The fissure for the ligamentum venosum separates the caudate lobe from the left lobe. The fissure cuts deeply in front of the caudate lobe and contains the two layers of the lesser omentum. The posterior surface of the left lobe bears a shallow impression near the upper end of the fissure for the ligamentum venosum that is caused by the abdominal oesophagus. The posterior surface of the left lobe to the left of this impression is related to the fundus of the stomach. Together, these posterior relations make up what is sometimes referred to as the 'bed' of the liver (see Fig. 67.1)

Inferior surface The inferior surface is bounded by the inferior edge of the liver. It blends with the posterior surface in the region of the origin of the lesser omentum, the porta hepatis and the inferior layer of the coronary ligament, and is marked near the midline by a sharp fissure that contains the ligamentum teres (the obliterated fetal left umbilical vein). The gallbladder usually lies in a shallow fossa but this is variable; it may have a short mesentery or be completely intrahepatic and lie within a cleft in the liver parenchyma. The quadrate lobe lies between the fissure for the ligamentum teres and the gallbladder.

The inferior surface of the left lobe is related inferiorly to the fundus of the stomach and the upper lesser omentum. The quadrate lobe lies adjacent to the pylorus, the first part of the duodenum and the lower part of the lesser omentum. Occasionally, the transverse colon lies between the duodenum and the quadrate lobe. To the right of the gallbladder, the inferior surface is related to the hepatic flexure of the colon, the right suprarenal gland and right kidney, and the first part of the duodenum (see Fig. 67.1).

## SUPPORTS OF THE LIVER

The liver is stabilized and maintained in its position in the right upper quadrant of the abdomen by both static and dynamic factors. A threetier classification of supporting structures has been proposed: the suspensory attachments at the posterior abdominal wall to the inferior vena cava, hepatic veins, coronary and triangular ligaments (primary factors); the support provided by the right kidney, right colic flexure and duodenopancreatic complex (secondary factors); and the attachment to the anterior abdominal wall and diaphragm by the falciform ligament (tertiary factors) (Flament et al 1982).

The surgical implications of these different factors are important for understanding the pathophysiology of blunt liver trauma and when considering the stability of transplanted liver grafts. The inferior vena cava and the hepatic veins, especially the right hepatic vein, appear to be the most important anatomical structures that support the bulk of the liver. Other factors that influence the position of the liver within the abdominal cavity include positive intra-abdominal pressure and the movement of the diaphragm during respiration.

## GROSS ANATOMICAL LOBES

Historically, the liver has been divided on the basis of its external appearance into right, left, caudate and quadrate lobes, which are, in part, defined by peritoneal ligamentous attachments. Additional liver lobes have been reported but are rare.

Right lobe The right lobe is the largest in volume and contributes to all surfaces of the liver. It is divided from the left lobe by the falciform ligament anteriorly and superiorly and the ligamentum venosum and fissure for the ligamentum teres inferiorly. On the inferior surface, to the right of the grooves formed by the ligamentum teres and ligamentum venosum, there are two prominences separated by the porta hepatis; the caudate lobe lies posterior, and the quadrate lobe lies anterior. The gallbladder lies in a shallow fossa to the right of the quadrate lobe.

Left lobe The left lobe is the smaller of the two main lobes, although it is nearly as large as the right lobe in young children. It lies to the left
of the falciform ligament with no subdivisions. It is substantially thinner than the right lobe, having a thin apex that points into the left upper quadrant.

Quadrate lobe The quadrate lobe is visible as a prominence on the inferior surface of the liver, to the right of the groove formed by the ligamentum teres (and thus is incorrectly said to arise from the right lobe, although it is functionally related to the left hemi-liver). It lies anterior to the porta hepatis and is bounded by the gallbladder fossa to the right, a short portion of the inferior border anteriorly, the fissure for the ligamentum teres to the left, and the porta hepatis posteriorly. Like the caudate lobe, its morphology varies between individuals (Joshi et al 2009).

Caudate lobe The caudate lobe is visible as a prominence on the inferior and posterior surfaces to the right of the groove formed by the ligamentum venosum; it lies posterior to the porta hepatis. To its right is the groove for the inferior vena cava. Above, it continues into the superior surface on the right of the upper end of the fissure for the ligamentum venosum. In gross anatomical descriptions, this lobe is said to arise from the right lobe but it is functionally separate.

## FUNCTIONAL ANATOMICAL DIVISIONS

Current understanding of the functional anatomy of the liver is based on Couinaud's division of the liver into eight (subsequently nine, then later revised back to eight) functional segments, based on the distribution of portal venous branches in the parenchyma (Couinaud 1957). Further understanding of the intrahepatic biliary anatomy, especially of the right ductal system, was enhanced by contributions from Hjortsjö (1951) and Healey and Schroy (1953), who used the biliary system as the main guide for division of the liver (Fig. 67.4).

The liver is divided into four portal sectors by the four main branches of the portal vein. These are right lateral, right medial, left medial and left lateral (sometimes, the term posterior is used in place of lateral, and anterior in place of medial). The three main hepatic veins lie between these sectors as intersectoral veins. These intersectoral planes are also called portal fissures (or scissures). Each sector is subdivided into segments (usually two), based on their supply by tertiary divisions of the vascular biliary (Glissonian) sheaths.

## Fissures of the liver

Knowledge of the fissures of the liver is essential for understanding liver surgery. Three major fissures (main, left and right portal fissures), not visible on the surface, run through the liver parenchyma and contain the three main hepatic veins. Three minor fissures (umbilical, venous and fissure of Gans) are visible as physical clefts of the liver surface. The fissure of Gans is also known as Rouvière's sulcus or the incisura hepatis dextra. Accessory fissures are rare.

Main portal fissure The main fissure, sometimes called Cantlie's line, extends from the midpoint of the gallbladder fossa at the inferior margin of the liver back to the midpoint of the inferior vena cava, and contains the middle hepatic vein. It separates the liver into right and left hemi-livers. Segments V and VIII lie immediately to the right, and segment IV immediately to the left, of the fissure.

Left portal fissure The left portal fissure divides the left hemi-liver into medial (anterior) and lateral (posterior) sectors. It extends from the midpoint of the inferior edge of the liver between the falciform ligament and the left triangular ligament to the point that marks the confluence of the left and middle hepatic veins. It contains the left hepatic vein and separates the left medial (anterior) and left lateral (posterior) sectors; segment III lies immediately anteriorly and segment II posteriorly.

Right portal fissure The right portal fissure divides the right hemiliver into lateral (posterior) and medial (anterior) sectors. The plane of the right fissure is the most variable of the portal fissures and runs approximately diagonally through the anatomical right lobe from the lateral end of the inferior border to the termination of the right hepatic vein. The fissure divides the right anterior sector to its left (segments V and VIII) from the right posterior sector to its right (segments VI and VII), and contains the right hepatic vein. The right fissure traverses the thickest portion of liver parenchyma that is commonly transected during liver resection.

Fig. 67.4 The fissures and sectors of the liver. (Right lateral $=$ right posterior; right medial = right anterior.)

Fig. 67.5 Segments of the liver (after Couinaud). A, Superior view. B, Posterior view. C, Anterior view. D, Inferior view. The segments are usually referred to by number (name): I (caudate); II (left lateral superior); III (left medial inferior); IV (left medial superior) (sometimes subdivided into superior and inferior parts); V (right medial inferior); VI (right lateral inferior); VII (right lateral superior); VIII (right medial superior).

Umbilical fissure The umbilical fissure (or fissure for the ligamentum teres) separates segment III from segment IV within the left medial sector and contains a major branch of the left hepatic vein (the umbilical fissure vein). It is marked anteriorly by the attachment of the falciform ligament and inferiorly by the ligamentum teres, where it may be covered by a bridge of liver tissue extending between segments III and IV. This liver bridge is usually avascular and can be divided safely with diathermy during surgery. The umbilical fissure also contains the umbilical portion of the left portal vein, segmental bile ducts converging to form the left hepatic duct, and the terminal branches of the left branch of the hepatic artery. The umbilical portion of the left portal vein offers direct surgical access to the left portal vein; this is important for mobilization of the left portal vein in surgery for hilar cholangiocarcinoma and in operations to restore intrahepatic portal blood flow after portal vein occlusion. A knowledge of the arrangement of the vascular and biliary structures within the umbilical fissure is also essential when splitting the liver for an adult and paediatric recipient and for live donor liver transplantation for a child recipient.

Venous fissure The venous fissure (or fissure for the ligamentum venosum) is in direct continuity with the umbilical fissure on the undersurface of the liver and contains the ligamentum venosum (the obliterated ductus venosus). It lies between the caudate lobe and segment II.
Fissure of Gans The fissure of Gans (or Rouvière's sulcus) lies on the undersurface of the right lobe of the liver behind the gallbladder fossa. It often marks the variable site of division of the portal pedicle to the right posterior sector.

## Sectors and segments of the liver

## Sectors

The sectors of the liver are made up of between one and three segments: right lateral sector $=$ segments VI and VII; right medial sector $=$ segments V and VIII; left medial sector = segments III and IV (and part of I); left lateral sector $=$ segment II (Fig. 67.5). Segments are numbered

Fig. 67.6 Segments of the liver seen on axial computed tomography (CT) scan. A, A contrast enhanced CT shows the left (L), middle (M) and right $(\mathrm{R})$ hepatic veins at the superior aspect of the liver, marking the left, main and right portal fissures. B, Inferior to this, the caudate lobe (segment I) lies between the inferior vena cava (IVC) and the portal vein (PV). The left portal vein (LPV) separates segment II superiorly from segment III inferiorly. C, The right portal vein (RPV) divides segments V and VI inferiorly (C) from segments VII and VIII superiorly (B).
clockwise from below, starting with segment I and ending with segment VIII (see Figs 67.4-67.5; Fig. 67.6).

Segment II Segment I corresponds to the anatomical caudate lobe and lies posterior to segment IV, with its left half directly adjacent to segment II and its medial half wrapped around the retrohepatic segment of the inferior vena cava to a variable extent. In European literature, it is subdivided into three parts (caudate process, Spiegel lobe and paracaval
portion), while in the Far East, right and left subdivisions are recognized. The Glissonian sheaths to segment I arise from both right and left main sheaths; the segment therefore receives vessels from both the left and right branches of the portal vein and hepatic arteries. The venous drainage of the caudate lobe is directly into the inferior vena cava by multiple small tributaries that nearly always arise from the lower, and occasionally from the middle, third of the segment, but rarely from the upper third. The bile ducts draining the segment are closely related to the confluence of the right and left hepatic ducts (see Chapter 68), such that excision of bile duct tumours affecting the hilum of the liver usually requires removal of segment I.

Segment II Segment II lies posterolateral to the left portal fissure and is the only segment in the left lateral sector of the liver. It often has only one Glissonian sheath and drains into the left hepatic vein. Rarely, a separate vein drains directly into the inferior vena cava.

Segment IIII Segment III lies between the umbilical fissure and the left portal fissure, and is supplied by one to three Glissonian sheaths; it drains into the left hepatic vein. The vein of the falciform ligament can provide an alternative drainage route for segment III. Very rarely, the venous drainage is to the middle hepatic vein and reconstruction is required following a right hepatectomy involving resection of the middle hepatic vein and in split liver transplantation (Dar et al 2008).

Segment IV Segment IV lies between the umbilical fissure and the main portal fissure, immediately anterior to segment I. Segment IV is supplied by three to five Glissonian sheaths, most of which arise in the umbilical fissure; their origins are often close to those that supply segments II and III. Occasionally, segment IV is supplied by branches from the main left pedicle. The main venous drainage of segment IV is into the middle hepatic vein but the segment can also drain into the left hepatic vein through the vein of the falciform ligament. Segment IV has been divided into IVa superiorly and IVb inferiorly; this is relevant to transverse hepatectomy, in which segments IVb, V and VI are removed along a transverse portal plane (Sugarbaker 1990).

Segment V Segment V is the inferior segment of the right medial sector and lies between the middle and the right hepatic veins. Its size is variable, as are the number of Glissonian sheaths that supply it from the right anterior sheath. Venous drainage is usually into the right and middle hepatic veins, but may be direct into the inferior vena cava via an inferior right hepatic vein.

Segment VI Segment VI forms the inferior part of the right lateral sector posterior to the right portal fissure. It is often supplied by two to three branches from the right posterior Glissonian sheath, and occasionally the Glissonian sheath to segment VI can arise directly from the right pedicle. Venous drainage is normally into the right hepatic vein but, like in segment $V$, may be via an inferior right hepatic vein directly into the inferior vena cava.

Segment VIII Segment VII forms the superior part of the right lateral sector and lies behind the right hepatic vein. The sheath to segment VII is often single. The venous drainage is into the right hepatic vein; occasionally, the segment can drain directly into the inferior vena cava.

Segment VIII Segment VIII is the superior part of the right medial sector. The right medial (anterior) sectoral sheath ends in segment VIII and supplies it, after giving off branches to segment V . Venous drainage is to the right and middle hepatic veins.

## Peritoneal attachments and ligaments of the liver

The liver is attached to the anterior abdominal wall, diaphragm and other viscera by several peritoneal ligaments.

## Falciform ligament and ligamentum teres

The liver is attached to the anterior abdominal wall by the falciform ligament, derived from the ventral mesogastrium in the embryo. The two layers of this ligament pass posteriorly and slightly to the right from the posterior surface of the anterior abdominal wall and the undersurface of the diaphragm in the midline, and attach to the anterior and superior surfaces of the liver. On the dome of the superior surface, the right leaf runs laterally and is continuous with the upper layer of the coronary ligament. The left layer of the falciform ligament turns medially and is continuous with the anterior layer of the left triangular
ligament. The ligamentum teres is the obliterated remnant of the left umbilical vein of the fetus; it runs in the lower free border of the falciform ligament and continues into a fissure on the inferior surface of the liver. In fetal life, the left umbilical vein opens into the left portal vein. It is supposed to be obliterated in adult life but frequently remains partially patent; in reality, its lumen is usually closed rather than obliterated and it can be dissected at the umbilicus, dilated and used to access the left portal vein in more than half of individuals. The ligamentum teres may reopen in conditions such as portal hypertension, when it forms a sizeable collateral channel.

The ligamentum teres is important in abdominal surgery for several reasons. It is often divided in upper abdominal surgery to optimize access to the upper abdominal viscera or as the first step in mobilization of the liver. It is vascularized by numerous small arterial branches (mainly from the artery to segment IV) and para-umbilical veins, and these anastomose with branches of the superior epigastric artery; it is therefore important to ligate or coagulate the ligament during its division. The ligamentum teres is a guide to the segment III hepatic duct in hepaticojejunostomy formation, and to the left portal vein lying in the umbilical fissure during mesenterico-portal bypass (Vellar et al 1998, di Francesco et al 2014).

## Coronary ligament

The coronary ligament is formed by the reflection of the peritoneum from the diaphragm on to the superior and posterior surfaces of the right lobe of the liver. A large triangular area of liver devoid of peritoneal covering, the so-called 'bare area' of the liver, lies between the two layers of the coronary ligament. Here, the liver is attached to the diaphragm by areolar tissue, which is in continuity inferiorly with the anterior pararenal space. On the right, the two layers of the coronary ligament converge laterally to form the right triangular ligament. On the left, the two layers become closely applied, and form the left triangular ligament. The upper layer of the coronary ligament is reflected superiorly on to the inferior surface of the diaphragm and inferiorly on to the right and superior surfaces of the liver. The lower layer of the coronary ligament is reflected inferiorly over the right suprarenal gland and right kidney, and superiorly on to the inferior surface of the liver. Surgical division of the right triangular and coronary ligaments allows the right lobe of the liver to be brought forwards, and exposes the lateral aspect of the inferior vena cava behind the liver.

## Triangular ligaments

The left triangular ligament is a double layer of peritoneum that extends for a variable length over the superior border of the left lobe of the liver. Medially, the anterior leaf is continuous with the left layer of the falciform ligament, and the posterior layer is continuous with the left layer of the lesser omentum. The left triangular ligament lies in front of the abdominal part of the oesophagus and part of the fundus of the stomach. Division of the left triangular ligament allows the left lobe of the liver to be mobilized for exposure of the abdominal oesophagus and crura of the diaphragm. The left triangular ligament is an important stabilizing factor for the left lobe after excision of the right lobe of the liver. Its division will result in the left lobe being unstable, to the extent that it can rotate and displace into the space created under the right hemidiaphragm, which, in turn, can compromise the venous outflow of the left lobe with consequent liver dysfunction. If it is divided, the left lobe should be stabilized by reattaching the falciform ligament to the anterior abdominal wall.

The right triangular ligament is a short structure that lies at the right lateral limit of the 'bare area' of the liver and represents the convergence laterally of the two layers of the coronary ligament.

## Lesser omentum

The lesser omentum is a double layer of peritoneum that extends from the lesser curvature of the stomach and proximal duodenum to the inferior surface of the liver. Its free margin contains the portal triad (Ch. 63). Its attachment to the inferior surface of the liver is L-shaped. The vertical component follows the line of the fissure for the ligamentum venosum, the fibrous remnant of the ductus venosus. More inferiorly, the attachment runs horizontally to complete the L in the porta hepatis. At its upper end, the left layer of the lesser omentum is continuous with the posterior layer of the left triangular ligament, and the right layer is continuous with the coronary ligament as it encloses the inferior vena cava. At its lower end, the two layers of the lesser omentum diverge to surround the structures of the porta hepatis. A thin, fibrous condensation of fascia usually runs from the medial end of the porta hepatis into the fissure for the ligamentum teres. This fascia is continuous with the lower border of the falciform ligament where the ligamentum teres re-emerges at the inferior border of the liver. Care should be taken when
dividing the lesser omentum because an aberrant or accessory left hepatic artery may run within it; when present, it invariably extends to the liver at the base of the umbilical fissure, and may be identified by a pulsation in the lesser omentum close to the umbilical fissure.

## Ligamentum venosum

The ligamentum venosum represents the obliterated venous connection that existed in the fetus between the left branch of the portal vein and the termination of the left hepatic vein (the ductus venosus). It is used as a guide to gain control of the left hepatic vein outside the liver during surgery. By dividing the ligament close to its insertion into the left hepatic vein and retracting it laterally, the angle between the left and the middle hepatic veins may be accessed.

This can be helpful in left liver resection with preservation of the caudate lobe, but if the caudate lobe is to be removed, the left hepatic vein (or, more usually, the confluence of the left and middle hepatic veins with the inferior vena cava) can be approached more posteriorly without division of the ligamentum venosum.

## Porta hepatis, hepatoduodenal ligament and hilar plate

The porta hepatis is a deep transverse fissure on the inferior surface of the liver. It is situated between the quadrate lobe anteriorly and the caudate process posteriorly, and contains the portal vein, hepatic artery and hepatic nervous plexuses as they ascend into the parenchyma of the liver, and the right and left hepatic ducts and some lymph vessels that emerge from the liver. The hepatic ducts usually lie anterior to the portal vein and its branches, and the hepatic artery with its branches lies between the two (Figs 67.7-67.8). However, the right hepatic artery sometimes lies anterior to the common hepatic duct; this variation is important during bile duct reconstruction by hepaticojejunostomy

Fig. 67.7 A cross-section of the structures at the porta hepatis viewed from above.

Fig. 67.8 An axial CT of the porta hepatis. The hepatic ducts lie anteriorly, the portal vein posteriorly, and hepatic artery between the two.
(Michels 1966). All these structures are enveloped within a perivascular sheath of loose connective tissue that surrounds the vessels and bile ducts as they course through the liver parenchyma, and is continuous with the fibrous hepatic capsule (of Glisson). The dense aggregation of vessels, supporting connective tissue, and liver parenchyma just above the porta hepatis is often referred to as the 'hilar plate' of the liver. Understanding the concept of the hilar plate is important in surgical approaches to the hilar structures; division or lowering of the hilar plate is essential for optimum surgical access to the left hepatic duct.

The hepatic artery, bile duct and portal vein extend between the porta hepatis and the upper border of the duodenum in the free edge of the hepatoduodenal ligament, which forms the anterior boundary of the epiploic foramen. Rapid control of the vessels entering the porta hepatis (the hepatic pedicle) can be obtained by compressing them in the free edge of the lesser omentum (a 'Pringle' manœuvre); this is conveniently done by dividing the lesser omentum immediately to the left of these structures and passing a tape around them through the epiploic foramen.

The left hepatic duct is extrahepatic as it descends obliquely along the undersurface of segment IV (the quadrate lobe) to the confluence of the hepatic ducts. Access to this extrahepatic segment of the left hepatic duct is particularly useful when performing a biliary-enteric bypass procedure to treat a stricture of the hepatic duct confluence. The right hepatic duct is more intrahepatic and extension of a hepaticojejunal anastomosis on to the right hepatic duct necessitates incision of the liver parenchyma in the gallbladder fossa.

## Glissonian sheaths

Glisson's capsule of the liver becomes condensed as Glissonian sheaths around the branches of the portal triad structures as they enter the liver parenchyma and subdivide into segmental branches. Thus, each bile duct, hepatic artery and portal vein is surrounded by a single fibrous sheath, which Couinaud called the 'Valoean sheath' (after Valoeus, an anatomist from the Middle Ages who first described the liver capsule). Within each sheath, the portal vein is surrounded by loose areolar connective tissue, making dissection of the portal vein relatively easy. The fibrous tissue around the bile ducts and hepatic artery is tougher, and dissection of these structures is more difficult. This sheath arrangement facilitates surgical control of the right and left vasculobiliary pedicles of the liver, as well as sectoral and segmental divisions in complex liver resections (Yamamoto et al 2012).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The blood vessels connected with the liver are the portal vein, hepatic artery and hepatic veins. The portal vein and hepatic artery ascend in the lesser omentum to the porta hepatis, where each usually bifurcates. The common hepatic duct and lymphatic vessels descend from the porta hepatis alongside the portal vein and hepatic artery (see Fig. 67.8). The hepatic veins leave the liver via its posterior surface and run directly into the inferior vena cava.

## Hepatic artery

In adults, the common hepatic artery is intermediate in size between the left gastric and splenic arteries. In fetal and early postnatal life, it is the largest branch of the coeliac trunk. The hepatic artery gives off the right gastric and gastroduodenal arteries, as well as branches to the bile duct and gallbladder from its right hepatic branch (Fig. 67.9A). After originating from the coeliac trunk, the hepatic artery passes anteriorly and laterally above the upper border of the pancreas to the upper aspect of the first part of the duodenum. It is subdivided into the common hepatic artery, from the coeliac trunk to the origin of the gastroduodenal artery, and the 'hepatic artery proper', from that point to its bifurcation. It ascends anterior to the portal vein and medial to the bile duct within the free margin of the lesser omentum in the anterior wall of the epiploic foramen. It divides into right and left branches at a variable level below the porta hepatis. The right branch of the hepatic artery usually crosses posterior (occasionally anterior) to the common hepatic duct (Fig. 67.9B). This close proximity often means that the right hepatic artery is involved in bile duct cancer earlier than the left hepatic artery. Occasionally, the right hepatic artery crosses anterior to the common hepatic duct and is more vulnerable to injury in biliary surgery. It almost always divides into an anterior branch supplying segments V and VIII, and a posterior branch supplying segments VI and VII. The anterior division also often supplies a branch to segment I and the gallbladder. The hepatic artery proper sometimes divides at a low level close to its origin and, occasionally, it divides at a higher level,

Fig. 67.9 The hepatic artery. A, Branches. B, Usual relations of the hepatic artery, bile duct and portal vein to each other in the lesser omentum: anterior aspect, portion of the liver removed.
well to the left of the porta hepatis. The main significance of an early division is that the right branch may pass behind the portal vein (Lanouis and Jamieson 1993). The segmental arteries of the liver are macroscopically end arteries, although some collateral circulation occurs between segments via fine terminal branches.

