissue; terminally, it is overlapped by the right pleura. It crosses anterior to the left internal thoracic, subclavian, brachiocephalic and common carotid arteries, left phrenic and vagus nerves, and the trachea. The aortic arch is inferior to it. Its tributaries are the left vertebral, internal thoracic, inferior thyroid and superior intercostal veins, and sometimes the first left posterior intercostal, thymic and pericardial veins.

In children, the length and diameter of the left brachiocephalic vein are closely related to height; the diameter reaches adult dimensions at the age of 10 years (Figs 58.9-58.10) (Sanjeev and Karpawich 2006).

## Superior vena cava

The superior vena cava returns blood to the heart from the tissues above the diaphragm. It is approximately 7 cm in length, and is formed by the junction of the brachiocephalic veins posterior to the lower border of the first right costal cartilage. It descends vertically, posterior to the first and second intercostal spaces, and drains into the upper right atrium posterior to the third right costal cartilage. Its inferior half is within the fibrous pericardium, which it pierces level with the second costal cartilage. Covered anterolaterally by serous pericardium (from which a retrocaval recess projects), it is slightly convex to the right (see Figs 57.3, $57.4 \mathrm{~A}, \mathrm{~B}, 57.12,29.14$ ). The superior vena cava is valveless. In children, the length and diameter of the superior vena cava are also closely related to height; the diameter reaches adult dimensions at the age of 10 years (see Figs 58.9-58.10) (Sanjeev and Karpawich 2006).

Relations The anterior margins of the right lung and pleura are anterior and the pericardium intervenes below; these structures separate the superior vena cava from the right internal thoracic artery, first and second intercostal spaces, and second and third costal cartilages. The trachea and right vagus nerve are posteromedial, the right lung and pleura are posterolateral, and the right pulmonary hilum is posterior. The right phrenic nerve and pleura are immediate right lateral relations and the brachiocephalic trunk and ascending aorta lie to the left, the aorta overlapping the superior vena cava (see Fig. 55.7).

Tributaries Tributaries of the superior vena cava are the azygos vein and small veins from the pericardium and other mediastinal structures (see Fig. 56.7A).

Superior vena cava obstruction Superior vena cava obstruction is characterized by headaches, facial and neck venous congestion, and oedema, reflecting impaired venous drainage of the head, neck and arms, and of the collateral circulation, resulting in chest wall telangiectasia. Several of the symptoms may subside with recumbency, or may be aggravated by standing up. The obstruction may be either partial or complete, and may occur suddenly or gradually. It is usually caused by mediastinally invasive right upper lobe primary bronchogenic carcinoma or by metastatic involvement of the right paratracheal lymph nodes.

Fig. 58.9 Sites of measurement of the left brachiocephalic (innominate) vein and superior vena cava at angiography. Key: A, distal brachiocephalic vein; B, mid-brachiocephalic vein; C, brachiocephalicsuperior vena cava junction; D, mid-superior vena cava. (Redrawn with permission from Sanjeev S, Karpawich PP. growing children: an aid for interventional
Pediatr Cardiol. 2006 Jul-Aug;27(4):414-9.)

Haemorrhagic intrathoracic goitre, mediastinitis (either benign, malignant or fibrous), mediastinal haematoma, constrictive pericarditis, mediastinal cyst, thrombosis of the superior vena cava and sarcoidosis are less common aetiologies. Radiographic findings might include widening of the upper mediastinum on the frontal film or obliteration of the retrosternal space on the lateral film. Other correlative findings may include pulmonary or mediastinal masses, lymphadenopathy, enlarged or obliterated azygos venous system, pleural effusion or rib notching. This is usually considered to be an oncological emergency and symptoms are often completely and promptly relieved by insertion of a vascular stent via the common femoral vein or by radiotherapy to the affected region after a tissue diagnosis is established.

## Variations of the brachiocephalic veins and superior vena cava

Available with the Gray's Anatomy e-book

## Inferior vena cava

The inferior vena cava returns blood to the heart from infradiaphragmatic tissues. It passes through the diaphragm between the right leaf
and central area of the central tendon of the diaphragm at the level of the eighth and ninth thoracic vertebrae, and drains into the inferoposterior part of the right atrium (see Fig. 55.1, 57.4B). The thoracic part is very short, and is partly inside and partly outside the pericardial sac. The extrapericardial part is separated from the right pleura and lung by the right phrenic nerve, and the intrapericardial part is covered, except posteriorly, by inflected serous pericardium. The abdominal course of the inferior vena cava is described in Chapter 62.

Collateral venous channels In obstruction of the upper inferior vena cava, the azygos and hemiazygos veins and vertebral venous plexuses are the main collateral channels that maintain venous circulation. They connect the superior and inferior venae cavae and communicate with the common iliac vein by the ascending lumbar veins and with many tributaries of the inferior vena cava.

Variations Broadly speaking, the inferior vena cava may be congenitally interrupted, duplicated, left-sided or even absent.

Fig. 58.10 Diameters of the distal brachiocephalic (innominate) vein midbrachiocephalic vein, brachiocephalicsuperior vena cava junction and mid-superior vena cava in children of varying ages.

The brachiocephalic veins may enter the right atrium separately, the right vein descending like a normal superior vena cava. During embryological development, if the cardinal vein does not become obliterated, it will persist as a left-sided superior vena cava. A left superior vena cava may have a slender connection with the right and then cross the left side of the aortic arch to pass anterior to the left pulmonary hilum before turning to enter the right atrium. It replaces the oblique vein of the left atrium and coronary sinus, and receives all the tributaries of the coronary sinus. The left brachiocephalic vein sometimes projects above the manubrium (more frequently in childhood), and crosses the suprasternal fossa in front of the trachea. A left-sided superior vena cava may cause difficulties when placing a cardiac catheter, pacing or defibrillating electrodes because the angle between the left superior vena cava and the left subclavian vein is much more acute than that between the subclavian and a normal left brachiocephalic vein. Its calibre may also be smaller than that of the right. Even if insertion of a catheter into a left superior vena cava is possible, the angle at which the catheter enters the right atrium causes difficulty when attempting to place it into the right ventricle and pulmonary trunk; this generally leaves the catheter tip against the coronary sinus, making it difficult to obtain blood samples. In the majority of persistent left superior venae cavae, blood drains into the right atrium via the coronary sinus. When this does not happen, the coronary sinus is absent, and the persistent left superior vena cava drains directly into the atrium. Cyanosis reflects a persistent right-to-left shunt and affected individuals have a higher risk for paradoxical embolism. Radiographically, there is a paramediastinal bulge before the aortic arch. Electrocardiograms show a left P-wave axis. Diagnosis can be confirmed by cardiac catheterization and angiography. Persistent left superior vena cava may be associated with extracardiac conditions such as VACTERL association (vertebral defects, anal atresia, cardiac malformations, tracheo-oesophageal fistula with oesophageal atresia, radial and renal dysplasia, and limb anomalies); trisomy 21; 22q11; CHARGE association (coloboma, heart defects, choanal atresia, mental retardation, genital and ear anomalies); and 45 XO karyotype (Turner's syndrome).

If the superior vena cava is duplicated, the right superior vena cava may drain into the right atrium and the left superior vena cava into the left atrium. Although double superior vena cava is largely asymptomatic, it is usually (along with a sole left-sided superior vena cava) associated with congenital cardiac anomalies, such as pulmonary stenosis, coarctation of the aorta, tetralogy of Fallot and atrial septal defects.

Embryologically, if the right subcardinal vein fails to anastomose with the hepatic sinusoids, the hepatic segment of the inferior vena cava fails to develop. When this occurs, the hemiazygos or azygos veins, which both originate from the cranial supracardinal veins, return blood to the heart. Azygos continuation of the inferior vena cava, characterized by a prominent azygos vein, is an entity of which the paediatric surgeon should be aware when undertaking repair of oesophageal atresia and tracheo-oesophageal atresia in neonates. The azygos vein, which is commonly ligated and divided during this procedure, should be spared because ligation of this vessel in neonates with azygos continuation of the inferior vena cava leads to intraoperative circulatory collapse and death. Double inferior vena cava (right side usually dominant) is a result of the persistence of all or any segments of the subcardinal veins. One of the most common variations is a left-sided inferior vena cava, which is formed if the right supracardinal vein regresses and the left supracardinal vein persists. There may also be a duplication of the inferior vena cava, which typically occurs below the renal veins, and is the result of persistence of the left lumbar and thoracic supracardinal veins and left suprasubcardinal anastomosis as well as malformation of right subcardinal-hepatic anastomosis. Abnormalities associated with duplication of the inferior vena cava include: congenital heart disease, congenital absence of the right kidney, cloacal extrophy, renal ectopia with abdominal aneurysm, right retrocaval ureter, left retrocaval ureter and congenital absence of the iliac anastomosis, abnormal left arm drainage and transcaval ureter.

In situs inversus with dextrocardia, the inferior vena cava passes inferiorly along the left side instead of the right (as opposed to situs inversus with levocardia, in which the inferior vena cava remains on the right side). In situs ambiguus, otherwise known as heterotaxy, the major organs are arranged ambiguously within the body. Prominent azygos veins with interrupted inferior vena cava are associated with heterotaxy (Punn and Olson 2010). Situs ambiguus with polysplenia is associated with an absence of portions of the inferior vena cava on the right side (with continuation through the azygos or hemiazygos vein), transposition of the inferior vena cava to the left side, or duplication of the inferior vena cava with one on the right and one on the left. Situs inversus with asplenia is similar to that of polysplenia, in that the inferior vena cava may be absent with azygos continuation or with the inferior vena cava to the left of the midline. In situs inversus totalis, transposition of the inferior vena cava consists of a right-sided inferior vena cava. The inferior vena cava may have an abnormally high insertion into the right atrium. Congenital agenesis of the inferior vena cava may occur and may be completely asymptomatic because venous drainage of the lower limbs occurs through anastomosed channels of the azygos and hemiazygos veins. That said, this condition may be associated with a higher risk for deep vein thrombosis.

# Technical aspects and applications of diagnostic radiology 

## Jonathan D Spratt

## Magnetic resonance imaging

Magnetic resonance imaging (MRI) produces images by first magnetizing a patient in the bore of a powerful magnet and then broadcasting short pulses of radiofrequency (RF) energy at 46.3 MHz that resonate mobile protons (hydrogen nuclei) in the fat, protein and water of the patient's soft tissues and bone marrow. The protons produce RF echoes when their resonant energy is released; their density and location can be exactly correlated into an image matrix by complex mathematical algorithms.

The spinning proton of the hydrogen nucleus acts like a tiny bar magnet, aligning either with or against the magnetic field, and producing a small net magnetic vector. RF energy from various types of coil, either built into the scanner or attached to specific body parts, generates a second magnetic field perpendicular to the static magnetic field that rotates or 'flips' the protons away from the static magnetic field. When the RF pulse is switched off, the protons flip back (relax) to their original position of equilibrium, emitting the RF energy they had acquired into the antenna around the patient. This information is then amplified, digitized and spatially encoded by the array processor.

MRI systems are graded according to the strength of the magnetic field they produce. Routine high-field systems are those capable of producing a magnetic field strength of $3-7 \mathrm{~T}$ (Tesla), using a superconducting electromagnet immersed in liquid helium. Open magnets for claustrophobic patients and limb scanners use permanent magnets of $0.2-0.75$ T. For comparison, Earth's magnetic field varies from 30 to $60 \mu \mathrm{~T}$. MRI does not present any recognized biological hazard. Patients who have any form of pacemaker or implanted electro-inductive device, ferromagnetic intracranial aneurysm clips, certain types of cardiac valve replacement or intraocular metallic foreign bodies must never be examined because there is a high risk of death or blindness. Many extracranial vascular clips and orthopaedic prostheses are now 'MRI-friendly' but may cause local artefacts; newer sequences exist to reduce artefact. Loose metal items, 'MR-unfriendly' anaesthetic equipment and credit cards must be excluded from the examination room. Pillows containing metallic coiled springs have been known nearly to suffocate patients, and heavy floor buffing equipment has been found wedged in the magnet bore because domestic staff had been suboptimally informed.

New methods of analysing normal and pathological brain anatomy are now at the forefront of research. These are MR spectroscopy (MRS); functional MRI (fMRI); diffusion tensor imaging (DTI); high angular resolution diffusion imaging (HARDI) for MR tractography (MRT, see below); and molecular MRI (mMRI), which has taken on a new direction since the description of the human genome.

MRS assesses function within the living brain. It capitalizes on the fact that protons residing in differing chemical environments possess slightly different resonant properties (chemical shift). For a given volume of brain, the distribution of these proton resonances can be displayed as a spectrum. Discernible peaks can be seen for certain neurotransmitters: $N$-acetylaspartate varies in multiple sclerosis, stroke and schizophrenia while choline and lactate levels have been used to evaluate certain brain tumours.
fMRI depends on the fact that haemoglobin is diamagnetic when oxygenated but paramagnetic when deoxygenated. These different signals can be weighted to the smaller vessels, and hence closer to the active neurones, by using larger magnetic fields. mMRI uses biomarkers that interact chemically with their surroundings and alter the image according to molecular changes occurring within the area of interest, potentially enabling early detection and treatment of disease and basic pharmaceutical development and quantitative testing.

High-field-strength magnets give significant improvement in spatial resolution and contrast. MR images of the microvasculature of the live human brain that allow close comparison with the detail seen in histological slides have been acquired at 8 T . This has significant implica-
tions for the treatment of reperfusion injury and research into the physiology of solid tumours and angiogenesis. There is every reason to believe that continued efforts to push the envelope of high-fieldstrength applications will open new vistas in what appears to be a never-ending array of potential clinical applications.

T1 weighted images best accentuate fat and other soft tissues, whereas fluid is low-signal; these images are nicknamed the 'anatomy weighting' amongst radiologists who publish or teach anatomy. T2 weighted images reveal fluid as high signal as well as fat. Fat suppression sequences using T2 'fat sat' (T2FS) or short tau inversion recovery (STIR) are very sensitive in highlighting the soft tissue or bone marrow oedema that almost invariably accompanies pathological states such as inflammation or tumours. Contrast-enhanced images with gadolinium, when used with T1 fat saturation (T1FS) sequences, also exquisitely highlight hypervascularity, particularly that associated with tumours and inflammation, especially in pathologies where the blood-brain barrier is compromised. Metallic artefact reduction sequences (MARS) are superior in imaging periprosthetic soft tissues after joint replacement or other orthopaedic metalwork implantation.

## MR tractography

MRT is a three-dimensional modelling technique used to represent neural tracts visually using data collected by DTI or, more recently, by HARDI, with results presented in two- and three-dimensional images (Nucifora et al 2007).

In addition to the long tracts that connect the brain to the rest of the body, there are complicated neural networks formed by short connections among different cortical and subcortical regions, their existence revealed by histochemistry and postmortem biological techniques. Central nervous system tracts are not identifiable by direct examination, CT or conventional MRI scans, explaining the paucity of their description in neuroanatomy atlases and the poor understanding of their functions.

The MRI sequences used look at the symmetry of water diffusion in the brain. Bundles of fibre tracts make the water diffuse asymmetrically in a 'tensor', the major axis parallel to the direction of the fibres. There is a direct relationship between the number of fibres and the degree of anisotropy. DTI assumes that the direction of least restriction corresponds to the direction of white matter tracts. Diffusion MRI was introduced in 1985. In the more recent evolution of the technique into diffusion tensor MRI (DTI), the relative mobility of the water molecules from the origin is modelled as an ellipsoid rather than a sphere. This allows full characterization of molecular diffusion in the three dimensions of space and the formation of tractograms. Barriers cause uneven anisotropic diffusion. In white matter, the principal barrier is the myelin sheath, whereas bundles of axons provide a barrier to perpendicular diffusion and a path for parallel diffusion along the orientation of the fibres. Anisotropic diffusion is expected to be increased overall in areas of high mature axonal order. Conditions where barriers offered by the myelin sheaths or the axons are disrupted, e.g. in trauma, tumours and inflammation, reduce anisotropy and yield DTI data used to seed various tractographic assessments of the brain (p. 391). Data sets may be rotated continuously into various planes in order to appreciate the structure better; colour may be assigned based on the dominant direction of the fibres. A leading clinical application of MRT is in the presurgical mapping of eloquent regions. Intraoperative electrical stimulation (IES) provides a clinical gold standard for the existence of functional motor pathways that can be used to determine the accuracy and sensitivity of fibre-tracking algorithms.

Intersecting tracts or partial volume averaging of adjacent pathways with different fibre orientations are the reasons why DTI does not accurately describe the microstructure in complex white matter voxels that contain more than one fibre population, e.g. in the centrum semiovale, where major white matter tracts such as the pyramidal tract, the
superior longitudinal fasciculus and the corpus callosum intersect. This has hindered preoperative mapping of the pyramidal tract in brain tumour patients. HARDI permits more accurate delineation of pathways within complex regions of white matter. The q-ball reconstruction of HARDI data provides an orientation distribution function (ODF) that can be used to determine the orientations of multiple fibre populations contributing to a voxel's diffusion MR signal, mapping fibre trajectories through regions of complex tissue architecture in a clinically feasible timeframe.

## Ultrasound

Uniquely, ultrasound images do not depend on the use of electromagnetic wave forms. The properties of high-frequency sound waves (longitudinal waves) and their interaction with biological tissues are responsible for the production of 'echograms' (Desser and Jeffrey 2001). A sound wave of appropriate frequency (diagnostic range $3.5-20 \mathrm{MHz}$ ) is produced by piezo-electric principles. Image production is determined by attenuation and reflection as the beam passes through tissues. Attenuation is caused by the loss of energy due to absorption, reflection and refraction in soft tissues, resulting in a reduction in signal intensity. Reflection of sound waves within the range of the receiver produces the image, and the echotexture is dependent on tiny differences in acoustic impedance between different tissues. Blood flow and velocity can be measured (using the Doppler principle) in duplex mode.

Techniques such as harmonic imaging and the use of ultrasound contrast agents (stabilized microbubbles) have enabled non-invasive determination of myocardial perfusion. These contrast agents also clearly improve the detection of metastases in the liver and spleen. Ultrasound is the most common medical imaging technique for producing elastograms, in which stiffness or strain images of soft tissue are used to detect or classify tumours. Cancer is 5-28 times stiffer than the background of normal soft tissue; when a mechanical compression or vibration is applied, a tumour deforms less than the surrounding tissue. Elastography may be used, for example, to measure the stiffness of the liver in vivo or in the detection of breast or thyroid tumours. A correlation between liver elasticity and the cirrhosis score has been shown (Yeh et al 2002, Foucher et al 2006).

Interpretation of anatomy and pathology from static ultrasound images is more difficult than that from other imaging modalities: compare the real-time nature ultrasound in Video 14.1 with the static images in Fig 14.4. The technique is highly operator-dependent and provides unique information on tissue structure and form not obtained from other imaging techniques.

## Nuclear medicine

Historically, the field of nuclear medicine began in 1946 when radioactive iodine was administered as an 'atomic cocktail' to treat thyroid cancer. Since that time, nuclear medicine has advanced to the point where it was recognized in the early 1970s as a diagnostic subspecialty

Unlike diagnostic radiology, where an image is created by passing energy through the body from an external source, nuclear medicine creates an image by measuring the radiation emitted from tracers taken internally. Overall, the radiation dosages are comparable with CT and vary depending on the examination. Nuclear medicine also differs from most other imaging modalities in that the tests demonstrate the physiological function of a specific area of the body. In some instances, this physiological information may be fused with the more anatomical imaging of CT or MRI, combining the strengths of anatomy and function for diagnosis.

Nuclear medicine uses pharmaceuticals that have been labelled with a radionuclide (radiopharmaceuticals) and which are administered to patients by intravenous injection, ingestion or inhalation (the method of administration depends on the type of examination and the organ or organ process to be imaged). Emitted radiation is detected and imaged with specialized equipment such as gamma cameras, positron emission tomography (PET) or single photon emission computed tomography (SPECT). Radiation may be measured from parts of the body by the use of probes, or samples may be taken from patients and measured in counters.

Radiopharmaceuticals may be used to image a disease process or to treat diseases. Those used for imaging emit a gamma ray $(\gamma)$ and those used for treatment emit a beta ( $\beta$ ) particle. Gamma rays are of higher energy in order to pass through the body and be detected by a detection camera, whereas $\beta$ particles travel only short distances and emit their
radiation dose to the target organ. For example, ${ }^{99 m}$ technetium or ${ }^{123}$ iodine may be used to detect thyroid disease, but certain thyroid diseases or thyroid cancer may be treated solely or in part with ${ }^{131}$ iodine. The difference in the agent used depends on the type and energy levels of the radiation particle that the radioisotope emits.

Radionuclides used in nuclear medicine are often chemically bound to a complex called a tracer. The way the body handles a tracer may differ in disease or pathological processes. For example, the tracer used in bone imaging is methylene-diphosphonate (MDP) bound to ${ }^{99 \mathrm{~m}}$ technetium. MDP attaches to hydroxyapatite in bone; altered bone physiology, such as occurs in a fracture, metastatic bone disease or arthritic change, produces an increase in biochemical bone activity and an accumulation of MDP that is seen as a focal 'hot spot' of the radiopharmaceutical on a bone scan.
${ }^{99 \mathrm{~m}}$ Technetium is the major workhorse radioisotope of nuclear medicine. It can be eluted from a molybdenum/technetium generator stored within a nuclear medicine department, allowing for easy access. It has a short half-life ( 6 hours), which allows for ease of medical imaging and disposal. Its pharmacological properties allow it to be easily bound to various tracers and it emits gamma rays that are of suitable energy for medical imaging. In addition to ${ }^{99 \mathrm{~m}}$ technetium, the most common intravenous radionuclides used in nuclear medicine are ${ }^{123}$ iodine and ${ }^{131}$ iodine, ${ }^{201}$ thallium, ${ }^{67}$ gallium, ${ }^{18}$ fluorodeoxyglucose (FDG) and ${ }^{111}$ indium-labelled leukocytes. The most common gaseous/aerosol radionuclides used are ${ }^{133}$ xenon, ${ }^{81 \mathrm{~m}}$ krypton, ${ }^{99 \mathrm{~m}}$ technetium (Technegas) and ${ }^{99 \mathrm{~m}}$ technetium diethylene triamine pentaacetic acid (DTPA).

The images obtained from nuclear medicine imaging can be single or multiple. Image sets may be represented by time sequence imaging (e.g. cine), such as dynamic imaging or cardiac gated sequences, or by spatial sequence imaging, where the gamma camera is moved relative to the patient, e.g. in SPECT imaging. Spatial sequence imaging allows the images to be presented as a slice-stack much in the way that CT or MRI images are displayed. It may also be fused with concomitant CT or MRI to provide combined physiological and anatomical imaging.

A PET scan is a specialized type of nuclear medicine imaging that measures important body functions, such as blood flow, oxygen use or glucose metabolism. It involves short-lived radioactive tracer isotopes that emit positrons (positively charged subatomic particles with the same mass and magnitude of charge as electrons). The radioisotopes are chemically incorporated into biologically active molecules: most commonly, the sugar FDG (2-deoxy-2-[fluorine-18]fluoro-D-glucose). An hour after injection, FDG becomes concentrated into the tissues of interest; images are obtained as the isotope undergoes positron emission decay. A positron travels only a few millimetres before reacting with an electron by annihilation, producing a pair of gamma photons that move in opposite directions. The PET scan detectors process only those photon pairs that are detected simultaneously (coincident detection) to create an image of tissue activity with respect to that particular isotope. These images may subsequently be fused with CT or MR images. The short half-life of the isotopes limits PET imaging; close access to a cyclotron for generation of the isotopes plays an important role in the feasible location of a PET scanner. Typical isotopes used in medical imaging and their half-lives are: ${ }^{11}$ carbon (about 20 min ), ${ }^{13}$ nitrogen (about 10 min ), ${ }^{13}$ oxygen (about 2 min ) and ${ }^{18}$ fluorine (about 110 min ).

## Angiography/interventional radiology

Angiographic imaging was first described in 1927, when Egas Moniz, a physician and neurologist, introduced contrast X-ray cerebral angiography. (Moniz was awarded the Nobel Prize for his work in 1949.) In 1953, the field was revolutionized by the Seldinger technique, in which no sharp needles remained inside the vascular lumen during imaging. Although angiography initially involved X-ray and fluoroscopic imaging of blood vessels and organs of the body after injecting radiopaque contrast agents into the blood stream, it has evolved to encompass so much more. Many of the procedures currently performed by angiography may be diagnostic; following the advent of minimally invasive procedures performed with image guidance, the name of the discipline changed to interventional radiology (or vascular and interventional radiology).

Angiograms are typically performed by gaining access to the blood vessels, through either the femoral artery, femoral vein or jugular vein, depending on the area of interest to be imaged (e.g. cerebral, coronary or pulmonary angiograms). Following vascular access, catheters are directed to the specific location to be imaged by the use of guidewires, and contrast agents are injected through these catheters to visualize the vessels or the organ with X-ray imaging. Imaging of the arterial and
venous circulation of the arms and legs may demonstrate peripheral vascular disease.

Treatment and/or interventions can often be performed through similar catheter-based examinations. Such procedures might involve angioplasties, where a balloon mechanism is placed across an area of narrowing (stenosis) in a vessel or lumen. With controlled inflation of the balloon, the area of narrowing can be widened.

Imaging in diagnostic or interventional procedures may produce still or motion (cine) images. The technique often used, digital subtraction angiography (DSA), involves taking images at 2-30 frames per second to allow imaging of the flow of blood through vessels. A preliminary image of the area is taken before the contrast is injected; this 'mask' image is then electronically subtracted from all subsequent images, leaving only the vessels filled with contrast. For optimal subtraction, the patient must remain motionless.

Angiograms of the heart may be performed to visualize the size and contractility of the chambers and the anatomy of the coronary vessels. The thorax may also be studied to evaluate the pulmonary arteries and veins for vascular malformations, blood clots and possible origins of haemoptysis. In the investigation of atherosclerotic disease, vascular malformations or tumoral vascularization, the neck is often imaged in order to visualize the vessels that supply the brain in their entirety, from the points at which they arise from the aortic arch to their termination as cerebral vessels. Renal artery imaging may elucidate the cause of hypertension in selected patients, and imaging of the mesenteric vessels may identify the origin of gastrointestinal bleeding or mesenteric angina.

In addition to angiograms and venograms, the field of interventional radiology also includes such procedures as coil embolization of aneurysms and vascular malformations; balloon angioplasty and stent placement; chemoembolization directly into tumours; drainage catheter insertion; embolization (e.g. uterine artery for treatment of fibroids); thrombolysis to dissolve blood clots; tissue biopsy (percutaneous or transvascular); radiofrequency ablation and cryoablation of tumours; line insertions for specialized vascular access; inferior vena cava filter placements; vertebroplasty; nephrostomy placement; gastrostomy tube placement for feeding; dialysis access; transjugular intrahepatic portosystemic shunt (TIPS) placement; biliary interventions; and, most recently, endovenous laser ablation of varicose veins.

## Computed tomography

The limitation of all plain radiographic techniques is the twodimensional representation of three-dimensional structures; the linear
attenuation coefficient of all the tissues in the path of the X-ray beam form the image. CT obtains a series of different angular X-ray projections that are processed by a computer to give a section of specified thickness. The CT image comprises a regular matrix of picture elements (pixels). All of the tissues contained within the pixel attenuate the X-ray projections and result in a mean attenuation value for the pixel. This value is compared with the attenuation value of water and is displayed on a scale (the Hounsfield scale). Water is said to have an attenuation of 0 Hounsfield units (HU); air typically has an HU number of -1000 ; fat is approximately -100 HU ; soft tissues are in the range +20 to +70 HU ; and bone is usually greater than +400 HU .

Modern multislice helical CT scanners can obtain images in subsecond times, and imaging of the whole body from the top of the head to the thighs can take as little as a single breath-hold of only a few seconds. The fast scan times allow dynamic imaging of arteries and veins at different times after the injection of intravenous contrast agents. The continuous acquisition of data from a helical CT scanner allows reconstruction of an image in any plane (multiplane reconstruction, MPR), commonly sagittal and coronal, as may be seen in many of the images throughout this forty-first edition of Gray's Anatomy. This orthogonal imaging greatly improves the understanding of the threedimensional aspects of radiological anatomy and now forms part of the standard practice of assessing disease.

No specific preparation is required for most CT examinations of the brain, spine or musculoskeletal system. Studies of the chest, abdomen and pelvis, and those of the brain with complex histories, usually require intravenous contrast medium that contains iodine because this defines vascular relationships and differentiates normal and pathological soft tissues more effectively. Opacification of the bowel in CT studies of the abdomen and pelvis may be accomplished by oral ingestion of a water-soluble contrast medium from 24 hours prior to the examination, in order to outline the colon, combined with further oral intake $0-60$ minutes prior to the scan, in order to outline the stomach and small bowel. This procedure is much less frequently performed with the latest generation of scanners, which exquisitely differentiate various enhancing layers within the bowel wall. Occasionally, direct insertion of rectal contrast to show the distal large bowel may be required.

Generally, all studies are performed with the patient supine and images are obtained in the transverse or axial plane. Modern CT scanners allow up to $25^{\circ}$ of gantry angulation, which is particularly valuable in spinal imaging. Occasionally, direct coronal images are obtained in the investigation of cranial and maxillofacial abnormalities; in these cases, the patient lies prone with the neck extended and the gantry appropriately angled, but this technique has largely been superseded by the orthogonal imaging described above.

# Endobronchial ultrasound 

Natalie M Cummings

#### Abstract

History It is more than 35 years since the first description of blind transbronchial needle aspiration (TBNA) biopsies of paratracheal masses was published (Wang et al 1978). Prior to this, surgery had been the only way to obtain tissue from mediastinal masses or lymph nodes. TBNA is less invasive than surgery but the blind nature of the technique dictates that sampling only bulky masses or nodal tissue results in an acceptable yield. In the early 1990s, the first report of the new technique of 'endobronchial sonography' appeared (Hürter and Hanrath 1992). A small ultrasound catheter was passed through the working channel of a bronchoscope, giving a $360^{\circ}$ (radial) ultrasound image. Biopsies could be taken by inserting standard biopsy forceps through a sheath left in place to mark the correct position once the ultrasound catheter was removed. In 2003, the first report of a prototype bronchoscope, incorporating a curved linear array electronic transducer at the end of the bronchoscope, was published (Krasnik et al 2003). When the transducer was closely applied to the bronchial wall, ultrasound scanning of mediastinal structures (to a depth of 5 cm ) was possible and a 22-gauge needle inserted through the biopsy channel and into the mass in question was visible in real time. This meant that smaller lesions could be biopsied more accurately, with reduced potential for the wrong area to be sampled inadvertently. This new biopsy technique was termed endobronchial ultrasound (EBUS)-TBNA or fine needle aspiration (EBUS-FNA).

## Technique

Although the initial procedures took place under general anaesthetic, most EBUS procedures today take place under conscious sedation and local anaesthetic. Using computed tomography (CT), with or without positron emission tomography (PET) scanning, the areas that require sampling are identified. These lymph nodes or masses are then found during bronchoscopy using the ultrasound scanning probe. The inflation of a small water-filled balloon around the scanning probe can improve contact with the bronchial wall, and thus image quality, although in most cases it is not needed. A needle is inserted through the working channel of the bronchoscope and suction applied, via a syringe, at the proximal end of the needle. Under direct vision, the needle is passed several times through the lesion in order to obtain a cytological specimen. Suction is removed and the needle withdrawn from the bronchoscope. The specimen is either smeared on to slides and air-dried, or placed into pots containing liquid preservative for laboratory processing (Medford et al 2010). The power Doppler facility enables safer identification of vessels to avoid puncture of these structures.

## Diagnosis and staging of lung cancer

The main use of EBUS in today's clinical practice is in the diagnosis and staging of lung cancer. Surgical sampling of the mediastinum, whilst remaining the gold standard, has a number of limitations, including invasiveness and cost. In 2009, a new lymph node map was published by the International Association for the Study of Lung Cancer (Rusch et al 2009). Using this as a guide, EBUS can access lymph node stations 2R, 2L, 3P, 4R, 4L, 7, 10R, 10L, 11R and 11L. When combined with endoscopic ultrasound (EUS), where an endoscope fitted with a linear ultrasound transducer is inserted into the oesophagus, additional stations 8 and 9 can be sampled, as well as the left suprarenal gland, the left lobe of the liver and the coeliac axis nodes, if necessary. Stations 5 and 6 can only be accessed via a surgical approach.

Wallace et al (2008) showed, in 42 patients with malignant mediastinal lymphadenopathy, that the sensitivity and negative predictive value (NPV) of combined EBUS/EUS-FNA were $93 \%$ and $97 \%$, respec-
tively, compared to $69 \%$ and $88 \%$ for EBUS-TBNA alone. A more recent study of 44 patients, where the same operator performed EBUS-TBNA and then EUS-FNA by inserting the EBUS bronchoscope into the oesophagus, found that the sensitivity, specificity and accuracy of mediastinal lymph node staging using combined EBUS/EUS-FNA were all $100 \%$, compared to $79 \%, 100 \%$ and $84 \%$, respectively, for EBUS alone (Lee et al 2014). The ASTER trial randomized 241 patients to either combined EBUS/EUS-FNA or conventional surgical staging (Annema et al 2010). Where endoscopic staging showed no evidence of locally advanced disease, the patient underwent surgical staging ( $n=65$ ). Sensitivity was significantly greater for combined surgical/endoscopic staging ( $94 \%$ versus $79 \%, P=0.02$ ) with similar NPVs ( $93 \%$ versus $86 \%$, $P=0.18$ ) and complication rates. A head-to-head study of EBUS-TBNA versus the surgical approach of video-assisted mediastinoscopy (VAM) in 153 patients was published in 2011 (Yasufuku et al 2011). No significant differences were found between the two procedures in determining the true pathological N -stage, although the authors admitted that the EBUS-TBNA yield may have been improved by the fact that the procedures were all carried out under general anaesthetic by thoracic surgeons who were extremely familiar with mediastinal anatomy. At present, the European Society of Thoracic Surgeons continue to recommend that patients with mediastinal lymphadenopathy on PET/CT and negative endoscopic staging proceed to VAM because of the higher NPV (de Leyn et al 2014). However, mediastinoscopy can be avoided if endoscopic staging is positive.

## Other uses

Although most commonly used in lung cancer investigation, EBUS is increasingly employed to diagnose other causes of mediastinal lymphadenopathy and paramediastinal masses. Von Bartheld et al (2013) carried out a randomized controlled trial demonstrating that EBUS- or EUS-FNA was superior to combined endobronchial and transbronchial biopsy (conventionally, the method of choice to obtain a tissue diagnosis in sarcoidosis) in the detection rate of non-caseating granulomas. Sensitivity for the diagnosis of Mycobacterium tuberculosis has been reported at $85-94 \%$ (Sun et al 2013, Navani et al 2011), whilst for lymphoma it may be as high as $89 \%$ and even higher for relapsed rather than de novo disease (Moonim et al 2013). Controversy remains about whether the cytological sample obtained at EBUS can give sufficient information about lymphoma subtype compared to the larger samples obtained by core or surgical biopsies that have been traditionally favoured. At present, the British Thoracic Society feels that there is insufficient evidence to justify the use of EBUS-TBNA in lymphoma diagnosis (du Rand et al 2011) but this may change in the future as endoscopists and cytopathologists become more skilled. Using EBUS, the diagnosis of metastatic extrathoracic malignancy (Ozgül et al 2013), chondrosarcoma (Wang et al 2014), malignant pleural mesothelioma (Lococo et al 2014), vertebral body tumour (Ojha et al 2014), pulmonary artery aneurysm (Lerner and Riker 2014), parathyroid adenoma (Buderi et al 2014) and various other benign pathologies have all been reported in the literature.

## Complications

A recent review of 190 studies published between 1995 and 2012, comprising 16,181 patients, found a serious adverse event rate of $0.05 \%$ for EBUS, increasing to $0.14 \%$ with the addition of figures for EUS (von Bartheld et al 2014). Abscess formation, sepsis, pneumothorax and other respiratory complications accounted for the EBUS adverse events, whereas EUS had higher rates of infectious complications (including mediastinitis), oesophageal perforation and haemorrhage. The results of the AQuIRE registry, published in 2013, reported a $1.44 \%$ complication rate in 1,317 patients undergoing EBUS, including pneumothorax,
bleeding, sustained hypoxia and respiratory failure (Eapen et al 2013); it is unclear how many of these cases also feature in the figures of the aforementioned meta-analysis. Single case reports of needle breakage (Ozgül et al 2014) and pneumomediastinum/pneumopericardium (Ortiz et al 2014) have also been published. However, the procedure is generally accepted to be safe.

## The future

In this era of increasingly personalized medicine, it is important for any sampling technique to provide sufficient tissue for molecular analysis. In a recent study of 106 patients with non-small cell lung cancer (NSCLC), 101 samples taken at either standard bronchoscopy, EBUSTBNA or CT-guided core biopsy were sufficient to yield RNA for further molecular testing (Schmid-Bindert et al 2013). EBUS-TBNA was found
to yield greater amounts of tumour RNA when compared to the other methods (although this only reached significance when compared to bronchoscopy). Certain genetic changes (particularly in the EGFR and ALK genes) may determine the chemotherapy agent of choice; a further study has demonstrated that 52 of 55 samples obtained by EBUS-TBNA in patients with NSCLC contained sufficient material for fluorescent in situ hybridization (FISH) analysis for ALK rearrangement or amplification (Neat et al 2013). Yarmus et al (2013) found that four needle passes (in conjunction with rapid on-site cytopathology evaluation) yielded adequate amounts of tissue for EGFR and KRAS mutation analysis on tumour DNA as well as ALK rearrangement testing by FISH (Yarmus et al 2013).

The applications of EBUS continue to expand and with increased experience of both the operators and the cytopathologists examining the samples, the technique goes from strength to strength.

## Abdomen and pelvis: overview and surface anatomy

## GENERAL STRUCTURE AND FUNCTION OF THE ABDOMINOPELVIC CAVITY

Although often considered separately, the abdomen and pelvis form the largest continuous visceral cavity of the body. Together, they provide multiple vital functions, including: housing and protection of the digestive and urinary tracts and of the internal reproductive organs; a conduit for neurovascular communication between the thorax and lower limb; support and attachment for the external genitalia; access to and from the internal reproductive organs and urinary tract; assistance with physiological functions such as respiration, defecation and micturition; support for the vertebral column in weight-bearing, maintenance of posture and movement; and, in women, the ability to support human gestation.

## MUSCULOSKELETAL FRAMEWORK OF THE ABDOMEN AND PELVIS

The walls of the abdominopelvic cavity consist of five lumbar vertebrae and their intervening intervertebral discs (lying in the posterior midline); the muscles of the anterior abdominal wall lying anteriorly (rectus abdominis) and anterolaterally (transversus abdominis, internal oblique and external oblique); the muscles of the posterior abdominal wall (psoas, quadratus lumborum and the diaphragm); the bony 'basin' formed by the walls of the false and true pelvis; the muscles of the pelvic floor and perineum lying inferiorly; and the diaphragm lying superiorly (Fig. 59.1). In addition, the upper abdominal cavity gains protection from the lower six ribs and their cartilages, even though these structures are technically part of the thoracic wall.

Fig. 59.1 The bony and muscular structures making up the abdominopelvic 'cavity'. The anterolateral abdominal muscles have been removed for clarity.

#### Abstract

The muscles of the abdominal wall play an important role in movement of the trunk (flexion, extension and rotation). The anterolateral muscles, in particular, provide assistance with rotation of the thorax in relation to the pelvis (or vice versa if the thorax is fixed).

The abdominal cavity is somewhat kidney-shaped in horizontal cross-section due to the posterior indentation of the vertebral column. Consequently, there are two distinct paravertebral gutters on either side of the spine. The lordosis of the lumbar spine combined with the backward angulation of the sacrum gives each paravertebral gutter a parabola shape in sagittal section. In standing, the pelvic brim lies at an angle of about $55^{\circ}$ to the horizontal such that the anterior superior iliac spines and pubic tubercles are in approximately the same coronal plane. The mean angle between the upper border of the first sacral vertebra and the horizontal plane is about $40-45^{\circ}$ (Woon et al 2013).

## Thoracoabdominal interface

The diaphragm constitutes the interface between the thoracic and abdominal cavities (Ch. 55). Three principal pathways exist between the two cavities across the diaphragm: the caval opening in the central tendon transmits the inferior vena cava and right phrenic nerve; the oesophageal hiatus, encircled by the right crus of the diaphragm, transmits the oesophagus, vagal trunks and vessels; and the aortic hiatus, posterior to the median arcuate ligament of the diaphragm, transmits the aorta, thoracic duct and, usually, the azygos vein. The hemiazygos vein usually enters the thorax through the left crus of the diaphragm. Other lymphatics from the abdomen drain to the thorax alongside the inferior vena cava and via small vessels passing through and around the diaphragm. Thoracic splanchnic nerves reach the abdomen through the diaphragmatic crura and behind the medial arcuate ligaments, and the left phrenic nerve pierces the muscle of the left hemidiaphragm. The subcostal vessels pass into the abdomen beneath the lateral arcuate ligaments of the diaphragm. Anteriorly, the superior epigastric vessels pass between the costal and xiphoid attachments of the diaphragm. Neurovascular structures also cross between the thorax and abdomen within the subcutaneous tissues.

## Pelvis-lower limb interface

The pelvis forms an integral part of the bony structure of both the abdominopelvic cavity and the lower limb. It transmits the weight of the upright body, as well as providing a stable platform for movement of the hip joint and bipedal locomotion. Its bony surfaces provide attachment sites for the muscles of the buttock and thigh (Ch. 80), the pelvic floor and perineal membrane, the abdominal wall and lower back. The pelvis also transmits the neurovascular structures that supply the lower limb. There are four principal pathways between the pelvis and lower limb: the interval beneath the inguinal ligament anterior to the superior pubic ramus and ilium, which transmits the femoral neurovascular structures and lymphatics; the greater and lesser sciatic foramina, which transmit the gluteal vessels and nerves, sciatic nerve, and internal pudendal vessels and pudendal nerve; and the obturator foramen, which transmits the obturator nerve, vessels and lymphatics. Autonomic nerves travel with the arterial supply to the lower limb and with the branches of the sacral plexus. Neurovascular structures also cross between the lower limb and pelvis within the subcutaneous tissues.

## GENERAL ARRANGEMENT OF ABDOMINOPELVIC AUTONOMIC NERVES

What follows is a brief overview of the autonomic nervous system in the abdominopelvic region; descriptions of the neurovascular supply to individual organs are given in the relevant chapters. The autonomic supply to the abdominal and pelvic viscera is via the abdominopelvic part of the sympathetic chain and the greater, lesser and least splanchnic nerves (sympathetic), and the vagus and pelvic splanchnic nerves (parasympathetic). Numerous interconnections occur between plexuses and ganglia, particularly in the major plexuses around the abdominal aorta; hence, the descriptions tend to be simplifications based on the 'main' supply to each organ (Fig. 59.2). The details of the terminations of these fibres are given in the description of the microstructure of the gut wall.

As a general rule, sympathetic neurones from the abdominopelvic autonomic plexuses inhibit visceral smooth muscle motility and glandular secretions, induce sphincter contraction and cause vasoconstric-
tion. Parasympathetic stimulation leads to opposing effects. Visceral afferents also pass through these autonomic plexuses.

## Sympathetic innervation

The cell bodies of neurones of the sympathetic supply of the abdomen and pelvis lie in the intermediolateral grey matter of the first to the twelfth thoracic and the first two lumbar spinal segments. Myelinated axons from these neurones travel in the ventral ramus of the spinal nerve of the same segmental level, leaving it via a white ramus communicans to enter a thoracic or lumbar paravertebral sympathetic ganglion. Visceral branches may exit at the same level or ascend or descend several levels in the sympathetic chain before exiting; they leave the ganglia without synapsing and pass medially, giving rise to the paired greater, lesser and least splanchnic nerves, and the lumbar and sacral splanchnic nerves. Axons destined to supply somatic structures synapse in the sympathetic ganglion of the same level, and postganglionic, unmyelinated axons leave the ganglion as one or more grey rami communicantes to enter the spinal nerve of the same segmental level.

## Greater splanchnic nerve

On each side, the greater splanchnic nerve is derived from the medial, visceral branches of the fifth to ninth thoracic sympathetic ganglia. It gives off branches to the descending aorta and enters the abdomen through the fibres of the ipsilateral crus of the diaphragm, on which it descends anteroinferiorly. The main trunk of the nerve enters the superior aspect of the coeliac ganglion, where most of the preganglionic fibres synapse (but not those destined for the suprarenal medulla).

## Lesser splanchnic nerve

On each side, the lesser splanchnic nerve is derived from the medial, visceral branches of the tenth and eleventh thoracic ganglia (or ninth and tenth). It enters the abdomen running through the lowermost fibres of the ipsilateral crus of the diaphragm or under the medial arcuate ligament, and then lies on the crus as it runs anteroinferiorly. The trunk of the nerve joins the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It occasionally joins the greater and least splanchnic nerves as a single splanchnic nerve.

## Least splanchnic nerve

On each side, the least splanchnic nerve is derived from the medial, visceral branches of the eleventh and/or twelfth thoracic ganglia. It enters the abdomen medial to the sympathetic chain under the medial arcuate ligament of the diaphragm and runs inferiorly to join the renal plexus. The trunk of the nerve enters the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It is sometimes part of the lesser splanchnic nerve, when it forms a twig that enters the renal plexus just below the aorticorenal ganglion.

The thoracic splanchnic nerves are subject to considerable individual variation in their origin and distribution (Loukas et al 2010). For example, the greater splanchnic nerve may receive a contribution from the fourth or tenth thoracic sympathetic ganglia or originate only from the sixth to ninth ganglia.

## Lumbar sympathetic system

The lumbar part of each sympathetic trunk usually contains four interconnected ganglia lying on the anterolateral aspects of the lumbar vertebrae along the medial margin of psoas major (see Figs 59.2, 62.14) (Murata et al 2003). Superiorly, it is continuous with the thoracic sympathetic trunk posterior to the medial arcuate ligament. Inferiorly, it passes posterior to the common iliac vessels and is continuous with the sacral sympathetic trunk. On the right side, it lies posterior to the inferior vena cava; on the left, it is posterior to the lateral aortic lymph nodes. It is anterior to most of the lumbar vessels but may pass behind some lumbar veins.

On each side, the first, second and, sometimes, the third lumbar ventral spinal rami are connected to the lumbar sympathetic trunk by white rami communicantes. All lumbar ventral rami are joined near their origins by long, slender, grey rami communicantes from the four lumbar sympathetic ganglia. Their arrangement is irregular: one ganglion may give rami to two or three lumbar ventral rami, one lumbar ventral ramus may receive rami from two ganglia, or grey rami may leave the sympathetic trunk between ganglia (Murata et al 2003).

## Somatic and vascular branches

Sympathetic nerve branches accompany the lumbar arteries round the sides of the vertebral bodies, medial to the fibrous arches to which psoas major is attached, to provide sympathetic innervation to the lumbar somatomes. Branches from the lumbar ganglia innervate the abdominal

aorta and common, external and internal iliac arteries, forming delicate nerve plexuses that extend along the vessels. Other postganglionic sympathetic nerves to vessels and skin travel with somatic nerves. Thus, the femoral nerve carries vasoconstrictor sympathetic nerves to the femoral artery and its branches in the thigh, as well as sympathetic fibres in its cutaneous branches. Postganglionic fibres travelling with the obturator nerve supply the obturator artery and the skin of the medial thigh. Sympathetic denervation of vessels in the lower limb can be effected by removing or ablating the upper three lumbar ganglia and intervening parts of the sympathetic trunk; this procedure may be useful in treating some varieties of vascular insufficiency of the lower limb.

## Lumbar splanchnic nerves

Four lumbar splanchnic nerves pass as medial branches from the ganglia to join the coeliac, inferior mesenteric and superior hypogastric plexuses. The first lumbar splanchnic nerve, from the first ganglion, gives branches to the coeliac, renal and inferior mesenteric plexuses. The second nerve joins the inferior part of the intermesenteric or inferior mesenteric plexus. The third nerve arises from the third or fourth ganglion and joins the superior hypogastric plexus. The fourth lumbar splanchnic nerve from the lowest ganglion passes anterior to the common iliac vessels to join the lower part of the superior hypogastric plexus, or the hypogastric nerves. It is important to note that lumbar splanchnic sympathetic nerves contribute to the superior and inferior hypogastric plexuses and, therefore, contribute to the innervation of the bladder neck, ductus deferens and prostate, among other structures.

Damage to these nerves, e.g. during aortoiliac surgery, can result in sexual dysfunction.

## Pelvic sympathetic system

The sacral region of the sympathetic trunk usually consists of four or five ganglia located medial or anterior to the anterior sacral foramina beneath the presacral fascia (Oh et al 2004). Occasionally, one or two coccygeal ganglia are present. The sacral sympathetic trunk is continuous above with the lumbar sympathetic trunk, and preganglionic fibres descend from the lower lumbar spinal cord segments via this route. The first sacral sympathetic ganglion is the largest. More caudal ganglia become progressively smaller (Blaszczyk 1981). The sacral sympathetic chain is often asymmetric, with absent or fused ganglia, and crosscommunications between each side are frequent. Each ganglion sends at least one grey ramus communicans to its adjacent spinal nerve but up to 11 such branches from a single ganglion have been reported (Potts 1925).

The pelvic sympathetic chain converges caudally to form a solitary retroperitoneal structure, the ganglion impar (or ganglion of Walther), which lies at a variable level between the sacrococcygeal joint and the tip of the coccyx; it is occasionally paired, unilateral or absent (Oh et al 2004). It conveys sympathetic efferents to and nociceptive afferents from the perineum and terminal urogenital regions. Ganglion impar blockade may be used to treat intractable perineal pain of sympathetic origin in patients with pelvic cancers (Toshniwal 2007).

## Somatic and vascular branches

Grey rami communicantes containing postganglionic sympathetic nerves pass from the pelvic sympathetic ganglia to the sacral and coccygeal spinal nerves. There are no white rami communicantes at this level. The postganglionic fibres are distributed via the sacral and coccygeal plexuses (Woon and Stringer 2014). Thus, sympathetic fibres in the tibial nerve are conveyed to the popliteal artery and its branches in the leg and foot, whilst those in the pudendal and superior and inferior gluteal nerves accompany these arteries to the perineum and buttocks. Small branches also travel with the median and lateral sacral arteries.

## Sacral splanchnic nerves

Sacral splanchnic nerves pass directly from the ganglia to the inferior hypogastric plexus and, from there, to pelvic viscera; they usually arise from the first two sacral sympathetic ganglia.

## Parasympathetic innervation

The parasympathetic neurones innervating the abdomen and pelvis lie either in the dorsal motor nucleus of the vagus nerve or in the intermediolateral grey matter of the second, third and fourth sacral spinal segments. The vagus nerves supply parasympathetic innervation to the abdominal viscera as far as the distal transverse colon, i.e. they supply the foregut and midgut. The hindgut is supplied by parasympathetic fibres travelling via the pelvic splanchnic nerves (see below); the overlap between these two supplies is variable. The vagal trunks are derived from the oesophageal plexus and enter the abdomen via the oesophageal hiatus, closely related to the anterior and posterior walls of the abdominal oesophagus (see Fig. 56.6). The anterior vagal trunk is mostly derived from the left vagus and the posterior from the right vagus. The nerves supply the intra-abdominal oesophagus and stomach directly. The anterior trunk gives off a hepatic branch, which innervates the liver parenchyma and vasculature, the biliary tree including the gallbladder, and the structures in the free edge of the lesser omentum. The posterior trunk supplies branches to the coeliac plexus; these fibres frequently constitute the largest portion of the fibres contributing to the plexus. They arise directly from the posterior vagal trunk and from its
gastric branch, and run beneath the peritoneum, deep to the posterior wall of the upper part of the lesser sac, to reach the coeliac plexus. Their synaptic relays with postganglionic neurones are situated in the myenteric (Auerbach's) and submucosal (Meissner's) plexuses in the wall of the gut (see below).

## Pelvic splanchnic nerves

Pelvic splanchnic nerves to the pelvic viscera travel in the anterior rami of the second, third and fourth sacral spinal nerves. They leave the nerves as they exit the anterior sacral foramina and pass in the presacral tissue as a fine network of branches that are distributed to three principal destinations. Most pass anterolaterally into the network of nerves that form the inferior hypogastric plexus; from here, they pass to the pelvic viscera. Some join directly with the hypogastric nerves and ascend out of the pelvis, as far as the superior hypogastric plexus; from here, they are distributed with branches of the inferior mesenteric artery (p. 1153). A few run superolaterally in the presacral tissue, over the pelvic brim anterior to the left iliac vessels, and pass directly into the tissue of the retroperitoneum and the mesentery of the sigmoid and descending colon.

The pelvic splanchnic nerves are motor to the smooth muscle of the hindgut and bladder wall, supply vasodilator fibres to the erectile tissue of the penis and clitoris, and are secretomotor to the hindgut.

## Abdominopelvic autonomic plexuses and ganglia

The abdominopelvic autonomic plexuses are somewhat variable and often fuse or are closely interrelated. The following descriptions recognize their main features (Figs 59.3-59.4).

## Coeliac plexus

The coeliac plexus is located at the level of the twelfth thoracic and first lumbar vertebrae, and is the largest major autonomic plexus. It is a dense network that unites the coeliac ganglia, and surrounds the coeliac artery and the root of the superior mesenteric artery. It is posterior to the stomach and lesser sac, and anterior to the crura of the diaphragm

Fig. 59.3 The autonomic plexuses innervating the abdominal and pelvic viscera: schematic diagram.

Fig. 59.5 Distribution of the upper abdominal autonomic plexuses.
and the beginning of the abdominal aorta, and lies medial to the suprarenal glands. The plexus and ganglia receive the greater and lesser splanchnic nerves and branches from the vagal trunks. The plexus is in continuity with small branches along adjacent arteries and is connected to the phrenic, splenic, hepatic, superior mesenteric, suprarenal, renal and gonadal plexuses (Fig. 59.5). Visceral afferents in the coeliac plexus convey pain and other sensations from upper abdominal viscera.

Anaesthesia or ablation of these nerves (coeliac plexus block) is sometimes undertaken to treat intractable pain from pancreatic disorders.

## Coeliac and aorticorenal ganglia

The coeliac ganglia are irregular neural masses, measuring approximately 2 cm across, located between the origin of the coeliac trunk and superior mesenteric artery, medial to the suprarenal glands and anterior
to the crura of the diaphragm (Zhang et al 2006). They vary in number, size, shape and precise location; there are often two, one on each side. The right ganglion is frequently posterior to the inferior vena cava, and the left ganglion often lies posterior to the origin of the splenic artery The ipsilateral greater splanchnic nerve joins the upper part of each ganglion and the lesser splanchnic nerve joins the lower part. The lowermost part of each ganglion forms a distinct subdivision, usually termed the aorticorenal ganglion, which receives the ipsilateral lesser splanchnic nerve and gives origin to the majority of the renal plexus (which, most commonly, lies anterior to the origin of the renal artery).

## Phrenic plexus

The phrenic plexus is a periarterial extension of the coeliac plexus around the right inferior phrenic artery, adjacent to the right crus of the diaphragm (Rusu 2006). It contains one or two phrenic ganglia and a definable nerve trunk that connects the coeliac plexus and phrenic nerve. The plexus supplies branches to the suprarenal glands and diaphragm.

## Superior mesenteric plexus and ganglion

The superior mesenteric plexus lies in the pre-aortic connective tissue posterior to the pancreas, around the origin of the superior mesenteric artery. It is an inferior continuation of the coeliac plexus, and includes branches from the posterior vagal trunk and coeliac plexus. Its branches accompany the superior mesenteric artery and its divisions. The superior mesenteric ganglion lies superiorly in the plexus, usually above the origin of the superior mesenteric artery.

## Intermesenteric plexus

Like other parts of the abdominal aortic autonomic plexus, the intermesenteric plexus is not a discrete structure but is part of a continuous periarterial nerve plexus connected to the gonadal, inferior mesenteric, iliac and superior hypogastric plexuses. It lies on the lateral and anterior aspects of the aorta, between the origins of the superior and inferior mesenteric arteries, and consists of numerous fine, interconnected nerve fibres and a few ganglia continuous superiorly with the superior mesenteric plexus and inferiorly with the superior hypogastric plexus. It is not well characterized but receives parasympathetic and sympathetic branches from the coeliac plexus and additional sympathetic rami from the first and second lumbar splanchnic nerves.

## Inferior mesenteric plexus

The inferior mesenteric plexus lies around the origin of the inferior mesenteric artery and is distributed along its branches. It is formed predominantly from the aortic plexus, supplemented by sympathetic fibres from the first and second lumbar splanchnic nerves and ascending pelvic parasympathetic fibres from the inferior hypogastric plexus (via the hypogastric nerves and superior hypogastric plexus). Disruption of the inferior mesenteric plexus alone rarely causes clinically significant disturbances of autonomic function.

## Superior hypogastric plexus

The superior hypogastric plexus lies anterior to the aortic bifurcation, the left common iliac vein, median sacral vessels, fifth lumbar vertebral body and sacral promontory, and between the common iliac arteries. It is occasionally referred to as the presacral nerve, but is seldom a single nerve and is prelumbar rather than presacral. It lies within extraperitoneal connective tissue in the midline, extending a little to the left. The breadth of the plexus and its constituent nerves varies; appearances range from a reticular-like arrangement to a band-like structure or one or two distinct nerve trunks (Paraskevas et al 2008). The medial attachment of the sigmoid mesocolon and upper limit of the mesorectum lie anterior to the lower part of the plexus, separated from it by a thin layer of loose connective tissue. The plexus is formed by branches from three main sources: the aortic plexus (sympathetic and parasympathetic), lumbar splanchnic nerves (sympathetic) and pelvic splanchnic nerves (parasympathetic), which ascend from the inferior hypogastric plexus via the right and left hypogastric nerves. Visceral afferents also pass through the plexus. The hypogastric nerves lie in loose connective tissue just posterolateral to the upper mesorectum and pass over the pelvic brim medial to the internal iliac vessels. The superior hypogastric plexus conveys branches to the inferior mesenteric plexus and to the ureteric, gonadal and common iliac nerve plexuses; additional small branches turn abruptly forwards into the upper mesorectum to travel with the superior rectal artery.

## Inferior hypogastric plexus

The inferior hypogastric plexus lies in the thin extraperitoneal connective tissue on the pelvic side wall anterolateral to the mesorectum. The
internal iliac vessels and the attachments of levator ani and obturator internus lie laterally, and the superior vesical and obliterated umbilical arteries superiorly. In males, the inferior hypogastric plexus lies posterolaterally on either side of the seminal vesicles, prostate and the base of the urinary bladder. In men, the point where the vas (ductus) deferens crosses the ureter provides an approximate guide to the upper limit of the plexus (Mauroy et al 2003). The upper border of the plexus lies beneath the peritoneum of the rectovesical pouch and is in contact with the lateral aspect of the base of the bladder. The anterior border reaches the posterior aspect of the prostate; at its inferior limit, the cavernous (deep, cavernosal) nerve passes forwards to reach the posterolateral aspect of the prostate (see Fig. 75.11). In females, each plexus lies lateral to the uterine cervix, vaginal fornix and the posterior part of the urinary bladder, often extending into the broad ligaments of the uterus. The upper limit of the plexus corresponds approximately to the level where the uterine artery crosses the ureter in the base of the broad ligament (Azaïs et al 2013).

The inferior hypogastric plexus is formed mainly from pelvic splanchnic (parasympathetic) and sacral splanchnic (sympathetic) branches; a smaller contribution is derived from sympathetic fibres (from the lower lumbar ganglia), which descend into the plexus from the superior hypogastric plexus via the hypogastric nerves. It gives origin to a complex network of small pelvic branches, which supply the pelvic viscera either directly or indirectly via periarterial plexuses. The branches of the inferior hypogastric plexus supply the vas deferens, seminal vesicles, prostate, accessory glands and penis in males; the ovary, Fallopian tubes, uterus, uterine cervix and vagina in females; and the urinary bladder and distal ureter in both sexes. The plexus plays a key role in continence and sexual function.

Hypogastric nerves The hypogastric nerves are usually paired nerve bundles but may consist instead of multiple filaments. They contain sympathetic fibres (mostly descending from the superior hypogastric plexus) and parasympathetic fibres (ascending from the inferior hypogastric plexus). The nerves run between the superior and inferior hypogastric plexuses on each side behind the presacral fascia medial to the internal iliac vessels and lateral to the anterior sacral foramina.

## Other autonomic plexuses and ganglia

Additional plexuses are described for abdominopelvic viscera, such as the hepatic and gonadal plexuses. Each tends to lie around the main arterial supply to the organ. They receive both sympathetic and parasympathetic fibres from one or more of the major autonomic plexuses and have one or more ganglia. Thus, autonomic ganglia supplying the testis are found around the origin of the testicular arteries from the abdominal aorta and have connections with the renal, lumbar and intermesenteric autonomic plexuses (Motoc et al 2010).

## Para-aortic bodies

The para-aortic bodies (also known as paraganglia or, collectively, as the organ of Zuckerkandl) are collections of neural crest-derived chromaffin tissue found in close relation to the aortic autonomic plexuses. They are relatively large in the fetus, reach a maximum size at around 3 years of age, and have usually regressed by adulthood. They are most commonly found as a pair of bodies lying anterolateral to the aorta in the region of the inferior mesenteric and superior hypogastric plexuses, but multiple smaller collections may be present. Occasionally, they are found as high as the coeliac plexus or as low as the inferior hypogastric plexus in the pelvis, or may be closely applied to the sympathetic ganglia of the lumbar chain. Scattered cells that persist into adulthood may, rarely, be the sites of paraganglioma (extra-adrenal phaeochromocytoma) (Subramanian and Maker 2006).

## GENERAL ARRANGEMENT OF ABDOMINOPELVIC VASCULAR SUPPLY

The major vessels that occupy the abdomen and pelvis not only supply the viscera, retroperitoneal structures and much of the bony and soft tissue walls of both cavities, but also course through the cavities en route to supply the lower limbs. The arteries and systemic veins of the abdomen and pelvis lie predominantly posteriorly in the abdomen and posterolaterally in the pelvis. From the caval and aortic openings in the diaphragm, they follow the general parabolic shape of the lumbar spine. The pelvic divisions follow the contours of the brim and side wall of the true pelvis (Figs 59.6-59.7). The individual parts of the aortoiliac and iliocaval systems are described in the relevant chapters.

Fig. 59.6 The overall arrangement of the aortoiliac arterial tree of the abdomen and pelvis.

## Arterial supply to the gastrointestinal tract

The arterial supply to the gastrointestinal tract is derived from the anterior midline visceral branches of the aorta. There are usually three anterior branches: the coeliac trunk and the superior and inferior mesenteric arteries. Major variants in the origin of the arteries are uncommon (Ch. 62). Accessory or replaced branches to the abdominal viscera are more common. The inferior mesenteric artery almost always arises separately but replaced, accessory or anastomotic vessels may arise from the proximal superior mesenteric artery or its branches. Occasionally, these may contribute to the arterial supply of the inferior mesenteric artery (Horton and Fishman 2002).

The coeliac trunk and its branches supply the part of the foregut that extends from the distal oesophagus to the mid part of the descending duodenum, together with associated viscera (liver, biliary tree, spleen, dorsal pancreas, greater and lesser omenta). The superior mesenteric artery supplies the midgut, which extends from the mid descending duodenum to the distal third of the transverse colon (including jejunum, ileum, caecum, appendix, ascending and transverse colon). The inferior mesenteric artery supplies the part of the hindgut that extends from the distal transverse colon to the upper anal canal. Even in the absence of accessory arteries, numerous anastomoses exist between these vascular territories. For example, anastomoses around the head of the pancreas and the duodenum are formed between the anterior and posterior superior pancreaticoduodenal arteries and the anterior and posterior inferior pancreaticoduodenal arteries, and between the posterior superior pancreaticoduodenal artery and jejunal arteries
(Ch. 69). Anastomoses between the territories of the superior and inferior mesenteric arteries are less numerous; the most consistent is the marginal artery of the colon (Ch. 66).

## Portal venous system

The (hepatic) portal system, like all portal venous systems, connects two capillary beds: that of the abdominal and pelvic parts of the gut from the abdominal part of the oesophagus to the lower anal canal, together with all derived organs other than the liver (i.e. the pancreas, gallbladder and spleen), and the hepatic sinusoidal 'capillary' bed. The intrahepatic portal vein ramifies and ends in the hepatic sinusoids; from here, blood drains to central veins that converge to form the hepatic veins which drain into the inferior vena cava (Ch. 67). In adults, the portal vein has no valves. In fetal and early postnatal life, valves are demonstrable in tributaries of the portal vein but they usually atrophy with further maturation.

## Portal vein

The portal vein is formed behind the neck of the pancreas at the level of the L1/2 intervertebral disc (in the transpyloric plane) from the convergence of the superior mesenteric and splenic veins (Fig. 59.8). It is approximately 8 cm long in the adult and ascends obliquely to the right behind the first part of the duodenum, the common bile duct and gastroduodenal artery; at this point, it is directly anterior to the inferior vena cava. It enters the right border of the lesser omentum and ascends anterior to the epiploic foramen to reach the right end of the porta

Fig. 59.7 The overall arrangement of the iliocaval venous system of the abdomen and pelvis.
hepatis, where it divides into right and left main branches, which accompany the corresponding branches of the hepatic artery into the liver. In the lesser omentum, the portal vein lies posterior to both the common bile duct and the hepatic artery. It is surrounded by the hepatic nerve plexus and accompanied by lymphatics and some lymph nodes.

## Tributaries of the portal vein

The main extrahepatic tributaries of the portal vein are the left gastric (coronary) vein and the posterior superior pancreaticoduodenal vein (Ch. 67). Within the liver, the left branch receives the obliterated umbilical vein via the ligamentum teres, which connects to its vertical portion.

## GENERAL MICROSTRUCTURE OF THE GUT WALL

The gut wall displays a common structural plan that is modified regionally to take account of local functional differences. The general microstructure is best appreciated by reference to the development of the gut (Ch. 60). Much of the alimentary canal originates as a tube of endoderm enclosed in splanchnopleuric mesoderm. Its external surface faces the embryonic coelom, and the endodermal lining forms the epithelium of the canal and also the secretory and ductal cells of various glands that secrete into the lumen, including the pancreas and liver. The splanchnopleuric mesoderm forms the connective tissue, muscle layers, blood vessels and lymphatics of the wall, and its external surface becomes the visceral mesothelium or serosa. There is no serosa surrounding the cervical and thoracic portions of the gut, or below where
the hindgut traverses the pelvic floor; in these sites, the gut tube is surrounded by a connective tissue adventitia. Neural elements invade the gut from neural crest tissue (Ch. 17). The smooth muscle of the muscularis externa layers of the alimentary canal is supplemented with striated muscle at the beginning (from the branchial arches) and end of the gut tube.

The mature gut wall has four main layers: mucosa, submucosa, muscularis externa and serosa (Fig. 59.9). The mucosa (mucous membrane) is the innermost layer and is subdivided into a lining epithelium, an underlying lamina propria (a layer of loose connective tissue, where many of the glands are also found) and a thin layer of smooth muscle, the muscularis mucosae. The submucosa is a strong and highly vascularized layer of connective tissue. The muscularis externa consists of inner circular and outer longitudinal layers of smooth muscle; an incomplete oblique muscle layer is present only in the stomach. The external surface is bounded by a serosa or adventitia, depending on its position within the body.

## Mucosa

## Epithelium

The epithelium is the site of secretion and absorption, and provides a defence against various threats, including microorganisms. Its protective function against mechanical, thermal and chemical injury is particularly evident in the oesophagus and anal canal, where it is thick, stratified and covered in mucus, which serves as a protective lubricant. At other sites, the epithelium lining the gut wall is single-layered, and

Fig. 59.8 The overall arrangement of the portal

venous system draining the abdominal viscera.
either cuboidal (in glands) or columnar. It contains cells modified for absorption, as well as various types of secretory cell.

The barrier function and selectivity of absorption depend on tight junctions over the entire epithelium. The surface area of the lumen available for secretion or absorption is increased by the presence of mucosal folds, crypts, villi and glands (see Fig. 59.9). Microvilli on the surfaces of individual absorptive cells amplify the area of apical plasma membrane in contact with the contents of the gut. Some glands lie in the lamina propria and some in the submucosa; others (the liver and pancreas) are totally external to the wall of the gut. All of these glands drain into the lumen of the gut through individual ducts. The epithelium also contains scattered neuroendocrine (enteroendocrine) cells.

## Lamina propria

The lamina propria consists of compact connective tissue, often rich in elastin fibres, which supports the surface epithelium and contains nutrient vessels and lymphatics. Lymphoid follicles are present in many regions of the gut, most notably in Peyer's patches. Cells within the lamina propria are the source of growth factors that regulate cell turnover, differentiation and repair in the overlying epithelium.

## Muscularis mucosae

The muscularis mucosae is particularly well developed in the oesophagus and in the large intestine, especially in the terminal part of the rectum. In addition, single muscle cells originating from the muscularis
mucosae are found inside the villi or between the tubular glands of the stomach and large intestine. By its contraction, the muscularis mucosae can alter the surface configuration of the mucosa locally, allowing it to adapt to the shapes and mechanical forces imposed by the contents of the lumen, and in the intestinal villi, promoting vascular exchange and lymphatic drainage.

## Submucosa

The submucosa contains large bundles of collagen and is the strongest layer of the gut wall. However, it is also pliable and deformable, and can therefore adjust to changes in the length and diameter of the gut. Its contained arterial network is relatively dense and supplies both the mucosa and the muscle coat. The submucosa extends into the rugae of the gastric wall, the plicae circulares of the small intestine (but not the villi), and the folds that project into the lumen of the colon and rectum.

## Muscularis externa

The muscularis externa usually consists of distinct inner circular and outer longitudinal layers that create waves of peristalsis responsible for the movement of ingested material through the lumen of the gut. In the stomach, where movements are more complex, there is an incomplete oblique layer of muscle, internal to the other two layers. The

Fig. 59.9 The general arrangement of the alimentary canal to show the layers of the gut wall at the levels indicated.
circular muscle layer is invariably thicker than the longitudinal muscle, except in the colon, where the longitudinal muscle is condensed into three cords (taenia coli).

The muscularis externa is composed almost exclusively of smooth muscle, except in the upper oesophagus, where smooth muscle blends with striated muscle. Although the upper oesophageal musculature resembles that of the pharynx, it is entirely under involuntary control. For most of its length, the smooth muscle of the gut wall consists of ill-defined bundles of cells, typically visceral in type, and somewhat larger than vascular smooth muscle cells. They are approximately $500 \mu \mathrm{~m}$ long, regardless of body size, and are electrically and mechanically coupled. Their fasciculi lack a perimysium but have sharp boundaries.

The arrangement of the musculature allows a segment of gut to undergo extensive changes in diameter (to virtual occlusion of the lumen) and length, although elongation is limited by the presence of mesenteries. The coordinated activity of the two muscle layers produces a characteristic motor behaviour that is mainly propulsive and directed aborally (peristalsis), combined with a non-propulsive motor activity that either mixes the luminal contents, as occurs in the
stomach, or partitions them, as occurs at the pyloric sphincter. The muscle maintains a constant volume, so that shortening of a segment of the gut wall is accompanied by an increase in thickness of the muscle layer.

Intestinal smooth muscle exhibits variable and changing degrees of contraction on which rhythmic (or phasic) contractions are superimposed. Slow waves of rhythmic electrical activity, driven by changes in membrane potentials in pacemaker cells (interstitial cells), spread throughout the thickness of the circular and longitudinal smooth muscle coats. After spreading circumferentially, slow waves can move in either oral or anal directions, causing segmental contraction. The distances of propagation and the patterns of this spontaneous activity vary between areas of the intestine. Neural regulation of slow and phasic contractions involves excitatory and inhibitory transmitters that are released from the myenteric plexus. This motor control is closely coordinated with mucosal absorption and secretion, and is mediated via intrinsic nerves in the submucous plexus. The peristaltic reflex occurs during passage of luminal contents down the intestine. It involves ascending contraction and descending relaxation; the sensory limb is mediated by sensory neurones that respond to either mucosal
stimulation（intrinsic primary afferents）or muscle stretch（extrinsic afferents）．

## Interstitial cells

Interstitial cells of Cajal（ICCs）are found throughout the entire length of the gastrointestinal tract，where they lie in close contact with nerve terminals；they have numerous gap junctions with each other and with smooth muscle cells．Distinct networks are found in the myenteric plexus between the circular and longitudinal muscle．Looser arrange－ ments exist within the individual muscle layers and the submucosa of the gut，and isolated or small groups of ICCs are also found in the subserosal region．ICCs originate from mesenchymal cells and resemble smooth muscle cells but have fewer contractile elements and their intermediate filaments contain vimentin rather than desmin．They are involved in the generation of pacemaker signals，the propagation of electrical slow wave activity，neuromuscular transmission，and mech－ anosensation（p．1135）（Sanders et al 2014）．Defective ICC function has been implicated in a wide range of gastrointestinal motility disorders （Al－Shboul 2013），and in the development of gastrointestinal stromal tumours（Roggin and Posner 2012）．

Cells with a similar morphology have been found in association with smooth muscle at many other sites，such as the urethra，ductus deferens，prostate，bladder，corpus cavernosum，ureter，uterine tube，and uterus．They may act as electrical pacemakers in the urethra and ureter but their role at other sites is less certain（Drumm et al 2014）．

## Serosa and adventitia

A layer of connective tissue，of variable thickness，lies external to the muscularis externa．In many places，it contains adipose tissue．Where the gut is covered by visceral peritoneum，the external layer is a serosa， consisting of mesothelium overlying a thin layer of connective tissue． In extraperitoneal regions，the surfaces of the gut in contact with the peritoneum are covered by serosa，while other parts are covered by con－ nective tissue that blends with the surrounding fasciae and is referred to as an adventitia．

## Vascular plexuses

Vascular plexuses are present at various levels of the wall，especially in the submucosa and mucosa；they connect with vessels that supply the surrounding tissues or those entering through the mesentery，and accompany the ducts of outlying glands．

## Innervation

The gut wall is densely innervated by both the enteric nervous system （intrinsic control）and the autonomic nervous system（extrinsic control）．

The latter is not essential for function，as evidenced by intestinal activity after transplantation of the extrinsically denervated gut．In contrast， neuropathies affecting the enteric nervous system，such as Hirsch－ sprung＇s disease，are potentially life－threatening．For a detailed descrip－ tion of the enteric nervous system，see Furness et al（2014）．

## Extrinsic innervation

Extrinsic innervation of the gut is from sympathetic，parasympathetic and visceral sensory nerves．The cell bodies of preganglionic parasym－ pathetic efferent axons are found in the vagal dorsal motor nucleus in the medulla oblongata and in the sacral segments of the spinal cord． Their main target in the gut is the enteric neurones of the myenteric plexus．Vagal efferents play a major role in oesophageal propulsion， gastric acid secretion and emptying，gallbladder contraction and pan－ creatic exocrine secretion．Pelvic efferents innervate the distal colon and rectum．Sympathetic efferent neurones have their cell bodies in the intermediolateral grey matter（lamina VII）of the thoracolumbar seg－ ments of the spinal cord；those destined for the smooth muscle of the gut mostly pass through the sympathetic chain without synapsing and relay in prevertebral ganglia（coeliac，mesenteric and pelvic），whereas those mediating vasoconstriction synapse in the sympathetic chain or prevertebral ganglia．Postganglionic sympathetic fibres are distributed with the branches of the coeliac trunk and mesenteric arteries to three principal targets：the myenteric and submucosal ganglia（causing inhi－ bition），blood vessels（inducing vasoconstriction）and sphincter muscle （inducing contraction）．

Visceral sensory endings are distributed throughout the layers of the gut wall．They respond to various stimuli，including excessive muscular contraction or distension，ischaemia and inflammation；their cell bodies are located in the nodose ganglion of the vagus nerve（vagal afferents）and in thoracic and lumbosacral dorsal root ganglia（visceral afferents，which run with sympathetic efferents）．Their central projec－ tions reach the brainstem and spinal cord，respectively．Vagal afferents are more numerous in the foregut than the midgut and are concerned with physiological responses such as satiety，whereas pain and discom－ fort are mediated by spinal pathways．

## Intrinsic innervation

The intrinsic innervation of the gut is derived from enteric neurones distributed throughout its wall in thousands of small ganglia，each consisting of neuronal cell bodies supported by enteric glial cells；it is estimated that there are between 200 and 600 million neurones in the human enteric nervous system．Enteric neurones are derived from neural crest cells．The enteric nervous system innervates the gut from oesophagus to anus，together with the pancreas and biliary tree．

The majority of enteric neurones in the wall of the gut are found in two ganglionated plexuses（Fig．59．10）．The most extensive of these is the myenteric（Auerbach＇s）plexus，which consists of a network of nerve

Fig．59．10 The organization of the enteric nervous system in the human small intestine．There are two ganglionated plexuses：the myenteric plexus between the longitudinal and circular layers of the external musculature，and the submucosal plexus（SMP），which has outer and inner components． Nerve fibre bundles connect the ganglia and form plexuses innervating the longitudinal muscle，circular muscle，muscularis mucosae，intrinsic arteries and the mucosa．Axons of extrinsic origin also run in these nerve fibre bundles．There are also innervations of gastroenteropancreatic（GEP）endocrine cells and gut－associated lymphoid tissue（GALT），which are not shown here．（Redrawn with permission from Furness JB．The enteric nervous system and neurogastroenterology．Nat Rev Gastroenterol Hepatol 2012；9：286－294．Reprinted with permission from Nature Publishing Group．）
fibres and small ganglia lying between the circular and longitudinal layers of the muscularis externa. It runs in continuity from the oesophagus to the anus. The submucosal (Meissner's) plexus has outer and inner components, and is present throughout the intestine but absent or minimal in the oesophagus and stomach.