Anatomical variants of the normal arrangement of the hepatic artery are found in about one-third of individuals and are important to recognize because they are relevant to surgical and interventional radiological procedures (Covey et al 2002, Michels 1966, López-Andújar et al 2007, Saba and Mallarini 2011). An artery that supplies part of the liver in addition to its normal artery is defined as an accessory artery. A replaced hepatic artery is an artery that does not originate from an orthodox position and provides the sole supply to that part of the liver.

The most common anatomical variants are a replaced or accessory left hepatic artery that arises from the left gastric artery, or a replaced or accessory right hepatic artery that arises from the superior mesenteric artery, both occurring in 10-20\% of individuals.

Variations in the intrahepatic arteries are common and may be surgically important. For example, the segment IV artery most commonly arises from the left hepatic artery, but in up to $30 \%$ of cases, it arises from the right hepatic artery or the hepatic artery proper (Onishi et al 2000). The segment IV artery never arises to the right of the common hepatic duct; thus, if the right hepatic artery is divided to the right of the common hepatic duct, this arterial supply to segment IV is not endangered. Failure to recognize this variation may compromise the blood supply to segment IV following right hepatectomy, and is especially important during right lobe donation for live donor liver transplantation.

A replaced hepatic artery proper may arise from the superior mesenteric artery (Fig. 67.10) and can be suspected at surgery by a relatively superficial portal vein (reflecting the absence of a hepatic artery that would normally ascend in front of the vein). More commonly, a replaced or accessory right hepatic artery arises from the superior mesenteric artery (see Fig. 67.10; Fig. 67.11). In such cases, the variant artery runs in the lesser omentum behind the portal vein and bile duct, and can usually be identified at surgery by palpable pulsation behind the portal vein. An accessory right hepatic artery may be injured during resection of the pancreatic head because the artery lies in close proximity to the portal vein. Occasionally, a replaced or accessory left hepatic
artery arises from the left gastric artery, entering the liver through the umbilical fissure; this artery provides a source of collateral supply in cases where the arteries at the porta hepatis are occluded, but it may also be injured during mobilization of the stomach, as it lies in the upper portion of the lesser omentum. Rarely, an accessory left or right hepatic artery may arise from the gastroduodenal artery or directly from the aorta. The presence of replaced arteries can be life-saving in patients with bile duct cancer; because they are further away from the bile duct they tend to be spared from infiltration by the cancer, making excision of the tumour feasible. Knowledge of these variations is also essential when performing whole and split liver transplantation.

Fig. 67.10 Common hepatic artery variants.

Fig. 67.11 Hepatic arteriograms. A, A selective hepatic arteriogram shows normal left hepatic artery branches and small right hepatic artery branches. B, The right hepatic artery is arising from the origin of the superior mesenteric artery.

## Veins

The liver has two venous systems. The portal system conveys venous blood from the majority of the gastrointestinal tract and its associated organs to the liver (p. 1039). The hepatic venous system drains blood from the liver parenchyma into the inferior vena cava.

## Portal vein

The portal vein is formed behind the neck of the pancreas, usually from the convergence of the superior mesenteric and splenic veins (Fig. 67.12; see also Figs 70.8b, 59.8). Its origin lies in the transpyloric plane between the lower border of the body of the first lumbar vertebra and the upper border of the body of the second lumbar vertebra (Mirjalili et al 2012). The portal vein is approximately 8 cm long and ascends obliquely to the right behind the first part of the duodenum, the common bile duct and gastroduodenal artery, and anterior to the inferior vena cava. It enters the right border of the lesser omentum and ascends anterior to the epiploic foramen to reach the right end of the porta hepatis, where it divides into right and left main branches, which enter the liver. In the lesser omentum, the portal vein lies posterior to both the bile duct and the hepatic artery. It is surrounded by the hepatic nerve plexus and accompanied by numerous lymphatics and some lymph nodes. The portal vein contains smooth muscle in its wall and, in experimental animals at least, has well-developed spontaneous contractions with frequencies between 0.01 and 1 Hz (Burt 2003). It is typically valveless.

Fig. 67.12 A coronal CT of the portal vein and superior mesenteric vein.

The main extrahepatic tributaries of the portal vein are the left gastric (coronary) vein, which ends in the left margin of the portal vein, and the posterior superior pancreaticoduodenal vein near the head of the pancreas. The portal vein divides into right and left branches at the hilum of the liver (Fig. 67.13). The left portal vein has a longer extrahepatic course $(4-5 \mathrm{~cm})$ than the right portal vein, tends to lie more horizontal, and is often smaller in calibre. It has a horizontal portion that runs along the inferior surface of segment IV and invariably gives branches to segment I and sometimes to segment IV. The left branch of the portal vein continues within the liver, giving off a segment II branch laterally before taking a more anterior and vertical course in the umbilical fissure. Here, it gives off branches to segments III and IV, and receives the obliterated left umbilical vein (ligamentum teres). The majority of the portal venous supply to segment IV comes from the left portal vein, and only occasionally from the right branch of the portal vein or its branches to segment V or VIII. The right branch of the portal vein is only $2-3 \mathrm{~cm}$ in length and usually divides into a right medial (anterior) sectoral division supplying segments V and VIII, and a right lateral (posterior) sectoral division supplying segments VI and VII. The medial division may give a branch to segment I.

Portal vein variations usually involve the right branch (Covey et al 2004). If the latter is absent, which occurs in about $10-15 \%$ of livers, the portal vein usually trifurcates into left portal, right medial and right lateral sectoral veins. This has implications for split liver and live donor liver transplantation, where its presence might be considered as a relative contraindication. The right lateral sectoral portal vein may arise from the portal vein, or the right medial sectoral portal vein may originate from the left portal vein, a variant that it is important to remember during left-sided liver resection. Rarely, the portal bifurcation is absent, in which case the portal vein enters the liver, giving off the right sectoral branches, and then turns left to supply the left lobe, which presents an added complexity in major liver surgery (Chaib 2009).

## Porto-systemic shunts

Increased pressure within the portal venous system may result in dilation of portal venous tributaries and reversed flow at sites of portosystemic anastomoses. Common sites of porto-systemic shunts are listed in Table 67.1.

## Hepatic veins

The liver drains by three major hepatic veins into the suprahepatic part of the inferior vena cava and via numerous minor hepatic veins that drain into the retrohepatic inferior vena cava. The adult retrohepatic inferior vena cava is 6-7 cm long and surrounded, to a variable extent, by segment I (Camargo et al 1996). The three major veins are located between the four sectors of the liver (see Fig. 67.6A; Figs 67.14-67.15). Thus, the right hepatic vein lies between the right medial and lateral sectors, the middle hepatic vein lies between the right and left hemilivers, and the left hepatic vein lies between the left medial and lateral sectors. During hepatic resection, the surgeon should transect the liver parenchyma slightly to the left or right of the particular fissure that is being opened to avoid the main trunk of a hepatic vein.

Fig. 67.13 The main portal vein and its intrahepatic branches. (Right lateral = right posterior; right medial = right anterior.)

Fig. 67.14 A sagittal ultrasound of the middle hepatic vein. The middle hepatic vein is seen draining into the inferior vena cava.

Table 67.1 Common sites of porto-systemic anastomoses in portal hypertension and associated clinical implications

| Portal vein tributaries | Systemic veins | Clinical presentations |
| :---: | :---: | :---: |
| Left gastric vein | Distal oesophageal veins draining into azygos and hemiazygos veins | Oesophageal and gastric varices |
| Superior rectal veins | Middle and inferior rectal veins draining into internal iliac and pudendal veins | Rectal varices |
| Persistent tributaries of left branch of portal vein in ligamentum teres | Periumbilical branches of epigastric and intercostal veins | 'Caput medusae' |
| Tributaries of right branch of portal vein overlying 'bare area' of liver | Retroperitoneal veins draining into azygos, hemiazygos, lumbar, intercostal and phrenic veins | Dilated retroperitoneal veins at risk during surgery or interventional procedures |
| Omental and colonic veins near hepatic and splenic flexures | Retroperitoneal veins near hepatic and splenic flexures | May be problematic during surgery |

## Right hepatic vein

This is the longest and largest hepatic vein. It is usually single, but occasionally remains as two trunks until it terminates by draining into the inferior vena cava. The right hepatic vein runs in the right portal fissure between the right medial and lateral sectors. It drains the whole of segments VI and VII, and variable proportions of segments V and VIII, depending on the extent to which these segments drain into the middle hepatic vein. The right hepatic vein is formed anteriorly near the inferior border of the liver and lies in a coronal plane through most of its course. It drains into the inferior vena cava near the upper border of the caudate lobe. Of the three major hepatic veins, the right hepatic vein is most variable in its size, not only due to the variable contribution of the middle hepatic vein to the drainage of segments V and VIII but also due to the existence of an accessory right inferior (30\%) and/ or middle hepatic vein (10\%) (Fang et al 2012). The hepatic venous anatomy is particularly important in right lobe living donation and can be assessed preoperatively by computed tomography (CT) or magnetic resonance imaging (MRI) and/or by intraoperative ultrasound.

## Middle hepatic vein

The middle hepatic vein lies in the main portal fissure between the right and left hemi-livers. It usually joins the left hepatic vein and terminates in the inferior vena cava as a short common trunk (about 5 mm long) ; it ends as a single trunk in the inferior vena cava in fewer than $10 \%$ of individuals. The middle hepatic vein drains the central part of the liver and receives constant tributaries from segments IV, V and VIII. The vein from segment IV lies in a sagittal plane and enters the middle hepatic vein on its left side. The vein from segment VIII runs transversely into

Fig. 67.15 Modern CT analysis techniques are helpful in demonstrating variations in hepatic venous anatomy and this is very useful for planning live donor surgery for liver transplantation. Abbreviations: inf. HV1, inf. HV2, right inferior hepatic veins; LHV, left hepatic vein; LHV4, left hepatic vein branch to segment 4; MHV4, middle hepatic vein branches to segment 4; MHV5, middle hepatic vein branches to segment 5 ; MHV8, middle hepatic vein branches to segment 8; RHV, right hepatic vein. (Courtesy of MeVis Medical Solutions AG, Bremen, Germany.)
the right side of the middle hepatic vein and is sometimes large enough to be mistaken for the middle hepatic vein. Anteriorly, the middle hepatic vein drains some of segment $V$; the sizes of the tributaries draining segments V and VIII are variable. Intrahepatic venous anastomoses between the middle and right hepatic veins, particularly in segment VIII, have been reported in up to one third of adult livers (Hribernik and Trotovšek 2014).

## Left hepatic vein

The left hepatic vein lies between the left medial and left lateral sectors of the liver and drains segments II, III and, occasionally, IV. Small veins draining segment II and, occasionally, the superior part of segment IV may drain directly into the inferior vena cava. Usually, a major tributary of the left hepatic vein, the umbilical fissure vein, runs between segments III and IV and contributes to their drainage. Occasionally, the vein draining segment III ends separately in the confluence of the left and middle hepatic veins. These variations in venous drainage are of significance in split liver transplantation and live donor liver transplantation.

## Minor hepatic veins

Segment I veins drain directly into the inferior vena cava and vary in number from one to five. Since this segment has an independent venous drainage from the rest of the liver, in patients with Budd-Chiari syndrome, in which the major hepatic veins are blocked, segment I often continues to drain effectively and undergoes compensatory hypertrophy. There may be an accessory inferior or middle right hepatic vein, as well as several smaller 'retrohepatic' veins that drain the right lobe directly into the inferior vena cava. When present, they are of surgical importance, especially if greater than 5 mm in diameter; they drain segments V and VI independently of the three major hepatic veins and, therefore, a tumour involving the latter can be resected safely as long as venous drainage from the accessory veins is preserved. In live donor and split liver transplantation, larger accessory veins must be individually anastomosed to the recipient inferior vena cava to ensure adequate venous drainage.

## Transjugular intrahepatic porto-systemic shunt (TIPS) procedure for portal hypertension

In extreme cases of chronic portal hypertension, a large-calibre anastomosis between the portal and systemic circulations may be created within the liver parenchyma by inserting a stent between a large portal and hepatic vein within the liver. The stent is introduced through a catheter inserted into the internal jugular vein and guided into the liver under radiological control. This large shunt relieves the severe portal hypertension but tends to worsen incipient hepatic encephalopathy.

## Segmental anatomy of the liver in relation to hepatic resection

## Available with the Gray's Anatomy e-book

## Lymphatic drainage

Lymph from the liver is rich in protein and is mostly a product of the hepatic sinusoids (Ohtani and Ohtani 2008). It passes, via deep and superficial pathways, to nodes above and below the diaphragm (Trutmann and Sasse 1994). Obstruction of hepatic venous drainage increases the flow of lymph in the thoracic duct.

## Superficial hepatic lymphatics

Superficial lymphatics run in subserosal areolar tissue over the surface of the liver and drain in four directions. Lymphatics from most of the posterior surface, including the caudate lobe, drain into nodes alongside the inferior vena cava; a few lymphatics from the posterior surface of the left lobe pass towards the oesophageal hiatus and nodes around the cardia. Lymphatics in the coronary and right triangular ligaments may pass directly to the thoracic duct. Lymphatics from most of the inferior, anterior and superior surfaces drain into hepatic nodes at the porta hepatis. A few lymphatics from the right superior surface accompany the inferior phrenic artery across the right diaphragmatic crus to drain into coeliac nodes.

## Deep hepatic lymphatics

Fine lymphatics within the portal triads and around interlobular veins merge to form larger vessels. Some ascend through the parenchyma to pass through the vena caval opening in the diaphragm and drain into inferior mediastinal nodes, but most drain to lymph nodes at the porta hepatis.

## INNERVATION

The liver has a dual innervation. The parenchyma is supplied by nerves arising from the hepatic plexus, which contains sympathetic and parasympathetic (vagal) fibres; they all enter the liver at the porta hepatis. The capsule is supplied by fine branches of the lower intercostal nerves, which also supply the parietal peritoneum, particularly around the 'bare
area' and superior surface; distension or disruption of the liver capsule causes quite well-localized, sharp pain.

## Hepatic plexus

The hepatic plexus receives preganglionic parasympathetic fibres from the anterior and, to a lesser extent, the posterior vagus, and postganglionic sympathetic fibres via the coeliac and superior mesenteric plexuses. Nerve fibres accompany the branches of the portal triad into the liver, penetrating as far as the hepatocytes. Aminergic, cholinergic, peptidergic and nitrergic nerve fibres have been identified and appear to be involved in hepatic metabolism and the control of sinusoidal blood flow (McCuskey 2004); however, the transplanted, denervated liver indicates that this role is not essential. Multiple fine branches from the plexus supply the extrahepatic bile ducts and gallbladder; the vagal fibres are motor to the muscle of the bile ducts and gallbladder, and inhibitory to the sphincter of the bile duct. Branches from the plexus also run inferiorly with the right gastric artery to contribute to the supply of the pylorus; with the gastroduodenal artery and its branches to reach the pylorus, proximal duodenum and pancreas; and with the right gastroepiploic artery to provide a small contribution to the nerve supply of the stomach.

## Referred pain

Pain arising from the parenchyma of the liver is poorly localized. In common with other structures of foregut origin, pain is referred to the epigastrium. Stretch or irritation of the liver capsule by inflammation or neoplasia produces well-localized 'somatic' pain. Pathology involving the diaphragmatic surface of the liver may be referred via the phrenic nerve to the right shoulder region ( $\mathrm{C} 3,4,5$ dermatomes).

## MICROSTRUCTURE

The liver is essentially an epithelial-mesenchymal outgrowth of the caudal part of the foregut, with which it remains connected via the biliary tree (see Ch. 60). Most of the surface of the liver is covered by a typical serosa, the visceral peritoneum. Beneath this, and enclosing the whole organ, is a thin $(50-100 \mu \mathrm{~m})$ capsule of connective tissue, from which extensions pass into the liver as septa and trabeculae. Branches of the hepatic artery and hepatic portal vein, together with bile ductules and ducts, run within these connective tissue trabeculae, which are termed portal tracts. The combination of the two types of vessel and a bile duct is termed a portal triad (Fig. 67.19); these

Fig. 67.19 The structural organization of human liver tissue. A, Lobules bordered by delicate connective tissue septa (arrows), in which run branches of the hepatic portal vein, hepatic artery and bile duct, grouped as portal triads. A central vein drains each lobule. B, A portal triad containing branches of the hepatic portal vein (PV; generally the largest profile), the hepatic artery (A) and a bile duct (B), with typical round epithelial nuclei. Other small bile ductule and arteriolar branches are also visible. C, A functional view, in which the territories of the hepatic lobules are shown as regular hexagons (unlike their real appearance, which is highly variable). Functionally, the liver microarchitecture is better considered in terms of acini extending between adjacent central venules and divided into three zones as shown. (A, With permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby. B, Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

In 1888, Rex described the midline division of the liver, and in the 1950s Claude Couinaud's detailed description of the segmental anatomy of the liver formed the basis for subsequent advances in liver imaging and surgery. Goldsmith and Woodburne also published a detailed description of liver anatomy in 1957 but used a different terminology; confusion in hepatic nomenclature has persisted for several decades.

Couinaud divided the right and left hemi-livers into two sectors each, according to the secondary divisions of the portal vein. In the right hemi-liver, the anteromedial and posterolateral sectors were each subdivided into a superior and an inferior segment, producing a total of four segments. In the left hemi-liver, the medial sector was divided into two segments separated by the falciform ligament and ligamentum teres, while the lateral sector consisted of a single segment (II). The smallest segment, which Couinaud designated segment I, was located in the central and posterior part of the liver between the bifurcation of the portal vein and the inferior vena cava, and had independent hepatic vein and portal vein tributaries. Couinaud, therefore, described eight liver segments, numbered I to VIII: segments II, III and IV made up the left hemi-liver and segments V, VI, VII and VIII made up the right hemi-liver. In 1994, he added segment IX to describe the small region of the right hemi-liver lying adjacent to the right side of the inferior vena cava, but later recognized that this was better considered as part of segment I.

In 1982, Henri Bismuth used Couinaud's anatomical descriptions with some modifications as the basis for developing anatomical liver resections (Bismuth 2013). Couinaud's studies had been based on corrosion casts of injected cadaveric livers that had undergone slight postmortem flattening from resting on a firm surface. Bismuth renamed Couinaud's anteromedial and posterolateral sectors in the right hemiliver as anterior and posterior, and also challenged Couinaud's subdivision of the left liver. Couinaud had described two sectors: a lateral sector consisting of a single segment, and a medial sector consisting of two segments separated by a branch of the left portal vein lying in continuity with the round ligament. Bismuth considered that this went against Couinaud's own description of individual segments containing a major branch of the portal vein, and suggested that the left medial sector also consisted of a single segment, i.e. segments III and IV were, in fact, 'half-segments' (Fig. 67.16). This scheme created a single sector containing two segments within the left hemi-liver. To avoid confusion, Bismuth chose to retain the segment numbers III and IV, albeit recognizing them as half-segments. The Bismuth classification recognized two hemi-livers, three sectors (right posterior, right anterior and left) and seven segments: segments 6 and 7 in the right posterior sector, segments 5 and 8 in the right anterior sector, half-segments 3 and 4 and segment 2 in the left sector, and segment 1 (numbering was changed from Roman to Arabic).

In 1986, Ken Takasaki described a different basis for subdividing the gross architecture of the liver, in which the portal vein had three branches (right, middle and left) and there were just two hepatic veins (right and middle, the left hepatic vein being a tributary of the middle hepatic vein; Fig. 67.17). Takasaki had divided the liver into three parts of almost equal volume, based on the three branches of the portal vein and the two hepatic veins. Apart from the terms used, Takasaki's description is similar to Bismuth's modification of Couinaud's anatomy in that the liver is considered to consist of three, and not four, territories. It fails to take into account the division of the left side of the liver by the falciform and round ligaments. The major advantage of Takasaki's description is the individualization of the middle part, facilitating the concept of central hepatectomy.

In 1998, the International Hepato-Pancreato-Biliary Association (IHPBA) developed an international committee on nomenclature of hepatic anatomy and resections, and this reported to the IHPBA General Assembly in Brisbane in 2000 (Terminology Committee of the IHPBA 2000). The chairman of the committee, Steven M. Strasberg, highlighted the confusion that arose from applying multiple terms to the same anatomical structure or operative procedure, and from using the same term to describe more than one structure or operation. For example, in 1997, there were 13 terms in use for the plane that defined the watershed between the right and left hemi-livers (called the midplane of the liver by the committee), and the terms 'lobe', 'lobectomy', 'segment' and 'segmentectomy' were being used to describe different parts of the liver and associated procedures, depending on whether the surgeon was European or North American. The anatomical basis for the Brisbane 2000 nomenclature was the usual branching pattern of the hepatic arteries and bile ducts within the liver. The ramification of the portal vein was said to follow an identical pattern in the right hemi-liver but to be different in the left hemi-liver. Three orders of branching resulted in successive division of the liver into two hemi-livers, four sections and eight segments. Watershed areas between territories subserved by branches of the hepatic artery and bile duct were demarcated by the midplane of the liver, a right and left intersectional plane, and several intersegmental planes. The terminology of liver resections was based directly on the anatomical terminology, and individual resections were termed hemihepatectomy (or hepatectomy), sectionectomy and segmentectomy; an extended resection of three sections was called a trisectionectomy (Fig. 67.18). There has been a clear trend towards adoption of this terminology since 2000 but it has not been universal, not least because the classification has some anatomical deficiencies. In particular, Couinaud's segments II and III became the left lateral section (which meant that removal became a left lateral sectionectomy) but this does not accurately represent the anatomical division. The introduction of the term 'section', as opposed to 'sector', was intended to introduce simpler terms for segments II and III (left lateral section) and segment IV (left medial section) that would mirror the arrangement in the right hemi-liver (right anterior and posterior sections).

Bismuth argued that classification of the lateral part of the left hemiliver was particularly problematic. According to Couinaud, individual liver territories contain portal vein branches but are separated by the major hepatic veins. However, the lateral part of the left hemi-liver is demarcated by the falciform and round ligaments. Resection of this part of the liver remains one of the most commonly performed hepatectomies. In classical anatomy, the term lobe relates to part of an organ defined by an external fissure; removal of the part of the liver to the left of the falciform and round ligaments was originally called a left lobectomy. According to subsequent classifications, this resection has been termed a left lateral segmentectomy (Goldsmith and Woodburne
1957), bisegmentectomy (Couinaud 1957), resection of half a segment (Takasaki et al 1986), and left lateral sectionectomy (Terminology Committee of the IHPBA 2000). To avoid confusion, the term lobectomy is no longer used but Bismuth has argued for a return to classical anatomy and the use of the term left lobectomy. He has also argued that all hepatectomies should be defined by the specific segments that are resected. Thus, removal of a single segment should be described as 'segmentectomy $n$ ' where $n$ is the specific number of the segment removed. Resection of two segments is a 'bisegmentectomy $\mathrm{n}+\mathrm{n} 1$ ', and that of three segments a trisegmentectomy $n+n 1+n 2$ (Bismuth 2013).