Interconnecting, non-ganglionated nerve plexuses lie at various levels in the wall of the gut, including the lamina propria (mucosal plexus), at the interface between the submucosa and muscularis externa, between the circular and longitudinal muscles (the non-ganglionated part of the myenteric plexus), and within the serosa.

Individual enteric neurones function in one of several ways: as afferent (sensory) nerves responding to mechanical and chemical stimuli; as efferent (motor) nerves innervating epithelial cells (influencing absorption, secretion and/or the release of hormones), smooth muscle (excitatory or inhibitory), arterioles (vasoconstriction or vasodilation) and lymphoid tissue; or as interneurones that relay and integrate signals. Collectively, they are involved in a hierarchy of enteric reflexes that include local reflexes within the gut wall; reflexes mediated through prevertebral sympathetic ganglia; and reflexes mediated through the central nervous system (the gut-brain axis). The functions of enteric neurones may be further modulated by local environmental factors, e.g. enteric glia, gut microbiota and feeding state, and by general factors in the host, e.g. the immune system, stress and disease (Brierley and Linden 2014). Pathological states become manifest by abnormal secretion, impaired absorption, disordered gastrointestinal motility and pain.

## SURFACE ANATOMY OF THE ABDOMEN AND PELVIS

## ABDOMINAL PLANES AND REGIONS

For descriptive purposes, the abdomen can be divided into regions using a combination of horizontal and vertical planes that are based on skeletal landmarks. Published descriptions of surface anatomy largely apply to adults, in whom attempts have been made to validate or update standard descriptions using cross-sectional imaging. The extent to which many of these surface projections can be extrapolated to children is uncertain; some differences are inevitable, particularly in infants, given their different visceral and body proportions (Stringer 2011). In this chapter, descriptions of the surface projections of abdominal structures refer to the most commonly encountered arrangement seen in adults. However, it is important to note that there is considerable individual variation in surface anatomy, compounded further by potential variations related to age, sex, posture, respiration, body mass and ethnicity (Mirjalili and Stringer 2012).

## Vertical lines and planes

The midline (or median plane) passes through the xiphoid process and the pubic symphysis. There are two paramedian lines, left and right, that extend from the mid-clavicular point to the mid-inguinal point, a point midway between the anterior superior iliac spine and the pubic symphysis (Fig. 59.11A); this line crosses the costal margin just lateral to the tip of the ninth costal cartilage. In the upper abdomen, it approximates to the lateral border of rectus abdominis.

## Horizontal lines and planes

Several horizontal reference planes have been defined but, with modern cross-sectional imaging, their clinical utility for positioning abdominal viscera has become limited. Nevertheless, they help to conceptualize the relative positions of abdominal viscera with respect to vertebral levels and bony surface landmarks.

The xiphisternal joint most often lies in the same horizontal (axial) plane as the T9 vertebra (Mirjalili et al 2012b).

The transpyloric plane lies midway between the suprasternal notch of the manubrium and the upper border of the pubic symphysis. This corresponds to a plane that is approximately midway between the xiphisternal joint and the umbilicus, or slightly below (Mirjalili et al 2012a). Posteriorly, the plane intersects the lower half of the body of the first lumbar vertebra, the L1/2 intervertebral disc, or the upper half of the body of the second lumbar vertebra in most individuals (range lower T12 to lower L2); it sits higher in males (lower L1-L1/2) than females (lower L2) (Mirjalili et al 2012a). Anteriorly, it intersects the costal margin at the ninth costal cartilage, where the linea semilunaris crosses, and where a distinct 'step' may be palpable in the rib margin. The following structures lie approximately within the transpyloric plane (Mirjalili et al 2012a, 2012b): the origin of the superior mesenteric artery; the origin of the portal vein (from the confluence of the superior
mesenteric and splenic veins behind the neck of the pancreas); the hilum of the left kidney (the hilum of the right kidney is slightly lower); the origin of the renal arteries; the level of the duodenojejunal flexure (Mirjalili 2012b); and the termination of the spinal cord. The pylorus may be found in the transpyloric plane but is not a constant feature.

The subcostal plane is defined by a line that joins the lowest point of the costal margin on each side (usually, the tenth costal cartilage); it is most commonly at the level of the second lumbar vertebra (range T12/L1 disc to upper L3) (Mirjalili et al 2012a).

The supracristal plane joins the highest point of the iliac crest on each side. It serves as a useful landmark when performing a lumbar puncture or spinal injection, and usually lies at the level of the L4 body or L4/5 disc and its spinous process (see Fig. 78.16). The bifurcation of the abdominal aorta lies approximately in this plane (Mirjalili et al 2012a).

The transtubercular plane joins the tubercles of the iliac crests and is traditionally reported to lie at the level of the body of L5, near its upper border. It is an approximate landmark for the origin of the inferior vena cava from the confluence of the common iliac veins.

The plane of the pubic crest is in line with the upper border of the pubic symphysis. In supine individuals, this plane frequently intersects the tip of the coccyx and the femoral head (Mirjalili et al 2012a), but there are variations relating to the degree of lumbar lordosis, sacral inclination and pelvic tilt.

## Abdominal regions

The abdomen can be divided into nine regions using the subcostal, transtubercular and two paramedian planes (Fig. 59.11A). These regions are used in clinical practice for descriptive localization of a patient's pain or tenderness, or the position of a mass, and can be used to reference the position of abdominal viscera. From superior to inferior, the nine regions are: the epigastrium, flanked by the right and left hypochondrium; the umbilical, or central, flanked by the right and left lumbar; and the suprapubic or hypogastrium, flanked by the right and left iliac fossae. In practice, these regions are often loosely defined without strict reference to their boundaries. An alternative system of description involves dividing the abdomen into quadrants using the median plane and a horizontal line passing through the umbilicus.

## ANTERIOR ABDOMINAL WALL

## Skeletal landmarks

The superior boundary of the anterior abdominal wall is formed by several clear landmarks (Fig. 59.11B). The xiphoid process is palpable at the inferior sternum, in the midline. From here, the costal margins can be felt passing inferolaterally from the seventh costal cartilage at the xiphisternal joint to the tip of the twelfth rib (the latter is often difficult to feel in the obese or if it is short). The lower border of the ninth costal cartilage can usually be defined as a distinct 'step' along the costal margin. The lowest part of the costal margin lies in the mid-axillary line and is formed by the inferior margin of the tenth costal cartilage.

The inferior boundary of the anterior abdominal wall is formed, from lateral to medial, by the iliac crest, which descends to the anterior superior iliac spine; the inguinal ligament, which runs obliquely downwards to the pubic tubercle; and the pubic crest, which extends from the pubic tubercle laterally to the pubic symphysis in the midline. The pubic tubercle is palpable on the anterosuperior surface of the pubic bone approximately 2 cm lateral to the midline. The prominent tendon of adductor longus (best felt with the hip flexed, abducted and externally rotated) attaches to the pubis directly below the pubic tubercle, and can therefore be used to verify its position.

The posterolateral boundary of the anterior abdominal wall is the mid-axillary line.

## Soft tissue landmarks

## Umbilicus

The umbilicus is an obvious but inconstant landmark. In the supine adult, it usually lies around the L4 level (range L2/3 disc to upper S1) (Mirjalili et al 2012b). The umbilicus may lie at a lower level in the erect position, and in children, the obese and in individuals with a pendulous abdomen.

## Rectus abdominis

In a thin, muscular individual, the tendinous intersections of rectus abdominis may be visible, especially when the muscle is tensed by lifting the head against resistance or by sitting up; the intersections are usually situated at the level of the umbilicus, the level of the xiphoid process and midway between these two points (Fig. 59.11B).

Fig. 59.11 A, Nine regions of the anterior abdominal wall. Key: 1, right hypochondrium; 2, epigastrium; 3, left hypochondrium; 4, right lumbar; 5, umbilical/central; 6, left lumbar; 7, right iliac fossa; 8, suprapubic/hypogastrium; 9, left iliac fossa; 10, paramedian line; 11, subcostal plane; 12, transtubercular plane. B, The surface projection of the abdominal viscera. Key: 1, diaphragm position: right dome level with fifth intercostal space and left dome with sixth rib; 2, liver: mapped between three points: right fifth rib/intercostal space mid-clavicular line, left fifth intercostal space/sixth rib mid-clavicular line and right tenth costal cartilage mid-axillary line; 3 , zone of gastro-oesophageal junction position (white): mainly located posterior to left seventh costal cartilage, at approximately T11; 4, transpyloric plane; 5, zone of gallbladder fundus position (white); 6, duodenum: four parts marked D1-D4; 7, linea semilunaris; 8, position of small intestine mesentery; 9 , linea alba; 10, tendinous intersection of rectus abdominis. C, The surface position of the spleen and kidneys. Key: 1, spleen; sits deep to ribs 10-12 with long axis aligned with rib 11; 2, supracristal plane. (C, Derived with permission from Mirjalili SA, McFadden SL, Buckenham T, Stringer MD. 2012b A reappraisal of adult abdominal surface anatomy. Clin Anat 25:844-50.)

## Linea alba

The linea alba is usually only visible in thin, muscular individuals. It is wider and more obvious above the umbilicus, and is almost linear and less visible below this level (Ch. 61) (Fig. 59.11B; see Fig. 61.2).

## Linea semilunaris

The linea semilunaris lies along the lateral margin of the rectus sheath and is visible as a shallow, curved groove in muscular individuals, particularly when the abdominal muscles are tensed, e.g. by sitting up from the lying position (Fig. 59.11B). It passes from the ninth costal cartilage to the pubic tubercle.

## Mid-inguinal point

The mid-inguinal point lies at the midpoint of a line between the pubic symphysis and the anterior superior iliac spine. In adults, it is the approximate surface marking of the femoral artery (just below the ligament) and the deep inguinal ring (just above the ligament) (Hale et al 2010).

## Inferior epigastric artery

The inferior epigastric artery lies along the medial border of the deep inguinal ring immediately above the inguinal ligament. Up to the level of the umbilicus, it follows a course that lies approximately $40 \%$ of the distance between the midline and a sagittal plane running through the anterior superior iliac spine (Epstein et al 2004). The surface anatomy of the artery is particularly important in laparoscopic surgery because trocar insertion may injure the vessel, causing a rectus sheath haematoma or intra-abdominal bleeding. The artery can be avoided if a trocar is inserted at least two-thirds of the distance along a horizontal line between the midline and a sagittal plane passing through the anterior superior iliac spine.

## Superficial reflexes

## Cremasteric reflex

Stroking the skin of the medial side of the thigh evokes a reflex contraction of cremaster, which elevates the ipsilateral testis. The reflex is mediated by the genitofemoral nerve (L1 and L2 nerve roots), although
the afferent arc of the reflex may be via sensory fibres in the ilioinguinal nerve. The reflex is usually absent if there is torsion of the testicle.

## Superficial abdominal reflex

Gently stroking each of the four quadrants of the anterior abdominal wall normally elicits a visible contraction of ipsilateral abdominal muscles. The reflex can be used to help localize lesions in the spinal cord but is now of minor clinical significance because of the availability of neuroimaging and the difficulties of eliciting the reflex in multiparous women, the elderly and the obese (Gosavi and Lo 2014).

## INTRA-ABDOMINAL VISCERA

The surface markings of the intra-abdominal viscera are variable and depend on age, sex, body habitus, nutritional state, phase of ventilation and body position. The availability of cross-sectional and ultrasound medical imaging of the abdominal viscera has led to a decline in the use of surface anatomy, except for descriptive purposes. The following descriptions are, at best, regarded as the most common or approximate markings in a healthy supine adult (Fig. 59.11B,C). The spinous processes of the lumbar vertebrae can be used to locate vertebral levels, with the lower part of the spinous process marking the level of the intervertebral disc below the correspondingly numbered vertebra.

## Diaphragm

In the supine position at end-tidal inspiration, the dome of the diaphragm is most frequently located level with the fifth intercostal space in the mid-clavicular line on the right and the sixth rib in the midclavicular line on the left, and ranges from the fourth intercostal space to below the costal margin (Mirialili et al 2012c) (see Fig. 59.11B) (see Ch. 55 for further discussion of the diaphragm). These levels are approximate, not only because of individual variation but also because diaphragmatic excursion in the erect position during quiet breathing is about 2 cm and increases to about 7 cm during deep breathing (Boussuges et al 2009). The dome of the diaphragm can reach as high as the fourth rib on maximal expiration.

## Stomach

The gastro-oesophageal junction lies to the left of the midline, posterior to the left seventh costal cartilage, at the level of the eleventh thoracic vertebra (range upper T10 to L1/2), with the level being lower in females and higher in the obese (Mirjalili et al 2012b) (see Fig. 59.11B). The stomach lies in a curve within the left hypochondrium and epigastrium, although, when distended, it may lie as far down as the umbilical or suprapubic regions. The epigastrium is the usual place to auscultate for a 'succussion splash' caused by gastric outlet obstruction or stasis, and is also the region where a thickened pylorus is palpable in infantile hypertrophic pyloric stenosis.

## Duodenum

The first part of the duodenum sometimes ascends above the transpyloric plane; the second part usually lies just to the right of the midline, alongside the second and third lumbar vertebrae; the third part usually crosses the midline at the level of the third lumbar vertebra; and the fourth part ascends to the left of the second lumbar vertebra, reaching the transpyloric plane in the region of the lower border of the first lumbar vertebra (see Fig. 59.11B). The duodenojejunal flexure commonly sits at L1 (range lower T11 to upper L3) (Mirjalili et al 2012b)

## Small intestine and its mesentery

The small intestine mesentery runs obliquely in a line from a point just to the left of the lower border of the first lumbar vertebra (in the transpyloric plane) towards the right iliac fossa.

## Appendix

The appendix is located in the right lower quadrant of the abdomen but is highly variable in its length and position. Studies analysing barium enemas in supine adults have shown the position of appendix base is variably located and rarely precisely at McBurney's point (a point two-thirds of the way along a line joining the anterior superior iliac spine to the umbilicus) (Ramsden et al 1993, Naraynsingh et al 2002).

## Liver

At the end of normal tidal inspiration, the inferior border of the liver extends along a line that passes from the right tenth costal cartilage in the mid-axillary line to the left fifth intercostal space/sixth rib in the mid-clavicular line (see Fig. 59.11B). It may be palpable in healthy adults on deep inspiration. The superior border of the liver follows a line that passes from the right fifth rib or intercostal space in the mid-clavicular
line to the left fifth intercostal space/sixth rib in the mid-clavicular line, and can be mapped with the contour of the diaphragm (Mirjalili et al 2012c). This border curves slightly downwards at its centre and crosses the midline behind the xiphisternal joint. The right border of the liver is curved to the right and joins the upper and lower right limits. The upper border of the liver may be defined by dullness to percussion when compared with the resonance of the lungs above.

## Gallbladder

The fundus of the gallbladder is commonly identified with the tip of the ninth costal cartilage (in the transpyloric plane), near the junction of the linea semilunaris with the costal margin (see Fig. 59.11B). Recent data have shown that the fundus lies in the transpyloric plane in approximately one-third of supine individuals and below the plane in most others (Mirjalili et al 2012b)

## Spleen

The spleen is traditionally described as sitting on the left posterolateral abdominal wall deep to ribs 9-11. Recent data show that the spleen sits deep to ribs $10-12$ in $50 \%$ of subjects and deep to ribs $9-11$ in $25 \%$ of supine individuals; its long axis corresponds most closely to the eleventh rib or tenth rib, respectively, and passes anterior to the mid-axillary line in most subjects (Mirjalili et al 2012b) (see Fig. 59.11C). The spleen extends from a point about 5 cm to the left of the posterior midline at the level of the eleventh thoracic spine and extends about 3 cm anterior to the mid-axillary line. Its normal size approximates roughly to that of the individual's clenched fist.

## RETROPERITONEAL VISCERA

The surface projections of the retroperitoneal viscera are reasonably reliable but have limited clinical utility since most interventions and procedures are guided by medical imaging.

## Pancreas

The surface projection of the head of the pancreas lies within the duodenal curve on the right side of the second lumbar vertebra; the neck lies in the transpyloric plane, level with the L1/2 intervertebral disc; and the body passes obliquely up and to the left towards the spleen, lying slightly above the transpyloric plane, near the tail.

## Kidney

The right kidney usually lies, on average, 2 cm lower than the left, although, in $10 \%$ of cases, the left kidney sits lower than the right (Mirjalili et al 2012b). The vertebral limits of the left kidney are T12L3 or L4, while those for the right kidney are L1-L4 (overall range upper T11 to lower L5) (see Fig. 59.11C). The upper poles of both kidneys lie anterior to rib 12 , and they lie anterior to the rib 11 in $30 \%$ (left) and $10 \%$ (right) of subjects. In supine adults at end-tidal inspiration, the centre of the renal hilum usually lies at L1/2 or L2 on the left and at a slightly lower vertebral level on the right. It is important to note that both kidneys move vertically by a mean of about 2 cm during deep respiration and both can descend by several centimetres when moving from lying to standing (Schwartz et al 1994, Reiff et al 1999).

The length of the normal adult kidney, measured along its long axis, is approximately 11.5 cm in men and 11.0 cm in women (Hale et al 2010); the left kidney is a few millimetres longer than the right (Cheong et al 2007, Glodny et al 2009, Mirjalili et al 2012b). There is a small reduction in renal length beyond 50 years of age (Glodny et al 2009). Each kidney is approximately $5-6 \mathrm{~cm}$ wide. Both its longitudinal and transverse axes are slightly oblique, such that the upper pole of each kidney is nearer the midline and the hilum is more anterior than the lateral surface. The centre of the hilum is approximately $5-6 \mathrm{~cm}$ from the midline.

The lower pole of the normal right kidney may occasionally be felt in thin individuals by bimanual palpation via the renal angle on full inspiration.

## Ureter

The ureter descends on either side from approximately the level of the transpyloric plane, slightly lower on the right, about 5 cm from the midline. Each passes downwards just medial to the tips of the transverse processes of the lumbar vertebrae. In the pelvic cavity, each ureter curves medially to enter the base of the bladder.

## Abdominal aorta and branches

The abdominal aorta begins at the level of the body of the twelfth thoracic vertebra near the midline. It descends and bifurcates at
approximately L4 (range lower L3 to lower L5), usually just to the left of the midline and up to 3 cm caudal to the umbilicus (Mirjalili et al 2012b). The position of the aortic bifurcation is shifted slightly proximally with a greater degree of lumbar lordosis (Moussallem et al 2012). The pulsations of the aorta can be felt in a thin, supine individual by pressing firmly in the midline backwards on to the lower lumbar spine. An easily palpable aorta in an obese person should raise the suspicion of an aneurysm.

## Unpaired visceral arteries

The coeliac trunk arises from the aorta immediately after it enters the abdomen at T12; the superior mesenteric artery arises most commonly at L1, close to the transpyloric plane; and the inferior mesenteric artery usually arises at L3 (Mirjalili et al 2012b).

## Renal arteries

The renal arteries most commonly arise from between lower L1 and upper L2, with the lower border of L1 (approximately, the transpyloric plane) being most common on both sides (Mirjalili et al 2012b).

## Iliac arteries

The surface projection of the common iliac artery corresponds to the superior third of a broad line, which is slightly convex laterally, from the aortic bifurcation (see above) to a point midway between the anterior superior iliac spine and the pubic symphysis. The external iliac artery corresponds to the inferior two-thirds of this line.

## Inferior vena cava

The inferior vena cava most commonly forms at L5 in the transtubercular plane (range upper L4 to upper S1) approximately to the right of the midline (Mirjalili et al 2012b). The inferior vena cava leaves the abdomen by traversing the diaphragm at the level of the eleventh thoracic vertebra.

## PELVIS

The posterior superior iliac spines lie at the level of the second sacral segment (McGaugh et al 2007); some individuals have an overlying sacral dimple. This palpable bony landmark corresponds approximately to the termination of the dural sac (Senoglu et al 2013) and the middle of the sacroiliac joint. The second dorsal sacral foramina lies approximately $2-3 \mathrm{~cm}$ medial to the posterior superior iliac spine on each side at an angle of $45^{\circ}$ (McGrath and Stringer 2011). The latter is potentially useful when localizing the branches of the dorsal sacral rami in the treatment of refractory sacroiliac pain.

## Sciatic nerve

The sciatic nerve leaves the pelvis approximately one-third of the way along a line between the posterior superior iliac spine and the ischial tuberosity and enters the thigh approximately half way between the greater trochanter and ischial tuberosity (see Fig. 78.16) (Currin et al 2014).

Other surface landmarks for pelvic structures are described in Chapter 78.

## COMMON CLINICAL PROCEDURES

## Pneumoperitoneum for laparoscopy

A pneumoperitoneum is frequently established by accessing the peritoneal cavity just below the umbilicus. An incision through the linea alba
allows access to the peritoneum at a point where there is relatively little extraperitoneal fat. Additional working ports are inserted through the anterior abdominal wall, avoiding major vessels such as the inferior epigastric artery.

## Surgical incisions

Most surgical incisions are sited according to surgical imperatives rather than anatomical constraints. Access to the peritoneal cavity is gained by dividing or splitting muscles. Common approaches include the midline incision through the relatively avascular linea alba, the transverse suprapubic (Pfannenstiel) incision for pelvic procedures, and, in infants and children, the upper abdominal transverse incision. In recent years, progressively more abdominal surgery has been performed using laparoscopic procedures (minimally invasive or 'keyhole' surgery).

## Intestinal stomas (ileostomy, colostomy)

When possible, intestinal stomas are usually formed through transrectus incisions. A cruciate incision is made in the anterior rectus sheath and the muscle fibres are split, avoiding injury to the epigastric vessels. This incision offers the advantage that fibres of rectus abdominis support the stoma, providing a dynamic, contractile surround that tends to reduce the risk of herniation occurring around the stoma.

## Suprapubic catheterization

The urinary bladder may be accessed for short- or long-term catheterization through the anterior abdominal wall. As the bladder fills, the upper part of its dome comes to lie in the preperitoneal 'space' in the suprapubic region, where it can be relatively easily accessed by a midline transcutaneous puncture through the linea alba.

## Endoscopic surgery

Endoscopic surgery is a broad term that encompasses all types of surgery that are performed using flexible or rigid fibreoptic endoscopes inserted through natural body orifices or small surgical incisions. It overlaps with the field of minimally invasive surgery. The aim is to minimize or eliminate external incisions and hasten the patient's recovery, whilst providing optimum treatment of the pathology with an acceptably low risk of complications. In the abdomen and pelvis, therefore, it includes therapeutic procedures performed using an endoscope inserted via the mouth (gastroscope or duodenoscope), anus (proctoscope, sigmoidoscope or colonoscope), urethra (cystoscope or ureteroscope) or vagina, or via small surgical incisions in the anterior or posterior abdominal wall (laparoscope and other endoscopic systems).

A refinement of the technique is natural orifice transluminal endoscopic surgery, in which abdominal operations are performed using an endoscope inserted through a natural orifice (e.g. mouth, anus, urethra) and then through an incision in the viscus that has been entered (e.g. stomach, bladder, vagina). For example, pelvic and intra-abdominal contents can be accessed through the vagina via the recto-uterine pouch. Hysterectomy, oophorectomy, pelvic organ prolapse repair and incontinence surgery are commonly performed using transvaginal techniques. This approach avoids the morbidity of abdominal incision but there are risks of sciatic, femoral and common fibular nerve injury from prolonged surgery in the lithotomy position.

A further development of endoscopic minimally invasive surgery has been the introduction of robotically assisted surgery, which allows the surgeon to manipulate precision instruments from a console that is remote from the patient whilst viewing the operative field in three dimensions. The procedure is becoming increasingly common in prostatectomy.

# Development of the peritoneal cavity, gastrointestinal tract and its adnexae 

## POSTPHARYNGEAL FOREGUT

The primitive gut is divided by head- and tail-folding into three main compartments. The foregut extends from the buccopharyngeal membrane to its continuation into the central midgut region via the cranial intestinal portal. The midgut extends between the intestinal portals and, in the early embryo, is in wide communication with the yolk sac. The hindgut extends from the caudal intestinal portal to the cloacal membrane. The cranial end of the foregut, the embryonic pharynx, is intimately associated with head and neck development (Ch. 36). The portion of foregut that passes dorsal to the pericardial cavity gives rise to the respiratory diverticulum and oesophagus within the thorax (Chs 36 and 52). Caudal to the developing diaphragm, the enteric gut is conventionally subdivided into three embryological portions: fore-, mid- and hindgut. There are no corresponding fundamental morphological and cytological distinctions between the three parts (Fig. 60.1), and so the foregut produces a portion of the duodenum, as does the midgut, and the midgut similarly produces large intestine, as does the hindgut. The differences between the portions of the gut develop as a result of interactions between the three embryonic tissue layers that give rise to the gut: namely, the endodermal inner epithelium, the thick layer of splanchnopleuric mesenchyme, and the outer layer of proliferating splanchnopleuric coelomic epithelium.

The epithelial layer of the mucosa and connected ducts and glands are derived from the endodermal epithelium. The lamina propria and

Fig. 60.1 Major epithelial populations within the early embryo. The early gut tube is close to the notochord and neural tube dorsally. The splanchnopleuric layer of the intraembryonic coelomic epithelium is in contact with the foregut ventrally and laterally, with the midgut laterally, and the hindgut ventrally and laterally,
muscularis mucosa, the connective tissue of the submucosa, the muscularis externa and the external connective tissue are all derived from the splanchnopleuric mesenchyme. The outer peritoneal epithelium is derived from the splanchnopleuric coelomic epithelium.

Throughout the gut, blood vessels, lymphatics and lymph nodes develop from local populations of angiogenic mesenchyme. The nerves, which are distributed within the enteric and autonomic systems, are derived from the neural crest. There is a craniocaudal developmental gradient along the gut, in that the stomach and small intestine develop in advance of the colon.

Figure 60.1 shows the fundamental relationship of the intraembryonic coelom to the developing gut. Figure 60.2 shows the gut in a stage 12 embryo in relation to the other developing viscera, especially the heart and liver. Figure 60.3 shows the overall development of the gut from stages 13 to 17 . These diagrams should be compared.

All regions of the gut develop from epithelial-mesenchymal interactions that are dependent on the sequential expression of a range of basic and specific genes; on the regulation of the developmental clock, seen in all areas of development; and on endogenous regulatory mechanisms and local environmental influences (Lebenthal 1989). Although all these factors pertain to the whole range of developing tissues, local differences in any one of these factors along the length of the developing gut promote the differentiation of, for example, the gastric mucosa and hepatocytes; the rotation of the midgut; and the final disposition of the sessile portions of the fully formed gastrointestinal tract. The hedgehog (Hh) ligands, Shh, Ihh and Dhh are expressed in the developing gut: Shh and Ihh in the endodermal epithelium and Dhh in endothelial cells. These ligands bind to the Patched receptors (Ptch-1 and Ptch-2), which activate the transcription factor Gli3. Knockout of Shh and Ihh has been associated with oesophageal atresia, gut malrotation, decreased development of the muscularis propria, enteric neurone anomalies and imperforate anus (Kolterud et al 2009). The gut is functional prior to birth and able to interact with the extrauterine environment in preterm infants.

## OESOPHAGUS

The oesophagus can be distinguished from the stomach at stage 13 (embryo length 5 mm ). It elongates during successive stages and its absolute length increases more rapidly than the embryo as a whole. Cranially, it is invested by splanchnopleuric mesenchyme posterior to the developing trachea and, more caudally, between the developing lungs and pericardioperitoneal canals posterior to the pericardium. Caudal to the pericardium, the terminal, pregastric segment of the oesophagus has a short, thick, dorsal meso-oesophagus (from splanchnopleuric mesenchyme), while ventrally, it is enclosed in the cranial stratum of the septum transversum mesenchyme. Each of the above is continuous caudally with its respective primitive dorsal and ventral mesogastria. Thus, the oesophagus has only limited areas related to a primary coelomic epithelium. However, it is important to note the subsequent development of the para-oesophageal right and left pneumatoenteric recesses (see Fig. 60.7), the relation of the ventral aspect of the middle third of the oesophagus to the oblique sinus of the pericardium, and the relation of its lateral walls in the lower thorax to the mediastinal pleura. All the foregoing are secondary extensions from the primary coelom.

The oesophageal mucosa consists of two layers of cells by stage 15 (week 5), but the proliferation of the mucosa does not occlude the lumen at any time. The mucosa becomes ciliated at 10 weeks, and stratified squamous epithelium is present at the end of the fifth month; occasionally, patches of ciliated epithelium may be present at birth. Circular muscle can be seen at stage 15 but longitudinal muscle has not been identified until stage 21 . Neuroblasts can be demonstrated in the early stages; the myenteric plexuses have cholinesterase activity by

Fig. 60.2 A, The digestive tube of a human embryo at stage 12, with 29 paired somites, a crown to rump length of 3.4 mm and an estimated age of 27 days. (Pharyngeal development is followed further in Figure 36.18.) B, Reconstruction of a human embryo at the end of the fourth week. The alimentary canal and its outgrowths are shown in median section. The brain is shown in outline but the spinal cord has been omitted. The heart is shown in perspective, and the left horn of the sinus venosus is cut just medial to the entrance of the common cardinal vein (see Fig. 52.8A-B). The somites are indicated in outline.
9.5 weeks and ganglion cells are differentiated by 13 weeks. It has been suggested that the oesophagus is capable of peristalsis in the first trimester. Periodic fetal swallowing can be seen on ultrasound from 16 weeks. The volume of amniotic fluid ingested increases during the third trimester to more than $500 \mathrm{ml} /$ day. Oesophageal atresia is one of the more common obstructive conditions of the alimentary tract; it may be indicated by polyhydramnios. There is evidence of maturation of the lower oesophageal sphincter at 32 weeks, when, with the prevention of free gastro-oesophageal reflex, stomach size increases (Hitchcock et al 1992).

## Oesophagus at birth

At birth, the oesophagus extends $8-10 \mathrm{~cm}$ from the cricoid cartilage to the gastric cardiac orifice. It starts and ends one to two vertebrae, respectively, higher than in the adult, extending from between the fourth to the sixth cervical vertebra to the level of the ninth thoracic vertebra (see Fig. 14.7). Its average diameter is 5 mm and it possesses the constrictions seen in the adult. The narrowest constriction is at its junction with the pharynx, where the inferior pharyngeal constrictor muscle functions to constrict the lumen; this region may be easily traumatized with instruments or catheters. In the neonate, the mucosa may contain scattered areas of ciliated columnar epithelium but these disappear soon after birth. Peristalsis along the oesophagus and at the lower oesophageal sphincter is immature at birth and results in frequent regurgitation of food in the newborn period. The pressure at the lower oesophageal sphincter approaches that of an adult at 3-6 weeks of age.

## STOMACH

At the end of the fourth and beginning of the fifth weeks, the stomach can be recognized as a fusiform dilation cranial to the wide opening of the midgut into the yolk sac (see Figs 60.2 and 60.3). By the fifth week, this opening has narrowed into a tubular vitelline intestinal duct, which soon loses its connection with the digestive tube. At this time, the stomach is median in position and separated cranially from the pericardium by the septum transversum (see Fig. 60.5A), which extends caudally on to the cranial side of the vitelline intestinal duct and ventrally to the somatopleure. Dorsally, the stomach is related to the aorta and, reflecting the presence of the pleuroperitoneal canals on each side, is connected to the body wall by a short dorsal mesentery, the dorsal mesogastrium (see Figs 60.5B and 60.6). The latter is directly continu-
ous with the dorsal mesentery (mesenteron) of almost all of the remainder of the intestine, except its caudal short segment.

In human embryos of 10 mm (stages 15-16), the characteristic gastric curvatures are already recognizable. Growth is more active along the dorsal border of the viscus; its convexity markedly increases and the rudimentary fundus appears. Because of more rapid growth along the dorsal border, the pyloric end of the stomach turns ventrally and the concave lesser curvature becomes apparent (see Figs 60.3, 60.6). The stomach is now displaced to the left of the median plane and, apparently, becomes physically rotated, which means that its original right surface becomes dorsal and its left surface becomes ventral. Accordingly, the right vagus is distributed mainly to the dorsal, and the left vagus mainly to the ventral, surfaces of the stomach. The dorsal mesogastrium increases in depth and becomes folded on itself. The ventral mesogastrium becomes more coronal than sagittal. The pancreaticoenteric recess (see Fig. 60.7B(ii)), until this point usually described as a simple depression on the right side of the dorsal mesogastrium, becomes dorsal to the stomach and excavates downwards and to the left between the folded layers. It may now be termed the inferior recess of the bursa omentalis. Put simply, the stomach has undergone two 'rotations'. The first is $90^{\circ}$ clockwise, viewed from the cranial end; the second is $90^{\circ}$ clockwise, about an anteroposterior axis. The displacement, morphological changes and apparent 'rotation' of the stomach have been attributed variously to its own and surrounding differential growth changes; extension of the pancreaticoenteric recess with changes in its mesenchymal walls; and pressure, particularly that exerted by the rapidly growing liver.

## Mucosa

Mucosal and submucosal development can be seen in the eighth to ninth weeks. No villi form in the stomach, unlike in other regions of the gut; instead, glandular pits can be seen in the body and fundus. These develop in the pylorus and cardia by weeks 10 and 11, when parietal cells can be demonstrated. Although acid secretion has not been demonstrated in the fetal stomach before 32 weeks' gestation, preterm infants, from 26 weeks' gestation onwards, are able to secrete acid soon after birth. Intrinsic factor has been detected after 11 weeks. This increases from the fourteenth to the twenty-fifth week, at which time the pylorus, which contains more parietal cells than it does in the adult, also contains a relatively larger quantity of intrinsic factor. The significance of the early production of intrinsic factor and the late production of acid by the parietal cells is not known. Chief cells can be

Fig. 60.3 The shape of the endodermal epithelium of the gut at succeeding stages. The scale is constant, illustrating the enormous growth of the gut over a 13-day period. A, Stage 13. B, Stage 14. C, Stage 15. D, Stage 16. E, Stage 17. Note the separation of the respiratory diverticulum; the elongation of the foregut and expansion of the stomach; the formation of the hepatic and pancreatic diverticula; the lengthening of the midgut loop, which protrudes into the umbilical cord; and the separation of the cloaca into enteric and allantoic portions. (Modified from O'Rahilly and Müller. Developmental Stages in Human Embryos 1987 Carnegie Institution of Washington. Pub 637.)
identified after weeks 12-13, although they cannot be demonstrated to contain pepsinogen until term. Mucous neck cells actively produce mucus from week 16. Gastrin-producing cells have been demonstrated in the antrum between 19 and 20 weeks, and gastrin levels have been measured in cord blood and in the plasma at term. Cord serum contains gastrin levels 2-3 times higher than those in maternal serum.

## Muscularis

The stomach muscularis externa develops its circular layer at 8-9 weeks, when neural plexuses are developing in the body and fundus. The longitudinal muscle develops slightly later. Few studies note a time of appearance of the oblique layer. The pyloric musculature is thicker than the rest of the stomach; in general, the thickness of the total musculature of the stomach at term is reduced, compared to the adult.

## Serosa

The serosa of the stomach is derived from the splanchnopleuric coelomic epithelium. No part of this serosa undergoes absorption. The original left side of the gastric serosa faces the greater sac; the right side faces the lesser sac.

## Stomach at birth

The stomach exhibits fetal characteristics until just after birth, when the initiation of pulmonary ventilation, the reflexes of coughing and swallowing, and crying cause the ingestion of large amounts of air and liquid. Once postnatal swallowing has started, the stomach distends to four or five times its contracted state, and shifts its position in relation to the state of expansion and contraction of the other abdominal viscera, and to the position of the body. In the neonate, the anterior surface of the stomach is generally covered by the left lobe of the liver, which extends nearly as far as the spleen (see Fig. 14.6B). Only a small portion of the greater curvature of the stomach is visible anteriorly. The capacity of the stomach is $30-35 \mathrm{ml}$ in the full-term neonate, rising to 75 ml in the second week and 100 ml by the fourth week (adult capacity is, on average, 1000 ml ). The mucosa and submucosa are relatively thicker than in the adult; however, the muscularis is only moderately developed and peristalsis is not coordinated. At birth, gastric acid secretion is low, which means that gastric pH is high for the first 12 postnatal hours. It falls rapidly with the onset of gastric acid secretion, usually after the first feed. Acid secretion usually remains low for the first 10 days postnatally. Gastric emptying and transit times are delayed in the neonate.

## DUODENUM

The duodenum develops from the caudal part of the foregut and the cranial part of the midgut. A ventral mesoduodenum, which is continuous cranially with the ventral mesogastrium, is attached only to the foregut portion. Posteriorly, the duodenum has a thick dorsal mesoduodenum, which is continuous with the dorsal mesogastrium cranially and the dorsal mesentery of the midgut caudally. Anteriorly, the extreme caudal edge of the ventral mesentery of the foregut extends on to the short initial segment of the duodenum. The liver arises as a diverticulum from the ventral surface of the duodenum at the foregut-midgut junction, i.e. where the midgut is continuous with the yolk sac wall (the cranial intestinal portal). The ventral pancreatic bud also arises from this diverticulum. The dorsal pancreatic bud evaginates posteriorly into the dorsal mesoduodenum slightly more cranially than the hepatic diverticulum. The rotation, differential growth, and cavitations related to the developing stomach and omenta cause corresponding movements in the duodenum, which forms a loop directed to the right, with its original right side now adjacent to the posterior abdominal wall (see Fig. 60.6). This shift is compounded by the migration of the bile duct and ventral pancreatic duct around the duodenal wall. Their origin shifts until it reaches the medial wall of the second part of the fully formed duodenum; the bile duct passes posteriorly to the duodenum and travels in the free edge of the ventral duodenum and ventral mesogastrium. Local adherence and subsequent absorption of part of the duodenal serosa and the parietal peritoneum result in almost the whole of the duodenum, other than a short initial segment, becoming retroperitoneal (sessile).

Duodenal atresia is a developmental defect found in 1 in 5000 live births (Whittle 1999). It may be associated with an anular pancreas, which may compress the duodenum externally ( $20 \%$ of duodenal
atresia), or with anomalies of the bile duct. In $40-60 \%$ of cases, the atresia is complete and pancreatic tissue fills the lumen. The condition can be diagnosed on ultrasound examination, which reveals a typical double bubble appearance, caused by fluid enlarging the stomach and the proximal duodenum. Polyhydramnios is invariably present and often is the indication for the scan. Duodenal atresia commonly occurs with other developmental defects, e.g. cardiac and skeletal anomalies, and in Down's syndrome.

## DORSAL AND VENTRAL MESENTERIES OF THE FOREGUT

The epithelium of the stomach and duodenum does not rotate relative to its investing mesenchyme. The rotation includes the coelomic epithelial walls of the pericardioperitoneal canals, which are on each side of the stomach and duodenum and form its serosa, and the elongating dorsal mesogastrium or the much shorter dorsal mesoduodenum. A ventral mesogastrium can be seen when the distance between the stomach and liver increases. Whereas the dorsal mesogastrium takes origin from the posterior body wall in the midline, its connection to the greater curvature of the stomach, which lengthens as the stomach grows, becomes directed to the left as the stomach undergoes its first rotation. With the second rotation, a portion of the dorsal mesogastrium now faces caudally (see Fig. 60.6). The ventral mesogastrium remains as a double layer of coelomic epithelium, which encloses mesenchyme and forms the lesser omentum (see Fig. 60.7).

Movement of the stomach is associated with an extensive lengthening of the dorsal mesogastrium, which becomes the greater omentum; this now, from its posterior origin, droops caudally over the small intestine, then folds back anteriorly and ascends to the greater curvature of the stomach. The greater omentum is, therefore, composed of a fold containing, technically, four layers of peritoneum. The dorsal mesoduodenum, or suspensory ligament of the duodenum, is a much thicker structure, and it fixes the position of the duodenum when the rest of the midgut and its dorsal mesentery elongate and pass into the umbilical cord.

## SPECIAL GLANDS OF THE <br> POSTPHARYNGEAL FOREGUT

## Pancreas

The pancreas develops from two evaginations of the foregut that fuse to form a single organ. A dorsal pancreatic bud can be seen in stage 13 embryos as a thickening of the endodermal tube that proliferates into the dorsal mesogastrium (see Fig. 60.3; Fig. 60.4). A ventral pancreatic bud evaginates in close proximity to the liver primordium but cannot be clearly identified until stage 14, when it appears as an evagination of the bile duct itself. At stage 16 ( 5 weeks), differential growth of the wall of the duodenum results in movement of the ventral pancreatic bud and the bile duct to the right side and, ultimately, to a dorsal position. It is not clear whether there is a corresponding shift of mesenchyme during this rotation. However, the ventral pancreatic bud and the bile duct rotate from a position within the ventral mesogastrium (ventral mesoduodenum) to one in the dorsal mesogastrium (dorsal mesoduodenum), which is destined to become fixed on to the posterior abdominal wall. By stage 17, the ventral and dorsal pancreatic buds have fused, although the origin of the ventral bud from the bile duct is still obvious. Three-dimensional reconstruction of the ventral and dorsal pancreatic buds has confirmed that the dorsal pancreatic bud forms the anterior part of the head, the body and the tail of the pancreas, and the ventral pancreatic bud forms the posterior part of the head and the posterior part of the uncinate process. The ventral pancreatic bud does not form all of the uncinate process (Collins 2002a).

The developing pancreatic ducts usually fuse in such a way that most of the dorsal duct drains into the proximal part of the ventral duct (see Figs 60.3-60.4). The proximal portion of the dorsal duct usually persists as an accessory duct. The fusion of the ducts takes place late in development or in the postnatal period; $85 \%$ of infants have patent accessory ducts, as compared to $40 \%$ of adults. Fusion may not occur in $10 \%$ of individuals, in which case separate drainage into the duodenum is maintained: so-called pancreatic divisum (pancreas divisum). Failure of the ventral pancreatic diverticulum to migrate will result in an anular pancreas, which may constrict the duodenum locally.

The ventral pancreas does not always extend anterior to the superior mesenteric vein but remains related to its right lateral surface. Initially,

Fig. 60.4 Development of the pancreas in a human embryo. A, An early stage, 7.5 mm embryo: lateral view. B, A later stage, 14.5 mm embryo: ventral view.
the body of the pancreas extends into the dorsal mesoduodenum and then cranially into the dorsal mesogastrium. As the stomach rotates, this portion of the dorsal mesogastrium is directed to the left, forming the posterior wall of the lesser sac. The posterior layer of this portion of dorsal mesogastrium fuses with the parietal layer of the coelom wall (peritoneum), and the pancreas becomes mainly retroperitoneal (see Fig. 60.7C). The region of fusion of the dorsal mesogastrium does not extend so far left as to include the tail of the pancreas, which passes into the splenorenal (lienorenal) ligament. The anterior border of the pancreas later provides the main line of attachment for the posterior leaves of the greater omentum.

## Cellular development of the pancreas

The early specification of pancreatic endoderm involves the proximity of the notochord to the dorsal endoderm, which locally represses the expression of Shh transcription factor. Endoderm caudal to the pancreatic region does not respond to notochordal signals. The ventral pancreatic endoderm does not seem to undergo the same induction. Pancreatic mesenchyme is derived from two regions. The mesenchyme that surrounds the dorsal pancreatic bud proliferates from the splanchnopleuric coelomic epithelium of the medial walls of the pericardioperitoneal canals, whereas the ventral pancreatic bud is invested by septum transversum mesenchyme and by mesenchyme derived from the lower ventral walls of the pericardioperitoneal canals.

The primitive endodermal ductal epithelium provides the stem cell population for all the secretory cells of the pancreas. Initially, these endocrine cells are located in the duct walls or in buds developing from them; later, they accumulate in pancreatic islets. The remaining primitive duct cells will differentiate into definitive ductal cells. In the fetus, they develop microvilli and cilia but lack the lateral interdigitations seen in the adult. Branches of the main duct become interlobular
ductules, which terminate as blind-ending acini or as tubular, acinar elements.

The ductal branching pattern and acinar structure of the pancreas are determined by the pancreatic mesenchyme. This mesenchyme gives rise to connective tissue between the ducts, which, in the fetus, appears to be important in stimulating pancreatic proliferation and maintaining the relative proportions of acinar, $\alpha$ and $\beta$ cells during development. It also provides cell lines for smooth muscle within the pancreas. Angiogenic mesenchyme invades the developing gland to produce blood and lymphatic vessels.

The process of islet differentiation is divided into two phases (Collins 2002a). Phase I, characterized by proliferation of polyhormonal cells, occurs from weeks 9-15. Phase II, characterized by differentiation of monohormonal cells, is seen from week 16 onwards. The $\beta$ cells, producing insulin and amylin, differentiate first, followed by $\alpha$ cells, which produce glucagon. The $\delta$ cells, which produce somatostatin, are seen after 30 weeks. The dorsal bud gives rise mostly to $\alpha$ cells, and the ventral bud to most of the pancreatic polypeptide-producing cells. The $\beta$ cells develop from the duct epithelium throughout development and into the neonatal period. Later, in weeks $10-15$, some of the primitive ducts differentiate into acinar cells, in which zymogen granules or acinar cell markers can be detected at 12-16 weeks.

The pancreas in the neonate has all of the normal subdivisions of the adult. The head is proportionately large in the newborn and there is a smooth continuation between the body and the tail. The inferior border of the head of the pancreas is found at the level of the second lumbar vertebra. The body and tail pass cranially and to the left, and the tail is in contact with the spleen (see Fig. 14.6).

## Liver

The liver is one of the most precocious embryonic organs and is the main centre for haemopoiesis in the fetus. It develops from an endodermal evagination of the foregut and from septum transversum mesenchyme, which is derived from the proliferating coelomic epithelium in the protocardiac region. The development of the liver is intimately related to the development of the heart. The vitelline veins, succeeded by the umbilical veins passing to the sinus venosus, are disrupted by the enlarging septum transversum to form a hepatic plexus, the forerunner of the hepatic sinusoids. (See Collins (2002b) for a detailed account of hepatic development.)

## Early liver development

As the head fold and early intraembryonic coelom form, the ventral parietal wall of the pericardial cavity gives rise to populations of cells termed precardiac or cardiac mesenchyme. Hepatic endoderm is induced to proliferate by this mesenchyme, although all portions of the early heart tube, truncus arteriosus, atria, ventricle, both endocardium and myocardium, have hepatic induction potency that is tissue-specific but not species-specific. As the heart and foregut become separated by the accumulation of the cardiac mesenchyme, the mesenchyme itself is renamed septum transversum. It is seen as a ventral mass, caudal to the heart, which passes dorsally on each side of the developing gut to join the mesenchyme proliferating from the walls of the pericardioperitoneal canals. The majority of the cells within the septum transversum are destined to become hepatic mesenchyme. For details of the molecular signalling of early hepatic development, see Lemaigre (2009).

In the stage 11 embryo, the location of the hepatic endoderm has been identified at the superior boundary of the rostral intestinal portal. By stage 12, the hepatic endodermal primordium is directed ventrally and begins to proliferate as a diverticulum. There are two parts: a caudal part, which will produce the cystic duct and gallbladder; and a cranial part, which forms the liver biliary system (see Fig. 60.3; Fig. 60.5A). The cells start to express liver-specific molecular markers and glycogen storage.

Around the cranial portion of the hepatic diverticulum, the basal lamina is progressively disrupted and individual epithelial cells migrate into the surrounding septum transversum mesenchyme. The previously smooth contour of the diverticulum merges into columnar extensions of endoderm, the epithelial trabeculae, which stimulate the hepatic mesenchymal cells to form blood islands and endothelium. The advance of the endodermal epithelial cells promotes the conversion of progressively more hepatic mesenchyme into endothelium and blood cells, and only a little remains to form the scanty liver capsule and interlobular connective tissue. This invasion by the hepatic epithelium is completed in stage 13, when it approaches the caudal surface of the pericardial cavity, and is separated from it only by a thin lamina of mesenchyme that will give rise to part of the diaphragm.

During this early phase of development, the liver is far more highly vascularized than the rest of the gut. The hepatic capillary plexus is connected bilaterally with the right and left vitelline veins. Dorsolaterally, they empty by multiple channels into enlarged hepatocardiac channels, which lead to the right and left horns of the sinus venosus (see Fig. 60.9); usually, the channel on the right side is most developed. Both left and right channels bulge into the pericardioperitoneal canals, forming sites for the exchange of fluid from the coelom into the vascular channels. The growth of the hepatic tissue in these regions is sometimes referred to as the left and right horns of the liver.

The liver remains proportionately large during its development and constitutes a sizeable organ dorsal to the heart at stage 14, then more caudally placed by stage 16 . By this stage, hepatic ducts can be seen separating the hepatic epithelium from the extrahepatic biliary system, but, even at stage 17, the ducts do not penetrate far into the liver.

## Maturation of the liver

At 3 months' gestation, the liver almost fills the abdominal cavity and its left lobe is nearly as large as its right. When the haemopoietic activity of the liver is assumed by the spleen and bone marrow, the left lobe undergoes some degeneration and becomes smaller than the right. The liver remains relatively larger than in the adult throughout the remainder of gestation. In the neonate, it constitutes $4 \%$ of the body weight, compared to $2.5-3.5 \%$ in adults. It is in contact with the greater part of the diaphragm and extends below the costal margin anteriorly, and, in some cases, to within 1 cm of the iliac crest posteriorly. The left lobe covers much of the anterior surface of the stomach and constitutes nearly one-third of the liver (see Fig. 14.6). Although its haemopoietic functions cease before birth, its enzymatic and synthetic functions are not completely mature at birth. Hepatocytes remain a heterogeneous population with different gene expressions and metabolic functions within different hepatic lobule locations. This metabolic zonation becomes fully established after birth (Lemaigre 2009).

## Development of intrahepatic biliary ducts

The development of the intrahepatic biliary ducts follows the branching pattern of the portal vein radicles (Collins 2002b). The cranial hepatic

Fig. 60.5 Early development of the liver and the supra-umbilical peritoneal cavities. A, The hepatic endodermal primordium proliferates ventrally into the septum transversum mesenchyme. The endodermal cells forming the hepatic trabeculae will become hepatocytes; the septum transversum mesenchymal cells will become the endothelium of the liver sinusoids and early blood cells. The developing lung buds can be seen expanding into the pericardioperitoneal cavities. B, The septum transversum mesenchyme and the stomach become enclosed by the right and left pericardioperitoneal canals (shown on transverse section). The apposition of the medial pericardioperitoneal walls forms the dorsal and ventral mesogastria. The proximity of the lung buds to the developing stomach can be seen. The pleural and supra-umbilical peritoneal cavities are transiently, and bilaterally, symmetrical above the umbilicus. C, The lower border of the ventral mesogastrium denotes the connection between the supra-umbilical peritoneal cavities: pleuroperitoneal canals, which can be identified by the position of the ventral pancreatic bud and common bile duct. The white arrows in B and C indicate the direction of movement of the dorsal and ventral mesogastria.
diverticulum gives rise to the liver hepatocytes, the intrahepatic large bile ducts (right and left hepatic ducts, segmental ducts, area ducts and their first branches) and the small bile ducts (septal bile ducts, interlobular ducts and bile ductules). The portal and hepatic veins arise together from the vitelline veins. Early in development, the accumulation of mesenchyme around these veins is similar, whereas later mesenchyme increases around the portal veins. This is a prerequisite for bile duct development. Primitive hepatocytes surround the portal vein branches and associated mesenchyme, and form a sleeve of cells termed the ductal plate. Individual cells of the ductal plate are termed cholangiocytes. Local hepatoblasts that are adjacent to the cholangiocytes arrange themselves to delineate a bile duct lumen and then also switch to a cholangiocyte lineage (Lemaigre 2009). As the bile ducts develop, angiogenic mesenchymal cells form blood vessels that connect to the hepatic artery from 10 weeks. Thus, the portal triads are patterned by the portal vein radicles, which initially induce bile duct formation and then artery formation. The development of the biliary system extends from the hilum to the periphery. Anomalies of the biliary tree are associated with abnormalities of the branching pattern of the portal vein. The developing bile ducts remain patent throughout development; the solid stage of ductal development previously promulgated has been refuted. Atresia of the extrahepatic bile ducts has been noted, often in association with extrahepatic atresia. The cause of this condition is not clear; inflammatory process may be involved, although some cases have features of ductal plate malformation (Howard 2002).

## Development of extrahepatic biliary ducts

The caudal part of the hepatic endodermal diverticulum forms the extrahepatic biliary system, the common hepatic duct, gallbladder, cystic duct and common bile duct.

The bile duct, which originated from the ventral wall of the foregut (now duodenum), migrates with the ventral pancreatic bud, first to the right and then dorsomedially into the dorsal mesoduodenum. The right and left hepatic ducts arise from the cranial end of the common hepatic duct from 12 weeks' gestation.

Atresia of the extrahepatic bile ducts in neonates occurs alone or in conjunction with a range of other anomalies, including situs inversus,
malrotation, polysplenia and cardiac defects. In such cases, the intrahepatic bile ducts have a mature tubular shape but also show features of ductal plate malformation.

In the neonate, the gallbladder has a smaller peritoneal surface than in the adult, and its fundus often does not extend to the liver margin. It is generally embedded in the liver and, in some cases, may be covered by bands of liver. After the second year, the gallbladder assumes the relative size it has in the adult.

## MIDGUT

The midgut forms the third and fourth parts of the duodenum, jejunum, ileum and two-thirds of the way along the transverse colon; its development produces most of the small, and a portion of the large, intestine In embryos of stages 10 and 11, it extends from the cranial to the caudal intestinal portals and communicates directly with the yolk sac over its entire length. Although it has a dorsal wall, the lateral walls have not yet formed at these stages. By stage 12, the connection with the yolk sac has narrowed, such that the midgut has ventral walls cranially and caudally. This connection is reduced to a yolk stalk containing the vitellointestinal duct during stage 13, at which time the yolk sac appears as a sphere in front of the embryo. Posterior to the midgut, the splanchnopleuric coelomic epithelia converge, forming the dorsal mesentery. Ventrolaterally, the intraembryonic coelom is in wide communication with the extraembryonic coelom. At stage 14 , the midgut has increased in length more than the axial length of the embryonic body and, with elongation of the dorsal mesentery, it bulges ventrally, deviating from the median plane. For all these stages, see Figure 60.3.

## PRIMARY INTESTINAL (OR MIDGUT) LOOP

The midgut loop can first be seen at stage 15, when a bulge - the caecal bud - can be discerned on the lower limb of the loop, caudal to the yolk stalk (which arises from the apex or summit of the loop). Later, the original proximal limb of the loop moves to the right and the distal limb to the left (see Fig. 60.3C). The longest portion of the dorsal mesentery is at the level of the yolk stalk; there is less relative lengthening near the caudal end of the duodenum or the cranial half of the colon. The midgut extends into the umbilical coelom, having already rotated through an angle of $90^{\circ}$ (anticlockwise, viewed from the ventral aspect). This relative position is approximately maintained so long as the protrusion persists, during which time the proximal limb that forms the small intestine elongates greatly. It becomes coiled, and its adjacent mesentery adopts a pleated appearance. The origin of the root of the mesentery is initially both median and vertical, while, at its intestinal attachment, it is elongated like a ruffle and folded along a horizontal zone. The mesenteric sheet and its contained vessels have spiralled through $90^{\circ}$. The distal, colic, part of the loop elongates less rapidly and has no tendency to become coiled. By the time the fetus has attained a length of 40 mm ( 10 weeks), the peritoneal cavity has enlarged and the relative size of the liver and mesonephros is much less. The re-entry of the gut occurs rapidly and in a particular sequence, during which it continues the process of rotation. The proximal loop returns first, with the jejunum mainly on the left and the ileum mainly on the right of the subhepatic abdominal cavity. As they re-enter the abdominal cavity, the coils of jejunum and ileum slide inwards over the right aspect of the descending mesocolon, and so displace the descending colon to the left. The transverse colon passes superiorly to the origin of the root of the mesentery (Fig. 60.6). The caecum is the last to re-enter and, at first, lies on coils of ileum on the right. Later development of the colon leads to its elongation and to the establishment of the hepatic and splenic flexures. A timetable for intestinal rotation in staged human embryos is given by Kim et al (2003).

## Anomalies of midgut rotation

If the midgut loop fails to return to the abdominal cavity at the appropriate time, a range of ventral defects can result. Failure of obliteration of the vitellointestinal duct connecting the midgut to the yolk sac results in Meckel's diverticulum. This may present as a short segment of vitelline duct attached to the original ventral side of the ileum; it may remain attached to the umbilicus as a fistula; or it may remain as a ligamentous attachment to the umbilicus.

An umbilical hernia occurs when loops of gut protrude into a widened umbilical cord at term. The degree of protuberance may increase when the infant cries, which raises the intra-abdominal pres-
sure; these hernias usually resolve without treatment. Exomphalos is a ventral wall defect with midline herniation of the intra-abdominal contents into the base of the umbilical cord. Herniated viscera are covered by the peritoneum internally and amnion externally. The omphalocele so formed ranges in size from a large umbilical hernia to a very large mass containing most of the visceral organs. Even after the exomphalos has been repaired, these babies will still have a deficient anterior abdominal wall.

Gastroschisis is a para-umbilical defect of the anterior abdominal wall associated with evisceration of the abdominal organs. The organs are not enclosed in membranes; thus, gastroschisis can be detected by prenatal ultrasonography and differentiated from exomphalos (see Fig. 14.5B). Gastroschisis is thought to result from periumbilical ischaemia, caused by vascular compromise of either the umbilical vein or arteries. The incidence of this condition appears to be increasing, especially in babies born to young women less than 20 years old (Whittle 1999, Ionescu et al 2014).

Congenital volvulus arises if the midgut loop does not rotate appropriately. A number of types of this condition are identified. Left-sided colon occurs if the midgut loop has not rotated at all; mixed rotation results in the caecum lying inferior to the pylorus; and failure of appropriate attachment of the peritoneum may result in the small intestine being attached at only two points on the posterior abdominal wall. All of these arrangements lead to a risk of volvulus, which may result in necrosis of the gut.

The position and configuration of the duodenal loop are of particular importance in children. The normal duodenal loop has a U-shaped configuration. The suspensory ligament of the duodenum (ligament of Treitz) is usually found to the left of the body of the first or second lumbar vertebral body after normal gut rotation; any other position of this ligament may indicate some degree of gut malrotation. On barium studies, the duodenojejunal flexure should, thus, lie to the left of the upper lumbar spine at the level of the pylorus.

If the caecum has remained in the right upper quadrant, it may become fixed in that position by peritoneal attachments passing to the right, the so-called Ladd's bands. These may compress the underlying duodenum and give rise to duodenal stenosis. The high positioning of the caecum close to the duodenal jejunal flexure - in some cases, in the midline - is associated with later development of volvulus.

The identification of intestinal malrotation can be made by X-ray investigation. However, ultrasonography has the advantage of showing the position of the superior mesenteric vein and artery. The vein should lie to the right of the artery. Most cases of volvulus will show inversion of this normal relationship but malrotation can occur with apparently normally related vessels, particularly in malrotation with bowel obstruction due to Ladd's bands and not volvulus.

## UMBILICAL CORD

During the period when the midgut loop protrudes into the umbilical coelom, the edges of the ventral body wall are becoming relatively closer, forming a more discrete root for the umbilical cord. Somatic mesenchyme, which will form the ventral body wall musculature, migrates into the somatopleuric mesenchyme and passes ventrally towards the midline. The umbilical cord forms all of the ventral body wall between the pericardial bulge and the developing external genitalia. It encloses a portion of the extraembryonic coelom, the umbilical coelom, into which midgut loop protrudes. When the midgut loop is abruptly returned to the abdominal cavity, the more recognizable umbilical cord forms. The vitellointestinal duct and vessels involute. The cranial end of the allantois becomes thinned and its lumen partially obliterated, and it forms the urachus. The mesenchymal core of the umbilical cord is derived by coalescence from somatopleuric amniotic mesenchyme, splanchnopleuric vitellointestinal (yolk sac) mesenchyme and splanchnopleuric allantoic (connecting stalk) mesenchyme. These various layers become fused and are gradually transformed into the viscid, mucoid, connective tissue (Wharton's jelly) that characterizes the more mature cord. The changes in the circulatory system result in a large, cranially orientated, left umbilical vein (the right umbilical vein regresses), and two spirally disposed umbilical arteries (see Fig. 52.19).

## MATURATION OF THE SMALL INTESTINE

## Mucosa

The exact timing of the cellular morphogenesis of the gut is difficult to establish, especially as it undergoes a proximodistal gradient in

Fig. 60.6 The major developmental sequences of the subdiaphragmatic embryonic and fetal guts, together with their associated major glands, peritoneum and mesenteries: left anterolateral aspect. A-F, The development sequence spans 1.5 months to the perinatal period. A-B, The top white arrows show the relative movements of the dorsal and ventral mesogastria that result in the longitudinal rotation of the stomach and limited entry to the lesser sac (see also Fig. 60.5). C-D, The lower white arrows associated with the midgut indicate the relative movements and rotation of the midgut loop within the umbilical coelom, and as it returns to the abdominal cavity.

Continued
maturation. Developmental differences between parts of the small intestine or colon have not yet been correlated with age. The endodermal cells of the small intestine proliferate and form a layer some three to four cells thick, with mitotic figures throughout. From 7 weeks, blunt projections of the endoderm have begun to form in the duodenum and proximal jejunum; these are the developing villi, which increase in length until, in the duodenum, the lumen becomes difficult to discern. The concept of occlusion of the lumen and recanalization, which is described in many accounts of development, does not match the cytodifferentiation that occurs in the gut epithelia. Thus, it is no longer thought that there is secondary recanalization of the gut lumen. By 9 weeks, the duodenum, jejunum and proximal ileum have villi, and the remaining distal portion of ileum develops villi by 11 weeks. The villi are covered by a simple epithelium. Primitive crypts, epithelial downgrowths into the mesenchyme between the villi, appear between 10 and 12 weeks and similarly follow a craniocaudal progression. Brun-
ner's glands are present in the duodenum from 15 weeks and the muscularis mucosa can be seen in the small intestine from 18 weeks.

Whereas mitotic figures are initially seen throughout the endodermal layer of the small intestine prior to villus formation, by 10-12 weeks they are limited to the intervillous regions and the developing crypts. It is believed that an 'adult' turnover of cells may exist when rounded-up cells can be observed at the villus tips, in position for exfoliation. The absorptive enterocytes have microvilli at their apical borders before 9 weeks. An apical tubular system appears at this time, and is composed of deep invaginations of the apical plasma membrane and membrane-bound vesicles and tubules; many lysosomal elements (meconium corpuscles) appear in the apical cytoplasm. These latter features are more developed in the ileum than jejunum, are most prominent at 16 weeks, and diminish by 21 weeks. There are abundant deposits of glycogen in the fetal epithelial cells, and it has been suggested that, prior to the appearance of hepatic glycogen, the intestinal

Fig. 60.6, cont'd The major developmental sequences of the subdiaphragmatic embryonic and fetal guts, together with their associated major glands, peritoneum and mesenteries: left anterolateral aspect. E-F, The lower white arrows associated with the midgut indicate the relative movements and rotation of the midgut loop within the umbilical coelom, and as it returns to the abdominal cavity. G-H, The approximate disposition in the adult abdomen of the gut $(\mathbf{G})$ and the mesenteric roots, showing their lines of attachment and principal contained vessels $(\mathbf{H})$.
epithelium serves as a major glycogen store. Goblet cells are present in small numbers by 8 weeks, Paneth's cells differentiate at the base of the crypts in weeks 11 and 12, and enteroendocrine cells appear between weeks 9 and 11. M cells (membrane or microfold cells) are present from 14 weeks.

Intestinal subepithelial myofibroblasts (ISEMFs) have been described within the villus cores and adjacent to the intervillous space at the base of the crypts from week 21 . They are arranged as a syncytium between the epithelium and the muscularis mucosae, where they contribute to the extracellular matrix. They demonstrate $\alpha$-smooth muscle actin (SMA) expression (McLin et al 2009). It is not clear whether these cells derive from splanchnopleuric mesenchyme fibroblasts, smooth muscle precursors or neural crest. They migrate from the crypts to the villous axis in a manner similar to enterocytes.

Meconium can be detected in the lumen of the intestine by the sixteenth week. It is derived from swallowed amniotic fluid, which
contains vernix and cellular debris, salivary, biliary, pancreatic and intestinal secretions, and sloughed enterocytes. As the mixture passes along the gut, water and solutes are removed and cellular debris and proteins concentrated. Meconium contains enzymes from the pancreas and proximal intestine in higher concentrations in preterm than in full-term babies.

## Muscularis layer

The muscularis layer is derived from the splanchnopleuric mesenchyme, as it is in other parts of the gut. Smooth muscle myoblasts are characterized by expression of $\alpha$-SMA. Longitudinal muscle can be seen from 12 weeks. At 26-30 weeks, the gut shows contractions without regular periodicity; from 30-33 weeks, repetitive groups of regular contractions have been seen in preterm neonates.

## Serosa

The small intestine possesses only a dorsal mesentery. The movement of the root of this dorsal mesentery, and the massive lengthening of its enteric border in order to match the longitudinal growth of the gut tube, reflect the spiralizing of the midgut loop in the umbilical coelom.

## Small intestine at birth

The radial patterning of the small intestine is completed before birth, with differentiation of the crypt-villous axis. Specification of the space between villi, crypt depth and villous length is a dynamic process dependent on the establishment of the intestinal microbiota. In the neonate, the small intestine forms an oval-shaped mass with its greater diameter transversely orientated in the abdomen, rather than vertically as in the adult. The mass of the small intestine inferior to the umbilicus is compressed by the urinary bladder, which is anterior at this point. The small intestine is $300-350 \mathrm{~cm}$ long at birth and its width, when empty, is $1-1.5 \mathrm{~cm}$. The ratio between the length of the small and the length of the large intestine at birth is similar to the adult ratio. The mucosa and submucosa are fairly well developed and villi are present throughout the small intestine; however, some epithelial differentiation is incomplete. The muscularis is very thin, particularly the longitudinal layer, and there is little elastic tissue in the wall. There are few or no circular folds in the small intestine, and the jejunum and ileum have little fat in their mesentery.

## PRIMITIVE HINDGUT

Just as the foregut has an extensive ventral endodermal diverticulum, which contributes to a system separate from the gut, so, too, the hindgut has a ventral diverticulum - the allantois - destined for a different system. However, unlike the respiratory diverticulum of the foregut, the allantois is formed very early in development, prior even to formation of the embryonic endoderm and tail-folding. With the reorganization of the caudal region of the embryo at stage 10, part of the allantois is drawn into the body cavity. The early embryonic hindgut thus consists of a dorsal tubular region extending from the caudal intestinal portal to the cloacal membrane, and a ventral blind-ending allantois extending from the cloacal region into the connecting stalk. The slightly dilated cavity, lined by endoderm, that cranially receives the enteric hindgut proper and the root of the allantoenteric diverticulum is termed the endodermal cloaca. It is closed ventrally by the cloacal membrane (endoderm opposed to proctodeal ectoderm), and it also has, transiently, a small recess of endoderm in the root of the tail, the postanal gut. As elsewhere, the hindgut, allantois and endodermal cloaca are encased in splanchnopleuric mesenchyme. Proliferation of the mesenchyme and endoderm in the angle of the junction of hindgut and allantois produces a urorectal septum (see Fig. 72.4B). Continued proliferation of the urorectal septum and elongation of the endodermal structures thrust the endodermal epithelium towards the cloacal membrane, with which it fuses centrally, separating the presumptive rectum and upper anal canal (dorsally) from the presumptive urinary bladder and urogenital sinus (ventrally) (see Fig. 72.4C). The cloacal membrane is thus divided into anal (dorsal) and urogenital (ventral) membranes. The nodal centre of division is the site of the future perineal body, the functional centre of the perineum.

## ENTERIC HINDGUT

The development of the large intestine, whether derived from mid- or hindgut, seems to be similar. The proximal end of the colon can be first identified at stage 15, when an enlargement of a local portion of gut on the caudal limb of the midgut loop defines the developing caecum. An evagination of the distal portion of the caecum forms the vermiform appendix at stage 17 (see Fig. 60.3E). Apart from the embryonic studies of Streeter (1942), there is little information about the development of the large intestine in humans. The early endodermal lining of the colon appears stratified, and mitoses occur throughout the layers. A series of longitudinal folds arise initially at the rectum and caecum, and later in the regions of colon between these two points. The folds segment into villi with new villi forming between. The developing mucosa invaginates into the underlying mesenchyme between the villi to form glands that increase in number by splitting longitudinally from the base upwards. The villi gradually diminish in size and are absent by the time of birth.

## MATURATION OF THE LARGE INTESTINE

The similarity of development of the small and large intestines is further mirrored in their cytological differentiation. Fetal gut, from 11 weeks, shows dipeptidase activity in the colon as well as in the small intestine. Throughout preterm development, meconium corpuscles are seen in the colon and in the small intestine; they are believed to be the phagocytosed remains of neighbouring cells that have died as a result of programmed cell death.

There is little direct evidence of colonic function in the human fetus and neonate. However, the specific results of mammalian studies are being correlated to human studies where possible. A number of distinct and important differences between the function of adult and fetal colon have been reported.

## Mucosa

The absorption of glucose and amino acids does not take place through the colonic mucosa in adult life, but there is evidence of direct absorption of these nutrients during development. At birth, the normal cycle of bile acids is not mature. In the adult, bile is secreted by the liver, stored in the gallbladder and then secreted into the intestine, where it is absorbed by the jejunum and ileum. In the fetus and neonate, the transport of bile acids by an active process from the ileum does not occur, and so bile salts pass on into the colon. In the adult, the presence of bile salts in the colon stimulates the secretion of water and electrolytes, which results in diarrhoeal syndrome; however, the fetal and neonatal colon seems protected from this effect. The colon is not considered a site of significant nutrient absorption in the adult, and yet neonates are unable to assimilate the full lactose load of a normal breast feed from the small intestine and a large proportion of it may be absorbed from the colon. Thus, it appears that the colon fulfils a slightly different role in the preterm and neonatal period, conserving nutrient absorption and minimizing fluid loss until the neonate has adjusted to extrauterine life, oral feeding and the establishment of the symbiotic bacterial flora.

## Muscularis

The muscularis is present and functioning by the eighth week, when peristaltic waves have been observed. The specific orientation of the longitudinal muscle layer into taeniae coli occurs in the eleventh to twelfth weeks, when haustra appear. The enteric nerves are present in Meissner's and Auerbach's plexuses at 8 and 12 weeks, respectively; there is a craniocaudal migration of neurones into the gut wall. A normal distribution of ganglion cells has been noted in preterm babies of 24 weeks, although there is a region devoid of ganglia just above the anal valves. Anomalous migration of neural crest cells to the gut may give rise to Hirschsprung's disease (see below). Puborectalis appears in 20-30 mm embryos, following opening of the anal membrane.

## Serosa

The development of the serosa of the intestine is considered with the development of the peritoneal cavity (see below)

## Colon at birth

In the neonate, the colon is typically 66 cm long and averages 1 cm in width. The caecum is relatively smaller than in the adult; it tapers into the vermiform appendix. The ascending colon is shorter in the neonate, reflecting the shorter lumbar region. The transverse colon is relatively long, whereas the descending colon is short, but twice the length of the ascending colon (see Fig. 14.6B). The sigmoid colon may be as long as the transverse colon; it often touches the inferior part of the anterior body wall on the left and, in about half of neonates, part of the sigmoid colon lies in the right iliac fossa. The muscularis, including the taeniae coli, is poorly developed in the colon, as it is in the small intestine. Appendices, epiploicae and haustra are not present, which gives a smooth external appearance to the colon. Haustra appear within the first 6 months. The rectum is relatively long; its junction with the anal canal forms at nearly a right angle.

## ANAL CANAL

Mesenchymal proliferation occurs around the rim of the ectodermal aspect of the anal membrane, which thus comes to lie at the bottom
of a depression, the proctodeum (see Fig. 72.7E). With the absorption and disappearance of the anal membrane, the anorectum communicates with the exterior. The lower part of the anal canal is formed from the proctodeal ectoderm and underlying mesenchyme, but its upper part is lined by endoderm. The line of union corresponds with the edges of the anal valves in the adult. The dual origin of the anal canal is reflected in its innervation: the endodermal portion is innervated by autonomic nerves, and the ectodermal proctodeum is innervated by spinal nerves.

In the fourth and fifth weeks, a small part of the hindgut, the postanal gut, projects caudally beyond the anal membrane (see Fig. 60.3B); it usually disappears before the end of the fifth week.

Imperforate anus is a term used to describe many different anorectal anomalies. The most common is anal agenesis, which is found in almost half of all cases of imperforate anus. The condition is usually associated with a fistula, which opens into the vulva (females) or into the urethra (males). It is more rare for the anal membrane to fail to perforate. The condition cannot reliably be diagnosed prenatally by ultrasound diagnosis, and it may be confused with Hirschsprung's disease (see below) and colonic atresia. The prognosis is good for low lesions of the anal canal. The principal concern, in all cases, is the degree of bowel control, urinary control and, in some cases, sexual function, which is compromised by the condition. Anorectal anomalies may be indicators of other anomalies, e.g. those forming the 'VATER' syndrome (vertebral, anal, tracheo-oesophageal and renal anomalies).

## ENTERIC NERVOUS SYSTEM

Enteric neurones are derived from cranial (vagal) neural crest cells at somite levels 1-7 and from 28 onwards (see Fig. 17.19 and p. 251) After neurulation, the crest cells begin their ventral migration and invade the gut via the dorsal mesentery (see Fig. 17.11). Glial cells associated with the gut have been identified as arising from similar levels. It is thought that the vagal and sacral neural crest cells have intrinsic differences in their ability to colonize the gut. The local splanchnopleuric mesenchyme patterns the crest cells, such that those that enter the gut layers attain an enteric fate, whereas those that remain outside the gut become committed as parasympathetic postganglionic neurones. The enteric neurones also migrate to the glands of the gut, e.g. the pancreas. Migrating vagal neural crest cells reach the midgut by week 5 and the entire length of the gut is colonized by week 7. Maturation of the myenteric plexus follows a craniocaudal progression. The submucosal plexus arises from centripetally migrating cells from the myenteric plexus 2-3 days later (Burns et al 2009). Interstitial cells of Cajal, which derive from splanchnopleuric mesenchyme, do not mature in a craniocaudal progression. They are seen around the myenteric ganglia along the entire gut from weeks 12-14 (Burns et al 2009). There is evidence that mucosal enteric glial cells, which move into the mucosa after birth, interact with the colonizing intestinal flora, suggesting a microbiota-driven homeostatic mechanism for gut function (Kabouridis et al 2015).

## Hirschsprung's disease

Hirschsprung's disease (commonly called megacolon) is usually characterized by an aganglionic portion of gut that does not display peristalsis, and a dilated segment of structurally normal colon proximal to this site Histologically, there is either an absence or a reduction in the number of ganglia and postganglionic neurones in the myenteric plexus of the affected segment of gut; postganglionic innervation of the muscle layers is also often defective. It is believed that the condition is caused by a failure of neural crest cells to colonize the gut wall appropriately (Gershon 2010). A variable length of large intestine may be affected; the lower and mid-rectum are the most common sites but, in severe cases, the rectum, sigmoid, descending and even proximal colon can be aganglionic. Occasionally, aganglionosis affects only a very short length of rectum proximal to the anorectal junction and the degree of functional obstruction is minimal; in these cases of 'ultra-short-segment Hirschsprung's disease', clinical anomalies arise later in life. Infants with Hirschsprung's disease show delay in the passage of meconium, constipation, vomiting and abdominal distension.

## GUT-ASSOCIATED LYMPHOID TISSUE

Individual lymphocytes appear in the lamina propria of the gut from approximately week 12 of development, and lymphoid aggregates Peyer's patches - have been noted between 15 and 20 weeks; it is not
clear whether these cells migrate in from distant sources or differentiate from the investing mesenchyme. The endodermal epithelium overlying the lymphoid aggregates is often distorted into a dome shape. The cells within the dome are a mixed population of enterocytes, endocrine cells, goblet cells and $M$ cells. $M$ cells are specialized to provide a mechanism for the transport of microorganisms and intact macromolecules across the epithelium to the intraepithelial space and lamina propria. They have been observed in the fetus by 17 weeks; it is believed that they are formed by a specialized epithelial-mesenchymal interaction of the endoderm and underlying lymphoid-type mesenchyme.

There are similarly specialized epithelial cells between the enterocytes. Intraepithelial leukocytes typically account for $15 \%$ of the epithelial cells of the gut in the adult. They have been observed at 11 weeks, with a distribution of 2-3 intraepithelial leukocytes per 100 gut epithelial cells. Both T and B lymphocytes have been described in the developing gut wall. For an account of the development of the immune cells of the gut, consult Butzner and Befus (1989). The neonatal gut becomes colonized by a range of bacterial flora; some of these exist in a symbiotic relationship with their host, and some of them may be considered pathogenic.

## ULTRASOUND ANTENATAL IMAGING OF THE FETAL GUT

The abdominal circumference, routinely estimated at 20 weeks, is calculated from the anteroposterior diameter and the transverse abdominal diameter perpendicular to it, taken at the widest part of the abdomen. The section usually includes one entire rib and the stomach cavity (termed stomach bubble) and can be confirmed on the left side of the body (see Fig 14.4G). Anteriorly, the connection of the umbilical cord can be confirmed (see Fig 14.4H). Anomalies of the anterior body wall, exomphalos and gastroschisis, are readily detected. In exomphalos, a mass of peritoneal organs herniate through the base of the umbilical ring; in gastroschisis, loops of small intestine and colon float free in the amniotic fluid (see Fig. 14.5B) (Ionescu 2014).

## FUNCTIONAL MATURITY OF THE GUT AT BIRTH

The postnatal maturation of the gut is dependent on the establishment of an intestinal microbiota, which, in turn, is affected by gestational age, mode of delivery, type of feeding and any medical interventions. In cases of chorioamnionitis, preterm infants ingest bacterial products from the amniotic fluid; it has been suggested that this may be associated with preterm labour (Neu and Mai 2012). Normal, term, vaginal delivery establishes the initial colonization of the neonatal gut with maternal vaginal and intestinal flora. Two-way interactions between enteric microbes in a biofilm within the luminal glycocalyx of enterocytes modify intestinal permeability, increase T and B lymphocyte numbers within the mucosal lamina propria and mesenteric lymph nodes, and stimulate postnatal immune development (Vaarala 2012, Wynn and Neu 2012, Martin et al 2012, Patel et al 2012, Gritz and Bhandari 2015). Delivery by caesarean section results in the establishment of skin microbiota, different intestinal microbes and low microbiota diversity. Failure to develop an appropriate, dynamic, microbiota is thought to be associated with allergic and inflammatory conditions in later life (Wynn and Neu 2012). (For further reading, see Neu (2012), Bäckhed et al (2015), Rodríguez et al (2015).)

The onset of feeding also contributes to gut maturity. Breast milk is a source of epidermal growth factor, which promotes postnatal mucosal development and helps mucosal repair. Breast feeding also affects the production of immunoglobulin A (IgA) in the gut mucosa (Vaarala 2012). Undernutrition leads to villous atrophy and, in the preterm infant, parenteral nutrition is associated with changes in intestinal structure and function that may lead to increased intestinal permeability (Martin et al 2012). Antibiotic therapy within the neonatal period can lead to changes in, and the establishment of, the normal intestinal microbiota (Martin et al 2012)

The first passage of faeces of the newborn is termed meconium. This is a dark, sticky, viscid substance formed from the passage of amniotic fluid, sloughed mucosal cells, digestive enzymes and bile salts along the fetal gut. Meconium becomes increasingly solid as gestation advances but does not usually pass out of the fetal body while in utero. Fetal distress produced by anoxia may induce the premature defecation of meconium into the amniotic fluid, with the risk of its inhalation. At birth, the colon contains $60-200 \mathrm{~g}$ of meconium. The majority of neonates defecate within the first 24 hours after birth. Delayed passage of stool beyond this time is associated with Hirschsprung's disease (see
above) or imperforate anus. The normal passage of meconium continues for the first 2 or 3 days after birth, and is followed by a transition to faecal stools by day 7 .

## PERITONEAL CAVITY

The early development of the intraembryonic coelom, which gives rise to the peritoneal cavity, is described on page 185. Figure 12.2 shows a scheme of the shape of the early peritoneal cavity and indicates the mesenchymal populations derived from its epithelial walls. Initially, the peritoneal cavity associated with the lower end of the foregut has separate right and left components: the pleuroperitoneal canals (see Fig. 60.1). At the level of the midgut, the pleuroperitoneal canals join a confluent cavity surrounding the developing gut, which transitorily is in communication with the extraembryonic coelom.

The description of the development of the peritoneal cavity that follows pertains to changes that occur as a consequence of the differential growth of the gut.

## PERITONEUM

Peritoneum develops from a specific portion of the intraembryonic coelomic walls. Initially, the intraembryonic coelomic epithelium is a pseudostratified germinal layer from which cellular progeny with different fates arise in specific sites and at specific developmental times. The portion that will give rise to the peritoneum is derived from the lower portion of the pericardioperitoneal canals and the somatopleure and splanchnopleure associated with the lower foregut, midgut and upper portions of the hindgut (see Figs 12.2, 60.1).

The proliferative splanchnopleuric epithelium produces cell populations for the mucosa and muscularis of the gut, and also for the lamina propria and epithelium of the visceral peritoneum (the serosa of the gut wall). The somatopleuric epithelium gives rise to the lamina propria and epithelium of the parietal peritoneum. The visceral and parietal peritoneal layers constitute a mesothelium, which denotes their origin from the intraembryonic mesoderm of the coelomic wall.

As the gut grows, splanchnic mesenchyme accumulates around the endodermal epithelium and the whole unit generally moves ventrally. There is a concomitant enlargement of the caudal ends of the developing pericardioperitoneal (pleuroperitoneal) canals and developing peritoneal cavity. The medial walls of the intraembryonic coelom move closer and there is a relative decrease in the mesenchyme between them. The regions where the medial portions of the intraembryonic coelom come together are termed mesenteries. They are composed of two layers of peritoneum with intervening mesenchyme and contain the neurovascular structures that pass to and from the gut. At the caudal ends of the pleuroperitoneal canals, the gut has both ventral and dorsal mesenteries, whereas, caudal to this, there is only a dorsal mesentery (see Fig. 60.6; Fig. 60.7).

The mesenteries attached to the gut lengthen to permit large movements or rotations of the gut tube. Later, when part or the whole of the mesentery lies against the parietal peritoneum, their apposed surfaces fuse and are absorbed, i.e. they become sessile. Only those viscera developed in direct apposition to one of the primary coelomic regions, or a secondary extension of the latter, retain a partial or almost complete visceral serous cover. Thus, the original line of reflection of mesenteries becomes altered, or, in some cases, the organ may become retroperitoneal. These mechanisms are significant throughout the subdiaphragmatic gut, but are predominant in the small and large intestine. All serous membranes may vary their thickness, lines of reflection, disposition, 'space' enclosed and their channels of communication, by a process of areal and thickness growth on one aspect, combined with cavitation (leading to expanding embryonic recess formation) on the other.

Although all of the gut tube and its derived glands are associated with mesenteries formed as described above, the nomenclature for some portions of the gut and glands is different. Thus, the mesenteries of the stomach are called omenta and the reflections of peritoneum around the liver, which develop from a confluence of splanchnopleuric, somatopleuric and septum transversum-derived portions, are called ligaments.

The movements of the developing viscera within the peritoneal cavity occur with associated movements of the mesothelia that surround them. The descriptions of peritoneal cavity development that follow are thus describing a sequence of changes that affect a complex space and its boundaries.

## Mesenteries of the developing gut

The cervicothoracic oesophagus develops between the pericardioperitoneal canals. It is encased in prevertebral, retrotracheal and retrocardiac mesenchyme. As the pericardioperitoneal canals expand with the developing lung buds, and the diaphragm forms immediately below them; the oesophagus, at this level, has no true dorsal or ventral mesentery. At superior and intermediate thoracic levels, parts of the lateral aspects of the oesophagus are closely related to the secondary, mediastinal, parietal pleura. In the lower thorax, the oesophagus inclines ventrally anterior to the descending thoracic aorta. The dorsocaudally sloping midline diaphragm between oesophageal and aortic orifices may be homologized with part of a dorsal meso-oesophagus, and is used in that context in descriptions of diaphragmatic development. A ventral midline diaphragmatic strip may also be considered to be a derivative of a ventral meso-oesophagus; however, this region is more usually thought of as septum transversum.

The alimentary tube, from the diaphragm to the start of the rectum, initially possesses a sagittal dorsal mesentery. Its line of continuity with the dorsal parietal peritoneum (i.e. its 'root' or 'line of reflection') is, initially, also midline.

The abdominal foregut, from the diaphragm to the future hepatopancreatic duodenal papilla, also has a ventral mesentery. This extends from the ventrolateral margins of the abdominal oesophagus and as yet 'unrotated' primitive stomach and proximal duodenum, cranially to the future diaphragm and anteriorly to the ventral abdominal wall (to the level of the cranial rim of the umbilicus). Caudally, between umbilicus and duodenum, it presents a crescentic free border.

The midgut and hindgut have no ventral mesentery; thus, the pleural and supra-umbilical peritoneal cavities are, initially and transiently, bilaterally symmetrical above the umbilicus. Below the umbilicus, the peritoneal cavity is freely continuous across the midline ventral to the gut (see Fig. 60.5A).

## Foregut mesenteries

The ventral and dorsal foregut mesenteries are relatively large compared with the slender endodermal tubes they encase; they are composed of mesenchyme sandwiched between two layers of splanchnopleuric coelomic epithelium. A complex series of recesses develop in the splanchnopleuric mesenchyme and become confluent. As a result of foregut rotation, differential growth of the stomach, liver, pancreas and spleen, and the completion of the diaphragm, the territories of the greater sac and lesser sac (omental bursa) are delimited, and the mesenteric complexes of these organs (omenta and 'ligaments') are defined (see Figs 60.6-60.7).

## Consequences of rotation of the stomach

A number of processes occur concurrently, which, conceptually, can be visualized as the movement of the right pleuroperitoneal canal to a position posterior to the stomach, such that its communication with the remainder of the peritoneal cavity is reduced. These processes include the differential growth of the walls of the stomach, the formation and specific local extension of the omenta (dorsal and ventral mesogastria), and the growth of the liver and, particularly, of the vessels and ducts that enter and leave the liver. These developments permit stomach expansion both anteriorly and posteriorly when food is ingested, and free movement of peristalsis. The right pleuroperitoneal canal forms a discrete region of the peritoneal cavity, the lesser sac, and the remaining left pleuroperitoneal canal and the remainder of the peritoneal cavity form the greater sac. The entrance to the original right pleuroperitoneal canal (lesser sac) becomes reduced in size. It is called the epiploic foramen, foramen of Winslow, or the aditus of the omental bursa (bursa omentalis).

## Early stages of lesser sac development

The lesser sac is first indicated by the appearance of multiple clefts in the para-oesophageal mesenchyme on both left and right aspects of the oesophagus. Although they may become confluent, the left clefts are transitory and soon atrophy. The right clefts merge to form the right pneumatoenteric recess that extends from the oesophageal end of the lesser curvature of the stomach as far as the caudal aspect of the right lung bud. At its gastric end, it communicates with the general peritoneal cavity and lies ventrolateral to the gut; more rostrally it lies directly lateral to the oesophagus. It is not, as commonly stated, a simple progressive excavation of the right side of the dorsal

C(ii)

Fig. 60.7 A-C, Stages of development of the subdiaphragmatic foregut and the right and left pericardioperitoneal/pleuroperitoneal canals, with particular reference to the terminal oesophagus, stomach, duodenum, spleen, the lesser sac of the peritoneum and the omenta, seen in semicoronal section (left column) and transverse section at the levels indicated by the arrows (right column). D-E, The lesser sac and dorsal and ventral mesogastria.
mesogastrium. The right pneumatoenteric recess undergoes further extension, subdivision and modification (see Fig. 60.7 A(i), B(i)). From its caudal end, a second process of cleft and cavity formation occurs, which produces the hepatoenteric recess. This thins and expands the splanchnopleure between the liver and the stomach and proximal duodenum, and reaches the diaphragm (see Fig. 60.7A(i), $\mathrm{C}(\mathrm{i})$ ). The resulting, structurally bilaminar, mesenteric sheet is the lesser omentum. It is derived, cranially to caudally, from the small
meso-oesophagus; the much larger ventral mesogastrium, and the most caudal free border, is from the ventral mesoduodenum. As differential growth of the duodenum occurs, the biliary duct is repositioned and most of the duodenum becomes sessile. The duodenal attachment of the free border and a continuous neighbouring strip of the lesser omentum become confined to the upper border of a short segment of its superior part. The contrasting growth and positioning of its attached viscera cause the free border to change gradually from the
horizontal to the vertical. It carries the bile duct, portal vein and hepatic artery, and its hepatic end is reflected around the porta hepatis. An alternative name for this part of the lesser omentum is the hepatoduodenal ligament; it forms the anterior wall of the epiploic foramen. The floor of the foramen is the initial segment of the superior part of the duodenum, its posterior wall is the peritoneum covering the immediately subhepatic part of the inferior vena cava, and its roof the peritonealized caudate process of the liver. The major part of the lesser omentum from the lesser gastric curvature passes in an approximately coronal plane to reach the floor of the increasingly deep groove for the ductus venosus on the hepatic dorsum; this part is sometimes called the hepatogastric ligament.

## Ligaments of the liver

The liver is precociously large during development because of its early role in haemopoiesis. Thus, the liver mass projects into the abdominal cavity with equal growth on the two sides of the peritoneal cavity. The ligaments associated with the liver develop from the ventral mesogastrium - which passes from the foregut to the ventral abdominal wall, down to the cranial rim of the intestinal portal - and from the reflections of peritoneum from the liver to the diaphragm.

The medial portions of the germinative coelomic epithelial walls, containing splanchnopleuric mesenchyme, septum transversum mesenchyme and developing liver, constitute the early ventral mesogastrium (see Fig. 60.5). The mesenchyme between these layers is continuous superiorly with the septum transversum mesenchyme of the diaphragm. The coelomic epithelial layers of the ventral mesogastrium almost touch anterior and posterior to the liver, and are separated by a slender lamina of mesenchyme. They form the falciform ligament and the lesser omentum, respectively, and where they are in contact with the liver directly, they form visceral peritoneum (see Fig. 60.7D).

When the diaphragm is formed above the liver, local cavities coalesce and open into the general coelomic cavity as extensions of the greater (and lesser) sacs. In this way, almost all the ventrosuperior, visceral and some of the posterior aspects of the liver become peritonealized. The process of extending the greater sac continues over the right lobe and stops when the future superior and inferior layers of the coronary ligament and the right triangular ligament are defined. Those, plus a medial boundary provided by an extension of the lesser sac, enclose the 'bare area' of the liver, where loose areolar tissue of septum transversum origin persists. Later in development, when the haemopoietic function of the liver declines, the left lobe becomes relatively smaller than the right; this, presumably, accounts for the smaller size of the left triangular ligament.

Where the superior layers of the coronary and left triangular ligaments meet, they continue as a (bilaminar) ventral mesentery attached to the ventrosuperior aspects of the liver. Its somewhat arched umbilicohepatic free caudal border carries the left umbilical vein. As the ventral body wall develops, this falciform ligament, which initially attaches to the early cranial intestinal portal, is drawn to the diminishing cranial rim of the umbilicus. It may be considered the final ventral part of the ventral mesogastrium, although its free border has a ventral mesoduodenal origin. Its passage to the ventral body wall becomes increasingly oblique, curved and falciform (sickle-shaped) as the umbilicus becomes more defined.

In the early embryo, the connection between one pericardioperitoneal canal and the other was directly across the ventral surface of the cranial midgut, immediately caudal to the developing primitive ventral mesogastrium. By stage 14, the passage from one side of the falciform ligament to the other necessitates passing below the greatly enlarged liver, or the curved lower edge of the falciform ligament, or the lesser omentum. The position of the falciform ligament is of clinical interest in the neonate in diagnosing pneumoperitoneum because it is silhouetted by air on abdominal X-rays.

## Caval fold

The caval fold is a linear eminence, with divergent cranial and caudal ends, which passes from the upper abdominal to the lower thoracic region and protrudes from the dorsal wall of the pleuroperitoneal canal. Cranially, it becomes continuous, lateromedially, with the root of the pulmonary anlage and pleural coelom, the uppermost portion of the septum transversum mesenchyme, and the retrocardiac mediastinal mesenchyme. Caudally, it forms an arch with dorsal and ventral horns. The dorsal horn merges with the primitive dorsal mesentery and the mesonephric ridge and associated gonad and suprarenal (adrenal) gland. The ventral horn is confluent with the dorsal surface of the septal mesenchyme.

Thus, the caval fold is a zone where intestinal, mesenteric, intermediate, hepatic, pericardial, pulmonary and mediastinal mesenchymes
meet and blend. It provides a mesenchymal route for the upper abdominal, transdiaphragmatic and transpericardial parts of the inferior vena cava, and it is also prominent in the development of parts of the liver, lesser sac of peritoneum, and certain mesenteries. The left fold regresses whereas the right fold enlarges rapidly (see Fig. 60.7A).

The pneumatoenteric recess continues to expand to the right into the substance of the caval fold. It stops near the left margin of the hepatic part of the inferior vena cava, which remains extraperitoneal and crosses the base of the now roughly triangular bare area of the liver and this new expanded line of reflection. With closure of the pleuroperitoneal canals, the rostral part of the right pneumatoenteric recess is sequestered by the diaphragm but often persists as a small serous sac in the right pulmonary ligament. The remaining caval fold mesenchyme to the left of the inferior vena cava - which forms the right wall of the upper part of the lesser sac - becomes completely invaded by embryonic hepatic tissue and is transformed into the caudate lobe of the liver. This smooth, vertically elongated, mass projects into the cavity of the lesser sac; both its posterior, and much of its anterior, surfaces become peritonealized as a result of the increasing depth of the groove for the ductus venosus and the attachment of the lesser omentum to its floor.

## Later stages of lesser sac development

The lower (inferior) part of the lesser sac can be first seen in embryos of $8-9 \mathrm{~mm}$ crown-rump length, and the early pneumatoenteric and hepatoenteric recesses are well established. Progressive differential gastric growth produces an elliptical transverse sectional profile, with a right-sided lesser curvature, which corresponds to the original ventral border of the gastric tube. The lesser omental gastric part of the ventral mesogastrium remains attached to this border. The greater curvature of the stomach is a new, rapidly expanding, region; its convex profile projects mainly to the left, but also cranially and caudally (see Fig. $60.7 \mathrm{~A}(\mathrm{i}), \mathrm{B}(\mathrm{i}), \mathrm{C}(\mathrm{i})$ ). The original dorsal border of the gastric tube now traverses the dorsal aspect of the expanding rudiment, curving along a line near the lesser curvature. The primitive dorsal mesogastrium is transiently attached to it, and blends with the thick layer of compound gastric mesenchyme clothing the posterior aspect and greater curvature of the miniature stomach. Because of its thickness, the mesenchyme projects cranially, caudally and, particularly, to the left, beyond the 'new' greater curvature of the endodermal lining of the stomach.

The processes already described in relation to the ventral mesenteries now supervene. Multiple clefts appear at various loci in the mesenchyme, and there are local mesenchyme to epithelial transitions. The groups of clefts rapidly coalesce to form transiently isolated closed spaces, which soon join with each other and with the preformed upper part of the lesser sac; the newly formed epithelia join the coelomic epithelium. In sequence, the initial loci occur in the compound posterior gastric mesenchyme nearer the lesser curvature and along its zone of blending with the primitive dorsal mesogastrium; in the dorsal mesoduodenum; and independently, in the caudal rim, where greater curvature mesenchyme and dorsal mesogastrium blend. As these cavities become confluent and their 'reniform' expansion follows, matches and then exceeds that of the gastric greater curvature, there are several major sequelae. The primitive dorsal mesogastrium increases in area by intrinsic growth, and, as cavitation proceeds, by incorporating substantial contributions from the dorsal lamella separated by cleavage of the posterior gastric mesenchyme; it is now called the secondary dorsal mesogastrium (see Fig. 60.7A(ii)). The gastric attachment of the secondary dorsal mesogastrium changes progressively. It may be regarded as a set of somewhat spiral lines, longitudinally disposed, that move with time to the left, from near the lesser curvature, towards and finally reaching the definitive greater curvature. The parietal mesogastrial and (cleaving) mesoduodenal attachment remains in the dorsal midline for a time, but it later undergoes profound changes. With the confluence of the cavities that collectively form the lower part of the lesser sac, its communication with the upper part (which corresponds to the lesser gastric curvature and right and left gastropancreatic folds) becomes better defined. Ventral to the lower part of the cavity, post-cleavage splanchnopleure covers the posteroinferior surface of the stomach and a short proximal segment of the duodenum. This ventral wall is continued beyond the greater curvature and duodenum as the splanchnopleuric strip of visceral attachment of the secondary dorsal mesogastrium and mesoduodenum. The radial width of the strip is relatively short cranially (gastric fundus) and gradually increases along the descending left part of the greater curvature. It is longest throughout the remaining perimeter of the greater curvature as far as the duodenum; this prominent part shows continued marginal (caudoventral and lateral) growth
with extended internal cavitation (its walls constitute the expanding greater omentum; see Fig. 60.6H). The margins of the cavity of the inferior part of the lesser sac are limited by the reflexed edges of the ventrally placed strata derived from the secondary dorsal mesogastrium just described. These converge to form the splanchnopleuric dorsal wall, which is initially 'free' throughout, except at its midline dorsal root. At roughly mid-gastric levels, the pancreatic rudiment grows obliquely encased in this dorsal wall; its tail ultimately reaches the left limit of the lesser sac at the level of the junction between gastric fundus and body (see Fig. 60.7C(ii)).

## Greater omentum

The greater omentum continues to grow, both laterally and, particularly, caudoventrally. It covers and is closely applied to the transverse mesocolon, transverse colon and inframesocolic and infracolic coils of small intestine (see Fig. 60.6D-G). At this stage, the quadrilaminar nature of the dependent part of the greater omentum is most easily appreciated. 'Simple' mesenteries are bilaminar: they possess two mesothelial surfaces derived from splanchnopleuric coelomic epithelium, which enclose a connective tissue core derived from splanchnopleuric mesenchyme. In the greater omentum, the gastric serosa covering its posteroinferior surface (single mesothelium) and the anterosuperior serosa (single mesothelium) converge to meet at the greater curvature and initial segment of the duodenum. The resulting bilaminar mesentery continues caudoventrally as the 'descending' stratum of the omentum. This, on reaching the omental margins, is reflexed and now passes craniodorsally to its parietal root as the 'ascending' posterior bilaminar stratum. The two bilaminar strata are, initially, in fairly close contact caudally, but are separated by a fine, fluid-containing, cleft-like extension of the lower part of the lesser sac. The posterior mesothelium of the posterior stratum makes equally close contact with the anterosuperior surface of the transverse colon, starting at the taenia omentalis, and with its transverse mesocolon.

## Maturation of the lesser sac

At this stage, and subsequently, it is convenient to designate the lower part of the lesser sac as consisting of three subregions: retrogastric, perigastric and greater omental (Fig. 60.7C(ii)). The names are selfexplanatory but their confines are all modified by various factors. Two phenomena are particularly prominent: namely, gastric 'descent' relative to the liver, and fusion of peritoneal layers with altered lines of reflection, adhesion of surfaces and loss of parts of cavities.

After the third month, hepatic growth, particularly of the left lobe, diminishes and the whole organ recedes into the upper abdomen. Meanwhile, the stomach elongates and some descent occurs, despite its relatively fixed cranial and caudal ends. This produces the angular flexure of the stomach, which persists postnatally. The concavity of the lesser curvature is now directed more precisely to the right; the lesser omentum is more exactly coronal and its free border vertical. Ventral to the liver, the free border of the falciform ligament passes steeply craniodorsally from umbilicus to liver (see disposition in the neonate in Figs 14.6-14.7). The mesenchymal dorsal wall of the lower part of the lesser sac, which is crossed obliquely by the growing pancreas, has, up to this point, remained free and retained its original dorsal midline root. Substantial areas now fuse with adjacent peritonealized surfaces of retroperitoneal viscera, the parietes, or another mesenteric sheet or fold. Where sheets fuse, there is a variable loss of apposed mesothelia and some continuity of their mesenchymal cores, but they remain surgically separable and no vascular anastomosis develops across the interzone. Above the pancreas, the posterior secondary dorsomesogastrial wall of the sac becomes closely applied to the peritoneum covering the posterior abdominal wall and its sessile organs, the diaphragm, much of the left suprarenal gland, the ventromedial part of the upper pole of the left kidney, the initial part of the abdominal aorta, the coeliac trunk and its branches, and other vessels, nerves and lymphatics. Their peritoneal surfaces fuse. However, albeit with some tissue loss, a single mesothelium remains covering these structures, intercalated as a new secondary dorsal wall for this part of the lesser sac.

The pancreas grows from the duodenal loop, penetrating the substance of the dorsal mesoduodenum and secondary dorsal mesogastrium; their mesenchymes and mesothelia initially clothe its whole surface, except where peritoneal lines of reflection exist. Its posterior peritoneum becomes closely applied to that covering all the posterior abdominal wall structures it crosses (the inferior vena cava, abdominal aorta, splenic vein, superior mesenteric vessels, inferior mesenteric
vein, portal vein, left renal vessels, the caudal pole of the left suprarenal gland, a broad ventral band on the left kidney and various muscles). The intervening peritoneal mesothelia fuse and atrophy, and the mesenchymal cores form fascial sheaths and septa. The pancreas is now sessile. The peritoneum covering the upper left part of its head, neck and the anterosuperior part of its body forms the central part of the dorsal wall of the lesser sac. The pancreatic tail remains peritonealized by a persisting part of the secondary dorsal mesogastrium as it curves from the ventral aspect of the left kidney towards the hilum of the spleen. The infracolic parts of the pancreas are covered with greater sac peritoneum. In the greater omental subregion of the lower part of the lesser sac, two contrasting forms of mesenteric adhesion occur. The posterior 'returning' bilaminar stratum of the omentum undergoes partial fusion with the peritoneum of the transverse colon at the taenia omentalis and with its mesocolon. The layers remain surgically separable; no anastomosis occurs between omental and colic vessels.

The original dorsal midline attachment to the parietes of the foregut dorsal mesentery is profoundly altered during the development of the lesser sac and its associated viscera. However, despite the extensive areas of fusion, virtually the whole of the gastric greater curvature (other than a small suboesophageal area) and its topographical continuation (the inferior border of the first $2-3 \mathrm{~cm}$ of the duodenum) retain true mesenteric derivatives of the secondary dorsal mesogastrium and its continuation, the dorsal mesoduodenum. Although regional names are used to assist identification and description, it is important to emphasize that they are all merely subregions of one continuous sheet.

The upper (oesophagophrenic) part of the lesser omentum arches across the diaphragm. As this bilaminar mesentery approaches the oesophageal hiatus, its laminae diverge, skirting the margins of the hiatus. They then descend for a limited distance and with variable inclination, to enclose reciprocally shaped areas on the dorsum of the gastric fundus and diaphragm. The area may be roughly triangular to quadrangular; it contains areolar tissue and constitutes the bare area of the stomach or, when large, the left extraperitoneal space. Its right lower angle is the base of the left gastropancreatic fold, and its left lower angle reconstitutes the bilaminar mesentery. The root of the latter arches downwards and to the left across the diaphragm and suprarenal gland, and gives the gastrophrenic ligament to the gastric fundus. It continues to arch across the ventral surface of the upper part of the left kidney, and its layers part to receive the pancreatic tail; they initially extend to the hilum of the spleen as the splenorenal ligament (see Figs 60.6C, 60.7D). The left half of this bilaminar 'ligament' provides an almost complete peritoneal tunic for the spleen. It then reunites with its fellow at the opposite rim of the splenic hilum, and continues to the next part of the gastric greater curvature as the gastrosplenic ligament. The remaining part (perhaps two-thirds) of the gastric greater curvature and its short duodenal extension provide attachment for the anterior, 'descending', bilaminar stratum of the greater omentum. Its returning, posterior, bilaminar stratum continues to its parietal root (which extends from the inferior limit assigned to the splenorenal ligament), and curves caudally and to the right along the anterior border of the body of the pancreas, immediately cranial to the line of attachment of the transverse mesocolon. Crossing the neck of the pancreas, the same curve is followed for a few centimetres on to its head; the omental root then sharply recurves cranially and to the left, to reach the inferior border of the duodenum. Thus, it reaches that part of the lesser sac provided by cleavage of the dorsal mesoduodenum from the greater sac. It enters the epiploic foramen, traverses the epiploic canal between the caudate hepatic process and proximal duodenum, then crosses the right gastropancreatic fold, and descends behind the proximal duodenum to enter the right marginal strip enclosed by the greater omentum. The definitive origins of the peritoneum from the posterior abdominal wall are shown in the adult in Figures 63.1, 68.5, 63.6B.

## Peritoneum associated with the mid- and hindgut

It is convenient to consider the mesenteries of the small and large intestine after rotation and the principal growth patterns have been achieved, and the developing pancreas is becoming retroperitoneal.

## Small intestine

Most of the duodenal loop encircles the head of the pancreas and is retroperitoneal. The peritoneum principally covers its ventral and
convex aspects. Areas not covered are a short initial segment of the superior (first) part, which is more completely peritonealized because it gives attachment to the right margins of the greater and lesser omenta; the sites where the transverse colon is closely apposed to the descending (second) part, or where the latter is crossed by the root of the transverse mesocolon; and the sites where the mesentery crosses the transverse (third) part, and descends across the ascending (fourth) part from its upper extremity at the duodenojejunal flexure. These regions are illustrated in the adult in Figure 63.2. In addition, one or more of up to six different duodenal recesses may develop (p. 1108).

From a mesenteric standpoint, the succeeding small intestine, from the duodenojejunal flexure to the ileocaecal junction, undergoes less modification of its embryonic form than other gut regions. Its early dorsal mesentery is a continuous, single (but structurally bilaminar) sheet, with a midline parietal attachment (line of reflection, or 'root'). The attachment of the root becomes an oblique narrow band from the left aspect of the second lumbar vertebra to the cranial aspect of the right sacroiliac joint (see Figs 60.6H, 63.2).

## Ascending colon

The caecum and vermiform appendix arise as a diverticulum from the antimesenteric border of the caudal limb of the midgut loop; consequently, the caecum does not possess a primitive mesocaecum. These regions of the gut undergo long periods of growth, often asymmetrical, and their final positions, dimensions and general topography show considerable variation. The vermiform appendix is almost wholly clothed with visceral peritoneum, derived from the diverging layers of its rather diminutive mesoappendix. The latter should perhaps be regarded as a direct derivative of the primitive dorsal mesentery, and perhaps a similar status for the vascular fold of the caecum should be considered.

The colonic gut retains its primitive dorsal mesentery, the mesocolon, until the differential growth, rotation and circumabdominal displacement of this part of the gut tube near completion. Its original root is still vertical in the dorsal midline, although the mesocolon diverges from it widely as an incomplete, flattened pyramid, to reach its colonic border at the future taenia mesocolica. During the fourth and fifth months, substantial areas of the primitive mesocolon adhere to, then fuse with, the parietal peritoneum. In this way, some colonic segments become sessile while others have a shorter mesocolon with an often profoundly altered parietal line of attachment. The mesocolon of the transverse and sigmoid segments normally persists, while the ascending colon, right (hepatic) flexure and descending colon become sessile; the ascending or descending, or both, colonic segments may also retain a mesocolon, which varies from a localized 'fold' to a complete mesocolon. When sessile, the ventral, medial and lateral aspects of the ascending or descending colon are clothed with peritoneum, and the protrusion of the viscus produces medial and lateral peritoneal paracolic gutters on each side. This form of apposition to underlying structures (zygosis) proceeds from the ascending colon to include the right colic (hepatic) flexure; from there, it continues anteroinferiorly to the left, so involving the right-sided initial segment of the transverse colon.

## Transverse colon

The right extremity of the transverse colon is sessile, and is separated by fibroareolar tissue from the anterior aspect of the descending (second) part of the duodenum and the corresponding aspect of most of the head of the pancreas. The remainder of the transverse colon, up to and including the left (splenic) colic flexure, is almost completely peritonealized by the diverging layers of the transverse mesocolon. The root of the latter reaches the neck and whole extent of the anterior border of the body of the pancreas. The long axis of the definitive pancreas lies obliquely. The splenic colonic flexure is considerably more rostral than the hepatic flexure and, consequently, the root of the mesocolon curves obliquely upwards as it crosses the upper abdomen from right to left. As it expands, the posteroinferior wall of the greater omental part of the lesser sac gradually covers, and becomes closely applied to, the transverse mesocolon and its contained colon, finally projecting beyond the latter. Craniocaudal adherence now occurs between the omental wall and the pericolonic and mesocolonic layers.

## Descending colon

The left colic flexure receives much of its peritoneal covering from the left extremity of the transverse mesocolon. It is also often connected to the parietal peritoneum of the diaphragm over the tenth and
eleventh ribs by a phrenicocolic ligament. The latter sometimes blends with a presplenic fold that radiates from the gastrosplenic ligament. The descending colon becomes sessile. The process of fusion and obliteration of both ascending and descending mesocolons starts laterally and progresses medially.

## Sigmoid colon

The sigmoid colon is most variable in its length and disposition. It retains its dorsal mesocolon, but the initial midline dorsal attachment of its root is considerably modified in its definitive state.

## Rectum

The rectum continues from the ventral aspect of the third sacral vertebra to its anorectal (perineal) flexure anteroinferior to the tip of the coccyx; the distance changes with age. All aspects of the rectum are encased by mesenchyme, and the early, dorsally placed, mass is named, by some authorities, the dorsal mesorectum. However, the latter does not form a true mesentery; with progressive skeletal development, it is reduced to a woven fibroareolar sheet that displays patterned variations in thickness and fibre orientation. The sheet is closely applied to the ventral concavity of the sacrum and coccyx, and encloses numerous fibromuscular and neurovascular elements. The rectum, therefore, becomes sessile, and visceral peritoneum is restricted to its lateral and ventral surfaces (see Fig. 72.4).

With the disappearance of the postanal gut by the end of the fifth week, the ventrolateral peritoneum reaches the superior surface of the pelvic floor musculature; this condition persists until late in the fourth month. In the male, the ventral rectal peritoneum is reflected over the posterior surface of the prostate, bladder trigone and associated structures. In the female, the ventral peritoneum initially receives a reflection that covers almost the whole posterior aspect of the vagina, and is continued over the uterus. Subsequently, the closely apposed walls of these deep peritoneal pouches fuse over much of their caudal extent, their mesothelia are lost, and the viscera are separated by an intervening, bilaminar (surgically separable), fibrous stratum. In the male, this becomes the rectovesical fascia and posterior wall of the prostatic sheath (see Fig. 72.10). In the female, it becomes the rectovaginal septum between the lower part of the vagina and the rectum (see Fig. 72.9). The proximal third of the rectum is covered by peritoneum ventrolaterally; the lateral extensions of this tunic are triangular and deep proximally, but taper to an acute angle by the middle third of the rectum. The middle third of the rectum is covered by peritoneum only on its ventral surface, where it forms the posterior wall of the shallower rectovesical or rectovagino-uterine pouch. The remaining rectum and anal canal are extraperitoneal.

## NEONATAL PERITONEAL CAVITY

The fully formed peritoneal cavity, although complex topographically, remains a single cavity with numerous intercommunicating regions, pouches and recesses (see Fig. 14.7). The only small peritoneal sacs to separate completely from the main cavity are the infracardiac bursa and the tunica vaginalis testis (see Fig. 72.17).

In fetal life, the greater omental cavity extends to the internal aspect of the lateral and caudal edges of the omentum. Postnatally, a slow but progressive fusion of the internal surfaces occurs, with obliteration of the most dependent part of the cavity; this proceeds rostrally and, when mature, the cavity does not usually extend appreciably beyond the transverse colon. Transverse mesocolon-greater omentum fusion begins early while the umbilical hernia of the midgut has not returned. It starts between the right margin of the early greater omentum and near the root of the presumptive mesocolon, and later spreads to the left.

In the neonate, the peritoneal cavity is ovoid (see Fig. 14.6). It is fairly shallow from anterior to posterior because the bilateral posterior extensions on each side of the vertebral column, which are prominent in the adult, are not present. Two factors lead to the protuberance of the anterior abdominal wall in the neonate and infant. The diaphragm is flatter in the newborn, which produces a caudal displacement of the viscera. The pelvic cavity is very small in the neonate, which means that organs that are normally pelvic in the adult, i.e. urinary bladder, ovaries and uterus, all extend superiorly into the abdomen (see Figs 14.7, 72.9-72.10). The pelvic cavity is joined to the abdominal cavity at less of an acute angle in the neonate because there is no lumbar vertebral curve and only a slight sacral curve.

The peritoneal attachments are similar to the adult. However, the greater omentum is relatively small; its constituent layers of peritoneum
may not be completely fused, and it does not extend much below the level of the umbilicus. Generally, the length of the mesentery of the small intestine and of the transverse and sigmoid mesocolons is greater than in the adult, whereas the area of attachment of the ascending and descending colons is relatively smaller. The peritoneal mesenteries and omenta contain little fat.

## SPLEEN

The spleen appears about the sixth week as a localized thickening of the coelomic epithelium of the dorsal mesogastrium near its cranial end (see Figs 60.6-60.7). The proliferating cells invade the underlying angiogenetic mesenchyme, which becomes condensed and vascularized. The process occurs simultaneously in several adjoining areas, which soon fuse to form a lobulated spleen of dual origin (from coelomic epithelium and from mesenchyme of the dorsal mesogastrium).

The vascular reticulum is well developed at 8-9 weeks, and contains immature reticulocytes and numerous closely spaced, thin-walled, vascular loops. From 11 weeks, the development of the spleen has been described in four stages: stage 0 has erythrocyte precursors, few macrophages and fewer lymphocytes; at stage I, lymphocytes begin colonization and arterial vascular lobules are seen; at stage II, T and B lymphocytes form peri-arteriolar clusters with B cells aggregated around the peripheral branches of splenic arterioles and $T$ cells centrally; at stage III, before birth, the lobular arrangement is no longer discernible (Steiniger et al 2007).

From week 17, $\alpha$-SMA-positive reticulum cells are found around arterioles. These increase in number and form a reticular framework from 20 to 23 weeks, when a primitive white pulp can be observed around arterioles. By 24 weeks, T and B lymphocytes become segregated, with T cells within the SMA-positive reticular framework, and B cells aggregating close to the peri-articular lymphoid sheath, where they form lymphoid follicles (Satoh et al 2009).

Initially, the splenic capsule consists of cuboidal cells bearing cilia and microvilli. The enlarging spleen projects to the left, so that its surfaces are covered by the peritoneum of the mesogastrium on its left aspect, which forms a boundary of the general extrabursal (greater) sac. When fusion occurs between the dorsal wall of the lesser sac and the dorsal parietal peritoneum, it does not extend to the left as far as the spleen, which remains connected to the dorsal abdominal wall by a short splenorenal ligament. Its original connection with the stomach persists as the gastrosplenic ligament. The earlier lobulated character of the spleen disappears, but is indicated by the presence of notches on its upper border in the adult.

The spleen displays various developmental anomalies, including complete agenesis, multiple spleens or polysplenia, isolated small additional spleniculi and persistent lobulation. Asplenia and polysplenia are associated with other anomalies, especially those involving the cardiac and pulmonary systems. Accessory spleens are very common in neonates, located in the greater omentum. At birth, the spleen weighs, on average, 13 g (see Fig. 14.6). It doubles its weight in the first postnatal year and triples it by the end of the third year.

## SUPRARENAL GLANDS

The suprarenal (adrenal) cortex is formed during the second month by a proliferation of the coelomic epithelium. Cells pass into the underlying mesenchyme between the root of the dorsal mesogastrium and the mesonephros (see Fig. 17.11). The proliferating tissue, which extends from the level of the sixth to the twelfth thoracic segments, is soon disorganized dorsomedially by invasion of neural crest cells from somite levels 18-24, which form the medulla, and also by the development of venous sinusoids. The latter are joined by capillaries, which arise from adjacent mesonephric arteries and penetrate the cortex in a radial manner. When proliferation of the coelomic epithelium stops, the cortex is enveloped ventrally, and later dorsally, by a mesenchymal capsule that is derived from the mesonephros. The subcapsular nests of cortical cells are the rudiment of the zona glomerulosa; they proliferate cords of cells that pass deeply between the capillaries and sinusoids. The cells in these cords degenerate in an erratic fashion as they pass towards the medulla, becoming granular, eosinophilic and, ultimately, autolysed. These cords of cells constitute the fetal cortex, which undergoes rapid involution during the first 2 years after birth. The fascicular and reticular zones of the adult cortex are proliferated from the glomerular zone after birth. Serial ultrasound measurements of the length of fetal suprarenal glands at 4 -week intervals from the fifteenth week of gestation have been published (van Vuuren et al 2012).

The most common anomaly of suprarenal gland development is congenital hyperplasia, which occurs in $1: 5000$ to $1: 15,000$ births. This condition is caused by a group of autosomal recessive disorders, in which there are deficiencies in enzymes required for the synthesis of cortisol. In $90 \%$ of cases, the cause is deficiency of the enzyme 21-hydroxylase, producing an accumulation of 17-hydroxyprogesterone, which is converted to androgens. The levels of androgens increase by several hundred times, causing female embryos and fetuses to undergo external genital masculinization ranging from clitoral hypertrophy to formation of a phallus and scrotum; masculinization of the brain has also been suggested. In male embryos, the levels do not cause any changes in external genitalia. Signs of androgen excess may appear in childhood with precocious masculinization and accelerated growth (Lewis et al 1999).

## SUPRARENAL GLANDS IN THE NEONATE

The suprarenal glands are relatively very large at birth (see Figs 14.6C, 72.8 ) and constitute $0.2 \%$ of the entire body weight, compared with $0.01 \%$ in the adult. The left gland is heavier and larger than the right, as it is in the adult. At term, each gland usually weighs 4 g ; the average weight of the two glands is 9 g (average in the adult is $7-12 \mathrm{~g}$ ). Estimation of the suprarenal gland volume can provide an estimate of fetal weight; a volume of greater than $420 \mathrm{~mm}^{3} / \mathrm{kg}$ is relevant in predicting preterm birth within 5 days of measurement (Turan et al 2012, Turan et al 2007). Within the first 2 weeks of postnatal life, the glands shrink to normal infantile size. The average weight of both glands is 5 g by the end of the second week, and 4 g by 3 months; gland birth weight is not regained until puberty. This rapid involution of the glands occurs regardless of gestational age. It is thought that parturition is the stimulus for suprarenal involution (Ben-David et al 2007). The cortex of the suprarenal gland is thicker than in the adult and the medulla of the gland is small. With normal involution, the fetal zone cells of the postnatal gland become smaller and they assume the appearance and organization typical of zona fasciculata.

## INFERIOR VENA CAVA, PORTAL CIRCULATION AND UMBILICAL VESSELS

## INFERIOR VENA CAVA

The inferior vena cava of the adult is a composite vessel that develops on the posterior abdominal wall dorsal to the developing peritoneal cavity. It forms as a consequence of the temporal remodelling of successive venous complexes (see Fig. 13.4). The precise mode of development of its postrenal segment (caudal to the renal vein) is still somewhat uncertain. Its function is initially carried out by the right and left postcardinal veins (Fig. 60.8; see also Fig. 13.4), which receive the venous drainage of the lower limb buds and pelvis, and run in the dorsal part of the mesonephric ridges, receiving tributaries from the body wall (intersegmental veins) and from the derivatives of the mesonephroi. It should be remembered that descriptions of venous development are very largely based on studies on animals, where the dimensions and final disposition of visceral organs differ from those found in humans. Many of the changes seen in the development of the infrahepatic caval and azygos systems in the human may result from lateral to medial movement of the vessels as a consequence of the growth of the abdominal viscera (Hikspoors et al 2015).

The early postcardinal veins communicate across the midline via an interpostcardinal anastomosis. This remains as an oblique transverse anastomosis between the iliac veins, and becomes the major part of the definitive left common iliac vein. It diverts an increasing volume of blood into the right longitudinal veins, which accounts for the ultimate disappearance of most of those on the left.

The supracardinal veins receive the larger venous drainage of the growing body wall. The right supracardinal vein persists and forms the greater part of the postrenal segment of the inferior vena cava. The continuity of the vessel is maintained by the persistence of the anastomosis between the right supracardinal and the right subcardinal in the renal collar. The left supracardinal disappears, but some of the renal collar formed by the left supracardinal-subcardinal anastomosis persists in the left renal vein. Both supracardinal veins drain cranially into the subcardinal veins. On the right side, the subcardinal vein comes into intimate relationship with the liver. An extension of the vessel takes place in a cranial direction and meets and establishes continuity with a corresponding new formation that is growing caudally from the right

Fig. 60.8 The inferior vena cava (IVC) develops within the posterior abdominal wall. It is a composite vessel formed by temporal remodelling of successive somatic venous anastomoses. A, The progressive asymmetry of the developing venous system. B, The definitive venous arrangement. (For early venous development, see Fig. 13.4.)
vitelline hepatocardiac (common hepatic) vein. In this way, on the right side, a more direct route is established to the heart and the prerenal (cranial) segment of the inferior vena. In summary, the inferior vena cava is formed from below upwards by the confluence of: the common iliac veins, a short segment of the right postcardinal vein, the postcardinal-supracardinal anastomosis, part of the right supracardinal vein, the right supracardinal-subcardinal anastomosis, right subcardinal vein, a new anastomotic channel of double origin (the hepatic segment of the inferior vena cava), and the cardiac termination of the right vitelline hepatocardiac vein (common hepatic vein).

Only the supracardinal part of the inferior vena cava receives intersegmental venous drainage. The postrenal (caudal) segment of the inferior vena cava is on a plane that lies dorsal to the plane of the prerenal (cranial) segment. Thus, the right phrenic, suprarenal and renal arteries, which represent persistent mesonephric arteries, pass behind the inferior vena cava, whereas the testicular or ovarian artery, which has a similar developmental origin, passes anterior to it.

In some animals, the right postcardinal vein constitutes a large part of the postrenal segment of the inferior vena cava. In these cases, the right ureter, on leaving the kidney, passes medially dorsal to the vessel and then, curving round its medial side, crosses its ventral aspect. Rarely, a similar condition is found in humans, and indicates the persistence of the right postcardinal vein and failure of the right supracardinal to play its normal part in the development of the inferior vena cava.

## PORTAL CIRCULATION

The heart first differentiates in splanchnopleure that, after head-fold formation, forms the dorsal wall of the primitive pericardial cavity (floor of the rostral foregut) and may, therefore, be considered a highly specialized vitelline vascular derivative. At the caudal extremity of the splanchnopleuric gut tube (the future lower rectum and upper anal canal), the vitelline venous drainage makes connections with the internal iliac radicles of the postcardinal complex.

The development of the gut occurs contemporaneously with changes to the early symmetrical embryonic circulation (Ch. 13). A symmetrical, segmental system of somatic arteries remains and supplies the body wall of the trunk. The underlying arrangement of these vessels is only slightly modified by subsequent development. The main changes to the
embryonic arrangement occur with the growth of the foregut, liver and paired viscera, i.e. kidneys and suprarenal glands.

The early development of the ventral splanchnic arteries is outlined in Chapter 13. Three main arterial trunks - the coeliac trunk, superior mesenteric and inferior mesenteric arteries - supply the fore-, mid- and hindgut, respectively. From the gastric terminal segment of the future oesophagus to the upper rectum, the developing endodermal epithelium is surrounded by splanchnopleuric mesenchyme permeated by a capillary plexus that drains into an anastomosing network of veins. This plexus is particularly dense ventrally where it is associated with the central midgut region; here, for a while, it receives a network of small veins from the definitive yolk sac. Later, in normal development, these vessels atrophy as the yolk sac diminishes. More rostrally, the splanchnopleuric capillaries associated with the foregut and upper portions of the yolk sac form longitudinal channels anterolateral to the gut and these become increasingly well defined as the embryonic abdominal vitelline veins. Entering the septum transversum, the right and left vitelline veins incline slightly, becoming parallel to the lateral aspects of the gut. They establish connections with capillary plexuses in the septal mesenchyme, and then continue, finally curving to enter the medial part of the cardiac sinual horn of their corresponding side. The parts of the gut closely related to the presinual segments of the vitelline veins are the future subdiaphragmatic end of the oesophagus, primitive stomach, the superior (first) and descending (second) regions of the duodenum, and the remainder of the duodenal tube.

The principal ascending vitelline veins flanking the sides of the abdominal part of the foregut receive venules from its splanchnopleuric capillaries and those of the septal mesenchyme. Within these venular nets, enlarged (but still plexiform) anastomoses connect the two vitelline veins (Fig. 60.9; see Fig. 13.1C). A subdiaphragmatic intervitelline anastomosis develops in the rostral septal mesenchyme, lying a little caudal to the cardiac sinuatrial chamber, connecting the veins near their sinual terminations. (The channel is sometimes termed suprahepatic because of the position of the hepatic primordium; with expansion of the latter, it becomes partly intrahepatic.) The presumptive duodenum is crossed by three transverse duodenal intervitelline anastomoses. Their relation to the gut tube alternates so that the most cranial, the subhepatic, is ventral, the intermediate is dorsal and the caudal is ventral (Fig. 60.9B). It has become customary to describe the paraduodenal vitelline veins and their associated anastomoses as forming a figure eight. At this early stage, when left and right embryonic veins are still symmetrical,

Fig. 60.9 Development of the vitelline, umbilical and terminal cardinal vein complexes: the early symmetrical condition. A, The early symmetrical arrangement of cardinal and umbilical veins entering the sinus venosus; blood from the yolk sac passes, via vitelline veins, through anastomoses forming in the septum transversum mesenchyme (green). B, The developing duodenum is surrounded by transverse duodenal intervitelline anastomoses. Changes in the developing gut and umbilical veins cause shifts in the routes taken by venous blood flowing to the sinus venosus.

Fig. 60.10 Development of the vitelline, umbilical and terminal cardinal vein complexes: a mid-stage of asymmetry has been reached between the early symmetrical condition (see Fig. 60.9) and the definitive late prenatal state. The extent of the liver within the septum transversum mesenchyme is shown in green.
the cranial duodenal anastomosis becomes connected with the subdiaphragmatic anastomosis by a median longitudinal channel, the primitive median ductus venosus, which is dorsal to the expanding hepatic primordium but ventral to the gut. The further development of the vitelline veins and anastomoses is, as indicated, closely interlocked, with rapid hepatic expansion and gut changes, and umbilical vein disposition and modification is closely involved.

## CHANGES IN THE VITELLO-UMBILICAL VEINS

Progressive changes in the vitello-umbilical veins are rapid, profound and closely linked with regional modifications in shape and position of the gut, expansion and invasion of venous channels by hepatic tissue, asymmetry of the heart and cardiac venous return. The principal events are summarized in Figures 60.9-60.11.

Fig. 60.11 The condition of some main upper abdominal and intrathoracic right atrial terminal veins in the later prenatal months. The rotation of the stomach and movement of the duodenum produce relative changes in the final arrangement of the duodenal intervitelline anastomoses that form the hepatic portal vein.
fibrous tags attached to the inferior wall of the coronary sinus. The right vitelline hepatocardiac vein continues enlarging and, ultimately, forms the terminal segment of the inferior vena cava. The latter receives the right efferent hepatic veins and new channels draining the territories of the left efferent hepatic veins. These collectively form the upper and lower groups of right and (secondary) left hepatic veins. The terminal caval segment also shows the orifice of the right half of the intervitelline subdiaphragmatic anastomosis, and a large new connection with the right subcardinal vein.

The hepatic terminals of the right and left duodenal parts of the vitelline veins are destined to form the corresponding branches of the hepatic portal vein, the left branch incorporating the cranial ventral intervitelline anastomosis. With rotation of the gut and formation of the duodenal loop, segments of the original vitelline veins and the caudal transverse anastomosis atrophy (indicated in Figs 60.10-60.11), while new splanchnopleuric venous channels - the superior mesenteric and splenic veins - converge and join the left end of the dorsal intermediate anastomosis. The numerous other radicles of the portal vein and its principal branches, including the inferior mesenteric vein, are later formations.

For a period, placental blood returns from the umbilicus via right and left umbilical veins, both discharging through afferent hepatic veins into the hepatic sinusoids, where admixture with vitelline blood occurs. At approximately 7 mm crown-rump length, the right umbilical vein retrogresses completely. The left umbilical vein retains some vessels discharging directly into the sinusoids, but new enlarging connections with the left half of the subhepatic intervitelline anastomosis emerge. The latter is the start of a bypass channel for the majority of the placental blood, which continues through the median ductus venosus and, finally, the right half of the subdiaphragmatic anastomosis, to reach the termination of the inferior vena cava (see Fig. 60.11).

The left and right hepatic portal veins and the ductus venosus are routinely observed in the second trimester ultrasound scan at the plane to estimate abdominal circumference (see Fig. 14.4G).

## FETAL/NEONATAL UMBILICAL VESSELS

## Umbilical arteries

The fetal umbilical arteries are in direct continuation with the internal iliac arteries. Their lumen is $2-3 \mathrm{~mm}$ in diameter at their origin, when distended. This narrows as they approach the umbilicus, where there is a reciprocal thickening of the tunica media, as a result, in particular, of an increase in the number of longitudinal smooth muscle fibres and

From the cranial portion of the early hepatic evagination of the foregut, interconnected sheets and 'cords' of endodermal cells, the presumptive hepatocytes, penetrate the septum transversum mesenchyme. Hepatic mesenchyme is composed of a mixed population of cells with endothelial/angiogenic and connective tissue lineages. Capillary plexuses develop within this mesenchyme and, possibly under the influence of the endodermal hepatic sheets, the plexuses become more profuse by further addition of angioblastic septal mesenchyme, which also forms masses of perivascular intrahepatic haemopoietic tissue. These processes extend along the plexiform connections of the vitelline, and later the umbilical, veins until their intrahepatic (trans-septal) zones themselves become largely plexiform. Initially capillary in nature, they transform into a mass of rather wider, irregular, sinusoidal vessels with a discontinuous endothelium containing many phagocytic cells. The lengths of vitelline veins involved in these processes are the intermediate parts of the segments extending from the subhepatic (cranioventral duodenal) to the suprahepatic (subdiaphragmatic) transverse intervitelline anastomoses, and the corresponding lengths of the umbilical veins. Thus, at this early stage, the liver sinusoids are perfused by mixed blood reaching them through a series of branching vessels collectively called the venae advehentes, or afferent hepatic veins: they are deoxygenated from the gut splanchnopleure via vitelline vein hepatic terminals, and oxygenated from the placenta via hepatic terminals of the umbilical veins (see Fig. 60.10). Blood leaves the liver through four venae revehentes (efferent hepatic veins); two on each side reach and open into their respective cardiac sinual horns. This full complement of four hepatocardiac veins is only transient and becomes reduced to one dominant, rapidly enlarging channel. The originally bilaterally symmetrical cardinal vein complexes, both rostral and caudal, develop transverse or oblique anastomoses so that the cardiac venous return is ultimately restricted to the definitive right atrium.

These cardiac and concomitant hepatoenteric changes are accompanied by events in supra-, intra- and subhepatic parts of the vitelloumbilical veins. Some vessels enlarge, persisting as definitive vessels to maturity; in places, they are joined later by other channels that become defined in already established capillary plexuses. Other vessels retrogress, either disappearing completely or remaining as vestigial tags and, occasionally, vessels of fine calibre. Some vessels of crucial importance in the circulatory patterns of embryonic and fetal life become obliterated postnatally and transformed to substantial fibrous cords. Both right and left umbilical hepatocardiac and the left vitelline hepatocardiac veins continue, for a time, to discharge blood into their sinual horns; however, they begin to retrogress (see Figs 60.9-60.10). The right umbilical channel atrophies completely. The left channels also disappear, but their cardiac terminals may, on occasion, be found as conical

Table 60.1 Key anatomical reference points for umbilical arterial catheterization

| Structure | Vertebral level |
| :--- | :--- |
| Ductus arteriosus | $\mathrm{T} 4-5$ |
| Coeliac artery | T 12 |
| Superior mesenteric artery | $\mathrm{T} 12-\mathrm{L} 1$ |
| Renal artery | L 1 |
| Inferior mesenteric artery | L 3 |
| Aortic bifurcation | $\mathrm{L} 4-5$ |

elastic fibres. Before birth, there is a proliferation of connective tissue within the vessel wall. The umbilical vessels constrict in response to handling, stretching, cooling and altered tensions of oxygen and carbon dioxide. Umbilical vessels are muscular, but devoid of a nerve supply in their extra-abdominal course. After the cord is severed, the umbilical arteries contract, preventing significant blood loss; thrombi often form in the distal ends of the arteries. The arteries obliterate from their distal ends until, by the end of the second or third postnatal month, involution has occurred at the level of the superior vesical arteries. The proximal parts of the obliterated vessels remain as the medial umbilical ligaments.

## Umbilical arterial catheterization

Insertion of an umbilical catheter is undertaken to provide direct access to the arterial circulation. Arterial blood can be withdrawn repeatedly for measurement of oxygen and carbon dioxide partial pressures, pH , base excess and many other parameters of blood biochemistry and haematology. The indwelling catheter also enables the continuous measurement of arterial blood pressure.

The catheter is inserted directly into either the cut end or the side of one of the two umbilical arteries in the umbilical cord stump that remains attached to the baby after transection of the umbilical cord at the time of delivery. The catheter tip is then advanced along the length of the umbilical artery, through the internal iliac artery, into the common iliac artery and, from there, into the aorta. In order to keep the catheter patent, a small volume of fluid is continuously infused through it. It is important for the tip of the catheter to be located well away from arteries branching from the aorta, to avoid potentially harmful perfusion of these arteries with the catheter fluid. Thus, umbilical arterial catheter tips are placed in the descending aorta either in a 'high' position, above the coeliac artery but well below the ductus arteriosus, or in a 'low' position, below the renal and inferior mesenteric arteries but above the point where the aorta bifurcates into the two common iliac arteries. The length of catheter to be inserted can be estimated from charts relating the required catheter length to external body measurements, or from birth weight. Positioning of the catheter is assessed by means of radiographs of the abdomen or chest: a 'high' catheter tip should be located in the descending aorta somewhere between the levels of the sixth and ninth thoracic vertebrae (T6-9), while a 'low' catheter tip should be at a level between the third and fourth lumbar vertebrae (L3-4). Relevant anatomical reference points are given in Table 60.1.

## Umbilical vein

The umbilical vein in the neonate is $2-3 \mathrm{~cm}$ long and $4-5 \mathrm{~mm}$ in diameter when distended. It passes from the umbilicus, within the layers of the falciform ligament, superiorly and to the right, to the porta hepatis. Here, it gives off several large intrahepatic branches to the liver and then joins the left branch of the portal vein and the ductus venosus. The umbilical vein is thin-walled; it possesses a definite internal lamina of elastic fibres at the umbilical ring but not in its intra-abdominal course. The tunica media contains smooth muscle fibres, collagen and elastic fibres. When the cord is severed, the umbilical vein contracts, but not so vigorously as the arteries. The rapid decrease in pressure in the umbilical vein after the cord is clamped means that the elastic tissue at the umbilical ring is sufficient to arrest any retrograde flow along the vessel. Before birth, there is a subintimal proliferation of connective tissue. After birth, the contraction of the collagen fibres in the tunica media and the increased subintimal connective tissue contribute to the transformation of the vessel into the ligamentum teres. Obliteration occurs from the umbilical ring towards the hepatic end. No thrombi are formed in the obliteration process. For up to 48 hours after birth, the intraabdominal portion of the umbilical vein can be easily dilated. In most adults, the original lumen of the vein persists through the ligamentum teres and can be dilated to $5-6 \mathrm{~mm}$ in diameter.

## Ductus venosus

The ductus venosus is a direct continuation of the umbilical vein and arises from the left branch of the portal vein, directly opposite the termination of the umbilical vein. It passes for $2-3 \mathrm{~cm}$ within the layers of the lesser omentum, in a groove between the left lobe and caudate lobe of the liver, before terminating in either the inferior vena cava, or in the left hepatic vein immediately before it joins the inferior vena cava. The tunica media of the ductus venosus contains circularly arranged smooth muscle fibres, an abundant amount of elastic fibres and some connective tissue.

The ductus venosus is already closed in about one-third of newborn infants. It shuts down by an unknown mechanism. Obliteration begins at the portal vein end in the second postnatal week and progresses to the vena cava; the lumen has been completely obliterated by the second or third month after birth. The fibrous remnant of the ductus venosus is the ligamentum venosum.

## Umbilical vein catheterization

The umbilical vein may be catheterized in the neonate to enable exchange and transfusion of blood, for central venous pressure measurement and, usually in an emergency, for vascular access. The catheter is inserted into the cut end of the umbilical vein and is advanced along the length of the vein, through the ductus venosus and into the inferior vena cava; the tip is placed between the ductus venosus and the right atrium. Positioning of the catheter tip is confirmed radiologically and it should be located just above the diaphragm at a point that is level with the ninth or tenth thoracic vertebra (T9/T10). As with umbilical arterial catheters, estimation of the required catheter length can be determined from standard charts.

## Anterior abdominal wall

The anterior abdominal wall constitutes a hexagonal area defined superiorly by the costal margins and xiphoid process, laterally by the midaxillary line, and inferiorly by the iliac crests, pubis and pubic symphysis. It is continuous with the posterior abdominal wall and paravertebral tissues, forming a flexible sheet of skin, muscle and connective tissue across the anterior and lateral aspects of the abdomen. These tissues also form the umbilicus and the inguinal canal, which connects the abdominal cavity to the scrotum in men or to the labia majora in women. The anterior abdominal wall maintains the shape of the abdomen and aids numerous physiological functions. However, its dysfunction is equally notable because hernia repair is the single most common operation performed by general surgeons.

## SKIN AND SOFT TISSUE

The integument of the anterior abdominal wall comprises skin, soft tissues, and lymphatic and vascular structures, as well as segmental nerves. The outer layer is formed from the skin and subcutaneous fat. The skin is non-specialized and variably hirsute, depending on sex and race. All postpubertal individuals have some extension of the pubic hair on to the anterior abdominal wall skin, although this is commonly most pronounced in males, in whom the hair may extend almost up to the umbilicus in a triangular pattern. The subcutaneous fat of the abdominal wall is highly variable in thickness, depending in part on gender and adiposity.

## SOFT TISSUE

## Superficial fascia

The 'superficial fascia' of the abdominal wall lies between the dermis and the muscles, and is conventionally divided into a superficial fatty layer (Camper's fascia) and a deep membranous layer (Scarpa's fascia). In reality, there are three layers, with a further layer of adipose tissue deep to the membranous layer (Lancerotto et al 2011). These three layers are particularly well defined in the child. Lying within the superficial fascia are blood vessels, lymphatics, nerves and, in the region of the groin, superficial inguinal lymph nodes.

## Superficial adipose layer

The superficial layer contains a variable amount of fat that is partitioned by fibrous septa connecting the dermis with the deeper membranous layer. Inferiorly, it is continuous with the superficial fascia of the thigh, and medially, it is continuous over the linea alba. In the male, this layer continues over the external genitalia, where it becomes thin and pale red, and contains very little adipose tissue. In the scrotum it also contains the smooth muscle fibres of the dartos muscle. In the female, it continues from the suprapubic region of the abdomen into the labia majora and perineum.

## Membranous layer

The membranous layer is a variably developed entity composed of connective tissue and elastic fibres. In the adult, its thickness varies over the anterior abdominal wall, becoming thinner in the upper abdomen (Lancerotto et al 2011). Measured histologically, it is between 0.5 and 1 mm thick but it appears thicker on computed tomography (CT) scans (Lancerotto et al 2011, Chopra et al 2011). It is loosely connected to the underlying external oblique aponeurosis and rectus sheath by oblique fibrous septa. Superiorly, it is continuous with the superficial fascia over the remainder of the trunk. In the midline, it is
adherent to the linea alba and pubic symphysis. Inferiorly, it fuses with the iliac crest, extends superficial to the inguinal ligament and fuses with the fascia lata at the inguinal flexure or skin crease of the thigh. In the male, it extends on to the dorsum of the penis, forming part of the superficial ligament of the penis, and on to the scrotum, where it becomes continuous with the membranous layer of superficial fascia of the perineum (Colles' fascia). In the female, it continues into the labia majora and is continuous with the fascia of the perineum.

In boys, the testis can frequently be retracted out of the scrotum into the loose areolar tissue between the membranous layer of superficial fascia over the inguinal canal and the external oblique aponeurosis. This 'space' is sometimes called the superficial inguinal pouch.

## Deep adipose layer

The thickness of the deep adipose layer is more variable than the superficial fatty layer. It is thin or absent where the membranous layer fuses with bony prominences and the linea alba, and becomes markedly thick in the morbidly obese. Its adipocytes show different metabolic activities to those in the superficial adipose layer (Chopra et al 2011). Liposuction preferentially removes this layer of fat with relative preservation of the superficial adipose layer in order to avoid skin dimpling and other skin contour irregularities (Markman and Barton 1987).

## Transversalis fascia

The transversalis fascia is a thin layer of connective tissue lying between the deep surface of transversus abdominis and the extraperitoneal fat. It is part of the general layer of thin fascia between the peritoneum and the abdominal wall. Posteriorly, it fuses with the anterior layer of the thoracolumbar fascia (p. 1083), and anteriorly, it forms a continuous sheet. Superiorly, it blends with the fascia covering the inferior surface of the diaphragm. Inferiorly, it is continuous with the iliac and pelvic parietal fasciae, and is attached to the iliac crest between the origins of transversus abdominis and iliacus, and to the posterior margin of the inguinal ligament between the anterior superior iliac spine and the femoral sheath. Medial to the femoral sheath it is thin and fused to the pubis behind the conjoint tendon. An inferior extension of the transversalis fascia forms the anterior part of the femoral sheath. The fascia displays a discrete thickening known as the iliopubic tract (also called the deep crural arch), which runs parallel to the inguinal ligament (Teoh et al 1999); it consists of transverse fibres that fan out laterally towards the anterior superior iliac spine to blend with the iliopsoas fascia and run medially behind the conjoint tendon to the pubic bone. The iliopubic tract is recognized as an important structure during open and laparoscopic inguinal hernia repair. A further thickening of the transversalis fascia, the interfoveolar ligament, runs inferior to the inguinal ligament at the medial margin of the deep inguinal ring; it may contain muscle fibres.

The transversalis fascia is prolonged as the internal spermatic fascia over the structures that pass through the deep inguinal ring (the testicular vessels and vas (ductus) deferens in the male and the round ligament of the uterus in the female).

## Extraperitoneal connective tissue

The extraperitoneal connective tissue lying between the peritoneum and the fasciae lining the abdominal and pelvic cavities contains a variable amount of fat. The fat is especially abundant on the posterior wall of the abdomen around the kidneys (particularly in obese men) and scanty above the iliac crest and in much of the pelvis.

Fig. 61.1 The blood supply of the anterior abdominal wall.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Understanding the blood supply of the abdominal wall is critical when planning incisions, raising myocutaneous flaps and reconstructing the abdominal wall during ventral hernia repair (Fig. 61.1).

## Superior epigastric artery and veins

The superior epigastric artery is a terminal branch of the internal thoracic artery. It arises at the level of the sixth costal cartilage and descends between the costal and xiphoid slips of the diaphragm, accompanied by two or more veins that drain to the internal thoracic vein (see Fig. 61.1; Fig. 61.2). The vessels pass anterior to the lower fibres of transversus thoracis and the upper fibres of transversus abdominis before entering the rectus sheath, where they run inferiorly behind rectus abdominis. They anastomose with the inferior epigastric arteries, usually above the level of the umbilicus, in one of several potential branching patterns (Rozen et al 2008).

Branches supply rectus abdominis and perforate the anterior lamina of the rectus sheath to supply the abdominal skin. A branch given off in the upper rectus sheath passes anterior to the xiphoid process of the sternum and anastomoses with a corresponding contralateral branch. This vessel may give rise to bleeding during surgical incisions that extend up to and alongside the xiphoid process. The superior epigastric
artery also gives small branches to the anterior part of the diaphragm. On the right, small branches reach the falciform ligament, where they anastomose with branches from the hepatic artery.

## Inferior epigastric artery and veins

The inferior epigastric artery (often referred to as the deep inferior epigastric artery in clinical practice in order to distinguish it from the superficial (inferior) epigastric artery) originates from the medial aspect of the external iliac artery just proximal to the inguinal ligament (see Figs 61.1-61.2; Fig. 61.3). Its accompanying veins, usually two, unite to form a single vein that drains into the external iliac vein (Rozen et al 2009). It curves forwards in the anterior extraperitoneal tissue and ascends obliquely along the medial margin of the deep inguinal ring. It lies posterior to the spermatic cord, separated from it by the transversalis fascia. It pierces the transversalis fascia and enters the rectus sheath by passing anterior to the arcuate line. In this part of its course, it is visible through the parietal peritoneum of the anterior abdominal wall and forms the lateral umbilical fold. Disruption of the artery at this site by surgical incisions (e.g. insertion of laparoscopic ports or abdominal drains) may result in a haematoma that can expand to considerable size because of the absence of adjacent tissue against which the bleeding can be tamponaded.

The vascular supply to the anterior abdominal wall can be divided into three zones. Zone I represents the epigastrium and central anterior abdominal wall within the region of rectus abdominis, and is supplied by the superior and inferior epigastric vessels. Zone II consists of the lower anterior abdominal wall below zone I and is predominantly supplied by the superficial epigastric, superficial external pudendal, and superficial circumflex iliac arteries. Zone III is lateral to zone I and is supplied by the musculophrenic, lower intercostal, subcostal and lumbar arteries.

The distance of the vertically running superior and deep inferior epigastric vessels from the midline is relevant to siting surgical incisions (Table 61.1).

Table 61.1 Distances of superior and deep inferior epigastric arteries from midline

| Level | Left | Right |
| :--- | :--- | :--- |
| Xiphoid cartilage | $4.5 \pm 0.1 \mathrm{~cm}$ | $4.4 \pm 0.1 \mathrm{~cm}$ |
| Between xiphoid and umbilicus | $5.4 \pm 0.2 \mathrm{~cm}$ | $5.5 \pm 0.2 \mathrm{~cm}$ |
| Umbilicus | $5.6 \pm 0.1 \mathrm{~cm}$ | $5.9 \pm 0.1 \mathrm{~cm}$ |
| Between umbilicus and pubic symphysis | $5.3 \pm 0.1 \mathrm{~cm}$ | $5.3 \pm 0.1 \mathrm{~cm}$ |
| Pubic symphysis | $7.5 \pm 0.1 \mathrm{~cm}$ | $7.5 \pm 0.1 \mathrm{~cm}$ |

Adapted from Saber AA, Meslemani AM, Davis R, Pimentel R 2004 Safety zones for anterior abdominal wall entry during laparoscopy: a CT scan mapping of epigastric vessels. Ann Surg 239:182-5.

Fig. 61.2 The deep muscles and arterial supply of the anterolateral abdominal wall. The greater part of the left rectus abdominis has been removed to show the superior and inferior epigastric vessels.

The inferior epigastric arteries ascend and anastomose with their superior counterpart without branching in about $30 \%$ of cases (El-Mrakby and Milner 2002). Branching into two vessels before anastomosis is the most common pattern, accounting for almost $60 \%$ of cases, with a trifurcation being present in the remainder. The inferior epigastric arteries have an average diameter of approximately 3 mm at their origin, compared to an average diameter of 1.6 mm at the origin of the superior epigastric arteries, presumably explaining why the inferior epigastric arteries provide the 'dominant' supply to rectus abdominis. Preliminary ligation of the inferior epigastric artery is often performed when preparing a myocutaneous flap using the mid or lower rectus abdominis based on the superior epigastric artery; this encourages the augmentation of the superior epigastric arterial supply.