Masatoshi Makuuchi, a member of the IHPBA Brisbane 2000 committee on nomenclature, has recently questioned the current status, pointing out that the differences in portal vein branching patterns in the left and right hemi-livers have been the major obstacle in consistently classifying liver territories to satisfy what is known about hepatic embryology, as well as descriptive and surgical anatomy. Makuuchi (2013) has commented that, in the embryo, the right and left hemilivers develop synchronously and that the right and left umbilical veins initially join the right and left branches of the portal vein, respectively. At 4-5 weeks' gestation, the right umbilical vein is resorbed so that the volume of the left side of the liver increases compared to the right, but after occlusion of the left umbilical vein after birth, the left hemi-liver gradually shrinks and the right side enlarges. Makuuchi argues that the left lateral sector (segment II) and right lateral sector (segments VI and VII) were so named by Couinaud because the portal vein branches to both sectors are the first large branches arising from the left and right divisions of the portal vein. These two sectors also share the characteristic of having a major hepatic vein running on their medial border. This is contrary to the views of both Bismuth and Takasaki, who maintain that segment II should be amalgamated with segments III and IV into a single sector, and of the IHPBA Brisbane 2000 nomenclature committee, who considered segment IV to be a full sector. Makuuchi postulates that the left lateral sector shrinks after birth and, if segment IV is determined to be a sector, then the right medial sector of the liver should be demarcated by a plane that corresponds to the embryonic right umbilical vein. As the main portal pedicle should be located at the centre of the sector and not at its border, if the left and right hemi-livers are each divided into two sectors, it is more logical to regard segment II as a sector, as suggested by Couinaud, rather than segment IV.

Makuuchi also discussed the use of the term 'extended', as proposed by Bismuth and the IHPBA Brisbane 2000 nomenclature committee. He suggested that ambiguity could be eliminated by adopting the wording 'extended into segment X ', where X is the specific segment number identified by Couinaud. Further revision of the nomenclature is likely in the future (Strasberg and Phillips 2013).

Fig. 67.18 Resectional terminology. (Redrawn with permission from Terminology Committee of the International Hepato-Pancreato-Biliary Association. The Brisbane 2000 terminology of liver anatomy and resections. HPB 2000;2:333-9.)
structures are usually accompanied by one or more lymphatic vessels and nerves.

The liver parenchyma consists of a complex network of epithelial cells, supported by connective tissue, and perfused by a rich blood supply from the portal vein and hepatic artery. The epithelial cells, hepatocytes, carry out the major metabolic activities, but additional cell types possess storage, phagocytic and mechanically supportive functions. In the mature liver, hepatocytes are arranged mainly in plates (or cords when seen in two-dimensional sections) that are usually only one cell thick and are separated by venous sinusoids, which anastomose with each other via gaps in the plates (Fig. 67.20; see Fig. 67.22). Until about 7 years of age, plates are normally two cells thick. This pattern recurs in liver regeneration, when a mixture of hyperplasia and hypertrophy results in cell plates that are several cells thick and composed of larger multinucleated hepatocytes, reverting over the course of about a year to single cell thickness.

Bile is secreted by hepatocytes and collected in a network of minute tubes (canaliculi). The hepatocytes can therefore be regarded as exocrine cells, secreting bile into the alimentary tract via the extrahepatic bile ducts. Their other metabolic functions involve complex biochemical exchanges with the blood.

The fetal liver is a major haemopoietic organ; erythrocytes, leukocytes and platelets develop from mesenchyme covering the sinusoidal endothelium.

## Lobulation of the liver

The structural unit of the liver is the lobule: a roughly hexagonal arrangement of plates of hepatocytes, separated by intervening sinusoids that radiate outwards from a central vein, with portal triads at the vertices of each hexagon (Fig. 67.21; see Fig. 67.19). The central veins drain into the hepatic veins. In some species, the classic lobular units are delimited microscopically by distinct connective tissue septa. However, the lobular organization of the human liver is not immediately evident in histological sections; the lobules do not have distinct boundaries, and connective tissue is sparse. The plates do not pass straight to the periphery of a lobule like the spokes of a wheel but run irregularly as they anastomose and branch.

Detailed studies of human liver, using three-dimensional reconstruction and morphometric analysis combined with histopathological observations, have revealed a highly ordered arrangement of functional units: the hepatic (portal) acini. Each acinus is an approximately ovoid mass of tissue, orientated around a terminal branch of a hepatic arteriole and portal venule, and with its long axis defined by two adjacent central veins (see Fig. 67.19). It includes the hepatic tissue served by these afferent vessels and is bounded by adjacent acini.

The acinar definition of hepatic microarchitecture has clarified the interpretation of liver histopathology, particularly in relation to zones of hypoxic damage, glycogen deposition and removal, and toxic injury, all of which are related to the direction of blood flow. There are also real metabolic differences between hepatocytes within the acini, which
can be divided into three zones: zone 1 (periportal) is nearest to the terminal branches of afferent vessels; zone 2 is the intermediate zone; and zone 3 is the area closest to the central vein.

## Blood supply

Preterminal hepatic arterioles within the acini convey arterial blood to the sinusoids, mostly via a fine capillary plexus that drains to branches of the portal veins; a small proportion of arterial blood passes directly to the hepatic sinusoids, bypassing these capillary plexuses. Sinusoids thus contain mixed venous and arterial blood. Central veins from adjacent lobules form interlobular veins that unite as hepatic veins and drain to the inferior vena cava.

## Hepatic plates (cords)

The endothelium of the sinusoids is fenestrated and lacks a basal lamina, which enables it to act as a dynamic blood filter (Fraser et al 1995). The sinusoids are separated from the plates of hepatocytes by a narrow gap, the perisinusoidal space of Disse, which is normally $0.2-0.5 \mu \mathrm{~m}$ wide but which distends in hypoxic states. The space contains interstitial fluid, the microvilli of adjacent hepatocytes, hepatic stellate cells, fine collagen fibres (mostly type III, with some types I and IV), and occasional non-myelinated nerve terminals.

A network of minute, interconnecting biliary canaliculi (approximately $1 \mu \mathrm{~m}$ in diameter) runs between the hepatic plates. The canaliculi are formed by the apposed plasma membranes of adjacent hepatocytes sealed by tight junctions. They conduct bile to the canals of Hering, trough-like structures lined by cholangiocytes and hepatocytes within the liver lobules. Each canal collects bile from multiple canaliculi and empties into a bile ductule (lined by cholangiocytes), which in turn drains into an interlobular bile duct within the portal tracts (Roskams et al 2004). The flow of bile is thus towards the periphery of the lobule, in the opposite direction to the blood flow, which is centripetal.

## Cells of the liver

Resident cells of the liver include hepatocytes, hepatic stellate cells (also known as fat-storing Ito cells), sinusoidal endothelial cells, macrophages (Kupffer cells), the epithelial cells of the biliary tree (cholangiocytes), hepatic stem cells, natural killer lymphocytes (pit cells), and connective tissue cells of the capsule and portal tracts (see Fig. 67.19B).

Hepatocytes About $80 \%$ of the liver volume and $60 \%$ of its cellular population is made up of hepatocytes (parenchymal cells) (see Fig. 67.21; Fig. 67.22). They are polyhedral, with $5-12$ sides, and measure $20-30 \mu \mathrm{~m}$ across. Their nuclei are round, euchromatic and often tetraploid, polyploid or multiple, with two or more in each cell. Their cytoplasm typically contains a considerable amount of rough and

Fig. 67.22 A schematic illustration of a hepatocyte and adjacent sinusoids. (Redrawn from O'Grady J, Lake JR, Howdle PD. Comprehensive Clinical Hepatology, Mosby 2000.)
homeostasis and regeneration. Hepatic stellate cells also play a major role in pathological processes (Yin et al 2013). In response to liver damage, they become activated and predominantly myofibroblast-like. They are responsible for the replacement of damaged hepatocytes with collagenous scar tissue, a process called hepatic fibrosis, that is seen initially in zone 3, around central veins. Fibrosis can progress to cirrhosis, where the parenchymal architecture and pattern of blood flow within the liver are destroyed, with major systemic consequences.

Sinusoidal endothelial cells Hepatic venous sinusoids are generally wider than blood capillaries and are lined by a thin but highly fenestrated endothelium that lacks a basal lamina. The endothelial cells are typically flattened, each with a central nucleus, and are joined to each other by junctional complexes. The fenestrae are grouped in clusters with a mean diameter of 100 nm , allowing plasma direct access to the basal plasma membranes of hepatocytes. Their cytoplasm contains numerous transcytotic vesicles.

Kupffer cells Kupffer cells are hepatic macrophages derived from circulating blood monocytes and originate in the bone marrow. They are long-term hepatic residents and lie within the sinusoidal lumen attached to the endothelial surface. Kupffer cells are irregular in shape and have long processes that extend into the sinusoidal lumen. They form a major part of the mononuclear phagocyte system, which is responsible for removing cellular and microbial debris from the circulation, and for secreting cytokines involved in defence. They remove aged and damaged red cells from the hepatic circulation, a function normally shared with the spleen but fulfilled entirely by the liver after splenectomy.

Hepatic stem cells Hepatic stem cells are undifferentiated, pluripotential cells and are understood to reside around the canals of Hering; they are derived from the ductal plate in fetal livers. Their progeny are small epithelial cells ( $8-18 \mu \mathrm{~m}$ ) with a large oval nucleus and scanty cytoplasm, expressing both biliary epithelial and hepatocyte markers (Roskams et al 2010).

## Gallbladder and biliary tree

The biliary tree consists of the system of ducts that collect and deliver bile from the liver to the second part of the duodenum. It is conventionally divided into intrahepatic and extrahepatic biliary trees. The intrahepatic ducts are formed from bile ductules that join to form segmental ducts. These merge to form right and left hepatic ducts close to the porta hepatis. The extrahepatic biliary tree consists of the extrahepatic segments of the right and left hepatic ducts, the common hepatic duct, the cystic duct and gallbladder, and the common bile duct (Fig. 68.1).

## GALLBLADDER

The gallbladder is a flask-shaped, blind-ending diverticulum attached to the bile duct by the cystic duct (Fig. 68.2). It stores and concentrates bile. In life, it is grey-blue in colour and is usually firmly attached by connective tissue to the inferior surface of the right lobe of the liver, between segments IV and V at the lower limit of the principal plane. In the adult, the gallbladder is between 7 and 10 cm long, with a resting volume of about 25 ml and a capacity of up to 50 ml (Di Ciaula et al 2012). It usually lies in a shallow fossa (the gallbladder bed) on the visceral surface of the right lobe of the liver, covered by peritoneum continued from the liver surface. This attachment can vary widely. Rarely, the gallbladder is almost completely buried within the liver (intrahepatic gallbladder; Guiteau et al 2009), or suspended from the liver by a peritoneal mesentery (when it is at risk of torsion; Gupta et al 2009), or connected to the duodenum by an extension of the free edge of the lesser omentum (cystoduodenal ligament; Ashaolu et al 2011).

Fig. 68.1 The overall arrangement of the intrahepatic and extrahepatic biliary tree. The segmental ducts often branch just before they enter the main ducts, or are multiple as they enter the main ducts, but for clarity are shown here as single ducts. Note that segment I often drains via both right and left hepatic ducts. The level of the liver parenchyma at the porta hepatis is shown by the dashed line.

The gallbladder is described as having a fundus, body and neck. The neck lies at the medial end, close to the porta hepatis, and almost always has a short peritoneal attachment (mesentery) to the liver, which usually contains the cystic artery. The mucosa at the medial end of the neck is obliquely ridged, forming a crescentic fold that is continuous with the spirally arranged mucosal folds in the cystic duct (Dasgupta and Stringer 2005). At its lateral end, the neck widens out to form the body of the gallbladder; when this widening is clearly demarcated as a result of gallstone disease, it is referred to as 'Hartmann's pouch'. The neck usually lies anterior to the second part of the duodenum. The body of the gallbladder normally lies in contact with the visceral surface of the liver. When the neck possesses a mesentery, this rapidly shortens along the length of the body as it lies in the gallbladder fossa. The body lies anterior to the second part of the duodenum and the right end of the transverse colon. The bulbous fundus lies at the lateral end of the body and usually projects past the inferior border of the liver to a variable extent. Here, it frequently lies in contact with the anterior abdominal wall behind the ninth costal cartilage, where the lateral edge of the right rectus abdominis crosses the costal margin. This is where enlargement of the gallbladder is best sought on clinical examination. The fundus commonly lies adjacent to the transverse colon.

The gallbladder varies in size and shape. The fundus may be elongated and highly mobile. Rarely, the fundus is folded back on the body of the gallbladder, the so-called Phrygian cap; on ultrasound, this may be wrongly interpreted as an apparent septum within an otherwise normal gallbladder. Other anatomical variants of the gallbladder include duplication, with or without a double cystic duct; agenesis; internal septation; and an ectopic location (most commonly left-sided) (Gross 1936, Faure et al 2008); although rare, these congenital anomalies are particularly important if the patient requires surgery for gallbladder or gallstone disease (Lamah et al 2001, Singh et al 2006, Castorina et al 2014, Chowbey et al 2004).

## INTRAHEPATIC BILIARY TREE

## SEGMENTAL AND SECTORAL DUCTS

The segmental ducts of the left hemi-liver have a relatively constant pattern, although more than one segmental duct may drain each particular segment. The left hepatic duct is formed by the union of segment II and III ducts, most often behind or to the left of the umbilical portion of the left portal vein (see Fig. 68.1). The biliary drainage of segment IV is more variable but is usually by a single duct into the left hepatic duct. The right hepatic duct is formed by the union of the right anterior (medial) and posterior (lateral) sectoral ducts. The right anterior (medial) sectoral bile duct drains segments V and VIII, and the right posterior (lateral) sectoral duct drains segments VI and VII. The right posterior sectoral duct usually curves around the posterior aspect of the right anterior duct before fusing with its medial aspect; this is known as Hjortsjö's crook and is an important technical consideration when performing liver resection (Fig. 68.3). The bile ducts draining the caudate lobe (segment I) usually join the origin of the left hepatic duct or may drain into both hepatic ducts near the hilar confluence.

The right hepatic duct and its branches are more often subject to variation than the left ductal system (Cucchetti et al 2011, Chaib et al 2014). These variations have been classified into six main types (Table 68.1, Fig. 68.4). Left intrahepatic ductal variations mostly relate to the drainage pattern of segment IV; this segmental bile duct usually drains into the left hepatic duct but it may open into a segment II or III bile duct, the right anterior sectoral duct, or even the common hepatic duct (Chaib et al 2014).

An oblique groove on the inferior surface of the liver posterior to the gallbladder bed is present in $70-80 \%$ of livers. It is variably known as the fissure of Gans, Rouviere's sulcus or the incisura hepatis dextra (Ch. 67). It overlies the division of the right posterior (lateral) portal pedicle, where it gives off the inferior segment VI branch. It has been increasingly recognized as a useful anatomical landmark during hepatic resection and in laparoscopic cholecystectomy (since the cystic duct and artery lie anterosuperior to the sulcus while the common bile duct lies posteroinferior) (Dahmane et al 2013).

| into the cystic duct or gallbladder |  |  |

(Data from Cucchetti et al 2011 and Chaib et al 2014.)
*This figure is higher in men and lower in women, i.e. women are more likely to have variant intrahepatic bile duct anatomy. N.B. The percentage of different types varies between populations.

## EXTRAHEPATIC BILIARY TREE

## CYSTIC DUCT

The cystic duct drains the gallbladder into the common bile duct. In adults, it is usually between 2 and 4 cm long and has a luminal diameter of $2-3 \mathrm{~mm}$ (Dasgupta and Stringer 2005). It passes posteriorly and medially from the neck of the gallbladder, often in a tortuous fashion, to unite with the common hepatic duct and form the common bile duct. The anatomy of the junction between the cystic duct and common hepatic duct is variable (see Fig. 68.4). In most individuals, the cystic duct joins the middle third of the combined lengths of the common hepatic and common bile ducts (Shaw et al 1993), but it may drain into the distal common bile duct or into a more proximal duct such as the proximal common hepatic duct or right hepatic duct; it usually joins the right lateral aspect of the common hepatic duct but may merge medially, anteriorly or posteriorly; and it usually forms an oblique angle with the common hepatic duct but can spiral around it or run parallel to it in the free edge of the lesser omentum for a variable distance before merging (Lamah et al 2001). Irrespective of the site or type of union, the terminal part of the cystic duct is frequently adherent to the common hepatic duct for a variable distance.

Rarely, the cystic duct is double or absent (when the gallbladder drains directly into the bile duct), or receives an anomalous hepatic duct from segment V of the liver. These variations in cystic duct anatomy are of considerable importance during surgical excision of the gallbladder (cholecystectomy). The cystic duct must be identified passing to the neck of the gallbladder and must be occluded some distance away from the bile duct to prevent injury to the latter. A preliminary operative cholangiogram is essential if the anatomy is unclear or anomalous.

The mucosa of the cystic duct has $2-10$ crescentic folds that project into the lumen and form a spiral; these are continuous with those in the neck of the gallbladder. The function of these spiral folds is unknown but they may help to preserve the patency of this narrow, tortuous duct

Fig. 68.4 Variations in the anatomy of the cystic and intrahepatic bile ducts. The cystic duct variations are labelled A1-A4 and the intrahepatic bile duct variations as types 1-4 (see Table 68.1).
rather than regulate the flow of bile, as is commonly stated (Dasgupta and Stringer 2005).

## HEPATIC DUCTS

The right and left hepatic ducts emerge from the liver and unite near the right end of the porta hepatis to form the common hepatic duct. The extrahepatic right duct is short $(0.5-2.0 \mathrm{~cm}$ in adults) and nearly vertical, while the left is longer ( $1.5-3.5 \mathrm{~cm}$ ) and more horizontal, and lies along the inferior border of segment IV. The accessibility of the extrahepatic segment of the left hepatic duct is exploited when performing a surgical biliary bypass in patients with benign hilar bile duct strictures (Myburgh 1993).

In adults, the common hepatic duct descends approximately 3 cm before being joined obliquely on its right by the cystic duct to form the common bile duct. The common hepatic duct lies to the right of the hepatic artery and anterior to the portal vein in the free edge of the lesser omentum. In adults, the luminal diameter of the normal common hepatic duct, as measured by ultrasound, is less than 5 mm .

## COMMON BILE DUCT

The common bile duct is formed near the porta hepatis, by the junction of the cystic and common hepatic ducts (Figs 68.5-68.6). In adults, it is usually between 6 and 8 cm long and its luminal diameter, as

A small bile duct from segment V of the liver may traverse the gallbladder fossa and join the right hepatic duct or its anterior sectoral branch or the common hepatic duct. This is often known as Luschka's duct and its importance lies in the fact that it may be injured during cholecystectomy, causing a postoperative bile leak (Spanos and Syrakos 2006). Postmortem studies have identified such a duct in up to onethird of individuals but many of these are small and relatively insignificant; if larger ducts $(1-2 \mathrm{~mm})$ are considered, the prevalence is nearer 5\% (Ko et al 2006). These ducts are more likely to be injured if the gallbladder is not dissected close to its wall. Luschka did not describe a duct draining directly into the gallbladder; this is referred to as a cystohepatic or cholecystohepatic duct and should not be confused with a hepatocystic duct (which is present when the common bile duct is absent and both hepatic ducts drain directly into the gallbladder which drains in turn via the cystic duct into the duodenum) (Losanoff et al 2002).

Fig. 68.3 Hjortsö's crook. The right posterior (lateral) sectoral bile duct usually hooks around the right anterior (medial) sectoral pedicle, rendering it vulnerable to injury when performing an extended left hepatectomy that includes segments V and VIII of the liver (left trisectionectomy).

Fig. 68.5 A, An endoscopic retrograde cholangiopancreatogram. (B, continued online)

Fig. 68.6 A magnetic resonance cholangiopancreatogram.
measured by ultrasound, is no more than 7 mm (Perret et al 2000); the diameter increases slightly with advancing age from a mean of 3.6 mm below 60 years to a mean of 4 mm after 80 years. The common bile duct can be divided into supraduodenal, retroduodenal and pancreatic segments. The supraduodenal segment descends posteriorly and slightly to the left, anterior to the epiploic foramen and inferior vena cava, in the free right border of the lesser omentum, where it lies anterior and to the right of the portal vein and to the right of the hepatic artery. This part of the common bile duct is the most accessible at surgery. The retroduodenal segment lies behind the first part of the duodenum with the gastroduodenal artery on its left. The pancreatic segment runs in a groove on the posterior surface of the head of the pancreas, embedded in the gland to a variable degree; it lies up to 2 cm away from the medial
wall of the second part of the duodenum and anterior to the right renal vein. The posterior superior pancreaticoduodenal branch of the gastroduodenal artery descends anterior to the retroduodenal portion of the common bile duct (at the superior border of the pancreas) before spiralling around the right side of the bile duct to reach the posterior surface of the head of the pancreas (Bertelli et al 1996).

## Hepatopancreatic ampulla

As it descends behind the head of the pancreas medial to the second part of the duodenum, the common bile duct approaches the right end of the pancreatic duct. The two ducts usually enter the duodenal wall together in a Y configuration to form a short common channel measuring between 2 and 10 mm in length (Flati et al 1994). This common channel often contains a dilation known as the hepatopancreatic ampulla (of Vater) and it opens via a single orifice on to the medial wall of the second part of the duodenum at the major duodenal papilla (Fig. 68.5B). In clinical practice, the whole region is often termed the pancreaticobiliary junction. Occasionally, the common bile duct and pancreatic duct unite outside the duodenal wall to form an abnormally long common channel or the two ducts are separated by a septum or drain into the duodenum separately (Kamisawa and Okamoto 2008).

The mucosa of the terminal $5-10 \mathrm{~mm}$ of the common bile and pancreatic ducts has a complex arrangement of circumferentially arranged folds (Purvis et al 2013) (Fig. 68.7). Their distribution and orientation impede reflux of duodenal contents into the bile and pancreatic ducts, and they may sometimes cause difficulty cannulating the major duodenal papilla during endoscopic retrograde cholangiopancreatography (ERCP).

A complex arrangement of smooth muscle with prominent circular fibres surrounds the distal common bile duct (bile duct sphincter) and hepatopancreatic ampulla (sphincter of Oddi); to a lesser extent, it also surrounds the terminal part of the main pancreatic duct (pancreatic duct sphincter) (Boyden 1957, Didio and Anderson 1968). The whole sphincter muscle complex lies mostly within the wall of the duodenum and, in adults, measures approximately $15-20 \mathrm{~mm}$ in length; it contains a high pressure zone that can be detected by manometry (Teilum 1991, Habib et al 1988). The smooth muscle of the ampullary sphincter is developmentally and anatomically distinct from the adjacent duodenal muscle. The sphincter regulates the flow of bile and pancreatic secretions into the duodenum and impedes reflux of duodenal contents into the ductal system (Guelrud et al 1990); it is inhibited by cholecystokinin (CCK), which not only relaxes the sphincter but also causes gallbladder contraction (Woods et al 2005). Division of the upper part of the ampullary sphincter (sphincterotomy) may be required to allow access to the common bile duct during ERCP.

The pancreaticobiliary junction is clinically important because it may be affected by various congenital and acquired disorders. An anomalous union between the bile and pancreatic ducts, particularly one resulting in an abnormally long common channel, may be associated with congenital bile duct dilation, recurrent pancreatitis, and/or gallbladder cancer (Kimura et al 1985, Misra and Dwivedi 1990, Stringer et al 1995). Acquired pathology in this region also includes gallstone obstruction and peri-ampullary tumours.

## Hepatobiliary triangle

The triangular region formed between the cystic duct, the common hepatic duct and the inferior surface of the liver is the hepatobiliary triangle (Fig. 68.8). It is often mistakenly referred to as Calot's triangle, which is an isosceles triangle based on the common hepatic duct, with the cystic artery and cystic duct forming its sides (Stringer 2009). The hepatobiliary triangle is bridged by the double layer of peritoneum that forms the short and variable mesentery of the cystic duct. Between these two layers there is a variable amount of fatty connective tissue, lymphatics, the cystic lymph node, autonomic nerves, and usually the cystic artery as it runs from the right hepatic artery to the gallbladder; occasionally, there may also be an accessory bile duct (see above). Understanding the variations in biliary and arterial anatomy as they relate to the triangle is of considerable importance during excision of the gallbladder in order to avoid injury to the common hepatic or common bile duct or right hepatic artery (Suzuki et al 2000, Talpur et al 2010).