Branches of the inferior epigastric artery anastomose with branches of the superior epigastric artery within the rectus sheath posterior to rectus abdominis at a variable level above the umbilicus (Rozen et al 2008). Other branches anastomose with terminal branches of the lower five posterior intercostal, subcostal and lumbar arteries at the lateral border of the rectus sheath. Inferolaterally, branches anastomose with the deep circumflex iliac artery. The inferior epigastric artery ascends along the medial margin of the deep inguinal ring. The vas deferens in the male, or the round ligament in the female, passes medially after hooking around the artery at the deep inguinal ring. The artery forms the lateral border of Hesselbach's inguinal triangle, an important landmark in laparoscopic inguinal hernia repair; the inferior border of the triangle is formed by the inguinal ligament, and the medial border is formed by the lateral margin of rectus abdominis.

The inferior epigastric artery also gives off the cremasteric artery, a pubic branch, and muscular and cutaneous branches. The cremasteric artery accompanies the spermatic cord in males, supplies cremaster and the other coverings of the cord and anastomoses with the testicular artery. In females, the artery is small and accompanies the round ligament. A pubic branch, near the femoral ring, descends posterior to the pubis and anastomoses with the pubic branch of the obturator artery. The pubic branch of the inferior epigastric artery may be larger than the obturator artery and supply most of the obturator artery territory in the thigh, in which case it is referred to as the aberrant obturator artery (Pai et al 2009). It lies close to the medial border of the femoral ring and may be damaged in medial dissection of the ring during femoral or
laparoscopic inguinal hernia repair or with pelvic fractures. Muscular branches supply the abdominal muscles and peritoneum, and anastomose with the circumflex iliac and lumbar arteries. Cutaneous branches perforate the aponeurosis of external oblique, supply the skin and anastomose with branches of the superficial epigastric artery. These musculocutaneous perforators have been mapped in detail because they are particularly important to plastic surgeons undertaking reconstructive surgery with (myo)cutaneous flaps (Rozen et al 2008).

Occasionally, the inferior epigastric artery arises from the femoral artery. It then ascends anterior to the femoral vein to follow its usual abdominal course. Rarely, it arises from the external iliac artery in common with an aberrant obturator artery or from the obturator artery.

The superior and inferior epigastric arteries are important sources of collateral blood flow between the internal thoracic artery and the external iliac artery when aortic blood flow is compromised. Small tributaries of the inferior epigastric vein draining the skin around the umbilicus anastomose with terminal branches of the umbilical vein draining the umbilical region via the falciform ligament. These portosystemic anastomoses may open widely in cases of portal hypertension, when portal venous blood may drain into the systemic circulation via the inferior epigastric veins. The pattern of dilated superficial veins radiating from the umbilicus is referred to as the 'caput medusae'.

## Posterior intercostal, subcostal and lumbar arteries

The tenth and eleventh posterior intercostal arteries, the subcostal artery, and the lumbar arteries pierce the posterior aponeurosis of transversus abdominis to enter the neurovascular plane of the abdominal wall deep to internal oblique (Fig. 61.4). The location of these arteries and their accompanying segmental nerves is of clinical importance when creating myofascial flaps during abdominal wall reconstruction. The arteries on either side run forwards, giving off muscular branches to the overlying internal and external oblique, before anastomosing with the lateral branches of the superior and inferior epigastric arteries at the lateral border of the rectus sheath (see Fig. 61.4). Perforating cutaneous vessels run vertically through the muscles to supply the overlying skin and subcutaneous tissue. A small contribution to the

Fig. 61.3 A, The deep aspect of the lower part of the anterior abdominal wall of the left side. The femoral and deep inguinal rings are displayed, together with the vessels and other structures in relation to them and also the opening into the obturator canal. $\mathbf{B}$, A laparoscopic view showing the parietal peritoneum covering the area. Abbreviations: D, vas (ductus) deferens; E , external iliac vessels; H , orifice of direct inguinal hernia; I, inferior epigastric vessels; T, testicular vessels. (B, With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray’s Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
supply of the lower abdominal muscles comes from branches of the deep circumflex iliac arteries.

The anterior abdominal wall is also supplied by branches of the femoral artery: namely, the superficial epigastric, superficial circumflex iliac, and superficial external pudendal arteries, and by the deep circumflex iliac artery arising from external iliac artery (see Fig. 78.7A).

## Lymphatic drainage

Superficial lymphatic vessels accompany the subcutaneous blood vessels immediately below the dermis (Tourani et al 2013). Vessels from the lumbar and gluteal regions run with the superficial circumflex iliac vessels, and those from the infra-umbilical skin run with the superficial epigastric vessels. Both drain into superficial inguinal nodes. The supraumbilical region is drained by vessels draining to axillary and parasternal nodes.

The deep lymphatic vessels accompany the deeper arteries. Laterally, they run either with the lumbar arteries to drain into the lateral aortic nodes, or with the intercostal and subcostal arteries to posterior mediastinal nodes. Lymphatics in the upper anterior abdominal wall run with the superior epigastric vessels to parasternal nodes while those in the
lower abdominal wall run with the deep circumflex iliac and inferior epigastric arteries to external iliac nodes.

## SEGMENTAL NERVES

The ventral rami of the sixth to eleventh intercostal nerves, the subcostal nerve (twelfth thoracic) and first lumbar nerve (iliohypogastric and ilioinguinal nerves) supply the muscles and skin of the anterior abdominal wall (Rozen et al 2008). The seventh to the twelfth thoracic ventral rami continue anteriorly from the intercostal and subcostal spaces into the abdominal wall (Fig. 61.5). Approaching the costal margin, the seventh to tenth nerves curve medially across the deep surface of the costal cartilages between the digitations of the diaphragm and transversus abdominis. The subcostal nerve gives a branch to the first lumbar ventral ramus (dorsolumbar nerve) that contributes to the lumbar plexus (Ch. 62). It accompanies the subcostal vessels along the inferior border of the twelfth rib, passing behind the lateral arcuate ligament and kidney, and anterior to the upper part of the quadratus lumborum.

All these segmental nerves run anteriorly within a thin layer of fascia in the neurovascular plane between transversus abdominis and internal oblique, where they branch and interconnect with adjacent nerves (Rozen et al 2008). Muscular branches innervate transversus abdominis and internal and external oblique. Cutaneous branches supply the skin of the lateral and anterior abdominal walls. The thoracic nerves enter the rectus sheath at its lateral margin and pass posterior to rectus abdominis, where they again intercommunicate. Each nerve then pierces rectus abdominis from its posterior aspect and gives off muscular branches to this muscle (and a branch to pyramidalis from the subcostal nerve), and cutaneous branches that pierce the anterior rectus sheath to supply overlying skin.

The ninth intercostal nerve supplies skin above the umbilicus, the tenth supplies skin that consistently includes the umbilicus, and the eleventh supplies skin below the umbilicus (see Fig. 16.10; Fig. 61.5). The subcostal nerve supplies the anterior gluteal skin just below the iliac crest, and the skin of the lower abdomen and inguinal region (overlapping with the L1 dermatome in this region) (Lee et al 2008). A typical dermatome map of the anterior abdominal wall is shown in Figure 16.10. The ventral rami of the lower intercostal and subcostal nerves also provide sensory fibres to the costal parts of the diaphragm and parietal peritoneum.

The transversus abdominis plane (TAP) block is a regional anaesthetic technique for abdominal surgery. Using ultrasound imaging guidance, local anaesthetic is injected into the neurovascular plane between internal oblique and transversus abdominis, targeting the segmental nerves of the anterolateral abdominal wall.

## Lesions of the intercostal nerves

The anterolateral abdominal wall muscles are innervated by several segmental nerves and injury to a single nerve does not produce a clinically detectable loss of muscle tone. The overlap between sequential dermatomes means that significant cutaneous anaesthesia is appreciated only after sectioning at least two sequential nerves.

## MUSCLES

## ANTEROLATERAL MUSCLES OF THE ABDOMEN

Rectus abdominis, pyramidalis, external oblique, internal oblique and transversus abdominis constitute the anterolateral muscles of the abdomen. They act together to perform a range of functions, some of which involve the generation of a positive pressure within one or more body cavity. Although many of these activities may occur with no 'forced assistance', expiration, defecation and micturition may be aided by the generation of a positive intra-abdominal pressure. Parturition, coughing and vomiting always require such a positive pressure. Under resting conditions, the tone developed within the muscles provides support for the abdominal viscera and retains the normal contour of the abdomen. The consequences of diminished muscular support can be seen in patients who have massive ventral hernias or conditions like 'prune belly syndrome', where there is congenital deficiency or absence of these muscles.

Active contraction of the muscles provides an important role in the maintenance of abdominal wall tone. The compression of the abdominal cavity required to increase intra-abdominal pressure is brought

Fig. 61.4 The arrangement of the anterolateral abdominal wall vessels at the level of the mid-abdomen.
about mainly by contraction of the diaphragm. The bony pelvis, spine and lower thoracic cage provide rigidity to part of the abdominal wall. During the generation of positive intra-abdominal pressure, the abdominal muscles act to hold the abdominal wall in a relatively fixed position, rather than to generate pressure directly; because the majority of the abdominal wall is muscular, the anterolateral abdominal wall muscles must be synchronously contracted to prevent displacement of the viscera and the resultant loss of pressure. The oblique muscles, acting through their anterior aponeuroses and the rectus sheath, provide the majority of this tension, although transversus abdominis and rectus abdominis contribute.

The anterolateral abdominal muscles contribute little to the movements of the trunk during normal sitting and standing; these movements are controlled predominantly by the paravertebral and spinal muscles. However, movements of the trunk against resistance or when the individual is supine require the anterolateral abdominal muscles. Rectus abdominis is the most important in these situations, producing anterior flexion of the trunk. If the pelvic girdle is fixed, flexion of the thoracic girdle occurs. With a fixed thoracic cage, contraction of rectus abdominis causes the pelvis to tilt and lift. Lateral flexion and rotation of the trunk against resistance is provided by unilateral contraction of the oblique muscles.

## Rectus abdominis

Rectus abdominis is a paired, long, strap-like muscle that extends along the entire length of the anterior abdominal wall on either side of the linea alba (Fig. 61.6). It is widest in the upper abdomen. The muscle fibres of rectus abdominis are partially interrupted by three fibrous bands or tendinous intersections, which pass transversely or obliquely across the muscle. One is usually situated at the level of the umbilicus, another opposite the free end of the xiphoid process and a third about midway between the other two. They are rarely full-thickness and usually extend only half-way through the anterior thickness of the
muscle, fusing with the fibres of the anterior lamina of the rectus sheath. Occasionally, one or two incomplete intersections are present below the umbilicus. The intersections may represent the myosepta delineating the myotomes that form the muscle.

The medial border of each rectus abdominis abuts the linea alba. Its lateral border may be visible on the surface of the anterior abdominal wall as a gently curved groove, the linea semilunaris, which extends from the tip of the ninth costal cartilage to the pubic tubercle. In a muscular individual it is readily visible, even when the muscle is not actively contracting, but in many normal and obese individuals it may be completely obscured.

Attachments Rectus abdominis arises by two tendons. The larger, lateral tendon is attached to the pubic crest and may extend beyond the pubic tubercle to the pectineal line. The medial tendon interlaces with the contralateral muscle and blends with ligamentous fibres covering the front of the pubic symphysis. Additional fibres may arise from the lower part of the linea alba. The pubic attachment of the tendon of rectus abdominis and its anterior sheath run over the anterior surface of the pubic symphysis and become continuous with the attachments of gracilis and adductor longus (Norton-Old et al 2013). Superiorly, rectus abdominis is attached by three slips of muscle to the fifth, sixth and seventh costal cartilages. The most lateral fibres are usually attached to the anterior end of the fifth rib; occasionally, this slip is absent or it extends to the fourth and third ribs. The most medial fibres are occasionally connected to the costoxiphoid ligaments and the side of the xiphoid process.

Vascular supply Rectus abdominis is supplied principally by the superior and inferior epigastric arteries, the latter being the dominant supply. Small terminal branches from the lower three posterior intercostal arteries, the subcostal artery, the lumbar arteries and the deep circumflex iliac artery may contribute, particularly at the lateral edges

Fig. 61.5 The cutaneous branches of the lower intercostal and lumbar nerves. Portions of the muscles of the anterior abdominal wall have been removed, including most of the anterior layer of the rectus sheath and parts of rectus abdominis.
and the lower parts of the muscle, where they anastomose with small lateral branches of the epigastric arteries. Rectus abdominis provides a reliable and versatile myocutaneous flap, either pedicled or free, because of the excellent vascularity provided by the epigastric vessels and because the muscle belly can be separated relatively easily from its surrounding sheath. The upper half of the muscle may be used for breast reconstruction, and the lower half may be transposed to the groin and upper thigh or rotated on its lower attachments and delivered into the perineum for reconstruction after radical pelvic and perineal resections.

Innervation Rectus abdominis is innervated segmentally by the terminal branches of the ventral rami of the lower six or seven thoracic spinal nerves. It may also receive a branch from the ilioinguinal nerve (Rozen et al 2008).

Actions The recti contribute to flexion of the trunk and the maintenance of abdominal wall tone required during straining.

## Rectus sheath

Rectus abdominis on each side is enclosed by a fibrous sheath (Figs 61.7-61.10). The anterior portion of this sheath extends the entire length of the muscle and fuses with periosteum and ligaments at sites of the muscle's attachments. The posterior part of the sheath is complete behind the upper two-thirds of the muscle but absent below this level, which corresponds to approximately one-third of the distance between the umbilicus and the pubis (Loukas et al 2008). The termination of the posterior rectus sheath is usually gradual but may be abrupt and marked by a clearly visible curved horizontal line known as the arcuate line (of Douglas). Below this level, rectus abdominis lies on the transversalis fascia and extraperitoneal connective tissue.

The rectus sheath is formed from the aponeuroses of all three lateral abdominal muscles: namely, external oblique, internal oblique and transversus abdominis. Each aponeurosis is bilaminar; the fibres
from all three anterior leaves run obliquely upwards, whereas the posterior leaves run obliquely downwards at right angles to the anterior leaves. Above the arcuate line, the anterior rectus sheath is composed of both leaves of the aponeurosis of external oblique and the anterior leaf of the aponeurosis of internal oblique fused together. The posterior rectus sheath is composed of the posterior leaf of the aponeurosis of internal oblique and both leaves of the aponeurosis of transversus abdominis. Thus, both the anterior and posterior layers of the rectus sheath consist of three layers of fibres with the middle layer running at right angles to the other two. At the midline, the anterior and posterior layers are closely approximated. Fibres from each layer decussate to the opposite side of the sheath, forming a continuous aponeurosis with the contralateral muscles. Fibres also decussate anteroposteriorly, crossing from the anterior sheath to the posterior sheath. The dense fibrous line caused by this decussation is called the linea alba. The external oblique, internal oblique and transversus abdominis muscles can therefore be regarded as digastric muscles with a central tendon comprising the linea alba (Rizk 1980). The decussating fibres at the linea alba can be used to identify the midline during surgical incisions. Below the arcuate line, all three aponeuroses from the oblique and transversus abdominis muscles pass into the anterior rectus sheath (see Fig. 61.7).

## Linea alba and umbilicus

The linea alba is a tendinous raphe extending from the xiphoid process to the pubic symphysis and pubic crest. It lies between the two recti and is formed by the interlacing and decussating aponeurotic fibres of external oblique, internal oblique and transversus abdominis. At its lower end, the linea alba has two attachments to the pubis: superficial fibres are attached to the pubic symphysis, and deeper fibres form a triangular lamella that is attached behind rectus abdominis to the posterior surface of both pubic crests (adminiculum lineae albae). The fundiform ligament of the penis and pyramidalis are attached to the suprapubic part of the linea alba. The linea alba is visible externally in those who

Fig. 61.6 Muscles of the left side of the trunk. External oblique has been removed to show internal oblique, but its digitations from the ribs have been preserved. The sheath of rectus abdominis has been opened and its anterior layer removed.

Fig. 61.7 Transverse sections through the anterior abdominal wall. A, Immediately above the umbilicus. B, Below the arcuate line. The bilaminar nature of each muscular aponeurosis is difficult to illustrate in cross-section. The fibres appear to fuse into a single sheet during formation of the rectus sheath. Note that rectus is supported directly by the transversalis fascia below the arcuate line.
are lean and muscular, as a shallow midline groove in the anterior abdominal wall. Its width varies along its length: it is wider above the umbilicus than below, and widest at the level of the umbilicus (Rath et al 1996). It is wider and thinner in women, in adults aged over 50 years, and in the obese and multiparous (Naraynsingh et al 2012). Its tensile strength is proportional to its thickness and density (Korenkov et al 2001). The linea alba is relatively bloodless but it is crossed superficially from side to side by a few small blood vessels.

The umbilicus is a fibrous cicatrix that lies a little below the midpoint of the linea alba, and is covered by an adherent area of skin. It
consists of skin, a fibrous layer (representing the area of fusion between the round ligament of the liver, the median umbilical ligament, and two medial umbilical ligaments), the transversalis fascia, the umbilical fascia surrounding the urachal remnant, and peritoneum (Fathi et al 2012). Its appearance and position are variable (Fathi et al 2012). In adults, it tends to lie at a relatively lower position with advancing age, in men, and in individuals with a higher body mass index.

In the fetus, the umbilicus transmits the umbilical vessels, urachus and, up to the third month of gestation, the vitelline or yolk stalk. It closes a few days after birth, but the vestiges of the vessels and urachus

Fig. 61.8 The rectus sheath. Computed tomography scan (A) and diagram (B) of the anterior abdominal wall, demonstrating the formation of the rectus sheath above the umbilicus. The anterior rectus sheath is composed of both leaves of the aponeurosis of external oblique and the anterior leaf of the aponeurosis of internal oblique, fused together. The posterior rectus sheath is composed of the posterior leaf of the aponeurosis of internal oblique and both leaves of the aponeurosis of transversus abdominis.

Fig. 61.9 The rectus sheath. Computed tomography scan (A) and diagram (B) of the anterior abdominal wall, demonstrating the formation of the rectus sheath below the umbilicus. The posterior rectus sheath is replaced by the transversalis fascia and extraperitoneal connective tissue.

Fig. 61.10 The concept of bilaminar aponeuroses of the oblique and transversus abdominis muscles. Note that the fibres of the superficial and deep laminae are approximately at right angles; decussations occur as part of the linea alba.
remain attached to its deep surface. The remnant of the embryonic left umbilical vein forms the round ligament of the liver. The obliterated umbilical arteries form the medial umbilical ligaments on the undersurface of the anterior abdominal wall and are covered by the medial umbilical folds. The partially obliterated remains of the urachus persist as the median umbilical ligament and fold. Both congenital and acquired umbilical hernias are common; most childhood umbilical hernias close spontaneously and do not require surgical repair. The umbilicus is the most common site for laparoscopic access to the peritoneal cavity.

## Divarication of the recti

Thinning and widening of the linea alba in the upper abdomen may occur, most commonly as a result of pregnancy, obesity or chronic straining (Akram and Matzen 2014). Abdominal viscera protrude beneath the thinned tissue as a broad midline bulge, particularly when intra-abdominal pressure is raised, and the recti become widely separated or divaricated. This state is not true herniation because all the layers of the abdominal wall in the region are intact.

## Pyramidalis

Attachments Pyramidalis is a triangular muscle that lies in front of the lower part of rectus abdominis within the rectus sheath. It is attached by tendinous fibres to the anterosuperior margin of the pubis and to ligamentous fibres in front of the symphysis. The muscle diminishes in size as it runs upwards, and ends in a pointed apex that is attached medially to the linea alba. This attachment often lies midway between the umbilicus and pubis, but may occur higher. The muscle varies con-
siderably in size. It may be larger on one side than on the other, sometimes absent on one or both sides, or rarely doubled.

Vascular supply Pyramidalis is supplied by branches of the inferior epigastric artery. A small artery frequently crosses the midline posterior to the belly of the muscle to anastomose with the contralateral vessel.

Innervation Pyramidalis is usually supplied by the terminal branches of the subcostal nerve, the ventral ramus of T12, but it may be innervated wholly or in part by fibres from L1 travelling in the subcostal or ilioinguinal nerves (Tokita 2006).

Actions Pyramidalis contributes to tensing the lower linea alba but is of doubtful physiological significance.

## External oblique

Attachments External oblique is the largest and most superficial of the three anterolateral abdominal muscles (Fig. 61.11). It curves around the lateral and anterior parts of the abdomen and is attached to the external surfaces and inferior borders of the lower eight ribs. The attachments rapidly become muscular and interdigitate with the lower fibres of serratus anterior and latissimus dorsi along an oblique line that extends downwards and backwards. The upper attachments are close to the cartilages of the corresponding ribs, the middle ones arise from the ribs at some distance from their cartilages, and the lowest are close to the apex of the cartilage of the twelfth rib. The fibres of external oblique diverge as they pass to their lower attachments. Those from the lower two ribs pass nearly vertically downwards and attach to the anterior half

Fig. 61.11 The left anterolateral abdominal wall muscles.
or more of the outer lip of the iliac crest. The middle and upper fibres pass downwards and forwards, and end in the anterior aponeurosis, whose fibres cross the midline (see above). The junction between muscle and aponeurosis extends along a vertical line from the ninth costal cartilage to just below the level of the umbilicus; muscle fibres do not usually descend beyond a line from the anterior superior iliac spine to the umbilicus. External oblique has a free posterior border.

The inguinal ligament is formed by the inferior margin of the aponeurosis of external oblique extending between the anterior superior iliac spine and the pubic tubercle. The fibres of the aponeurosis of external oblique are not parallel to the long axis of the inguinal ligament; they approach the ligament obliquely at an angle of $10-20^{\circ}$ and then turn medially to run along the ligament to reach the pubic tubercle (Lytle 1974). The deepest fibres of the aponeurosis spread out posteromedially to insert into the pectineal line.

The upper and lower rib attachments of the muscle may be absent. Digitations or even the entire muscle may be duplicated. The upper attachments of the muscle are sometimes continuous with pectoralis major or serratus anterior.

Vascular supply External oblique is mainly supplied by branches from the lower posterior intercostal and subcostal arteries above and the deep circumflex iliac artery below. There are additional smaller contributions (Schlenz et al 1999).

Innervation External oblique is innervated by the terminal branches of the lower five intercostal nerves and the subcostal nerve from the ventral rami of the lower six thoracic spinal nerves.

Actions External oblique contributes to the maintenance of abdominal tone, increasing intra-abdominal pressure, and lateral flexion of the trunk against resistance.

## Inguinal ligament

The inguinal ligament is the thick lower border of the aponeurosis of external oblique that stretches between the anterior superior iliac spine and the pubic tubercle. Its medial half is curled in on itself, forming the gutter-like 'floor' of the inguinal canal. The ligament is not exactly linear but has an inferior and an anterior convexity. At its lower border, it is fused with the fascia lata. Laterally, it is fused with the iliopsoas fascia (Lytle 1974). At the medial end of the inguinal ligament, near its site of attachment to the pubic tubercle, some of its fibres extend posteriorly and laterally to attach to the pectineal line, forming the triangular, shelf-like lacunar ligament. Other fibres pass upwards and medially behind the superficial inguinal ring and external oblique aponeurosis to join the rectus sheath and linea alba; these constitute the reflected part of the inguinal ligament (Tubbs et al 2009). Fibres from both sides decussate in the linea alba.

## Internal oblique

Attachments Internal oblique lies deep to external oblique for most of its course (see Fig. 61.6). It is thinner and less bulky than external oblique. Its fibres are traditionally stated to arise from the lateral twothirds of the inguinal ligament but, in fact, arise from the corresponding length of a slightly deeper structure known as the iliopectineal arch (Acland 2008), a thickened band of iliopsoas fascia that passes downwards and medially from the anterior superior iliac spine to the iliopectineal eminence of the hip bone. Further laterally, internal oblique is attached to the anterior two-thirds of the iliac crest deep to the attachment of external oblique. Posteriorly, some fibres are attached to the thoracolumbar fascia. The fibres originating from the posterior end of the iliac attachment pass obliquely upwards and are attached to the inferior borders and tips of the lower three or four ribs and their cartilages. Here, the attachments merge with those of the internal intercostal muscles. The uppermost fibres form a short, free superior border. The fibres from the anterior end of the iliac crest diverge and end in the anterior aponeurosis, which gradually broadens from below upwards. The uppermost part of the aponeurosis is attached to the cartilages of the seventh, eighth and ninth ribs. The fibres that originate adjacent to the inguinal ligament arch downwards and medially across the spermatic cord in the male and the round ligament of the uterus in the female. They become tendinous, fuse with the corresponding part of the aponeurosis of transversus abdominis, and attach to the pubic crest and medial part of the pectineal line, forming the conjoint tendon.

Vascular supply Internal oblique is mainly supplied by branches from the lower posterior intercostal and subcostal arteries, the inferior epigastric artery, and the deep circumflex iliac artery. There are several smaller contributions (Yang et al 2003).

Innervation Internal oblique is innervated by the terminal branches of the lower five intercostal nerves and the subcostal nerve from the ventral rami of the lower six thoracic spinal nerves. In addition, it receives a small contribution from the iliohypogastric and ilioinguinal nerves derived from the ventral ramus of the first lumbar spinal nerve.

Actions Internal oblique contributes to the maintenance of abdominal tone, increasing intra-abdominal pressure, and lateral flexion of the trunk against resistance.

## Transversus abdominis

Attachments Transversus abdominis is the deepest of the anterolateral abdominal muscles (Fig. 61.12). It is attached to the iliopectineal arch deep to the lateral third of the inguinal ligament, the anterior twothirds of the inner lip of the anterior segment of the iliac crest, the thoracolumbar fascia between the iliac crest and the twelfth rib, and the internal aspects of the lower six costal cartilages. The costal attachments interdigitate with those of the diaphragm. The muscle ends anteriorly in an aponeurosis; the lower fibres of the aponeurosis curve downwards and medially, together with those of the aponeurosis of internal oblique, and insert into the pubic crest and pectineal line to form the conjoint tendon. A few muscle fibres may run from the lower border of transversus abdominis to the inguinal ligament and reinforce the interfoveolar ligament (see above). The remainder of the aponeurosis passes medially and the fibres decussate at, and blend with, the linea alba. The upper costal and anterior iliac fibres of transversus abdominis are short and the thoracolumbar fibres are the longest. Near the xiphoid process, the aponeurosis is formed only a few centimetres from the linea alba and so the muscular part of transversus abdominis extends behind rectus abdominis into the posterior layer of the rectus sheath. The medial edge of the muscle, at the origin of the aponeurosis, curves downwards and laterally, and is furthest from the lateral edge of the rectus sheath at the level of the umbilicus. It then curves downwards and medially towards the superficial inguinal ring.

Occasional defects may occur in the lower muscular and aponeurotic parts of both internal oblique and transversus abdominis. The two muscles are sometimes fused and, rarely, transversus abdominis may be absent.

Vascular supply Transversus abdominis is supplied by branches from the lower posterior intercostal and subcostal arteries, the superior and inferior epigastric arteries, the superficial and deep circumflex iliac arteries and the posterior lumbar arteries.

Innervation Transversus abdominis is innervated by the terminal branches of the lower five intercostal nerves, the subcostal nerve and the iliohypogastric and ilioinguinal nerves. These arise from the ventral rami of the lower six thoracic and first lumbar spinal nerves.

Actions Transversus abdominis contributes mainly to the maintenance of abdominal tone and increasing intra-abdominal pressure.

## Conjoint tendon

The conjoint tendon is formed from the lower fibres of internal oblique and the lower part of the aponeurosis of transversus abdominis. It is attached to the pubic crest and extends to a variable extent along the pectineal line (see Fig. 61.16). It descends behind the superficial inguinal ring and acts to strengthen the medial portion of the posterior wall of the inguinal canal. Medially, the upper fibres of the tendon fuse with the anterior wall of the rectus sheath, and laterally, some fibres may blend with the interfoveolar ligament.

## Cremaster

Attachments Cremaster consists of loosely arranged muscle fasciculi lying along the spermatic cord or round ligament of the uterus. It is variable in thickness but thickest in young men. Together with connective tissue, it forms an incomplete coating around the spermatic cord, known as the cremasteric fascia, which extends down around the testis deep to the external spermatic fascia. The muscle consists of a lateral part that arises mainly from the inferomedial border of internal oblique and transversus abdominis but also has attachments to the middle of the inguinal ligament, and a medial part attached to the pubic tubercle, lateral pubic crest and the lower border of transversus abdominis; this part is variably developed, and may be absent (Shafik 1977). The longitudinal muscle fibres spread out over the spermatic cord as it approaches the superficial inguinal ring. Cremaster is composed of both striated and smooth muscle fibre bundles (Kayalioglu et al 2008).
Vascular supply Cremaster is supplied by the cremasteric artery, a branch of the inferior epigastric artery.

Fig. 61.12 The left transversus abdominis. The aponeurosis of transversus abdominis fuses into the posterior layer of the rectus sheath above the arcuate line. The position of the lateral border of rectus abdominis is shown by the dotted white line.

Innervation Cremaster is innervated by the genital branch of the genitofemoral nerve, derived from the first and second lumbar spinal nerves.

Actions Cremaster pulls the testis up towards the superficial inguinal ring. Although it contains striated muscle fibres, it is not usually under voluntary control. Stroking the skin of the medial side of the thigh evokes a reflex contraction of the muscle, the cremasteric reflex, which is most pronounced in boys. It may represent a protective reflex. The cremaster may also have a role in testicular thermoregulation since it is activated by the cold.

## Inguinal canal

The inguinal canal is a natural passageway between the muscle layers of the anterior abdominal wall in the region of the groin (Figs 61.1361.15; see Figs 76.15, 76.16). Its size and form vary with age, and although it is present in both sexes, it is best developed in the male. The canal is an oblique tunnel, with deep (internal) and superficial (external) openings or rings. It transmits the spermatic cord in males, the round ligament of the uterus in females, and the ilioinguinal nerve in both sexes.

## Superficial inguinal ring

The superficial inguinal ring is a hiatus in the aponeurosis of external oblique, just above and lateral to the crest of the pubis. The ring is actually triangular, with its apex pointing laterally towards the anterior superior iliac spine. Although it varies in size, it does not usually extend laterally beyond the medial third of the inguinal ligament. The ring is smaller in the female. The base of the triangular opening lies along the crest of the pubis. Its sides are the lateral and medial crura of the opening in the aponeurosis. The lateral crus is stronger and is attached to the pubic tubercle. The medial crus is thinner and its fibres attach to the front of the pubic symphysis and interlace with those from the opposite side. A few intercrural fibres arch above the apex of the superficial inguinal ring (see Fig. 61.13). Some fibres from the external

Fig. 61.13 Superficial structures of the inguinal region and lower part of the anterior abdominal wall on the left side.

Fig. 61.14 Dissection of the regions shown in Figure 61.13, with part of external oblique removed.

Fig. 61.15 Dissection of the inguinal region and lower part of the anterior abdominal wall on the left side, with parts of external and internal oblique muscles removed.
oblique aponeurosis and its overlying fascia continue downwards from the crura of the ring over the spermatic cord, and form the delicate external spermatic fascia; consequently, the 'ring' appears less of a discrete opening in the living.

## Deep inguinal ring

The deep inguinal ring is an opening in the transversalis fascia, approximately midway between the anterior superior iliac spine and the pubic symphysis, and about 1 cm above the inguinal ligament (Hale et al 2010). It is oval, with a roughly vertical long axis. Its size varies between individuals but it is usually $1-2 \mathrm{~cm}$ wide in adults and larger in the male. It is related above to the arched lower margin of transversus abdominis and medially to the interfoveolar ligament (see Fig. 61.16). The inferior epigastric vessels run in the medial border of the deep inguinal ring. Traction on the fascial ring exerted by contraction of internal oblique may narrow the opening when intra-abdominal pressure is increased.

Fig. 61.16 Deep structures of the inguinal canal. The aponeurosis of external oblique has been removed. For clarity, the fibres of internal oblique and rectus abdominis have been divided, and the structures passing posteroinferiorly to the inguinal ligament have been excluded.

## Boundaries

The inguinal canal slants obliquely downwards and medially, parallel to and just above the medial part of the inguinal ligament. It extends from the deep to the superficial inguinal rings; the length depends on the age of the individual, but in the adult is between 3 and 6 cm long. The canal is bounded anteriorly by skin, superficial fascia and the aponeurosis of external oblique. In its lateral third, the anterior wall is reinforced by the muscular fibres of the internal oblique just above their origin from the iliopectineal arch. Posteriorly lie the reflected inguinal ligament, the conjoint tendon and the transversalis fascia, which separate it from extraperitoneal connective tissue and peritoneum. Superiorly lie the arched fibres of internal oblique and transversus abdominis, forming the conjoint tendon medially. Inferiorly is the union of the transversalis fascia with the inguinal ligament and, at the medial end, the lacunar ligament.

In the newborn, the deep and superficial rings are nearly superimposed and the canal is extremely short. In infants undergoing inguinal hernia repair, the canal is only about 1 cm long (Parnis et al 1997). As a child grows, the anterior abdominal wall muscles develop further, causing the positions of the rings to separate and the canal to lengthen. The canal becomes progressively more oblique so that, by adulthood, it has separate anterior and posterior walls, creating a 'shutter' effect. At the superficial ring and medial end of the anterior wall, where the canal is weakest, the posterior wall is strengthened by the conjoint tendon and reflected inguinal ligament. Increases in intra-abdominal pressure transmitted to the posterior wall of the canal are resisted by contraction of the three anterolateral abdominal wall muscles. The fibres of internal oblique and transversus abdominis, which form the conjoint tendon, are constantly active in standing; this activity increases during episodes of increased intra-abdominal pressure.

## Relations

The inferior epigastric vessels are important medial relations of the deep inguinal ring (Fig. 61.16). They lie on the transversalis fascia as they ascend obliquely behind the conjoint tendon to enter the rectus sheath. The inguinal triangle (of Hesselbach) is an important clinical landmark
related to the posterior wall of the inguinal canal and is best appreciated by examining the inguinal canal region from within the abdomen (see Fig. 61.3). The triangle is bounded inferiorly by the medial third of the inguinal ligament, medially by the lower lateral border of rectus abdominis, and laterally by the inferior epigastric vessels.

## Lacunar ligament

The lacunar ligament is a triangular band of fibrous tissue lying mainly posterior to the medial end of the inguinal ligament. It measures approximately 2 cm from base to apex and is a little larger in the male. It is formed from fibres of the medial end of the inguinal ligament together with fibres from the fascia lata of the thigh, which join the medial end of the inguinal ligament from below (Lytle 1974). The inguinal fibres run posteriorly and laterally to the medial end of the pectineal line and are continuous with the pectineal fascia. They form a near-horizontal, triangular sheet with a curved lateral border, which forms the medial border of the femoral canal. The apex of the triangle is attached to the pubic tubercle. A strong fibrous band, the pectineal ligament, extends laterally along the pectineal line from the pectineal attachment of the lacunar ligament (Faure et al 2001).

## HERNIAS OF THE ANTERIOR ABDOMINAL WALL

A wide range of anterior abdominal wall hernias are described. These include inguinal, umbilical, incisional, para-umbilical, femoral, and rarer types such as Spigelian hernias (Larson and Farley 2002; Dabbas et al 2011).

## INGUINAL HERNIA

Although the inguinal canal is arranged such that the weaknesses in the anterior abdominal wall caused by the deep and superficial inguinal rings are supported, the region is a common site of herniation, particularly in males. An inguinal hernia involves the protrusion of a viscus through the tissues of the inguinal region of the abdominal wall.

## Indirect inguinal hernia

An indirect inguinal hernia arises through the deep inguinal ring lateral to the inferior epigastric vessels. Many indirect hernias are related to the abnormal persistence of a patent processus vaginalis, a tube-like extension of peritoneum through the inguinal canal that is present during normal development and normally becomes occluded after birth (p. 1215). Others are acquired as a result of progressive weakening of the posterior wall of the inguinal canal in the region of the deep inguinal ring. The hernia may pass through the deep ring or may expand the deep ring such that it is no longer a clear entity. Small indirect hernias lie below and lateral to the fibres of the conjoint tendon, but larger hernias often distort and thin the tendon superiorly. Small indirect hernias that do not protrude beyond the inguinal canal are covered by the same inner layers as the spermatic cord: namely, the internal spermatic fascia and cremaster. If the hernia extends through the superficial inguinal ring, it is also covered by external spermatic fascia. In hernias related to a persistent fully patent processus vaginalis, the hernia contents may descend as far as the tunica vaginalis anterior to the testis. In many individuals with a partial or fully patent processus vaginalis, an indirect hernia will manifest in childhood, but in others, an actual hernia into the potential sac may not develop until adult life, often as a consequence of increased intra-abdominal pressure or sudden muscular strain.

## Direct inguinal hernia

A direct inguinal hernia arises medial to the inferior epigastric vessels. Direct hernias are always caused by an acquired weakness of the posterior wall of the inguinal canal (see Fig. 61.3B); as they enlarge, they frequently extend through the anterior wall of the inguinal canal or superficial inguinal ring, becoming covered by external spermatic fascia in the process. A direct inguinal hernia may closely resemble an indirect hernia and can be difficult to distinguish on clinical examination.

## Clinical features of inguinal hernias

Indirect inguinal hernias often descend from lateral to medial, following the path of the inguinal canal, whereas direct inguinal hernias tend to protrude more directly anteriorly. With the hernia reduced, pressure applied over the region of the deep inguinal ring may prevent the appearance of an indirect hernia on standing or straining, but distinguishing an indirect from a direct inguinal hernia by clinical examination alone is not reliable (Ralphs et al 1980, Tromp et al 2014). Direct hernias are more likely to have a wide neck, making strangulation less likely.

## UMBILICAL HERNIA

The most extreme variety of umbilical hernia is known as an omphalocele or exomphalos, a congenital malformation in which abdominal viscera, covered by a membrane, protrude through a wide umbilical defect (Fig. 61.17). The defect arises from a failure of closure of the umbilical ring after return of the herniated midgut loop in the embryo. The most common variety of umbilical hernia is caused by a weakness of the umbilical scar tissue, and is often seen in babies, especially those of African descent. The vast majority of these will close spontaneously during early childhood. Most umbilical hernias in adults are acquired as a result of stretching of the supporting umbilical fascia and are due to obesity and chronically increased intra-abdominal pressure (e.g. from multiple pregnancies or ascites).

## FEMORAL HERNIA

The femoral sheath is continuous with the transversalis fascia anteriorly and the iliopsoas fascia posteriorly (p. 1338). The medial compartment of the sheath is the femoral canal, which typically contains lymphatics embedded in loose adipose connective tissue. The opening of the canal is the femoral ring, bounded anteriorly by the inguinal ligament, posteriorly by the pectineal ligament, medially by the crescentic lateral margin of the lacunar ligament and laterally by the femoral vein. A femoral hernia protrudes through the femoral ring, which is normally closed by a femoral septum of extraperitoneal tissue, and is therefore a site of potential weakness. In females, the ring is relatively wider and changes during pregnancy, which helps to explain why femoral hernias account for about $20 \%$ of all groin hernias in women but less than $1 \%$ of groin hernias in men (Whalen et al 2011). The ring also widens with advancing age. Variations in the attachment of the pectineal part of the lacunar ligament may also be a factor.

When a tongue of omentum or a loop of intestine bulges through the ring, it pushes out a hernial sac of peritoneum that is covered by extraperitoneal tissue (the femoral septum) and descends within the femoral canal to the saphenous opening. It is prevented from descending further by the configuration of the femoral sheath and by the attachment of fascia to the inferior rim of the saphenous opening. The hernial sac hence turns forwards, stretching the cribriform fascia and curving upwards over the inguinal ligament within the subcutaneous tissues. While in the canal, the hernia is usually small because it is contained by the surrounding tissues, but it enlarges as it expands into the subcutaneous tissues.

The small size of some femoral hernias explains why they can be easily missed on examination, particularly in the obese. They are also much more prone to strangulation than inguinal hernias (Whalen et al 2011). The site of strangulation varies: it may be at the neck of the hernial sac, or at the saphenous opening, but is most often at the junction of the falciform margin of the saphenous opening with the free edge of the pectineal part of the inguinal ligament. When the lacunar ligament is being divided to release the neck of the hernia, care must be taken to avoid or control an aberrant obturator artery (see above).

The pubic tubercle can be a useful landmark when attempting to distinguish an inguinal from a femoral hernia; a femoral hernia lies below and lateral to this landmark, whilst an inguinal hernia is above. However, clinical differentiation of groin hernias can be relatively unreliable (Hair et al 2001), prompting the use of imaging in suspected cases (Whalen et al 2011).

## SPIGELIAN HERNIA

A Spigelian hernia is a protrusion of preperitoneal fat or a peritoneal sac through a congenital or acquired defect in the abdominal wall in

The goal of repairing massive ventral hernias lies in reapproximation of the rectus sheath，thereby restoring anatomy and maximizing the physiological potential of the abdominal wall．However，large fascial defects often will not permit primary reapproximation without undue tension．Many techniques have been developed that utilize the layered nature of the abdominal wall musculature，allowing additional mobi－ lization of the fascial edges by＇releasing＇incisions in myofascial layers （Rosen 2011）．This section reviews some of the more common tech－ niques．These repairs are often reinforced with synthetic or biopros－ thetic mesh applied in various ways：onlay（superficial to the fascia）， sublay（within the myofascial layers）or underlay（beneath the fascia and exposed to intraperitoneal contents）．

The Ramirez technique，originally described in 1990，refers to bilat－ eral release of the external oblique muscles，which can potentially provide up to $10 \mathrm{~cm}, 20 \mathrm{~cm}$ and 8 cm of medial mobilization at the upper，mid and lower abdomen，respectively（Ramirez et al 1990）．A disadvantage of this technique is that，in order to access and isolate the external oblique muscles lateral to the linea semilunaris from a midline incision，large subcutaneous flaps must be raised．This process neces－ sitates ligation of perforating vessels that supply the overlying subcuta－ neous tissue，rendering the flaps vulnerable to ischaemia，necrosis and infection．In an attempt to overcome this limitation，an endoscopic technique was developed to access the same myofascial layer through smaller，lateral incisions．This technique obviates the need for large subcutaneous flaps，a compromised blood supply，and the creation of a large dead space for potential seroma formation．While reducing the likelihood of wound necrosis and infection，the endoscopic technique also reduces the maximum medial advancement by $1-2 \mathrm{~cm}$ on each side．When release of the external oblique layer is insufficient，an addi－ tional $2-4 \mathrm{~cm}$ of fascial advancement can be gained by simultaneous release of the posterior rectus sheath．

Often，the posterior rectus sheath can be incised independently of external oblique release，allowing access to the retromuscular space and providing several other options for medial advancement．The tradi－ tional Rives－Stoppa－Wantz technique，developed in the 1970s，involves incising the posterior rectus sheath just lateral to the linea alba，allow－ ing a retromuscular dissection to the lateral edge of the rectus sheath． If this does not gain sufficient medial advancement，further extension can be obtained by release of transversus abdominis（Novitsky et al 2012）．The posterior rectus sheath can be incised again $1-2 \mathrm{~cm}$ medial to the linea semilunaris，safely preserving the laterally perforating neu－ rovascular bundles．This release exposes the underlying transversus abdominis．Delicate transection of this muscle at its most medial inser－ tion allows access to a plane beneath transversus abdominis and super－ ficial to the transversalis fascia，preperitoneal fat and peritoneum．This plane of dissection can be extended laterally to psoas major，inferiorly to the space of Retzius，and superiorly beneath the diaphragm．The same preperitoneal plane can be entered directly at the linea alba and allows for lateral dissection，but does not provide the benefit of any fascial advancement／release．

In addition to the medial mobilization of fascia aided by myofascial flaps and component separations，these myofascial planes allow for mesh reinforcement with extensive overlap without exposure to intra－ peritoneal contents（Heller et al 2012）．

Fig．61．17 A，A neonatal exomphalos．B，A persistent umbilical hernia in a child．（A，B，Courtesy of Professor Mark Stringer．）
the region of the intersection of the linea semilunaris with the arcuate line (Skandalakis et al 2006, Larson and Farley 2002). Below this level, the aponeuroses of external and internal oblique and transversus abdominis pass anterior to rectus abdominis and the posterior rectus sheath ends. A Spigelian hernia is an interstitial hernia in that the hernia passes through a defect in the transversus and internal oblique aponeuroses but remains deep to the overlying external oblique aponeurosis. It is frequently associated with diagnostic delay.

## INCISIONAL HERNIA

Incisional hernias now comprise as many as $20 \%$ of all anterior abdominal wall hernias. This complication of abdominal laparotomy incisions is due to technical failures, wound infection, and patient-related factors such as obesity, medical comorbidities and old age (Carlson et al
1995). There is currently little consensus among surgeons as to the optimum method of repairing a large incisional hernia and numerous techniques are described (Cassar and Munro 2002). Needless to say, an understanding of abdominal wall anatomy is paramount to providing a durable repair without compromising physiological function.

Saber AA, Meslemani AM, Davis R et al 2004 Safety zones for anterior abdominal wall entry during laparoscopy: a CT scan mapping of epigastric vessels. Ann Surg 239:182-5.
Trauma to abdominal wall blood vessels occurs in 0.2-2\% of laparoscopic procedures. Both superficial and deep abdominal wall vessels are at risk. The superficial vessels may be located by transillumination; however, the deep epigastric vessels cannot be effectively located by transillumination and, thus, other techniques should be used to minimize the risk of injury to these vessels. This study utilizes CT scans to map the pathway of the epigastric vessels.

Skandalakis PN, Zoras O, Skandalakis JE et al 2006 Spigelian hernia: surgical anatomy, embryology, and technique of repair. Am Surg 72:42-8. An account of Spigelian hernia ( $1-2 \%$ of all hernias), the protrusion of preperitoneal fat, peritoneal sac or organ(s) through a congenital or acquired defect in the Spigelian aponeurosis (i.e. the aponeurosis of the transverse abdominal muscle limited by the linea semilunaris laterally and the lateral edge of the rectus muscle medially). Mostly, these hernias lie in the 'Spigelian hernia belt', a transverse 6 cm -wide zone above the interspinal plane; lower hernias are rare and should be differentiated from direct inguinal or supravescical hernias. Although named after Adriaan van der Spieghel, the semilunar line (linea Spigeli) was only described by Spieghel in 1645. Josef Klinkosch first defined the Spigelian hernia as a defect in the semilunar line in 1764. Defects in the aponeurosis of transverse abdominal muscle (mainly under the arcuate line and more often in obese individuals) have been considered as the principal aetiological factor.

# Posterior abdominal wall and retroperitoneum 

## DEFINITIONS, BOUNDARIES AND CONTENTS

The posterior abdominal wall does not have an agreed uniform definition. It represents the posterior boundary of the abdominal cavity. In common with the anterior and lateral abdominal walls, it is composed of several layers (skin, superficial fascia, muscle, extraperitoneal fat/ fascia and parietal peritoneum). The vertebral column and paravertebral muscles of the back are part of the posterior abdominal wall, but are usually not considered in this context. The posterior abdominal wall is continuous with the posterior thoracic wall at the posterior attachment of the diaphragm, with the posterior wall of the pelvis inferiorly, and with the anterolateral abdominal wall laterally.

The retroperitoneum is a three-dimensional compartment bounded anteriorly by the parietal peritoneum of the posterior abdominal wall and superiorly by the diaphragm. Inferiorly and laterally, it is continuous with the extraperitoneal connective tissues lining the pelvis and anterolateral abdominal wall, respectively. The posterior boundary of the retroperitoneum is variably defined, depending on whether the psoas muscles and quadratus lumborum are regarded as contents or boundaries of this compartment.

The posterior abdominal wall and the retroperitoneum are related but different concepts. The retroperitoneum is a compartment and a three-dimensional space, a concept invoked when localization, spread and containment of disease are primary considerations. The posterior abdominal wall is a part of the parietal coverings of abdominal viscera, a concept invoked when considering posteriorly directed surgery from within the abdomen, posterolateral access to retroperitoneal organs (e.g. nephrectomy or percutaneous endoscopic renal access), or else in contradistinction to the anterior abdominal wall. Advances in crosssectional imaging have promoted a better understanding of the anatomy of the retroperitoneum, particularly its compartmental anatomy, and with it the retroperitoneum has become the more prevalent clinical concept outside of specific surgical circumstances.

The retroperitoneum houses the paired viscera originating from the embryonic extracoelomic space: the kidneys and ureters (Ch. 74), and the suprarenal glands (Ch. 71) and their vessels and nerves. It also houses the unpaired derivatives of the embryonic intracoelomic gut tube secondarily retroperitonealized: the duodenum (Ch. 65), the pancreas (Ch. 69), and the ascending and descending colon (Ch. 66) and their vessels and nerves.

Attached to the retroperitoneum are the mesenteries of the small bowel (Ch. 65), transverse and sigmoid colons (Ch. 66), and the peritoneal ligaments of the liver (Ch. 67) and spleen (Ch. 70).

The retroperitoneum contains the abdominal aorta and branches; the inferior vena cava and tributaries; the origins of the azygos and hemiazygos veins; the pre- and para-aortic (lumbar) lymph nodes, cisterna chyli and the origin of the thoracic duct (Ch. 56); the diaphragmatic crura (Ch. 55); the lumbar plexus and lumbosacral trunk; and the autonomic plexuses of the abdomen (Ch. 59).

## SKIN AND SOFT TISSUES

The skin of the posterior abdominal wall is supplied by musculocutaneous branches of the lumbar arteries and veins, and innervated by the dorsal rami of the lower thoracic and lumbar spinal nerves. However, the cutaneous distribution of the dorsal rami of L4 and L5 is variable and controversial (Lee et al 2008).

In the muscular posterior abdominal wall, intermuscular fascial layers delineate compartments and provide the conceptual anatomical framework. In the retroperitoneum, the compartments (the clinical synonym is 'spaces') and their interrelationships provide the conceptual framework, particularly in cross-sectional anatomy, with the dividing fasciae often hard to visualize unless outlined by disease processes.

## THORACOLUMBAR FASCIA

The thoracolumbar fascia is composed of a complex arrangement of multiple fascial layers that is most prominent at the caudal end of the lumbar spine (Ch. 43) (Willard et al 2012). In the lumbar region, it is often described as having three layers (Figs 62.1-62.3, see Fig. 43.6). The posterior layer is attached medially to the spines of the lumbar vertebrae and to the supraspinous ligament; it has a superficial lamina (the aponeurosis of latissimus dorsi) and a deep lamina that covers the posterior surface of the paraspinal muscles. The middle layer is attached medially to the tips of the transverse processes of the lumbar vertebrae and extends laterally behind quadratus lumborum; inferiorly, it attaches to the iliac crest, and superiorly to the lower border of the twelfth rib. The anterior layer covers the anterior surface of quadratus lumborum and is attached medially to the transverse processes of the lumbar vertebrae behind psoas major. Laterally, it fuses with the transversalis fascia and the aponeurosis of transversus abdominis. Inferiorly, it is attached to the iliolumbar ligament and adjoining iliac crest. Superiorly, it is attached to the inferior border of the twelfth rib and extends to the transverse process of the first lumbar vertebra, forming the lateral arcuate ligament of the diaphragm. The posterior and middle layers of the thoracolumbar fascia fuse at the lateral margin of the paraspinal muscles (the so-called 'lateral raphe'), thereby enclosing the paraspinal muscles in an osteofascial compartment. Although contained in layers of thoracolumbar fascia, the paraspinal muscles are conceptualized as part of 'the back'. The aponeurosis of transversus abdominis fuses with both the anterior layer of thoracolumbar fascia at the lateral margin of quadratus lumborum and with the lateral raphe behind quadratus lumborum.

## ILIOPSOAS FASCIA

## Psoas fascia

A relatively dense layer of fascia covers the anterior surface of psoas major. Medially, it is continuous with the attachments of the muscle to the transverse processes and bodies of the lumbar vertebrae and the tendinous arches. Laterally, the fascia blends with the fascia over quadratus lumborum above and is continuous with the iliac fascia below. Superiorly, the fascia merges with the medial arcuate ligament, while, inferiorly, it extends down into the thigh around the iliopsoas tendon. The psoas fascia separates the anterior surface of the muscle and the lumbar plexus within it from the retroperitoneal structures lying anteriorly. A psoas abscess, which can arise by haematogenous seeding or from direct extension of infection from adjacent structures (e.g. the spine, kidneys or colon), often tracks along the muscle within the fascia, and, rarely, may 'point' in the groin.

## lliac fascia

The iliac fascia overlies iliacus. Superiorly and laterally, it is attached to the inner aspect of the iliac crest, and medially it blends with the anterior layer of thoracolumbar fascia over quadratus lumborum and with the psoas fascia. Inferiorly and laterally, it continues into the thigh to fuse with the femoral sheath, while medially, it is attached to the periosteum of the ilium and iliopubic eminence at the pelvic brim. Both the femoral nerve and lateral femoral cutaneous nerve lie under the iliac fascia in the pelvis, where they can be targeted for image-guided nerve blocks (Hebbard et al 2011).

## VISCERAL FASCIAE

The organization of the retroperitoneum is most easily conceptualized in terms of compartments (synonym: spaces) rather than fasciae (Dodds

Fig. 62.1 Compartments and fasciae of the upper retroperitoneum (left side). A transverse section at approximately the level of the first lumbar vertebra, showing the location and relations of the peripancreatic space.

Fig. 62.2 Compartments and fasciae of the mid-retroperitoneum (left side). A transverse section at approximately the level of the third lumbar vertebra, showing the location and relations of the perirenal space.
et al 1986). The fasciae bounding the compartments limit or direct the spread of blood, fluid, gas or malignant disease, but are variable and often difficult to see with cross-sectional imaging.

The fascial layers located between the posterior parietal peritoneum and the quadratus lumborum have been described in confusing eponymous terms in the literature. Different authors have used the same

Fig. 62.3 Compartments and fasciae of the lower retroperitoneum (left side). A transverse section at approximately the L4 vertebral level, showing the location and relations of the pericolic space.
eponym for different fasciae; different eponyms have been used to refer to the same fascia. Thus, 'Gerota's fascia' has been used to refer to the entire perirenal fascia or to its anterior or posterior layers (Chesbrough et al 1989). 'Toldt's fascia' has been used to refer to the fusion fascia behind the ascending or descending colon (Culligan et al 2013), or to the posterior perirenal fascia, or to the fusion fascia behind the tail of the pancreas (Kimura et al 2010). 'Zuckerkandl's fascia' has been used to refer to the posterior or anterior perirenal fascia (Chesbrough et al 1989). 'Treitz's fascia' has been used to refer to the fusion fascia behind the head of the pancreas (Kimura et al 2010).

The concept of 'fusion fascia' describes a retroperitoneal fascia formed by the fusion of an embryonic mesentery with embryonic retroperitoneum. It is an avascular layer that allows a dissection plane to be developed, and also limits the spread of disease. The retropancreaticoduodenal fascia and the retrocolic/retromesocolic fascia (right and left) are fusion fascias, and delimit their respective compartments. They were first described in detail by the Austrian anatomist Carl Toldt, and only later reported in the English literature (Congdon et al 1942).

Traditional compartmental anatomy of the retroperitoneum divides it into the anterior and posterior pararenal spaces, and the perirenal space. 'Anterior pararenal space' describes the compartment between the posterior peritoneum and the anterior perirenal fascia. This is an oversimplification and is unable to explain all patterns of disease containment or spread. The smallest set of compartments sufficient to explain most such phenomena is as follows.

## Perirenal space

The paired perirenal space is bounded by the perirenal fascia, which envelops the kidney and suprarenal gland on each side. Perirenal fascia is traditionally described as having anterior and posterior layers, which are continuous with each other laterally (see Figs 62.1-62.3; Ch. 74). The perirenal fascia can usually be identified on cross-sectional imaging as a thin layer surrounding the kidney and suprarenal gland, separated from the renal capsule by a variable amount of perirenal fat. Inferiorly, the perirenal space continues down around the ureter but becomes progressively narrower and may or may not extend into the pelvic retroperitoneum. Medially, the two perirenal spaces may interconnect anterior to the aorta and inferior vena cava (Kneeland et al 1987). The existence of a fascial partition separating the kidney and ipsilateral suprarenal gland within the perirenal fascial envelope is controversial (Amin et al 1976).

## Anterior and posterior pararenal spaces

The anterior pararenal space (an oversimplification) refers to the region between the anterior layer of perirenal fascia and the posterior parietal peritoneum; it is not a single compartment. On the right, it contains the second part of the duodenum, ascending colon and its mesentery, and on the left, the fourth part of the duodenum, descending colon and its mesentery (see Figs 62.1-62.3).

The potential compartment between the posterior layer of perirenal fascia and the thoracolumbar and psoas fasciae on each side is the posterior pararenal space. It contains a variable amount of fat. Laterally, it is continuous with the extraperitoneal (properitoneal) fat of the anterolateral abdominal wall, and inferiorly, with the retroperitoneal fat overlying iliacus and the pelvic wall, and the perivesical fat (Coffin et al 2015).

When the ascending or descending colon is retrorenal (an anatomical variant), the colon and pericolic space lie in a groove between the posterior layer of perirenal fascia and the posterior pararenal space.

## Peripancreatic space

The peripancreatic space contains the duodenum and pancreas along with the origins of the superior mesenteric vessels and the retroperitoneal segments of the common bile duct, portal vein and hepatic artery. The posterior boundary is a fusion fascia formed by fusion of the embryonic duodenal mesentery to the embryonic retroperitoneum (Dodds et al 1986). This fascia is termed 'retropancreatic' or 'retropancreaticoduodenal' fascia in the imaging literature, and 'fusion fascia of Treitz' in the surgical literature (Kimura et al 2010). The fascia forms a relatively bloodless dissection plane, used to mobilize the duodenum and head of the pancreas.

The lateral extent of the peripancreatic space is variable; it lies posterior to the ascending and descending colon and anterior to the perirenal space (see Fig. 62.1). At the tail of the pancreas, the peripancreatic space lies in continuity with the splenorenal ligament. Anteriorly, it is in continuity with the transverse mesocolon and small bowel mesentery. Consequently, peripancreatic fluid collections may extend into both mesenteries and extend posterior to the ascending and descending colon but do not usually cross into the perirenal and pericolic spaces.

## Pericolic spaces

The ascending and descending pericolic spaces are narrow compartments surrounding the respective parts of the colon and in continuity
medially with the mesocolon (see Figs 62.1-62.3). The pericolic spaces contain a variable amount of fat and are limited anteriorly, superiorly and laterally by the colonic serosa. Inferiorly, the pericolic spaces are continuous with the retroperitoneal spaces of the iliac fossae. Posteriorly, each pericolic space is limited by a fusion fascia formed by the right leaf of the embryonic mesocolon fusing to the left leaf of the embryonic duodenal mesentery and embryonic retroperitoneum further laterally. This retrocolic fascia (of Toldt) (Culligan et al 2013, Culligan et al 2014) forms the classic bloodless plane of dissection when performing a hemicolectomy. Its plane is entered by incising the junction of the colonic serosa with the parietal peritoneum at the white line (of Toldt) in the paracolic gutter. Radiologically, the retrocolic fascia may be indistinguishable from the anterior perirenal fascia when lateral to the duodenum and pancreas.

Variation in colonic retroperitonealization may produce a free mesocolic pedicle instead (most commonly seen at the caecum).

## Lateroconal fascia

Lateroconal fascia was originally defined as the fascial layer extending from the junction of the anterior and posterior perirenal fasciae to the parietal peritoneum in the lateral paracolic gutter (Congdon and Edson 1941). It is better understood as the lateral extension of the retrocolic fusion fascia that blends with the parietal peritoneum (see Figs 62.1-62.3).

The various compartments described above are illustrated in the context of clinical disease in Figures 62.4-62.6.

## BONES

The posterior abdominal wall is supported by the vertebral column and bony pelvis. The individual bones are the lower two ribs, the twelfth thoracic and five lumbar vertebrae, and the sacrum and ilium, together with their interconnecting ligaments (Chs 43,53).

## MUSCLES

The majority of the muscles of the posterior abdominal wall are functionally part of the lower limb or vertebral column. They provide the surface against which the neurovascular and visceral structures of the retroperitoneum lie (Fig. 62.7; see Fig. 62.14).

## Quadratus lumborum

Quadratus lumborum is an irregularly shaped quadrilateral muscle, broader at its inferior attachment than superiorly.

Attachments The inferior attachment is by aponeurotic fibres to the iliac crest over an area $5-7 \mathrm{~cm}$ lateral to the tip of the L4 transverse process and/or the iliolumbar ligament. The superior attachment is to the lower anterior surface of the twelfth rib, the lateral surface of the twelfth thoracic vertebra, and the apices of the transverse processes of the upper four lumbar vertebrae. Fascicles vary in number and size but are arranged in three layers: anterior, middle and posterior (Phillips et al 2008).

Relations Anteriorly are the colon (ascending on the right, descending on the left), kidney, psoas major and minor, and diaphragm. The subcostal, iliohypogastric and ilioinguinal nerves lie on the fascia anterior to the muscle, bound down to it by the medial continuation of the transversalis fascia.

Vascular supply Quadratus lumborum is supplied by branches of the lumbar arteries, the arteria lumbales imae from the median sacral artery, the lumbar branch of the iliolumbar artery, and branches of the subcostal artery.

Innervation The muscle is innervated by the ventral rami of the twelfth thoracic and upper three or four lumbar spinal nerves.

Actions Quadratus lumborum fixes the twelfth rib, and acts as a muscle of inspiration by helping to stabilize the lower attachments of the diaphragm. With the pelvis fixed, unilateral contraction flexes the vertebral column to the same side, and bilateral contraction probably helps to extend the lumbar part of the vertebral column. These actions on the lumbar spine are reported to be weak (Phillips et al 2008) and yet the muscle undergoes considerable hypertrophy in some sporting activities (Ranson et al 2008).

Fig. 62.4 A 58-year-old male with chronic pancreatitis and a peripancreatic pseudocyst. Oral and intravenous contrast-enhanced computed tomography (CT; axial and sagittal planes). The pseudocyst, containing gas and fluid, has expanded the peripancreatic space. The fusion fasciae forming the boundaries of the peripancreatic space are thickened through chronic inflammation and are easily visible. A, A transverse section at the level of the body of the second lumbar vertebra. Key: 1, neck of pancreas; 2, gas in anterior part of collection (outlining peripancreatic space); 3 , fluid and debris in posterior (dependent) part of collection (outlining peripancreatic space); 4, retropancreatic fusion fascia (anterior perirenal fascia fused to right leaf of mesoduodenum); 5, anterior peripancreatic fascia fused to right leaf of left mesocolon; 6, anterior peripancreatic fascia deep to left mesocolon and collapsed lesser sac; 7, anterior peripancreatic fascia fused to peritoneum of lesser sac in gastric bed; 8, superior mesenteric artery; 9, abdominal aorta; 10, inferior vena cava; 11, left renal vein; 12, left kidney parenchyma; 13, left perirenal space (not distinguishable from left posterior pararenal space); 14, right kidney parenchyma; 15, right perirenal space (not distinguishable from right posterior pararenal space); 16, upper L2 vertebral body; 17, splenic flexure; 18, stomach (elevated and compressed by collection); 19, gallbladder; 20, right lobe of liver (segments 5 and 6); 21, right crus of diaphragm; 22, origin of left psoas major; 23, left quadratus lumborum; 24, left erector spinae group. B, A transverse section at the level of the body of the fourth lumbar vertebra. Key: 1, inferior part of body and uncinate process of pancreas; 2, distal second part of duodenum; 3, third part of duodenum; 4, peripancreatic space collection (around and anterior to pancreas and duodenum); 5 , superior mesenteric vein; 6, superior mesenteric artery; 7 , small bowel mesentery; 8, part of collection dissecting into transverse mesocolon; 9, transverse mesocolon (fused to greater omentum); 10, transverse colon; 11 , collection dissecting behind ascending colon; 12, ascending colon; 13, collection (with gas) dissecting behind descending colon; 14, descending colon; 15, left kidney parenchyma; 16, left perirenal space; 17, left posterior perirenal fascia (normal thickness, therefore faint); 18, left posterior pararenal space; 19, right kidney parenchyma; 20, right perirenal space; 21, right posterior perirenal fascia; 22, right posterior pararenal space; 23 , anterior pararenal fascia (thickened through chronic inflammation); 24, upper L4 vertebral body; 25, abdominal aorta; 26, inferior vena cava; 27 , right psoas major; 28, left quadratus lumborum; 29, left erector spinae group. C, A mid-sagittal section. Key: 1, neck of pancreas; 2, gas in anterior part of collection; 3, fluid in posterior part of collection; 4, coeliac trunk; 5, superior mesenteric artery; 6 , left renal vein; 7, abdominal aorta; 8, diaphragmatic crura; 9, left lobe of liver; 10, antrum of stomach (collapsed); 11, part of collection dissecting into transverse mesocolon; 12, transverse colon; 13, part of collection dissecting into small bowel mesentery; 14, third part of duodenum. D, A left sagittal section through left renal hilum. Key: 1, body of pancreas; 2, fluid collection; 3, fundus of stomach (containing oral contrast); 4, body of stomach (containing oral contrast and displaced); 5 , left anterior perirenal fascia fused with retropancreatic fascia; 6, left anterior perirenal fascia fused with right leaf of left mesocolon (fusion fascia of Toldt); 7, fourth part of duodenum; 8, left kidney parenchyma; 9, spleen.

Fig. 62.5 A 43-year-old male with subacute retrocaecal appendicitis. Inflammatory fluid and stranding in the right pericolic space. The fused right anterior perirenal fascia and right mesocolon (the fusion fascia of Toldt) is visible. A, A transverse section through the vermiform appendix. Key: 1, thickened and inflamed retrocaecal appendix; 2, inflammatory fluid tracking posteriorly in right pericolic space, anterior to right perirenal space; 3 , anterior perirenal fascia (fused with retrocolic/mesocolic) fascia; 4, caecum/ascending colon; 5, right kidney parenchyma; 6, right perirenal space 7, right posterior pararenal space (the posterior perirenal fascia is difficult to identify); 8 , right quadratus lumborum; 9, right psoas major; 10, inferior vena cava; 11, abdominal aorta; 12, left psoas major; 13, left quadratus lumborum; 14, left erector spinae group; 15, left kidney parenchyma; 16, left posterior perirenal fascia; 17, left perirenal space; 18, left posterior pararenal space; 19, descending colon. B, A coronal section through the appendix. Key: 1, thickened and inflamed retrocaecal appendix; 2, inflammatory fluid and oedema extending along right mesocolon towards root of mesentery; 3 , enlarged inflamed right ileocolic lymph node; 4, inflammatory fluid tracking in right mesocolon; 5 , inferior vena cava - retrohepatic segment; 6 , inferior vena cava - infrahepatic peritonealized segment; 7, inferior vena cava - renal segment; 8, inferior vena cava - infrarenal segment; 9, left renal vein; 10 , superior mesenteric artery; 11, coeliac trunk; 12, abdominal aorta; 13, right common iliac artery; 14, left common iliac artery (origin); 15 , tail of pancreas.

Fig. 62.6 A 61-year-old male with mid-ureteric calculus causing highgrade obstruction of the left ureter and extravasation of urine from the left renal hilum. Oral and intravenous contrast-enhanced CT. A transverse section through the left renal hilum (the calculus is below the plane of this section). Key: 1, left kidney parenchyma; 2, extravasated urine in left perirenal space; 3 , posterior perirenal fascia; 4 , anterior perirenal fascia (fused medially with retropancreatic fascia and fused laterally with right leaf of descending mesocolon); 5, left posterior pararenal space; 6, descending colon; 7, third part of duodenum; 8 , inferior vena cava; 9 , abdominal aorta; 10, right psoas major; 11, right quadratus lumborum; 12, right erector spinae group; 13, aortocaval lymph node (borderline enlarged); 14, left para-aortic lymph nodes (borderline enlarged).

## Psoas major, psoas minor and iliacus

Psoas major and iliacus are functionally important in the lower limb and are described together with psoas minor in Chapter 80.

## Posterior abdominal wall hernias

In the absence of a previous surgical incision, herniation through the posterior abdominal wall is rare because the muscular and fascial layers usually protect against protrusion of the posterior abdominal viscera, which are relatively immobile. However, the posterior free border of external oblique, the inferior free border of latissimus dorsi, and the iliac crest delimit the lumbar triangle (of Petit), an area of potential weakness through which a lumbar hernia may develop (Stamatiou et al 2009).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ABDOMINAL AORTA

The abdominal aorta begins at the aortic hiatus of the diaphragm, anterior to the twelfth thoracic vertebra (Mirjalili et al 2012a). It descends anterior to the lumbar vertebrae and bifurcates into two common iliac arteries anterior to the fourth lumbar vertebra or the L4/5 intervertebral disc, slightly to the left of the midline (Mirjalili et al 2012b, Moussallem et al 2012) (Figs 62.8-62.10). The angle of bifurcation is very variable (Moussallem et al 2012). The mean adult infrarenal aortic diameter measured by computed tomography is $19-21 \mathrm{~mm}$ in men and 16-18 mm in women (Rogers et al 2013), but there are ethnic variations (Jasper et al 2014). Measured by ultrasound, equivalent values are 20 mm (SD 2.5 mm ) in men and 17 mm (SD 1.5 mm ) in women (Needleman 2006). The mean calibre of the abdominal aorta decreases slightly from proximal to distal. With advancing age, there is a progressive increase in abdominal aortic diameter in both sexes and

Fig. 62.7 Bones and deep muscles of the posterior abdominal wall. Left psoas major and the diaphragm have been removed. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
the tapering becomes more pronounced (Fleischmann et al 2001). In the elderly, the abdominal aorta frequently becomes ectatic and tortuous, changing the angle and position of the bifurcation and rotating the origins of the major branches.

Approximately $80 \%$ of abdominal aortic aneurysms occur in the infrarenal segment of the aorta. Men with atherosclerosis are most at risk of developing the condition, particularly from the sixth decade onwards (Takayama and Yamanouchi 2013). The high mortality risk from spontaneous rupture has prompted the development of ultrasound screening programmes to detect occult aneurysms and repair them electively. The most common clinical cut-off diameter for the presence of an abdominal aortic aneurysm is 3 cm (Needleman 2006, Wegener 1992, Allan 2006, Moeller and Reif 2000). Repair is most commonly performed by open surgery or endovascular stenting (endovascular aneurysm repair).

## Relations

The upper abdominal aorta is directly related anteriorly to the coeliac trunk and its branches, autonomic nerve plexuses and lymphatics. Below the coeliac trunk, the superior mesenteric artery leaves the aorta, descending anterior to the left renal vein. Anterior to these vessels lies the body of the pancreas, with the splenic vein on its posterior surface, extending obliquely up and to the left (see Fig. 62.8). Further anteriorly, the lesser sac separates the upper abdominal aorta from the lesser omentum, stomach and left lobe of the liver. Below the pancreas, the horizontal third part of the duodenum crosses the aorta anteriorly. The most inferior part of the abdominal aorta is covered by the posterior parietal peritoneum and crossed obliquely by the origin of the small bowel mesentery.

The twelfth thoracic vertebra, the upper four lumbar vertebrae, intervening intervertebral discs and the anterior longitudinal ligament lie
posterior to the abdominal aorta. Lumbar arteries arise from its dorsal aspect, and the third and fourth (and sometimes the second) left lumbar veins cross behind it to reach the inferior vena cava. The abdominal aorta may overlap the medial border of the left psoas major muscle.

On the right, the abdominal aorta is related superiorly to the cisterna chyli and thoracic duct, the azygos vein and the right crus of the diaphragm, which overlaps and separates it from the inferior vena cava and right coeliac ganglion. Below the second lumbar vertebra, it is closely applied to the left side of the inferior vena cava. This close relationship allows the development of an aortocaval fistula, which is a rare complication of aneurysmal disease or trauma. On the left, the aorta is related superiorly to the left crus of the diaphragm and left coeliac ganglion. Level with the second lumbar vertebra, it is related to the fourth part of the duodenum, the left sympathetic trunk, and the inferior mesenteric vein.

## Branches

The branches of the aorta are described as anterior, lateral and dorsal (see Figs 62.8-62.10). The anterior (unpaired) and lateral (paired) branches are distributed to the viscera, while the dorsal branches supply the body wall, vertebral column, vertebral canal and its contents. The aorta terminates by dividing into the right and left common iliac arteries.

## Anterior group Coeliac trunk

The coeliac trunk is the first anterior branch and arises just below the aortic hiatus, usually at the level of the vertebral body of T12. It is $1-3 \mathrm{~cm}$ long and passes almost horizontally forwards and slightly to the right above the body of the pancreas and splenic vein. In most individuals, it trifurcates into the left gastric, common hepatic and splenic arteries. Variations occasionally occur and include a separate origin of the left gastric artery from the abdominal aorta, one or both inferior phrenic arteries arising from the coeliac trunk, and the superior mesenteric artery or one or more of its branches arising in common with the coeliac trunk (Panagouli et al 2013). Anterior to the coeliac trunk lies the lesser sac. The coeliac plexus surrounds the trunk, sending extensions along its branches. On the right lie the right coeliac ganglion, right crus of the diaphragm and the caudate lobe of the liver. To the left lies the left coeliac ganglion, left crus of the diaphragm and the cardiac region of the stomach. Rarely, the coeliac trunk can be compressed by the median arcuate ligament, resulting in visceral ischaemia and abdominal pain (Loukas et al 2007a).

## Superior mesenteric artery

The superior mesenteric artery originates from the aorta approximately $1-2 \mathrm{~cm}$ below the coeliac trunk, at the level of the L1 vertebral body (Mirjalili et al 2012b) (Chs 65-66). It lies posterior to the body of the pancreas and splenic vein, and is separated from the aorta by the left renal vein. It passes forwards and inferiorly, anterior to the uncinate process of the pancreas and the third part of the duodenum, to enter the root of the small bowel mesentery and supply the midgut. Numerous anatomical variants have been described (Bergman et al 2014), the most common being an accessory or replaced right hepatic artery arising near the origin of the superior mesenteric artery. Present in about $15 \%$ of individuals, the accessory or replaced right hepatic artery courses posterior to the portal vein and ascends posterolateral to the common bile duct (Winston et al 2007).

## Inferior mesenteric artery

The inferior mesenteric artery is smaller than the superior mesenteric artery. It arises from the anterior or left anterolateral aspect of the aorta at about the level of the L3 vertebral body, 3 or 4 cm above the aortic bifurcation and posterior to the inferior border of the horizontal part of the duodenum (Ch. 66).

## Lateral group

## Suprarenal artery

The right and left middle suprarenal arteries arise from each side of the abdominal aorta, level with the superior mesenteric artery. Each passes laterally over the crus of the diaphragm to the suprarenal gland, where it anastomoses with the suprarenal branches of the ipsilateral inferior phrenic and renal arteries (Toni et al 1988) (Ch. 71). The right middle suprarenal artery passes behind the inferior vena cava, near the right coeliac ganglion. The left middle suprarenal artery passes close to the left coeliac ganglion, splenic artery and the superior border of the pancreas.

Fig. 62.8 The abdominal aorta and inferior vena cava, and their branches. The fasciae, lymphatics and connective tissue have been removed for clarity.

Fig. 62.9 The branches of the abdominal aorta.

## Renal artery

The renal arteries are two of the largest branches of the abdominal aorta and arise laterally just below the origin of the superior mesenteric artery at about the level of the L1 vertebral body (Mirjalili et al 2012b) (Ch. 74). When the arteries arise at different cranio-caudal levels, the right ostium is more commonly higher than the left. The right renal artery is longer and passes posterior to the inferior vena cava, right renal vein, head of the pancreas and second part of the duodenum. The left renal artery passes behind the left renal vein, the body of the pancreas and the splenic vein. Variations in the number, origin, course and branching patterns of the renal arteries are common.

## Gonadal artery

The gonadal arteries are two long, slender vessels that arise from the aorta a little inferior to the renal arteries. Each passes inferolaterally under the parietal peritoneum on psoas major to supply the ipsilateral gonad (Chs 76-77). One or both gonadal arteries may arise from a renal artery or be double.

## Dorsal group <br> Inferior phrenic arteries

The inferior phrenic arteries usually arise either from the aorta, just above the level of the coeliac trunk, or directly from the coeliac trunk; occasionally, they originate from the renal artery (Loukas et al 2005a, Gwon et al 2007). They contribute to the arterial supply of the diaphragm. Each artery ascends laterally, anterior to the crus of the diaphragm, near the medial border of the ipsilateral suprarenal gland. It then divides into an ascending and a descending branch. The left ascending branch passes behind the oesophagus and then runs anteriorly on the left side of the oesophageal hiatus, where it bifurcates; one branch curves forwards to anastomose with its counterpart in front of the central tendon of the diaphragm and the other branch approaches the thoracic wall to anastomose with the musculophrenic and pericardiacophrenic arteries. The right ascending branch passes behind the inferior vena cava and then bifurcates; one branch runs anteriorly on the right side of the diaphragmatic opening for the inferior vena cava (which it supplies) before anastomosing with its counterpart in front of the central tendon of the diaphragm, and the other branch passes

Fig. 62.10 The abdominal aorta and its branches. A 36-year-old female investigated by CT aortogram for possible Marfan's aortic dissection; only the normal abdominal aorta part of the dataset is shown in this threedimensional reconstruction. Surface shaded display. Key: 1, apex of left ventricle; 2, low thoracic aorta; 3, approximate position of diaphragmatic hiatus; 4, coeliac trunk; 5, common hepatic artery; 6, splenic artery; 7, left gastric artery; 8 , proper hepatic artery; 9 , left hepatic artery; 10, right hepatic artery; 11, gastroduodenal artery; 12, superior mesenteric artery; 13 , right renal artery; 14, left renal artery partly obscured by proper hepatic artery lying more superficial (with arrow); 15, inferior mesenteric artery; 16, superior rectal artery; 17, aortic bifurcation in front of L4; 18, right common iliac artery; 19, left common iliac artery; 20, right external iliac artery; 21, right internal iliac artery; 22, left external iliac artery; 23, left internal iliac artery; 24, right superior gluteal artery; 25, right inferior epigastric artery; 26, left inferior epigastric artery; 27, right T12 segmental artery; 28, right L1 segmental artery; 29, right L2 segmental artery; 30, right L3 segmental artery; 31, right L4 segmental artery; 32, right iliolumbar artery; 33, median sacral artery; 34, right superior epigastric artery (continuing from right internal thoracic artery).
laterally on the undersurface of the diaphragm. The descending branches on each side supply the muscular diaphragm and anastomose with the lower posterior intercostal and musculophrenic arteries. Each inferior phrenic artery gives off two or three small suprarenal branches. The abdominal oesophagus, capsule of the liver, and upper pole of the spleen may also receive small arterial twigs.

The inferior phrenic artery may be a source of significant collateral blood flow to large hepatocellular cancers and is sometimes specifically occluded, along with the relevant hepatic artery, when treating such tumours by arterial embolization.

## Lumbar arteries

There are usually four lumbar arteries on each side, in series with the posterior intercostal arteries. They arise from the posterolateral aspect of the abdominal aorta, opposite the lumbar vertebrae. A fifth, smaller, pair occasionally arise from the median sacral artery, but lumbar branches of the iliolumbar arteries often take their place. The lumbar arteries run posterolaterally on the first to the fourth lumbar vertebral bodies, passing behind the sympathetic trunk and tendinous arches formed by the attachments of psoas major to the vertebral bodies. The right lumbar arteries pass posterior to the inferior vena cava. The upper two right lumbar arteries and the first left lumbar artery lie behind the corresponding crus of the diaphragm. Just beyond the intervertebral foramina, each lumbar artery divides into a medial branch, which gives off spinal and ganglionic branches; a middle branch, from which dorsal and anastomotic branches arise; and a lateral branch, which supplies the abdominal wall (Arslan et al 2011). Of particular importance is the

Fig. 62.11 Tributaries of the inferior vena cava and lumbar veins. Only the left lumbar venous system is shown, for clarity.
spinal branch known as the arteria radicularis magna (the artery of Adamkiewicz) (p. 770), which frequently originates from an upper lumbar artery, particularly on the left side (Biglioli et al 2004) (Ch. 45). Injury to this vessel, e.g. during thoracoabdominal aortic surgery, can cause spinal cord infarction.

The lateral branch of each lumbar artery runs posterior to psoas major and the lumbar plexus, then across the anterior surface of quadratus lumborum, before piercing the posterior limit of transversus abdominis to run forwards between it and the internal oblique. Perforating branches pass posteriorly to supply the muscles and skin of the posterior abdominal wall (Kiil et al 2009). The lumbar arteries anastomose with one another and the lower posterior intercostal, subcostal, iliolumbar, deep circumflex iliac and inferior epigastric arteries.

The dorsal branch of each lumbar artery passes backwards between the adjacent transverse vertebral processes to supply the dorsal muscles, vertebrae, joints and skin of the back.

## Median sacral artery

The median sacral artery is a small branch that arises from the posterior aspect of the aorta a little above its bifurcation. It descends close to the midline, anterior to the fourth and fifth lumbar vertebrae, sacrum and coccyx. At the level of the fifth lumbar vertebra, it is crossed by the left common iliac vein and often gives off a small lumbar artery (arteria lumbales imae), small branches of which reach the anorectum via the anococcygeal ligament. Anterior to the fifth lumbar vertebra, the median sacral artery anastomoses with a lumbar branch of the iliolumbar artery. Anterior to the sacrum, it anastomoses with the lateral sacral arteries and sends branches into the anterior sacral foramina.

## INFERIOR VENA CAVA

The inferior vena cava (Figs 62.11-62.12) conveys blood to the right atrium from almost all of the structures below the diaphragm. Most of

Fig. 62.12 A 41-year-old male investigated for microscopic haematuria. CT intravenous urogram. Normal study. Late phase acquisition. Oblique coronal, mid-abdominal 15 mm slab, maximal intensity projection (MIP) reformats. Key: 1, inferior vena cava, hepatic segment; 2, inferior vena cava, peritonealized segment; 3, inferior vena cava, renal segment; 4, right renal vein; 5 , left renal vein crossing in front of the aorta; 6 , inferior vena cava, infrarenal segment; 7, inferior vena cava, confluence (partly obscured by right common iliac artery); 8, left common iliac vein (coursing posteriorly out of slab; right common iliac vein obscured); 9, right hepatic vein joining inferior vena cava; 10, liver parenchyma; 11, right kidney lower pole parenchyma; 12, right ureter (with excreted contrast); 13, urinary bladder (with excreted contrast); 14, right psoas major; 15, right iliacus; 16, right external iliac artery; 17, right external iliac vein; 18, left external iliac artery; 19, left external iliac vein; 20, low thoracic aorta; 21, coeliac axis; 22, superior mesenteric artery; 23 , right renal artery passing behind inferior vena cava; 24, aorta, infrarenal segment; 25, aortic bifurcation (partly obscured); 26, right common iliac artery (left common iliac artery courses posteriorly out of slab).
its course is within the abdomen, but a small segment lies within the pericardium in the thorax.

The inferior vena cava is formed by the junction of the left and right common iliac veins anterior to the fifth lumbar vertebral body, about 1 cm to the right of the midline. It ascends anterior to the vertebral column, to the right of the aorta, and lies in a deep groove on the posterior surface of the liver, sometimes completely embedded by liver tissue. It traverses the central tendon of the diaphragm between its median and right 'leaves', and passes through the fibrous pericardium and a posterior inflection of the serous pericardium to open into the posteroinferior part of the right atrium. The abdominal portion of the inferior vena cava is devoid of valves.

The inferior vena cava can be encircled and controlled between the renal veins below and the hepatic veins above (e.g. when operating on a renal cell carcinoma extending into the inferior vena cava).

## Relations of the abdominal part of the inferior vena cava

The inferior vena cava lies behind the peritoneum of the posterior abdominal wall. At its origin, it is related anteriorly to the right common
iliac artery. From below upwards, its anterior surface is crossed obliquely by the root of the small bowel mesentery and its contained vessels and nerves, the right gonadal artery and the third part of the duodenum. Further cranially, it lies behind the head of the pancreas and first part of the duodenum, separated from these structures by the common bile duct and portal vein. Above the duodenum, its anterior surface is covered by the peritoneum of the posterior abdominal wall, which forms the posterior wall of the epiploic foramen, and which separates the inferior vena cava from the right free border of the lesser omentum and its contents. Above this, it is intimately related to the liver anteriorly.

The posterior relations of the inferior vena cava include the lower three lumbar vertebral bodies and their intervertebral discs, the anterior longitudinal ligament, sympathetic trunk, right third and fourth lumbar arteries, and the right psoas major. Superior to these structures, the inferior vena cava is related posteriorly to the right renal and middle suprarenal arteries, the medial part of the right suprarenal gland, the right coeliac ganglion and the right inferior phrenic arteries.

The right ureter, medial border of the right kidney, second part of the duodenum, and the right lobe of the liver are all lateral to the right side of the inferior vena cava. The abdominal aorta, right crus of the diaphragm and the caudate lobe of the liver are left-sided relations.

The normal diameter of the adult inferior vena cava is up to 30 mm (Moeller and Reif 2000); its cross-sectional shape and calibre reflect the degree of venous filling. Anatomical variants of the inferior vena cava related to its complex embryogenesis are well described. Among these are a double inferior vena cava (the left-sided vessel usually joins the left renal vein); azygos continuation of the inferior vena cava; or a leftsided inferior vena cava (which may exist in isolation or as part of situs inversus) (Ang et al 2013, Spentzouris et al 2014).

## Tributaries

The inferior vena cava usually receives the common iliac veins at its origin and the lumbar, right gonadal, renal, right suprarenal, hepatic and inferior phrenic veins throughout its course (see Figs 62.1162.12).

## Lumbar veins

Four pairs of lumbar veins collect blood from the territories supplied by the corresponding lumbar arteries (see above), including the dorsal, lateral and anterior abdominal wall. These branches anastomose posteriorly with tributaries of the azygos and hemiazygos veins, and anteriorly with branches of the epigastric, circumflex iliac and lateral thoracic veins. These superficial anastomoses provide alternative routes of venous drainage from the pelvis and lower limbs to the heart in the presence of inferior vena caval obstruction. The lumbar veins also communicate with the external and internal vertebral venous plexuses, providing an additional collateral pathway for venous return. The paired longitudinal ascending lumbar veins connect ipsilateral lumbar veins. The third and fourth lumbar veins usually pass forwards on the sides of the corresponding vertebral bodies to enter the posterior aspect of the inferior vena cava; the left lumbar veins pass behind the abdominal aorta and are, therefore, longer. The first and second lumbar veins are much more variable; they may drain into the inferior vena cava, ascending lumbar, lumbar azygos and renal vein (on the left), and are often connected to each other. Indeed, the first lumbar vein often passes inferiorly to join the second lumbar vein or, less commonly, drains directly into the ascending lumbar vein or passes forwards over the L1 vertebral body to join the lumbar azygos vein. The second lumbar vein may join the inferior vena cava at or near the level of the renal veins or, less commonly, joins the third lumbar or ascending lumbar vein.

## Ascending lumbar veins

The paired ascending lumbar veins run medial to psoas major and connect ipsilateral common iliac, iliolumbar and lumbar veins. The ascending lumbar vein is variable in its course and connections; rarely, the whole vein or a segment may be absent on one side (Lolis et al 2011). It commonly joins the subcostal vein to form the azygos vein on the right and the hemiazygos on the left. The azygos and hemiazygos veins run forwards over the twelfth thoracic vertebral body, and pass deep to or through the right and left crus of the diaphragm, respectively, into the thorax (Ch. 56). The ascending lumbar vein is usually joined by a small vein, the lumbar azygos vein, from the back of the inferior vena cava or left renal vein. Sometimes, the ascending lumbar vein ends in the first lumbar vein, which then joins the lumbar azygos vein at the level of the first lumbar vertebra. Blood flow in the ascending lumbar veins can occur in either direction (Morita et al 2007).

## Gonadal veins

The right gonadal vein enters the inferior vena cava directly on its right anterolateral aspect at an acute angle about 2 cm inferior to the left renal vein in adults; occasionally, it drains into the right renal vein (Barber et al 2012). The left gonadal vein terminates in the left renal vein. Both veins may be replaced by multiple vessels in the lower abdomen and sometimes remain double as far as their termination. Of the two gonadal veins, the left is more prone to develop venous incompetence.

## Renal veins

The renal veins are large-calibre vessels, which lie anterior to the renal arteries and open into the inferior vena cava almost at right angles (Ch. 74). The left is three times longer than the right (approximately 7.5 cm and 2.5 cm , respectively). The left vein lies on the posterior abdominal wall posterior to the splenic vein and body of the pancreas. It passes to the right in the angle between the abdominal aorta posteriorly and the superior mesenteric artery anteriorly, to empty into the inferior vena cava. Occasionally, the left renal vein or an accessory left renal vein is retroaortic. The right renal vein lies posterior to the second part of the duodenum and, sometimes, the lateral part of the head of the pancreas

## Suprarenal vein

Most commonly, a single vein drains each suprarenal gland (Ch. 71). The short right suprarenal vein drains directly into the inferior vena cava at the level of the twelfth thoracic vertebra; the longer left vein usually joins the left renal vein and may receive the left inferior phrenic vein. Numerous anatomical variations have been described (Cesmebasi et al 2014).

## Inferior phrenic veins

The inferior phrenic veins usually originate on the superior surface of the diaphragm but run mostly on its inferior surface to drain into the posterolateral aspect of the inferior vena cava. Both veins receive several diaphragmatic tributaries. The left vein runs to the left of the oesophageal hiatus, whereas the right courses to the right of the opening in the diaphragm for the inferior vena cava, each receiving an oesophageal tributary (Loukas et al 2005b). Further, the left inferior phrenic vein frequently communicates with the left gastric vein and hence may become prominent in portal hypertension. Both inferior phrenic veins usually drain directly into the inferior vena cava just below the diaphragm, sometimes joining anteriorly to form a short common trunk. The right may occasionally drain into the right hepatic vein or inferior vena cava above the diaphragm. In contrast, the left frequently drains into the left suprarenal, left renal or left hepatic vein.

## Collaterals in inferior vena caval occlusion

Obstruction of the inferior vena cava from thrombosis, embolism, extrinsic compression or intrinsic disease results in the development of an extensive venous collateral circulation via tributaries that ultimately connect to the superior vena cava. These include the azygos-hemiazygos venous system, the vertebral venous plexuses, and superficial body wall veins. The lumbar veins contribute significantly to these pathways (Golub et al 1992).

## LYMPHATIC DRAINAGE

Lymph from the skin and subcutaneous tissues of the abdominal wall drains via small-calibre superficial lymphatics to axillary and inguinal nodes (Tourani et al 2013). The midline and the level of the umbilicus form inconstant and variable watershed boundaries for these drainage territories. Lymphatics from the deeper layers of the body wall and the abdominal and pelvic viscera drain almost exclusively to the cisterna chyli and thoracic duct. The former drains via ipsilateral retroperitoneal lymph nodes that are concentrated around the external iliac and common iliac vessels and along the lateral aspects of the aorta and inferior vena cava. There is considerable overlap between the lymphatic drainage basins of individual viscera. At certain sites, there is a craniocaudal sequence of lymph nodes, e.g. para-oesophageal, retrocrural and para-aortic nodes; mediastinal and gastro-oesophageal nodes; and parasternal, superior and inferior epigastric nodes. Some lymphatic drainage occurs directly across the diaphragm to the chest from the bare area of the liver.

The paired retroperitoneal viscera drain to lateral aortic (also termed para-aortic) nodes around the origin of their arterial supply. Thus, the kidneys and suprarenal glands drain to nodes around the renal hilum and to lateral aortic nodes around the origin of the renal arteries (L1-2 vertebral level). The testes drain to para-aortic and paracaval nodes
(approximately L2); the pattern of lymphatic spread from a testicular malignancy suggests that lymph from the left testis drains to left paraaortic nodes en route to the cisterna chyli, whereas lymph from the right testis drains to right and then left para-aortic nodes before reaching the cisterna chyli. Lymph from the ovary may also drain via lymphatics in the broad ligament and round ligament to internal iliac and inguinal lymph nodes, respectively. Lymphatic drainage of the ureters is less well defined but follows a regional pattern to nearby nodes.

The lymphatic drainage of the retroperitoneal colon and rectum is described in Chapter 66. The pancreas drains to numerous peripancreatic nodes (Ch. 69) as well as portal, splenic, paracaval, superior mesenteric and coeliac nodes. The lymphatic drainage of the duodenum is not well described but the lymphatics generally drain to nodal stations related to local arteries (Ch. 65). Whilst the clinical pattern of nodal metastases usually reflects normal lymphatic drainage pathways, lymphatic obstruction may lead to metastases at unusual nodal sites.

## Cisterna chyli and abdominal lymph trunks

The abdominal origin of the thoracic duct usually lies to the right of the midline at the level of the twelfth thoracic vertebral body or the thoracolumbar intervertebral disc. It receives almost all the lymph from below the diaphragm via the cisterna chyli, a localized lymphatic dilation formed most commonly by the union of the intestinal lymph trunk and the left lumbar trunk (Phang et al 2014). The cisterna chyli is a saccular or fusiform lymphatic dilation measuring, on average, about 1 cm wide and 2 cm long in the cadaver (Loukas et al 2007b). Recent studies using magnetic resonance imaging (MRI) in vivo have shown remarkable postural variations in the cross-sectional area of the cisterna chyli, which expands considerably when moving from supine to sitting, and again from sitting to standing (Niggemann et al 2010). The cisterna chyli usually lies in front of the first and second lumbar vertebrae behind the right crus of the diaphragm to the right of the abdominal aorta but may be located at a higher vertebral level. The formation of the cisterna chyli is variable. The most common configuration, found in approximately two-thirds of individuals, is a single structure formed from the union of the intestinal lymph trunk and the left (or, less commonly, the right) lumbar lymph trunk (Loukas et al 2007b). In most other individuals, it is formed by the confluence of the intestinal and both lumbar lymph trunks, with additional small branches from intercostal lymphatics and retro-aortic lymph nodes. The upper two right lumbar arteries and the right lumbar azygos vein lie between the cisterna chyli and the vertebral column. The medial edge of the right crus of the diaphragm lies anterior to the abdominal confluence of lymph trunks.

The lumbar lymph trunks are formed by lymphatic vessels draining para-aortic nodes. The intestinal lymph trunk (which may be double) receives vessels draining from pre-aortic nodes, i.e. coeliac, superior and inferior mesenteric nodes, which drain the entire abdominal gastrointestinal tract down to the anal canal. The thoracic duct leaves the superior end of the cisterna chyli and passes through the aortic hiatus of the diaphragm posterolateral to the right side of the aorta. Its thoracic continuation is described on page 979.

The major lymphatic vessels adjacent to the abdominal aorta are at risk of injury during surgical procedures that involve peri-aortic dissection and/or lymphadenectomy. Damage to these lymphatic trunks or their obstruction by malignant disease may cause major lymph leaks manifesting as chylous ascites or chylothorax

## Retroperitoneal lymph node groups

The lymphatic drainage of the rectum, colon, stomach, pancreas, oesophagus and other organs is often described in terms of lymph node stations and levels of dissection that relate to the management of malignant disease. The terminology and classification of retroperitoneal lymph nodes are based on their location. In classic anatomical descriptions, the lymph nodes of the retroperitoneum around the abdominal aorta are grouped into pre-aortic, lateral or para-aortic, and retro-aortic groups (Fig. 62.13). However, it should be noted that adjacent nodal groups merge into one another with no clear demarcating boundaries. Normal lymph node dimensions are very variable. Cross-sectional imaging frequently uses 10 mm as an approximate measure for the upper limit of normal lymph node dimensions in the adult (Moeller and Reif 2000), even though some normal retroperitoneal nodes, such as the portacaval node, are typically larger.

## Pre-aortic nodes

The pre-aortic nodes drain the gastrointestinal viscera, including the pancreas, liver, and spleen. These nodes lie anterior to the aorta

Fig. 62.13 Peri-aortic lymph node groups. The main pre-aortic groups are shown. Only the left-sided lateral aortic (para-aortic) nodes are shown, for clarity. N.B. The cisterna chyli is more commonly formed by the intestinal lymph trunk and the left lumbar lymph trunk (rather than the right lumbar lymph trunk shown in this diagram).
clustered around its anterior unpaired visceral arteries and can be subdivided into coeliac, superior mesenteric and inferior mesenteric nodes. Efferent lymphatics from these nodes contribute to the formation of the intestinal lymph trunk.

## Coeliac nodes

These drain lymph from nodes around the stomach, hilum of the spleen, porta hepatis, cystic duct, lesser omentum, portacaval nodes, peripancreatic nodes and pancreaticoduodenal nodes. They also receive lymph from superior and inferior mesenteric lymph nodes. Efferent lymphatics drain to the intestinal lymph trunk.

## Superior mesenteric nodes

There is extensive overlap with the drainage territory of coeliac nodes, with subsidiary nodal groups that include peripancreatic, pancreaticoduodenal, portacaval, small bowel mesenteric, ileocolic, mesocolic and inferior mesenteric nodes. Efferent lymphatics drain directly to the intestinal lymph trunk or via coeliac nodes.

## Inferior mesenteric nodes

These nodes drain lymph from the hindgut, which includes the distal transverse colon, descending and sigmoid colon, and rectum (including superior rectal, mesorectal and presacral nodes)

## Lateral aortic groups

The lateral aortic (or para-aortic) nodes lie on either side of the abdominal aorta and inferior vena cava anterior to the medial margins of psoas major, diaphragmatic crura and sympathetic trunks. Constituent nodal groups that are recognized clinically include: retrocrural (posterior to the diaphragmatic crura at the aortic hiatus); left and right renal hilar; and aortocaval, paracaval, retrocaval and precaval nodes. Retro-aortic lymph nodes are also para-aortic and are, therefore, sometimes included within the lateral aortic group. The lateral aortic nodes drain into the paired lumbar lymph trunks, one on each side, which terminate directly or indirectly in the cisterna chyli and thoracic duct. Lymphatic connections exist between lateral aortic, pre-aortic, retro-aortic and contralateral lateral aortic nodes.

The lateral aortic nodes drain the deep layers of the body wall, retroperitoneal paired viscera (including the gonads) and the iliac nodal
chains. Lymphatic drainage from the right testis is via lymphatics travelling with the gonadal vessels to the right para-aortic and aortocaval nodes at the level of the second lumbar vertebra, whereas the left testis drains to the left para-aortic nodes just inferior to the left renal vein (Paño et al 2011).

## lliac nodes

The paired iliac nodes are distributed around the common, external and internal iliac arteries and veins. Constituent groups include: common iliac, external iliac, internal iliac, circumflex iliac and obturator nodes. Obturator nodes are located near the obturator foramen and, along with the iliac nodes, are a common site of lymph node metastasis in prostate cancer. 'Pelvic side-wall' nodes, lying adjacent to the ilium but not associated with a large artery or vein, are also described in the clinical literature. The iliac nodes drain the pelvic viscera and walls, except for the ovaries and those parts of the rectum drained by superior rectal drainage pathways (see above). They also drain lymph from the inguinal nodes and lower limbs.

## INNERVATION

The posterior abdominal wall contains the lumbar plexus and numerous autonomic plexuses and ganglia, which lie close to the abdominal aorta and its branches (Fig. 62.14).

## LUMBAR PLEXUS

The lumbar ventral rami pass laterally into the posterior part of psoas major, anterior to the transverse processes of the lumbar vertebrae; the plexus lies in a coronal plane that is in line with the posterior part of the vertebral body at L1 but becomes more anterior in the lower lumbar spine (Moro et al 2003, Benglis et al 2009) (see Fig. 62.14; Fig. 62.15). The first four lumbar ventral rami, together with a contribution from the twelfth thoracic ventral ramus (the dorsolumbar nerve), form the lumbar plexus. Although there are many variations, the most common arrangement of the plexus is described here.

The first lumbar ventral ramus is joined by a branch from the twelfth thoracic ventral ramus, and these roots contribute to the formation of the iliohypogastric and ilioinguinal nerves, which run laterally on the posterior abdominal wall (see Fig. 62.14). A branch from the ventral ramus of L1 unites with a branch from the second lumbar ventral ramus to form the genitofemoral nerve. The second, third and most of the fourth lumbar ventral rami divide into ventral and dorsal divisions; the ventral divisions unite to form the obturator nerve, while most of the nerve fibres in the dorsal divisions form the femoral nerve. The remaining fibres from the fourth lumbar ventral ramus join the fifth lumbar ventral ramus to form the lumbosacral trunk, which descends to join the sacral plexus (p. 1229). Branches from the dorsal divisions of the second and third lumbar rami unite to form the lateral femoral cutaneous nerve (lateral cutaneous nerve of thigh). The accessory obturator nerve, when present, usually arises from the third and fourth ventral divisions. The lumbar plexus is supplied by branches from the lumbar vessels that supply psoas major.

The branches of the lumbar plexus are listed in Table 62.1.
Division of constituent ventral rami into ventral and dorsal branches is not as clear in the lumbar and sacral plexuses as it is in the brachial plexus. Lateral cutaneous branches of the twelfth thoracic and first lumbar ventral rami are drawn into the gluteal skin, but otherwise these nerves are similar to intercostal nerves. The second lumbar ventral ramus is more complex. It not only contributes substantially to the femoral and obturator nerves, but also has an anterior terminal branch (the genital branch of the genitofemoral) and a lateral cutaneous branch (which contributes to the lateral femoral cutaneous nerve and the femoral branch of the genitofemoral nerve). Anterior terminal branches of the third to fifth lumbar and first sacral rami are suppressed, but the corresponding branches of the second and third sacral rami supply perineal skin.

The furcal nerve is an independent nerve with its own ventral and dorsal rootlets most commonly arising alongside the L4 nerve root. Its branches contribute to the femoral and obturator nerves arising from the lumbar plexus and to the lumbosacral trunk, which joins the sacral plexus (Harshavardhana and Dabke 2014). The term furcal refers to its forked nature since it links the lumbar and sacral plexuses. Occasionally, the furcal nerve arises at the level of the third or the fifth lumbar nerve roots, in which case the sacral plexus is considered prefixed or postfixed, respectively.

Fig. 62.14 Muscles and nerves of the posterior abdominal wall. The left psoas major has been removed to expose the origins of the lumbar plexus and quadratus lumborum.

Inflammatory processes, such as retrocaecal appendicitis on the right and diverticular abscess on the left, may occur in the posterior abdominal wall in the tissues immediately anterior to psoas major. These may irritate one or more branches of the lumbar plexus, causing pain or sensory disturbance in the distribution of the affected nerves, e.g. the skin of the thigh, hip or buttock.

## Muscular branches

Small branches from the lumbar roots supply adjacent muscles such as psoas major and quadratus lumborum.

## Iliohypogastric nerve

## Distribution

The iliohypogastric nerve usually originates from the L1 ventral ramus but may arise wholly or in part from the T12 ventral ramus (Klaassen et al 2011). It emerges from the upper lateral border of psoas major, and crosses obliquely behind the lower renal pole on the anterior surface of quadratus lumborum. Above the iliac crest, it enters the posterior part of transversus abdominis and then runs forwards between transversus abdominis and internal oblique, which it supplies. It gives off a lateral cutaneous branch that pierces internal and external oblique above the iliac crest and supplies the posterolateral gluteal skin. It continues forwards, pierces the internal oblique approximately 3 cm medial and 1 cm inferior to the anterior superior iliac spine (in adults), and then penetrates the external oblique aponeurosis approximately 3 cm above and medial to the superficial inguinal ring to supply the suprapubic skin. The iliohypogastric nerve frequently connects with the ilioinguinal nerve and, less commonly, with the subcostal nerve (see Fig. 61.5).

## Motor

The iliohypogastric nerve contributes motor nerves to transversus abdominis and internal oblique, including the conjoint tendon.

## Sensory

The iliohypogastric nerve supplies sensory fibres to transversus abdominis, internal oblique and external oblique, and innervates the posterolateral gluteal and suprapubic skin.

## Injury

The nerve is occasionally injured by a surgical incision in the right iliac fossa (e.g. during an inguinal hernia repair, open appendicectomy or trocar placement) but there is rarely any noticeable sensory loss because the suprapubic skin is innervated from several sources. Division of the iliohypogastric nerve above the anterior superior iliac spine may weaken the posterior wall of the inguinal canal and predispose to formation of a direct inguinal hernia.

## llioinguinal nerve

## Distribution

The ilioinguinal nerve usually originates from the L1 ventral ramus but may receive a contribution from T12 or L2 (Klaassen et al 2011). It emerges from the lateral border of psoas major, with or just inferior to the iliohypogastric nerve. It passes obliquely across quadratus lumborum and the upper part of iliacus and enters transversus abdominis about 3 cm medial and 4 cm inferior to the anterior superior iliac spine (in the adult); at this site, it is readily blocked by local anaesthetic. In this region, a branch may connect with the iliohypogastric or lateral femoral cutaneous nerve (see Fig. 61.5). It pierces internal oblique a little lower down, supplies it, and then traverses the inguinal canal superficial to the spermatic cord or round ligament. It emerges with the cord from the superficial inguinal ring and divides into terminal sensory branches.

Numerous anatomical variations are described (Al-dabbagh 2002, Ndiaye et al 2007). The ilioinguinal and genitofemoral nerves may interconnect within the inguinal canal and, consequently, each innervates the skin of the genitalia to a variable extent (Rab et al 2001, Cesmebasi et al 2015). The ilioinguinal nerve may pierce the external

Fig. 62.15 The lumbar plexus and its branches.

Table 62.1 Branches of the lumbar plexus

| Muscular | $\mathrm{T} 12, \mathrm{~L} 1-4$ |
| :--- | :--- |
| lliohypogastric | L 1 |
| Ilioinguinal | L 1 |
| Genitofemoral | $\mathrm{L} 1, \mathrm{~L} 2$ |
| Lateral femoral cutaneous | $\mathrm{L} 2, \mathrm{~L} 3$ |
| Femoral | $\mathrm{L} 2-4$ dorsal divisions |
| Obturator | $\mathrm{L} 2-4$ ventral divisions |
| Accessory obturator | $\mathrm{L} 3, \mathrm{~L} 4$ |

oblique aponeurosis proximal to the superficial inguinal ring or divide into terminal branches within the inguinal canal. It may form a common trunk with the iliohypogastric nerve as far as the midpoint of the inguinal canal. It may be very small or completely absent, in which case the iliohypogastric and genital branch of the genitofemoral nerves
supplies its territory. Rarely, it may arise as a branch of the genitofemoral nerve.

## Motor

The ilioinguinal nerve supplies motor nerves to transversus abdominis and internal oblique; these fibres are given off before the nerve enters the lateral end of the inguinal canal.

## Sensory

The ilioinguinal nerve supplies sensory fibres to transversus abdominis and internal oblique. It innervates the skin of the proximal medial thigh and the skin over the root of the penis and upper part of the scrotum in males, or the skin covering the mons pubis and the adjoining labium majus in females.

## Injury

The nerve may be injured or entrapped during inguinal surgery, particularly for inguinal hernia, leading to sensory disturbances and pain
over the skin of the genitalia and upper medial thigh (Ndiaye et al 2007).

## Genitofemoral nerve

## Distribution

The genitofemoral nerve originates from the L1 and L2 ventral rami and is formed within the substance of psoas major. It descends obliquely forwards through the muscle to emerge on its anterior surface nearer the medial border, opposite the third or fourth lumbar vertebra (Moro et al 2003). It then descends beneath the peritoneum on psoas major, crosses obliquely behind the ureter, and divides into genital and femoral branches; it may divide close to its origin such that its branches emerge separately from psoas major. The genital branch crosses the lower part of the external iliac artery, enters the inguinal canal through the deep ring and accompanies the spermatic cord or round ligament. It exits the superficial inguinal ring, usually dorsal to the spermatic cord or round ligament, and supplies the cremaster muscle and skin of the external genitalia. The femoral branch descends lateral to the external iliac artery before crossing the deep circumflex iliac artery, to pass behind the inguinal ligament (occasionally, through it) (Rab et al 2001) and enter the femoral sheath lateral to the femoral artery. It pierces the anterior layer of the femoral sheath and fascia lata, and supplies the skin of the upper part of the femoral triangle. It may connect with the lateral femoral cutaneous and intermediate femoral cutaneous nerves.

## Motor

The genitofemoral nerve innervates cremaster via the genital branch.

## Sensory

The genitofemoral nerve innervates the skin of the scrotum in males, or that of the mons pubis and labium majus in females, via its genital branch; there is considerable overlap and variability with the cutaneous distribution of the ilioinguinal nerve (Cesmebasi et al 2015). It also innervates the anteromedial skin of the thigh via its femoral branch.

The genitofemoral nerve is also understood to play a critical role in inguinoscrotal descent of the developing testis (Hutson et al 2015).

## Injury

Like the ilioinguinal nerve, the genital branch may be injured during inguinal surgery (open and laparoscopic), leading to neuralgic pain (Cesmebasi et al 2015).

## Femoral nerve

The femoral nerve descends through psoas major and emerges on or under its lateral border, about 4 cm above the inguinal ligament (Moore and Stringer 2011). It passes between psoas major and iliacus deep to the iliac fascia and runs posterior to the inguinal ligament into the thigh. It gives off branches that supply iliacus and pectineus, and sends sensory fibres to the femoral artery. Posterior to the inguinal ligament, it lies lateral to the femoral artery and sheath. The further course and distribution are described on page 1372.

## Lateral femoral cutaneous nerve (lateral cutaneous nerve of the thigh)

The lateral femoral cutaneous nerve (lateral cutaneous nerve of the thigh) is usually derived from the ventral rami of L2 and 3, but variable contributions from L1 to L3 are described (de Ridder et al 1999). It emerges from the posterolateral border of psoas major and crosses iliacus obliquely towards the anterior superior iliac spine. It supplies sensory fibres to the parietal peritoneum in the iliac fossa. On the right, the nerve passes posterolateral to the caecum, separated from it by the iliac fascia and peritoneum. The left nerve passes behind the lower part of the descending colon. Both nerves usually pass behind the inguinal ligament about $1-2 \mathrm{~cm}$ medial to the anterior superior iliac spine; occasionally, they pass through or, rarely, anterior to the ligament (Ray et al 2010). Occasionally, the nerve lies anterior or superior to the anterior superior iliac spine as it enters the thigh. In the thigh, the lateral femoral cutaneous nerve usually passes anterior or lateral to sartorius but may pierce the muscle. The further course and distribution are described on page 1371.

## Obturator nerve

The obturator nerve descends within the substance of psoas major to emerge from its posteromedial border near the L5 vertebra (Kirchmair et al 2008). It passes posterior to the common iliac vessels and lateral to the internal iliac vessels. It then descends on the lateral wall of the pelvis attached to the fascia over obturator internus and lies anterosuperior to the obturator vessels before running into the obturator foramen to enter the thigh. It has no branches in the abdomen or pelvis. The further course and distribution are described on page 1372.

## Accessory obturator nerve

The accessory obturator nerve is sometimes present, more often on the left (Katritsis et al 1980). It is usually formed by the ventral rami of L3 and L4. It emerges from the medial border of psoas major and runs along the posterior surface of the superior pubic ramus posterior to pectineus, where it gives off branches to supply pectineus and the hip joint, and may join with the anterior branch of the obturator nerve (p. 1372).

## LUMBAR SYMPATHETIC SYSTEM

The lumbar part of each sympathetic trunk usually contains four interconnected ganglia lying in extraperitoneal connective tissue on the anterolateral aspects of the lumbar vertebrae along the medial margin of psoas major (see Fig. 62.14). Superiorly, it is continuous with the thoracic sympathetic trunk posterior to the medial arcuate ligament at the L1/2 vertebral level (Feigl et al 2011). Inferiorly, it passes posterior to the common iliac vessels and is continuous with the sacral sympathetic trunk. On the right side, it lies posterior to the inferior vena cava; on the left, it is posterior to the lateral aortic lymph nodes. It is anterior to most of the lumbar vessels but may pass behind some lumbar veins.

The first, second and, sometimes, the third lumbar ventral rami are each connected to the lumbar sympathetic trunk by a white ramus communicans. All lumbar ventral rami are joined near their origins by long, slender grey rami communicantes from the four lumbar sympathetic ganglia. Their arrangement is irregular: one ganglion may give rami to two or three lumbar ventral rami, one lumbar ventral ramus may receive rami from two ganglia, or grey rami may leave the sympathetic trunk between ganglia (Murata et al 2003).

The lumbar sympathetic trunks are vulnerable during retroperitoneal nodal dissection and their injury can impair seminal emission and lead to retrograde ejaculation.

## LUMBAR PARASYMPATHETIC SYSTEM

The parasympathetic supply to the abdominal viscera is provided by the vagus nerve to the coeliac and superior mesenteric plexuses, and by pelvic splanchnic nerves that are distributed through the hypogastric and inferior mesenteric plexuses (Ch. 59).

## PARA-AORTIC BODIES

The para-aortic bodies (also known as paraganglia or, collectively, as the organ of Zuckerkandl) are collections of neural crest-derived chromaffin tissue found in close relation to the aortic autonomic plexuses. They are relatively large in the fetus, where they may have a role in maintaining blood pressure by catecholamine secretion. They reach a maximum size at around 3 years of age, and have usually regressed by adulthood. They are usually found as a pair of bodies lying anterolateral to the aorta in the region of the inferior mesenteric and superior hypogastric plexuses, but multiple smaller collections may be present. Occasionally, they are found as high as the coeliac plexus or as low as the inferior hypogastric plexus in the pelvis, or are closely applied to the sympathetic ganglia of the lumbar chain. Scattered cells that persist into adulthood may, rarely, be the sites of paraganglioma (extra-adrenal phaeochromocytoma) (Subramanian and Maker 2006).

The peritoneum is the largest serous membrane in the body, and its arrangements are complex. In males it forms a closed sac, but in females it is open at the lateral ends of the uterine tubes. Although its smooth appearance is unremarkable, its structure is complex and varies greatly in different locations. Directly beneath the monolayer of mesothelium is a well-developed basement membrane, outside which is a rich lymphatic plexus. Microscopic mesothelial pores or peritoneal stomata are distributed throughout the peritoneum but particularly on the undersurface of the diaphragm and anterior abdominal wall (Wassilev et al 1998). At peritoneal stomata, the mesothelium is in close proximity to underlying lymphatic endothelial cells and there is no intervening basement membrane. Both peritoneal stomata and sites of lymphoid aggregates ('milky spots') in the omenta contribute to peritoneal fluid absorption, and their occlusion by malignant cells may result in ascites (Hagiwara et al 1994). Neighbouring mesothelial cells are joined by junctional complexes but probably permit the passage of macrophages. The submesothelial connective tissue may also contain macrophages, lymphocytes and adipocytes (in some regions). Mesothelial cells may transform into fibroblasts, which may play an important role in inflammation of the peritoneum and the formation of peritoneal adhesions after surgery (Schnüriger et al 2011).

The normal pressure within the peritoneal cavity is about $2-10 \mathrm{mmHg}$ (higher in pregnancy and obese individuals) (Sanchez et al 2001). It can be measured directly using a catheter inserted into the abdomen, or indirectly, by monitoring the pressure in the bladder or stomach. The pressure inside the abdomen may increase after trauma as a result of the accumulation of blood, fluid or oedema, leading to an 'abdominal compartment syndrome'. In such patients, monitoring of intraabdominal pressure can identify major increases in pressure (above about 25 mmHg ) that could jeopardize the blood flow to vital organs and dictate the need for urgent decompression.

## PERITONEAL FLUID

The peritoneal cavity is a potential space between the parietal peritoneum, which lines the abdominal wall, and the visceral peritoneum, which covers the abdominal viscera and associated mesenteries within the cavity. It contains a small amount of peritoneal fluid that rarely exceeds 5 ml in healthy males and postmenopausal females (Yoshikawa et al 2013). In healthy young females, up to 25 ml of fluid may be present, depending on the phase of the menstrual cycle (Koninckx et al 1980). The fluid lubricates the mobile viscera, allowing them to glide freely on the abdominal wall and against each other within the limits imposed by their attachments. However, the parietal peritoneum can be surgically removed without necessarily having adverse effects on gut function (Sugarbaker 2012). Normal peritoneal fluid contains water, proteins (less than 30 g of protein per litre), electrolytes and solutes derived from interstitial fluid in the adjacent tissues and from plasma in local capillaries. It also contains a few cells, including desquamated mesothelium, nomadic peritoneal macrophages, mast cells, fibroblasts, lymphocytes and other leukocytes. Macrophages migrate freely between the peritoneal cavity and the surrounding connective tissue. In females, blood or fluid may enter the peritoneal cavity from a ruptured ovarian follicle (mittelschmerz) or from the retrograde flow of menstrual fluid along the uterine tubes (which may cause endometriosis). Peritoneal fluid is absorbed via peritoneal stomata and milky spots (see above). Under normal circumstances, the peritoneal cavity never contains gas.

The peritoneum and its fluid have important defensive properties (Autio 1964). Peritoneal fluid gravitates to dependent sites within the peritoneal cavity; diaphragmatic respiratory movements, negative intrathoracic pressure and intestinal peristalsis encourage flow from the pelvis to the subphrenic regions, even when the individual is erect. Fluid preferentially ascends from the lower abdomen and pelvis to the right subhepatic and subphrenic 'spaces' via the right paracolic gutter, which is deeper than the left paracolic gutter and has no obstructing phrenico-
colic ligament (Meyers 1973). Passage across the midline to the left subphrenic space is prevented by the falciform ligament. Peritoneal fluid flows in a predominantly clockwise direction around the peritoneal cavity (Fig. 63.1); it reaches the surface of the greater omentum, where it is processed by the immune system (Meyers et al 1987, Meyers 1994). Malignant cells may become trapped within peritoneal recesses or in the milky spots of the greater omentum, where they may proliferate and produce visible and palpable tumour deposits. These sites must be deliberately examined when searching for peritoneal metastases (Zonca et al 2008). Gross infiltration of the omentum by cancer, often referred to as an 'omental cake', emphasizes the capacity of the omentum to trap malignant cells. The movement of peritoneal fluid explains the presence of disease at sites such as the undersurface of the right hemidiaphragm and the pelvic pouches. An example is the Fitz-Hugh-Curtis syndrome, in which gonorrhoea or chlamydia organisms enter the peritoneal cavity through the uterine tubes and are transported in the peritoneal fluid to the right upper quadrant, where they cause perihepatic inflammation. Disruption of the integrity of the peritoneum by percutaneous puncture, laparoscopy or open surgery profoundly affects its defensive function and can create 'sticky' sites where pathogens or malignant cells can settle and proliferate.

Direct communication of abdominal and pleural spaces called pleuroperitoneal fenestrae may rarely exist (Pestieau et al 2000, Simmons and Mir 1989).

## PERITONEAL ATTACHMENTS

The parietal peritoneum is attached to the muscular layers of the abdominal wall by extraperitoneal connective tissue. Around the bladder and rectum, it is only loosely attached to allow for alterations in the size of these viscera, whereas it is firmly adherent to the inferior surface of the diaphragm and linea alba. The extraperitoneal tissue over the posterior abdominal wall frequently contains large amounts of fat, especially in obese males. The visceral peritoneum is firmly adherent to the underlying viscera and often blends with connective tissue in the wall of the organ; it rarely contains loose connective or adipose tissue. The visceral peritoneum is often considered as part of the underlying viscus for clinical and pathological purposes such as the staging of cancer. Because of its attachments, removal of the parietal peritoneum in the management of peritoneal metastases is possible without resection of underlying tissues, whereas cancer deposits on visceral peritoneum usually require partial resection of the viscus for complete removal (see Video 63.1).

## GENERAL ARRANGEMENT OF THE PERITONEUM

The alimentary tract develops as a single tube suspended in the coelomic cavity by ventral and dorsal mesenteries (Ch. 60). Ultimately, the ventral mesentery is largely resorbed, although some parts persist in the upper abdomen and form structures such as the lesser omentum and falciform ligament. The mesenteries of the intestines in the adult are the remnants of the dorsal mesentery. The migration and subsequent fixation of parts of the gastrointestinal tract produce the so-called 'retroperitoneal' segments of bowel (most of the duodenum, ascending colon, descending colon, and rectum) (Fig. 63.2), and four separate intraperitoneal bowel loops suspended by mesenteries of variable lengths. These are all covered by visceral peritoneum, which is continuous with the parietal peritoneum covering the posterior abdominal wall. The first intraperitoneal loop is formed by the abdominal oesophagus, stomach and first part of the duodenum. The second loop is made up of the duodenojejunal junction, jejunum, ileum and usually the caecum. The third loop contains the transverse colon, and the final loop contains the sigmoid colon and occasionally the distal descending colon.

Where visceral peritoneum encloses or suspends organs within the peritoneal cavity，the peritoneum and related connective tissues form ＇peritoneal ligaments＇，omenta or mesenteries．All but the greater omentum are composed of two layers of visceral peritoneum separated by variable amounts of fatty connective tissue．The greater omentum is folded back on itself and therefore consists of four layers of visceral peritoneum separated by variable amounts of adipose tissue．Mesenter－ ies attach their respective viscera to the posterior abdominal wall；the attachment of the mesentery of the small intestine to the posterior abdominal wall is referred to as the root of the mesentery（see Fig． 63．2）．The mesenteries contain the neurovascular bundles and lym－ phatic channels that supply the suspended organs．In obese individuals， extensive adipose tissue within the mesenteries and omenta may obscure these neurovascular bundles．In contrast，in the very young，the elderly or the malnourished，the mesenteries and omenta may contain little adipose tissue and the neurovascular bundles are more obvious．

Although they are described as intraperitoneal，the suspended viscera，strictly speaking，do not lie within the peritoneal cavity because they are covered by visceral peritoneum．They are in continuity with extraperitoneal tissues，including the retroperitoneum．The loose areolar connective tissue that forms the extraperitoneal and retroperi－ toneal tissues is often divided into potential＇spaces＇as evidenced by the presence of discrete collections of fluid or blood in pathological conditions（see Figs 62．4－62．6）．

## PERITONEUM OF THE UPPER ABDOMEN

The abdominal oesophagus，stomach，liver and spleen all lie within a double fold of visceral peritoneum that runs from the posterior to the anterior abdominal wall．This fold has no recognized name but has been referred to as the mesogastrium，from which it is derived（Coakley
and Hricak 1999）．It has a complex attachment to the wall of the abdominal cavity and forms the falciform ligament，coronary liga－ ments，lesser omentum（gastrohepatic and hepatoduodenal ligaments）， greater omentum（including the gastrocolic ligament），gastrosplenic ligament，splenorenal ligament and phrenicocolic ligament（see Fig． 63．2；Figs 63．3－63．5）．

## Falciform ligament

The falciform ligament is a thin anteroposterior double fold of perito－ neum that connects the liver to the posterior aspect of the anterior abdominal wall just to the right of the midline．Adjacent to the ante－ rior abdominal wall，it contains a variable amount of fat（Feldberg and van Leeuwen 1990）．It extends inferiorly to the level of the umbilicus and superiorly it narrows to a depth of $1-2 \mathrm{~cm}$ as the distance between the liver and anterior abdominal wall decreases．Its two peritoneal layers separate to enclose the liver，to which it is firmly adherent．Supe－ riorly，the two peritoneal layers are continuous with the parietal peritoneum on the undersurface of the diaphragm but are reflected laterally to form the superior layer of the coronary ligament of the liver on the right and the left triangular ligament of the liver on the left．The inferior aspect of the falciform ligament forms a free border，where the two peritoneal layers are continuous with each other as they enclose the ligamentum teres．Because the peritoneum of the falciform liga－ ment is in continuity with that covering the posterior abdominal wall and with the parietal peritoneum of the anterior abdominal wall， blood from a retroperitoneal haemorrhage（commonly，acute haemor－ rhagic pancreatitis）may track between the folds of peritoneum and appear as haemorrhagic discolouration around the umbilicus（Cullen＇s sign）．The bloodstained fluid reaches the periumbilical region via the lesser omentum and falciform ligament or via the pararenal spaces and abdominal wall．

Fig. 63.2 The posterior abdominal wall, showing the lines of peritoneal reflection, after removal of the liver, spleen, stomach, jejunum, ileum, caecum, transverse colon and sigmoid colon. The various sessile (retroperitoneal) organs can be seen through the posterior parietal peritoneum. Note the ascending and descending colon, duodenum, kidneys, suprarenal glands, pancreas and inferior vena cava. Line W-W represents the plane of Figure 63.3. Line $X-X$ represents the plane of Figure 63.4. Line $Y-Y$ represents the plane of Figure 63.5. Line A-A represents the plane of Figure 63.6A. Line B-B represents the plane of Figure 63.6B. Line C-C represents the plane of Figure 63.6C.

## Peritoneal connections of the liver

The liver is almost completely covered in visceral peritoneum; only the 'bare area' posteriorly is in direct contact with the right hemidiaphragm. Peritoneal ligaments run from the liver to the surrounding viscera and to the abdominal wall and diaphragm (see Fig. 63.2; Fig. 63.6); they are described in detail in Chapter 67.

The coronary ligament is formed by the reflection of the peritoneum from the diaphragm on to the superior and posterior surfaces of the right lobe of the liver. Between the two layers of this ligament, a large triangular area, the 'bare area' of the liver, is devoid of peritoneal covering. Here, the liver is connected to the diaphragm by areolar tissue, which is in continuity inferiorly with the anterior pararenal space. On the right, the two layers of the coronary ligament converge laterally to form the right triangular ligament. On the left, the two layers fuse to form the left triangular ligament. The upper layer of the coronary ligament is reflected superiorly on to the undersurface of the diaphragm and inferiorly on to the right and superior surfaces of the liver. The lower layer of the coronary ligament is reflected inferiorly from the posterior surface of the liver on to the posterior abdominal wall over the right suprarenal gland and kidney. The peritoneal recess formed between the inferior surface of the liver and the upper pole of the right
kidney is known as the hepatorenal pouch (of Morison) (Stringer 2009). In the supine position, this is the most dependent part of the peritoneal cavity in the upper abdomen and is a site where fluid or peritoneal metastases may localize.

The lower layer of the coronary ligament is continuous with the peritoneum that descends over the anterior surface of the right kidney and to the front of the first part of the duodenum and hepatic flexure of the colon (see Fig. 63.2). Medially, it passes in front of a short segment of the inferior vena cava lying between the first part of the duodenum below and the caudate process of the liver above, forming the posterior wall of the epiploic foramen. This narrow strip broadens out as the peritoneum continues across the midline on to the posterior wall of the lesser sac.

The right triangular ligament is a short, V-shaped fold at the right lateral limit of the bare area of the liver, where the two layers of the coronary ligament converge. It is continuous with the peritoneum of the right posterolateral abdominal wall. Surgical division of the right triangular and coronary ligaments allows the right lobe of the liver to be retracted forwards, exposing the lateral aspect of the inferior vena cava behind the liver.

The left triangular ligament is a double layer of peritoneum that extends for a variable length over the superior border of the left lobe
of the liver．Medially，the anterior leaf is continuous with the left layer of the falciform ligament，while the posterior layer is continuous with the lesser omentum．The left triangular ligament lies in front of the abdominal oesophagus，the upper limits of the lesser omentum，and part of the fundus of the stomach．Division of the left triangular liga－

Fig．63．3 A sagittal section through the abdomen to the right of the epiploic foramen along the line of $\mathrm{W}-\mathrm{W}$ in Figure 63．2．
ment allows the left lobe of the liver to be mobilized．The left triangular ligament is an important stabilizing factor for the left lobe after excision of the right lobe of the liver．

The peritoneum of the left triangular ligament is continuous with that lining the undersurface of the left dome of the diaphragm，which， in turn，is continuous with that lining the posterior abdominal wall． Here it passes behind the spleen on to the most lateral part of the mesentery of the transverse colon and the splenic flexure．It continues down lateral to the descending colon into the pelvis，forming the left paracolic gutter．Medially，the peritoneum covering the left upper pos－ terior abdominal wall is reflected anteriorly to merge with the upper end of the lesser omentum，the peritoneum overlying the left aspect of the abdominal oesophagus，and the left layer of the gastrosplenic liga－ ment（see Fig．63．2）．

Parietal peritoneum lines the posterior abdominal wall over the diaphragmatic crura，the upper abdominal aorta and its associated branches，lymph nodes and nerve plexuses，and the upper anterior surface of the pancreas．Below the liver，it continues down the posterior abdominal wall，forming the right paracolic gutter between the antero－ lateral abdominal wall and the ascending colon．

## Lesser omentum

The lesser omentum is formed by two layers of peritoneum separated by a variable amount of connective tissue and fat．It is derived from the ventral mesogastrium．It runs between the inferior visceral surface of the liver and the abdominal oesophagus，stomach，pylorus and first part of the duodenum．Superiorly，its attachment to the inferior surface of the liver forms an L shape．The vertical component of the L is formed by the fissure for the ligamentum venosum；inferiorly，the attachment turns horizontally to complete the L in the porta hepatis．The part of the lesser omentum running between the liver and the stomach is known as the gastrohepatic ligament and the part between the liver and duodenum is the hepatoduodenal ligament．The right and left gastric vessels，branches of the vagus nerves and lymph nodes are contained within the two layers of the gastrohepatic ligament close to its gastric attachment．An accessory or replaced left hepatic artery is sometimes present（p．1166）．The anterior layer of the lesser omentum descends from the fissure for the ligamentum venosum on to the anterior surface of the abdominal oesophagus，stomach and duodenum．The posterior layer descends from the fissure and runs on to the posterior surface of the stomach and pylorus．At the lesser curvature of the stomach，the peritoneal layers of the lesser omentum split to enclose the stomach

Fig．63．4 A section through the upper part of the abdominal cavity，along the line $\mathrm{X}-\mathrm{X}$ in Figure 63．2．The boundaries of the epiploic foramen are shown and a small recess of the lesser sac is displayed anterior to the head of the pancreas．Note that the transverse colon and its mesocolon are adherent to the posterior two layers of the greater omentum． Four peritoneal layers contribute to the formation of the greater omentum because the apron of omentum is folded back on itself．

Fig. 63.5 A sagittal section through the abdomen, approximately in the median plane. Compare with Figure 63.2. The section cuts the posterior abdominal wall along the line $\mathrm{Y}-\mathrm{Y}$ in Figure 63.2. The peritoneum is shown in blue except along its cut edges, which are left white.
and are continuous with the visceral peritoneum covering the anterior and posterior surfaces of the stomach. The posterior layer of the lesser omentum forms part of the anterior surface of the lesser sac (see Fig. 63.5).

The free right lateral border of the lesser omentum is thickened and extends from the porta hepatis to the junction between the first and second parts of the duodenum. This free border forms the anterior boundary of the epiploic foramen and contains the portal vein (posteriorly), the bile duct (anteriorly to the right), and hepatic artery proper (anteriorly to the left) (see Fig. 63.6B), together with lymphatics, lymph nodes and hepatic autonomic nerves. An accessory or replaced right hepatic artery arising from the superior mesenteric artery may sometimes be found in the free edge of the lesser omentum, usually running posterior to the portal vein. Occasionally, the free margin of the lesser omentum extends to the right and runs on to the gallbladder, when it is referred to as the cystoduodenal ligament (Ashaolu et al 2011).

The upper border of the lesser omentum is short and runs over the inferior surface of the diaphragm between the liver and medial aspect of the abdominal oesophagus. The lesser omentum is thinner in this region and may be fenestrated or incomplete; variations in thickness are dependent on the amount of connective tissue, especially fat.

## Greater omentum

The greater omentum is the largest peritoneal fold and hangs inferiorly from the greater curvature of the stomach. When the undisturbed abdomen is opened, the greater omentum is frequently draped over the upper abdominal organs, but often not in the even distribution shown in many illustrations. It is usually thin but always contains some adipose tissue and is a common site for storage of fat in obese individuals, particularly males (Coulier 2009). The greater omentum is a double sheet: each sheet consists of two layers of peritoneum separated by a scant amount of connective tissue. The two sheets are folded back on themselves and firmly adherent to each other below the transverse colon. Above this level the anterior sheet separates from the posterior
sheet and is attached to the greater curve of the stomach (see Fig. 63.5); this supracolic part of the greater omentum is known as the gastrocolic ligament. The most anterior layer of peritoneum of the greater omentum is continuous with the visceral peritoneum over the anterior surface of the stomach and duodenum. The anterior sheet descends from the greater curvature of the stomach and first part of the duodenum for a variable distance into the peritoneal cavity and then turns sharply backwards on itself to ascend as the posterior sheet. The posterior sheet passes anterior to the transverse colon and transverse mesocolon, and is attached to the posterior abdominal wall above the origin of the transverse mesocolon and anterior to the head and body of the pancreas (see Figs 63.2, 63.5). The anterior peritoneal layer of the posterior sheet is continuous with the peritoneum of the posterior wall of the lesser sac. The posterior peritoneal layer is reflected sharply inferiorly and is continuous with the anterior layer of the transverse mesocolon. The posterior sheet is adherent to the transverse colon and its mesentery. In early fetal life, the greater omentum and transverse mesocolon are separate structures, and this arrangement occasionally persists. During surgery, the natural adhesions between the transverse mesocolon and greater omentum can be divided, and the greater omentum can be detached from the transverse colon and mesocolon if required. Access into the lesser sac can then be obtained by dividing the upper part of the posterior sheet of greater omentum. This gives a relatively bloodless surgical approach to the posterior wall of the stomach and the anterior surface of the pancreas.

On the left side of the abdomen, the greater omentum is continuous with the gastrosplenic ligament; on the right side, it extends to the beginning of the duodenum (see Fig. 63.2). A fold of peritoneum, the hepatocolic ligament, may run from either the inferior surface of the right lobe of the liver or the first part of the duodenum to the right side of the greater omentum or hepatic flexure of the colon. The right border of the greater omentum is usually adherent to the anterior surface of the hepatic flexure and upper ascending colon but its peritoneal layers are not continuous with the visceral peritoneum over this part of the colon. The right border of the greater omentum may also be attached to a thin but vascular peritoneal band (Jackson's membrane),

Fig. 63.6 Transverse sections through the abdomen. A, At the level of the line A-A in Figure 63.2. The line passes through the bare area of the liver at the superior end of the lesser omentum. The parts of the left subphrenic space are clearly seen, although they are continuous with each other. B, At the level of line B-B in Figure 63.2, viewed from below. The peritoneal cavity is shown by blue shading; the peritoneum and its cut edges are in pale blue. C, A transverse section through the abdomen at the level of the line C-C in Figure 63.2, viewed from below. Colours as in Figure 63.2.
which, when present, runs from the anterior aspect of the ascending colon and caecum to the posterolateral abdominal wall. Other peritoneal folds between the ascending colon and posterolateral abdominal wall in the right lateral paracolic gutter are occasionally present. Less commonly, the left border of the greater omentum is adherent to the anterior surface of the descending colon.

The greater omentum has a rich blood supply derived from the right and left gastroepiploic vessels that run between the two peritoneal layers of the anterior sheet of greater omentum, close to the greater curvature of the stomach. These vessels give off numerous omental (epiploic) branches that run the length of the omentum. Microscopic capillary convolutions, sometimes termed 'omental glomeruli', lie directly beneath the mesothelium of the greater omentum. They are surrounded by aggregations of macrophages and lymphocytes (milky spots) that drain into lymphatic channels (Shimotsuma et al 1993); the macrophages form clusters near the mesothelial surface, while B and T lymphocytes are grouped around vessels. The fenestrated endothelium lining the omental glomeruli and the mesothelium overlying the milky spots share a similar mesodermal origin and together they form sites of leukocyte migration and peritoneal fluid absorption (Platell et al 2000). The number and size of milky spots increase in the presence of peritoneal inflammation, highlighting their defensive role.

The greater omentum serves several important functions. It is highly mobile and frequently becomes adherent to inflamed viscera or foreign bodies within the abdominal cavity. This can limit the spread of infection, as in the walling off of acute appendicitis, and promote haemostasis. However, it may also block peritoneal drains and catheters (such that omentectomy is sometimes performed when placing some intraperitoneal catheters). It absorbs peritoneal fluid. It contains macrophages and lymphoid tissue capable of destroying pathogens; macrophages and neutrophils readily migrate from the greater omentum into the peritoneal cavity in the presence of peritonitis. It promotes neovascularization of structures to which it becomes adherent and thus promotes healing of ischaemic tissues and supports splenic autotransplantation (Ch. 70). It is rarely the site of primary pathology; reports of segmental infarction, torsion or other disorders are rare.

The remarkable capacity of the greater omentum to participate in reparative processes is highlighted by its use as an omental pedicle flap or free flap in reconstructive surgery. It has been used to close gastrointestinal perforations, fill 'dead space' after surgical excision of pathology, and cover wound defects. A greater omental pedicle or free flap based on the right gastroepiploic vessels may be mobilized by dividing the gastric branches of these vessels close to the surface of the stomach and the left gastroepiploic vessels near their origin.

## Peritoneal connections of the spleen

The peritoneal connections of the spleen anchor it in the left upper quadrant of the abdomen; they include the gastrosplenic, splenorenal and phrenicocolic ligaments. The gastrosplenic ligament runs between the greater curvature of the stomach and the hilum of the spleen, and is in continuity with the left side of the greater omentum. The peritoneal layers of the gastrosplenic ligament separate to enclose the spleen and then rejoin to form the splenorenal and phrenicocolic ligaments. The splenorenal ligament extends from the spleen to the posterior abdominal wall, and the phrenicocolic ligament connects the splenic flexure of the colon to the diaphragm.

The splenorenal ligament is formed from two layers of peritoneum (see Fig. 63.6B). The anterior layer is continuous medially with the peritoneum of the posterior wall of the lesser sac over the left kidney and runs up to the splenic hilum, where it is continuous with the posterior layer of the gastrosplenic ligament. The posterior layer of the splenorenal ligament is continuous laterally with the peritoneum over the inferior surface of the diaphragm and runs on to the splenic surface over the renal impression. The splenic vessels lie between the layers of the splenorenal ligament, and the tail of the pancreas is usually present in its lower portion

The gastrosplenic ligament is also formed from two layers of peritoneum (see Fig. 63.6B). The posterior layer is continuous with the peritoneum of the splenic hilum and the peritoneum over the posterior surface of the stomach. The anterior layer is continuous with the peritoneum reflected off the gastric impression of the spleen and with the peritoneum over the anterior surface of the stomach. The short gastric and left gastroepiploic branches of the splenic artery, with their corresponding veins, pass between the layers of the gastrosplenic ligament. A fan-shaped fold of peritoneum often extends from the anterior aspect of the gastrosplenic ligament below the inferior pole of the spleen and blends with the phrenicocolic ligament. The phrenicocolic ligament
extends from the splenic flexure of the colon to the diaphragm at about the level of the eleventh rib. Inferiorly, it is continuous with the peritoneum of the lateral end of the transverse mesocolon near the tip of the pancreatic tail, and the splenorenal ligament at the hilum of the spleen.

Undue traction on the peritoneal attachments of the spleen at surgery may cause a capsular tear and serious bleeding. Downward traction on the phrenicocolic ligament during mobilization of the splenic flexure is particularly hazardous; medial traction on the greater omentum may also injure the spleen if the omentum is adherent to the splenic capsule.

## PERITONEUM OF THE LOWER ABDOMEN

The posterior surface of the lower anterior abdominal wall is lined by parietal peritoneum, which extends from the linea alba centrally to the lateral paracolic gutters, where it is reflected over the front and sides of the ascending colon on the right and the descending colon on the left (see Fig. 63.2). Occasionally, the ascending and descending colon are suspended by a short mesentery from the posterior abdominal wall (Ch. 66). Between the ascending and descending colon, the peritoneum covers the posterior abdominal wall, except where it is reflected over the oblique root of the mesentery of the small intestine. Over the posterior abdominal wall, it covers psoas major and quadratus lumborum, the inferior vena cava, duodenum, vertebral column and both ureters. In the upper abdomen, the posterior parietal peritoneum is reflected anteriorly where it is continuous with the peritoneum of the posterior layer of the transverse mesocolon.

## Transverse mesocolon

The mesentery of the transverse colon is a broad fold of visceral peritoneum reflected anteriorly from the posterior abdominal wall. It suspends the transverse colon in the peritoneal cavity. The root of the transverse mesocolon passes obliquely from the anterior aspect of the second part of the duodenum, over the head and neck of the pancreas, superior to the duodenojejunal junction over the upper pole of the left kidney to the splenic flexure (see Fig. 63.2). It varies considerably in length but is shortest at either end. It contains the middle colic vessels and their branches, together with autonomic nerves from the aortic plexus, lymphatics and lymph nodes. Near the splenic flexure, the ascending branch of the left colic artery terminates within the transverse mesocolon. Its two peritoneal layers pass to the posterior surface of the transverse colon, where they separate to invest the colon. The upper layer of peritoneum is continuous with the posterior layer of the greater omentum, to which it is adherent (see Fig. 63.5). The lower layer of peritoneum of the transverse mesocolon is continuous with the peritoneum of the posterior abdominal wall. Lateral extensions of the transverse mesocolon produce two folds: on the right, the duodenocolic ligament extends from the transverse mesocolon at the hepatic flexure to the second part of the duodenum; on the left, the phrenicocolic ligament extends from the transverse mesocolon at the splenic flexure to the diaphragm. The root of the transverse mesocolon is closely related to the upper limit of the root of the mesentery of the small intestine near the uncinate process of the pancreas.

## Mesentery of the small intestine

The mesentery of the small intestine is arranged as a complex fan that is formed from two layers of peritoneum (anterosuperior and posteroinferior) separated by fatty connective tissue containing vessels and nerves. The root of the mesentery lies along a line running diagonally from the duodenojejunal flexure on the left side of the second lumbar vertebral body to the right sacroiliac joint (see Fig. 63.2). The root crosses over the third part of the duodenum, abdominal aorta, inferior vena cava, right ureter and right psoas major. The average length of the root of the mesentery is 15 cm in adults while along its intestinal attachment it measures the same length as the small intestine (approximately 5 m ). Consequently, the mesentery is usually thrown into multiple folds along its intestinal border. The average depth of the mesentery from the root to the intestinal border is 20 cm , but this varies along the length of the small intestine: it is shortest at the jejunum and terminal ileum, and longest in the mid-ileal region. Its two peritoneal layers contain the jejunal and ileal branches of the superior mesenteric vessels, nerves related to the superior mesenteric plexus, lymphatics and regional lymph nodes. The length and mobility of the mesentery may make it difficult to determine the site and orientation of a loop of small intestine through a small surgical incision. Tracing the continuity of a
peritoneal layer of the mesentery on to the posterior abdominal wall may be useful in orientating an isolated loop if the duodenojejunal flexure or ileocaecal junction is not readily accessible. The mesentery of the small intestine is sometimes joined to the transverse mesocolon at the duodenojejunal flexure by a peritoneal band. Occasionally, the fourth part of the duodenum possesses a very short mesentery that is continuous with the upper end of the root of the mesentery of the small intestine. Additional bands of peritoneum may connect the terminal ileum to the posterior abdominal wall. The root of the mesentery of the small intestine is continuous with the peritoneum that surrounds the appendix and caecum in the right iliac fossa.

## Mesoappendix

The mesentery of the appendix is a fatty, triangular fold of peritoneum that passes between the posterior surface of the mesentery of the terminal ileum close to the ileocaecal junction and the vermiform appendix. It may end short of the tip of the appendix, in which case a thin, shallow fold of peritoneum containing fat is present towards the tip. It encloses the blood vessels, nerves and lymph vessels of the vermiform appendix, and usually contains a lymph node. A small fold of peritoneum runs between the terminal ileum and the anterior layer of the mesoappendix (the 'bloodless fold of Treves'), and another fold of peritoneum containing the anterior caecal artery may extend from the terminal ileal mesentery to the anterior wall of the caecum (see below).

## Sigmoid mesocolon

The sigmoid mesocolon varies in length and depth between individuals. The root of the sigmoid colon usually has a shallow, inverted V-shaped attachment; the apex of the V overlies the division of the left common iliac artery (see Fig. 63.2). Alternatively, the attachment may form a gentle curve. The left limb of the attachment runs over the left psoas major and along the external iliac vessels. The right limb passes over the pelvic brim towards the midline at the level of the third sacral vertebra. The anteromedial peritoneal layer of the sigmoid mesocolon is continuous with the peritoneum of the lower left posterior abdominal wall, and its posterolateral layer is continuous with the peritoneum of the lateral abdominal wall. Bands of peritoneum may be present running from the proximal sigmoid colon to the posterior abdominal wall. The sigmoid and superior rectal vessels run between its layers and the left ureter descends into the pelvis behind its apex and anterior to the bifurcation of the left common iliac artery.

## Peritoneum of the lower anterior abdominal wall

The peritoneum of the lower anterior abdominal wall is raised into five folds (sometimes referred to as 'ligaments'), which diverge as they descend from the umbilicus. They are the median, right and left medial, and right and left lateral, umbilical folds (Fig. 63.7, see Fig. 75.9). The median umbilical fold extends from the umbilicus to the apex of the bladder and contains the urachus or its remnant (Ch. 72). The medial umbilical fold overlies the obliterated umbilical artery, which ascends from the internal iliac artery in the pelvis to the umbilicus. The lateral umbilical fold covers the inferior epigastric vessels below their entry into the rectus sheath. The supravesical fossa lies between the medial and median umbilical folds on each side of the midline, and the medial and lateral inguinal fossae lie on either side of each lateral umbilical fold. The lateral inguinal fossa overlies the deep inguinal ring, and the medial inguinal fossa overlies the femoral ring (Healy and Reznek 1999).

## PERITONEUM OF THE PELVIS

The parietal peritoneum of the abdominal wall is continuous with the parietal peritoneum that lines the side walls of the pelvis. The arrangement of the pelvic visceral peritoneum differs between the sexes.

## Peritoneum of the male pelvis

In males, the peritoneum of the left lower abdominal wall is reflected from the distal sigmoid colon and anterolateral surface of the upper rectum to the side walls of the true pelvis, where it forms the right and left pararectal fossae (Fig. 63.8); these vary in size according to the degree of distension of the rectum. The peritoneum is reflected anteri-

Fig. 63.7 The infra-umbilical part of the anterior abdominal wall of a male subject: posterior surface, with the peritoneum in situ.
orly from the anterior surface of the rectum over the upper poles of the seminal vesicles and on to the posterior surface of the bladder, producing the rectovesical pouch. The pouch is limited laterally by sacrogenital folds of peritoneum, which extend posteriorly from the sides of the bladder to the anterior aspect of the sacrum. The peritoneum covering the posterosuperior surface of the bladder forms a paravesical fossa on each side that is limited laterally by a ridge of peritoneum containing the vas deferens; the depth of the paravesical fossae depends on the volume of urine in the bladder. When the bladder is empty, a transverse vesical fold may be visible at laparoscopy; its medial portion overlies the superior vesical artery or arteries (Boaz et al 2011). Between the paravesical and pararectal fossae, the ureters and internal iliac vessels may cause slight elevations in the peritoneum. From the apex of the bladder, the median umbilical fold extends superiorly on the posterior surface of the lower anterior abdominal wall to the umbilicus. When the bladder distends, the overlying peritoneum is lifted so that part of the anterior surface of the bladder comes into direct contact with the posterior surface of the lower anterior abdominal wall. This means that a distended bladder can be punctured directly through the lower anterior abdominal wall without traversing the peritoneal cavity (suprapubic puncture).

## Peritoneum of the female pelvis

In females, peritoneum covers the anterolateral surface of the upper rectum as it does in the male, but it descends further over the anterior surface of the rectum. The pararectal and paravesical fossae are limited laterally by the peritoneum that covers the uterosacral and round ligaments of the uterus, respectively (see Figs 77.14, 77.15, 77.18). The presence of the uterus and vagina means that there are two pelvic pouches instead of the single rectovesical pouch seen in males. The peritoneum from the rectum is reflected anteriorly on to the posterior surface of the posterior fornix of the vagina and the uterus, forming the recto-uterine pouch (of Douglas). The depth of the pouch - namely, the extent to which it descends on the posterior surface of the vagina - is variable (Baessler and Schuessler 2000). The peritoneum covers the fundus and body of the uterus, descending on its anterior surface as far as the junction of the body and cervix; from here, it is reflected forwards on to the posterosuperior surface of the bladder, forming a shallow vesico-uterine pouch. As in males, the peritoneum over the dome of the bladder is reflected on to the posterior surface of the lower anterior abdominal wall. Recto-uterine folds containing the uterosacral ligaments pass posteriorly from the sides of the cervix to the sacrum, running lateral to the rectum. Peritoneum is also reflected from the anterior and posterior uterine surfaces to the lateral pelvic walls as the broad ligament of the uterus (see Fig. 77.18). This consists of anterior and posterior layers that are continuous at the upper border of the ligament. The broad ligament contains the uterine tubes in its free upper border; the ovaries are suspended from its posterior layer. Inferiorly, the

Fig. 63.8 The peritoneum of the male pelvis: anterosuperior view.
peritoneum at the base of the broad ligament merges with the pelvic parietal peritoneum. The ovarian fossa is a shallow depression in the peritoneal lining of the lateral pelvic wall between the peritoneal ridges formed by the obliterated umbilical arteries anteriorly, the ureter posteriorly, and the external iliac vessels above; it lies behind the lateral attachment of the broad ligament and usually contains the ovary in nulliparous females.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Parietal and visceral peritoneum develops from the somatopleural and splanchnopleural layers, respectively, of the lateral plate mesoderm (p. 1059). Parietal peritoneum is supplied by the somatic blood vessels of the abdominal and pelvic walls, and its lymphatics join those in the body wall and drain to parietal lymph nodes. Visceral peritoneum is best considered as an integral part of the viscus it covers: its blood supply and lymphatic drainage therefore correspond to those of the associated viscus.