## GALLSTONES

Gallstones are relatively common and usually form in the gallbladder. Gallbladder contraction may move a gallstone towards the narrow cystic

Fig. 68.5 B, Endoscopic image of the major duodenal papilla (arrow) on the medial wall of the descending duodenum.

Fig. 68.7 A scanning electron micrograph showing mucosal folds (arrows) lining the wall the hepatopancreatic ampulla. Abbreviations: I, inferior; L, lateral; M, medial; S, superior.

Fig. 68.8 A view of the hepatobiliary triangle (dashed line) at laparoscopic cholecystectomy. In this patient, the cystic artery can be seen crossing the triangle superficially en route to the gallbladder. (Courtesy of Richard Flint, Christchurch Hospital.)
duct, where it can cause obstruction and pain (biliary colic). If the stone continues to occlude the cystic duct, it will lead to inflammation of the gallbladder (acute cholecystitis) or a sterile distension of the gallbladder (mucocele); providing the gallbladder has not been inflamed previously, it will be non-fibrotic and distensible, and the fundus often becomes palpable below the costal margin. A gallstone lodged in the cystic duct or neck of the gallbladder may also produce an inflammatory swelling that compresses the common hepatic duct, resulting in partial obstruction to the flow of bile and the development of jaundice (the so-called 'Mirizzi syndrome'; Stringer 2009). If the gallstone passes through the cystic duct, it may become impacted in the distal common bile duct or at the pancreaticobiliary junction, causing obstructive jaundice, cholangitis and/or acute pancreatitis.

## ENDOSCOPIC CHOLANGIOPANCREATOGRAPHY

The common bile duct and/or pancreatic duct may be accessed endoscopically from the duodenum for diagnostic cholangiography and/or pancreatography, and for therapeutic interventions such as the relief of biliary obstruction by insertion of an internal stent. The acute angle between the distal common bile duct and pancreatic duct may make direct cannulation of the bile duct difficult. In such cases, the upper part of the major duodenal papilla may be incised (pre-cut sphincterotomy) to facilitate cannulation of the common bile duct. This incision, and the more extensive sphincterotomy that may be performed to release an impacted gallstone (Sakai et al 2012), are occasionally complicated by arterial bleeding. The risk may be reduced by making the incision in the $10-11$ o'clock region of the sphincter (Mirjalili and Stringer 2011). Endoscopic sphincterotomy can result in uncontrolled reflux of duodenal contents into the distal common bile duct and ascending biliary infection.

## BILIARY DRAINAGE

The proximity of the fundus of the gallbladder to the anterior abdominal wall facilitates ultrasound-guided percutaneous drainage of a distended, obstructed gallbladder. Because of the small calibre of the cystic duct and its spiral folds, drainage of the gallbladder is rarely sufficient to decompress the biliary tree when the common bile duct is obstructed. In such cases, temporary or permanent biliary drainage may be achieved by the endoscopic insertion of a biliary stent through the obstruction via the major duodenal papilla, surgical bile diversion, or percutaneous transhepatic drainage. The latter involves image-guided puncture of a dilated intrahepatic bile duct and the insertion of an external drain or an internal stent through the biliary obstruction.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Cystic artery

The cystic artery usually arises from the right branch of the hepatic artery (Fig. 68.9, but see Fig. 68.10) and most often passes posterior to

Fig. 68.9 Normal anatomy of the cystic artery.
the common hepatic duct within the hepatobiliary triangle, where it lies superior to the cystic duct. On reaching the superior aspect of the neck of the gallbladder, it divides into a superficial branch that runs along the peritoneal (inferior) surface of the gallbladder, and a deep branch that runs between the gallbladder and its fossa; the branches anastomose over the surface of the body and fundus. The cystic artery is usually less than 3 mm in diameter, and a larger artery in the hepatobiliary triangle is more likely to be the right branch of the hepatic artery.

The origin of the cystic artery is variable (Fig. 68.10). The most common variant is an origin from the hepatic artery proper, when it often crosses anterior to the common bile duct or common hepatic duct to reach the gallbladder. Rarely, it may arise from the left hepatic, gastroduodenal, superior pancreaticoduodenal, coeliac, right gastric or superior mesenteric arteries; in these cases, the cystic artery may not traverse the hepatobiliary triangle. The cystic artery frequently bifurcates close to its origin, giving rise to two vessels. Alternatively, an accessory cystic artery may arise from the hepatic artery or one of its branches. There appear to be racial differences in the frequency of these variants (Saidi et al 2007). Small arterial branches from the parenchyma of segment IV or V of the liver may contribute to the supply of the body of the gallbladder, particularly when it is substantially intrahepatic; these help to protect the gallbladder from ischaemic necrosis if inflammation results in thrombosis of the cystic artery.

The cystic artery also gives rise to multiple fine branches that contribute to the blood supply of the extrahepatic bile ducts.

## Ductal arteries

The common bile duct and hepatic ducts are supplied by a fine network of arteries arising from several sources. The common bile duct is frequently supplied by 2-4 small-calibre arteries that form a long, tortuous, anastomotic network along its length; these narrow vessels tend to be concentrated at the 3 and $9 o^{\prime}$ clock positions around the circumference of the duct (Northover and Terblanche 1979). The network is fed by arteries from the right branch of the hepatic artery above, reinforced by fine branches from the cystic artery. Branches from three main arterial sources often supply the duct from below: the posterior superior pancreaticoduodenal artery, the retroduodenal artery (both of which originate from the gastroduodenal artery and cross anterior to the

Fig. 68.10 Variant anatomy of the cystic artery.
retroduodenal segment of the bile duct), and a retroportal artery arising from the superior mesenteric artery or coeliac trunk and passing to the right on the posterior surface of the portal vein (Chen et al 1999). The supraduodenal segment of the bile duct is relatively less well vascularized than the retroduodenal and pancreatic segments, and excessive dissection of this segment may result in an ischaemic bile duct stricture.

The hilar ducts are supplied by a fine network of periductal arteries that arise from the right and left branches of the hepatic artery and form an anastomotic plexus within the connective tissue of the hilar plate. The intrahepatic ducts are supplied by segmental branches of the hepatic artery arising within the Glissonian sheaths (Stapleton et al 1998, Vellar 1999). The dependence of the intrahepatic bile ducts on their hepatic arterial blood supply is well recognized in liver transplantation since hepatic artery thrombosis may lead to diffuse intrahepatic biliary strictures despite preservation of portal venous blood flow.

## Cystic veins

The venous drainage of the gallbladder is rarely by a single cystic vein. There are usually multiple small veins. Those arising from the superior surface of the body and neck lie in areolar tissue between the gallbladder and liver, and drain into segmental portal veins within the liver. The remainder of the organ drains by one or two small cystic veins into either portal vein branches within the liver or portal venous tributaries draining the hepatic ducts and upper bile duct (Sugita et al 2000). Only rarely does a single or double cystic vein drain directly into the right branch of the portal vein.

## Lymphatic drainage

Lymph from the gallbladder and cystic duct drains via several pathways: to the cystic node, which usually lies above the cystic duct in the hepatobiliary triangle, and from here via nodes in the free edge of the lesser omentum and along the common hepatic artery to coeliac lymph nodes; via lymphatics that descend along the common bile duct to the superior retropancreaticoduodenal node (which communicates with para-aortic nodes); and directly to superior mesenteric nodes (Sato et al 2013). Lymphatics on the hepatic aspect of the gallbladder connect directly with intrahepatic lymph vessels.

Lymphatic vessels accompanying the hepatic ducts and upper bile duct drain to hepatic nodes at the porta hepatis and then via lymph nodes in the free edge of the lesser omentum to coeliac nodes. Lymphatics from the lower common bile duct also drain to the latter but some pass directly to retropancreatic and superior mesenteric nodes.

## INNERVATION

The gallbladder and the extrahepatic biliary tree are innervated by branches from the hepatic plexus. Gallbladder contraction occurs in response to cholecystokinin (CCK) and parasympathetic (vagal) stimulation. Postganglionic sympathetic nerve fibres from the coeliac and superior mesenteric ganglia are inhibitory to gallbladder smooth muscle. Sympathetic afferents from the gallbladder convey pain sensation; they travel with the greater and lesser splanchnic nerves and have their cell bodies in the T7-9 spinal cord segments. Visceral pain from the gallbladder is referred to the right hypochondrium and epigastrium and may radiate around the back below the right scapula. Inflammation of the parietal peritoneum overlying the gallbladder produces localized right upper quadrant pain. A diverse range of neurotransmitters have been identified within intrinsic neurones of the gallbladder (Balemba et al 2004).

The common bile duct and smooth muscle of the hepatopancreatic ampulla are also innervated by the vagi, either directly or via the hepatic plexus, and by sympathetic nerves.

## MICROSTRUCTURE

## GALLBLADDER

The fundus of the gallbladder is completely covered by a serosa, and the inferior surfaces and sides of the body and neck of the gallbladder are usually covered by a serosa. If the gallbladder possesses a mesentery, the serosa extends around the sides of the body and neck on to the superior surface and continues into the serosa of the mesentery, whereas the serosa is limited to the inferior surfaces only if the gallbladder is intrahepatic. Beneath the serosa is subserous loose connective and adipose peritoneal tissue. The gallbladder wall microstructure generally
resembles that of the small intestine. The mucosa is yellowish brown and elevated into minute rugae with a honeycomb appearance (see Fig. 68.2). In section, projections of the mucosa into the gallbladder lumen resemble intestinal villi, but they are not fixed structures and the surface flattens as the gallbladder fills with bile. The epithelium is a single layer of columnar cells with apical microvilli; basally, the spaces between epithelial cells are dilated (Fig. 68.11). Many capillaries lie beneath the basement membrane. The epithelial cells actively absorb water and solutes from the bile and concentrate it up to ten-fold. There are no goblet cells in the epithelium. The thin fibromuscular layer is composed of fibrous tissue mixed with smooth muscle cells arranged loosely in longitudinal, circular and oblique bundles.

## BILE DUCTS

The walls of the large biliary ducts consist of external fibrous and internal mucosal layers (Fig. 68.12). The outer layer is fibrous connective tissue containing a variable amount of longitudinal, oblique and circular smooth muscle cells. The mucosa is continuous with that in the

Fig. 68.11 A low-power micrograph showing the gallbladder wall, with a mucosal projection that flattens in the full gallbladder, and the thin muscular layer.

(Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
hepatic ducts, gallbladder and duodenum. The epithelium is columnar and there are numerous tubulo-alveolar (or tubulo-acinar) mucous glands in the duct walls.

Expulsion of gallbladder contents is under neuroendocrine control. Fat in the duodenum causes the release of CCK by intestinal neuroendocrine cells, which stimulates the gallbladder to contract because muscle cells in its walls bear surface receptors for CCK. When the pressure exceeds $100 \mathrm{mmH}_{2} \mathrm{O}$ of bile, the sphincter of Oddi relaxes and bile enters the duodenum. The termination of the united bile and pancreatic ducts is packed with villous, valvular folds of mucosa that contain muscle cells in their connective tissue cores. Contraction is thought to result in retraction and clumping of these folds, so preventing reflux of duodenal contents and controlling the exit of bile.

The pancreas is one of the largest digestive glands. The major part of the gland is exocrine, secreting enzymes involved in the digestion of lipids, carbohydrates and proteins. It has an additional endocrine function derived from clusters of cells scattered throughout the substance of the gland, which take part in glucose homeostasis and the control of upper gastrointestinal motility and function.

The healthy pancreas is creamy pink in colour, with a soft to firm consistency and lobulated surface. It is divided into a head, neck, body, tail and uncinate process on the basis of its anatomical relations (Figs 69.1-69.3A). In adults, the gland measures $12-15 \mathrm{~cm}$ in length and is shaped as a flattened 'tongue' of tissue lying in the retroperitoneum, thicker at its medial end (head) and thinner towards the lateral end (tail). The head lies within the ' C ' loop of the duodenum and the remainder of the gland extends transversely and slightly cranially across the retroperitoneum and posterior to the stomach to the hilum of the spleen. It is 'draped' over the vertebral column and other retroperitoneal structures, forming a distinct shallow curve, with the neck and medial body lying most anteriorly. In adults, it has an average volume of $70-80 \mathrm{~cm}^{3}$, although this varies considerably between individuals (with a range of $40-170 \mathrm{~cm}^{3}$ ) and tends to be greater in males (DjuricStefanovic et al 2012). Pancreatic volume increases with age, to reach a peak in the fourth decade. From about 60 years of age, the gland atrophies and fatty connective tissue replaces exocrine tissue (Caglar et al 2012, Saisho et al 2007).

The ventral surface of the pancreas is covered by parietal peritoneum and is crossed by the root of the transverse mesocolon. A loose connective tissue layer immediately posterior to the pancreas, sometimes known the fusion fascia of Treitz in the region of the pancreatic head and the fusion fascia of Toldt in the region of the body and tail, contains vessels that supply the pancreas (Kimura 2000).

## HEAD

The head of the pancreas lies to the right of the midline, anterior and to the right of the vertebral column, within the curve of the duodenum. It is the thickest and broadest part of the pancreas but is still flattened in the anteroposterior plane. Superiorly, it lies adjacent to the first part of the duodenum; close to the pylorus, however, where the duodenum is on a short mesentery, it overlaps the upper part of the head anteriorly. The duodenal border of the head is flattened, slightly concave and adherent to the second part of the duodenum, particularly around the duodenal papillae. The superior and inferior pancreaticoduodenal arteries lie adjacent to this region. The inferior border of the pancreatic head lies superior to the third part of the
duodenum and is continuous with the uncinate process. The anterior surface of the head is covered by peritoneum and related to the origin of the transverse mesocolon (Fig. 69.3B). Posteriorly, the common bile duct is partially embedded within the head of the gland just proximal to where it joins the pancreatic duct near the major duodenal papilla (Burgard et al 1991, Nagai 2003). The posterior surface of the pancreatic head is also related to the inferior vena cava, the right crus of the diaphragm and the termination of the right gonadal vein (Ch. 76; see Fig. 76.5). Near the midline, the head of the pancreas becomes continuous with the neck.

## NECK

The neck of the pancreas is approximately 2 cm wide and links the head and body. It is often the most anterior part of the gland and may be defined as that part of the pancreas lying anterior to the formation of the portal vein (usually the union of the superior mesenteric and splenic veins) in the transpyloric plane (Fig. 69.4D,E). This is a crucial relationship when evaluating pancreatic cancer because malignant involvement of these vessels may make resection impossible. The superior mesenteric vein and portal vein groove the posterior aspect of the neck. The inferior mesenteric vein joins the confluence of the superior mesenteric vein and splenic vein in one-third of individuals (Kimura 2000; see Fig. 69.7). The anterior surface of the pancreatic neck is covered by peritoneum and lies adjacent to the pylorus. The anterior superior pancreaticoduodenal branch of the gastroduodenal artery descends in front of the gland at the junction of the head and neck.

## BODY

The body of the pancreas is the longest part of the gland and runs from the neck to the tail, becoming progressively thinner. It is slightly triangular in cross-section, and has anterior and posterior surfaces and superior and inferior borders.

Anterior surface The anterior surface is covered by peritoneum, which is reflected anteroinferiorly from the surface of the gland to be continuous with the posterior layer of the greater omentum and the transverse mesocolon (see Fig. 63.4). The two layers of the transverse mesocolon diverge along this surface (see Fig. 69.3B). Above the attachment of the transverse mesocolon, the anterior surface of the pancreas is separated from the stomach by the lesser sac. Inferiorly, it lies within the infracolic compartment, and its anterior relations include

Fig. 69.1 Relations of the pancreas.
the fourth part of the duodenum, the duodenojejunal flexure and coils of jejunum.

Posterior surface The posterior surface of the pancreas is devoid of peritoneum. It lies on fascia (the fusion fascia of Toldt) anterior to the aorta and the origin of the superior mesenteric artery, the left crus of the diaphragm, left suprarenal gland, the upper pole of the left kidney surrounded by perirenal fascia, and left renal vein (Kimura 2000; see Figs 69.1, 69.4A-G). The splenic vein runs from left to right directly on this surface of the gland and indents the parenchyma to a variable extent, ranging from a shallow groove to almost a tunnel.

Superior border To the right, the superior border of the body of the pancreas is blunt but it becomes narrower and sharper to the left. An

Fig. 69.2 A coronal reformat computed tomogram (CT) of the pancreas showing its relations in the upper abdomen. (Courtesy of the Department of Radiology, Global Hospital, Chennai, India.)

Fig. 69.3 A, Regions and anterior surfaces and borders of the pancreas. B, Anterior relations of the pancreas. Areas covered in peritoneum are shown in blue and structures overlying these areas are separated from the pancreas by peritoneal 'spaces'. The spleen lies anterior to the anterior leaf of the splenorenal ligament and not in direct contact with pancreatic tissue. Abbreviations: D1, first part of the duodenum; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

A

Fig. 69.4 A, Posterior relations of the pancreas, with planes of section labelled as shown in B, D and F. B, Diagrammatic cross-section taken at the mid level of the uncinate process, and equivalent CT axial slice (C).

Fig. 69.4, cont'd Diagrammatic cross-sections and equivalent CT axial slices taken at the head and neck (D-E), and tail (F-G) of the pancreas.
omental tuberosity usually projects from the right end of the superior border above the level of the lesser curvature of the stomach. The superior border is related to the coeliac artery and its branches; the common hepatic artery runs to the right just above the gland, and the splenic artery passes to the left in a tortuous manner, projecting above the superior border at several points.

Inferior border At the medial end of the inferior border, adjacent to the neck of the pancreas, the superior mesenteric vessels emerge from behind the gland. Laterally, the inferior mesenteric vein runs behind the inferior border to join the splenic vein or the confluence of the splenic and superior mesenteric veins. This is a useful site for identification of the inferior mesenteric vein on computed tomographic (CT) imaging and during left-sided colonic resections.

## TAIL

The tail of the pancreas is the narrowest, most lateral portion of the gland and is continuous medially with the body. It is between 1.5 and 3.5 cm long in adults and lies between the layers of the splenorenal
ligament. It may terminate at the base of the splenorenal ligament or extend up to the splenic hilum, when it is at risk of injury at splenectomy during ligation or stapling of the splenic vessels. The splenic artery and its branches, and the splenic vein and its tributaries, lie posterior to the tail (see Fig. 69.4F,G).

## UNCINATE PROCESS

The uncinate process is a hook-shaped continuation of the inferomedial part of the head of the gland. Embryologically, it is separate from the rest of the gland (p. 1051). The superior mesenteric vein and, occasionally, the superior mesenteric artery descend on its anterior surface before running forwards into the root of the mesentery of the small intestine. The uncinate process extends medially anterior to the abdominal aorta above the third part of the duodenum, which may be compressed by a pancreatic tumour at this site. On sagittal cross-sectional imaging, the left renal vein, uncinate process, and third part of duodenum can be seen lying between the superior mesenteric artery anteriorly and the abdominal aorta posteriorly.

Fig. 69.5 Variations in the ductal anatomy of the pancreas. A, Normal. The main pancreatic duct is formed by fusion of the dorsal and ventral bud ducts, and communicates with the accessory pancreatic duct. B, Normal. There is no communication between the main duct and a normally sited accessory duct. C, Pancreas divisum. The majority of the pancreas drains via a dominant dorsal duct that enters the duodenum at the minor papilla. A short ventral duct is seen draining, along with the bile duct, into the major duodenal papilla. D, Absence of accessory duct. (E-G, continued online)

## PANCREATIC DUCTS

The exocrine pancreatic tissue drains into multiple small lobular ducts. The arrangement of the main ducts draining the pancreas is subject to variation but the most common arrangement is a single main and a single accessory duct (Fig. 69.5). This arrangement reflects the embryological development of the dorsal and ventral pancreatic ducts (p. 1051; see Figs 60.3-60.4). The main pancreatic duct (of Wirsung) usually runs within the substance of the gland from left to right. It lies midway between the superior and inferior borders of the pancreas, usually slightly more towards the posterior surface of the gland. It is formed by the junction of several lobular (secondary) ducts in the tail and increases
in calibre within the body of the gland as it receives further lobular ducts that join it almost at right angles to its axis, forming a 'herringbone pattern'. In adults, the duct can often be demonstrated on ultrasound, measuring approximately 3 mm in diameter in the head, 2 mm in the body and 1 mm in the tail; the calibre of the duct increases from about the fifth decade onwards (Glaser et al 1987). As it reaches the neck of the gland, it turns inferiorly and posteriorly towards the bile duct, which lies on its right side. The two ducts unite to form a short common channel, which enters the wall of the descending part of the duodenum obliquely; it may contain a dilation known as the hepatopancreatic ampulla (of Vater) (p. 1175). The terminal part of the main pancreatic duct contains a few mucosal folds that impede reflux of pancreatic juice (Purvis et al 2013). The length of the common pancreaticobiliary channel is variable and measures up to $5-7 \mathrm{~mm}$ in normal individuals (Horaguchi et al 2014).

The accessory (dorsal) pancreatic duct (of Santorini) drains the upper part of the anterior portion of the pancreatic head. Much smaller in calibre than the main duct, it is formed within the substance of the head from several lobular ducts and usually communicates with the main pancreatic duct near the neck of the gland or near its first inferior branch (Kamisawa and Okamoto 2008, Kamisawa 2004). The accessory duct usually opens on to a small, rounded minor duodenal papilla, which lies about 2 cm proximal to the major papilla (see Fig. 69.5A). If the duodenal end of the accessory duct fails to develop, the lobular ducts drain via small channel(s) into the main duct (Hernandez-Jover et al 2011). The anatomy of the main and accessory pancreatic ducts may vary, reflecting anomalies in the development and fusion of the dorsal and ventral pancreatic ducts.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The pancreas has a rich arterial supply via branches from the coeliac trunk and superior mesenteric artery (Figs 69.6A-C; see also Fig. 65.4). The head and adjoining duodenum are supplied mainly by four arteries: two from the coeliac trunk via the gastroduodenal artery (anterior and posterior superior pancreaticoduodenal arteries), and two from the superior mesenteric artery via the inferior pancreaticoduodenal artery (anterior and posterior inferior pancreaticoduodenal arteries). The two anterior arteries supply the ventral aspects of the duodenum, pancreatic head and uncinate process, and join to form the anterior pancreaticoduodenal arcade. The two posterior arteries supply the dorsal aspect of the pancreatic head, adjacent duodenum and distal bile duct, and may join to form a posterior pancreaticoduodenal arcade.

The body and tail of the pancreas are supplied by multiple branches from the splenic artery, including the dorsal pancreatic artery. Small arteries characteristically run along the superior and inferior borders of the gland, lying in a deep groove or within the parenchyma. They are fed along their length by the pancreaticoduodenal and splenic arteries. Bleeding from these vessels is avoided by ligating the upper and lower borders of the pancreas prior to transection.

## Posterior superior pancreaticoduodenal artery

The posterior superior pancreaticoduodenal artery usually arises as the first branch of the gastroduodenal artery at the superior edge of the first part of the duodenum. It runs to the right, anterior to the supraduodenal portion of the bile duct, before spiralling posteriorly around the common bile duct and descending on the posterior surface of the pancreatic head. It gives branches to the duodenum, head of the pancreas, and bile duct before anastomosing with the posterior inferior pancreaticoduodenal artery to form the posterior pancreaticoduodenal arcade. The posterior superior pancreaticoduodenal artery may also give origin to the retroduodenal and supraduodenal arteries, which supply the duodenum (Bertelli et al 1996a). The spiral course of the posterior superior pancreaticoduodenal artery reflects its embryonic development: it is the artery to the anterior aspect of the ventral pancreatic bud and the bile duct, which subsequently rotate clockwise behind the duodenum and dorsal pancreatic bud (Bertelli et al 1997).

## Anterior superior pancreaticoduodenal artery

The anterior superior pancreaticoduodenal artery usually arises as the smaller terminal branch of the gastroduodenal artery, together with the right gastroepiploic artery. It originates behind the first part of the duodenum and runs inferiorly on the anterior aspect of the pancreatic head at a variable distance medial to the groove between the descending duodenum and pancreatic head. It passes inferiorly around the right or inferior border of the pancreatic head, often piercing the gland to reach the posterior surface of the uncinate process, where it joins the anterior

An abnormally long common channel may occur in isolation or with congenital choledochal dilation, and is associated with pancreaticobiliary reflux and an increased risk of gallbladder cancer (Kamisawa et al 2010a).

Patients who develop acute pancreatitis are more likely to have a poorly developed minor papilla; if this were not so, the patent accessory duct system might act as a secondary drainage mechanism for the main ductal system and so prevent elevation of intraductal pressures likely to cause acute pancreatitis (Kamisawa et al 2010b). One clinically important variation is 'pancreas divisum', seen in $5-10 \%$ of individuals (Rana et al 2012; see Fig. 69.5C, G). In this condition, there is a failure of normal duct fusion and the accessory pancreatic duct drains the entire pancreas via the minor papilla, except that part of the head and uncinate process that develop from the ventral bud. The relatively small size of the minor papilla might impair pancreatic drainage, leading to recurrent pancreatitis.

Fig. 69.5, cont'd Variations in the ductal anatomy of the pancreas. E, Intraoperative cholangiogram visualizing the main pancreatic duct opening into the duodenum through the major duodenal papilla, the accessory duct opening through the minor duodenal papilla and its communicating branch. $\mathbf{F}$, Normal magnetic resonance cholangiopancreatogram (MRCP). The dorsal duct joins with the distal ventral duct in the head of the pancreas. $\mathbf{G}$, Pancreas divisum. MRCP reconstruction shows that the dorsal duct is dominant and enters the duodenum at the minor duodenal papilla. A short ventral pancreatic duct is seen draining with the bile duct into the major papilla. (Figs 69.5E-G, courtesy of Mohamed Rela, Global Hospitals, Chennai, India.)

Fig. 69.6 A, The arterial supply of the pancreas. B, A CT angiographic reconstruction. The black arrow shows the coeliac trunk, and the white arrow shows the superior mesenteric artery. Anastomotic arcades, both ventral and dorsal, can be seen coursing around the head of the pancreas. The body and tail of the pancreas are supplied by multiple pancreatic branches (PB) from the splenic artery and the dorsal pancreatic artery (DPA), which, in this example, arises from the superior mesenteric artery, and gives origin to the transverse pancreatic artery (TPA). Other abbreviations: AIPD, anterior inferior pancreaticoduodenal artery; ASPD, anterior superior pancreaticoduodenal artery; CHA, common hepatic artery; GDA, gastroduodenal artery; IPD, inferior pancreaticoduodenal artery; LGA, left gastric artery; LHA, left hepatic artery; PIPD, posterior inferior pancreaticoduodenal artery; PSPD, posterior superior pancreaticoduodenal artery; RGE, right gastroepiploic artery; RHA, right hepatic artery; SA, splenic artery. C, The anterior and posterior pancreaticoduodenal arterial arcades and a typical communicating artery. (Adapted with permission from Mirjalili SA, Stringer MD. The arterial supply of the major duodenal papilla and its relevance to endoscopic sphincterotomy. Endoscopy 2011; 43(4): 307-11.)
inferior pancreaticoduodenal artery to form the anterior pancreaticoduodenal arcade (Bertelli et al 1995).

## Inferior pancreaticoduodenal artery

An inferior pancreaticoduodenal artery is present in most individuals. It usually arises either directly from the superior mesenteric artery at the inferior border of the pancreas or as a common vessel with the first jejunal artery (a pancreaticoduodenojejunal trunk) from the posterior or left aspect of the superior mesenteric artery (Horiguchi et al 2008, Bertelli et al 1996b). It runs to the right, posterior to the superior mesenteric vein, to reach the posterior surface of the uncinate process, where it divides into anterior and posterior inferior pancreaticoduodenal arteries. When arising as a pancreaticoduodenojejunal trunk, the
artery gives off a jejunal branch and then runs posterior to both the superior mesenteric artery and vein before dividing into its terminal branches. Occasionally, the inferior pancreaticoduodenal artery is absent and the anterior and posterior inferior pancreaticoduodenal arteries arise separately from the superior mesenteric artery.

The smaller anterior inferior pancreaticoduodenal artery runs to the right on the posterior surface of the uncinate process to join the anterior superior pancreaticoduodenal artery and form the anterior pancreaticoduodenal arcade. The larger posterior inferior pancreaticoduodenal artery runs on the posterior surface of the head of the pancreas, parallel and superior to the anterior inferior pancreaticoduodenal artery. It joins the posterior superior pancreaticoduodenal artery to form the posterior pancreaticoduodenal arcade (Bertelli et al 1997).

## Communicating arteries

Multiple small arteries run between the anterior and posterior pancreaticoduodenal arcades, either via the pancreaticoduodenal groove or through the substance of the gland. The largest and most consistent of these is the communicating artery (sometimes known as the middle pancreaticoduodenal arcade), which passes between the main and accessory pancreatic ducts and connects the anterior pancreaticoduodenal arterial arcade and the posterior superior pancreaticoduodenal artery (Yamaguchi et al 2001; Fig. 69.6C; see also Fig. 65.4). This artery gives rise to the majority of small arteries that supply the major duodenal papilla (Mirjalili and Stringer 2011).

## Other arterial arcades in the head of the pancreas

Kirk's arcade is formed by a right branch of the dorsal pancreatic artery that emerges on to the anterior surface of the head of the gland and anastomoses with a branch of either the gastroduodenal or the anterior pancreaticoduodenal arcade (Woodburne and Olsen 1951). It supplies blood to the ventral surface of the head and neck of the gland.

## Splenic artery

The splenic artery arises from the coeliac trunk and runs behind the superior border of the pancreas to the splenic hilum (see Fig. 69.6A). It gives multiple small branches along its course that penetrate and supply the pancreatic parenchyma. Prominent among these are the dorsal pancreatic artery (see below); great pancreatic artery (arteria pancreatica magna), arising approximately two-thirds of the way along the gland; and the artery to the tail of the pancreas (arteria caudae pancreatis), arising near the tail. These branches lie on or within the posterior aspect of the gland and often anastomose with the transverse pancreatic artery. Anatomical variations are not unusual; the dorsal, great or transverse pancreatic arteries may be dominant in any one individual (Wu et al 2011).

## Dorsal pancreatic artery

The dorsal pancreatic artery commonly arises from the initial 2 cm of the splenic artery, although it may take origin from the common hepatic or superior mesenteric artery or the coeliac trunk (Horiguchi et al 2008). The artery is short and gives off numerous branches, including a terminal left branch near the inferior border of the gland. Several right-sided branches run to the head of the pancreas, passing either behind or in front of the superior mesenteric vein to supply the posterior or anterior surface of the pancreatic head, respectively; they anastomose with arteries of the pancreaticoduodenal arcade (Tsutsumi et al 2014). The terminal left branch anastomoses with the transverse pancreatic artery.

The length and course of the dorsal pancreatic artery depend primarily on its site of origin. When it arises from the splenic artery, common hepatic artery or coeliac trunk, the artery runs inferiorly on the dorsal surface of the pancreas, whereas if it arises from the superior mesenteric artery, it runs superiorly. The artery uniformly terminates near the inferior border of the pancreas close to the confluence of the splenic and superior mesenteric veins (Bertelli et al 1998).

## Transverse pancreatic artery

The transverse pancreatic artery, also called the inferior pancreatic artery, commonly originates from the left terminal branch of the dorsal pancreatic artery. It runs to the left on the posterior surface of the gland close to its inferior border, gives multiple branches to the body and tail, and anastomoses with other pancreatic branches of the splenic artery.

The transverse pancreatic artery may occasionally originate from the gastroduodenal artery or the anterior superior pancreaticoduodenal artery, crossing the anterior surface of the pancreatic head to reach the inferior border of the neck of the gland and then the tail. In such cases, it may be the dominant artery to the pancreatic body, and its injury or deliberate ligation during pancreaticoduodenectomy may cause ischaemia of the remnant pancreas.

## Arterial segmentation of the pancreas

Available with the Gray's Anatomy e-book

## Venous drainage of the pancreas

Multiple veins drain the pancreas into the portal, superior mesenteric and splenic veins (Mourad et al 1994; Fig. 69.7). Although variations are common, the anterior superior pancreaticoduodenal vein typically joins either the confluence of the right gastroepiploic and right colic

Superior pancreaticoduodenal veins (anterior and posterior)

Fig. 69.7 Venous drainage of the pancreas. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
veins (the gastrocolic trunk of Henle) or the right gastroepiploic vein alone, to drain into the superior mesenteric vein at the inferior border of the neck of the pancreas (Mourad et al 1994, Lange et al 2000). The posterior superior pancreaticoduodenal vein drains cranially into the portal vein. Both anterior and posterior inferior pancreaticoduodenal veins usually drain directly into the superior mesenteric vein. Veins from the body and tail of the gland drain directly into the splenic vein. A transverse (or inferior) pancreatic vein may be present, running along the inferior border of the pancreas to join the inferior mesenteric vein. A few pancreatic veins communicate with systemic veins in the retroperitoneum (veins of Retzius); these may form retroperitoneal varices in portal hypertension.

## Lymphatic drainage

The lymphatic drainage of the pancreas is extensive (see Fig. 64.14B), which, in part, explains the poor prognosis of pancreatic cancer. Lymphatic vessels commence within the connective tissue septa within the gland and join to form larger lymphatics that follow local arteries (Deki and Sato 1988, O'Morchoe 1997). Lymphatics from the tail and body drain mostly into nodes along the splenic artery and inferior border of the gland, and from there to pre-aortic nodes between the coeliac trunk and superior mesenteric artery. Lymphatics from the neck and head drain more widely into nodes along the pancreaticoduodenal, superior mesenteric and hepatic arteries, and, ultimately, into pre-aortic nodes (Donatini and Hidden 1992). There is no evidence of lymphatic channels within the pancreatic islets.

## INNERVATION OF THE PANCREAS

The pancreas has a rich autonomic nerve supply (Love et al 2007). Parasympathetic afferents convey sensory information from pancreatic ducts, acini and islets via the vagus nerve. Preganglionic vagal efferents have their cell bodies in the dorsal motor nucleus of the vagus and reach the pancreas via hepatic, gastric and coeliac branches of the nerve. They synapse with postganglionic parasympathetic pancreatic neurones, which are distributed singly or clustered in ganglia in the interlobular connective tissue, lobules and islets. Pancreatic ganglia are most abundant in the head and neck of the gland. The ganglia contain neurones that are dominantly cholinergic but nitrergic, peptidergic and dopaminergic neurones are also present. These pancreatic neurones receive input not only from vagal efferents but also from enteric neurones from the stomach and duodenum, sympathetic efferents and other pancreatic neurones. Their nerve fibres ramify in the interacinar spaces and supply acinar cells and islets, modulating both exocrine and endocrine secretion (see Fig. 69.10). A network of

The pancreas may be divided into two arterial 'segments' that are separated by a relatively avascular plane; there is disagreement on the definition of these segments. One view is that the two segments are separated by a plane passing to the left of the superior mesenteric artery, such that the head and neck are supplied by branches of the gastroduodenal and superior mesenteric arteries, and the body and tail are supplied by branches of the splenic artery (Busnardo et al 1988). An alternative view holds that the anterior segment consists of the superior part of the pancreatic head, neck, body and tail of the gland (derived from the dorsal pancreatic bud), and the posterior segment consists of the inferior part of the head and the uncinate process (derived from the ventral pancreatic bud) (Sakamoto et al 2000). In both schemes, the main pancreatic duct crosses between the segments. Currently, segmental anatomy is of limited practical surgical significance.
interstitial cells (of Cajal) provides an additional link between autonomic nerves and pancreatic acini.

Visceral afferents transmit pain and other sensory information to cell bodies in the sixth to twelfth thoracic dorsal root ganglia via the coeliac plexus and thoracic splanchnic nerves. The cell bodies of preganglionic sympathetic nerves are located in the intermediolateral columns of the spinal cord (T6-12); their axons travel in the thoracic splanchnic nerves and synapse in the coeliac and superior mesenteric ganglia. Postganglionic sympathetic nerves innervate the blood vessels, ganglia and ducts within the pancreas, causing vasoconstriction and inhibiting exocrine secretion.

Perineural invasion is relatively common in pancreatic cancer and not only adversely affects prognosis but may also be a factor in the pain associated with this disease (Bapat et al 2011).

## Referred pain

Pain arising in the pancreas is poorly localized. In common with other foregut structures, the majority of pain arising from the pancreas is referred to the epigastrium. Inflammatory or infiltrative processes arising from the gland rapidly involve the tissues of the retroperitoneum that are innervated by somatic nerves; pain is then localized to the lower thoracic spine. Intractable pain from chronic pancreatitis or inoperable pancreatic tumours can be temporarily controlled by thermal or chemical ablation of the coeliac plexus.

## MICROSTRUCTURE

The pancreas is composed of exocrine and endocrine tissues. The main tissue mass is exocrine, forming $98 \%$ of the pancreas, in which
pancreatic islets, forming the endocrine component, are embedded (Figs 69.8-69.10).

## Exocrine pancreas

The exocrine pancreas is a branched acinar gland (see Fig. 2.6), surrounded and incompletely lobulated by delicate loose connective tissue. Individual acini are composed of roughly spherical clusters of pyramidal cells that secrete digestive enzymes, water and bicarbonate. A narrow intralobular duct lined by flattened or cuboidal centro-acinar cells originates from within each secretory acinus. Intralobular ducts unite to form larger interlobular ducts lined by taller cuboidal and, eventually, columnar epithelium. The latter are surrounded by connective tissue septa, containing smooth muscle, autonomic nerves and fat. Neuroendocrine cells are present among the columnar ductal cells, and mast cells are numerous in the surrounding connective tissue. A network of intralobular arteries, arterioles and capillaries form capillary networks around the terminal ducts, acini and the richly vascularized endocrine islets (Love et al 2007).

Acinar cells Acinar cells have a basal nucleus surrounded by abundant basophilic rough endoplasmic reticulum and an apical region containing dense eosinophilic secretory zymogen granules. A prominent supranuclear Golgi complex is associated with large, membranebound granules containing the protein constituents of pancreatic secretion, including enzymes that are only active after release. Ganglionic neurones and cords of undifferentiated epithelial cells are also found within the acini. The structure of the exocrine pancreas and its functional regulation are summarized in Figure 69.8.

Fig. 69.8 The microstructure of the exocrine pancreas and the mechanisms by which its secretion is controlled. Pancreatic stellate cells (see text) are not shown.

Fig. 69.9 Microstructure of the pancreas. The exocrine tissue consists of acini with pyramid-shaped columnar cells arranged in spherical clusters. Acinar secretions drain into intralobular ducts, which, in turn, join larger interlobular ducts, present in connective tissue septa containing blood vessels. Interspersed between the acini are islets of Langerhans, which appear as clusters of pale-staining cells surrounded by a network of capillaries, seen as narrow clear spaces. Adipocytes may also be present. Haematoxylin and eosin. (Courtesy of Dr Mukul Vij, Global Hospital, Chennai, India.)

| Cell types | Secretion |
| :--- | :--- |
| A (Alpha cells) | Glucagon |
| $B$ (Beta cells) | Insulin |
| $D$ (Delta cells) | Somatostatin, gastrin |
| F cells | Pancreatic polypeptide |

Fig. 69.10 The microstructure and control of function of the endocrine pancreas.

Stellate cells Pancreatic stellate cells are myofibroblast-like cells distributed in the exocrine part of the pancreas, mainly in the peri-acinar space, where their long cytoplasmic processes encircle the base of the acinus, and in perivascular and periductal regions of the pancreas. They are usually in a quiescent state but, when activated, they have been implicated in the pathogenesis of chronic pancreatitis and pancreatic cancer (Omary et al 2007, Masamune and Shimosegawa 2013).

## Endocrine pancreas

Pancreatic islets (of Langerhans) constitute the endocrine component of the pancreas. The human pancreas may contain more than a million islets distributed throughout the gland but most numerous in the tail. Each islet consists of a highly vascularized cluster of polyhedral cells arranged in a trabecular pattern, closely approximated to a dense network of fenestrated capillaries, which enables bidirectional transport of substrates between the islet cells and the circulation (In't Veld and Marichal 2010). Islets are also supplied by autonomic nerve fibres, which travel with the blood vessels and end blindly in the pericapillary space. True synaptic contact between these nerve fibres and islet cells has not been demonstrated, though their role in islet function has been suggested (Rodriguez-Diaz et al 2012). Specialized staining techniques are necessary to distinguish various islet cells, designated alpha, beta, delta, epsilon and pancreatic polypeptide (PP) or F cells. Beta cells secrete insulin and are the most abundant (nearly 50\% in human islets), followed by glucagon-secreting alpha cells (30-40\%). Delta cells and PP cells are less common and secrete somatostatin and pancreatic polypeptide, respectively. Epsilon cells secrete ghrelin. Unlike mouse islets, where beta cells form the core of the islet and are surrounded by alpha cells, human islets do not show cell-type specific localization. The various cell types are uniformly distributed along the microvasculature and have extensive interlinkages with other islet cells. Their general organization is shown in Figure 69.10.

One of the earliest comprehensive reviews of pancreatic arterial anatomy.

Acute inflammation of the pancreas occurs in response to a variety of pancreatic insults, including gallstone obstruction of the hepatopancreatic ampulla, which causes reflux of bile and pancreatic juice into the pancreatic duct. This precipitates intraparenchymal activation of inactive digestive enzymes, leading to cell injury, an inflammatory cascade and destruction of pancreatic tissue.

The regional anatomy of the pancreas explains most of the clinical complications of acute pancreatitis. Irritation of the stomach contributes to gastric stasis and vomiting; inflammation of the superior mesenteric plexus may contribute to paralytic ileus; and vascular inflammation may cause superior mesenteric or portal vein thrombosis, arterial bleeding or pseudoaneurysms, and ischaemia of the transverse colon. Haemorrhagic fluid may accumulate in the loose retroperitoneal tissues around the pancreas and track laterally to the flanks (Grey Turner's sign), down to the inguinal ligaments (Fox's sign), or via the lesser omentum and 'bare area' of the liver to the falciform ligament and the skin around the umbilicus (Cullen's sign), manifesting as diffuse bruising.

Peripancreatic acute fluid collections frequently resolve spontaneously as the inflammation in the pancreas subsides. Accumulation of fluid anterior to the pancreas, just beneath the posterior wall of the lesser sac, can result in a 'pseudocyst' containing amylase-rich fluid and debris but lacking a true epithelial lining (Banks et al 2013). A large pseudocyst bulges forwards into the lesser sac in contact with the posterior wall of the stomach, lesser omentum and gastrosplenic ligament. If it does not resolve spontaneously, the pseudocyst can be drained internally through the posterior wall of the stomach by endoscopic or open surgery, or externally by means of a percutaneous drain inserted under radiological guidance.

Sustained injury to the pancreas can cause permanent damage, leading to parenchymal fibrosis and calcification within the parenchyma and the pancreatic ducts. This often causes chronic pain, diabetes mellitus and pancreatic exocrine insufficiency with steatorrhoea and malnutrition. Fibrosis can involve the bile duct in the head of the pancreas, leading to obstructive jaundice, and/or the splenic vein, causing splenic vein thrombosis and 'left-sided' portal hypertension.

The vast majority of pancreatic tumours are ductal adenocarcinomas derived from exocrine ductal epithelium. Up to two-thirds of such tumours are located in the head of the pancreas. Tumours in the head of the pancreas often obstruct the pancreatic segment of the bile duct early in the course of disease, leading to obstructive jaundice. The appearance of a dilated common bile duct and main pancreatic duct on cross-sectional imaging (the 'double duct' sign) is a characteristic sign in tumours of the pancreatic head. Advanced tumours may invade the adjacent duodenum, causing gastric outlet obstruction and/or the portal or superior mesenteric veins posterior to the neck of the pancreas. A tumour in the body or tail of the gland often grows to a large size before presenting as an abdominal mass or with back pain and weight loss (Yeo et al 2002). Tumours of the uncinate process can cause early involvement of the superior mesenteric vessels and duodenum (O'Sullivan et al 2009). Peripancreatic and pre-aortic lymph nodes may be involved, together with hepatic nodes, in pancreatic head tumours, and splenic hilar nodes may be involved in pancreatic tail tumours.

Surgery for pancreatic head tumours usually involves combined resection of the pancreatic head and duodenum (pancreaticoduodenectomy) because of their shared blood supply. The resectability of the tumour depends on the presence and extent of major vascular involvement, particularly the portal vein and superior mesenteric vessels. An accessory or replaced right hepatic artery (p. 1166) running cranially on the posterior surface of the pancreatic head and behind the supraduodenal segment of the bile duct is at risk of injury during such procedures (Turrini et al 2010). Recognition of this variation and preservation of the artery are essential to maintain the arterial supply to the right lobe of the liver. In distal or total pancreatectomy, spleen-preserving resections are generally undertaken if the underlying pathology does not involve the splenic vein lying in the groove on the posterior surface of the gland, taking care to control the multiple small pancreatic venous tributaries. In duodenum-preserving resection of the pancreatic head, which is sometimes undertaken for chronic pancreatitis and benign pancreatic tumours, it is important to preserve an adequate duodenal blood supply from the pancreaticoduodenal arterial arcades (Kimura

Fig. 69.11 An intraoperative photograph taken during pancreaticoduodenectomy. This patient had coeliac artery stenosis and consequently hypertrophied pancreaticoduodenal arcade arteries (A) provided the arterial supply to the liver. The pancreatic head and duodenum were resected, preserving the arcade. Note the cut stump at the proximal body of the pancreas $(\mathrm{B})$ and the exposed portal/superior mesenteric vein (C). The arcade communicates with the hepatic artery (E) to supply the liver (D). (Courtesy of Mohamed Rela, Global Hospitals, Chennai, India.)
and Nagai 1995). Stenosis of the coeliac artery is common in elderly individuals with atherosclerosis. Here, the arterial blood supply to the liver is provided by the superior mesenteric artery through hypertrophied arteries of the anterior and posterior pancreaticoduodenal arcades. Care should be taken to avoid ligation of these branches during pancreatic surgery since this could cause hepatic ischemia (Fig. 69.11).

The pancreas is usually transplanted along with the kidney (this is termed a simultaneous pancreas-kidney transplant) in patients with end-stage renal disease caused by diabetes mellitus. In selected patients, the pancreas alone can be transplanted to treat poor glycaemic control and hypoglycaemia unawareness (White et al 2009).

Donor pancreas is recovered from deceased donors, usually as part of a multi-organ recovery procedure. The entire pancreas, along with the duodenal C loop (attached to the head of pancreas) and spleen (closely related to the tail of the pancreas), is recovered to prevent damage to the vascular arcades in the pancreaticoduodenal groove and minimize handling of the pancreas during organ recovery (Abu-Elmagd et al 2000). The arterial supply for the pancreas graft is based on the splenic artery and the superior mesenteric artery, both of which should be carefully preserved during the donor operation. Both arteries are reconstructed to a Y-shaped deceased donor iliac artery graft to enable a single arterial anastomosis in the recipient. The venous drainage is through the portal vein. The pancreas graft is implanted heterotopically in the pelvis (not in its normal anatomical position, i.e. the upper retroperitoneum). The reconstructed artery is anastomosed to the external iliac artery. The portal vein of the graft can be anastomosed to either the iliac vein or the superior mesenteric vein of the recipient. Though portal and systemic venous drainage each has its own supporters, there is no evidence regarding the superiority of one technique versus the other (Bazerbachi et al 2012). Drainage of the pancreas exocrine secretions is into the ileum through a duodeno-ileal anastomosis or into the recipient urinary bladder through a duodeno-cystic anastomosis. Complications of the procedure are primarily a result of the damage the delicate pancreas sustains during the organ recovery, storage and transplantation process. Complications include graft pancreatitis, graft necrosis leading to bleeding, thrombosis of vascular anastomoses and sepsis (Delis et al 2004, Troppmann 2010). However, in the majority of patients, pancreas transplantation provides the potential for an insulinfree life and retards the development of diabetes-related complications (Gruessner et al 2012).