## INNERVATION

The parietal peritoneum is innervated by somatic efferent and afferent nerves that also supply the muscles and skin of the overlying body wall. The visceral peritoneum is innervated by afferent nerves that travel with the autonomic supply to the underlying viscera. Sensations arising from pathologies that affect the parietal or visceral peritoneum reflect these different patterns of innervation. Well-localized pain is elicited by mechanical, thermal or chemical stimulation of nociceptors in the parietal peritoneum; the pain is usually well localized to the affected region. Somatic nerves that innervate the parietal peritoneum also supply the corresponding segmental skin and muscles; when the parietal peritoneum is irritated, local reflex muscle contraction occurs, resulting in clinical signs of guarding or even rigidity of the abdominal wall. The parietal diaphragmatic peritoneum is supplied centrally by afferent fibres from the phrenic nerves and peripherally by the lower intercostal and subcostal nerves; peripheral irritation of the diaphragm may therefore result in pain localized in the distribution of the lower thoracic spinal nerves, while central irritation causes referred pain in the cutaneous distribution of the third to fifth cervical spinal nerves (the shoulder region). The innervation of the parietal peritoneum of the true pelvis is poorly documented but the obturator nerve makes a significant contribution.

Irritation or stretch of the visceral peritoneum causes poorly localized discomfort. The sensation of pain is referred to a diffuse area of the abdominal wall. Thus, discomfort from structures derived from
the foregut is felt in the epigastric region, that from midgut structures in the umbilical region, and that from hindgut structures in the suprapubic region; none of these sensations is significantly lateralized. Pain from the pancreas, gallbladder and even the small bowel may radiate to the back. Stretch or irritation of the visceral peritoneum may also elicit profound reflex vasomotor and cardiac changes mediated by autonomic nerves, including a vasovagal response. This is of considerable clinical relevance. Painful responses to manipulation of the parietal peritoneum may be abolished by local or regional anaesthesia. In marked contrast, the direct central connections of visceral afferents, particularly via the vagus nerve, mean that stretching the visceral peritoneum may induce profound effects, including acute haemodynamic instability, despite local or regional (including spinal) anaesthesia.

## GENERAL ARRANGEMENT OF THE PERITONEAL CAVITY

The peritoneal cavity is a single continuous space between the parietal peritoneum lining the abdominal wall and the visceral peritoneum enveloping the abdominal organs. It consists of the greater sac, which is the main peritoneal cavity surrounding most of the abdominal and pelvic viscera, and the lesser sac, or omental bursa, which is a small diverticulum situated behind the stomach and lesser omentum and in front of the pancreas. These two sacs communicate via the epiploic foramen.

For clinical purposes, the peritoneal cavity can be divided into several 'spaces'; pathological processes are often contained within these spaces and their anatomy may influence diagnosis and treatment. It is useful to divide the peritoneal cavity into two main compartments, supramesocolic (often simply called supracolic) and inframesocolic (or infracolic), which are partially separated by the transverse colon and its mesentery. The pelvic peritoneal spaces are described above.

## SUPRAMESOCOLIC COMPARTMENT

This lies between the diaphragm and the transverse mesocolon. It can be arbitrarily divided into right and left supramesocolic spaces. The right supramesocolic space can be subdivided into the right subphrenic space, the right subhepatic space and the lesser sac. The left supramesocolic space can be divided into two subspaces: the left subphrenic space and the left perihepatic space. These 'spaces' usually communicate but may nevertheless be sites of localized fluid collections.

## Right subphrenic space

The right subphrenic space lies between the diaphragm and the anterior, superior and right lateral surfaces of the right lobe of the liver. It is bounded on the left by the falciform ligament and posteriorly by the upper layer of the coronary ligament (see Fig. 63.3). Because of the clockwise flow of peritoneal fluid from the lower abdomen and pelvis, it is a relatively common site for an infected fluid collection after a perforated appendicitis or duodenal ulcer.

## Right subhepatic space (hepatorenal pouch)

The right subhepatic space lies between the inferior surface of the right lobe of the liver and the upper pole of the right kidney. It is bounded superiorly by the inferior layer of the coronary ligament, laterally by the right lateral abdominal wall, posteriorly by the anterior surface of the upper pole of the right kidney, and inferomedially by the hepatic flexure, transverse mesocolon, second part of the duodenum, and part of the head of the pancreas. In the supine position, the hepatorenal pouch (of Morison) is more dependent than the right paracolic gutter. It is a site where a pathological fluid collection may develop.

## Lesser sac (omental bursa)

The lesser sac is a cavity lined with peritoneum and connected to the main peritoneal cavity (greater sac) by the epiploic foramen (of Winslow). It is considered part of the right supramesocolic compartment because it develops in the embryo on the right side of the ventral mesogastrium (p. 1059). It has posterior and anterior walls and superior, inferior, right and left borders. The sac varies in size according to the volume of the viscera making up its walls; it may be partially obliterated by natural adhesions between the anterior and posterior walls.

The anterior wall of the lesser sac consists of the posterior peritoneal layer of the lesser omentum, the peritoneum over the posterior wall of the stomach and first part of the duodenum, and the posterior upper part of the anterior sheet of the greater omentum (see Fig. 63.5). At its right border, the anterior wall is mostly formed by the lesser omentum but, towards the left, the lesser omentum becomes progressively shorter and more of the anterior wall is formed by the posterior surface of the stomach and greater omentum.

The lower part of the posterior wall of the lesser sac is formed by the anterior peritoneal layer of the posterior sheet of the greater omentum, which overlies the transverse mesocolon. More superiorly, the peritoneum of the posterior wall covers, from below upwards, a small part of the head and the whole neck and body of the pancreas, the medial part of the anterior aspect of the upper pole of the left kidney, most of the left suprarenal gland, the commencement of the abdominal aorta, the coeliac trunk and part of the diaphragm (see Fig. 63.2). The inferior phrenic, splenic, left gastric and common hepatic arteries lie partly behind the bursa. Many of these structures form the 'bed' of the stomach and are separated from it only by the linings of the lesser sac.

The superior border of the lesser sac is narrow and lies between the right side of the oesophagus and the upper end of the fissure for the ligamentum venosum; it is sometimes referred to as the superior recess of the omental bursa. Here, the peritoneum of the posterior wall of the lesser sac is reflected anteriorly from the diaphragm to join the posterior layer of the lesser omentum. The inferior border runs along the line of fusion of the layers of the greater omentum, which extends from the gastrosplenic ligament on the left to the peritoneal fold behind the first part of the duodenum on the right. If the layers of the greater omentum are not completely fused, the lesser sac may extend to the inferior limit of this structure, but this is rarely demonstrable at surgery.

The right border of the lesser sac is where the peritoneum overlying the head and neck of the pancreas is reflected on to the inferior aspect of the first part of the duodenum. The line of this reflection ascends to the left, along the medial side of the gastroduodenal artery. Near the upper duodenal border, the right border joins the floor of the epiploic foramen round the hepatic artery proper. The epiploic foramen therefore interrupts the right border. Above the epiploic foramen, the right border is formed by the peritoneal reflection from the diaphragm to the right margin of the caudate lobe of the liver, which then crosses the inferior vena cava. The left border of the lesser sac runs from the left end of the root of the transverse mesocolon and is mostly formed by the inner peritoneal layers of the splenorenal and gastrosplenic ligaments (see Fig. 63.6). The part of the lesser sac lying between the splenorenal and gastrosplenic ligaments is referred to as the splenic recess. Above the spleen, the two ligaments merge to form the short gastrophrenic ligament, which passes forwards from the diaphragm to
the posterior aspect of the fundus of the stomach and forms part of the upper left border of the lesser sac. The two layers of the gastrophrenic ligament diverge near the abdominal oesophagus, leaving part of the posterior gastric surface devoid of peritoneum. The left gastric artery runs forwards here into the lesser omentum.

The lesser sac is indented by a crescentic peritoneal fold that runs from the upper border of the neck of the pancreas to the upper part of the lesser curvature of the stomach. It is variably described but commonly known as the gastropancreatic fold. The upper part of this fold overlies the left gastric artery as it runs from the posterior abdominal wall to the lesser curvature of the stomach. The lower part of the fold overlies the common hepatic artery as it runs from the posterior abdominal wall to the lesser omentum. When the fold is prominent, it divides the lesser sac into a smaller superior and a larger inferior recess. The superior recess lies posterior to the lesser omentum and encloses the caudate lobe of the liver; it extends superiorly into the fissure for the ligamentum venosum and lies adjacent to the right crus of the diaphragm posteriorly. The inferior recess of the lesser sac lies between the stomach and pancreas, and is contained within the double sheet of the greater omentum.

Acute pancreatitis is probably the most common cause of a fluid collection within the lesser sac (or just behind its posterior peritoneal lining) (p. 1182). Bleeding from trauma or a ruptured splenic artery aneurysm and perforation of a posterior gastric ulcer are other causes of lesser sac collections.

## Epiploic foramen

The epiploic foramen (foramen of Winslow or aditus to the lesser sac) is a short, vertical slit, about 3 cm in height in adults, behind the free right border of the lesser omentum. It is the entrance to the lesser sac from the greater sac. The hepatoduodenal ligament, formed by the thickened free right margin of the lesser omentum and extending between the porta hepatis above and the upper border of the first part of the duodenum below, forms the anterior boundary of the foramen. Within this free border lie the bile duct (anteriorly on the right), the hepatic artery (anteriorly on the left) and the portal vein (posteriorly), together with nerves and lymphatics (see above). Rapid control of the hepatic artery and portal vein can be obtained by compression of the free edge of the lesser omentum (a 'Pringle' manœuvre), which is a potentially useful technique in liver trauma and surgery. Superiorly, the peritoneum of the posterior layer of the hepatoduodenal ligament runs over the caudate process of the liver, forming the roof of the epiploic foramen. This layer of peritoneum is then reflected on to the inferior vena cava, which forms the posterior border of the foramen. The floor of the foramen is formed by the peritoneal reflection overlying the upper border of the first part of the duodenum as it runs forwards above the head of the pancreas. A narrow passage, the vestibule of the lesser sac, may be formed to the left of the foramen between the caudate process above and the first part of the duodenum below. To the right, the rim of the foramen is continuous with the peritoneum of the greater sac. The anterior and posterior walls of the foramen are normally apposed, which partly explains why patients can develop large fluid collections isolated to the greater or lesser sac (Shrestha et al 2010).

## Left subphrenic space

The left subphrenic space lies between the diaphragm, the anterior and superior surfaces of the left lobe of the liver, the anterosuperior surface of the stomach and the diaphragmatic surface of the spleen. To the right it is bounded by the falciform ligament. It is expanded in the absence of the spleen and is a common site for fluid collection after splenectomy. The left subphrenic space is substantially larger than the right and can be divided into a left perihepatic space and anterior and posterior subphrenic spaces (see Fig. 63.6); these are in continuity in the absence of disease. The definitions of the boundaries of these spaces vary.

The left anterior subphrenic space is large and lies between the superior and anterolateral surfaces of the spleen and the diaphragm. Inferiorly and medially, this space is bounded by the phrenicocolic, splenorenal and gastrosplenic ligaments. The phrenicocolic ligament partially obstructs the flow of fluid from the left paracolic gutter (Meyers 1973), which may explain why left subphrenic collections are less frequent than right subphrenic collections after lower abdominal and pelvic surgery. Nevertheless, the left subphrenic space is a relatively common site of fluid collection after upper abdominal surgery, particularly surgery involving the spleen or distal pancreas. The left posterior subphrenic space is small and lies between the fundus of the stomach and the diaphragm above the origin of the splenorenal ligament.

The left perihepatic space is sometimes subdivided into anterior and posterior spaces. The left anterior perihepatic space lies between the

Free tumour cells in the peritoneal cavity, especially from mucinous tumours, may gain access to the lesser sac and settle by gravity into the inferior recess of the lesser sac. This is more likely on the right side of the lesser sac in an area recognized surgically as the 'subpyloric space'. Growth of tumour at this site may cause gastric outlet obstruction.

During surgical exploration of the abdomen, some peritoneal surfaces cannot be visualized without the aid of specific surgical manœuvres. One of these sites is the posterior aspect of the hepatoduodenal ligament. The recess created by the posterior aspect of the hepatoduodenal ligament and the caudate process is an important site for mucinous peritoneal metastases. It can be visualized during cytoreductive surgery by passing a tape around the structures in the free edge of the lesser omentum and retracting them forwards.
anterosuperior surface of the left lobe of the liver and diaphragm. The left posterior perihepatic space, also known as the gastrohepatic recess, lies inferior to the left lobe of the liver. It extends into the fissure for the ligamentum venosum on the right. Posteriorly, it is separated from the superior recess of the lesser sac by the lesser omentum.

## Extraperitoneal subphrenic spaces

There are two potential subphrenic spaces that actually lie outside the peritoneum but are of clinical relevance because they may be sites of fluid accumulation. The right extraperitoneal space is bounded by the two layers of the coronary ligament, the bare area of the liver, and the inferior surface of the right hemidiaphragm. The left extraperitoneal space lies anterior to the left suprarenal gland and upper pole of the left kidney.

## INFRAMESOCOLIC COMPARTMENT

The inframesocolic compartment (also called the infracolic compartment) lies below the transverse mesocolon and transverse colon, and is divided into two unequal spaces by the root of the mesentery of the small intestine (see Fig. 63.2). It contains the right and left paracolic gutters lateral to the ascending and descending colon, respectively. As a consequence of the mobility of the transverse mesocolon and mesentery of the small intestine, and the open boundaries of the inframesocolic compartment, disease processes are rarely confined to the compartment. Continuous peristalsis of the small bowel may explain the relative lack of peritoneal metastases on intestinal and mesenteric surfaces.

## Right infracolic space

The right infracolic space is a triangular space. It is smaller than its leftsided counterpart and lies posterior and inferior to the transverse colon and mesocolon to the right of the small intestinal mesentery. The space is narrowest inferiorly because the attachment of the root of the mesentery of the small intestine lies well to the right of the midline.

## Left infracolic space

The left infracolic space is larger than its right-sided counterpart and is in free communication with the pelvis. It lies posterior and inferior to the transverse colon and mesocolon, and to the left of the mesentery of the small intestine. The sigmoid colon and its mesentery may partially restrict the flow of fluid or blood from this space into the pelvis to the left of the midline.

## Paracolic gutters

The right and left paracolic gutters are peritoneal depressions on the posterior abdominal wall alongside the ascending and descending colon, respectively. The principal paracolic gutter lies lateral to the colon on each side. A less obvious medial paracolic gutter may be present, more often on the right side, if the ascending or descending colon possesses a short mesentery for part of its length. The right (lateral) paracolic gutter runs from the superolateral aspect of the hepatic flexure of the colon, down the lateral aspect of the ascending colon and caecum. It is continuous with the peritoneum of the pelvic cavity below. Superiorly, it is continuous with the peritoneum that lines the hepatorenal pouch and with the lesser sac through the epiploic foramen. Bile, pus, blood or other fluid may run along the gutter and collect in sites distant to the organ of origin. In supine patients, infected fluid from the right iliac fossa may ascend in the gutter to the right subphrenic space. In erect or semi-recumbent positions, fluid from the stomach, duodenum or gallbladder may run down the gutter to collect in the right iliac fossa (mimicking acute appendicitis) or pelvis to form an abscess. The right paracolic gutter is deeper than the left, which, together with the partial barrier provided by the phrenicocolic ligament, may explain why subphrenic collections are more common on the right.

## RECESSES OF THE PERITONEAL CAVITY

Peritoneal fossae or recesses within the peritoneal cavity are occasionally sites of internal herniation. If a loop of intestine becomes stuck in

Fig. 63.9 The superior and inferior duodenal recesses. Note that the transverse colon and jejunum have been displaced.
a fossa or recess, the bowel may become obstructed or strangulate from a constriction at the entrance to the recess. The contents of the peritoneal fold forming the fossa/recess must be considered when repairing such a hernia.

## Lesser sac

Although not usually classified as a peritoneal recess, the lesser sac may be a site of internal herniation. There are reports of the small intestine, caecum, transverse colon or gallbladder migrating through the epiploic foramen into the lesser sac and causing acute abdominal symptoms (Shrestha et al 2010).

## Duodenal recesses

Several folds of peritoneum may exist around the fourth part of the duodenum and the duodenojejunal junction, forming a number of named recesses (Fig. 63.9). They probably arise during development as a result of minor aberrations of duodenal rotation and fixation. Some are potential sites of internal herniation (Zonca et al 2008).

## Superior duodenal recess

The superior duodenal recess is occasionally present, often in association with an inferior duodenal recess. It lies directly to the left of the fourth part of the duodenum, adjacent to the second lumbar vertebra, and behind a crescentic superior duodenal fold. The fold has a semilunar free lower margin, which merges laterally with the peritoneum overlying the left kidney. The inferior mesenteric vein lies under the parietal peritoneum, directly behind the lateral end of this fold. The recess extends superiorly and varies in size, but commonly admits a fingertip.

## Inferior duodenal recess

The inferior duodenal recess is usually present, often in association with a superior recess, with which it may share an orifice. It lies to the left of the fourth part of the duodenum, adjacent to the third lumbar vertebra, behind an avascular, triangular inferior duodenal fold, which has a sharp upper edge. It usually admits one or two fingertips and extends inferiorly, sometimes behind the fourth part of the duodenum and to the left, in front of the ascending branch of the left colic artery and the inferior mesenteric vein.

## Paraduodenal recess

The paraduodenal recess may occur in conjunction with superior and inferior duodenal recesses. It lies a little to the left and slightly behind the fourth part of the duodenum, behind a falciform fold of peritoneum. The free right edge of this fold contains the inferior mesenteric vein and ascending branch of the left colic artery, and is part of the left colic mesentery. This recess is the site of a 'left paraduodenal hernia' (Khan et al 1998).

## Retroduodenal recess

The retroduodenal recess is the largest of the duodenal recesses but is rarely present. It lies behind the third and fourth parts of the duodenum in front of the abdominal aorta, is up to 10 cm deep, and has a wide orifice flanked by duodenoparietal peritoneal folds.

The distribution of peritoneal metastases via the paracolic gutters is not the same on each side. Peritoneal fluid usually tracks freely along the right paracolic gutter, whereas the flow of peritoneal fluid running down the left paracolic gutter from the upper abdomen will be impeded by any attachments of the sigmoid colon to the left abdominal wall. Cancer deposits at this site tend to invade the mesentery of the junction between the sigmoid and descending colon, and therefore necessitate sigmoid colectomy for tumour clearance.

The superior and inferior recesses of the duodenum may be sites of occult peritoneal metastases and must be examined in patients having surgery for peritoneal metastases.

Fig. 63.10 The peritoneal folds and recesses in the caecal region.

## Duodenojejunal recess

The duodenojejunal or mesocolic recess occurs in a minority of adults. When present, it is almost never associated with other duodenal recesses. It is approximately 3 cm deep and lies to the left of the abdominal aorta, between the duodenojejunal junction and the root of the transverse mesocolon. It is bounded above by the pancreas, on the left by the kidney, and below by the left renal vein. Its circular opening lies between two peritoneal folds and faces down and to the right.

## Mesentericoparietal recess

The mesentericoparietal recess or fossa is rarely present. It lies just below the third part of the duodenum and invaginates the upper part of the mesentery of the small intestine towards the right. Its orifice is large and faces to the left, behind a fold of mesentery raised by the superior mesenteric artery. This recess is the site of the rare 'right paraduodenal hernia'.

## Caecal recesses

Peritoneal folds around the caecum may form a variety recesses (Fig. 63.10); these have the potential to become sites of internal herniation (Rivkind et al 1986). Paracaecal recesses are common sites for abscess formation after acute appendicitis.

## Superior ileocaecal recess

The superior ileocaecal recess is usually best developed in children and may be absent in the aged or obese. It is a narrow slit bounded in front by a vascular fold of peritoneum containing the anterior caecal vessels, behind by the ileal mesentery, below by the terminal ileum and on the right by the ileocaecal junction. Its orifice opens to the left.

## Inferior ileocaecal recess

The inferior ileocaecal recess is similarly well developed in the young but frequently obliterated by fat in adults. It is formed by the ileocaecal fold, which extends from the anteroinferior aspect of the terminal ileum to the front of the mesoappendix (or to the appendix or caecum). It is also known as the 'bloodless fold of Treves', although it sometimes contains blood vessels that bleed if divided during surgery. If inflamed, especially when the appendix and its mesentery are retrocaecal, it may be mistaken for the mesoappendix. The recess is bounded in front by the ileocaecal fold, above by the terminal ileum and its mesentery, to the right by the caecum, and behind by the upper part of the mesoappendix. Its orifice opens downwards to the left.

## Retrocaecal recess

The retrocaecal recess lies behind the caecum. It ascends behind the ascending colon to a variable extent, often being large enough to admit an entire finger. It is bounded in front by the caecum (and sometimes the proximal ascending colon), behind by the parietal peritoneum, and on each side by caecal folds (parietocolic folds) passing from the caecum to the posterior abdominal wall. The vermiform appendix frequently occupies this retrocaecal recess (p. 1142).

In addition to these caecal recesses, one or more shallow paracaecal or paracolic recesses may be present. These are simply depressions within the right paracolic gutter and are not sites of internal herniation.

## Intersigmoid recess

The intersigmoid recess is present in fetal life and infancy, but often disappears subsequently. It lies behind and inferior to the apex of the V-shaped attachment of the sigmoid mesocolon. It opens downwards and varies in shape from a slight depression to a shallow fossa. Its posterior wall is formed by the parietal peritoneum of the posterior abdominal wall, where it covers the left ureter as it crosses the bifurcation of the left common iliac artery. It is a rare site for an internal hernia (Harrison et al 2011).

## Internal hernias

An internal hernia is a protrusion of a viscus through a normal or abnormal aperture (which includes a surgically created opening) within the confines of the peritoneal cavity (Martin et al 2006). It is possible for any of the peritoneal recesses, foramina or cul-de-sacs described in this chapter to be associated with the development of an internal hernia, but with a clinically apparent internal hernia the relevant peritoneal recess is usually enlarged and its aperture narrowed compared to normal. Among the many potential sites for an internal hernia, the most common are paraduodenal, followed by pericaecal, and hernias through the epiploic foramen.

## ADDITIONAL CLINICAL ASPECTS OF THE PERITONEAL CAVITY

## Peritoneal fluid collections

Fluid collections frequently develop within the peritoneal cavity in response to a wide range of pathological processes. In the absence of inflammation, peritoneal adhesions or previous surgery, serous fluid tends to be distributed widely between the peritoneal spaces. Simple ascites can therefore be drained freely from any convenient dependent part of the peritoneal cavity; drainage is most commonly performed by blind puncture or ultrasound-guided insertion of a catheter into the lower left or right paracolic gutters. The mobility of the small bowel makes it very unlikely to be injured during this procedure.

Fluid collections caused by inflammatory processes are often much thicker because they contain pus, fibrin or blood. Furthermore, they are usually associated with peritoneal adhesions arising from peritoneal inflammation. These factors predispose to the formation of localized fluid collections, which may become walled-off as the inflammatory process progresses. Any of the peritoneal spaces may develop a localized collection, but the subphrenic, subhepatic and pelvic spaces are the most common sites since they are well defined by peritoneal folds and organs forming their boundaries. These spaces are also the most dependent regions within the peritoneal cavity.

Surgical access to the peritoneal spaces is less often needed today because of advances in radiologically guided percutaneous drainage using fluoroscopy, ultrasound, computed tomography (CT) or magnetic resonance imaging (MRI) guidance. These techniques offer reliable and versatile methods of accessing peritoneal spaces, including relatively inaccessible subhepatic, perihepatic or intermesenteric collections. Posterolateral translumbar or trans-sciatic approaches can also be used to access the retroperitoneum and pelvis, respectively. Occasionally, a surgical approach is necessary; thus, a subcostal or lateral intercostal incision may be required to drain a subphrenic abscess or an inguinal incision to drain a pelvic abscess.

## Peritoneal dialysis

The mean surface area of the peritoneum in the adult (female) has been estimated to be about $1.4 \mathrm{~m}^{2}$ (with the visceral peritoneum accounting for about $80 \%$ of the total) (Albanese et al 2009). Mesothelium resembles vascular endothelium in that it allows the passage of ions and small molecules. Normally, the volume of fluid transmitted by peritoneal surfaces is small, but large volumes of fluid can be instilled into the peritoneal cavity and then siphoned out, using the peritoneum as a dialysing membrane. This can be used to support individuals with acute or chronic renal failure.

## Ventriculoperitoneal shunts

The absorptive capabilities of the peritoneum can be exploited to absorb excess transitional fluids from several sites in the body. The most common of these is the absorption of cerebrospinal fluid diverted into the peritoneal cavity using a shunt (a fine catheter) from the cerebral ventricles or the intrathecal space. The catheter placed within the peritoneal cavity can be equipped with a one-way valve to prevent reflux of peritoneal fluid into the cerebrospinal fluid. The cerebrospinal fluid is continuously absorbed by the peritoneum, maintaining a low pressure within the intraventricular or intrathecal space.

## Intraperitoneal cancer chemotherapy

In patients with peritoneal metastases, attempts to optimize the benefits of cytoreductive surgery may involve the administration of
chemotherapeutic agents (diluted in large volumes of fluid) directly into the peritoneal cavity. Peritoneal access may be achieved via an intraperitoneal catheter connected to a subcutaneous port or by repeated paracentesis. The infused chemotherapeutic agents may be retained locally for longer than systemically administered agents. Targeting drugs to the peritoneal space may improve the results of treatment if complete tumour resection is not possible.

## Abdominal oesophagus and stomach

## ABDOMINAL OESOPHAGUS

The abdominal oesophagus is $1-2.5 \mathrm{~cm}$ in length, and is slightly broader at the cardiac orifice than at the diaphragmatic aperture. It lies to the left of the midline and enters the abdomen through the oesophageal aperture (formed by the two diaphragmatic crura) at the level of the eleventh thoracic vertebra (Mirjalili et al 2012). It runs obliquely to the left and slightly posteriorly, and ends at the gastro-oesophageal junction, where it is continuous with the cardiac orifice of the stomach. The anterior wall of the abdominal oesophagus is effectively longer than the posterior wall because of the obliquity of the crura. The abdominal oesophagus lies posterior to the left lobe of the liver, and anterior to the left crus, the left inferior phrenic vessels and the left greater and lesser splanchnic nerves; its surface is covered by a thin layer of connective tissue and visceral peritoneum that contain the anterior and posterior vagus nerves, as well as the oesophageal branches of the left gastric vessels. The anterior and posterior vagi may be single or composed of multiple trunks (Jackson 1949); the anterior is closely applied to the anterior outer surface of the longitudinal muscle coat of the oesophagus while the posterior usually lies within loose connective tissue immediately posterior and to the right of the oesophagus, making its identification during surgery somewhat easier. Unlike the more proximal parts of the oesophagus, the muscular wall of the abdominal oesophagus is composed entirely of smooth muscle.

The abdominal oesophagus is effectively tethered to the margins of the muscular oesophageal hiatus in the diaphragm by the phrenooesophageal ligament (Fig. 64.1) (Kwok et al 1999). This is formed by two circumferential layers of elastin-rich connective tissue containing some smooth muscle fibres. The inferior layer is an extension of the subperitoneal transversalis fascia below the diaphragm; it is thin and only loosely attached to the oesophagus. The superior layer is continu-

Fig. 64.1 The anatomical structures around the abdominal oesophagus. (Reprinted from Netter Anatomy Illustration Collection, © Elsevier Inc. All Rights Reserved.)
ous with the subpleural endothoracic fascia above the diaphragm; it is thicker, contains more elastin than its inferior counterpart, and runs cranially and obliquely to fuse firmly with the wall of the oesophagus. A variable amount of adipose tissue lies in the triangular interval between the two layers of the ligament. The phreno-oesophageal ligament helps to anchor the oesophagus to the crural muscle fibres of the diaphragm and probably acts to limit upward and downward mobility of the oesophagus within the hiatus (Kwok et al 1999). In the elderly, the ligament tends to become attenuated and contain more adipose tissue. The phreno-oesophageal ligament is denser anteriorly where it bridges between the outer layer of the oesophageal wall and the arching fibres of the diaphragmatic crura.

The peritoneal reflection posterior to the abdominal oesophagus is short and continues directly on to the posterior surface of the fundus of the stomach; it is sometimes referred to as the gastrophrenic ligament. It encloses the oesophageal branches of the left gastric vessels and the coeliac branches of the posterior vagus and can thus be considered to form an extremely short, wide mesentery to the abdominal oesophagus. In adults, a fat pad may be visible beneath the peritoneum over the anterior surface of the gastro-oesophageal junction and can be a useful surgical marker of the gastro-oesophageal junction.

## Hiatus hernia

Available with the Gray's Anatomy e-book

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The abdominal oesophagus is supplied by numerous oesophageal branches of the left gastric artery. These ascend beneath the visceral peritoneum to supply perforating branches to the intramural and submucosal plexuses. The posterior surface usually receives an additional supply via branches of the upper short gastric arteries, reinforced by terminal arteries from the oesophageal branches of the thoracic aorta and occasionally an ascending branch of the posterior gastric artery (Liebermann-Meffert et al 1987).

## Veins

Mucosal and submucosal veins drain via plexuses to the left gastric and upper short gastric veins in the abdomen and to the azygos/hemiazygos system of veins in the thorax. The distal oesophagus is an important site of portosystemic anastomosis where oesophageal varices develop in portal hypertension (see below).

## Lymphatic drainage

The oesophagus has a freely anastomosing plexus of lymphatics in the lamina propria, submucosa and muscularis propria. The lower third primarily drains caudally to left gastric and left and right paracardial nodes, and from there to coeliac nodes. In lower oesophageal cancer, lymph also drains cranially to mediastinal lymph nodes (Aikou et al 1987).

## INNERVATION

The oesophagus has a well-developed intrinsic nervous system consisting of a ganglionated myenteric plexus and a sparsely ganglionated submucosal plexus, modulated by extrinsic autonomic nerves. Parasympathetic innervation of the abdominal oesophagus is derived directly

Hiatus hernia is a relatively common condition involving expansion of the oesophageal hiatus and herniation of the stomach through the diaphragm into the mediastinum. It is more common in the elderly and the obese. There are two types of hiatus hernia: the sliding type, which accounts for at least $90 \%$, and the para-oesophageal or mixed type, which makes up the remainder (Roman and Kahrilas 2014). A hiatus hernia may not cause any symptoms or it may be associated with symptoms of gastro-oesophageal reflux. Para-oesophageal hernias can cause obstruction and/or ischaemia of the herniated stomach. Treatment of a symptomatic sliding hiatal hernia is directed at managing associated gastro-oesophageal reflux, which may require anti-reflux surgery.
from the thoracic peri-oesophageal plexus and, to a lesser extent, from the anterior and posterior vagi. These nerves are motor to the distal oesophagus and both stimulatory and inhibitory to the lower oesophageal sphincter, maintaining basal tone and coordinating distal oesophageal peristalsis with relaxation of the sphincter during swallowing (the latter being mediated by intrinsic nitrergic inhibitory neurones under vagal control). Sympathetic supply of the distal oesophagus originates from the fifth to twelfth thoracic spinal segments mainly via the greater and lesser splanchnic nerves and the coeliac plexus. Nociceptive signals are conveyed by afferent nerves accompanying sympathetic nerves and by vagal afferents, which are also involved in mechanosensory signalling (Neuhuber et al 2006).

## STOMACH

The stomach is the widest part of the alimentary tract and lies between the oesophagus and the duodenum. It performs numerous functions, including the temporary storage of ingested nutrients; mechanical breakdown of solid food; chemical digestion of proteins; regulation of the passage of chyme into the duodenum; secretion of intrinsic factor for vitamin $B_{12}$ absorption; secretion of gut hormones; and secretion of acid to aid digestion (including the absorption of iron). It is also important in microbial defence.

The stomach is situated in the upper abdomen, extending from the left upper quadrant downwards, forwards and to the right, lying in the left hypochondrium, epigastrium and umbilical regions. It occupies a recess beneath the diaphragm and anterior abdominal wall bounded by the upper abdominal viscera on either side. The mean capacity of the stomach increases from approximately $20-30 \mathrm{ml}$ at birth to approximately 1000-1500 ml in adults. The peritoneal surface of the stomach is interrupted by the attachments of the greater and lesser omenta, which define the greater and lesser curvatures and separate the anterior and posterior surfaces.

## PARTS OF THE STOMACH

For descriptive purposes, the stomach can be divided into a fundus, body, pyloric antrum and pylorus by artificial lines drawn on its external surface (Fig. 64.2). The internal appearance and microstructure of these regions vary. The fundus is dome-shaped and projects above and to the left of the oesophageal opening (cardiac (cardial) orifice) to lie in contact with the left dome of the diaphragm; it lies above a horizontal line from the cardiac notch to the greater curvature. The body extends from the fundus to the angular incisure (incisura angularis), a constant external notch at the lower end of the lesser curvature. The cardia is the region of the stomach adjacent to the oesophageal opening. A line
drawn from the angular incisure to an inconstant indentation on the greater curvature defines the lower boundary of the body. The pyloric antrum extends from this line to where the stomach narrows to become the pyloric canal ( $1-2 \mathrm{~cm}$ long), which terminates at the pyloric orifice (Didio and Anderson 1968).

## GASTRIC RELATIONS

## Gastric curvatures

## Lesser curvature

The lesser curvature extends between the cardiac and pyloric orifices and forms the medial border of the stomach. It descends from the medial side of the oesophagus in front of the decussating fibres of the right crus of the diaphragm, curves downwards and to the right, and lies anterior to the superior border of the pancreas (Fig. 64.3). It ends at the pylorus, just to the right of the midline. In the most dependent

Fig. 64.2 The parts of the stomach.

Fig. 64.3 The posterior relations of the stomach.
part, there is typically a notch, the angular incisure, whose position and appearance vary with gastric distension. The lesser omentum is attached to the lesser curvature and contains the right and left gastric vessels.

## Greater curvature

The greater curvature is two to three times longer than the lesser (Csendes and Burgos 2005). It starts from the cardiac notch, formed between the lateral border of the abdominal oesophagus and the fundus of the stomach, and arches upwards, posterolaterally and to the left. Its highest convexity, the apex of the fundus, is approximately level with the left sixth rib anteriorly but varies between individuals and with respiration (Mirjalili et al 2012). From this point, it sweeps inferiorly and anteriorly, slightly convex to the left, almost as far as the tenth costal cartilage in the supine position, where it turns medially to end at the pylorus in the transpyloric plane at the lower border of the first lumbar vertebra. There is frequently a groove, the intermediate sulcus, in the curvature close to the pyloric canal. The start of the greater curvature is covered by peritoneum, which continues over the anterior surface of the stomach. Laterally, the greater curvature gives attachment to the gastrosplenic ligament and, below this, to the greater omentum, which contains the gastroepiploic vessels. The gastrosplenic ligament and the greater omentum, together with the gastrophrenic and splenorenal ligaments, are continuous derivatives of the original dorsal mesogastrium; their names merely indicate regions of the same continuous sheet of peritoneum and its associated connective tissue.

## Gastric volvulus

Available with the Gray's Anatomy e-book

## Gastric surfaces

When the stomach is empty and contracted, the anterior and posterior surfaces tend to face superiorly and inferiorly, but as the stomach distends, they face progressively more anteriorly and posteriorly (Fig. 64.4).

## Anterior (superior) surface

The entire anterior (superior) surface of the stomach is covered by peritoneum. The lateral part of the anterior surface lies posterior to the left costal margin in contact with the diaphragm, which separates it from the left pleura, the base of the left lung, the pericardium and the left seventh to ninth ribs and costal cartilages (Fig. 64.5). It also lies posterior to the costal attachments of the upper fibres of transversus abdominis. The upper left part of this surface curves posteriorly and lies in contact with the visceral surface of the spleen. The right half of the anterior surface is related superiorly to the left lobe of the liver and inferiorly to the anterior abdominal wall, through which it can be accessed by a needle for placement of a gastrostomy tube (see below). When the stomach is empty, the transverse colon may lie adjacent to the anterior surface.

## Posterior (inferior) surface

The posterior surface is covered by peritoneum, except near the cardiac orifice, where a small, triangular area contacts the left diaphragmatic

Fig. 64.4 Axes of the empty and full stomach. As the stomach distends, the greater curvature 'rolls' downwards and the anterosuperior surface comes to lie almost completely vertical as the anterior surface.
crus and sometimes the left suprarenal gland. The left gastric vessels reach the lesser curvature at the right extremity of this bare area. The gastrophrenic ligament passes from the lateral aspect of this bare area to the inferior surface of the diaphragm. The posterior surface of the stomach lies anterior to the left crus and lower fibres of the diaphragm, the left inferior phrenic vessels, the left suprarenal gland, the superior pole of the left kidney, the splenic artery, the anterior surface of the pancreas, and the upper layer of the transverse mesocolon (see Fig. 64.3). Together, these form the shallow stomach bed, which is separated from the stomach by the lesser sac (over which the stomach slides as it distends). The upper left part of the posterior surface curves anterolaterally and lies in contact with the visceral surface of the spleen. The transverse mesocolon separates the stomach from the duodenojejunal flexure and proximal jejunum.

## GASTRIC ORIFICES

## Cardiac orifice and gastrooesophageal junction

The oesophagus opens into the stomach at the cardiac orifice (see Fig. 64.1). It is usually situated to the left of the midline behind the seventh costal cartilage at the level of the eleventh thoracic vertebra (Mirjalili et al 2012). It is, on average, about 40 cm from the incisor teeth in the adult. The right side of the abdominal oesophagus is continuous with the lesser curvature and the left side with the greater curvature.

Internally, the transition between the oesophagus and stomach is difficult to define because gastric fundal mucosal folds extend a variable distance up the abdominal oesophagus. For practical purposes, the gastro-oesophageal junction is usually identified by a circumferential 'zigzag' line ('Z line') between the pale pink oesophageal squamous epithelium above and the red columnar epithelium below. In the healthy oesophagus, the Z line is located at the proximal extent of the gastric mucosal folds. When metaplastic columnar epithelium extends above the gastric folds into the lower oesophagus, it is regarded as pathological and termed Barrett's oesophagus. The presence of a sliding hiatus hernia with or without Barrett's oesophagus can make

Fig. 64.5 Anterior relations of the stomach, viewed from behind. The fibres of the diaphragm (oblique), transversus abdominis (transverse) and rectus abdominis (vertical) can be seen through the outlines of the stomach and its visceral relations.

Volvulus of the stomach is much less common than volvulus of either the sigmoid colon or the caecum. Two types of gastric volvulus may occur. The first, organoaxial volvulus, occurs about an axis of rotation running from below the cardiac orifice to the pylorus. The antrum, body and fundus rotate upwards, such that the greater curvature comes to lie above the lesser curvature. The second type, mesenteroaxial volvulus, occurs about an axis drawn 'across' the body of the stomach, usually just above the angular incisure. This type of volvulus is perpendicular to the axis of organoaxial volvulus. The distal body and antrum rotate anteriorly, superiorly and laterally while the upper body and fundus rotate posteriorly, medially and inferiorly. Although it is relatively mobile within the upper abdomen, the stomach is normally tethered at the gastro-oesophageal junction and the pylorus, to the spleen by the gastrosplenic ligament, and to the liver by the lesser omentum. The attachment to the transverse colon via the gastrocolic omentum also restrains the stomach but it is the most mobile attachment. For either type of gastric volvulus to occur, some or all of these points of tethering must be loosened either by previous surgical division or by chronic lengthening and laxity of their connective tissue. Organoaxial volvulus is most common because the lesser omentum, gastrosplenic ligament and gastrocolic omentum are more likely to undergo chronic lengthening by traction than the other attachments of the stomach. Mesenteroaxial volvulus requires the gastro-oesophageal junction and pylorus to be sufficiently mobile as to come into close approximation, which is much less common. Despite the rich arterial supply of the stomach, either type of volvulus may cause a strangulating obstruction.

Provided the detorted stomach is viable, gastric volvulus is typically managed by fixation of the anterior surface of the stomach to the anterior abdominal wall ('gastropexy') (García et al 2013). Gastric volvulus of the organoaxial type is frequently associated with a para-oesophageal hiatus hernia, which must also be repaired. This surgery can usually be carried out laparoscopically.
endoscopic identification of the gastro-oesophageal junction particularly difficult.

Externally, a fat pad is often present in adults beneath the peritoneum over the anterior surface of the gastro-oesophageal junction. The junction is also demarcated by a sling of longitudinal and oblique gastric muscle fibres that forms a loop on the superior, left, side of the gastro-oesophageal junction between the oesophagus and the stomach.

## Lower oesophageal sphincter and gastrooesophageal reflux

At rest, there is a pressure gradient across the gastro-oesophageal junction, reflecting the negative intrathoracic pressure transmitted to the thoracic oesophagus and the positive intra-abdominal pressure transmitted to the stomach (augmented by any contraction of the stomach). Several anatomical and physiological factors normally prevent gastrooesophageal reflux. The two major anti-reflux mechanisms are the tonically contracted, specialized, thickened intrinsic circular smooth muscle of the lower oesophagus, which is reinforced by the extrinsic encircling fibres of the right diaphragmatic crus. Together, they exert a radial pressure on the lower $2-4 \mathrm{~cm}$ of oesophagus, creating an effective highpressure zone (HPZ) that can be measured by electromyography or manometry (Paterson 2001, Mittal and Goyal 2006, Hershcovici et al 2011). The description of the intrinsic muscles of the lower oesophageal sphincter can be refined further to include clasp-like semicircular smooth muscle fibres on the right side of the oesophagus and sling-like oblique gastric muscle fibres on the left side (Preiksaitis and Diamant 1997, Stein et al 1995). The distribution of these muscle fibres corresponds to the anatomical and functional asymmetry of the HPZ.

At and just below the level of entry of the abdominal oesophagus into the stomach, the circular fibres of the intermediate layer of the muscularis externa lying over the upper lesser curvature are particularly pronounced; they are sometimes referred to as 'clasp' fibres and exert fairly constant myogenic tone (Fig. 64.6). Since the oesophagus passes obliquely into the stomach, the tone in the clasp fibres rises with increasing gastric distension and they may act to draw the anterior and posterior surfaces together, increasing the tone at the gastro-oesophageal junction and contributing to the HPZ. Several minor anti-reflux factors also exist: the folds of gastric mucosa present at the gastro-oesophageal junction form a mucosal rosette that helps to create a fluid- and gastight seal from the basal tonic contraction of the muscular wall of the lower oesophagus; the angle of the cardiac orifice (angle of His), formed, in part, by the pull of the oblique fibres of the innermost layer of gastric smooth muscle, thereby constituting a type of 'flap valve'; and the length of the abdominal oesophagus, which is buttressed externally by pads of adipose tissue at and below the level of the oesophageal hiatus. These anatomical and physiological features are collectively referred to as the lower oesophageal sphincter. The oesophageal part of the lower oesophageal sphincter is controlled by the intramural plexuses of the enteric nervous system; activation of inhibitory neurones

Fig. 64.6 Detail of the arrangements of the muscle layers of the oesophageal and gastric walls. (Reproduced and modified from Netter Anatomy Illustration Collection, © Elsevier Inc. All Rights Reserved.)
releasing nitric oxide leads to relaxation of the sphincter. Muscle tone is reduced in advance of the oesophageal peristaltic wave during swallowing and raised again after the food bolus has passed. During inspiration, the greater negative intrathoracic pressure increases the gastro-oesophageal pressure gradient, but this is offset by increased pressure in the HPZ from contraction of the peri-oesophageal fibres of the right diaphragmatic crus. Activation of the crural muscle slightly before the rest of the diaphragmatic muscle facilitates this anti-reflux mechanism.

Reflux of gastric contents into the lower oesophagus as a result of transient relaxation of the lower oesophageal sphincter occurs as a normal event in most individuals on a daily basis. Prolonged episodes of acid reflux as a result of a weak lower oesophageal sphincter or sliding hiatus hernia may cause oesophagitis and its associated complications. Surgical procedures to prevent abnormal reflux aim to restore a normal length of intra-abdominal oesophagus, repair any hiatus hernia and increase the pressure surrounding the intra-abdominal oesophagus; this is usually achieved by wrapping the fundus of the stomach around the intra-abdominal oesophagus (fundoplication).

The converse type of lower oesophageal sphincter dysfunction occurs in achalasia, which is characterized by reduced or absent ganglion cells in the myenteric plexus of the distal oesophagus and gastro-oesophageal junction. Loss of inhibitory innervation of the sphincter leads to impaired relaxation, causing dysphagia and proximal oesophageal dilation. Management of this condition involves disruption of the hypertonic muscle fibres by balloon dilation or surgical myotomy ('Heller's cardiomyotomy').

## Barrett's oesophagus

The squamous epithelium lining the lower oesophagus may be pathologically replaced by a metaplastic 'intestinalized' columnar epithelium known as 'Barrett's oesophagus' (see Commentary 1.4). This process results from chronic episodic reflux of gastric acid and bile into the lower oesophagus (Dvorak et al 2007). The abnormal intestinal metaplasia may extend proximally for a variable length from the gastrooesophageal junction and associated macroscopic mucosal changes can be seen on endoscopy. The presence of Barrett's oesophagus confers a significantly increased risk of oesophageal adenocarcinoma, although the condition can remain stable or even regress with appropriate medical therapy (Yousef et al 2008).

## Pyloric orifice

The pyloric orifice is the opening from the stomach into the duodenum. When the body is supine and the stomach empty, it typically lies $1-2 \mathrm{~cm}$ to the right of the midline in the transpyloric plane (the lower border of the body of the first lumbar vertebra). The pyloric sphincter is formed by a circumferential thickening of circular muscle interlaced with connective tissue septa and some longitudinal muscle fibres, and is palpably thicker than the adjacent stomach and duodenum. The circular pyloric constriction on the surface of the stomach usually indicates the location of the pyloric sphincter, and may be marked by a prepyloric vein that crosses the anterior surface in a caudal direction.

Infantile hypertrophic pyloric stenosis is due to idiopathic hypertrophy of the circular muscle of the pylorus and causes gastric outlet obstruction in early infancy. It is readily treated by dividing the thickened pyloric muscle (pyloromyotomy).

## GASTRIC FORM AND INTERNAL APPEARANCES

Numerous factors influence both the form and the position of the stomach, including the posture and build of the individual, the extent to which the stomach is filled, the position of the surrounding viscera, and the tone of the abdominal wall and gastric musculature. The empty stomach is most commonly J-shaped, the fundus usually contains gas, and, in the erect posture, the pylorus descends to the level of the second or third lumbar vertebra. The lowest part of the antrum may lie below the level of the umbilicus, and the overall axis of the organ is slightly inclined from the vertical (Fig. 64.7). In short, obese individuals, the axis of the stomach lies more towards the horizontal as a 'steer-horn' shape.

The extent of filling mainly affects the shape and position of the body of the stomach. As the stomach fills, it expands forwards and downwards but, when the colon or small bowel is distended, the fundus enlarges towards the liver and diaphragm. As stomach capacity increases, the pylorus is displaced to the right and the axis of the whole organ lies in a more oblique direction (see Fig. 64.4).

Fig. 64.7 Double contrast barium meal films. A, In the erect position, the stomach has a more ' $J$ '-shaped configuration. B, Initial stomach filling demonstrates a horizontally lying stomach with prominent gastric rugal folds. $\mathbf{C}$, The areae gastricae within the antrum are clearly identified on distension of the stomach.

Fig. 64.8 Endoscopic appearances of the stomach. A, The cardiac orifice and fundus from below, showing the pronounced lateral mucosal fold at the cardiac orifice. B, The body and greater curvature, showing mucosal folds ('magenstrasse'). C, The antrum, showing the internal appearance of the incisura angularis. D, The prepyloric antrum and opening of the pyloric canal.

## Internal appearances

During endoscopic examination (Fig. 64.8), the stomach is typically at least partially distended by air. The cardiac orifice and the lowest portion of the abdominal oesophagus viewed from above are typically closed at rest by tonic contraction of the lower oesophageal sphincter. The transition between the pale pink squamous epithelium of the oesophagus and the red columnar epithelium of the stomach, the ' Z line', is usually clearly visible at the proximal extent of the gastric mucosal folds (Silverstein and Tytgat 1991). Viewed retrogradely from within the distended stomach, the cardiac orifice lies medial to the fundus, with a mucosal fold between the two corresponding to the acute angle at this orifice. The mucosa also appears slightly thickened, forming part of the 'mucosal rosette' that lines the orifice and contributes to its closure (see above).

In the partially distended stomach, the mucosa of the body and, to a lesser extent, the fundus is thrown into longitudinal folds (rugae) (see Fig. 64.7). These are most obvious on the anterolateral, lateral and posterolateral parts of the stomach, towards the greater curvature. The smoother mucosa along the lesser curvature forms a 'gastric canal' or 'magenstrasse' that enables liquids entering the stomach to be fasttracked to the pylorus (see Fig. 64.8).

The areae gastricae within the antrum are small undulations of the mucosal surface that give a subtle cobblestone-type appearance on double contrast barium meal examination (see Fig. 64.7) (Mackintosh and Kreel 1977). The few folds present in the antrum when the stomach is relaxed disappear with distension. The antrum adjacent to the pyloric canal, the prepyloric antrum, has a smooth mucosal surface that culminates in a slight puckering of the mucosa at the pyloric orifice, caused by contraction of the pyloric sphincter.

Fig. 64.9 The arterial supply of the stomach. A posterior gastric artery is not shown in this illustration.

## Gastrostomy

Available with the Gray's Anatomy e-book

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The arterial supply to the stomach comes predominantly from the coeliac trunk, although intramural anastomoses exist with arteries of other origins at the two ends of the stomach (Figs 64.9-64.11). The left gastric artery usually arises directly from the coeliac trunk. The short gastric arteries, left gastroepiploic artery and, when present, the posterior gastric artery are branches of the splenic artery. The right gastric artery and right gastroepiploic artery arise from the hepatic artery and its gastroduodenal branch, respectively.

## Left gastric artery

The left gastric artery is the smallest branch of the coeliac trunk. It ascends to the left of the midline and crosses over the lower end of the left crus of the diaphragm beneath a fold of peritoneum in the upper posterior wall of the lesser sac (the gastropancreatic fold). Here, it lies adjacent to the left inferior phrenic artery and medial or anterior to the left suprarenal gland. It runs forwards into the superior portion of the lesser omentum adjacent to the upper end of the lesser curvature, and then turns anteroinferiorly to run along the lesser curvature between the two peritoneal leaves of the lesser omentum. At the highest point of its course, it gives off one or more oesophageal branches. In its course along the lesser curvature, it gives off multiple branches that run on to the anterior and posterior surfaces of the stomach, after which it anastomoses with the right gastric artery in the region of the angular incisure

The left gastric artery (replaced or accessory) may rarely arise from the common hepatic artery or its left branch, or directly from the abdominal aorta (Panagouli et al 2013). The most common of these variations is an origin from the left branch of the hepatic artery, when the left gastric artery passes between the peritoneal layers of the upper lesser omentum to reach the lesser curvature of the stomach. However, a replaced/accessory left hepatic artery arising from the left gastric artery is more common than a replaced/accessory left gastric artery origin.

## Short gastric arteries

For practical purposes, the short gastric arteries may be defined as those arteries arising above the level of the splenic artery and supplying the fundus of the stomach on its greater curvature. The short gastric arteries are variable in number: commonly, between five and seven. They arise from the splenic artery or its terminal divisions, or from the proximal left gastroepiploic artery, and pass between the layers of the gastrosplenic ligament to supply the gastric fundus and cardiac orifice. They

Fig. 64.10 The coeliac trunk and its branches. A, Digital subtraction angiogram. B-C, Digital reformatted multislice CT angiograms. (A, Courtesy of Dr James McCall, Chelsea \& Westminster Hospital, London. B and C, Courtesy of GE Worldwide Medical Systems.)
anastomose with branches of the left gastric and left gastroepiploic arteries. Rarely, an accessory left gastric artery may arise with these vessels from the distal splenic artery.

## Left gastroepiploic artery

The left gastroepiploic artery is the largest branch of the splenic artery. It arises near the splenic hilum and runs anteroinferiorly between the layers of the gastrosplenic ligament into the upper gastrocolic omentum. Here, it descends between the layers of peritoneum close to the greater curvature and often anastomoses with the right gastroepiploic artery. It gives off gastric branches to the fundus of the stomach through the gastrosplenic ligament, and to the body of the stomach through the gastrocolic omentum. These are necessarily longer than the gastric branches of the right gastroepiploic artery and may be up to 8 cm long.

Since the lower half of the anterior surface of the stomach lies adjacent to the anterior abdominal wall in the left upper quadrant, it may be readily accessed to form a gastrostomy. The mobility of the stomach allows it to be approximated to the parietal peritoneum on the upper anterior abdominal wall, and a communication can then be established between the lumen of the stomach and the skin surface. This may be performed as an open surgical procedure but is much more commonly undertaken by percutaneous puncture of the stomach, guided by an endoscope within the gastric lumen or by radiological or laparoscopic visualization of the stomach. Caution is needed to avoid inadvertent transfixion of the transverse colon, which may be interposed between the stomach and anterior abdominal wall.

Fig. 64.11 Principal variations in the gastric arterial supply. Accessory vessels or possible replaced origins of vessels are shown by pale pink lines.

Epiploic (omental) branches arise along the course of the vessel and descend between the layers of the gastrocolic omentum into the greater omentum. A particularly large epiploic branch commonly originates close to the origin of the left gastroepiploic artery, descends in the lateral portion of the greater omentum and provides a large arterial supply to the lateral half of the omentum.

## Posterior gastric artery

A posterior gastric artery supplying the posterior wall of the upper part of the gastric body is commonly present but there has been a lack of consensus regarding its origin, course and distribution. It usually arises from the splenic artery (usually from its mid section), posterior to the body of the stomach (see Fig. 64.11), and ascends behind the peritoneum of the lesser sac towards the fundus to reach the posterior surface of the stomach. It may also arise from the left gastric artery or coeliac trunk (Loukas et al 2007).

## Right gastric artery

The right gastric artery is a relatively small artery that usually arises from the hepatic artery proper and runs forwards into the lesser omentum just above the first part of the duodenum. It then travels within the lesser omentum along the lesser curvature of the stomach, giving off multiple branches to the anterior and posterior surfaces of the stomach, before anastomosing with the left gastric artery. In a significant minority of individuals, it may originate from the common hepatic artery, left hepatic artery or gastroduodenal artery (Yamagami et al 2010).

## Right gastroepiploic artery

The right gastroepiploic artery usually originates from the gastroduodenal artery behind the first part of the duodenum, anterior to the head of the pancreas. It passes inferiorly towards the midline just below the pylorus and then runs laterally along the greater curvature between the layers of the gastrocolic omentum about $1-2 \mathrm{~cm}$ from the greater curvature of the stomach. It ends by anastomosing with the left gastroepiploic artery (although this anastomosis is variably developed (Ndoye et al 2006) and may be absent). The right gastroepiploic artery gives off gastric branches that ascend on to the anterior and posterior surfaces of the antrum and lower body of the stomach; epiploic branches that descend into the greater omentum; and branches that contribute to the supply of the inferior aspect of the first part of the duodenum.

## Arterial anastomoses of the stomach

Oesophageal arteries originating from the thoracic aorta anastomose with vessels supplying the fundus of the stomach in the region of the cardiac orifice. At the pyloric orifice, the extensive network of vessels supplying the duodenum allows for some anastomosis between branches of the superior mesenteric artery and pyloric vessels derived from arteries arising from the coeliac trunk. The major named vessels

Fig. 64.12 The blood supply of the stomach and the proximal duodenum: a scheme of arterial arrangements at the gastroduodenal junction. Dotted lines indicate sites where the submucous plexus may be non-continuous. Shaded areas represent the muscular layer of the visceral wall. (Redrawn courtesy of C Piasecki, Department of Anatomy, Royal Free Hospital School of Medicine, London, and the Journal of Anatomy.)
supplying the stomach form extensive arterial anastomoses throughout the wall of the stomach but particularly in the submucosa. The right and left gastroepiploic arteries and left and right gastric arteries anastomose along the greater and lesser curvatures, respectively. Anastomoses also exist in the fundus between the short gastric and left gastric arteries, and in the antrum between the right gastric and right gastroepiploic arteries. The rich arterial supply to the stomach ensures that the high mucosal blood flow required for physiological functioning is maintained even if one or more vessels become occluded; the stomach shows considerable resistance to ischaemia, even when multiple arterial supplies are lost.

The pyloric arteries are branches of the right gastric and right gastroepiploic arteries. They pierce the duodenal wall around its entire circumference just distal to the sphincter and reach the submucosa. Here, they divide into two or three rami that run towards the stomach in the submucosa of the pyloric canal and terminate in the mucosa of the pyloric antrum (Fig. 64.12) (Piasecki 1974). The pyloric arteries anastomose with submucosal arteries in the duodenum and gastric antrum close to their origin and termination, respectively. The pyloric sphincter muscle is supplied by gastric and pyloric arteries via branches that leave their parent vessels in the subserosal and submucosal levels to penetrate the sphincter.

## Veins

The veins draining the stomach ultimately empty into the portal vein. A rich submucosal and intramural venous network gives rise to veins that usually accompany the corresponding named arteries and drain into either the splenic or superior mesenteric veins, although some pass directly into the portal vein. The course and distribution of the veins is highly variable even up to the level of the major named vessels.

## Short gastric veins

Three to five short gastric veins drain the gastric fundus and the upper part of the greater curvature into the splenic vein or one of its large tributaries.

## Left gastroepiploic vein

The left gastroepiploic vein drains both anterior and posterior surfaces of the body of the stomach and the adjacent greater omentum via multiple tributaries. It runs superolaterally along the greater curvature, between the layers of the gastrocolic omentum, and drains into the splenic vein within the gastrosplenic ligament.

In patients requiring replacement of the oesophagus for severe congenital anomalies or after resection for cancer, a gastric tube supplied by the left gastroepiploic artery can be fashioned from the greater curvature of the stomach and anastomosed to the cervical oesophagus (Arul and Parikh 2008).

The right gastroepiploic artery has been used for coronary artery revascularization in some centres and this may pose a particular hazard if the patient subsequently requires surgery for gastric cancer.

Abnormalities of the intramural vascularity of the stomach are a rare cause of acute upper gastrointestinal haemorrhage. The so-called 'Dieulafoy' lesion occurs most often near the lesser curvature within a few centimetres of the gastro-oesophageal junction and consists of an abnormally large artery that penetrates the muscular coat of the stomach, runs a tortuous course in the submucosa, and protrudes through a small mucosal defect, where it is vulnerable to rupture (Baxter and Aly 2010).

## Right gastroepiploic vein

The right gastroepiploic vein drains the greater omentum, distal body and antrum of the stomach. It runs medially along the greater curvature in the upper part of the gastrocolic omentum. Just proximal to the pylorus, it passes posteriorly to drain into the superior mesenteric vein below the neck of the pancreas. The right gastroepiploic vein may receive the right colic vein (forming a 'gastrocolic trunk') and/or superior pancreaticoduodenal vein close to its entry into the superior mesenteric vein (Yamaguchi et al 2002).

## Left gastric vein

The left gastric vein drains the upper body and fundus of the stomach. It ascends along the lesser curvature to the oesophageal opening, where it receives several lower oesophageal veins. It then curves posteriorly and medially behind the posterior peritoneal surface of the lesser sac, passing either anterior or posterior to the common hepatic artery. It usually drains into the portal vein at the level of the upper border of the first part of the duodenum, which corresponds to $1-2 \mathrm{~cm}$ from the origin of the portal vein (Rebibo et al 2012). In up to one-third of individuals, the left gastric vein terminates in the splenic vein. On rare occasions, it drains into the left portal vein within the liver (Ohkubo 2000), which may be clinically important in portal hypertension.

## Right gastric vein

The right gastric vein is typically small and runs along the medial end of the lesser curvature, passing under the peritoneum as it is reflected from the posterior aspect of the pylorus and first part of the duodenum on to the posterior wall of the lesser sac. It drains directly into the portal vein at the level of the first part of the duodenum. It receives the prepyloric vein as it ascends anterior to the pylorus at the level of the pyloric opening. Rarely, the right gastric vein drains directly into a branch of the portal vein within the liver.

## Posterior gastric veins

One or more distinct posterior gastric veins may be present, draining the middle of the posterior surface of the stomach into the splenic vein. They may become particularly prominent in portal hypertension (Kimura et al 1990).

## Oesophageal and gastric varices

Blood from the oesophageal mucosa normally drains into a submucosal venous plexus, then into a deeper intrinsic venous plexus and finally into peri-oesophageal veins via perforating veins. In the abdominal oesophagus, the perforating veins drain into tributaries of the left gastric vein, whereas, in the lower thoracic oesophagus, they drain into tributaries of the azygos and hemiazygos systems. Bidirectional flow is possible in this region, and accommodates pressure changes that occur during breathing and Valsalva manœuures.

Oesophageal and gastric varices are abnormally dilated veins that occur in the submucosal plexus of the distal oesophagus and gastric fundus when portal venous pressure is chronically elevated (typically greater than 15 mmHg ). This may develop as a consequence of liver fibrosis or cirrhosis, or portal vein thrombosis, or from a variety of other causes. Portal hypertension leads to the recanalization of occluded embryonic venous channels between venous tributaries of the portal system and the systemic venous circulation (e.g. the ligamentum teres) and progressive dilation of small, naturally occurring venous anastomoses between portal and systemic venous tributaries (Paquet 2000). Valves within these veins become incompetent, permitting retrograde flow and causing the development of varices. Varices in the distal oesophagus are readily visible at endoscopy because they are situated superficially and protrude into the oesophageal lumen (Fig. 64.13); they are vulnerable to rupture and a source of major gastrointestinal bleeding. Gastric varices may also be present on the inferior aspect of the cardiac orifice.

## INNERVATION

The stomach is innervated by sympathetic and parasympathetic nerves. A variety of neurotransmitters have been identified within pyloric muscle, including acetylcholine, nitric oxide, enkephalins and vasoactive intestinal polypeptide. Inhibition of the sphincter is mediated by nitrergic fibres whilst basal tone is mostly cholinergic (although it should be noted that many other factors, including acid and luminal nutrients, influence pyloric contraction; Ramkumar and Schulze (2005)).

## Sympathetic innervation

The sympathetic supply to the stomach originates from the fifth to twelfth thoracic spinal segments, and is mainly distributed via the greater and lesser splanchnic nerves and the coeliac plexus. Peri-arterial plexuses form along the arteries arising from the coeliac trunk. Additional innervation comes from fibres of the hepatic plexus, which pass to the upper body and fundus via the lesser omentum and by direct branches from the greater splanchnic nerves.

Sympathetic activity causes vasoconstriction, inhibits gastric motility and constricts the pylorus. Afferent sensory pathways, including pain, travel with sympathetic efferent nerves.

## Parasympathetic innervation

The parasympathetic supply to the stomach is from the vagus nerves (Fig. 64.15). The anterior vagal trunk (formed mainly from fibres from the left vagus nerve within the oesophageal plexus) is often double or even triple, and supplies filaments to the cardiac orifice. The nerve is closely applied to the anterior surface of the outer muscle of the abdominal oesophagus and usually divides near the gastro-oesophageal junction into gastric, pyloric and hepatic branches (Jackson 1949). Upper gastric branches radiate on the anterior surface of the upper body and fundus but the main gastric branch (also known as the anterior nerve of the lesser curvature or greater anterior gastric nerve) lies in the lesser omentum near the lesser curvature. It supplies branches to the body and antrum, and usually terminates near the angular incisure in a crow's foot type of pattern (Shanthi and Sudhayesshayyan 2011). The hepatic branch runs almost transversely between the peritoneal layers of the lesser omentum towards its free edge to reach the hilum of the liver, where hepatic branches ramify. From here, some fibres descend adjacent to the hepatic artery to supply the pylorus, duodenum and pancreas. An additional pyloric branch often arises from the greater anterior gastric nerve during its course; this runs inferomedially to the pyloric antrum, where it gives off branches to the pylorus before running superiorly to contribute to the hepatic plexus. Variations in the anterior nerve include accessory pyloric branches and high and low courses of the hepatic and pyloric branches in the lesser omentum.

The posterior vagal trunk usually lies within loose connective tissue immediately posterior and to the right of the oesophagus. It divides into gastric branches and one or more coeliac branches. Gastric branches run behind the cardiac orifice and body of the stomach and extend to the proximal antrum, but do not normally reach the pyloric sphincter. The largest gastric branch (also known as the posterior nerve of the lesser curvature or the greater posterior gastric nerve) descends posteriorly near the lesser curvature. The coeliac branch arises from the posterior vagal trunk and carries the majority of fibres contributing to the coeliac plexus. One or two small hepatic branches may also originate from the coeliac division of the nerve.

The parasympathetic nerve supply is secretomotor to the gastric mucosa and motor to the gastric musculature. It is responsible for coordinated relaxation of the pyloric sphincter during gastric emptying. However, the majority of fibres within the vagus nerves are afferent; these convey gut sensation, including fullness, nausea and probably pain.

## Referred pain

Pain sensation from the stomach is poorly localized and, in common with other structures of foregut origin, is referred to the epigastrium. Pain arising from the gastro-oesophageal junction is commonly referred to the lower retrosternal and subxiphoid areas.

## MICROSTRUCTURE

The gastric wall consists of the major layers found elsewhere in the gut, i.e. mucosa, submucosa, muscularis externa and serosa, together with

Fig. 64.13 The endoscopic appearance of oesophageal and gastric varices in portal hypertension. A, Oesophageal varices. B, Fundal varices seen from within the stomach after retroflexion of the gastroscope. C, Portal gastropathy (gastric antrum) due to venous congestion of the gastric mucosa. (Courtesy of Professor Mark Stringer.)

Surgery for gastro-oesophageal malignancy involves varying degrees of radical resection of lymph nodes that drain the tumour. Locoregional lymphatic spread can occur in the absence of haematogenous spread and gastric cancer may therefore remain a localized disease, even when lymph nodes are involved (UICC et al 1997). Hence, gastrectomy with meticulous lymphadenectomy can be curative in a proportion of patients with gastric cancer and nodal involvement.

The extent of potential/actual nodal involvement by the tumour is classified as N1 (locoregional nodes specific to the tumour site); N2 (regional and major named vessel nodes draining the tumour); and N3
(wider-draining nodes, including para-aortic nodes). Gastrectomies can be classified according to the node groups excised with the tumour: D1 (removal of the affected portion of the stomach and en bloc resection of N1 nodes); D2 (total gastrectomy, including all N1 and N2 nodes); and D3 (total gastrectomy plus extensive lymphadenectomy that includes the associated upper abdominal lymph nodes: namely, pancreatic, superior mesenteric, coeliac, hepatic and transverse colic) (Japanese Gastric Cancer Association 1998, Japanese Research Society for Gastric Cancer 1998).

Fig. 64.14 The main lymph node stations of the stomach ( $\mathbf{A}$ ) and upper abdominal viscera (B). The sagittal relationships of the node groups around the neck of the pancreas are shown bottom right. The para-aortic nodes are among the highest nodes for these viscera but have been removed for clarity.

Fig. 64.15 The distribution of the vagal nerves to the stomach. The two most common variations in the anterior vagus are shown in pink. Key: A, multiple main trunks; B, low origin of the hepatic/pyloric branch lying close to the lesser curvature.
gastric vessels and nerves (Figs 64.16-64.17). The microstructure reflects the functions of the stomach as an expandable muscular sac lined by secretory epithelium, although there are local structural and functional variations in this pattern.

## Mucosa

The mucosa is a thick layer with a soft, smooth surface that is mostly reddish brown in life but pink in the pyloric region. In the contracted stomach, the mucosa is folded into numerous folds, or rugae, most of which are longitudinal. They are most marked towards the pyloric end and along the greater curvature. The rugae represent large folds in the submucosal connective tissue (see below) rather than variations in the thickness of the mucosa covering them, and they are obliterated when the stomach is distended. As elsewhere in the gut, the mucosa is composed of a surface epithelium, lamina propria and muscularis mucosae.

## Epithelium

When viewed microscopically at low magnification, the internal surface of the stomach wall appears honeycombed by small, irregular gastric pits: there are approximately 60 to 100 gastric pits per square millimeter of gastric mucosa, each pit having a diameter of approximately $70 \mu \mathrm{~m}$ and a depth of about 0.2 mm (Lillibridge 1964) (see Figs 64.16-64.17). The base of each gastric pit receives several long, tubular gastric glands that extend deep into the lamina propria as far as the muscularis mucosae. Simple columnar mucus-secreting epithelium covers the entire luminal surface, including the gastric pits, and is composed of a continuous layer of surface mucous cells that release gastric mucus from their apical surfaces to form a thick, protective, lubricant layer over the gastric lining. This epithelium commences abruptly at the Z line at the cardiac orifice, where there is a sudden transition from oesophageal stratified squamous epithelium.

## Gastric glands

Although all gastric glands are tubular, they vary in form and cellular composition in different parts of the stomach. They can be divided into three groups: cardiac, principal and pyloric. The most highly specialized are the principal glands.

## Principal gastric glands

The principal glands are found in the body and fundus, three to seven opening into each gastric pit. Their junction with the base of the pit is the isthmus; immediately basal to this is the neck; and the remainder is the base. The walls of the gland contain at least five distinct cell types: chief, parietal, mucous neck, stem and neuroendocrine.

Chief (peptic) cells (see Fig. 64.16) are the source of the digestive enzymes pepsin and lipase. They are usually basal in position and
cuboidal in shape, and their nuclei are rounded and euchromatic. They contain secretory zymogen granules and their abundant cytoplasmic RNA renders them strongly basophilic. Parietal (oxyntic) cells are the source of gastric acid and of intrinsic factor, a glycoprotein necessary for the absorption of vitamin $\mathrm{B}_{12}$. They are large, oval and strongly eosinophilic, and have centrally placed nuclei.

Parietal cells occur intermittently along the walls of the more apical half of the gland but can reach as far as the isthmus; they bulge laterally into the surrounding connective tissue. They have a unique ultrastructure related to their ability to secrete hydrochloric acid. The luminal side of the cell is deeply invaginated to form a series of blind-ended channels (canaliculi) that bear numerous irregular microvilli covered by a plasma membrane rich in $\mathrm{H}^{+} / \mathrm{K}^{+}$ATPase antiporter channels. The latter actively secrete hydrogen ions into the lumen; chloride ions follow along the electrochemical gradient. The mitochondria-rich cytoplasm facing these channels contains a tubulo-vesicular system of abundant fine membranous tubules directed towards the canalicular surface. The precise structure of the cell varies with its secretory phase: when stimulated, the number and surface area of the microvilli increases up to five-fold, probably as a result of the rapid fusion of the tubulovesicular system with the plasma membrane. This process is reversed at the end of stimulated secretion, when the excess membrane retreats back into the tubulo-alveolar system and microvilli are lost.

Mucous neck cells are numerous at the necks of the glands and are scattered along the walls of the more basal regions. They are typical mucus-secreting cells, displaying apical secretory vesicles, containing mucins, and basally displaced nuclei; their products are distinct histochemically from those of the superficial mucous cells.

Stem cells are relatively undifferentiated mitotic cells from which the other types of gland cell are derived. They are relatively few in number, and are situated in the isthmus of the gland and the bases of the gastric pits. Stem cells are columnar and possess a few short apical microvilli. They periodically undergo mitosis; their progeny migrate either apically, to differentiate into new surface mucous cells, or basally, to form mucous neck, parietal, chief or neuroendocrine cells. All of these cells have a limited lifespan, especially the mucus-secreting types, and so they are constantly replaced. The typical replacement period for surface mucous cells is 3 days, and that for mucous neck cells is 1 week. Other cell types appear to live much longer.

Neuroendocrine (enteroendocrine) cells occur in all types of gastric gland but more frequently in the body and fundus of the stomach. They are situated mainly in the deeper parts of the glands, among the chief cells. They are basally situated, pleomorphic cells and display irregular nuclei surrounded by granular cytoplasm that contains clusters of large $(0.3 \mu \mathrm{~m})$ secretory granules. Neuroendocrine cells synthesize a number of biogenic amines and polypeptides that are important in the control of gut motility and glandular secretion. They are part of the system of dispersed neuroendocrine cells. In the stomach, they include gastrinproducing G cells; somatostatin-producing D cells; histamine-producing ECL (enterochromaffin-like) cells; serotonin-producing enterochromaffin cells; and ghrelin-producing $\mathrm{P} / \mathrm{D}(1)$-type endocrine cells (Sakata and Sakai 2010).

## Cardiac glands

Cardiac glands are confined to a small area near the cardiac orifice; some are simple tubular glands, others are compound branched tubular glands. Mucus-secreting cells predominate; parietal and chief cells are present but sparse.

## Pyloric glands

Pyloric glands empty via groups of two or three short, convoluted tubes into the bases of the deep gastric pits of the pyloric antrum; the pits occupy about two-thirds of the mucosal depth (Fig. 64.18). The glands are populated mainly by mucus-secreting cells but they also contain neuroendocrine cells, especially G cells, which secrete gastrin when activated by appropriate mechanical stimulation (causing increased gastric motility and secretion of gastric juices). Although parietal and chief cells are scarce, parietal cells are always present in both fetal and postnatal pyloric glands, and may also appear in the duodenal mucosa, proximally near the pylorus, in adult tissue.

## Lamina propria

The lamina propria forms a connective tissue framework between the glands. It contains small masses of lymphoid tissue, gastric lymphatic follicles, which resemble solitary intestinal follicles (especially in early life). It also contains a complex periglandular vascular plexus involved in the maintenance of the mucosal environment, e.g. the removal of bicarbonate produced in the tissues as a counterpart to acid secretion, and neural plexuses rich in both sensory and motor terminals.

Fig. 64.16 Principal regions of the interior of the stomach and the microstructure of tissues and cells within its wall. Undifferentiated, dividing cells are shown in white. Abbreviations: ECL, enterochromaffin-like.

## Muscularis mucosae

The muscularis mucosae is a thin layer of smooth muscle fibres lying external to the layer of glands, arranged as continuous inner circular and outer longitudinal layers, and a discontinuous external circular layer. The inner layer sends strands of smooth muscle cells between the glands; their contraction probably assists in emptying into the gastric pits.

## Submucosa

The submucosa is a variable layer of loose connective tissue. It contains thick bundles of collagen, numerous elastin fibres, blood vessels and nervous plexuses, including the ganglionated submucosal (Meissner's) plexus.

## Muscularis externa

The muscularis externa is a thick muscle coat immediately under the serosa, with which it is closely connected by subserous loose connective tissue. From innermost outwards, it contains oblique, circular and longitudinal layers of smooth muscle fibres (see Fig. 64.6). The layers are
variably developed in different regions of the stomach and not easily separated. Clasp-like semicircular smooth muscle fibres are present on the right side of the oesophagus and sling-like oblique gastric muscle fibres on the left side; the latter radiate horizontally towards the greater curvature and maintain the angle between the oesophagus and stomach. The circular muscle layer is thicker in the distal pyloric antrum, where it forms the anular pyloric sphincter. The outer longitudinal layer is most pronounced in the upper two-thirds of the stomach.

The muscularis externa enables the stomach to produce churning movements that mix food with the gastric secretions. When the muscles contract, they reduce the volume of the stomach and throw the mucosa into longitudinal folds or rugae (see above). Muscle activity is controlled by a network of unmyelinated autonomic nerve fibres and their ganglia, which lie between the muscle layers in the myenteric (Auerbach's) plexus.