The spleen is a large, encapsulated, complex mass of vascular and lymphoid tissue situated in the upper left quadrant of the abdominal cavity between the fundus of the stomach and the diaphragm. It is mainly concerned with phagocytosis and immune responses. Although documented for more than 3,000 years, there are many aspects of the spleen that remain poorly understood. It plays important roles in immunological defence, metabolism and maintenance of circulating blood elements (Petroianu 2011, Tarantino et al 2013; Table 70.1). In the fetus, it is also a major site of haemopoiesis and can resume this role postnatally in certain pathological conditions (Üngör et al 2007). However, it is not essential for life; if the spleen is removed, many of its functions can be assumed by the liver and other tissues of the mononuclear phagocytic system.

The most common clinical manifestations of splenic disorders are splenomegaly and a decrease in the number of cellular elements in the blood (cytopenias). Other clinical manifestations include infections, lassitude and abdominal discomfort (Coetzee 1982, Oguro et al 1993, Petroianu 2011, Tarantino et al 2013). Chronic splenomegaly in children may be associated with growth retardation (Petroianu 2003, Petroianu 1996). The most serious long-term consequence of removal of the spleen is severe sepsis, which carries a $2 \%$ mortality in otherwise healthy adults and an even greater risk of death in children, the elderly, and patients with chronic diseases.

## GROSS ANATOMY

The size and weight of the spleen vary with age and sex, and can also vary slightly in the same individual under different conditions. The adult spleen is usually $9-14 \mathrm{~cm}$ long, $6-8 \mathrm{~cm}$ wide and $3-5 \mathrm{~cm}$ thick, and fits comfortably in the individual's cupped hand. It reaches its largest dimension in puberty and diminishes thereafter (DeLand 1970, Jakobsen and Jakobsen 1997). Although its weight increases during puberty, it is comparatively largest in the young child and tends to diminish in size and weight in old age (Coquet et al 2010, DeLand 1970, Jakobsen and Jakobsen 1997, Scothorne 1985, Skandalakis et al

Table 70.1 Summary of splenic functions

| General functions | Specific functions |
| :--- | :--- |
| Haematological and immunological | Haemopoiesis |
|  | Maturation of blood elements |
|  | Immunoglobulin activation |
|  | Recirculation of T and B lymphocytes |
| Production | Leukocytes |
|  | Peptides |
|  | Immunoglobulins (mainly IgM) |
|  | Opsonins |
|  | Tuftsin |
|  | Properdin |
|  | Complement factors |
|  | Stem cells |
|  | Leukocytes |
|  | Platelets |

1993, Üngör et al 2007). The average adult weight is dependent on the volume of contained blood; emptied of blood, it weighs between 70 and 120 g , whereas in vivo its weight ranges from 150 to 350 g (Nakamura et al 1989, Petroianu 2011, Skandalakis et al 1993).

The shape of the spleen is also variable and mostly determined by its relations to neighbouring structures during development; it often appears as a slightly curved wedge. The superolateral aspect is shaped by the left dome of the diaphragm, and the inferomedial aspect mostly by the neighbouring stomach, left kidney and splenic flexure of the colon. In the fetus, the spleen is lobulated (Ch. 60; Coetzee 1982, Faller 1985, Gupta et al 1976, Petroianu 2011, Scothorne 1985, Skandalakis et al 1993, Üngör et al 2007); the adult spleen usually only retains a notch on its anterior border, although additional surface notches may persist (Mikhail et al 1979).

A splenic lobule that fails to coalesce with the developing spleen can persist as a supernumerary or accessory spleen (also known as a splenunculus; Gupta et al 1976). This fully functional island of splenic tissue is found in approximately $10 \%$ of individuals and may be located in any part of the abdomen, or even outside it, but is most commonly present near the splenic hilum within the gastrosplenic ligament or greater omentum (Faller 1985, Petroianu 2011; Fig. 70.1).

A normal adult spleen is not palpable on abdominal examination. In living supine healthy adults, it is most frequently located between the tenth and twelfth ribs, with its long axis along the eleventh rib (Gupta et al 1976, Mirjalili et al 2012). Its posterior border is approximately 4 cm from the midline at the level of the tenth thoracic vertebral spine and it extends about 3 cm anterior to the mid-axillary line. In the absence of long peritoneal ligaments, it has to triple in size before it becomes palpable below the left costal margin (Mikhail et al 1979, Üngör et al 2007).

## RELATIONS

The spleen has superolateral diaphragmatic and inferomedial visceral surfaces (Fig. 70.2), anterosuperior and posteroinferior borders, and

Fig. 70.2 The visceral surface of the spleen.

Spleens in men are proportionally heavier than those in women. In pathological conditions, the spleen may expand and retain blood; weights rarely exceed 700 g but gigantic spleens exceeding 10 kg have been reported (Coquet et al 2010, DeLand 1970, Jakobsen and Jakobsen 1997, Skandalakis et al 1993). Splenomegaly compresses and displaces adjacent organs, causing abdominal discomfort, dyspepsia, respiratory restriction and difficulty walking (Coetzee 1982, Petroianu 2011).

Fig. 70.1 A supernumerary spleen located in the greater omentum (arrow). Supernumerary spleens are usually isolated and may be connected to the spleen or splenic pedicle by thin vessels.

Fig. 70.3 The posterior relations ('bed') of the spleen. (Adapted from Drake, RL, Vogl, AW, Mitchell, A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

Fig. 70.4 The gross appearance of the spleen in situ. An intra-abdominal image of the spleen (1) and its relation with the stomach (4), liver (3), colon (6), diaphragm (2) and greater omentum (5).
superior and inferior poles. The convex, smooth diaphragmatic surface faces mostly superiorly and laterally, although the posterior part may face posteriorly (Mirjalili et al 2012). The diaphragmatic surface is separated from the left pleural costodiaphragmatic recess, lower lobe of the left lung and the tenth to twelfth left ribs by the underside of the left dome of the diaphragm (Figs 70.3-70.4); splenic inflammation or surgery may lead to a left-sided basal pleural effusion and left lower lobe atelectasis (Petroianu 2011).

The visceral surface is irregular, faces inferomedially towards the abdominal cavity and is marked by gastric, renal and colic impressions. The gastric impression faces anteromedially and is broad and concave where the spleen lies adjacent to the posterior aspect of the fundus, upper body and upper greater curvature of the stomach. It is separated from the stomach by a peritoneal recess, limited by the gastrosplenic ligament. The renal impression is slightly concave and lies on the posteroinferior part of the visceral surface, separated from the gastric impression above by a ridge of splenic tissue and the splenic hilum. It faces inferomedially and slightly backwards, and is related to the upper lateral area of the anterior surface of the left kidney and sometimes to the superior pole of the left suprarenal gland. The colic impression is usually flat; it lies at the inferior pole of the spleen and is related to the splenic flexure of the colon and the phrenicocolic ligament. The hilum
of the spleen is a long fissure pierced by the splenic vessels, nerves and lymphatics, and lies on the visceral surface closer to the posteroinferior border (Petroianu 2011).

The anterosuperior border separates the diaphragmatic surface from the gastric impression and is usually convex. Inferiorly, it may bear one or two notches that have persisted from the lobulated form of the spleen in early fetal life (p. 1064). However, the notch may be absent and is not a completely reliable guide to identification of the spleen during clinical examination. The posteroinferior border separates the renal impression from the diaphragmatic surface and is more rounded and blunt than the anterosuperior border. The superior pole corresponds to the posterior extremity and usually faces the vertebral column. The inferior pole is longer and less angulated than the superior pole and connects the anterosuperior and posteroinferior borders anteriorly; it is related to the colic impression and often lies adjacent to the splenic flexure and phrenicocolic ligament (Petroianu 2011)

The inferior pole of the spleen is particularly at risk of injury from blunt abdominal trauma or during surgical procedures on the stomach, pancreatic tail, left kidney, left suprarenal gland and left colon. Excessive traction of the stomach, transverse colon or greater omentum may tear the splenic capsule and superficial parenchyma by way of their peritoneal attachments, causing bleeding that may be difficult to control (Merchea et al 2012).

## SPLENIC LIGAMENTS

The spleen develops between the two leaves of the dorsal mesogastrium (see Figs 60.6-60.7) and so is almost entirely invested in visceral peritoneum that is firmly adherent to its capsule (Üngör et al 2007). The dorsal mesogastric attachments persist as peritoneal ligaments. Thus, the superior pole of the spleen is connected to the stomach via the gastrosplenic ligament, and to the posterior abdominal wall by a variably developed phrenicosplenic ligament. The inferior pole of the spleen is connected to the posterior abdominal wall by the splenorenal ligament and to the splenic flexure of the colon. The phrenicocolic ligament lies just inferior to the lower pole (Fig. 70.5). Each of these ligaments is made up of two layers of peritoneum containing fat, blood and lymphatic vessels and nerves (Petroianu 2011, Skandalakis et al 1993). The phrenicosplenic ligament runs between the spleen and the peritoneum of the undersurface of the diaphragm. The anterior layer of the splenorenal ligament is continuous with the peritoneum of the posterior wall of the lesser sac over the left kidney, and with the posterior layer of the gastrosplenic ligament at the splenic hilum. The posterior layer of the splenorenal ligament is continuous with the peritoneum over the inferior surface of the diaphragm and anterior surface of the left kidney. The terminal portions of the splenic artery and vein, and, more inferiorly, the tail of the pancreas, lie between the two peritoneal layers of the splenorenal ligament. The tail of the pancreas may be injured during dissection when ligating and dividing the splenic vessels, resulting in bleeding, local pancreatitis and pancreatic fistula formation (Petroianu 2011, Skandalakis et al 1993).

The gastrosplenic ligament is continuous with the phrenicosplenic ligament, the splenic capsule, the gastric serosa and the greater omentum. It contains the short gastric and superior polar arteries, and the left gastroepiploic artery, all of which arise from the splenic artery, and their corresponding veins. During splenectomy or mobilization of the fundus of the stomach, the short gastric vessels must not be ligated too close to the stomach in order to avoid the risk of local gastric necrosis, perforation and their consequences.

The phrenicocolic ligament connects the splenic flexure of the colon to the diaphragm and runs inferior and lateral to the lower pole of the spleen. It is continuous with the peritoneum of the lateral end of the transverse mesocolon at the end of the pancreatic tail, and the splenorenal ligament at the hilum of the spleen (Merchea et al 2012, Skandalakis et al 1993). When the phrenicocolic ligament is being divided, particularly when electrocautery is used, the colon is at risk of injury.

Mobile spleen The length of the peritoneal ligaments associated with the spleen vary; longer ligaments afford the spleen greater mobility, which can stretch its vascular pedicle. This facilitates surgical mobilization but may render the spleen more susceptible to injury from shear forces during trauma.

A floating or wandering spleen is characterized by excessive mobility and migration of the organ outside the left hypochondrium. In such cases, the spleen may undergo torsion or cause bladder or rectal symptoms from local pressure; imaging usually confirms the diagnosis (Fig. 70.6). If surgical treatment is necessary, the spleen is freed from local

Operating on a normal-sized spleen is a relatively straightforward procedure for most surgeons. Mobilization of the spleen requires division of the phrenicocolic, gastrosplenic and phrenicosplenic ligaments. Undue traction on the phrenicocolic ligament during mobilization of the splenic flexure may tear the splenic capsule, causing bleeding (Merchea et al 2012). This is less likely if the phrenicocolic ligament is retracted laterally rather than inferiorly and medially (Merchea et al 2012). The anterosuperior border and anterior diaphragmatic surface of the spleen are often adherent to the greater omentum and care must be taken when retracting the latter. The diaphragmatic surface of the spleen is occasionally adherent to the peritoneum on the undersurface of the diaphragm; these adhesions may follow inflammation of the spleen or be congenital in origin (Petroianu 2011, Skandalakis et al 1993).

Fig. 70.5 The peritoneal connections of the spleen. A, The posterior peritoneal connections, seen as if the spleen has been removed, with the folds fixed in their 'normal' positions. B, The anterior peritoneal connections, seen with the spleen in place, as if the stomach and greater omentum have been removed, with the folds fixed in their 'normal' positions. (Adapted from Drake, RL, Vogl, AW, Mitchell, A (eds), Gray’s Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
adhesions and returned to the left hypochondrium, the surgeon shortening and suturing its ligaments to the diaphragm (McFee et al 1995, Petroianu 2011, Üngör et al 2007).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The spleen is supplied by the splenic artery, one of the most tortuous arteries in the body (Fig. 70.7). The pathophysiology of the tortuosity of this vessel, which may become more pronounced with advancing age, is not understood, although several theories have been proposed (Borley et al 1995, Cortés and Pellico 1988, García-Porrero and Lemes

1988, Liu et al 1996, Pandey et al 2004, Sylvester et al 1995). Almost always, the splenic artery arises from the coeliac trunk, in common with the left gastric and common hepatic arteries. However, it may originate from the common hepatic artery or the left gastric artery, or rarely directly from the aorta either in isolation or as a splenomesenteric trunk (Cortés and Pellico 1988, García-Porrero and Lemes 1988, Liu et al 1996, Pandey et al 2004, Torres 1998, Trubel 1985).

From its origin, the artery runs a little way inferiorly before turning to the left behind the stomach to run horizontally posterior to the upper border of the body and tail of the pancreas. Multiple loops or even coils of the artery appear above the superior border of the pancreas (McFee et al 1995, Pandey et al 2004). The splenic artery courses anterior to the left kidney and left suprarenal gland, and runs in the splenorenal ligament behind or above the tail of the pancreas. In its course, it gives off numerous branches to the pancreas (dorsal pancreatic, greater pancreatic artery, and arteries to the tail) and, near its termination, it gives off the short gastric arteries and the left gastroepiploic artery (Gürleyik et al 2000, Liu et al 1996, Mikhail et al 1979, Pandey et al 2004, Skandalakis et al 1993, Trubel et al 1985, Trubel et al 1988). Additional branches include a posterior gastric artery in $40 \%$ of individuals and small retroperitoneal branches.

The splenic artery varies between 8 and 32 cm in length and its calibre usually exceeds that of the common hepatic and left gastric arteries, ranging from 3 to 12 mm . Splenic artery blood flow is approximately $3 \mathrm{ml} / \mathrm{sec} / 100 \mathrm{~g}$, corresponding to approximately $7 \%$ of cardiac output (Cortés and Pellico 1988, García-Porrero and Lemes 1988, Nakamura et al 1989, Pandey et al 2004, Petroianu 2011, Skandalakis et al 1993, Torres 1998, Trubel et al 1985).

The splenic artery usually divides into two, or occasionally three, branches before entering the hilum of the spleen. The superior and inferior branches are sometimes known as superior and inferior polar arteries; as they enter the hilum they divide into four or five segmental arteries that each supply a segment of splenic tissue. There is relatively little arterial collateral circulation between segments, which means that occlusion of a segmental vessel often leads to infarction of part of the spleen (Cortés and Pellico 1988, García-Porrero and Lemes 1988, Gupta et al 1976, Liu et al 1996, Mikhail et al 1979, Pandey et al 2004, Torres 1998, Trubel al 1985, Trubel et al 1988). Segmental arteries divide within the splenic trabeculae and give rise to follicular arterioles, which are surrounded by a thick lymphoid sheath of white pulp. These feed the sinusoids of the red pulp. There is considerable communication between arterioles (García-Porrero and Lemes 1988, Liu et al 1996, Mikhail et al 1979, Skandalakis et al 1993, Sow et al 1991, Trubel et al 1988).

The superior pole of the spleen gains an additional arterial supply, distinct from the splenic hilar vessels, from the short gastric arteries in the gastrosplenic ligament. These vessels connect the superior pole of the spleen to the gastric fundus and preserve viability of this region of the spleen after ligation of the splenic pedicle (García-Porrero and Lemes 1988, Gürleyik et al 2000, Liu et al 1996, Petroianu 2011, Petroianu and Petroianu 1994, Petroianu et al 1989, Skandalakis et al 1993, Torres 1998, Trubel et al 1988).

## Veins

Blood from the parenchyma of the spleen is collected by trabecular veins. They join to form segmental veins that drain individual splenic segments. In general, there are no anastomoses between intrasegmental venous tributaries. Segmental veins join to form two (superior and inferior) or three (superior, middle and inferior) 'lobar' veins that emerge from the length of the splenic hilum and unite to form the splenic vein within the splenorenal ligament (see Fig. 70.2; Fig. 70.8). Communicating veins may interconnect lobar veins (DeLand 1970, Gupta et al 1980, Liu et al 1996, Par et al 1965, Sow et al 1991).

The splenic vein runs medially below the splenic artery and posterior to the tail and body of the pancreas (see Fig. 69.4 D-G) (Gürleyik et al 2000, Par et al 1965). It crosses the posterior abdominal wall anterior to the left kidney, renal hilum and abdominal aorta, separated from the left sympathetic trunk and left crus of the diaphragm by the left renal vessels, and from the abdominal aorta by the superior mesenteric artery and left renal vein (Gupta et al 1976, Gupta et al 1980, Liu et al 1996, Par et al 1965). It ends posterior to the neck of the pancreas, where it joins the superior mesenteric vein to form the portal vein. Along its course it receives the short gastric veins, left gastroepiploic veins, retroperitoneal veins (Retzius's retroperitoneal venous plexus), pancreatic veins, posterior gastric vein, left gastric vein (occasionally) and the inferior mesenteric vein. Approximately $60 \%$ of portal vein blood flow is derived from the gut and the remainder from the spleen and pancreas

Fig. 70.6 A mobile enlarged spleen located in the left side of the pelvis. A, A computed tomography (CT) scan showing the abnormal location of an enlarged spleen (S). B, A surgical view of the same spleen, which appears congested due to partial obstruction of its venous drainage at the splenic hilum (arrow). Note the lack of restraining peritoneal ligaments.

Fig. 70.7 A, A three-dimensional reconstructed contrast-enhanced CT scan. Key: 1, spleen; 2, liver; 3, kidneys; 4, splenic vein; 5, superior polar vein; 6, portal vein; 7, aorta. B, A splenic digital subtraction arteriogram showing the splenic artery (1) and its branches. Note the primary division of the splenic artery (2) into superior (3) and inferior branches (4). C, An excised spleen demonstrating the hilar vessels.

Superior mesenteric vein

Fig. 70.8 A, A splenoportogram. B, An axial oblique CT slice showing the portal and splenic veins.
(Dawson et al 1986, Gupta et al 1980, Gürleyik et al 2000, Liu et al 1996, Oguro et al 1993, Par et al 1965).

Obstruction to portal or splenic venous drainage leads to reversed venous flow through the splenic vein and its tributaries, resulting in splenomegaly and widespread varices (Petroianu 1988, Petroianu 1992, Petroianu 2011, Petroianu et al 1989, Re et al 1985, Skandalakis et al 1993).

## Lymphatic drainage

Lymphatic drainage begins in the white pulp. Lymphatics travel with the blood vessels towards a lymphatic subcapsular plexus, which drains via larger lymphatic channels to lymph nodes at the splenic hilum and around the tail of the pancreas (Fig. 70.9). From here, lymph drains to suprapancreatic, infrapancreatic and omental lymph nodes, and from there to coeliac nodes and the cisterna chyli.

## INNERVATION

The spleen is innervated by both components of the autonomic nervous system; the sympathetic supply is dominant. Postganglionic sympathetic nerves from the coeliac plexus and parasympathetic nerves from the vagal trunks travel with the splenic vessels (see Fig. 70.9). Sympathetic fibres innervate arteries at least to the trabecular level and have the potential to influence blood flow within the human spleen (Kudoh et al 1979). Unlike in some animals, the motor innervation of the human splenic capsule is largely vestigial; it contains minimal quantities of smooth muscle and therefore does not contract. In contrast, the capsule and parenchyma are innervated by sensory fibres that convey pain. Mild to moderate splenomegaly is often painless but splenic inflammation from infection, infarction (e.g. sickle cell disease, embolization) or abrupt distension of the capsule (e.g. haematoma) may cause severe pain, intensified by inflammation of the overlying parietal peritoneum. Referred pain from the splenic pulp is poorly localized to the epigastrium (Petroianu 2011).

## MICROSTRUCTURE

The spleen contains the largest single mass of lymphoid tissue in the body in direct continuity with the circulation. Splenic parenchyma is divided into two principal regions - white pulp and red pulp named according to the appearance of the cut surface of a fresh spleen (Fig. 70.10).

Fig. 70.10 A section through the spleen. White pulp (W) is present as ovoid areas of basophilic tissue. Red pulp (R) lies between white pulp tissue and consists of splenic sinusoids and intervening cellular cords. Part of the capsule (C) is seen top right, from which trabeculae (T) extend into the splenic tissue. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

## Fibrous framework

The serosa of the peritoneum covers the entire spleen, except at its hilum and where the peritoneal ligaments are attached. The connective tissue capsule, deep to the serosa, is approximately 1.5 mm thick and contains abundant type I collagen fibres and some elastin fibres. It is composed of an outer and inner lamina in which the directions of the collagen fibres differ, so increasing its strength. Numerous trabeculae extend from the capsule into the substance of the spleen, where they branch to form a connective tissue scaffold (Faller 1985, Scothorne 1985). The largest trabeculae enter at the hilum and divide into branches in the splenic pulp, providing conduits for the splenic vessels and nerves (see Fig. 70.10; Figs 70.11-70.12). Within the spleen, these branches become continuous with a delicate network of type III (reticular) collagen fibres that pervades both red and white pulps and is maintained by fibroblasts within its interstices (Gupta et al 1976, Krieken and Velde 1988, Scothorne 1985).

## White pulp

In an adult, white pulp accounts for between $5 \%$ and $20 \%$ of the splenic tissue. Branches of the splenic artery radiate out into the parenchyma of the spleen from the hilum, ramifying within trabeculae. In their terminal few millimetres, their connective tissue adventitia is replaced by a sheath of T lymphocytes, the peri-arteriolar lymphatic sheath (PALS). This is expanded in places by aggregations of B lymphocytes, lymphoid follicles measuring $0.25-1 \mathrm{~mm}$ in diameter and visible to the naked eye on the freshly cut surface of the spleen as white semi-opaque dots, in contrast to the surrounding deep reddish purple of the red pulp. Follicles are usually situated near the terminal branches of arterioles and typically protrude to one side of a vessel, which consequently appears eccentrically placed within the follicle. Arterioles branch laterally within follicles to form a series of parallel terminal arterioles, penicillar arterioles (Krieken and Velde 1988, Scothorne 1985; see Figs 70.10-70.12).

Like peri-arteriolar sheaths, follicles are centres of lymphocyte aggregation and proliferation. After antigenic stimulation, they become sites of intensive B-cell proliferation, developing germinal centres similar to those found in lymph nodes; antigen presentation by follicular dendritic cells is involved in this process. Germinal centres regress when the stimulus abates. Follicles tend to atrophy with advancing age and may be absent in the very elderly (Krieken and Velde 1988, Petroianu 2011, Scothorne 1985; see Figs 70.10-70.12).