## Interstitial cells of Cajal

Like smooth muscle elsewhere in the gut, interstitial cells of Cajal are present within the submucosa and muscular layers of the stomach. These spindle-shaped cells contact nerve fibres and form gap junctions

Fig. 64.17 A low-power micrograph showing the stomach wall, thrown into longitudinal folds or rugae that are visible macroscopically. The surface epithelium is infolded microscopically to form gastric pits. Gastric glands extend through the thickness of the mucosal lamina propria and open into the bases of the gastric pits. A muscularis mucosae layer and submucosa follow the contours of the rugae. Part of the external muscularis layers is seen below left. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
with smooth muscle cells, consistent with their role in modulating motor neurotransmission. Interstitial cells of Cajal are involved in the generation of rhythmic gastric slow-wave contractions and play an important role in gastric motility. They have been implicated in the pathogenesis of gastric motility disorders such as diabetic gastric paresis (Negreanu et al 2008) and in the development of gastric stromal tumours (Roggin and Posner 2012).

## Serosa or visceral peritoneum

The serosa is an extension of the visceral peritoneum. It covers the entire surface of the stomach other than along the attachments of the greater and lesser omenta to the greater and lesser curvatures, respectively, where the peritoneal layers are separated by vessels and nerves, and over a small posterosuperior area near the cardiac orifice, where the stomach contacts the diaphragm at the reflections of the gastrophrenic and left gastropancreatic folds.

## Endoscopic mucosal resection

Endoscopic mucosal resection (EMR) is a technique that can be applied in the oesophagus and stomach in order to excise dysplastic lesions or early cancers that remain confined to the mucosa (Pech et al 2008). EMR is a misnomer since the technique involves resection of both the mucosa and submucosa. The technique is inappropriate for tumours that have invaded the submucosa since these are associated with a significant risk of lymph node metastases and therefore require formal surgical resection (oesophagectomy or gastrectomy) and lymphadenectomy (Ancona 2008).

Fig. 64.18 A micrograph showing the pyloric region of the stomach. Pyloric glands are stained with the periodic acid-Schiff (PAS) technique to show mucin (magenta) in the gastric pits and glands. Pale-staining cells are the larger parietal cells (P) and smaller enteroendocrine cells (E). (Courtesy of Dr JB Kerr, Monash University with permission from Kerr JB 1999 Atlas of Functional Histology. London: Mosby.)

## GASTRIC MOTILITY

In simple terms, the proximal region of the stomach (fundus and upper body) functions mostly as a temporary storage compartment, regulating intragastric pressure and the onward passage of chyme into the distal stomach. Proximal gastric tone decreases with swallowing (receptive relaxation) and in response to gastric distension (gastric accommodation). Its activity is modulated by enterogastric reflexes (e.g. acid, protein or fat in the duodenum inhibits proximal gastric muscle contraction) and gut hormones (e.g. cholecystokinin, gastrin, glucagon and vasoactive intestinal polypeptide). The vagus nerve plays a key role in these reflexes. In contrast to this activity, the muscle of the distal region of the stomach exhibits strong phasic contractions that increase in amplitude towards the pylorus; these occur about three times per minute and act to grind the food mechanically and propel it towards the pylorus. Solid material lags behind liquids, and when the contents of the antrum reach the contracted pylorus, only the liquid and small particulate solids can be expelled into the duodenum; larger solid matter is retropulsed back into the stomach for further breakdown (Patrick and Epstein 2008).

## OVERVIEW

The small intestine consists of the duodenum, jejunum and ileum. It extends from the distal end of the pyloric canal to the ileocaecal junction and has a mean length of 5 metres (3-8.5 metres) when measured intraoperatively in the living adult (Teitelbaum et al 2013). The duodenum extends from the stomach to the duodenojejunal junction. The remaining small intestine is often referred to as the 'small bowel', the proximal two-fifths of which is referred to as the jejunum and the distal three-fifths as the ileum. There is no clear boundary between the two parts, but there is a gradual transition in morphology from the proximal to distal ends of the small bowel. The distal 30 cm or so of the ileum is often referred to as the terminal ileum, which has some specialized physiological functions.

The duodenum is in the upper abdomen and is mostly retroperitoneal. The jejunum and ileum occupy the central and lower parts of the abdominal cavity and usually lie within the boundary formed by the colon. The small bowel is attached to the posterior abdominal wall by a mesentery that allows the intestinal loops to be mobile. In the supine position, loops of jejunum may be found anterior to the transverse colon, stomach and even lesser omentum, whereas in the erect position, loops of ileum may descend into the pelvis anterior to the rectum. The greater omentum covers the upper jejunum and ileum to a variable extent. The jejunum and ileum are covered by visceral peritoneum on all but their mesenteric borders, where the peritoneum is reflected to enclose the adipose tissue of the mesentery. The small bowel mesentery abuts about $20 \%$ of the circumference of the muscular wall of the ileum and somewhat less of the jejunum.

## DUODENUM

The adult duodenum is approximately 25 cm long and is the shortest, widest and most predictably placed part of the small intestine. The proximal 2.5 cm is intraperitoneal and the remainder is retroperitoneal. The duodenum forms an elongated ' C ' that lies between the level of the first and third lumbar vertebrae in the supine position. The lower 'limb' of the C extends further to the left of the midline than the upper limb. The head and uncinate process of the pancreas lie within the concavity of the duodenum, which is 'draped' over the prominence formed by the lumbar spine; the duodenum therefore curves in an anteroposterior direction as well as forming a ' C '. The duodenum lies entirely above the level of the umbilicus. It is described as having four parts (Fig. 65.1).

## FIRST (SUPERIOR) PART

The first, and most mobile, part of the duodenum is about 5 cm long. It starts at the duodenal end of the pylorus and ends at the superior duodenal flexure. The proximal 2.5 cm is intraperitoneal while the distal 2.5 cm is covered by peritoneum on its anterior and superior surfaces and forms the inferior boundary of the epiploic foramen. The lesser omentum is attached to its upper border and the greater omentum to its lower border. The first $2-3 \mathrm{~cm}$ of the duodenum is lined by relatively smooth mucosa and readily distends on insufflation during endoscopy. This part is frequently referred to as the duodenal 'cap'. During contrast radiology, it shows a few longitudinal folds continuous with the pylorus (Mather Cordiner and Calthrop 1936) and has a triangular appearance; it is often visible on plain radiographs of the abdomen as an isolated triangular gas shadow to the right of the first or second lumbar vertebra. The first part of the duodenum passes superiorly, posteriorly and laterally for 5 cm before curving sharply inferiorly at the superior duodenal flexure. It becomes more retroperitoneal

Fig. 65.1 A, The four parts of the duodenum. B, Anterior relations of the duodenum. C, Posterior relations of the duodenum.
during this part of its course, until peritoneum only covers its anterior aspect. The section from the duodenal cap to the superior duodenal flexure lies posterior and inferior to the quadrate lobe of the liver. Beyond the duodenal cap, the internal appearance is characterized by circumferential mucosal folds that remain pronounced, even during endoscopic insufflation (Fig. 65.2).

The first part of the duodenum lies anterior to the gastroduodenal artery, common bile duct and portal vein, and anterosuperior to the head and neck of the pancreas. The gastroduodenal artery lies immediately behind the posterior wall of the duodenum; a penetrating peptic ulcer on the posterior wall may erode into the gastroduodenal artery or one its branches and cause dramatic haemorrhage. A penetrating peptic ulcer on the anterior wall may perforate into the peritoneal cavity

Fig. 65.2 The contrast radiographic appearance of the duodenum showing a distended duodenal cap and the remainder of the duodenum up to the duodenojejunal flexure.
because the anterior surface of the first part is covered only by peritoneum.

The common hepatic and hepatoduodenal lymph nodes lie close to the first part of the duodenum (see Fig. 64.14B) and can be visualized using endoscopic ultrasound; this may be important in the staging of gastric, pancreatic or bile duct tumours. The proximity of the common bile duct to the first part of the duodenum allows endoscopic ultrasound examination of the distal common bile duct and the formation of a surgical anastomosis between bile duct and duodenum (choledochoduodenostomy) when required.

The junction of the first and second parts of the duodenum lies posterior to the neck of the gallbladder.

## SECOND (DESCENDING) PART

The second part of the duodenum is approximately 8 cm long. It starts at the superior duodenal flexure and runs inferiorly in a gentle curve, convex to the right side of the vertebral column and extending to the lower border of the third lumbar vertebral body. It then turns sharply medially at the inferior duodenal flexure, which marks its junction with the third part of the duodenum. It is covered by peritoneum only on its upper anterior surface, lies posterior to the gallbladder and the right lobe of the liver at its start, and is crossed anteriorly by the transverse colon. The right end of the gastrocolic omentum and the origin of the transverse mesocolon are attached to the anterior surface of the duodenum by loose connective tissue. Below the attachment of the transverse mesocolon, the connective tissue and vessels forming the mesentery of the upper ascending colon and hepatic flexure are loosely attached to its anterior surface. This part of duodenum is at risk of injury during surgical mobilization of the ascending colon and hepatic flexure.

The second part lies anterior to the hilum of the right kidney, the right renal vessels, the lateral edge of the inferior vena cava and the right psoas major (see Fig. 65.1C). The head of the pancreas and the common bile duct are medial and the hepatic flexure is above and lateral. Part of the pancreatic head is sometimes embedded in the medial duodenal wall, and pancreatic 'rests' in the duodenal wall may produce small filling defects on contrast radiology. The internal appearance is similar to that of the distal portion of the first part of the duodenum, with pronounced mucosal folds (Fig. 65.3). The common bile duct and pancreatic duct enter the medial wall, where they usually unite to form a common channel, which frequently contains a dilated segment known as the hepatopancreatic ampulla (of Vater) (p. 1175). The narrow distal end of this channel opens on the summit of the major duodenal papilla, a mucosal elevation situated on the posteromedial wall of the second part, $8-10 \mathrm{~cm}$ distal to the pylorus. A duodenal mucosal fold often partially encircles the major papilla, forming a hood (Horiguchi and Kamisawa 2010) (see Fig. 65.3). A second, accessory pancreatic duct is

Fig. 65.3 The endoscopic appearance of the duodenum. A, Duodenal cap (first part). B, Second part, showing the pronounced, 'branched' mucosal folds. C, Major duodenal papilla. D, Third part.
sometimes present and opens about 2 cm proximal to the major papilla on a minor duodenal papilla (Suda 2010, Kamisawa et al 2010).

## Duodenal diverticula

The duodenum is the most common site for a diverticulum in the small intestine. Diverticula are usually solitary and may be congenital (containing all layers of the duodenal wall) or acquired (protrusion of the mucosa and submucosa through a defect in the muscular coat of the bowel wall). They are typically located on the medial wall of the second part of the duodenum, intimately related to the head of the pancreas, and the major duodenal papilla is frequently found either on the mucosal fold at the mouth of a diverticulum or arising from the mucosa within it. Diverticula may complicate interpretation of contrast radiographs of the duodenum or biliary system, and may cause difficulties during attempted endoscopic cannulation of the major duodenal papilla. Most are asymptomatic but they may be complicated by bleeding, inflammation, perforation and, occasionally, pancreatitis or biliary complications (Fotiades et al 2005).

## THIRD (HORIZONTAL) PART

The third part of the duodenum starts at the inferior duodenal flexure and is approximately 10 cm long. It runs from the right side of the lower border of the third lumbar vertebra, and passes to the left and slightly superiorly, anterior to the inferior vena cava and abdominal aorta, becoming continuous with the ascending fourth part (see Fig. 65.1C). It lies posterior to the transverse mesocolon, and is crossed anteriorly by the origin of the small bowel mesentery and the superior mesenteric vessels. The lower portion of its anterior aspect is covered by peritoneum, which is reflected anteriorly to form the posterior layer of the root of the small bowel mesentery. The anterior surface of the left end, close to the junction with the fourth part, is also covered by peritoneum.

The third part lies anterior to the right ureter, right psoas major, right gonadal vessels, inferior vena cava and abdominal aorta (at the origin of the inferior mesenteric artery), and inferior to the head of the pancreas. Anteroinferiorly, loops of jejunum lie in the right and left infracolic compartments. The mid portion of the third part lies in the angle between the superior mesenteric artery anteriorly and the abdominal aorta posteriorly; narrowing of this angle may occur from loss of perivascular adipose tissue or spinal straightening and is a rare cause of duodenal obstruction (Merrett et al 2009).

## FOURTH (ASCENDING) PART

The fourth part of the duodenum is 2.5 cm long. It starts just to the left of the aorta, runs superiorly and laterally to the level of the upper border of the second lumbar vertebra, then turns sharply anteroinferiorly at the duodenojejunal flexure to become continuous with the jejunum. The inferior mesenteric vein lies either posterior to the duodenojejunal flexure or at its lateral margin beneath a peritoneal fold. The duodenojejunal flexure is a useful landmark to locate the vein radiologically or surgically. The aorta, left sympathetic trunk, left psoas major, left renal and left gonadal vessels are all posterior relations, the left kidney and left ureter are posterolateral, and the transverse colon and mesocolon are anterior, separating it from the stomach (see Fig. 62.8). The inferior border of the body of the pancreas is superior. The peritoneum of the root of the small bowel mesentery descends over its anterior surface.

At its left lateral limit, the fourth part becomes progressively invested in peritoneum, such that the duodenojejunal flexure is suspended from the retroperitoneum by a double fold of peritoneum, the suspensory ligament of the duodenum (or ligament of Treitz). The ligament of Treitz is in two parts; the first part may contain skeletal muscle fibres and runs from the right crus of the diaphragm to connective tissue around the coeliac trunk, and the second part contains smooth muscle and descends from connective tissue around the coeliac trunk to the duodenum, passing behind the pancreas anterior to the left renal vein. The ligament is often absent or rudimentary in adults and its function is unknown (Kim et al 2008). The ligament of Treitz is avascular; the vascular supply to the fourth part of the duodenum enters its wall from the posteromedial aspect.

The duodenojejunal flexure is an important landmark in the radiological diagnosis of incomplete rotation and malrotation of the small intestine (p. 1054).

Fig. 65.4 The arterial supply of the duodenum. Only representative branches of the small vessels, which may be multiple, are shown.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The main vessels supplying the duodenum are the superior and inferior pancreaticoduodenal arteries. The first and second parts also receive contributions from other sources, including the right gastric, supraduodenal, right gastroepiploic, hepatic and gastroduodenal arteries (Fig. 65.4). Branches of the superior pancreaticoduodenal artery may contribute to the supply of the pyloric canal, anastomosing to a minor extent with the gastric arteries within the muscular layer of the pyloroduodenal junction.

## Gastroduodenal artery

The gastroduodenal artery usually arises from the common hepatic artery behind or above the first part of the duodenum. It descends behind the retroperitoneal portion of the first part of the duodenum to the left of the common bile duct. At the lower border of the first part of the duodenum, it is commonly described as dividing into the right gastroepiploic and superior pancreaticoduodenal arteries but this anatomical arrangement is rare (Bradley 1973, Bertelli et al 1995, Bertelli et al 1996) and its usual branching pattern is as follows. As it descends behind the first part of the duodenum, it usually gives off the posterior superior pancreaticoduodenal artery, several retroduodenal branches that supply the first part and proximal portion of the second part of the duodenum, and a supraduodenal artery that supplies the anterosuperior part of the proximal duodenum (Bianchi and Albanèse 1989). As the gastroduodenal artery emerges below the first part of the duodenum, it usually gives off the right gastroepiploic artery and several pyloric branches. It then descends on the anterior surface of the pancreas, where it divides into the anterior superior pancreaticoduodenal artery and pancreatic branches. Although the gastroduodenal artery usually branches from the common hepatic artery, it may occasionally originate from other sources, including: as a trifurcation with the right and left hepatic arteries; the coeliac trunk; the superior mesenteric artery; or from the right or left branch of the hepatic artery.

The gastroduodenal artery or one of its branches may be a source of haemorrhage from a penetrating posterior duodenal ulcer (see above) or it may be the site of aneurysm or pseudoaneurysm formation; for these reasons, it is an important vessel for interventional radiologists.

## Superior pancreaticoduodenal arteries

There are usually two superior pancreaticoduodenal arteries: a posterior and anterior. The posterior superior pancreaticoduodenal artery is usually a separate branch of the gastroduodenal artery and is given off behind the upper border of the first part of the duodenum. It descends to the right, anterior to the portal vein and common bile duct, where the latter lies behind the first part of the duodenum. It then spirals around the right side of the bile duct to run behind the head of the
pancreas, crosses posterior to the retropancreatic segment of the common bile duct (which is embedded, to a variable degree, in the head of the pancreas), and anastomoses with the posterior division of the inferior pancreaticoduodenal artery (Bertelli et al 1996). The posterior artery supplies branches to the head of the pancreas, the first and second parts of the duodenum, and several branches to the lowest part of the common bile duct.

The anterior superior pancreaticoduodenal artery is usually a terminal branch of the gastroduodenal artery and descends in the anterior groove between the second part of the duodenum and the head of the pancreas or on the anterior surface of the gland parallel to the groove (Bertelli et al 1995). It supplies branches to the first and second parts of the duodenum and to the head of the pancreas, and then passes posteriorly to anastomose with the anterior division of the inferior pancreaticoduodenal artery.

## Inferior pancreaticoduodenal artery

The inferior pancreaticoduodenal artery usually arises from the superior mesenteric artery or its first jejunal branch, near the superior border of the third part of the duodenum (Bertelli et al 1996). It crosses behind the superior mesenteric vein and passes behind the uncinate process of the pancreas, where it divides into anterior and posterior branches. The anterior branch passes to the right, immediately inferior and then anterior to the lower border of the head of the pancreas, and runs superiorly to anastomose with the anterior superior pancreaticoduodenal artery. The posterior branch runs posteriorly to the right behind the head of the pancreas, and anastomoses with the posterior superior pancreaticoduodenal artery (Bertelli et al 1997). Both branches supply the pancreatic head, its uncinate process, and the second and third parts of the duodenum. Occasionally, the anterior and posterior branches arise separately from the superior mesenteric or first jejunal artery.

## Jejunal artery branches

Branches from the first jejunal branch of the superior mesenteric artery supply the fourth part of the duodenum and frequently anastomose with a terminal branch of the anterior superior pancreaticoduodenal artery. The fourth part of the duodenum therefore receives a potential collateral supply from the coeliac trunk and superior mesenteric artery, which means that it is not commonly affected by ischaemia.

## Veins

Submucosal and intramural veins give rise to small veins that accompany corresponding named arteries. The venous anatomy of this region is variable and not well characterized. The superior pancreaticoduodenal vein runs superiorly on the posterior surface of the head of the pancreas, posterior to the distal common bile duct, and usually drains into the portal vein. The inferior pancreaticoduodenal vein runs inferiorly and usually drains into the superior mesenteric vein or its first jejunal tributary. Small veins from the first and upper second parts of the duodenum drain directly into the portal vein, and veins from the third and fourth parts may drain directly into the superior mesenteric vein. Numerous small anastomoses are present between veins of the second and third parts of the duodenum and retroperitoneal veins (Murakami et al 1999).

## Lymphatic drainage

Duodenal lymphatics run to superior and inferior pancreaticoduodenal lymph nodes, and from there to supra- and infrapyloric, hepatoduodenal, common hepatic, coeliac and superior mesenteric nodes. Lymphatic drainage to para-aortic nodes has also been described (Hirai et al 2001).

## Duodenal feeding

## Available with the Gray's Anatomy e-book

## INNERVATION

The duodenum is innervated by both parasympathetic and sympathetic neurones

Preganglionic sympathetic neurones have their cell bodies in the intermediolateral columns of the grey matter in the fifth to the twelfth thoracic spinal segments. Their fibres travel via the greater and lesser splanchnic nerves to the coeliac plexus and synapse in the coeliac and superior mesenteric ganglia; postganglionic axons are distributed to the duodenal wall via peri-arterial plexuses on the branches of the coeliac trunk and superior mesenteric artery. The sympathetic nerves are vasoconstrictor to the duodenal vasculature and inhibitory to duodenal musculature.

The preganglionic parasympathetic supply is carried by vagal fibres that travel from the coeliac plexus and synapse on neurones in the duodenal wall. The parasympathetic supply is secretomotor to the duodenal mucosa and motor to the duodenal musculature.

## Referred pain

In common with other structures derived from the foregut, pain arising from the proximal duodenum is poorly localized and referred to the epigastrium. It is mediated by afferent fibres that accompany the sympathetic neurones.

## JEJUNUM

The jejunum has an external diameter of about 4 cm and an internal diameter of about 3 cm . It has a thicker wall than the ileum and a rich arterial blood supply. The plicae circulares (see below) are most pronounced in the proximal jejunum, where they are more numerous and deeper than elsewhere in the small bowel (Figs 65.5-65.6). They frequently 'branch' around the lumen and may appear to be stacked on top of each other, giving the jejunum a characteristic appearance during single contrast radiography (see Fig. 65.6), computed tomographic (CT) enterography (Fig. 65.7A) or magnetic resonance (MR) enterography (Fig. 65.7B). The plicae circulares are also clearly visible by capsule endoscopy, in which images of the small bowel are transmitted wirelessly from a small swallowed camera that is the size of a pill (Fig. 65.8).

Fig. 65.5 Typical cross-sections through the proximal jejunum (A) and terminal ileum (B). The mesenteric attachment is wider in the jejunum, and two leaves of vessels enter the bowel wall. The latter is also thicker in the jejunum.

When gastric emptying is functionally impaired - as, for example, in gastroparesis, nutrition may be delivered directly into the duodenum or jejunum via a nasal transpyloric feeding tube.

Fig. 65.7 A, Computed tomographic (CT) enterography. Coronal slice showing small intestinal loops and superior mesenteric vessels. B, Magnetic resonance (MR) enterography. Coronal slice showing the small intestine and transverse colon.

In the supine position, the jejunum usually occupies the upper left infracolic compartment, extending down to the umbilical region. The first one or two loops often occupy a recess between the left part of the transverse mesocolon and the left kidney. On supine radiological examination, the jejunal loops are characteristically situated in the upper abdomen, to the left of the midline, whereas the ileal loops tend to lie in the lower right part of the abdomen and pelvis. This distribution can be reversed in small bowel obstruction due to rotation of the dilated bowel around its mesenteric attachment.

Fig. 65.6 Barium studies of the jejunum and ileum. A, Barium followthrough. The feathery appearance of the small intestine is due to the plicae circulares and is most prominent in the jejunum. The constrictions (arrows) are the result of peristalsis. B, Small bowel enema (enteroclysis). The plicae circulares are clearly demonstrated by this technique. Abbreviations: C, caecum; I, ileum; J, jejunum; PC, plicae circulares; TI, terminal part of ileum.

Jejunal feeding In patients with a functioning intestine who cannot tolerate adequate oral or intragastric feeding, jejunal feeding is often the preferred option. Compared to parenteral (intravenous) nutrition, enteral feeding is associated with fewer complications. Furthermore, it maintains the integrity of the gut mucosa (thereby reducing bacterial translocation from the gut lumen), decreases the likelihood of aspiration from gastro-oesophageal reflux, and is less of a stimulus for pancreaticobiliary secretion. Jejunal feeds can be delivered via a nasojejunal or gastrojejunal tube, or directly into the jejunum; gastrojejunal and jejunal tubes may be inserted endoscopically, radiologically or surgically. The end of the feeding tube must lie beyond the duodenojejunal flexure to prevent reflux of feed into the duodenum and stomach.

## ILEUM

The ileum has a median external diameter of about 3 cm , an internal diameter of about 2.5 cm and tends to have a thinner wall than the jejunum (see Fig. 65.5B). The plicae circulares become progressively less obvious in the distal ileum; they tend to be single and flatter (see Figs 65.6-65.7; Fig. 65.9). The mucosa of the terminal ileum immediately proximal to the ileocaecal junction may appear almost flat at endoscopy, although the villi can be seen when viewed close up (see Fig. 65.9) and at capsule endoscopy (see Fig. 65.8).

In the supine position, the ileum lies mainly in the hypogastric region and right iliac fossa. The terminal ileum frequently lies in the pelvis, from where it ascends over the right psoas major and right iliac vessels, to end by opening at the ileocaecal junction in the right iliac fossa.

## ANATOMICAL DIFFERENCES BETWEEN THE JEJUNUM AND ILEUM

While there is no clear boundary between the jejunum (the proximal two-fifths of the small intestine beyond the duodenum) and the ileum (the distal three-fifths), there are general anatomical differences between these regions. The wall of the jejunum is thicker and more vascular, has a greater number of more prominent plicae circulares, and contains less

Fig. 65.9 The endoscopic appearance of the terminal ileum.

Fig. 65.8 The small intestine visualized by capsule endoscopy (PillCam®). A, The proximal jejunum at 1 h 34 mins. B, The distal jejunum at 1 h 51 min. C, The proximal ileum at 2 h 25 min . Fig. 65.11 A Meckel's diverticulum containing ectopic mucosa at its tip. (Courtesy of Professor Mark Stringer, Christchurch Hospital, New Zealand.)

The mean length of the small bowel, measured from the duodenojejunal flexure to the ileocaecal junction in vivo, is about 5 m but can range from 3 to 8.5 m (Teitelbaum et al 2013). Males have a longer small bowel than females, and height is positively associated with small bowel length (Teitelbaum et al 2013). Short bowel syndrome results from surgical resection, congenital deficiency or disease-associated loss of absorption, and is characterized by the inability to maintain proteinenergy, fluid, electrolyte or micronutrient balances when on a conventionally accepted, normal diet (O'Keefe et al 2006). Left untreated, short bowel syndrome leads to dehydration, malnutrition and weight loss. Adults with the greatest risk of developing intestinal failure fall into three groups: those with an end-jejunostomy and $<100 \mathrm{~cm}$ of residual small bowel, those with a jejunocolic anastomosis and $<50 \mathrm{~cm}$ residual small bowel, and those with a jejunoileal anastomosis and $<35 \mathrm{~cm}$ of residual small bowel (despite the presence of an ileocaecal junction and colon) (Nightingale and Woodward 2006, Jeppesen 2013).

After surgical resection, the remaining small bowel undergoes an adaptive process that involves morphological and functional changes. The small bowel dilates and villus height and crypt depth increase, expanding the absorptive surface area. Adaptation begins soon after intestinal resection and may continue for up to 2 years (Jeppesen and Mortensen 2002). However, there are differences between the ability of the proximal and distal small bowel to adapt; the likelihood of regaining intestinal autonomy is greatest in patients with a retained segment of ileum and colon in continuity, as compared to patients with a residual duodenojejunal segment and an end-jejunostomy (Jeppesen 2013).

Fig. 65.12 A temporary loop ileostomy in an infant. The skin marking around the stoma is from the stoma bag adhesive. (Courtesy of Professor Mark Stringer, Christchurch Hospital, New Zealand.)

Small bowel transplantation has become a standard clinical procedure for selected patients with intestinal failure. The small intestine may be transplanted in isolation or along with the liver and/or other abdominal organs such as the pancreas (multivisceral transplant). Postoperatively, patients are recommenced on parenteral nutrition, and enteral feeding is started via a feeding jejunostomy once intestinal motility has returned. Protein is delivered as peptides and fats as medium-chain triglycerides, which are absorbed directly into the mesenteric veins and not via the lymphatics (which are divided when the graft is taken from the donor). Parenteral nutrition can usually be discontinued 3-6 weeks after transplantation but may continue to be used to supplement enteral feeding when stoma losses are large.

Intestinal dysmotility is common after intestinal transplantation. There is no extrinsic nerve supply to the graft but intrinsic small bowel motility usually recovers within 48-72 hours after transplantation (Gunning and Friend 1998). Adequate gastric emptying is often delayed for several weeks, despite pyloroplasty and the administration of drugs to enhance gastric motility. Reinnervation of the allograft via its vascular pedicle is a slow process (Walther et al 2013). Intestinal motility is also affected by any inflammatory response caused by rejection. Denervation and division of the lymphatic drainage of the intestinal allograft do not appear to seriously impair longer-term function. In animal models, lymphatic drainage is re-established within 21-28 days, which is consistent with observations in patients (Kocandrle et al 1966).

Fig. 65.10 Specimens of the jejunum (A) and ileum (B) from a cadaver where the superior mesenteric artery was injected with red-coloured gelatin before fixation. Subsequently, the specimens were dehydrated and then cleared in benzene, followed by methyl salicylate. The largest vessels present are the jejunal and ileal branches of the superior mesenteric artery and these are succeeded by anastomotic arterial arcades, which are relatively few in number (1-3) in the jejunum, becoming more numerous (2-6) in the ileum. From the arcades, straight arteries (arteriae recta) pass towards the gut wall; frequently, successive straight arteries are distributed to opposite sides of the gut. Note the denser vascularity of the jejunal wall. (Specimens prepared by MCE Hutchinson; photographs by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)
lymphoid tissue than the ileum. There are also differences between the mesenteric vessels in the jejunum and ileum (Conley et al 2010). The jejunal mesentery, measured from the superior mesenteric artery to the mesenteric border of the bowel, is shorter than the ileal mesentery, and the jejunal arteries are slightly larger than their ileal counterparts. The jejunum typically contains 1-3 tiers of vascular arcades, whereas there are often 2-6 tiers in the ileum (Fig. 65.10). The arteriae recta in the ileum are more numerous, shorter and narrower than in the jejunum. The jejunal and ileal arteries, arcades and arteriae recta are muscular arteries capable of influencing splanchnic blood flow, which can vary between $10 \%$ and $35 \%$ of cardiac output (Rosenblum et al 1997).

Solitary lymphoid follicles are scattered throughout the small intestinal mucosa but are most numerous in the distal ileum. Aggregated lymphoid follicles, Peyer's patches, are circular or oval masses containing 5-260 follicles. They vary in size, shape and distribution, most measuring $2-8 \mathrm{~cm}$ and visible macroscopically as dome-like elevations, usually along the antimesenteric border of the intestine. They are rarely present in the duodenum; small, circular, few in number and impalpable in the distal jejunum; and larger, more numerous and often palpable in the ileum (particularly in the terminal 25 cm ; Van Kruiningen et al 2002). Villi are small or absent over the larger follicular masses. Lymphoid aggregates are most prominent in early childhood and, when enlarged in viral infections, may form the apex of an intussusception. They become less prominent around puberty, and decrease further in number during adult life (Cornes 1965).

Meckel's diverticulum A congenital ileal diverticulum (of Meckel) is found in $2-3 \%$ of individuals and represents the remnant of the proximal part of the vitellointestinal duct. It projects from the antimesenteric border of the terminal ileum and is commonly located between 50 and 100 cm from the ileocaecal junction. It is variable in length (usually $2-5 \mathrm{~cm}$ in adults) and often possesses a short 'mesentery' of adipose tissue containing a vitellointestinal artery (from the termination of the superior mesenteric artery) that extends from the ileal mesentery to its base (Fig. 65.11). The lumen of the diverticulum usually has a calibre similar to that of the ileum. The tip is normally free but occasionally it may be connected to the anterior abdominal wall near the umbilicus by a fibrous band. The mucosa is typically ileal, but small heterotopic areas of gastric body type epithelium, pancreatic, colonic or other tissues may also occur in the wall of a diverticulum. Unopposed acid secretion by heterotopic gastric body type epithelium may give rise to ulceration and bleeding in the adjacent normal ileal mucosa. Diverticular inflammation may mimic acute appendicitis; since Meckel's diverticulum and the appendix are both derived from midgut structures, pain from either structure is referred to the periumbilical region. Rarer complications of a Meckel's diverticulum include intestinal obstruction, intussusception, perforation, calculi and tumours (Sagar et al 2006, Uppal et al 2011).

Jejunostomy and ileostomy In clinical practice, a stoma is a surgically created opening from a hollow viscus to the skin, classified according to its location. An intestinal stoma may be either an end stoma, in which only the proximal end of the divided bowel is anastomosed to the skin, or a loop stoma, in which both the proximal and distal ends of the bowel are exteriorized on the surface (Fig. 65.12). The output of a jejunostomy is greater than that of an ileostomy and more likely to result in excessive fluid, electrolyte and nutrient losses.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

Branches from the superior mesenteric artery supply the jejunum and ileum. The arteries divide as they approach the mesenteric border of the intestine (see Fig. 65.5), giving off numerous branches that extend between the muscular layers before forming a submucosal arterial plexus that supplies the mucosa. Although there is a rich anastomotic network of arteries within the intestinal mesentery, anastomoses between the terminal branches close to the intestinal wall are few. The intramural and submucosal arterial networks consist of small-calibre vessels only. Consequently, division or occlusion of several consecutive vasa recta may produce segmental ischaemia of the bowel, while division of more proximal arterial branches in the small bowel mesentery may not cause ischaemia because of collateral flow through vascular arcades.

## Superior mesenteric artery

The superior mesenteric artery originates from the abdominal aorta 1 cm below the coeliac trunk, at the level of the lower border of the first lumbar vertebra in the transpyloric plane (Figs 65.13-65.14). The angle of its origin from the aorta is acute (mean value $45^{\circ}$, range $38-60^{\circ}$ and greater in individuals with a greater body mass index; Ozkurt et al 2007); this can make cannulation via the transfemoral route somewhat difficult. The artery is usually surrounded by fat, lymphatics and neural tissue at its origin, which helps to increase the angle and distance between it and the aorta, thereby preventing compression of the duodenum where it is crossed by the artery. The artery descends anterior to the uncinate process of the pancreas and the third part of the duodenum, and posterior to the splenic vein and the body of the pancreas. The left renal vein lies behind it and separates it from the aorta (Fig. 65.15B). Within the small bowel mesentery, the superior mesenteric artery crosses anterior to the inferior vena cava, right ureter and right psoas major. Its calibre progressively decreases as successive branches are given off to the jejunum and ileum, and its terminal branch anastomoses with the termination of the ileocolic artery.

The superior mesenteric artery usually gives off the inferior pancreaticoduodenal, middle colic, right colic and ileocolic branches from its right side, and jejunal and ileal branches from its left side. Its jejunal and ileal branches form vascular arcades within the small bowel mesentery. The last of these arcades forms an irregular and incomplete 'marginal artery' of the small intestine. Straight arteries, the arteriae recta, are given off from the most distal arcades and pass directly to the small intestine.

Anatomical variations in the origin and branching pattern of the superior mesenteric artery are well described (Winston et al 2007, Horton and Fishman 2010) (see also p. 1144). It may be the source of the common hepatic, gastroduodenal, accessory or replaced right

Fig. 65.13 The superior mesenteric artery and its branches. The outlines of representative ileal and jejunal loops, appendix, caecum, ascending and transverse colon are shown for reference. Only the origin of jejunal and ileal branches is shown. For details of arcades, see Figure 65.10.
hepatic, accessory pancreatic, splenic or rarely the inferior mesenteric artery. Also rare is a superior mesenteric artery arising from a common coeliacomesenteric trunk (Rountas et al 2013).

The remnant of the vitellointestinal artery (the embryonic artery that originally connected the intestinal circulation to the yolk sac) is usually obliterated; when present, it forms the artery supplying a Meckel's diverticulum. It is occasionally represented in the mesentery by a fibrous strand from the termination of the superior mesenteric artery to the ileum.

Jejunal branches There are usually 4-6 jejunal branches, which arise from the left side of the upper portion of the superior mesenteric artery (see Figs 65.13-65.14). They are distributed to the jejunum via 1-3 tiers of arterial arcades, the most distal of which gives rise to straight arteries. The latter run almost parallel in the mesentery before being distributed alternately to either side of the small bowel, forming two distinct 'leaves' of vessels within the mesentery separated by a relatively avascular plane (see Fig. 65.5A).

This vascular arrangement allows a dilated segment of small bowel to be bisected longitudinally and tubularized to double its length, a potentially useful technique to achieve small bowel lengthening in short bowel syndrome (Bianchi 1984).

Small twigs from the jejunal arteries supply regional mesenteric lymph nodes.
lleal branches Ileal branches are more numerous (around 8-12) and slightly smaller in calibre than the jejunal branches. They arise from the left and anterior aspects of the superior mesenteric artery. The length of the mesentery from the superior mesenteric artery to the mesenteric border of the bowel is greater in the ileum, and the branches form between two and six arcades before giving rise to multiple straight arteries that run directly towards the ileal wall (see Fig. 65.10B). These branches run parallel in the mesentery and are distributed to both aspects of the ileum. They are shorter and thinner than their jejunal counterparts, particularly in the distal ileum, and do not form such distinct parallel 'leaves' of vessels. The terminal ileal arcades are supplied by the ileal branch of the ileocolic artery and the last ileal branch of the superior mesenteric artery (see Fig. 65.13). Few other vessels connect the ileocolic and superior mesenteric artery territories, which makes surgical dissection of the ileocolic artery up to its origin relatively simple.

## Veins

## Superior mesenteric vein

The superior mesenteric vein drains the small intestine, caecum, ascending and transverse parts of the colon, and parts of the stomach and greater omentum (Fig. 65.16; see Fig. 59.8). It is formed in the mesentery of the small bowel by the union of tributaries from the terminal
ileum, caecum and vermiform appendix. It ascends in the mesentery to the right of the superior mesenteric artery, passing anterior to the right ureter, inferior vena cava, third part of the duodenum and uncinate process of the pancreas. It joins the splenic vein behind the neck of the pancreas in the transpyloric plane (lower border of L1 vertebra) to form the portal vein.

The superior mesenteric vein receives jejunal, ileal, ileocolic, right colic, middle colic, right gastroepiploic and inferior pancreaticoduodenal veins. A major proximal jejunal branch usually runs transversely behind the superior mesenteric artery to enter the right posterolateral aspect of the superior mesenteric vein (Kim et al 2007). The right colic vein is highly variable. When present, it may drain into the superior mesenteric vein directly, or may join the right gastroepiploic or inferior pancreaticoduodenal vein to form a 'gastrocolic trunk', which then drains into the superior mesenteric vein (Yamaguchi et al 2002). Although the inferior mesenteric vein usually drains into the splenic vein, it may join the superior mesenteric vein directly or its confluence with the splenic vein (Graf et al 1997).

## Lymphatic drainage

The lymphatic system of the small intestine regulates tissue fluid homeostasis, participates in immune surveillance, and transports dietary fat and fat-soluble vitamins from the gut lumen. It is organized into two networks. Firstly, lacteals from the villi drain into a plexus of lymphatics in the submucosa and are joined by vessels from lymph spaces at the bases of solitary lymphoid follicles; these lymphatic vessels have few, if any, valves. Secondly, a coarse plexus of lymphatics also runs in the muscularis externa between the two muscle layers. The submucosal and muscular networks share few connections but both communicate freely with larger valved collecting lymphatics at the mesenteric border of the small intestine (Miller et al 2010). Mesenteric lymphatics pass between the layers of the mesentery and drain via a series of mesenteric lymph nodes concentrated around the regional mesenteric vessels. Individual segments of small bowel have a relatively wide field of lymphatic drainage, which makes radical surgical resection of draining lymph nodes difficult if the blood supply to the remaining unaffected small bowel is to be preserved. Mesenteric nodes drain into superior mesenteric nodes around the root of the superior mesenteric artery.

## INNERVATION

The jejunum and ileum are innervated by parasympathetic and sympathetic fibres via the superior mesenteric plexus (see Figs 59.2-59.4). Preganglionic sympathetic axons originate from neurones in the intermediolateral grey matter of the mid-thoracic spinal segments and travel in the greater and lesser splanchnic nerves to the coeliac and superior mesenteric ganglia, where they synapse. Postganglionic axons

Splenic vein

(C, continued online)
accompany the superior mesenteric artery into the mesentery and are distributed along branches of the artery. The sympathetic nerves are vasoconstrictor to the vasculature and inhibitory to the musculature of the jejunum and ileum. Sympathetic neurotransmitters also have an immunomodulatory role by influencing mucosa-associated lymphoid tissue (Straub et al 2006). Preganglionic parasympathetic axons travel in the vagus nerves and are secretomotor to the mucosa and motor to the smooth muscle of the jejunum and ileum. Visceral afferents from the small bowel, conveying pain and other gut sensations, travel with the splanchnic and vagus nerves.

## Referred pain

In common with other structures derived from the midgut, the visceral sensation of pain arising from the jejunum or ileum is poorly localized, and is usually referred to the periumbilical region.

## SMALL INTESTINE PHYSIOLOGY

The principal functions of the small intestine are fluid and electrolyte haemostasis, digestion and absorption of nutrients, immunoregulation, and secretion of hormones. The absorptive capacity of the small

Fig. 65.15 C, An axial ultrasound image showing the superior mesenteric artery and the splenic vein.

intestine is greatly enhanced by the plicae circulares, villi and microvilli, which increase its surface area by factors of approximately 2,7 and 13, respectively (Helander and Fändriks 2014), yielding a total estimated surface area of almost $30 \mathrm{~m}^{2}$.

## MICROSTRUCTURE

The intestinal wall is composed of mucosa, submucosa, muscularis externa and serosa or adventitia (see Fig. 59.9). The mucosa is thick and very vascular in the proximal small intestine, but thinner and less vascular distally. In places, it is ridged by the underlying submucosa to form circular folds, plicae circulares, which protrude into the lumen; mucosal finger- or leaf-like intestinal villi cover the whole surface (Fig. 65.17). There are numerous simple, tubular intestinal glands or crypts between the bases of the villi, and additional submucosal glands in the

Fig. 65.17 The internal aspect of a representative sample of the proximal jejunum, showing circular folds.

Fig. 65.18 A low-power micrograph showing several circular folds (arrows) in the wall of the ileum. The folds are covered with villi $(\mathrm{V}$ ) projecting into the lumen, and the submucosa (SM) extends into the core of each fold. Circular (innermost) and longitudinal smooth muscle layers form the underlying muscularis externa. Large masses of lymphoid tissue (Peyer's patches, P) lie in the mucosa. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
duodenum (see Fig. 59.9). The submucosa contains aggregates of lymphoid tissue, most numerous in the ileum.

## Circular folds

Except in the first part of the duodenum, large circular folds of mucosa (known as plicae circulares or valvulae conniventes) project into the lumen of the small intestine, orientated either transversely or slightly obliquely to its long axis (see Figs. 65.8, 65.17; Fig 65.18). Unlike gastric folds, they do not disappear during physiological distension of the intestine. Most extend round half or two-thirds of the luminal circumference, some are complete circles, some bifurcate and join adjacent folds, while others are spiral and extend one or more times round the lumen. Larger folds are up to 8 mm deep but most are smaller than this, and larger folds often alternate with smaller ones. Folds begin to appear $2.5-5 \mathrm{~cm}$ beyond the pylorus and are relatively large and close together in the distal duodenum and proximal jejunum. Beyond this point, they diminish in size and disappear almost completely in the terminal ileum, which therefore has a relatively thin wall. The circular folds increase the absorptive surface area and enhance mechanical segmentation in the small intestine. They are visible at endoscopy (see Fig. 65.3), during small bowel contrast studies (see Fig. 65.6), and sometimes on plain radiographs.

The secretion and absorption of electrolytes and fluid are two essential functions of the small intestinal epithelium. In healthy adults, the gastrointestinal tract is capable of secreting 8-10 litres of fluid per day in addition to the 1.5-2 litres ingested each day. To reduce this volume to the typical ileocaecal daily flow of approximately 2 litres per day, the small intestinal epithelium has a large number of transport molecules and regulatory proteins. Net fluid movement across the gastrointestinal epithelium is primarily the result of the active transport of $\mathrm{Na}^{+}, \mathrm{Cl}^{-}$, and $\mathrm{HCO}_{3}^{-}$ions. The jejunum can only absorb sodium across a small sodium gradient and therefore does not normally absorb salt and water, but secretes it into the lumen. Most fluid and electrolyte absorption occurs in the ileum, which is able to absorb across a larger sodium gradient (Nightingale and Spiller 2001).

The mucosal brush border has an abundance of enzymes and pumps on its surface. Examples include the sodium-dependent glucose transporter protein (SGLT1) and the fructose transporter protein (GLUT5). Most carbohydrates are broken down by enzymes to monosaccharides before being transported across the mucosa. A deficiency of lactase on the mucosal brush border is relatively common and results in lactose intolerance. Proteins are broken down into single amino acids and small peptides. The peptidase gradient across the microvillus brush border increases along the length of the small bowel, suggesting that amino acids are absorbed more distally than carbohydrates. Dietary fats are emulsified by biliary secretions and then broken down by pancreatic lipase into free fatty acids and phospholipids, which form micelles. The lipid components are then absorbed within the distal small bowel and converted into chylomicrons in the enterocytes before being secreted into the lymphatic system. Minerals such as calcium, magnesium, phosphorus and iron, and the water- and fat-soluble vitamins, are predominantly absorbed in the duodenum and proximal jejunum (Farrell 2002, Malik and Westergaard 2002). Vitamin $\mathrm{B}_{12}$ is absorbed in the terminal ileum after binding to intrinsic factor released by gastric parietal cells.

The motility of the small intestine differs, depending on whether the individual is fasting or postprandial. In the fasting state, the smooth
muscle of the small intestine exhibits cyclical myoelectrical activity, the so-called migrating motor complex (MMC). The frequency of these slow waves is regulated by interstitial cells of Cajal and is about 11/ minute in the jejunum, decreasing along the length of the small intestine to $7-8 /$ minute in the ileum (Husebye 1999). When slow waves are amplified beyond a threshold by neural, endocrine or paracrine stimulation, action potentials are generated, resulting in smooth muscle contraction. This spreads circumferentially at first and then propagates along the entire circumference of the bowel in an aboral direction, causing a ring-like contraction of the circular smooth muscle that progresses down the small bowel (with about $10 \%$ of contractions reaching the ileum).

The MMC consists of three phases: phase I is a period of quiescence, phase II is composed of irregular contractions, and phase III is a short burst of phasic contractions at the maximum frequency of the slow waves for that part of the intestine. The velocity of migration is $5-10 \mathrm{~cm} /$ minute in the jejunum, decreasing gradually along the small bowel to about $1 \mathrm{~cm} /$ minute in the ileum. The MMC requires an intact enteric nervous system and does not depend on extrinsic innervation. Consequently, MMCs are present in the transplanted (denervated) small bowel. However, there is evidence that extrinsic innervation modulates the MMC. For example, sleep causes the almost complete disappearance of phase II. Phase III activity normally recovers in the proximal small bowel within a few hours of major abdominal surgery but the pressure wave amplitude is temporarily reduced. Somatostatin and opioids decrease phase II activity.

After a meal, the cyclical fasting activity is abolished for several hours and replaced by irregular contractions that consist of both segmental 'stationary' contractions and propulsive contractions (Barnert 2007).

Assessment of small bowel motility can complement detailed microscopic examination of full-thickness biopsy specimens of the intestine when characterizing conditions associated with intestinal dysmotility, helping to distinguish intestinal neuropathy from visceral myopathy.

## Intestinal villi

Intestinal villi are highly vascular projections of the mucosal surface, just visible to the naked eye (see Fig. 65.18; Figs 65.19-65.21; Commentary 8.2 ). They cover the entire small intestinal mucosa, increase the surface area of the lumen about seven-fold (Helander and Fändriks 2014), and give it a velvety texture. Villi are large and numerous in the duodenum and jejunum, and smaller and fewer in the ileum. In the first part of the duodenum, they appear as broad ridges, become tall and foliate in the distal duodenum and proximal jejunum, and then gradually shorten to a finger-like form in the distal jejunum and ileum. Villi vary in density from 10 to 40 per $\mathrm{mm}^{2}$ and from 0.5 to 1.0 mm in height (see Fig. 65.19). Infoldings of the mucosa dip down from the base of the villi for a short distance into the lamina propria. These crypts (of Lieberkühn) are most prominent in the proximal small intestine (see Fig. 65.20).

## Mucosa

The mucosa consists of epithelium, lamina propria and muscularis mucosae.

## Epithelium

A single-layered epithelium covers the intestinal villi (see Figs 65.20, 2.2C) and also lines the intestinal glands (crypts) that open between the bases of villi. Two types of cell, enterocytes and goblet cells, cover the surfaces of the villi, whereas microfold cells (M cells) are restricted to the dome epithelium that covers localized accumulations of lymphoid tissues. These cell types are all in contact basally with a basal lamina to which they adhere, and all are derived from a common stem cell in the intestinal crypts.

Enterocytes Enterocytes are columnar absorptive cells, approximately $20 \mu \mathrm{~m}$ tall. They are the most numerous type of cell in the small intestinal lining, and are responsible for nutrient absorption. Their surfaces bear up to 3000 microvilli, which greatly increase the surface area for absorption (Marsh and Swift 1969). Collectively, microvilli are visible by light microscopy as a brush border $1 \mu \mathrm{~m}$ thick; individual microvilli can be resolved only by electron microscopy. Enterocyte nuclei are elongated vertically, mainly euchromatic and located just below the centre of the cell.

The apical cell surface is resistant to protease attack because microvilli possess a specialized glycoprotein-rich surface coat (glycocalyx), which, with an overlying layer of mucus (Johansson et al 2011), protects
the epithelium against pancreatic enzymes in the intestinal lumen. The cell coat also contains a number of digestive enzymes as integral membrane proteins. These include enzymes that degrade disaccharides and oligopeptides prior to absorption.

The luminal surface is an important barrier to diffusion. Nutrients generally have to pass through enterocytes (transcellular absorption) before they reach the underlying lamina propria and its blood vessels and lymphatics (lacteals). Classical epithelial junctional complexes encircle the apical plasma membranes of adjacent enterocytes; their tight junctions form an effective barrier to non-selective diffusion between the gut lumen and the body as a whole. The lateral plasma membranes of enterocytes are highly folded, interdigitating with each other to form complex intercellular boundaries, anchored periodically by desmosomes, and making contact at gap junctions. The lateral intercellular space expands during active absorption and is an additional conduit (supplementing transport across the basal cell surface) for the passage of fluids, nutrients and other solutes to the vessels of the lamina propria.

Enterocytes have a lifespan after differentiation of about 5 days. Their position on the villus wall reflects their stage in the life cycle; at the tips of intestinal villi, they undergo programmed, apoptotic, cell death and are shed from the epithelium. They are replaced at the base of the villus by stem cell mitosis.

Goblet cells Goblet cells are most numerous in the distal small intestine, increasing in number from the duodenum to their highest density in the terminal ileum. They have elongated basal nuclei, an apical region containing many membrane-bound mucinogen granules, and apical surfaces that bear a few short microvilli. Goblet cell mucins contribute to protection against microorganisms and toxins in the gut lumen, and also provide lubrication and mechanical protection from the intestinal contents.

Microfold ( $\mathbf{M}$ ) cells Microfold cells are present where the epithelium covers lymphoid aggregates in the intestinal wall. They are cuboidal or flattened in shape and have long, widely spaced microfolds rather than microvilli on their apical surfaces. They sample luminal antigens by endocytosis, and transport antigen to lymphocytes lying within intercellular pockets formed by deep invaginations of the M-cell basolateral plasma membranes. See Chapter 4 for details of antigen processing and presentation.

Lymphocytes Intraepithelial lymphocytes are found in close association with M cells and also between the basolateral regions of enterocytes and goblet cells. They are migratory cells derived from the underlying lymphoid tissue and constitute an important means of immune defence.

## Intestinal glands or crypts

Intestinal glands or crypts (of Lieberkühn) are tubular pits that open into the lumen throughout the intestinal mucosa via small circular apertures between the bases of the villi (see Fig. 65.20). Their thin walls are composed of columnar enterocytes supplemented by mucous cells, Paneth cells, stem cells and neuroendocrine cells. They are separated by a basal lamina from a rich capillary plexus within the lamina propria.

Enterocytes Enterocytes in the crypts secrete ions and alkaline fluid to dilute chyme and aid absorption by structurally similar cells that cover the villi.

Mucous cells The mucous cells in the crypts are similar to the goblet cells of the villi.

Paneth cells Paneth cells are highly specialized epithelial cells of the small intestine, involved in the coordination of many physiological functions. They were first identified more than a century ago on the basis of their readily discernible secretory acidophilic granules that stain strongly with eosin or phosphotungstic haematoxylin. Paneth cells are numerous in the deeper parts of the intestinal crypts. They synthesize and secrete lysozyme, a highly specific antibacterial enzyme, other defensive proteins (defensins) and tumour necrosis factor alpha (TNF$\alpha$ ), which help to protect the luminal surface. Recent studies have shown that these antimicrobial molecules are key mediators of hostmicrobe interactions, including maintaining the homeostatic balance with colonizing microbiota and providing innate immune protection from enteric pathogens (Clevers and Bevins 2013). In addition, Paneth cells secrete factors that help sustain and modulate epithelial stem and progenitor cells in the crypts.

Fig. 65.20 The architecture of an intestinal villus. The various layers and cells are not drawn to scale.

Fig. 65.21 The endoscopic appearance of the terminal villi (magnified).

Stem cells Stem cells occur in a zone just above the basal region of the crypts. Lineage tracing has demonstrated that Lgr5 ${ }^{\text {hi }}$ crypt base columnar stem cells generate all cell types of the small intestinal epithelium (Barker et al 2007). These cells divide rapidly in the crypt compartment directly above the Paneth cells. Their progeny (transitamplifying cells) move upwards from this compartment on to the surfaces of the villi while differentiating into goblet cells, tuft cells, neuroendocrine cells and enterocytes. An individual cell takes only $4-5$ days to reach the villus tip and undergo apoptosis. Paneth cells escape this upward flow and migrate downwards instead to settle at the base of the crypt, where they can remain for one month or more (Clevers and Bevins 2013). Stem cell daughter cells and young transitamplifying cells retain their plasticity and are able to revert back to stem cells if the crypt is damaged and existing stem cells are lost.

Neuroendocrine cells Several types of neuroendocrine cell are scattered among the walls of the intestinal crypts, and less commonly over the villi. They secrete bioactive peptides, such as gastrin, cholecystokinin and secretin, basally into the surrounding lamina propria. Crypt neuroendocrine cells are derived from stem cells, which also give rise to enterocytes and other epithelial elements.

## Lamina propria

The lamina propria is composed of connective tissue and provides mechanical support for the epithelium. It has a rich vascular plexus, receives nutrients absorbed by the enterocytes, and forms the cores of the villi. It contains lymphoid tissue, fibroblasts and connective tissue extracellular matrix fibres, smooth muscle cells, eosinophils, macrophages, mast cells, capillaries, lymphatic vessels and unmyelinated nerve fibres. Plasma cells are numerous. Lymphocytes may be clustered in solitary or aggregated follicles, some of which extend through the muscularis mucosae into the submucosa.

## Villus core

Each villus has a core of delicate connective tissue that contains a large, blind-ending lymphatic vessel or lacteal (so called because of its content of suspended chylomicrons, the droplets of apoprotein-lipid complex elaborated by enterocytes from absorbed dietary fats). The core also contains blood vessels, nerves and smooth muscle cells derived from fine extensions of the muscularis mucosae. Each lacteal, usually single but occasionally double, starts in a closed dilated extremity near the tip of a villus, and extends through the core to the base of the villus, where it joins a narrower lymphatic plexus in the deeper lamina propria. Its wall is a single layer of endothelial cells. Smooth muscle cells surround the lacteal throughout the villus and their contraction propels its contents into the underlying lymphatic plexus. Capillaries within the core are lined by fenestrated endothelium to facilitate the rapid intake of nutrients diffusing from the covering absorptive epithelium.

## Mucosa-associated lymphoid tissue

Mucosa-associated lymphoid tissue (MALT) consists of lymphoid follicles covered by follicle-associated intestinal epithelium, which includes scattered M cells. MALT is found mainly in the lamina propria but sometimes expands into the submucosa; it is the source of B and T lymphocytes and other related cells involved in the immune defence of the gut wall.

Like other masses of MALT (except lymph nodes), solitary and aggregated lymphoid follicles are most prominent around the age of puberty, after which they diminish in number and size, although many persist into old age. For further details of intestinal MALT and its function, including Peyer's patches, see Didierlaurent et al (2005).

## Muscularis mucosae

The muscularis mucosae forms the base of the mucosa, and has external longitudinal and internal circular layers of smooth muscle cells. It follows the surface profiles of the circular folds and sends fine fascicles of smooth muscle cells into the cores of the villi.

## Submucosa

The submucosa is composed of loose connective tissue and contains blood vessels, lymphatics and nerves. Its ridged elevations form the cores of the circular folds. The geometry of its collagen and elastin fibres permits the considerable changes in transverse and longitudinal dimensions that accompany peristalsis, whilst still providing adequate support, elasticity and strength.

## Submucosal (Brunner's) glands

Submucosal glands are limited to the submucosa of the duodenum and often referred to as 'Brunner's glands' (see Fig. 65.19). Their ducts traverse the muscularis mucosae to enter the bases of the mucosal crypts. They are largest and most numerous near the pylorus and form an almost complete layer in the proximal half of the descending duodenum; thereafter, they gradually diminish in number and disappear at
the duodenojejunal junction. They are small, branched tubuloacinar glands; each has several secretory acini lined by low columnar epithelial cells, which produce an alkaline ( pH 9 ) mucoid secretion that effectively neutralizes acidic chyme from the stomach. Many neuroendocrine cells are present among the acinar cells.

## Muscularis externa

The muscularis externa consists of a thin, external, longitudinal layer and a thick, internal, circular layer of smooth muscle cells. It is thicker in the proximal small intestine and is mainly responsible for the differential appearance of proximal jejunum and distal ileum on CT scanning.

## Interstitial cells of Cajal

Interstitial cells of Cajal (ICC; p. 1043) are found throughout the entire length of the gastrointestinal tract, where they lie in close contact with nerve terminals (Farrugia 2008). They originate from mesenchymal cells and may be considered to be specialized smooth muscle cells. However, whereas smooth muscle cells develop an extensive array of contractile elements, ICCs are fusiform cells with a large oval nucleus, sparse cytoplasm, dendritic-like processes, few contractile elements, an abundance of endoplasmic reticulum and mitochondria, and characteristic sets of channels in their membrane (Mostafa et al 2010). Distinct networks are found in the myenteric plexus between the circular and longitudinal muscle layers; ICCs contact each other and neighbouring smooth muscle cells via gap junctions. Looser arrangements exist within the individual muscle layers and the submucosa of the gut. Isolated or small groups of ICCs are also found in connective tissue septa and the subserosal region. The cells are involved in the generation of pacemaker signals, the propagation of electrical slow wave activity, neuromuscular transmission, and mechanosensation (Sanders et al 2014). Defective ICC function has been implicated in a wide range of intestinal motility disorders (Al-Shboul 2013).

## Serosa

Serosa is visceral peritoneum and consists of a subserous stratum of loose connective tissue covered by mesothelium. It covers the majority of the muscularis externa; the only exceptions are the part adjacent to mesenteric adipose tissue and the retroperitoneal portions of the duodenum, both of which are covered mainly by a connective tissue adventitia rather than by serosa.

## OVERVIEW

The large intestine extends from the ileocaecal junction to the anus. It begins as the caecum and vermiform appendix, which are usually located in the right iliac fossa. The ascending or right colon passes upwards in the right flank to the right hypochondrium, where it bends to the left to form the hepatic flexure (right colic flexure) and become the transverse colon. This loops across the abdomen with an anteroinferior convexity until it reaches the left hypochondrium, where it curves inferiorly to form the splenic flexure (left colic flexure). From here, it descends in the left flank as the descending or left colon before continuing as the sigmoid colon in the left iliac region. The sigmoid colon descends into the true pelvis and becomes the rectum anterior to the third sacral vertebra. The rectum transitions to the anal canal at the level of the pelvic floor (Figs 66.1-66.2). The large intestine thus runs from the ileocaecal (ileocolic) junction to the anal verge. It is formed from the distal midgut, all of the hindgut, and the proctodeum (Ch. 72 and Figs 72.4 and 72.7 E ). Knowledge of the development of the large intestine not only helps to explain its anatomy, relations (including peritoneal attachments) and neurovascular supply (Ch. 60), but is also fundamental to understanding congenital large bowel disorders such as anorectal malformations and malrotation of the gut.

In the adult, the large intestine is approximately $1-1.5 \mathrm{~m}$ long in vivo, although there is considerable individual variation. The large intestine differs from the small intestine in several ways: it has a greater calibre; for much of its course it is more fixed in position; the outer longitudinal muscle layer of the colon is concentrated into three longitudinal bands, taeniae coli; small fatty projections, appendices epiploicae, are scattered over its free surface (although these tend to be
absent from the caecum, vermiform appendix and rectum); and the colonic wall is puckered into sacculations (haustrations), visible on plain radiographs as incomplete septations arising from the bowel wall (see Fig. 66.2; Fig. 66.3). Its calibre is greatest near the caecum, gradually diminishes towards the sigmoid colon, and then increases again in the rectum, where the lower third is dilated to form the rectal ampulla. The mean internal diameter of the large intestine is 4.8 cm (Helander and Fändriks 2014).

During development, the large intestine is temporarily suspended by a midline dorsal mesentery. However, after rotation of the gut in utero, large portions of it come to lie adherent to the retroperitoneum, while other segments remain suspended by a mesentery within the peritoneal cavity. The mesenteries of the colon consist of two layers of visceral peritoneum enclosing adipose and connective tissues and surrounding vessels, nerves and lymphatics that run forward from retroperitoneal structures. Where colonic mesenteries lie in contact with the retroperitoneum, the potential space between the retroperitoneum and mesentery, referred to as the 'subperitoneal space', forms an avascular plane during surgical dissection and allows the tracking of fluid, blood and disease (Oliphant et al 1996, Coffey 2013) (Ch. 62). The caecum may be firmly adherent to the retroperitoneum but is frequently suspended by a short mesentery, especially in infants. The ascending colon is usually adherent to the retroperitoneum, while the transverse colon is suspended by a mesocolon and is freely mobile within the upper abdomen. The hepatic and splenic flexures may have a short mesentery. The descending colon is adherent to the retroperitoneum, usually down to the level of the left iliac crest, and the sigmoid colon has a mesentery of variable length. The sigmoid mesentery shortens as it approaches the pelvis and practically disappears at the level of the rectosigmoid junction. The rectum is a retroperitoneal structure.

Fig. 66.1 An overview of the abdominal colon and its relations.

Fig. 66.2 The appearance of the colon on double contrast barium enema examination, demonstrating the transverse colon and hepatic and splenic flexures.

The posterior attachments of the small bowel mesentery and transverse mesocolon result in the peritoneal cavity being divisible into named compartments (Ch. 62). The supracolic and infracolic compartments are separated by the attachment of the transverse mesocolon to the posterior abdominal wall. Anteriorly, the transverse colon and transverse mesocolon are adherent to the posterior surface of the greater omentum. Lifting the greater omentum upwards exposes the infracolic compartment. This is divided by the root of the small bowel mesentery that descends obliquely from left to right; to the right lies the right infracolic compartment, its apex the ileocaecal junction, and to the left, the left infracolic compartment, bordered laterally by the descending colon and continuous below with the pelvic cavity.

The microstructure of the large bowel corresponds to the general pattern of the gut wall, having a mucous membrane consisting of epithelium, lamina propria and muscularis mucosa, surrounded by an inner circular and outer longitudinal layer of muscle and a serosa (see Figs $66.3,66.51$ ). The mucosa also contains scattered neuroendocrine cells derived from the amine precursor uptake and decarboxylation (APUD) cell lineage; these cells produce amines and/or peptides, which act as hormones or neurotransmitters. Unlike the small intestine, the mucosa of the large intestine lacks villi and the glands (crypts) contain a high proportion of goblet (mucin-secreting) cells. In the appendix, the glands are sparse and numerous lymphoid follicles are found in the mucosa and submucosa. Although it is not a vital organ, the primary function of the colon is transmission and elimination of intestinal contents, but it also has important absorptive and secretory roles. The anal sphincter is responsible for both continence and evacuation. The large intestine has its own intrinsic (enteric) nerve supply, the activity of which is modulated by extrinsic innervation.

## EXTERNAL APPEARANCE

The haustrations of the colon are frequently absent in the caecum and often relatively sparse in the ascending and proximal transverse colon. They become more pronounced beyond the middle of the transverse colon. The sigmoid colon often has marked sacculation. Appendices epiploicae are small, fat-filled pouches of peritoneum that project from the external surface of the colon and are supplied by blood vessels that perforate the bowel wall. There are few, if any, appendices epiploicae on the serosal surface of the caecum, and only a limited number scattered along the ascending colon. They are more common over the distal colon and particularly numerous on the surface of the sigmoid colon, where they can be large in the obese individual. The rectum has no appendices epiploicae.

The three taeniae coli are located in fairly constant positions beneath the serosal surface of the colon, except in the transverse colon. They are found on the anti-mesenteric aspect of the colon directly opposite the mesentery (taenia libera), posterolaterally (taenia omentalis) and posteromedially (taenia mesocolica) midway between the taenia libera and the mesentery (see Fig. 66.3). In the ascending and descending colon, the posterolateral taenia is often obscured from view by the peritoneal

Fig. 66.3 Layers of the colonic wall.
reflection on to the colonic wall. In the transverse colon, the taeniae are rotated as a consequence of the dependent position of this segment of colon and so anterior becomes inferior, posteromedial becomes posterior, and posterolateral becomes superior. The width of the taeniae coli remains fairly constant throughout the colon but they broaden out in the distal part of the sigmoid colon and gradually merge to form a complete longitudinal muscle layer around the rectum, which therefore has no external sacculations.

## INTERNAL APPEARANCE

Colonic haustrations represent sites where the mucosa and submucosa of the colonic wall is infolded; these folds partially span the bowel lumen but never form a complete, circumferential ring. The pattern of haustrations and appearance of the colonic mucosa help the clinician appreciate the level reached during flexible endoscopic examinations of the colon (Silverstein and Tytgat 1991). In the caecum, the three longitudinal taeniae coli converge to form a characteristic 'trefoil' pattern on the caecal wall (Fig. 66.4). The lower pole of the caecum is usually devoid of haustrations, although a spiral mucosal pattern is often seen in the region of the orifice of the appendix (Fig. 66.5). The upper caecum and ascending colon possess shallow but deep haustrations, which may extend across one-third of the lumen (Fig. 66.6). In the transverse colon, the haustrations often confer a triangular appearance to the cross-section of the lumen when viewed along its axis at colonoscopy (Fig. 66.7). The haustrations of the descending and sigmoid colon tend to be thicker and shorter, producing a more circular crosssection to the lumen (Figs 66.8-66.9). The wall of the colon is thinnest in the region of the caecum and ascending colon, where it is most at risk of perforation during therapeutic endoscopic procedures. The overall luminal diameter is often smallest in the descending colon. The tortuosity of the sigmoid colon means that shorter lengths of colon are visible during endoscopy than elsewhere in the colon. The haustrations of the rectum usually form consistent and recognizable transverse folds and the submucosal vessels tend to be more pronounced than in the colon (Fig. 66.10). Distinct veins are usually visible during endoscopy, and are most marked above the anorectal junction.

## RADIOGRAPHIC APPEARANCES

Cross-sectional imaging of the colon can be performed with computed tomography (CT) and magnetic resonance imaging (MRI). On axial imaging, the colon may be filled with particulate faeces and air (Fig. 66.11). The wall in normal individuals is thin. The caecum and ascending colon often contain faecal residue and are easily identified in the

Fig. 66.4 The endoscopic appearance of the caecum. The characteristic trefoil appearance of the confluence of the three taeniae is usually obvious.

Fig. 66.5 The endoscopic appearance of the orifice of the appendix, seen as a slit-like depression near the centre of this view of the caecal pole. The orifice varies from a small depression to an obvious luminal structure. The ileocaecal junction is just visible in the top left corner. (Courtesy of Dr Michael Schultz.)

Fig. 66.6 The endoscopic appearance of the ascending colon.

Fig. 66.7 The endoscopic appearance of the transverse colon. Note the characteristic triangular appearance of the haustrations when viewed collectively (see also Fig. 66.11C).

Fig. 66.8 The
endoscopic appearance of the descending colon. The lumen tends to look rather more featureless than the more proximal colon.
retroperitoneum on the right. The transverse colon may contain faeces or gas and lies in a variable position, suspended by its mesentery. The descending colon lies in the retroperitoneum on the left and often contains little faecal residue. The volume data sets produced by modern multislice CT can now produce virtual colonoscopic mucosal images of the distended and cleaned colon, and surface-rendered images of the internal surface of the bowel (Fenlon 2002).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The arterial supply of the large intestine is derived from both the superior and the inferior mesenteric arteries (Fig. 66.12) (Jackson 1999). The caecum, appendix, ascending colon and proximal two-thirds of the transverse colon (derived from the midgut) are supplied from ileocolic, right colic and middle colic branches of the superior mesenteric artery The distal third of the transverse colon, descending and sigmoid colon, rectum and upper anal canal (hindgut derivatives) are supplied predominantly from the inferior mesenteric artery via the left colic, sigmoid

Fig. 66.9 The
endoscopic appearance of the sigmoid colon.
Multiple large mucosal
folds are characteristic.
and superior rectal arteries, with a small contribution from branches of the internal iliac artery (the middle and inferior rectal arteries).

The arteries of the midgut and hindgut contribute to an anastomotic vessel, the marginal artery of Drummond, which runs in the mesentery along the inner margin of the colon and gives off short terminal branches to the bowel wall. These divide into vasa brevia, which pass directly through the muscularis externa of the colonic wall, and vasa longa, which travel through the subserosa for a short distance before running through the circular muscle, giving off branches to the appendices epiploicae (Fig. 66.13). The marginal artery is formed by the main branches and arcades arising from the ileocolic, right colic, middle colic and left colic arteries. It is most apparent in the ascending, transverse and descending colons (Fig. 66.14) and poorly developed in the sigmoid colon. The marginal artery in the region of the splenic flexure may be absent or of insufficient calibre to be of functional significance. Nevertheless, it may dilate considerably when one of the main visceral arteries is compromised since it then provides a collateral arterial supply to the colon. The most susceptible part of the chain of anastomosing vessels is at the junction of midgut and hindgut in the distal transverse colon near the splenic flexure. However, the arterial supply to this

Fig. 66.12 The main branches of the superior and inferior mesenteric arteries.
region may be augmented by an inner arterial arc (of Riolan), which runs a meandering course in the colonic mesentery between the main trunk of the middle colic artery and the ascending branch of the left colic artery (Fisher and Fry 1987, Gourley and Gering 2005). When present, this vessel is usually only prominent when there is occlusion of the superior or inferior mesenteric artery.

## Colonic vascular occlusion

The marginal artery of the colon may become massively dilated when there is chronic stenosis or occlusion of the superior or inferior mesenteric artery. The latter may occur, for example, in association with
an abdominal aortic aneurysm, when the descending colon remains viable because the marginal artery continues to receive an adequate blood supply from the left branch of the middle colic artery and the sigmoid colon gains its supply from the middle and inferior rectal arteries via the superior rectal and sigmoid arteries. When colonic ischaemia does occur, it is usually maximal in the region of the splenic flexure and proximal descending colon because this segment is furthest from the collateral arterial supplies. Occlusion of the common iliac arteries may also result in dilation of the marginal and inferior mesenteric arteries, which become an important collateral supply to the lower limbs via dilated middle rectal arteries arising from the internal iliac artery.

## Veins

The venous drainage of the large intestine is primarily into the portal vein via the superior mesenteric and inferior mesenteric veins, although some drainage from the rectum occurs via middle rectal veins into the internal iliac veins, and inferior rectal veins into the internal pudendal veins. Those parts of the colon derived from the midgut (caecum, appendix, ascending colon and proximal two-thirds of the transverse colon) drain into colic branches of the superior mesenteric vein, while hindgut derivatives (distal third of the transverse colon, descending and sigmoid colon, rectum and upper anal canal) drain into the inferior mesenteric vein (Fig. 66.15).

## Lymphatic drainage

Lymph drainage from the large intestine follows the course of the arteries. Thus, lymphatic vessels of the caecum, ascending and proximal transverse colon drain ultimately into lymph nodes related to the superior mesenteric artery, while those of the distal transverse colon,

Fig. 66.13 The typical pericolic arrangement of the arterial vasculature.
descending colon, sigmoid colon and rectum drain into nodes following the course of the inferior mesenteric artery (Fig. 66.16). In cases where the distal transverse colon or splenic flexure is predominantly supplied by vessels from the middle colic artery, the lymphatic drainage of this area may be predominantly to superior mesenteric nodes.

Fig. 66.14 The marginal artery running parallel to the colon and providing an anastomosis between the branches of the superior mesenteric artery supplying the right side of the colon and the branches of the inferior mesenteric artery supplying the left side of the colon (digital subtraction arteriogram). (Courtesy of Dr J Jackson, Hammersmith Hospital, London.)

Fig. 66.15 The main branches of the superior and inferior mesenteric veins.

Fig. 66.16 The lymph vessels and nodes draining the large intestine.

## Colic nodes

Lymph nodes related to the colon form four groups: epicolic, paracolic, intermediate colic and preterminal colic nodes. Epicolic nodes are minute whitish nodules on the serosal surface of the colon, sometimes within the appendices epiploicae. Paracolic nodes lie along the medial borders of the ascending and descending colon and along the mesenteric borders of the transverse and sigmoid colon. Intermediate colic nodes lie along the named colic vessels (the ileocolic, right colic, middle colic, left colic, sigmoid and superior rectal arteries). Preterminal colic nodes lie along the main trunks of the superior and inferior mesenteric arteries and drain into pre-aortic nodes at the origin of these vessels.

Ascending mesocolic lymph nodes are significantly larger than sigmoid mesocolic lymph nodes; this is relevant to lymph node retrieval and examination after resection for colonic cancer (Ahmadi et al 2015).

Radical lymphadenectomy during resection of colorectal cancer requires removal of the highest possible lymph nodes draining the region of colon in which the tumour is located. In cases of cancer of the rectum or sigmoid colon, this usually involves excision of the preterminal colic nodes along the inferior mesenteric artery with ligation of the artery at its root or just below the origin of the left colic artery.

## MIDGUT REGION OF LARGE INTESTINE

## CAECUM

This blind pouch, measuring approximately 6 cm in length, lies below the level of the ileocolic junction, anterior to the fascia covering the right iliacus and psoas major, with the lateral cutaneous nerve of the thigh interposed. The caecum usually lies adjacent to the anterior abdominal wall unless the greater omentum or loops of small bowel are interposed. The caecum is often completely covered by peritoneum, which is reflected posteriorly and inferiorly to the floor of the right iliac fossa. Peritoneal folds from the posterior caecal wall may create a variety of peritoneal recesses around the caecum that have the potential to become sites of internal herniation; a superior and inferior ileocaecal recess, a retrocaecal recess and a paracolic recess have been described (Rivkind et al 1986). The retrocaecal recess frequently contains the vermiform appendix. The three taeniae coli lie anteriorly, posteromedially and posterolaterally, and converge on the base of the appendix. During childhood, the lateral caecal wall outgrows the medial wall such that the orifice of the appendix, which is originally at the apex of the caecum (Fig. 66.17), usually comes to lie slightly posteromedially.

Fluid and electrolyte reabsorption by the large intestine begins in the caecum but occurs mostly in the ascending and transverse colon. The distensible 'sac-like' morphology of the caecum allows storage of large volumes of semi-liquid chyme from the small intestine. The rela-

Fig. 66.17 The caecum and ileocolic junction, double contrast barium enema appearance.
tively large diameter of the caecum makes it liable to distension with increased intracolonic pressure and it is the region of the large intestine at greatest risk of perforation secondary to colonic distension (from obstruction or other pathology).