## Red pulp

The red pulp constitutes up to $90 \%$ of the total splenic volume and is a unique filtration device that enables the spleen to clear particulate material from the blood as it perfuses the organ (Krieken and Velde 1988, Petroianu 2011, Scothorne 1985; see Fig. 70.11). It contains large numbers of venous sinusoids that ultimately drain into tributaries of the splenic vein. The sinusoids are separated from each other by a fibrocellular network of small bundles of collagen fibres, the reticulum, numerous reticular fibroblasts and splenic macrophages. Seen in two dimensions, these intersinusoidal regions appear as strips of tissue, the splenic cords (see Figs 70.11-70.12), whereas in reality they form a three-dimensional continuum around the venous spaces (Chen 1978, Krieken and Velde 1988, Scothorne 1985, Weiss 1983).

Venous sinusoids are elongated ovoid vessels, approximately $50 \mu \mathrm{~m}$ in diameter, supported externally by circumferential and longitudinal reticular fibres (Krieken and Velde 1988, Scothorne 1985, Weiss 1983), and lined by a characteristic, discontinuous endothelium that is unique to the spleen. The long, narrow endothelial cells are aligned with the long axis of the sinusoid; they are also called stave cells because they resemble the planks in a barrel (see Fig. 70.12). Stave cells are attached to their neighbours at intervals along their length by short stretches of intercellular junctions that alternate with intercellular slits that allow blood cells to squeeze into the lumen of the sinusoid from the surrounding splenic cords. A discontinuous basal lamina is present on the abluminal aspect of the sinus.

Large, stellate fibroblasts - reticular cells - lie around the sinusoids. They synthesize the matrix components of the reticulum, including collagen and proteoglycans, and their cytoplasmic processes help to compartmentalize the reticular space. Blood from the open ends of the capillaries that originate from penicillar arterioles percolates through the reticular spaces within the splenic cords. Macrophages in the spaces remove blood-borne particulate material, including ageing and damaged erythrocytes. If the number of damaged erythrocytes increases, the

Fig. 70.9 The lymph nodes related to the spleen. The pancreas has been rendered partially transparent to visualize the major blood vessels lying posteriorly. The greater curvature of the stomach has been reflected superiorly to expose its posterior surface and the peritoneal lining of the posterior wall of the lesser sac removed. (Courtesy of Dr Andy Petroianu and Dr Iriam Starling.)

In malignant neoplasms of the greater curvature of the stomach, distal pancreas or distal transverse colon, it may be necessary to remove the spleen and tail of the pancreas to achieve a radical resection. In leukaemias and lymphomas, lymphadenopathy of splenic hilar nodes may be found along with splenomegaly during staging investigations (Petroianu 2011).

Fig. 70.11 The microstructure of the spleen (haematoxylin and eosin staining). A, Red pulp covered by the splenic capsule (arrow). B, Trabeculae (arrows) inside the red pulp. Trabecular arterioles (1) and venules (2), containing erythrocytes, are also shown. C, Red pulp (1), marginal or perifollicular zone (2), and white pulp (3) containing a follicular arteriole surrounded by a peri-arteriolar lymphatic sheath (arrow). D, Red pulp containing several sinusoid capillaries (*) with discontinuous endothelial cells and surrounded by macrophages containing phagocytosed particles within their cytoplasm (arrows).

Fig. 70.12 The main features of splenic structure, not to scale. The capsule, trabeculae, reticular fibres and cells, the perivascular lymphoid sheaths and follicles (white pulp), and the cellular cords and venous sinusoids of the red pulp are shown. The 'open' and 'closed' theories of splenic circulation are illustrated; it is likely that most of the circulation is of the open form. The venous sinusoids are lined by specialized endothelial 'stave' cells; the intercellular gaps of these have been over-emphasized for clarity.
reticular cells proliferate and the red pulp expands, causing the spleen to enlarge (Kudoh et al 1979, Scothorne 1985).

## Perifollicular zone

The perifollicular (marginal) zone lies at the interface between the white and red pulp; it is the site where blood is delivered into the red pulp and where many lymphocytes leave the circulation to migrate to their respective T- and B-lymphocyte aggregations in the white pulp. These lymphocytes are more loosely arranged than they are in the white pulp, and are held in a dense network of reticular fibres and cells. The arterioles leaving the white pulp are also surrounded by a small aggregation of macrophages: the peri-arteriolar macrophage sheath (Krieken and Velde 1988, Petroianu 2011, Scothorne 1985; see Fig. 70.11C).

## Splenic microcirculation

Segmental splenic arteries ramify in the trabeculae (trabecular arteries) before tapering to become arterioles that pass through the white pulp and give off penicillar arterioles (García-Porrero and Lemes 1988, Gupta et al 1976, Scothorne 1985). These exit the white pulp and traverse the perifollicular marginal zone before entering the red pulp. Evidence supports a dominantly 'open' circulation in humans, in which blood empties into and percolates slowly through the reticular tissue of the splenic cords before re-entering the vascular lumen through slits in the walls of the venous sinusoids (Cavalli et al 1982, Chen 1978; see Fig. 70.12). From the venous sinusoids, blood collects in venules that unite to form small veins that run within the trabeculae and drain into segmental splenic veins (Cavalli et al 1982, Chen 1978, Petroianu 2011, Scothorne 1985). Some blood probably takes an alternative, 'closed' route and enters the venous sinusoids directly from arterioles and capillaries in the marginal zone. Either way, the blood is exposed to macrophages and the filtering mechanism of the spleen responsible for
removing abnormal and effete cells, blood cell particles, bacteria, parasites and foreign antigens.

## SPLENIC TRAUMA

The spleen is one of the most frequently damaged organs in blunt abdominal trauma (Table 70.2, Fig. 70.15). It is particularly prone to injury during rapid deceleration or compression, and its peritoneal ligaments render it vulnerable to shearing injuries of the parenchyma and splenic vessels. Fractures of the lower left ribs may be associated with blunt injuries (Buntain et al 1988). Traction on peritoneal ligaments or adhesions may lead to inadvertent capsular tears during surgical procedures such as splenic flexure mobilization. There is insufficient evidence to know whether enlarged spleens are at a significantly greater risk of trauma (Skandalakis et al 1993), but this is frequently postulated.

Imaging demonstrates the gross morphology and vascular supply of the spleen, and can also be used to assess splenic function. Imaging modalities include ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), arteriography, splenoportography and scintigraphy (Buntain et al 1988, Merran et al 2007, Nakamura et al 1989, Xu et al 2009; see Figs 70.7-70.8; Fig. 70.13). Cross-sectional imaging is particularly useful for assessing tumours and infiltrations of the spleen. Percutaneous drainage of splenic and perisplenic fluid collections is routinely performed under image guidance, and percutaneous splenic biopsy is being increasingly utilized in diagnosis. Arteriography is essential for selective embolization and the insertion of an arterial stent to treat splenic artery aneurysm. Scintigraphy can be used to investigate splenic phagocytic function by quantifying the uptake of radioactive labelled agents (e.g. ${ }^{99 \mathrm{~m}}$ technetium sulphur colloid or heatdamaged erythrocytes) (Hermann and Winkel 1977, Merran et al 2007, Petroianu 2011, Xu et al 2009).

The numerous causes of splenomegaly may broadly be classified into haematological (e.g. lymphoproliferative, myeloproliferative, erythrocyte disorders); vascular (e.g. portal hypertension); infectious (e.g. viral, bacterial, other); autoimmune; and infiltrative (e.g. storage disorders and tumours) (Cavalli et al 1982, Petroianu 1988, Petroianu 2011, Re et al 1985; Fig. 70.14).

Contrast-enhanced CT imaging is particularly useful in the assessment of splenic trauma. The majority of splenic injuries from blunt abdominal trauma are successfully treated by conservative management. Extensive burst injuries with persistent bleeding or major injuries to the hilar vessels may require splenectomy but various repair techniques are available. With hilar injuries, a subtotal splenectomy, preserving the short gastric vessels and superior pole only, is one option. Minor intraoperative capsular tears may be controlled by the topical application of haemostatic agents and sutures, although direct suture repair is challenging because the splenic pulp is fragile. Arteriography and embolization are additional techniques that can be used to control bleeding or treat vascular lesions (Petroianu 2011).

Most surgical procedures performed on the spleen should start with ligation of the splenic artery at the superior border of the pancreatic tail. This can be difficult in patients with portal hypertension, splenic artery aneurysm, retroperitoneal fibrosis, regional lymphadenopathy or inflammatory conditions. After splenic artery ligation, the spleen becomes softer because most of its contained blood returns to the circulation. Despite the interruption of splenic artery inflow, the superior pole of the spleen continues to be perfused by the short gastric arteries, and the inferior pole may be supplied retrogradely via the left gastroepiploic artery. Ligation and division of the splenic vein should be the last step before removal of the spleen to maximize autotransfusion of blood from the spleen (Liu et al 1996, Petroianu 2011, Petroianu and Petroianu 1994, Petroianu et al 1989, Skandalakis et al 1993, Sow et al 1991).

In partial or subtotal splenectomy, the vessels that supply the part of the spleen to be removed are ligated and divided close to the organ. The devascularized region turns dark blue, demarcating it from the residual viable splenic tissue; the organ is then divided in this plane (Christo and DiDio 1997, Gürleyik et al 2000, Liu et al 1996, Petroianu and Petroianu 1994, Sow et al 1991). Wedge excision leaves two flaps of splenic capsule that can be sutured or stapled to cover the remaining raw parenchyma, after suture of any visible bleeding vessels (Petroianu 2011, Petroianu 1993, Petroianu et al 1989, Petroianu 1988; Fig. 70.16).

If total splenectomy is required to treat splenic trauma, autotransplantation of splenic tissue into the greater omentum or mesentery of the bowel can preserve useful splenic function (see Fig. 70.16). Approximately $20 \%$ of the original splenic mass needs to be transplanted and venous drainage of this tissue must be to the portal venous system to maintain the metabolic and immunological functions of the splenic tissue (Oguro et al 1993, Petroianu 2011).

Total splenectomy has numerous potential consequences. Intraoperatively, bleeding or damage to the pancreas, stomach or colon may occur. Early postoperative complications include left-sided basal pulmonary atelectasis and pleural effusion, subphrenic abscess, transient leukocytosis and thrombocytosis with the risk of thrombotic complications. In the longer term, there is an increased risk of infection (especially from encapsulated bacteria), which may be fatal (Petroianu 2011).

Conservative management of splenic trauma and partial splenectomy now enable splenic function to be preserved in situations where splenectomy would once have been routinely performed. Furthermore, most surgical procedures on the spleen can now be performed laparoscopically, which readily affords inspection of the spleen from all perspectives (Poulin and Thibaut 1993, Sow et al 1991).

## Suprarenal (adrenal) gland

The suprarenal (adrenal) glands lie immediately superior and slightly anterior to the upper pole of each kidney (see Figs 74.5, 62.8). Golden yellow in colour, each gland possesses two functionally and structurally distinct areas: an outer cortex and an inner medulla. The glands are surrounded by perinephric fat enclosed within the renal fascia, and separated from the kidneys by a small amount of fibrous tissue.

The dimensions of the suprarenal glands in adults in vivo have been measured from axial computed tomography (CT) scans (Vincent et al 1994). The mean maximum width of the body of the suprarenal gland is 61 mm (right) and 79 mm (left), and the mean width of each limb of the gland (medial and lateral) is approximately 30 mm . No individual suprarenal limb should measure more than 5 mm in transverse section. In adults, each suprarenal gland weighs approximately 5 g (the medulla contributes about one-tenth of the total weight) and has a volume of approximately $3-6 \mathrm{~cm}^{3}$ (Wang et al 2013).

The glands are macroscopically slightly different in external appearance (Fig. 71.1). The right is pyramidal in shape and has two welldeveloped lower projections (limbs), giving a cross-sectional appearance similar to a three-pointed star. The left gland is more semilunar in

A

Right
Left

B

Right
Left
Fig. 71.1 The suprarenal glands. A, Anterior aspect. B, Posterior aspect.
shape, flattened in the anteroposterior plane and marginally larger than the right. The bulk of the right suprarenal sits on the apex of the right kidney and usually lies slightly higher than the left gland, which lies on the anteromedial aspect of the upper pole of the left kidney.

At birth, the glands are proportionately larger and are approximately one-third the size of the ipsilateral kidney. The cortex of each gland is expanded by a well-developed 'fetal zone', responsible for producing dehydroepiandrosterone (DHEA), the substrate for placental oestrogen, in the fetus. The suprarenal cortex (specifically the fetal zone) reduces in size immediately after birth and the medulla grows comparatively little. By the end of the second postnatal month, the weight of the suprarenal has reduced by more than $50 \%$. The glands begin to grow again by the end of the second year and regain their weight at birth by puberty. There is little further weight increase in adult life.

Small accessory suprarenal nodules, composed mainly of cortical tissue (also known as 'adrenal rests'), may occur in the areolar tissue near the suprarenal glands. They are also occasionally found in the spermatic cord, epididymis or testis in boys (Altin et al 1992), and ovary or broad ligament of the uterus in girls. Ectopic suprarenal tissue may cause diagnostic confusion and is rarely the site of neoplastic change.

## RIGHT SUPRARENAL GLAND

The right suprarenal gland lies posterior to the inferior vena cava, separated from it by only a thin layer of fascia and connective tissue. It also lies posterior to the right lobe of the liver and anterior to the right crus of the diaphragm and superior pole of the right kidney (Fig. 71.2). Its inferior surface or base overlaps the anterosuperior aspect of the upper pole of the right kidney, with the two lower projections (limbs) of the gland straddling the renal tissue. The anterior surface has two distinct facets: a narrow medial facet that lies posterior to the inferior vena cava, and a triangular lateral facet that lies in contact with the bare area of the liver. The lowest part of the anterior surface may be covered by the peritoneal reflection of the inferior layer of the coronary ligament, which also represents the upper recess of the hepatorenal pouch (see Fig. 63.2). Here, the gland lies posterior to the lateral border of the second part of the duodenum. Below the apex, near the anterior border of the gland, the right suprarenal vein emerges from the hilum to join the inferior vena cava. This vein is short, which makes surgical resection of the gland or mobilization of the inferior vena cava potentially hazardous. It may be inadvertently avulsed from the inferior vena cava during surgery or, occasionally, by high-energy deceleration injuries. The posterior surface of the gland is divided into upper and lower areas by a curved transverse ridge. The large upper area is slightly convex and abuts the diaphragm, whereas the small lower area is concave and lies in contact with the superior aspect of the upper pole of the right kidney. The medial border of the gland is thin and lies lateral to the right coeliac ganglion and the right inferior phrenic artery where the artery runs over the right crus of the diaphragm.

## LEFT SUPRARENAL GLAND

The left suprarenal gland is closely applied to the left crus of the diaphragm, separated from it by a thin layer of fascia (see Fig. 71.2). The medial aspect is convex longitudinally, whereas the lateral aspect is concave because it is moulded by the medial surface of the upper pole of the left kidney. The superior border is sharply defined while the inferior surface is more rounded. The upper part of the anterior surface is covered by the peritoneum of the posterior wall of the lesser sac, which separates it from the stomach and sometimes from the posteroinferior border of the spleen. A small lower part of the anterior surface

Fig. 71.2 Magnetic resonance imaging (MRI) of the suprarenal glands. A, Axial T1 weighted MRI. B, Coronal T2 weighted MRI. (Courtesy of Dr Louise Moore, Chelsea \& Westminster Hospital.)
is not covered by peritoneum and lies adjacent to the pancreas and splenic artery. The hilum faces inferiorly from the lower part of the medial aspect. The left suprarenal vein emerges from the hilum and runs inferomedially to join the left renal vein. The posterior surface of the gland is divided by a ridge into a lateral area adjoining the kidney and a smaller medial area that lies in contact with the left crus of the diaphragm. The medial border lies lateral to the left coeliac ganglion and the left inferior phrenic and left gastric arteries, which ascend on the left crus of the diaphragm.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The suprarenal glands have one of the highest arterial flow rates per gram of tissue (up to $5 \mathrm{ml} / \mathrm{g} / \mathrm{min}$ ) (Williams and Leggett 1989). Each gland is supplied by superior, middle and inferior suprarenal arteries, whose main branches may be multiple (Fig. 71.3). They ramify over

Right kidney
Inferior suprarenal artery
Middle suprarenal artery

Fig. 71.3 The arterial supply and venous drainage of the suprarenal glands. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
the capsule before penetrating the gland to form a subcapsular arterial plexus, from which fenestrated sinusoids pass around clustered glomerulosa cells and between the columns in the zona fasciculata to a deep plexus in the zona reticularis. Venules from this plexus pass between medullary chromaffin cells to medullary veins, which they enter between prominent bundles of smooth muscle fibres. Some relatively large arteries bypass this indirect route and pass directly to the medulla (Fig. 71.4). The arterial supply of the suprarenal gland is prone to considerable variation (Manso and DiDio 2000, Dutta 2010); only the main variants will be described here.

## Superior suprarenal arteries

The superior suprarenal artery usually arises from the ipsilateral inferior phrenic artery and passes to the gland as four or five small branches; it may occasionally arise from the abdominal aorta.

## Middle suprarenal arteries

The middle suprarenal artery is usually single, but may be multiple or absent. It often arises from the lateral aspect of the abdominal aorta at around the level of the superior mesenteric artery and ascends slightly over the crura of the diaphragm to anastomose with the other suprarenal arteries on the surface of the gland. The right middle suprarenal artery passes behind the inferior vena cava close to the right coeliac ganglion, whereas the left middle suprarenal artery passes close to the left coeliac ganglion, splenic artery and the superior border of the pancreas. The middle suprarenal artery may originate from either the ipsilateral inferior phrenic or renal artery.

## Inferior suprarenal arteries

The inferior suprarenal arteries often contribute most of the arterial supply to the gland. One or two arteries usually arise from the ipsilateral renal artery, but the inferior suprarenal arteries may originate from either the abdominal aorta or the ipsilateral gonadal artery.

## Veins

Medullary veins emerge from the hilum to form a suprarenal vein, which is usually single. The right vein is very short, and passes directly and horizontally into the posterior aspect of the inferior vena cava. An accessory right suprarenal vein is occasionally present and runs from the hilum superomedially to join the inferior vena cava above the right suprarenal vein. The short course renders the right suprarenal vein(s) vulnerable to injury or even avulsion from the inferior vena cava during surgery if undue traction is applied. The left suprarenal vein is longer and descends medially, anterolateral to the left coeliac ganglion, then passes posterior to the pancreatic body and usually drains into the left renal vein; it may receive the left inferior phrenic vein (Loukas et al 2005). Since the venous drainage from each gland is usually via a single

The cortex is shown at higher magnification to demonstrate the outer capsule (C), the zona glomerulosa (ZG), zona fasciculata (ZF) and zona reticularis (ZR). The boundaries between zones are indistinct and variable. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
vein, infarction of the gland is more likely to be caused by damage to a suprarenal vein than to one of the suprarenal arteries.

Understanding variant suprarenal venous anatomy is important to avoid bleeding during minimally invasive adrenalectomy, particularly in patients with large tumours and phaeochromocytomas. Cadaver studies have shown little variation in suprarenal venous anatomy but suggest that variants are more commonly found on the right (Cesmebasi et al 2014). However, a small clinical series showed that there may be a higher rate of suprarenal vein variants in patients with phaeochromocytoma (Parnaby et al 2008).

Anticipating variant suprarenal venous anatomy is key to minimizing bleeding during laparoscopic adrenalectomy, particularly in patients with large tumours or phaeochromocytomas. Sholten et al (2013) reported variant suprarenal veins in $13 \%$ of individuals undergoing laparoscopic adrenalectomy, more often on the right (17\%) than the left ( $9 \%$ ). Common variants included an absent main suprarenal vein; two or more suprarenal veins draining one side; and veins draining to the inferior phrenic vein or, on the left, to the inferior vena cava.

## Lymphatic drainage

Lymphatic channels within the capsule of the suprarenal gland communicate with subserous lymphatics that drain medially to para-aortic and paracaval nodes (Merklin 1966). A few capsular lymphatics communicate with lymph vessels that pass through the diaphragm.

## INNERVATION

The suprarenal gland, relative to its size, has a greater autonomic supply than any other organ. The nerves are distributed throughout the gland: around blood vessels (regulating blood flow), in the medulla (stimulating the release of catecholamines from chromaffin cells), and in the cortex (where they may influence steroid hormone production; Tóth et al (1997)). A suprarenal plexus lies between the medial aspect of each gland and the coeliac and aorticorenal ganglia. It contains predominantly preganglionic sympathetic fibres that originate in the lower thoracic spinal segments, reach the plexus via branches of the greater splanchnic nerves, and synapse on clusters of large medullary chromaffin cells (which can be regarded as homologous with postganglionic
sympathetic neurones). A smaller proportion of postganglionic sympathetic nerve fibres innervate cortical blood vessels. Other nerve fibres containing a variety of neurotransmitters have been identified within the suprarenal cortex and may be involved in modulating steroid hormone secretion. The cell bodies of afferent nerve fibres arising in the suprarenal medulla are almost all located in dorsal root ganglia, although some lie in vagal ganglia; their precise function is unknown (Mravec 2005).

## MICROSTRUCTURE

In section, the suprarenal gland has an outer cortex, which is yellowish in colour and forms the main mass, and a thin medulla, forming about one-tenth of the gland, which is dark red or greyish, depending on its content of blood (see Fig. 71.4; Fig. 71.5). The medulla is completely enclosed by cortex, except at the hilum. The gland has a thick collagenous capsule from which trabeculae extend deep into the cortex. The capsule contains a rich arterial plexus (see above) that supplies branches to the gland.

## Suprarenal cortex

The suprarenal cortex is composed of a zona glomerulosa, a zona fasciculata and a zona reticularis (see Fig. 71.5). The outer, subcapsular, zona glomerulosa consists of a narrow region of small polyhedral cells arranged in rounded clusters. The cells have deeply staining nuclei and a basophilic cytoplasm containing a few lipid droplets. Ultrastructurally, their cytoplasm displays an abundant smooth endoplasmic reticulum that is typical of steroid-synthesizing cells. The broader, intermediate, zona fasciculata consists of large polyhedral basophilic cells arranged in straight columns, two cells wide, separated by parallel fenestrated venous sinusoids. The cells contain many lipid droplets and large amounts of smooth endoplasmic reticulum. The innermost part of the cortex, the zona reticularis, consists of branching interconnected columns of rounded cells with cytoplasm containing smooth endoplasmic reticulum, numerous lysosomes and aggregates of brown lipofuscin pigment that accumulate with age.

Cortical cells produce several hormones, and the cells of the zonae fasciculata and reticularis are also rich in ascorbic acid. Cells in the zona glomerulosa produce mineralocorticoids, e.g. aldosterone, which regulates electrolyte and water balance; cells in the zona fasciculata produce hormones maintaining carbohydrate balance (glucocorticoids), e.g. cortisol (hydrocortisone); and cells in the zona reticularis produce sex hormones (progesterone, oestrogens and androgens). The suprarenal cortex is essential to life and its complete removal is lethal without replacement therapy. It exerts considerable control over lymphocytes and lymphoid tissue; an increased secretion of corticosteroids can result in a marked reduction in lymphocyte numbers.

The deeper part of the zona fasciculata widens in pregnancy. Cortical atrophy in elderly males is greatest in the same region.

## Suprarenal medulla

The suprarenal medulla is composed of groups and columns of chromaffin cells (phaeochromocytes), separated by wide venous sinusoids and supported by a network of reticular fibres. Chromaffin cells, so called from their colour reaction to dichromate fixatives, form part of the neuroendocrine system and are functionally equivalent to postganglionic sympathetic neurones. They synthesize, store (as granules) and release the catecholamines noradrenaline (norepinephrine) and adrenaline (epinephrine) into the venous sinusoids. Release is under preganglionic sympathetic control, mediated by the sympathetic neurones that occur either singly or in small groups in the medulla.