## Ileocolic junction

The terminal ileum joins the posteromedial aspect of the large intestine at the junction of the caecum and colon, where it projects into the lumen of the large intestine as the ileal papilla (Fig. 66.18A). It consists of two labial folds; its precise shape and form varies from slit-like to an oval mucosal rosette, depending, in part, on the state of contraction or distension of the caecum. The upper labial fold is approximately horizontal and is at the junction between the ileum and colon; the lower lip is longer and more concave, and is at the junction between the ileum and caecum. At their bases, the labia fuse and continue as narrow mucosal ridges or frenula.

Fig. 66.18 A, The endoscopic appearance of the ileocolic junction ('ileocaecal valve'), which appears as a bilabial structure on the left of this view of the caecal pole. B, A photomicrograph showing a longitudinal section through the inferior labium of the ileal papilla (haematoxylin and eosin); the ileal mucosa is visible superiorly. (A, Courtesy of Dr Michael Schultz. B, Courtesy of Drs. Matthew Pollard and Mark Stringer.)

The ileal papilla is formed by the mucosa, submucosa and external muscle layers of the ileum, continuing through the wall of the colon and combining with corresponding layers from the caecum inferiorly and the colon superiorly (Fig. 66.18B). The internal surface of the papilla is lined by small intestinal mucosa and its colonic surface is covered by large bowel mucosa; these epithelial surfaces meet near the tip of the papilla. A localized thickening of the muscle at the base of the ileal papilla is consistent with physiological data that suggest the presence of an intrinsic anatomical sphincter (Pollard et al 2012). In addition, the bilabial configuration of the papilla may confer a valvular function. The ileocolic junction performs several roles: it provides partial mechanical and functional separation of the luminal environments of the small and large intestine, which differ in their composition, pH and bacterial content; it impedes reflux from the colon; and it helps to regulate antegrade small bowel transit.

## Caecal volvulus

If the caecum and ascending colon are attached to the posterior abdominal wall by a narrow mesentery, the ileocolic region is at risk of twisting about its mesenteric pedicle, creating a caecal volvulus. In such cases, the caecum becomes markedly distended as a consequence of the strangulating closed loop bowel obstruction that develops. Nonanatomical factors such as caecal distension may also contribute to the pathogenesis of caecal volvulus (Madiba and Thomson 2002).

## APPENDIX

The vermiform (worm-like) appendix is a narrow, blind-ending tube, usually between 6 and 10 cm long in the adult. It joins the posteromedial wall of the caecum below the ileocolic junction. The appendix grows in length and diameter during early childhood, reaching almost mature dimensions by about 3 years of age (Searle et al 2013). The appendix usually lies in the right iliac fossa but its tip may occupy one of several positions (Fig. 66.19) (Buschard and Kjaeldgaard 1973). In clinical practice, the tip is most commonly retrocaecal or retrocolic (behind the caecum or lower ascending colon, respectively, anterior to iliacus and psoas major), or pelvic (when the appendix descends over the pelvic brim, in close relation to the right uterine tube and ovary in females). Other positions include subcaecal, and pre- or post-ileal (anterior or posterior to the terminal ileum, respectively), especially when a long appendicular mesentery allows greater mobility. The surface marking for the base of the appendix has traditionally been described by McBurney's point (two-thirds of the way along a line between the umbilicus and right anterior superior iliac spine) but its position is variable and affected by posture, caecal distension and other factors (Hale et al 2010).

The appendix has a continuous outer layer of longitudinal muscle formed by the coalescence of the three taeniae coli. Its lumen is irregularly narrowed by submucosal lymphoid tissue. The mesoappendix is a triangular mesentery running between the terminal ileum and appendix; it contains a variable amount of fat and frequently ends short of the tip of the appendix. A small fold of peritoneum runs between the terminal ileum and the anterior layer of the mesoappendix (the so-called 'bloodless fold of Treves'), and another fold of peritoneum containing the anterior caecal vessels extends from the terminal ileal mesentery to the anterior wall of the caecum (and contains the anterior caecal

Fig. 66.19 The major positions of the appendix encountered at surgery or postmortem.
artery) (see Fig. 63.10). The luminal orifice is sometimes partially covered by a mucosal fold forming an asymmetrical 'valve' (see Fig. 66.5). The lumen may be widely patent in early childhood but is often partially or wholly obliterated in the elderly. Agenesis or duplication of the appendix are exceptionally rare (Barlow et al 2013).

## Microstructure

The layers of the wall of the appendix are similar to those of the large intestine in general but with some notable differences. The serosa forms a complete covering, except along the mesenteric attachment. The outer longitudinal muscle is a complete layer of uniform thickness, except in a few small areas where the muscularis externa is deficient, allowing the serosa to come into contact with the submucosa.

The submucosa typically contains large lymphoid aggregates that may extend into the mucosa and disrupt the integrity of the muscularis mucosae (Fig. 66.20). The mucosa is covered by a columnar epithelium, which contains $M$ cells where it overlies the mucosal lymphoid tissue. Glands (crypts) (see Fig. 4.5) are similar to those of the colon but are fewer in number and less densely packed. They penetrate deep into the lamina propria. The submucosal lymphoid tissue frequently exhibits germinal centres within its follicles (see Fig. 4.10), indicative of B-cell activation. Lymphoid follicles are absent at birth but accumulate during the first 10 years of life to become prominent. In adults, the lymphoid follicles gradually atrophy; in the elderly, the lumen of the appendix may be partially obliterated by fibrous tissue.

## Acute appendicitis

Acute appendicitis may develop as a consequence of obstruction of the lumen from inspissated material, a faecolith (appendicolith) or lymphoid swelling. This can lead to suppuration, infarction and necrosis. Appendicoliths are more common in children than adults but their prevalence is variable, reflecting differences between populations, definitions and methods of detection. In one radiographic study of normal appendices removed incidentally at surgery or at autopsy, calcified faecoliths were identified in $2.7 \%$ (Felson 1949). The increased size of the appendicular orifice in early childhood and the decreased lumen in the elderly may be reasons why acute appendicitis is less common in these age groups. Although the appendix is well supplied by arterial anastomoses at its base, the appendicular artery is an end artery; its close proximity to the wall of the appendix makes it susceptible to thrombosis during acute appendicitis, which explains the high frequency of gangrenous perforation seen in the disease.

Visceral afferent nerves are responsible for the initial symptoms of acute appendicitis arising from distension and inflammation of the organ: namely, colicky pain with or without vomiting. These afferent nerves enter the spinal cord at around the level of the tenth thoracic spinal segment. Abdominal pain from appendicitis is poorly localized initially and referred to the central (periumbilical) region of the abdomen, consistent with the midgut origin of the appendix. It is not until parietal tissues adjacent to the appendix become involved in the inflammatory process that somatic nociceptors are stimulated, resulting in localization of pain to the right iliac fossa. Removal of the appendix is not by itself associated with any discernible long-term sequelae but this does not mean that it is an entirely vestigial organ. There is some evidence that the appendix acts as a reservoir for normal gut flora, enabling the large bowel flora to recover more rapidly after severe gastroenteritis (Randal Bollinger et al 2007).

Fig. 66.20 A low-power micrograph of the appendix in transverse section, showing part of its circumference and a faecal pellet lodged in its lumen. Lymphoid tissue (basophilic staining) occupies much of the mucosa between crypts, and part of the submucosa. The muscularis externa and outermost serosal layer are seen at the right of the field.

Fig. 66.21 Posterior relations of the ascending colon.

## ASCENDING COLON

The ascending colon is $15-20 \mathrm{~cm}$ long and passes upwards from the ileocolic junction to the right colic (hepatic) flexure, separated posteriorly by loose connective tissue from the iliac fascia, iliolumbar ligament, quadratus lumborum, transversus abdominis, and the renal fascia anterior and inferolateral to the right kidney. The lateral femoral cutaneous nerve, usually the fourth lumbar artery, and sometimes the ilioinguinal and iliohypogastric nerves lie posteriorly as they cross quadratus lumborum (Fig. 66.21). Both the lateral and anterior surfaces

Fig. 66.22 Axial CT images of the ascending colon obtained $(\mathbf{A})$ at the level of the mid ascending colon and (B) at the level of the hepatic flexure, showing the relationship of the ascending colon and hepatic flexure to the right lobe of the liver, the right kidney, the second part of the duodenum, and the gallbladder. (Courtesy of Dr Louise Moore, Chelsea and Westminster Hospital, London.)
of the ascending colon are covered by peritoneum, which runs laterally into the right paracolic gutter and medially into the right infracolic compartment. The ascending mesocolon is composed of two layers of mesothelium containing fat embedded within a connective tissue lattice, vessels and nerves; it is attached to the retroperitoneum of the posterior abdominal wall via a layer of connective tissue (Coffey 2013, Culligan et al 2014), known as Toldt's fascia, which forms the plane of dissection when performing a right hemicolectomy.

## Hepatic flexure

The hepatic flexure, forming the junction between the ascending and transverse colon, is variable in position, and has a less acute angle than the splenic flexure. It overlies the anterior surface of the lower pole of the right kidney, abutting the inferior surface of the right lobe of the liver above (see Fig. 66.21; Fig. 66.22B), the second part of the duodenum medially, and the fundus of the gallbladder anteromedially. The posterior aspect of the hepatic flexure is not covered by peritoneum and is in direct contact with renal fascia. The greater omentum often extends from its attachment to the transverse colon on to the hepatic flexure.

## TRANSVERSE COLON

The transverse colon is intraperitoneal. It is highly variable both in length (approximately 50 cm long on average) and the extent to which it hangs down anterior to the small bowel between sites of attachment at the right (hepatic) and left (splenic) colic flexures. The greater curvature of the stomach and the gastrocolic omentum, which fuses with the

Occasionally, the ascending mesocolon is reflected forwards from the posterior abdominal wall, conferring greater mobility on this usually retroperitoneal part of the large bowel (Saunders et al 1995).
transverse colon anteriorly and continues inferiorly as the greater omentum, are superior. The transverse colon is suspended by the transverse mesocolon, which is attached from the lower pole of the right kidney, across the second part of the duodenum and pancreas, to the upper pole of the left kidney (see Fig. 63.2). The splenic flexure lies at a higher level than the hepatic flexure, often abutting the spleen under the left lower ribs. The disposition of the transverse colon and more posteriorly sited flexures results in the anterior taenia of the ascending (and descending) colon lying inferiorly (see above). The transverse mesocolon affords considerable mobility to the transverse colon. Occasionally, the colon may be interposed between the liver and the diaphragm, when it may be mistaken for free intraperitoneal gas on imaging; when associated with gastrointestinal symptoms it is referred to as Chilaiditi's syndrome (Murphy et al 2000).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE MIDGUT

## Arteries

## Superior mesenteric artery

The artery of the midgut is the superior mesenteric artery, which arises from the anterior surface of the aorta at the level of the lower border of the body of the first lumbar vertebra. It runs steeply downwards, posterior to the splenic vein and body of the pancreas, with the superior mesenteric vein on its right, and directly anterior to the left renal vein, the uncinate process of the pancreas and the third part of the duodenum. It then enters the root of the mesentery of the small intestine and passes obliquely downwards and to the right, giving off several branches to the large intestine.

## Ileocolic artery

The ileocolic artery arises from the superior mesenteric artery near the root of the mesentery of the small intestine, descending within the mesentery to the right towards the caecum, and crossing anterior to the right ureter, gonadal vessels and psoas major. It usually divides into superior and inferior branches, the superior branch running up along the left side of the ascending colon to anastomose with the right colic artery (or right branch of the middle colic artery) (Veeresh et al 2012). The inferior branch runs to the ileocolic junction and divides into anterior and posterior caecal arteries, the appendicular artery, and an ileal branch that passes to the left in the ileal mesentery to anastomose with a terminal ileal branch of the superior mesenteric artery (Fig. 66.23). The latter therefore provides a collateral arterial supply to the caecum. The ileocolic artery provides the major arterial supply to the caecum; traction on the caecum in the direction of the anterior superior iliac spine will cause the artery to tent up the mesentery, allowing easy identification of the vessel.

The appendicular artery usually arises directly from the ileocolic artery and descends posterior to the terminal ileum to enter the mesoappendix a short distance from the base of the appendix (see Fig. 66.23). Here, it gives off a recurrent branch, which anastomoses at the base of the appendix with a branch of the posterior caecal artery. The appendicular artery approaches the tip of the organ, at first near to, and then in the edge of, the mesoappendix. The terminal part of the artery lies on the wall of the appendix and may become thrombosed in appendicitis, resulting in distal gangrene or necrosis. Less commonly, the appendicular artery may arise from the posterior caecal artery or an

Accessory right colic artery: 10\%
ileal artery (Ouattara et al 2007) (see Fig. 66.12). Accessory appendicular arteries are common; two or more arteries may supply the appendix.

## Right colic artery

The right colic artery is relatively small and variable in its anatomy (Batra et al 2013). It usually arises as a common trunk with the middle colic artery, but may originate directly from the superior mesenteric artery, or from the ileocolic artery (when it is referred to as an accessory right colic artery) (Fig. 66.24). It passes to the right, across the right psoas major and quadratus lumborum, crossing the right gonadal vessels and ureter, just posterior to the peritoneal floor of the right infracolic compartment. Near the left side of the ascending colon, it divides into a descending branch, which runs down to anastomose with the superior branch of the ileocolic artery, and an ascending branch, which passes up across the lower pole of the right kidney to the hepatic flexure, where it anastomoses with a branch of the middle colic artery. Together, these anastomoses form the marginal artery at the hepatic flexure.

## Middle colic artery

The middle colic artery arises from the right side of the superior mesenteric artery, either separately or in common with the right colic artery, just inferior to the neck of the pancreas, and passes anteriorly and superiorly within the transverse mesocolon, just to the right of the midline. As it approaches the colon, it usually divides into right and left branches. The right branch anastomoses with the ascending branch of the right colic artery. The left branch supplies the terminal part of the midgut and anastomoses with a branch of the left colic artery near the splenic flexure. The marginal artery thus formed lies a few centimetres from the mesenteric edge of the transverse colon. Sometimes, the middle colic artery divides into three or more branches within the

Fig. 66.23 The arteries of the caecum, vermiform appendix and ascending colon.

Fig. 66.24 Anatomical variants of the right colic artery.

A

Left colic artery

B

-
transverse mesocolon, in which case the most lateral branches form the arterial anastomoses. An accessory, or rarely a replaced, middle colic artery may arise directly from the aorta (Yoshida et al 1993), dorsal pancreatic, hepatic, inferior mesenteric or left colic arteries (Fig. 66.25). In addition, an accessory middle colic artery is occasionally found arising from the superior mesenteric artery proximal to the origin of the actual middle colic artery (Turmezei and Cockburn 2009).

## Veins

All the branches of the superior mesenteric artery are accompanied by correspondingly named veins. These tributaries drain into the superior mesenteric vein, which ascends to the right of the artery, crossing the third part of the duodenum and uncinate process of the pancreas. Behind the neck of the pancreas, at the level of the transpyloric plane (the lower border of the body of the first lumbar vertebra), it joins the splenic vein to form the portal vein, which ascends behind the first part of the duodenum to reach the liver. The right colic vein is highly variable: it may drain either directly into the superior mesenteric vein, or into the right gastroepiploic or inferior pancreaticoduodenal veins to form a 'gastrocolic trunk' that drains into the superior mesenteric vein, or it may be entirely absent (Yamaguchi et al 2002). Several tributaries draining into one or more middle colic veins are highly variable in extent and position. The middle colic veins drain either into the superior mesenteric vein, just before its junction with the splenic vein, or directly into the hepatic portal vein. The appendicular vein usually joins the caecal vein to become the ileocolic vein; infection from the appendix can therefore be carried directly to the liver via the portal vein.

## Lymphatic drainage

Lymphatic vessels originate from both anterior and posterior aspects of the colon. Lymph drainage from the midgut follows the course of the superior mesenteric artery. Thus, lymph from the caecum and appendix drains to nodes associated with the ileocolic artery, and from the distal ascending colon and hepatic flexure to nodes along the right colic artery (see Fig. 66.16). When the distal transverse colon and splenic flexure are predominantly supplied by the middle colic artery, lymph drainage of this segment is also largely to superior mesenteric nodes. Lymphatic vessels in the appendix are numerous and combine to form vessels that ascend in the mesoappendix, occasionally interrupted by one or more nodes. They unite to form three or four larger vessels that anastomose with lymphatic vessels draining the ascending colon into ileocolic nodes.

## HINDGUT REGION OF LARGE INTESTINE

## Splenic flexure

The splenic flexure marks the junction between the transverse and descending colon, and lies in the left hypochondrium, anterior to the tail of the pancreas and the left kidney (Fig. 66.26). Its position with respect to the spleen is variable: it usually lies inferomedial to the lower pole, forming the colic impression, but it may lie anterior to the splenic hilum, or even a little above. The splenic flexure is often attached to the splenic capsule by a peritoneal ligament and inadvertent downward traction on the flexure during surgery may tear the splenic capsule. The phrenicocolic ligament attaches the flexure to the diaphragm below the inferior pole of the spleen at about the level of the tenth rib. The splenic flexure often adopts a very acute angle such that the end of the transverse colon overlaps the beginning of the descending colon; there may

C

Fig. 66.25 Variants in the origin of the middle colic artery; only replaced arteries have been illustrated for simplicity. Accessory arteries are more common than completely replaced arteries. Fig. 66.26 Relations of the splenic flexure.
be peritoneal and omental adhesions between the two structures. It lies more superiorly and posteriorly than the hepatic flexure.

## DESCENDING COLON

The descending colon is $25-30 \mathrm{~cm}$ long and descends from the splenic flexure in the left hypochondrium to the level of the iliac crest, where it curves medially anterior to iliacus to become the sigmoid colon. In most adults it is retroperitoneal, covered anteriorly and on both sides by peritoneum, but occasionally the descending colon is more mobile, being suspended from the posterior abdominal wall by a short mesocolon (Saunders et al 1995). Its lateral peritoneal reflection in the left paracolic gutter is marked by a white line (of Toldt). The posterior surface of the descending colon is separated by a layer of loose connective tissue from the anterior renal fascia inferolateral to the left kidney, transversus abdominis, quadratus lumborum, iliacus and the lateral margin of psoas major (Fig. 66.27). The subcostal vessels and nerves, iliohypogastric, ilioinguinal, lateral femoral cutaneous, femoral and genitofemoral nerves, and, usually, the fourth lumbar artery also lie posteriorly, and loops of jejunum are anterior. The descending colon is smaller in calibre and more deeply placed than the ascending colon. Appendices epiploicae are more common in this part of the colon.

Fig. 66.27 Posterior relations of the descending colon.

## SIGMOID COLON

The sigmoid colon runs from the lesser pelvis to the beginning of the rectum at the level of the third sacral vertebra. It is usually suspended from the posterior abdominal and pelvic walls by a fan-shaped sigmoid mesocolon, but may be tethered by congenital adhesions to the parietal peritoneum over iliacus. Consequently, its length and position are highly variable. It usually lies within the pelvic cavity anterior to the rectum on the peritoneal surface of the bladder (and uterus in the female). It is usually completely invested in peritoneum. The root of the sigmoid mesocolon has an inverted $V$-shaped attachment; the right limb of this inverted ' V ' ascends from a point anterior to the third sacral vertebra to the bifurcation of the left common iliac vessels (crossed by the left ureter) and descends from this point along the external iliac vessels.

Between the fixed junctions with the descending colon and rectum, the relations of the sigmoid colon are quite variable (Fig. 66.28). Laterally are the left external iliac vessels, the obturator nerve, ovary or vas deferens, and the lateral pelvic wall; posteriorly lie the left external and internal iliac and gonadal vessels, ureter, piriformis and the sacral plexus; anteroinferiorly lie the bladder in males, or the uterus and bladder in females; superiorly and to the right, the sigmoid colon is in contact with loops of the ileum. The gonadal vessels and ureter lie in a distinct fascial plane, which is the inferior extension of the retroperitoneal perirenal fascia and is separate from the sigmoid mesocolon. This plane can be recognized and separated during surgical resection of the sigmoid mesocolon. The taeniae coli of the sigmoid colon are wider than elsewhere in the colon, and coalesce at its distal end to form a complete circumferential longitudinal muscle layer. Appendices epiploicae are particularly prominent in the sigmoid colon.

The position and shape of the sigmoid colon depend on its length (which increases with age) and mobility; the length of the sigmoid mesocolon (usually longer in males); and the degree of distension of the colon, rectum, bladder and uterus. The length of the sigmoid colon and its mesentery vary between ethnic groups (Alatise et al 2013).

## Sigmoid volvulus

Fig. 66.28 Posterior relations of the sigmoid colon.

## Diverticular disease

Available with the Gray's Anatomy e-book

## MESOCOLON

The mesocolon extends along the entire length of the colon and is continuous with the small bowel mesentery proximally and the mesorectum distally. The mesocolon consists of fat embedded within a connective tissue lattice and sandwiched between two layers of mesothelium; it also contains nerves, blood and lymphatic vessels, and lymph nodes. A layer of loose connective tissue, known as Toldt's fascia, lies immediately posterior to the mesocolon, where it is adherent to the retroperitoneum of the posterior abdominal wall (Culligan et al 2014). Complete excision of the relevant segment of mesocolon by dissecting within or behind the plane of Toldt's fascia has been shown to improve survival in colon cancer (Søndenaa et al 2014).

## RECTUM

The rectum is continuous with the sigmoid colon at the level of the third sacral vertebra and ends as it passes through the pelvic floor (the puborectalis part of levator ani), where it is continuous with the anal canal. It descends within the sacrococcygeal concavity, at first running posteriorly and then curving anteriorly. The junction between the anteriorly directed distal rectum and the posteriorly directed anal canal is the anorectal angle, which is maintained by puborectalis. This is $2-3 \mathrm{~cm}$ anterior to and slightly below the tip of the coccyx, level with the apex of the prostate in males. The rectum also deviates in three lateral curves: upper, convex to the right; middle (the most prominent), convex to the left; and lower, convex to the right. Both ends of the rectum are in the median plane (Fig. 66.30).

Although variable in absolute length, the rectum is often defined in clinical practice as extending approximately 15 cm above the external anal margin. Its upper diameter is similar to that of the sigmoid colon, but more inferiorly it becomes dilated as the rectal ampulla. Unlike the sigmoid colon, the rectum has no sacculations, appendices epiploicae or taeniae coli. The taeniae merge a few centimetres above the rectosigmoid junction, initially forming wide anterior and posterior muscular bands that then fuse to form a continuous outer layer of longitudinal muscle investing the entire length of the rectum. At the rectal ampulla, a few longitudinal muscle fibres pass forwards from the anterior rectal wall to the perineal body and urethra (rectourethralis).

The upper third of the rectum is covered by peritoneum on its anterior and lateral aspects, and the middle third by peritoneum on its anterior aspect only; the lower third is below the peritoneum. The

Rotation or volvulus of the sigmoid colon may occur around its mesenteric attachment. Volvulus is more likely when the length of the sigmoid colon and the length and width of its mesentery are greater (Akinkuotu et al 2011). Volvulus does not occur when the sigmoid colon and its mesocolon are short. The anatomical features predisposing to sigmoid volvulus are most commonly found in sub-Saharan Africans and chronically institutionalized patients.

Acquired diverticula commonly occur in the sigmoid colon, particularly in Western populations. These diverticula frequently develop in parallel rows between the mesenteric taenia coli and the two antimesenteric taeniae where the colonic wall is weaker; at this site, the outer longitudinal muscle is deficient and the circular muscle is traversed by arteries supplying the submucosal vascular plexus (Slack 1962). However, the predilection of diverticula in the sigmoid colon probably relates to causative factors rather than intrinsic differences in the structure of this segment of the colon. In contrast, congenital diverticula may occur at any site in the colon (Fig. 66.29) and are often found along the mesenteric border.

Fig. 66.29 A CT scan (coronal reformat) showing both right colonic and sigmoid diverticulosis. (Courtesy of Dr Kamini Patel, Homerton Hospital, London.)

Fig. 66.30 A, A coronal T2-weighted MRI of the rectum. B, A line diagram illustrating the main features in $\mathbf{A}$.
peritoneum is reflected anteriorly on to the urinary bladder in males to form the rectovesical pouch, or on to the posterior vaginal fornix in females to form the recto-uterine pouch (of Douglas). The level of this reflection is higher in males; the rectovesical pouch is approximately 7.5 cm above the anorectal junction in males, while the recto-uterine pouch is approximately 5.5 cm above the anorectal junction in females. In neonatal boys, the peritoneum extends on the anterior rectal wall as far as the lower limit of the prostate. Superiorly, the peritoneum is firmly attached to the muscle layer of the sigmoid colon by fibrous connective tissue, but as it descends on to the rectum, it is more loosely attached by fatty connective tissue, which allows considerable expansion of the upper half of the rectum.

When the rectum is empty, the mucosa has several longitudinal folds in its lower part, which become effaced during distension. The rectum commonly has three permanent semilunar transverse or horizontal folds (although the number can vary), which are most marked in rectal distension (see Fig. 66.10). Two types of horizontal fold have been recognized. One consists of the mucosa, the circular muscle layer and part of the longitudinal muscle, and is marked externally by an indentation. The other is devoid of longitudinal muscle and has no external marking. The most superior fold at the beginning of the rectum may be on either the left or the right and occasionally encircles the rectal lumen. The middle fold is largest and most constant, and lies immediately above the rectal ampulla, projecting from the anterior and right wall just below the level of the anterior peritoneal reflection; the circular muscle is particularly prominent in this fold. The inferior fold is on the left and the most variable.

Relations Posterior to the rectum and mesorectum, separated by the presacral fascia, are the lower three sacral vertebrae, coccyx, median and lateral sacral vessels, and the lowest portion of the sacral sympathetic chain. Laterally, the upper rectum is related to the sigmoid colon and/ or small bowel, while below the peritoneal reflection lie levator ani, obturator internus, the obturator nerve and vessels, ureters, the inferior hypogastric plexus, internal iliac vessels, piriformis and the sacral plexus. Anteriorly, the rectum is related to the sigmoid colon and/or small bowel in both sexes, and the base of the bladder, seminal vesicles, vas deferens, terminal parts of the ureters, and the prostate in males (see Figs 66.34, 76.17). In females, the cervix/body of the uterus and vagina are anterior, the latter separated from the rectum by a rectovaginal septum. In postmenopausal females, and after childbirth, the connective tissue of the rectovaginal septum may atrophy or become thinned, reducing the support of the anterior rectal and posterior vaginal walls.

## MESORECTUM AND RECTAL FASCIAE

Although the rectum has no mesentery, its surrounding fat is enclosed within a fascial envelope known as the mesorectum. This constitutes a distinct compartment that is intimately related to the rectum down to the level of levator ani (Figs 66.31-66.36). It contains the superior rectal artery and its branches, the superior rectal vein and its tributaries, lymphatic vessels and nodes, and adipose connective tissue. The mesorectum is much bulkier posteriorly (see Figs 66.31, 66.32). It is enclosed
by mesorectal fascia, a distinct layer of connective tissue that is also called the fascia propria of the rectum. This fascia limits the mesorectum posteriorly and lies anterior to the presacral fascia (of Waldeyer), separated by a so-called retrorectal 'space'. The rectum and mesorectal fascia are connected to the parietal fascia of the pelvis by two 'lateral ligaments' (see below) and one posterior ligament, the rectosacral fascia (Gaudio et al 2010). The latter is a thin layer of connective tissue that passes obliquely downwards from the presacral fascia to fuse with the mesorectal fascia posterior to the rectum 3-5 cm above the anorectal junction (García-Armengol et al 2008). The mesorectal fascia is surrounded by a thin and relatively avascular layer of loose areolar tissue, which separates it from the posterior and lateral walls of the true pelvis. Superiorly, the mesorectal fascia blends with the connective tissue bounding the sigmoid mesentery. Laterally, it extends around the rectum and mesorectum, and becomes contiguous anteriorly with a denser condensation of fascia, conveniently described eponymously as Denonvilliers' fascia. This fascia is sometimes confusingly known as rectovesical fascia in males but it extends caudal to the bladder and is particularly dense posterior to the prostate and seminal vesicles; it lies immediately anterior to the mesorectal fascia, to which it may be fused (Lindsey et al 2000). In females, Denonvilliers' fascia combines with the anterior mesorectal fascia to form the rectovaginal septum (Zhai et al 2009).

Mesorectal fascia is visible by CT, MRI and dissection (Bissett et al 2001). On MRI scans, the mesorectum appears as a fat-filled envelope containing blood vessels and lymph nodes; small nerves are not visible but interlacing connective tissue strands can be seen. The mesorectal fascia is recognizable on axial MRI images as a low-signal layer surrounding the mesorectum, corresponding to a distinct condensation of fascia seen on histological sections (Brown et al 1999). Identification of this layer in patients with a malignant rectal tumour can help predict the success of surgical resection. Branches of the inferior hypogastric plexus and middle rectal vessels enter the mesorectum anterolaterally. They are ensheathed by fascia and are sometimes collectively referred to as the 'lateral rectal ligaments'. The number and calibre of the middle rectal vessels are highly variable; they may be very small or even absent (Sato and Sato 1991). The 'lateral ligaments' are not clearly seen on MRI or CT scanning, and only appear as an identifiable structure with surgical traction on the rectum. The fascia of the 'ligaments' is flimsy and probably plays little role in support of the rectum. Parietal fascia covers levator ani and the muscles of the side wall of the pelvis, and is continuous posteriorly with the presacral fascia (see Fig. 66.36).

## Rectal cancer

In prolapse of the rectum involving all layers of the rectal wall，the mid and upper rectum descend towards the pelvic floor on straining．Descent occurs within the lumen of the rectum as a form of intussusception， and may be a consequence of the large diameter of the rectal ampulla and relative fixation of the anal canal．The loose adipose tissue of the upper mesorectum and the＇lateral ligaments＇offer only limited resist－ ance against rectal descent．Chronic enlargement of the anorectal space bound by levator ani commonly occurs in patients suffering from recur－ rent rectal prolapse，but is probably a consequence rather than a cause of the prolapse．In females，the recto－uterine pouch also descends with the anterior rectal wall．

When the rectovaginal septum is grossly effaced，especially in post－ menopausal females，the pressure of defecation can cause bulging of the rectal wall into the posterior vagina and，in extreme cases，through the vaginal introitus．Weakness of the pelvic floor muscles contributes to the prolapse by allowing descent of the perineum during straining．

An important concept in the surgical treatment of adenocarcinoma of the rectum is the necessity of excising the rectum in continuity with the mesorectum and its contained lymph nodes in order to avoid local
tumour recurrence（Heald et al 1982）．In total mesorectal excision，the posterolateral plane of dissection is outside the mesorectal fascia but anterior to the presacral fascia and its underlying venous plexus．Later－ ally，the plane is interrupted only by small branches of the middle rectal vessels；anteriorly，it merges with the rectovesical or rectovaginal fascia． The inferior hypogastric plexus is closely related to the plane of dissec－ tion laterally；these nerves must be preserved to retain bladder and sexual function．Total mesorectal excision involves complete excision of the rectum down to the level of the pelvic floor，where the puborec－ talis component of levator ani merges with the deep component of the external anal sphincter．Superiorly，the inferior mesenteric artery is ligated near its origin．

In abdominoperineal excision of the rectum，it should be noted that the mesorectum becomes extremely thin at the point where the rectum passes through levator ani．To achieve adequate surgical margins，the plane of dissection is through the ischio－anal fossa and levator ani outside the puborectalis sling and into the mesorectal plane well above the pelvic floor．

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE HINDGUT

## Arteries

## Inferior mesenteric artery

The artery of the hindgut is the inferior mesenteric artery (Figs 66.3766.39), which arises from the anterior or left anterolateral aspect of the aorta behind the inferior border of the third part of the duodenum $3-4 \mathrm{~cm}$ above the aortic bifurcation, at the level of the third lumbar vertebra. It runs obliquely down to the pelvic brim, beneath the peritoneal floor of the left infracolic compartment, initially anterior and then to the left of the aorta. It gives off the left colic and sigmoid arteries, and crosses the origin of the left common iliac artery medial to the ureter, with the inferior mesenteric vein lying between. Beyond the pelvic brim, it continues in the root of the sigmoid mesocolon as the superior rectal artery.

## Left colic artery

The left colic artery usually arises from the inferior mesenteric artery shortly after its origin, ascends within the left colic mesentery and divides into an ascending and a descending branch (see Figs 66.3866.39). The ascending branch passes upwards across the left psoas major, gonadal vessels, ureter and left kidney, and is crossed by the inferior mesenteric vein; its terminal branches anastomose with those of the left branch of the middle colic artery within the transverse mesocolon. The descending branch passes laterally and downwards, and anastomoses with branches from the ascending branch and the highest sigmoid artery to form part of the marginal artery. The arterial arcades

Fig. 66.38 The inferior mesenteric artery.
thus formed supply the distal third of the transverse and the descending colon. The left colic artery may originate from or in common with a sigmoid artery (Murono et al 2015). Occasionally, an accessory, or rarely a replaced, left colic artery may originate from the trunk of the superior mesenteric artery or its middle colic or first jejunal branch (Fig. 66.40). When present, it runs laterally in the upper left colic mesentery just inferior to the duodenojejunal flexure to supply the upper descending colon, and forms part or all of the marginal artery in the region of the distal transverse colon. The left colic artery may itself give rise to an accessory left middle colic artery. Occasionally, the left colic artery gives rise to a branch shortly after its origin, which ascends in the mesentery and anastomoses directly with a similar descending branch of the left branch of the middle colic artery (the so-called arc of Riolan; van Gulik and Schoots 2005).

The dominant arterial supply of the splenic flexure is usually from the left colic artery but may be from the left branch of the middle colic artery. The marginal artery in this region may be absent or small, but it may enlarge considerably if the inferior mesenteric artery is stenosed or occluded (see p. 1100).

Fig. 66.40 A replaced left colic artery arising from the middle colic branch of the superior mesenteric artery.

## Sigmoid arteries

The inferior mesenteric artery gives rise to between two and five sigmoid arteries, which descend obliquely in the sigmoid mesocolon anterior to the left psoas major, ureter and gonadal vessels. They supply the distal descending colon and sigmoid colon, and anastomose superiorly with the left colic artery and inferiorly with the superior rectal artery. Unlike the arrangement in the small intestine, arterial arcades do not form until the arteries are close to the wall of the colon, when small branches arise that supply the sigmoid colon directly. A true marginal artery is less obvious in the sigmoid colon. A significant interval often exists in the mesentery between the highest sigmoid artery and the descending branch of the left colic artery; this forms a useful guide to the arterial territories during surgical dissection.

Fig. 66.41 The arterial supply of the rectum.

## Vascular ligation in left colonic resections

During resection of the distal descending and sigmoid colon, ligation of the inferior mesenteric artery close to its origin preserves the bifurcation of the left colic artery and helps to maintain the arterial supply to the proximal descending colon via the anastomosis between the left branch of the middle colic artery and the ascending branch of the left colic artery. Ligation of the left colic artery close to its bifurcation may interfere with this supply and render the proximal descending colon more likely to become ischaemic. Similarly, if the inferior mesenteric vein is ligated, then the bifurcation of the left colic vein forms the route of venous drainage from the proximal descending colon to the middle colic vein.

## Superior rectal artery

The principal arterial supply to the upper two-thirds of the rectum is via the artery of the hindgut - specifically, its pelvic continuation, the superior rectal artery (Fig. 66.41). The inferior mesenteric artery crosses the left common iliac vessels medial to the ureter and descends in the medial limb of the sigmoid mesocolon, straddled by the inferior hypogastric nerves on either side. As it crosses the pelvic brim, it becomes the superior rectal artery. At the level of the third sacral vertebra, where the rectum begins, the artery enters the upper mesorectum in the midline and divides into two branches that descend, initially posterolaterally, and then on each side of the rectum. Terminal branches pierce the rectal wall and anastomose with branches of the middle and inferior rectal arteries within the rectal submucosa.

## Middle and inferior rectal arteries

The middle rectal arteries arise either directly from the anterior division of the internal iliac artery or from the inferior vesical artery (vaginal artery in females). When present, they enter the mesorectum anterolaterally in the 'lateral ligaments' and provide some additional supply to the middle third of the rectum. The inferior rectal arteries are terminal branches of the internal pudendal arteries. They cross the ischioanal fossa to enter the upper anal canal laterally and supply the internal and external anal sphincters, the anal canal and perianal skin. Ascending branches supply the distal third of the rectum, anastomosing with terminal branches of the superior rectal artery in the rectal submucosa. The rectum also receives a small arterial supply from the median sacral artery via a branch that enters posteriorly at the level of the anorectal junction.

## Veins

## Inferior mesenteric vein

The inferior mesenteric vein drains the rectum, sigmoid, descending and distal transverse colon (see Fig. 66.15; Fig. 66.42). It begins as the continuation of the superior rectal vein from the rectal plexus, through which it connects with the middle and inferior rectal veins. The inferior mesenteric vein lies to the left of the inferior mesenteric artery in the retroperitoneum and ascends anterior to the left psoas major and left ureter; it may cross the gonadal vessels or ascend medial to them. It lies just lateral or occasionally posterior to the duodenojejunal flexure, where it can be located intraoperatively. The inferior mesenteric vein

Fig. 66.42 The inferior mesenteric vein and its tributaries, digital subtraction arteriogram. (Courtesy of Dr Adam Mitchell, Charing Cross Hospital, London.)
receives the superior rectal vein, several sigmoid veins, and the left colic vein. It usually passes posterior to the lower border of the body of the pancreas and anterior to the left renal vein to drain into the splenic vein, but it may drain into the confluence of the splenic and superior mesenteric veins or directly into the superior mesenteric vein (Graf et al 1997).

## Rectal venous plexus

A rectal venous plexus surrounds the rectum and connects anteriorly with the vesical plexus in males or the uterovaginal plexus in females. It consists of internal veins beneath the mucosa of the rectum and upper anal canal, and external veins lying outside the muscular wall. The upper two-thirds of the rectum and the internal part of the rectal venous plexus drain mainly to the superior rectal vein and, from there, to the inferior mesenteric vein; the middle third of the rectum drains by one or more middle rectal veins into the internal iliac vein; and the lower third of the rectum and anal canal drains via inferior rectal veins into the internal pudendal veins. The rectal venous plexus is therefore a site of communication between the portal and systemic venous systems.

## Superior rectal vein

Venous tributaries from the rectal venous plexus ascend in the rectal submucosa and pierce the rectal wall to form the superior rectal vein. This runs in the upper mesorectum and root of the sigmoid mesocolon to the left of the superior rectal artery, crossing the pelvic brim and left common iliac vessels to form the inferior mesenteric vein (see Figs $66.15,66.44$ ).

## Left colic vein

The left colic vein is formed from several tributaries, including ascending and descending branches that correspond to similarly named arteries. The left colic vein usually lies superior to its corresponding artery, and has a shorter course because the inferior mesenteric vein lies lateral to the inferior mesenteric artery (see Fig. 66.42). Occasionally, there are two left colic veins that both drain into the inferior mesenteric vein.

## Lymphatic drainage

Small lymphoid aggregates measuring no more than a few millimetres are occasionally visible on the surface of the large bowel (epicolic and epirectal nodes). Lymph from the descending colon drains to paracolic nodes in the mesentery adjacent to the bowel and, from there, to intermediate nodes along the left colic artery (Jamieson and Dobson 1909). Lymphatics from the sigmoid colon follow a similar pathway from

Fig. 66.43 Lymph nodes of the rectum and upper anal canal (viewed from behind).
paracolic to intermediate nodes in the sigmoid mesocolon. Intramural lymph from the rectum and anal canal above the dentate line drains predominantly to pararectal nodes in the adipose tissue of the mesorectum and then along lymphatics accompanying the superior rectal artery (Fig. 66.43). These intermediate nodes then drain to lymph nodes along the inferior mesenteric artery and, from there, to pre-aortic nodes. Some lymphatics from the lower rectum travel with the middle and inferior rectal arteries to internal iliac nodes, and along the median sacral artery to presacral nodes. The clinical significance of such drainage in relation to the spread of malignancy from the lower rectum is debated (Bell et al 2009).

## INNERVATION OF THE LARGE INTESTINE

The innervation of the large intestine is complex, and includes the enteric nervous system (made up of motor neurones, intrinsic sensory neurones, and interneurones lying within the wall of the gut); the autonomic nervous system (sympathetic and parasympathetic innervation); and extrinsic sensory innervation (visceral afferents) (Brookes et al 2009) (Ch. 59).

The enteric nervous system consists of ganglionated nerve plexuses lying in the submucosa (Meissner's plexus) and between the longitudinal and circular smooth muscle layers (Auerbach's myenteric plexus). Collectively, these nerves are concerned with control of mucosal functions (secretion, blood flow) and the propulsion of luminal contents by rhythmic and synchronized contractions. Motor neurones may be inhibitory or excitatory. Intrinsic sensory neurones are activated by mechanical stimuli such as stretch and muscle tension, and by chemical stimuli released by neuroendocrine cells in the wall of the gut (see Fig. 3.26). Sensory neurones project locally on to myenteric interneurones and motor neurones, allowing the spread of reflex activity along the gut. Interstitial cells of Cajal are present within the submucosal and myenteric nerve plexuses. In summary, they act as a link between smooth muscle cells and extrinsic neurones, and are responsible for the intrinsic pacemaker activity of the gut; their activity is modulated by autonomic nerves.

The large intestine is richly innervated by sympathetic neurones that originate either directly from the sympathetic chain or indirectly via the aortic plexus; the former are mostly involved in the control of blood flow (vasoconstriction), while the latter also influence the secretory activity and motility of the gut. The cell bodies of preganglionic sympathetic fibres supplying the midgut are found in the intermediolateral
columns of the fifth to the twelfth thoracic spinal segments and those of the hindgut in the intermediolateral columns of the first and second lumbar spinal segments. Postganglionic sympathetic neurones from both sources release noradrenaline (norepinephrine), causing presynaptic inhibition within enteric circuits, slowing gut motility and driving contraction of the ileocaecal and internal anal sphincters. Sympathetic supply to the midgut is conveyed to the coeliac and superior mesenteric plexuses via the greater and lesser splanchnic nerves; postganglionic axons are distributed with branches of the superior mesenteric artery. Sympathetic supply of the hindgut is conveyed via the lumbar splanchnic nerves that synapse in the abdominal aortic and inferior mesenteric plexuses, and via sacral splanchnic nerves that synapse in the superior and inferior hypogastric plexuses; postganglionic fibres are distributed with branches of the inferior mesenteric artery and are inhibitory to colonic muscle.

The midgut receives its parasympathetic innervation from the vagus, via the coeliac and superior mesenteric plexuses, whereas the hindgut receives its parasympathetic innervation from the pelvic splanchnic nerves. The cell bodies of the pelvic splanchnic nerves are located in the second to fourth sacral spinal segments, the sacral parasympathetic nucleus. These parasympathetic fibres enter the inferior hypogastric plexus, where some synapse. From here, some pass directly to the rectum and other pelvic viscera while others ascend by one of two routes: either within the hypogastric nerves to the superior hypogastric plexus to be distributed along branches of the inferior mesenteric artery, or by passing directly through the retroperitoneal tissues to reach the splenic flexure and descending and sigmoid colon. Most preganglionic parasympathetic neurones synapse in intramural plexuses in the gut wall; from here, postganglionic neurones innervate the glands (secretomotor) and muscle (motor) of the large intestine. Parasympathetic stimulation is integral to colonic propulsion and defecation and to relaxation of the internal anal sphincter.

Visceral afferent impulses mediating sensations of distension and spasm from the midgut travel with the vagus nerve while the hindgut is innervated by afferent neurones with cell bodies in the lumbar (mostly L2 and L3) and sacral dorsal root ganglia (mostly S1 and S2) (Brookes et al 2009). These travel alongside autonomic nerves and are often erroneously referred to as 'sympathetic afferents' or 'parasympathetic afferents'. Visceral afferent innervation of intramural colonic blood vessels probably conveys the sensation of colonic distension (Song et al 2009), while visceral afferents in the rectum convey the sensation of rectal filling and are involved in reflex propulsive activity.

## MOTOR FUNCTION OF THE LARGE INTESTINE

Healthy colorectal function includes absorption of water and sodium from the bowel lumen, net antegrade propulsion of intestinal contents at an adequate rate, and temporary faecal storage. Colonic motor activity is greatest during the day and increases on waking and after meals. It is characterized by sustained tonic contractions and brief phasic contractions. Phasic contractions are subdivided according to whether or not they propagate along the colon. Non-propagating contractions are associated with segmental mixing of luminal contents, whereas propagated sequences can be retrograde or antegrade. In the normal colon, antegrade activity occurs more frequently than retrograde sequences, which are seen more in the proximal colon. High-amplitude propagated contractions occur in adults 4-6 times per day, originate anywhere in the colon (but mostly proximally), and migrate for a variable distance distally (Narducci et al 1987, Bharucha 2012). They are often associated with defecation or passing flatus. The sigmoid colon exhibits cyclical bursts of motor activity, which may be important in modulating the delivery of faeces to the rectum. A high-pressure zone with unique contractile properties in response to sigmoid and rectal distension or contraction has been demonstrated in the distal sigmoid (the so-called rectosigmoid sphincter; Shafik et al 2003). Rectal motor activity is characterized by motor complexes that can be triggered by propagating contractions from the proximal colon and by the delivery of stool or gas from the sigmoid colon. However, since these frequently propagate retrogradely, it has been suggested that they help to keep the rectum empty, thereby preventing the untimely delivery of colonic contents.

## ANAL CANAL

The anal canal begins at the anorectal junction and ends at the anal verge (Figs 66.44-66.46). It is directed posteriorly because the sling-like puborectalis component of levator ani pulls the rectum forwards to
create the anorectal angle. The anal canal lies $2-3 \mathrm{~cm}$ anterior and slightly inferior to the tip of the coccyx, opposite the apex of the prostate in males. At the anal verge, the squamous epithelium lining the lower anal canal becomes continuous with the skin of the perineum. The area of pigmentation of skin around the anal verge corresponds approximately to the extent of the external anal sphincter. Identification of the anal verge may be difficult, particularly in males in whom the perineum may 'funnel' upwards into the lower anal canal, but the characteristic puckering of the skin formed by the penetrating fibres of the conjoint longitudinal muscle of the anal canal provides a useful landmark.

The anal canal consists of an inner epithelial lining, a vascular subepithelium, the internal and external anal sphincters, and fibromuscular supporting tissue, as well as dense neuronal networks of autonomic and somatic origin. Functionally, it represents a zone of high pressure. It is between 2 and 5 cm long in adults; the anterior wall is slightly shorter than the posterior. It is usually shorter in females. At rest, it forms an oval or triradiate slit in the anteroposterior plane rather than a truly circular canal. The arrangement of the external anal sphincter and its attachments to the perineal body and coccyx create sites of maximum pressure in the anterior and posterior midline of the canal.

Anteriorly, the middle third of the anal canal is attached by dense connective tissue to the perineal body, which separates it from the membranous urethra in males and from the lower vagina in females. Laterally and posteriorly, the anal canal is surrounded by the loose adipose tissue of the ischio-anal fossae; this arrangement allows expansion of the canal but offers a potential pathway for the spread of perianal sepsis. Posteriorly, the anal canal is attached to the coccyx via the anococcygeal ligament, a midline fibroelastic structure that runs between the posterior aspect of the middle region of the external anal sphincter and the coccyx. The anococcygeal ligament is traditionally regarded as lying just inferior to the midline raphe of levator ani but its relationship to the raphe is more complex (Kinugasa et al 2011).

The ischial spines may be palpated laterally by an examining finger in the upper anal canal. The pudendal nerves pass over the attachment of the sacrospinous ligament at this point and pudendal nerve motor terminal latency may be measured digitally using a modified electrode worn on the examining glove.

## LINING OF THE ANAL CANAL

The upper part of the anal canal is lined by reddish columnar epithelium similar to that of the rectum; it contains secretory and absorptive cells with numerous tubular glands or crypts. Distally, the epithelium becomes cuboidal and darker just above the level of the anal valves (Fig. 66.47). The subepithelial tissues are mobile and relatively distensible, and contain submucosal arterial and venous plexuses.

In the mid-anal canal, there are 6-10 vertical mucosal folds, the anal columns. These are better defined in children than in adults. The columns frequently contain a terminal branch of the superior rectal artery and vein, supplemented to a variable degree by middle and inferior rectal vessels (Thomson 1975). Dilated submucosal veins in the upper anal canal form an internal haemorrhoidal venous plexus. Tiny arteriovenous connections to these dilated submucosal veins give the blood within them a higher oxygen tension and therefore a redder colour than normal venous blood. The submucosal vessels are most prominent in the left-lateral, right-posterior and right-anterior quadrants of the wall of the canal (approximately 3, 7 and 9 o'clock when viewed in the lithotomy position); here, the subepithelial tissues are expanded into three 'anal cushions'. Although variable in number and position, the cushions help to seal the anal canal and contribute to the maintenance of continence to flatus and fluid. The anal cushions are important in the pathogenesis of haemorrhoids. The lower ends of the columns form small crescentic folds, called anal valves, between which lie small recesses known as anal sinuses. The anal valves and sinuses together form the scalloped dentate (or pectinate) line, which is firmly anchored to submucosal connective tissue. Anal glands open into small depressions, anal crypts, in the anal valves. The glands are branched and lined by stratified columnar epithelium. Cystic dilations in the glands may extend through the internal anal sphincter and even into the external sphincter (Seow-Cheon and Ho 1994).

The epithelium below the dentate line is smooth and typically shows an abrupt transition to parchment-coloured, non-keratinized, stratified squamous epithelium, which lacks sweat and sebaceous glands and hair follicles but contains numerous somatic sensory nerve endings conveying sensations of touch, pain and temperature. It extends down to the intersphincteric groove, a palpable depression at the lower border of the internal sphincter. Below the intersphincteric groove, the anal canal

Fig. 66.44 A, A coronal section through the anal canal; glandular and vascular structures are shown unilaterally for clarity. B, A sagittal section through the anal canal; the anal canal is angled posteriorly and so anterior sphincteric structures appear to be lower than posterior structures. The glandular, vascular and fibromuscular structures have been omitted for clarity.
is lined by hair-bearing keratinizing, stratified squamous epithelium, which is continuous with the perianal skin. Dilated veins in the subepithelial tissue below the dentate line contribute to an external haemorrhoidal venous plexus (see Fig. 66.44); this can be seen on clinical examination as a circumferential ring at the anal margin if the subject is asked to bear down.

The junction between the columnar epithelium above and the squamous epithelium below is referred to as the anal transition zone (ATZ). It is variable in length and position but often extends about 1 cm proximal to the dentate line (Fenger 1987). Nerve endings, including thermoreceptors, exist in the submucosa around the upper anal transition zone; they probably play a role in continence by providing a highly specialized 'sampling' mechanism to identify the contents of the lower rectum when the upper anal canal relaxes (Duthie and Gairns 1960).

The well-defined muscularis mucosae of the rectum continues into the upper canal. Some fibres from the conjoint longitudinal muscle of the anal canal traverse the internal anal sphincter and turn cranially to merge with the muscularis mucosae, forming the submucosal muscle of the anal canal (also called the musculus submucosae ani, or musculus canalis ani, or Treitz's muscle). Attachments of the longitudinal fibres to the submucosal muscle of the anal canal are particularly dense at the dentate line (the mucosal suspensory ligament (of Parks)), causing the mucosa to be tethered more firmly at this level and approximately marking the watershed between the portal and systemic venous drainage of the haemorrhoidal plexuses. The attachments of fibres from the longitudinal muscle layer, the muscularis mucosae of the anal canal, also create 'spaces' within the submucosa: a proximal submucous space, a marginal space extending from the dentate line to the intersphincteric groove, and a perianal space distally.

Fig. 66.45 A, A mid-coronal MRI endocoil image of the anal canal. B, An anterior coronal MRI endocoil section in a woman showing the transverse perineii (TP) joining the external anal sphincter anteriorly (between arrows). Other abbreviations: EAS, external anal sphincter; IAS, internal anal sphincter; $P R$, puborectalis.

Fig. 66.47 The endoscopic appearance of the anorectal junction viewed internally from above. The endoscope is visible in the upper left corner of the image.

## MUSCLES OF THE ANAL CANAL

The anal canal is surrounded by internal and external anal sphincters, separated by the conjoint longitudinal muscle layer, the whole arrangement being referred to as the anal sphincter complex (Figs 66.4866.49) (Al-Ali et al 2009). The anatomy of this region has been clarified in recent years using endoanal sonography and MRI.

## Internal anal sphincter

The internal anal sphincter is the specialized, white, thickened terminal part of the inner circular muscle of the large intestine. It is thicker in males and in patients with chronic constipation. The muscle fibre arrangement is not truly circular, but rather a tight spiral that shortens and widens with relaxation. It commences at the anorectal junction and ends above the anal verge; its lower border is palpable at the intersphincteric groove, which corresponds to the proximal limit of the subcutaneous part of the external anal sphincter. It is traversed by fibres passing medially from the conjoint longitudinal muscle into the submucosa.

At rest, it is tonically contracted but it relaxes as a consequence of reflex activity, predominantly during defecation. Transient relaxation of the upper internal anal sphincter occurs in response to rectal distension (the recto-anal inhibitory reflex) and postprandial rectal contractions (the sampling reflex). Relaxation allows the passage of distal rectal contents into the upper anal canal, enabling a conscious or subconscious perception of their physical nature; this is accompanied by sustained contraction of the distal internal anal sphincter and contraction of the external anal sphincter to maintain continence. The recto-anal inhibitory reflex is primarily mediated by the enteric nervous system, although spinal pathways may have a modulatory role. It is absent in patients with Hirschsprung's disease.

## Vascular supply and innervation

The internal anal sphincter is supplied by terminal branches of the superior and inferior rectal vessels, and innervated extrinsically by autonomic nerves. Sympathetic fibres originate in the upper two lumbar spinal segments, and parasympathetic fibres originate in the second to fourth sacral spinal segments, both being distributed via the inferior hypogastric plexus. Stimulation of cholinergic muscarinic receptors (parasympathetic) causes internal anal sphincter relaxation and longitudinal anal muscle contraction, while $\alpha$-adrenergic receptor stimulation (sympathetic) causes contraction of both the internal anal sphincter and longitudinal muscle. Activation of nitrergic nerves also mediates internal anal sphincter relaxation and is the rationale for using topical nitroglycerine and other drugs that promote nitric oxide release in the treatment of pathological conditions associated with increased resting anal tone.

## Conjoint longitudinal muscle

The conjoint longitudinal muscle of the anal canal is a direct continuation of the outer longitudinal smooth muscle of the rectum, descending between internal and external anal sphincters, and augmented in its upper part by striated muscle fibres from the medial aspect of levator ani (Lunniss and Phillips 1992). The muscle is particularly prominent in the fetus, where it is actually thicker than the internal anal sphincter. With advancing age, there is gradual replacement of muscle by connective tissue, such that the layer becomes thin in the elderly and few muscle fibres are seen in its distal part. As it passes down the anal canal, muscle fibres peel off in three directions: internally, through the internal anal sphincter to reach the anal submucosa; inferiorly, through the striated muscle of the lower subcutaneous part of the external anal sphincter to insert into the perianal skin (some of these fibres encircling the anal orifice); and outwards, through the upper part of the external

Fig. 66.48 A-C, Axial views of the anal canal at three levels on endoanal ultrasound in a woman. The endoanal ultrasound probe is the central black structure. A, The upper anal canal. The ' $U$ ' shape of puborectalis is visible. B, The middle anal canal. The external anal sphincter is now a complete ring anteriorly (arrowhead). C, The lower anal canal. Below the termination of the internal anal sphincter, the longitudinal layer extends through the subcutaneous external anal sphincter (between arrowheads). D-F, An MRI of the anal canal. D, At upper anal canal level, the sling of puborectalis extends anteriorly to the pubic bones. E, At mid anal canal level, the transverse perineii fuse into the external anal sphincter anteriorly. The superficial (middle) external anal sphincter is attached either side of the anococcygeal ligament. F, The low anal canal level, below the internal anal sphincter. G, A key for levels of the anal canal. Abbreviations: Acl, anococcygeal ligament; Eas, external anal sphincter; las, internal anal sphincter; Lm, longitudinal muscle; PR, puborectalis; S, subepithelial tissues; ScEas, subcutaneous (lower) part of the external anal sphincter; SpEas, superficial (middle) external anal sphincter; Tp, transverse perineii; Ur, urethra; Vag, vagina.
anal sphincter (see Fig. 66.44). The lowermost fibres create a honeycomb arrangement in the subcutaneous fat and separate a superficial perianal space from the deeper ischio-anal fossa. Additional ramifications of this muscle beyond the external anal sphincter have been described, emphasizing its central role in anorectal stability (Courtney 1950).

The conjoint longitudinal muscle is innervated by autonomic nerves that share their origin with those supplying the internal anal sphincter (see above). Its contraction during defecation shortens and widens the anal canal, and everts the anal orifice. Degeneration of the muscle and its gradual replacement by connective tissue occurs with age (Haas et al

1984 ) and is central to the development of haemorrhoids. Its extensions provide pathways for the spread and containment of infection.

## External anal sphincter

The external anal sphincter forms the bulk of the anal sphincter complex. It is an oval tube of striated muscle composed mostly of type I slow twitch muscle fibres adapted for prolonged contraction. The length and thickness of the external anal sphincter is less in females (Rociu et al 2000). The historical concept of the muscle having three parts (deep, superficial and subcutaneous) is no longer valid, but upper (deep) and lower (superficial or subcutaneous) parts are described by

Fig. 66.49 A transilluminated 2.5 mm thick coronal section of a male pelvis processed for epoxy resin E12 sheet plastination, showing the entire length of the anal canal and its muscular layers: namely, the external anal sphincter, conjoint longitudinal muscle and internal anal sphincter. Note the continuity of the external anal sphincter with levator ani superiorly, consisting of two parts: the upper part and the lower part. The upper part of the conjoint longitudinal muscle is continuous with the longitudinal muscular layer of the rectum and, inferiorly, its fibres traverse the lower part of the external anal sphincter to blend with or form fibro-fatty, honeycomb-like compartments around the perianal region (asterisks). The internal anal sphincter ends above the lower part of the external anal sphincter. (Courtesy of Dr Saad Al-Ali, with permission from Al-Ali S, Blyth P, Beatty S, Duang A, Parry B, Bissett IP. (2009) Correlation between gross anatomical topography, sectional sheet plastination, microscopic anatomy and endoanal sonography of the anal sphincter complex in human males. J. Anat. 215; 212-220.)
some authors. The upper part surrounds the internal anal sphincter while the lowermost part encircles the anal canal inferior to the internal anal sphincter (Fritsch et al 2002, Al-Ali et al 2009).

The upper part of the external anal sphincter is attached to the anococcygeal ligament posteriorly and to the perineal body anteriorly; some muscle fibres on each side of the sphincter decussate to form a commissure in the anterior and posterior midline. The uppermost fibres blend with the lower medial fibres of puborectalis and attach to the anococcygeal raphe posteriorly and the transverse perineal muscles anteriorly. The lower part of the external anal sphincter extends below the internal anal sphincter and is traversed by the terminal fibres of the conjoint longitudinal muscle (see above). Anteriorly, it is attached to bulbospongiosus and bulbocavernosus (Fig. 66.50) (Shafik et al 2007). Like the levator ani and internal anal sphincter, the external anal sphincter is tonically contracted at rest (the postural reflex).

## Vascular supply and innervation

The external anal sphincter is supplied by the inferior rectal vessels, with a small contribution from the median sacral artery. It is innervated bilaterally by the inferior rectal branch of the pudendal nerve (containing contributions from the second, third and fourth sacral spinal nerves). The pudendal nerve also carries afferent fibres from the lining of the anal canal and perianal skin. The upper external anal sphincter may also receive motor fibres from the nerve to levator ani (ventral rami of predominantly the third and fourth sacral spinal nerves).

## Intersphincteric space and anal glands

The intersphincteric 'space' is a potential space between the conjoint longitudinal muscle layer and the external anal sphincter. It can be

Fig. 66.50 A dissection of the male external anal sphincter in a fresh cadaver, viewed from below. (Courtesy of Dr Robert P Myers.)
entered surgically to provide access in a variety of operations (e.g. intersphincteric excision of the rectum and intersphincteric approaches to fistulae). Within the space lie the intersphincteric anal glands, the source of most anal fistulae (Parks 1961). There is an average of twelve intersphincteric anal glands within the adult anal canal, evenly distributed around the circumference. Their function is unknown, but they secrete mucin (different in composition from that secreted by rectal mucosa) and they communicate with the anal lumen via ducts (lined by epithelium similar to that of the anal transition zone), which cross the internal anal sphincter to open at the level of the anal valves immediately above the dentate line (Seow-Choen and Ho 1994). Retrograde passage of bacteria from the anal canal to the gland is understood to cause infection; inflammatory occlusion of the duct prevents spontaneous drainage back into the lumen of the anal canal. Sepsis may then spread along a variety of routes to cause abscesses and fistulae within various spaces (Parks et al 1976).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE ANUS

## Arteries

The anal canal is supplied by terminal branches of the superior rectal artery and the inferior rectal branch of the internal pudendal artery, together with a small contribution from the median sacral artery. The arterial supply to the epithelium of the lower anal canal in the midline, particularly posteriorly, is relatively deficient (Klosterhalfen et al 1989); this is further diminished if the internal anal sphincter is hypertonic (Schouten et al 1996). The epithelium is more firmly tethered to underlying structures in the midline, which may also be a focal point of pressure in the anal canal. Collectively, these factors are thought to predispose to the occurrence of acute and chronic anal fissures, which are most commonly found in the midline, especially posteriorly.

## Veins

The venous drainage of the anal canal parallels the arterial supply. The upper canal is drained predominantly by the superior rectal veins, tributaries of the inferior mesenteric vein and the portomesenteric venous system; some blood returns to the internal iliac veins via the middle rectal veins. The lower part of the anal canal, including the external haemorrhoidal venous plexus, drains via the inferior rectal branches of the internal pudendal vein into the internal iliac vein.

## Haemorrhoids

Haemorrhoids develop when the supporting connective tissues of the anal cushions degenerate, causing downward displacement of the cushions and abnormal venous dilation (Lohsiriwat 2012). They are associated with laxity of the anal canal submucosa and enlargement of the terminal branches of the superior rectal artery supplying the anal cushions.

## Lymphatic drainage

Lymph from the upper anal canal drains cranially into the submucosal and intramural lymphatics of the rectum. Lymphatics around puborectalis drain to internal iliac lymph nodes. Lymph from the lower anal canal and external sphincter drains to inguinal lymph nodes. This pattern of drainage is particularly important when considering lymphatic spread of malignant tumours from the lower rectum and anal canal. Blockage of lymph drainage along normal routes can lead to unusual patterns of dissemination.

## DEFECATION

Defecation is the act of voiding stool from the anus and involves the coordinated function of the colon and rectum, pelvic floor and anal sphincter. It is influenced by multiple factors, including colonic transit, stool volume and consistency, posture, age, gender, psychology and behaviour, culture and lifestyle (Palit et al 2012). Social behaviour entrains defecation to occur at a time of convenience rather than simply in response to a defecatory urge. The urge to defecate is preceded by high-amplitude propagated contractions in the colon, which result in the antegrade propulsion of intraluminal contents to the rectum; these contractions increase in frequency and intensity just before expulsion. The response to rectal filling involves intact rectal afferent nerves, reflex rectal contractions and normal rectal wall biomechanics. The rectum acts as a reservoir and is able to relax to accommodate faecal material and gas (adaptive relaxation). Periodic sampling within the upper anal canal helps to determine the nature of the rectal content. If the defecatory urge is inconvenient, puborectalis
and the external anal sphincter, which are tonically contracted at rest, can be further contracted voluntarily to move stool back up from the distal rectum. If the defecatory urge is associated with a conscious decision to evacuate, distal progression of colonic high-amplitude propagating complexes, rectal contractions, raised intra-abdominal pressure from voluntary straining (the efficiency of which is influenced by posture), relaxation of puborectalis (which straightens the anorectal angle) and the anal sphincters all combine to enable defecation. Relaxation of the internal anal sphincter is a reflex response to rectal distension, whereas relaxation of the external anal sphincter is voluntary. During defecation, contraction of the conjoint longitudinal muscle shortens and opens the anal canal and flattens the anal cushions. Both rectal and a variable quantity of colonic contents are evacuated. After defecation, the external anal sphincter contracts (the closing reflex), the internal anal sphincter gradually recovers its resting tone, and the postural reflex is reactivated. The conjoint longitudinal muscle relaxes, permitting the anal canal to elongate and the anal cushions to re-expand.

Problems with defecation may result from impaired colonic transit or from a variety of functional or mechanical rectal disorders (Lunniss et al 2009). Functional causes include inadequate or ineffective expulsive effort, paradoxical contraction of the pelvic floor and external anal sphincter (dyssynergia), and lack of normal sensation (rectal hyposensitivity). Mechanical causes include impedance to evacuation when straining (rectal intussusception, obstructing masses or anal stenosis), misdirection of force vectors during straining (rectocele), or dissipation of evacuatory forces (ballooning perineum).

## Anal continence and incontinence

As long as anal pressure exceeds rectal pressure, faecal continence will be maintained. Anal resting tone is derived mainly from sympathetically mediated tonic contraction of the internal anal sphincter, augmented by contraction of the external anal sphincter. The anal cushions contribute by providing an effective seal. Anal continence involves central, spinal and peripheral pathways, somatic, autonomic and enteric nerves, intact sacral sensorimotor reflexes, and structurally and functionally intact smooth and striated musculature.

Fig. 66.51 The microstructure of the colonic wall and its epithelial cells. Note the aggregations of lymphocytes (blue) and undifferentiated epithelial cells (white).

Sphincteric causes of faecal incontinence may be structural (disruption or atrophy of part of the sphincter musculature) or neuropathic (damage to the nerve supply to the sphincters), or a combination of both. The most common causes of sphincter disruption are obstetric injury, anal surgery (for haemorrhoids, fistula or fissure) and trauma. Pudendal neuropathy is most commonly associated with childbirth (prolonged second stage) and chronic straining.

Although the anus constitutes the final barrier to faecal incontinence, suprasphincteric factors are also essential in maintaining faecal continence, particularly the rate at which the stool is delivered to the rectum, rectal sensation and compliance, and adaptive relaxation. Thus, even in the presence of structurally and functionally intact sphincter mechanisms, faecal incontinence may occur: for instance, in diarrhoeal states or conditions where there is loss of rectal reservoir function (Scott and Lunniss 2007). Conversely, chronic rectal distension with retained faeces may result in passive (overflow) leakage, possibly as a result of a chronically relaxed internal anal sphincter consequent on a persistently activated recto-anal inhibitory reflex, together with blunted rectal sensation causing diminished conscious contraction of the external anal sphincter.

## MICROSTRUCTURE OF THE LARGE INTESTINE

## Available with the Gray's Anatomy e-book

The layers of tissue in the large intestinal wall (Fig. 66.51) resemble those in the small intestine (Ch. 65), except that villi and circular folds are absent and the glands (crypts) are longer.

## Bonus e-book image

## Mucosa

The mucosa is pale, smooth and, in the colon, raised into numerous crescent-shaped folds between the sacculi. It is thicker, darker, more vascular, and more loosely attached to the submucosa in the rectum.

## Epithelium

The luminal surface of all but the anorectal junction is lined by columnar cells, mucous (goblet) cells and occasional microfold (M) cells that are restricted to the epithelium overlying lymphoid follicles.

Columnar (absorptive) cells Columnar (absorptive) cells are the most numerous of the epithelial cell types. Although there is some variation in their structure, they all bear apical microvilli which are shorter and less regular than those on enterocytes in the small intestine. Typical junctional complexes around their apices limit extracellular diffusion from the lumen across the intestine wall.

Mucous (goblet) cells Mucous cells have a similar structure to those of the small intestine but they are more numerous. They are outnumbered by absorptive cells for most of the length of the colon but they are equally frequent towards the rectum, where their numbers increase.

Microfold (M) cells Microfold cells are similar to those of the small intestine.

## Intestinal glands (crypts)

Intestinal crypts are narrow, perpendicular tubular glands that are longer, more numerous and closer together than those of the small intestine. Their orifices lend a cribriform appearance to the mucosa in surface view. The glands are lined by low columnar epithelial cells, mainly goblet cells, augmented by columnar absorptive cells and neuroendocrine cells. The latter are situated mainly at the bases of the glands, and secrete basally into the lamina propria. In general, the glands lack Paneth cells but some may be present in the caecum. Stem cells located at or near the bases of the intestinal glands (crypts) are the source of the other epithelial cell types in the large intestine. They provide cells that migrate towards the luminal surface of the intestine; their progeny differentiate, undergo apoptosis and are shed after approximately 5 days.

## Lamina propria

The lamina propria is composed of connective tissue that supports the epithelium, forming a specialized pericryptal myofibroblast sheath around each intestinal gland. Solitary lymphoid follicles within the lamina propria, similar to those of the small intestine, are most abundant in the caecum, appendix and rectum, but are also present scattered along the rest of the large intestine; efferent lymphatic vessels originate within them. Lymphatic vessels are absent from the intercryptal lamina propria.

## Muscularis mucosae

The muscularis mucosae of the large intestine is essentially similar to that of the small intestine.

## Submucosa

The submucosa of the large intestine is similar to that of the small intestine.

## Muscularis externa

The muscularis externa has outer longitudinal and inner circular layers of smooth muscle. The longitudinal fibres form a continuous layer that is aggregated into macroscopically visible longitudinal bands or taeniae coli (see Figs 66.3 and 66.13). Between the taeniae coli, the longitudinal layer is much thinner, less than half the thickness of the circular layer. The circular fibres constitute a thin layer over the caecum and colon, and a thicker layer in the walls of the rectum; they form the internal anal sphincter in the anal canal. Interchange of fascicles between circular and longitudinal layers occurs, especially near the taeniae coli. Deviation of longitudinal fibres from the taeniae coli to the circular layer may, in some instances, explain the haustrations of the colon.

## Serosa

The serosa or visceral peritoneum is variable in extent. Small, fat-filled appendices epiploicae are most numerous on the sigmoid and transverse colon but generally absent from the rectum.

The liver is the largest of the abdominal viscera, occupying a substantial portion of the upper abdominal cavity. It occupies most of the right hypochondrium and epigastrium, and frequently extends into the left hypochondrium as far as the left anterior axillary line (Fig. 67.1). As the body grows from infancy to adulthood, the liver rapidly increases in size. This period of growth reaches a plateau around 18 years and is followed by a gradual decrease in liver weight from middle age. The ratio of liver to body weight decreases with growth from infancy to adulthood. The liver weight is $4-5 \%$ of body weight in infancy and decreases to approximately $2 \%$ in adulthood. The size of the liver also varies according to sex, being smaller in females, and body size, enlarging with fat deposition. It has an overall wedge shape, which is, in part, determined by the form of the upper abdominal cavity into which it grows. The narrow end of the wedge lies towards the left hypochondrium, and the anterior edge points anteriorly and inferiorly. The superior and right lateral aspects are shaped by the anterolateral abdominal and chest wall, as well as the diaphragm. The inferior aspect is shaped by the adjacent viscera. The capsule is no longer thought to play an important part in maintaining the shape of the liver; it is notable that it allows expansion when the liver hypertrophies in response to disease, surgical resection or contralateral embolization of the portal vein or hepatic artery.

Throughout life, the liver is reddish brown in colour, although this can vary, depending on the fat content. Obesity is the most common cause of excess fat in the liver (steatosis); the liver assumes a more yellowish tinge as its fat content increases and gains a bluish tinge with venous obstruction. The texture of the organ is usually soft to firm, although it depends partly on the volume of blood it contains and on its fat and fibrous tissue content.

The liver performs a wide range of metabolic activities required for homeostasis, nutrition and immune defence. For example, it is important in the removal and breakdown of toxic, or potentially toxic, materials from the blood; the regulation of blood glucose and lipids; the storage of certain vitamins, iron and other micronutrients; the synthesis
of proteins and clotting factors; the metabolism of amino acids; and bile production. It is involved in a plethora of other biochemical reactions. Since the majority of these processes are exothermic, a substantial part of the thermal energy production of the body, especially at rest, is provided by the liver. The liver is populated by phagocytic macrophages, components of the mononuclear phagocyte system capable of removing particulates from the blood stream. It is an important site of haemopoiesis in the fetus.

An account of the more common eponyms relating to the anatomy and surgery of the liver is provided in Stringer (2009).

## SURFACES OF THE LIVER

The liver is usually described as having superior, anterior, right, posterior and inferior surfaces, and has a distinct inferior border (Figs 67.267.3). However, the superior, anterior and right surfaces are continuous and no definable borders separate them. It is more appropriate to group them as the diaphragmatic surface, which is mostly separated from the inferior, or visceral, surface by a narrow inferior border. At the infrasternal angle, the inferior border is adjacent to the anterior abdominal wall and accessible to examination by percussion, but not usually palpable, except on deep inspiration. In the midline, the inferior border of the liver is near the transpyloric plane. In women and children, the border often projects a little below the right costal margin.

Superior surface The superior surface is the largest and lies immediately below the diaphragm, separated from it by peritoneum, except for a small triangular area where the two layers of the falciform ligament diverge. The majority of the superior surface lies beneath the right dome, but there is a shallow cardiac impression centrally that corresponds to the position of the heart above the central tendon of the diaphragm. The left side of the superior surface lies beneath part of the left dome of the diaphragm.

Fig. 67.1 The 'bed' of the liver. The outline of the liver is shaded green. The central bare area is unshaded.

Fig. 67.2 The surfaces and external features of the liver. A, Superior view. B, Posterior view. C, Anterior view. D, Inferior view.

Fig. 67.3 Relations of the liver. A, Superior view. B, Posterior view. C, Anterior view. D, Inferior view.

Anterior surface The anterior surface is approximately triangular and convex, and is covered by peritoneum, except at the attachment of the falciform ligament. Much of it is in contact with the anterior attachment of the diaphragm. On the right, the diaphragm separates it from the pleura and sixth to tenth ribs and cartilages, and on the left, from the seventh and eighth costal cartilages.

Right surface The right surface is covered by peritoneum and lies adjacent to the right dome of the diaphragm, which separates it from the right lung and pleura and the seventh to eleventh ribs. The right lung and basal pleura lie above and lateral to its upper third, between
the diaphragm and the seventh and eighth ribs. The diaphragm, the costodiaphragmatic recess lined by pleura, and the ninth and tenth ribs lie lateral to the middle and lower thirds of the right surface. Lateral to the lower third, the diaphragm and thoracic wall are in direct contact. Rarely, the hepatic flexure and proximal transverse colon lie on a long mesentery over the right, anterior and superior surfaces of the liver; this may lead to misdiagnosis of pneumoperitoneum on a radiograph or very rarely cause symptoms (Chilaiditi's syndrome) (see p. 1144).

Posterior surface The posterior surface is convex, wide on the right but narrow on the left. A median concavity corresponds to the forward
convexity of the vertebral column close to the attachment of the ligamentum venosum. Much of the posterior surface is attached to the diaphragm by loose connective tissue, forming the triangular 'bare area'. The inferior vena cava lies in a groove or tunnel in the medial end of the 'bare area'. To the left of the caval groove, the posterior surface of the liver is formed by the caudate lobe, and covered by a layer of peritoneum continuous with that of the inferior layer of the coronary ligament and the layers of the lesser omentum. The caudate lobe is related to the diaphragmatic crura and the right inferior phrenic artery above the aortic hiatus, and separated by these structures from the descending thoracic aorta.