The majority of chromaffin cells synthesize adrenaline and store it in small granules with a dense core. Less numerous noradrenalinesecreting cells have larger granules with a dense eccentric core. Some cells synthesize both hormones. Chromogranin proteins package catecholamines within the granules, which also contain enkephalins, opiate-like proteins that may have endogenous analgesic effects in some circumstances. All of the cells are large, with large nuclei and basophilic, faintly granular cytoplasm. They form single rows along the venous sinusoids. Sympathetic axon terminals synapse with the chromaffin cells on the surfaces that face away from the sinusoids.

The sinusoids are lined by fenestrated endothelium and drain to the central medullary vein and hilar suprarenal vein. Under normal circumstances, little adrenaline or noradrenaline is released; secretion is increased in response to fear, anger or stress. Unlike the cortex, the suprarenal medulla is not essential to life.

## SUPRARENAL GLAND EXCISION

Removal of one or both of the suprarenal glands may be performed using 'open surgery', which remains the standard of care for patients with adrenocortical carcinoma who require en bloc resection of the
tumour. For other tumours and disorders of the suprarenal gland requiring surgery, minimally invasive techniques are now generally preferred. The original laparoscopic approaches were described in 1992 (transabdominal; Gagner et al 1992) and 1995 (posterior retroperitoneal; Mercan et al 1995). The posterior approach is considered superior on account of its safety, rapidity, avoidance of the peritoneal cavity, and the ability to operate on both sides without repositioning the patient (Morris and Perrier 2012). This has been confirmed in several large cohort studies (Walz et al 2006, Dickson et al 2011).

Nevertheless, conventional laparoscopy has certain disadvantages, such as a two-dimensional view, unstable camera platform, and rigid instrumentation. Robotic surgery is a new and emerging technique now performed in many centres and offers the advantages of a threedimensional stable platform, seven degrees of freedom, and enhanced vision (Taskin and Berber 2013). During the last decade, experience with robotic adrenalectomy has highlighted several facets, including a steep learning curve, no significant reduction in the need to convert to an open procedure, operative complications or blood loss compared to conventional laparoscopy, and longer operative times (although this decreases with experience). Robotic surgery is also more expensive. However, with appropriate patient selection, robotic adrenalectomy can be advantageous. For example, patients with familial suprarenal disorders, who are more likely to have bilateral pathology, require cortical sparing, or have glands that may be difficult to access posteriorly, are particularly good candidates for robotic surgery.

In the posterior retroperitoneal approach, the patient is placed in the prone jack-knife position to open up the interval between the costal margin and iliac crest posteriorly. A small incision is made 2 cm inferior and parallel to the twelfth rib, and the perinephric fascia is entered using blunt dissection or with the aid of laparoscopic visualization. A dissecting balloon is then inserted and inflated under laparoscopic control, after which a 12 mm trocar is inserted into the cavity and $\mathrm{CO}_{2}$ is insufflated up to a pressure of $20-25 \mathrm{mmHg}$. The $0^{\circ}$ laparoscope is replaced by a $45^{\circ}$ telescope, and two additional 5 - or 10 mm ports are inserted medial and lateral to the initial port. Dissection is initiated at the superior aspect of the suprarenal gland and proceeds laterally and then inferiorly. The medial surface of the gland is dissected last and the adrenal vessels isolated and divided either with clips or a harmonic scalpel (Lal and Clark 2010).

Similar steps are taken in the robotic approach. The robot is docked after insertion of the 5 - and 10 mm secondary ports; the robotic grasper is placed in the lateral port and the harmonic scalpel in the medial before proceeding with the dissection.

In obese (or Cushingoid) patients, identification of a relatively normal-sized suprarenal gland can be extremely difficult and timeconsuming. The suprarenal vein emerges from the lower medial border of the gland and is often a very substantial structure. In contrast, the supplying arteries tend to be small and named arteries are often difficult to identify during surgery.

## Development of the urogenital system

## URINARY SYSTEM

The urinary and reproductive systems develop from intermediate mesenchyme and are intimately associated with one another, especially in the earlier stages of their development. The urinary system develops ahead of the reproductive or genital systems.

Intermediate mesenchyme is disposed longitudinally in the trunk, subjacent to the somites (in the folded embryo), at the junction between the splanchnopleuric mesenchyme (adjacent to the gut medially) and the somatopleuric mesenchyme (subjacent to the ectoderm laterally) (Fig. 72.1). In lower vertebrates, intermediate mesenchyme typically develops serial, segmental, epithelial diverticula termed nephrotomes. Each nephrotome encloses a cavity, the nephrocele, which communicates with the coelom through a peritoneal funnel, the nephrostome (Fig. 72.2). The dorsal wall of a nephrotome evaginates as a nephric tubule. The dorsal tips of the cranial nephric tubules bend caudally and fuse to form a longitudinal primary excretory duct, which grows caudally and curves ventrally to open into the cloaca. The more caudally placed, and therefore chronologically later, tubules open secondarily into this duct or into tubular outgrowths from it. Glomeruli, specific arrangements of capillaries and overlying coelomic epithelium, arise from the ventral wall of the nephrocele (internal glomeruli) or the roof of the coelom adjacent to the peritoneal funnels (coelomic or external glomeruli), or in both situations (see Fig. 72.2).

It has been customary to regard the renal excretory system as three organs - the pronephros, mesonephros and metanephros - succeeding each other in time and space, such that the last to develop is retained as the permanent kidney (see Figs 72.1-72.2). However, it is difficult to provide reliable criteria by which to distinguish these stages or to define their precise limits in embryos.

## Pronephros

The intermediate mesenchyme becomes visible in stage 10 embryos and can be distinguished as a nephrogenic cord when 10 somites are present.

A pronephros is present in human embryos only as clusters of cells in the most cranial portions of the nephrogenic cord (see Figs 72.1-72.2). More caudally, similar groups of cells appear and become vesicular. The dorsal ends of the most caudal of the vesicles join the primary excretory duct. Their central ends are connected with the coelomic epithelium by cellular strands, which probably represent rudimentary peritoneal funnels. Glomeruli do not develop in association with these cranially situated nephric tubules, which ultimately disappear. It is doubtful whether external glomeruli develop in human embryos.

## Primary excretory duct

In stage 11 embryos of approximately 14 somites, the primary excretory duct can be seen as a solid rod of cells in the dorsal part of the nephrogenic cord. Its cranial end is about the level of the ninth somite and its caudal tip merges with the undifferentiated mesenchyme of the cord. It differentiates before any nephric tubules and, when the latter appear, it is at first unconnected with them. In older embryos, the duct has lengthened and its caudal end becomes detached from the nephrogenic cord to lie immediately beneath the ectoderm. From this level, it grows caudally, independent of the nephrogenic mesenchyme, and then curves ventrally to reach the wall of the cloaca. It becomes canalized progressively from its caudal end to form a true duct, which opens into the cloaca in embryos at stage 12. Clearly, up to this stage, the name 'duct' is scarcely appropriate.

## Mesonephros

From stage 12, mesonephric tubules, which develop from the intermediate mesenchyme between somite levels 8-20, begin to connect to the primary excretory duct, which is now renamed the mesonephric duct. More caudally, a continuous ridge of nephrogenic mesenchyme extends to the level of somite 24 . The mesonephric tubules (nephrons) are not metameric; there may be two or more mesonephric tubules opposite each somite.

Within the mesonephros, each tubule first appears as a condensation of mesenchyme cells, which epithelialize and form a vesicle. One end

Fig. 72.3 The relative positions of the mesonephros and early gonad in the abdomen in the ambisexual stage of development. The mesonephric and paramesonephric ducts run within the tubal fold to the urogenital sinus.
of the vesicle grows towards and opens into the mesonephric duct, while the other dilates and invaginates. The outer stratum forms the glomerular capsule, while the inner cells differentiate into mesonephric podocytes, which clothe the invaginating capillaries to form a glomerulus. The capillaries are supplied with blood through lateral branches of the aorta. It has been estimated that 70-80 mesonephric tubules and a corresponding number of glomeruli develop. However, these tubules are not all present at the same time; it is rare to find more than 30-40 in an individual embryo because the cranial tubules and glomeruli develop and atrophy before the development of those situated more caudally.

By the end of the sixth week, each mesonephros is an elongated, spindle-shaped organ that projects into the coelomic cavity, one on each side of the dorsal mesentery, from the level of the septum transversum to the third lumbar segment. This whole projection is called the mesonephric ridge, mesonephros or Wolffian body (see Fig. 72.1B-C; Fig. 72.3). It develops subregions, and a gonad develops on its medial surface. There are striking similarities in structure between the mesonephros and the permanent kidney or metanephros, but the mesonephric nephrons lack a segment that corresponds to the descending limb of the loop of Henle. The mesonephros is believed to produce urine by stage 17. A detailed comparison of the development and function of the mesonephros and metanephros in staged human embryos is not available.

In stage 18 embryos (13-17 mm), the mesonephric ridge extends cranially to about the level of rib 9. In both sexes, the cranial end of the mesonephros atrophies; in embryos $20-\mathrm{mm}$ in length (stage 19), a mesonephros is found only in the first three lumbar segments, although it may still possess as many as 26 tubules. The most cranial one or two tubules persist as rostral aberrant ductules (see Fig. 72.13); the succeeding five or six tubules develop into either the efferent ductules of the testis and lobules of the head of the epididymis (male), or the tubules of the epoophoron (female); the caudal tubules form the caudal aberrant ductules and the paradidymis (male), or the paroophoron (female).

## Mesonephric duct

Once mesonephric nephrons connect to the primary excretory duct, it is renamed the mesonephric duct. This runs caudally in the lateral part
of the nephric ridge, and, at the caudal end of the ridge, it projects into the cavity of the coelom in the substance of a mesonephric fold (see Fig. 72.3). As the mesonephric ducts from each side approach the urogenital sinus, the two mesonephric folds fuse, between the bladder ventrally and the rectum dorsally, forming a transverse partition across the cavity of the pelvis, which is somewhat inappropriately called the genital cord (see Fig. 72.3). In the male, the peritoneal fossa between the bladder and the genital cord becomes obliterated, but it persists in the female as the uterovesical pouch. In the male, the mesonephric duct itself becomes the canal of the epididymis, vas deferens and ejaculatory duct.

## Urogenital sinus

The primitive hindgut ends in a cloacal region. This is connected ventrally with a blind-ending diverticulum, the allantois, which is intimately related to the development of the caudal portion of the urinary system. The enteric and allantoic portions of the hindgut are separated by the proliferation of the urorectal septum, a partition of mesenchyme and endoderm in the angle of the junction of hindgut and allantois (Fig. 72.4; see Fig. 72.7). Molecular markers of the urorectal septum mesenchyme, also termed the intercloacal mesenchyme, include Six1 and Six2 (Wang et al 2011, Wang et al 2013). The endodermal epithelium beneath the mesenchyme of the urorectal septum approaches but does not fuse with the cloacal membrane; it effectively divides the membrane into anal (dorsal) and urogenital (ventral) membranes, and the cloacal region into dorsal and ventral portions. The dorsal portion of the cloacal region is the putative rectum. The ventral portion can be further divided into: a cranial vesico-urethral canal, continuous above with the allantoic duct; a middle, narrow channel, the pelvic portion; and a caudal, deep, phallic section, which is closed externally by the urogenital membrane. The second and third parts together constitute the urogenital sinus. The ventral pericloacal mesenchyme contributes to the genital tubercle (Wang et al 2013) (see Fig. 72.20).

## Metanephros

The pronephros and mesonephros are linear structures. They both contain stacks of tubules distributed along the craniocaudal axis of the embryo, an arrangement that results in the production of hypotonic urine. In marked contrast, the tubules in the metanephric kidney are arranged concentrically, and the loops of Henle are directed towards the renal pelvis. This arrangement allows different concentration gradients to develop within the kidney and results in the production of hypertonic urine. Metanephric nephrons do not join with the existing mesonephric duct but with an evagination of that duct, which branches dichotomously to produce a characteristic pattern of collecting ducts.

The metanephric kidney develops from three sources. An evagination of the mesonephric duct, the ureteric bud, and a local condensation of mesenchyme, the metanephric blastema, form the nephric structure (Fig. 72.5). Angiogenic mesenchyme migrates into the metanephric blastema slightly later to produce the glomeruli and vasa recta. It is possible that an intact nerve supply is also required for metanephric kidney induction. The actions of a range of intra- and extracellular factors involved in metanephric development have been presented (Kanwar et al 2004).

An epithelial-mesenchymal interaction between the duct system and the surrounding mesenchyme occurs in both mesonephric and metanephric systems. In the mesonephric kidney, development proceeds in a craniocaudal progression, and cranial nephrons degenerate before caudal ones are produced. In the metanephric kidney, a proportion of the mesenchyme remains as stem cells that continue to divide and which enter the nephrogenic pathway later, when the individual collecting ducts lengthen. The temporal development of the metanephric kidney is patterned radially, such that the outer cortex is the last part to be formed. The following interactions occur in the development of the metanephric kidney (see Fig. 72.5). The ureteric bud undergoes a series of bifurcations within the surrounding metanephric mesenchyme, and forms smaller ureteric ducts. At the same time, the metanephric mesenchyme condenses around the dividing ducts to form S-shaped clusters, which transform into epithelia and fuse with the ureteric ducts at their distal ends. Blood vessels invade the proximal ends of the S-shaped clusters to form vascularized glomeruli.

The ureteric bud bifurcates when it comes into contact with the metanephric blastema in response to extracellular matrix molecules synthesized by the mesenchyme. Both chondroitin sulphate proteoglycan synthesis and chondroitin sulphate glycosaminoglycan processing are necessary for the dichotomous branching of the ureteric bud. In metanephric culture, incubation of fetal kidneys in $\beta$-D-xyloside, an inhibitor of chondroitin sulphate synthesis, dramatically inhibits ureteric bud branching.

Fig. 72.4 The division of the hindgut into urinary and enteric parts: left ventrolateral view of the intraembryonic coelom and corresponding midsagittal sections. A, The early cloaca.
B, Proliferation of the urorectal septum. C, Complete separation of the urethra and anal canal, and position of the perineal body.

Subsequent divisions of the ureteric bud and associated mesenchyme define the gross structure of the kidney and the major and minor calyces, the distal branches of the ureteric ducts that will form the collecting ducts of the kidney. The proximal position of the ureteric bud elongates to form the developing ureter (see Fig. 72.6). As the collecting ducts elongate, the metanephric mesenchyme condenses around them. An adhesion molecule, syndecan, can be detected between the mesenchymal cells in the condensate. The cells switch off expression of neural cell adhesion molecule (N-CAM), fibronectin and collagen I, and start to synthesize liver cell adhesion molecule (L-CAM; also called E cadherin) and the basal lamina constituents, laminin and collagen IV. The mesenchymal clusters are thus converted to small groups of epithelial cells, which undergo complex morphogenetic changes. Each epithelial group elongates, and forms first a comma-shaped, then an S-shaped, body, which continues to elongate and subsequently fuses with a branch of the ureteric duct at its distal end, while expanding as a dilated sac at its proximal end (see Fig. 72.5). The latter involutes, and cells differentiate locally such that the outer cells become the parietal glomerular cells, while the inner ones become visceral epithelial podocytes. The podocytes develop in close proximity to invading capillaries derived from angiogenic mesenchyme outside the nephrogenic mesenchyme. This third source of mesenchyme produces the endothelial and mesangial cells within the glomerulus. The (metanephric-derived) podocytes and
the angiogenic mesenchyme produce fibronectin and other components of the glomerular basement membrane. The isoforms of type-IV collagen within this layer follow a specific programme of maturation as the filtration of macromolecules from the plasma becomes restricted. Although the timing of human development is not the same as other mammalian species, similar growth and transcription factors are thought to underpin kidney development (Chai et al 2013, Batchelder et al 2010, Davidson 2009, Faa et al 2012). A number of genes involved in the development of the renal medulla and vasa recta in the mouse have been identified (Song and Yosypiv 2012). The genetic, epigenetic and in utero environmental factors in the pathogenesis of non-syndromic forms of human congenital anomalies of the kidney and urinary tract (CAKUT) have been considered (Yosypiv 2012).

Platelet-derived growth factor (PDGF) $\beta$-chain and the PDGF receptor $\beta$-subunit (PDGFR $\beta$ ) have been detected in developing human glomeruli between 54 and 109 days' gestation. PDGF $\beta$-chain is localized in the differentiating epithelium of the glomerular vesicle during its comma- and S-shaped stages, while PDGFR $\beta$ is expressed in the undifferentiated metanephric blastema, vascular structures and interstitial cells. Both PDGF $\beta$-chain and PDGFR $\beta$ are expressed by mesangial cells, which may promote further mesangial cell proliferation.

Metanephric mesenchyme will develop successfully in vitro, which makes experimental perturbation of kidney development comparatively

Fig. 72.5 An overview of metanephric kidney development. A, The ureteric bud arises from the mesonephric duct. The metanephric mesenchyme proliferates and separates with each subdivision of the ureteric bud. B, The metanephric mesenchyme converts to epithelia, forming comma- and S-shaped vesicles, which become metanephric nephrons. C, All stages of metanephric development are present concurrently. The most recently formed nephrons are on the outer aspect of the kidney.
easy to evaluate. Early experimental studies demonstrated that other mesenchymal populations, and spinal cord, were able to induce ureteric bud division and metanephric development. Nerves enter the developing kidney very early, travelling along the developing ureter. If developing kidney rudiments are incubated with antisense oligonucleotides, which neutralize nerve growth factor receptor (NGF-R) mRNA, nephrogenesis is completely blocked, suggesting that metanephric mesenchyme induction is a response to innervation. The powerful inductive effect of the spinal cord on metanephric mesenchyme may be a further expression of this phenomenon. All stages of nephron differentiation are present concurrently in the developing metanephric kidney (see Fig. 72.5). Antigens for the brush border of the renal tubule appear when the S-shaped body has formed. They appear first in the inner cortical area. The metanephric kidney is lobulated throughout fetal life, but this condition usually disappears during the first year after birth (see Fig. 72.8). Varying degrees of lobulation occasionally persist throughout life.

The growth of left and right kidneys is well matched during development. Fetal kidney volume increases most during the second trimester in both sexes. For reasons that are not understood, male fetuses show
greater values for renal volume than female fetuses from the third trimester onwards. Kidney weight is lower in infants with a birth weight less than -2 SDs for gestational age, reflecting a decreased number of nephrons. This relative smaller kidney size continues into early childhood and may be a factor in adult kidney pathology (Geelhoed et al 2009).

## Endocrine development of the kidney

The kidney functions not only as an excretory organ, but also as an endocrine organ, secreting hormones that are concerned with renal haemodynamics. Before birth, homeostasis is controlled by the placenta. The fetal kidney produces amniotic fluid. The kidneys of premature babies of less than 36 weeks are immature. They contain incompletely differentiated cortical nephrons, which compromise their ability to maintain homeostasis. Problems of immaturity are further compounded by the effects of hypoxia and asphyxia, which modify renal hormones.

Renal hormones include the renin-angiotensin system, renal prostaglandins, the kallikrein-kinin system and renal dopamine. Renin is found in the smooth muscle cells of arterioles, interlobular arteries and

Fig. 72.6 The development of the urinary part of the urogenital sinus and formation of the trigone of the bladder. A-C, E, Posterior views. D, Male and female, median sagittal sections. (Based on Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)
branches of the renal artery, and has also been described in the distal convoluted tubule cells. Kallikrein has been demonstrated in rat fetal kidney, and prostaglandins have been demonstrated in the renal medulla and renal tubule. Renal dopamine is produced (mainly) by the enzymatic conversion of L -dopa to dopamine in the early segments of the proximal convoluted tubule, and is also sourced locally from dopaminergic nerves. Other renal hormones include an antihypertensive lipid, which is produced in the interstitial cells of the renal medulla, and, possibly, histamine and serotonin. Growth factors produced by human embryonic kidney cells include erythropoietin and interleukin $\beta$ (which stimulate megakaryocyte maturation) and transforming growth factor- $\beta$.

## Ascent of the kidney

The metanephric kidney is initially sacral. As the ureteric outgrowth lengthens, it becomes positioned more and more cranially. The metanephric pelvis lies on a level with the second lumbar vertebra when the embryo reaches a length of about 13 mm . During this period the ascending kidney receives its blood supply sequentially from arteries in its immediate neighbourhood, i.e. the middle sacral and common iliac arteries. The definitive renal artery is not recognizable until the beginning of the third month. It arises from the most caudal of the three suprarenal arteries, all of which represent persistent mesonephric or lateral splanchnic arteries. Additional renal arteries are relatively common, and may enter at the hilum or at the upper or lower pole of the gland - they also represent persistent mesonephric arteries.

## Ureter

The wall of the early ureter is initially highly permeable. Its lumen later becomes obliterated and is subsequently recanalized. Both of these processes begin in intermediate portions of the ureter and proceed cranially and caudally. Recanalization is not associated with metanephric function, but perhaps reflects the rapid elongation of the ureter as the embryo grows. Two fusiform enlargements appear at the lumbar and pelvic levels of the ureter at 5 and 9 months, respectively (the pelvic enlargement is inconstant). As a result, the ureter shows a constriction at its proximal end (pelviureteric region) and another as it crosses the pelvic brim. A third narrowing is always present at its distal end and is related to the growth of the bladder wall.

At first, the distal end of the ureter is connected to the dorsomedial aspect of the mesonephric duct but, as a result of differential growth, this connection comes to lie lateral to the duct.

## Urinary bladder

The urinary bladder develops from the cranial vesico-urethral canal, which is continuous above with the allantoic duct (see Fig. 72.4; Figs 72.6, 72.7). The mesonephric ducts open into the urogenital sinus early in development. The ureters develop as branches of the mesonephric ducts, which attain their own access to the developing bladder, and their orifices open separately into the bladder on the lateral side of the opening of the mesonephric ducts. Later, the two orifices become separated still further and, although the ureter retains its point of entry into the bladder, the mesonephric duct opens into that part of the urogenital sinus that subsequently becomes the prostatic urethra (see Fig. 72.6E).

F

Fig. 72.7 A, The caudal end of a human embryo, 4 weeks, showing the left lateral aspects of the spinal cord, notochord and endodermal cloaca. B, The endodermal cloaca of a human embryo, near the end of the fifth week. Part of the left wall of the cloaca, including the left mesonephric duct, has been removed, together with the adjoining portions of the walls of the developing bladder and rectum. A piece of the ectoderm around the cloacal membrane has been left in situ. A wire is shown passing along the right mesonephric duct into the cloaca. $\mathbf{C}$, The caudal end of a human embryo, 5 weeks, showing the endodermal cloaca. D, The caudal end of a human embryo, 6 weeks. The cloaca is becoming divided by the urorectal septum. E, The caudal end of a female human fetus, $81 / 2-9$ weeks, from the left-hand side, showing structures in and near the median plane. The cloaca is now completely divided into urogenital and intestinal segments. F, Part of the vesico-urethral portion of the endodermal cloaca of a female human fetus, $81 / 2-9$ weeks. The sinus tubercle is the elevation on the posterior wall of the urogenital sinus, caused by the fusion with the paramesonephric ducts.

The remainder of the vesico-urethral canal forms the body of the bladder and urethra, and its apex is prolonged to the umbilicus as a narrow canal, the urachus.

For many years, it was believed that the absorption of the mesonephric ducts into the urogenital sinus contributed a mesodermal epithelium into the endodermal bladder, limited to the trigone and the dorsal wall of the proximal half of the prostatic urethra to the opening of the prostatic utricle and ejaculatory ducts, or its female homologue, the whole female urethral dorsal wall. Antibody labelling and studies on transgenic mice have now demonstrated that the region of the combined ducts close to the urogenital sinus, referred to as the common nephric duct, undergoes local apoptosis as a part of the normal development of the trigone region of the bladder and the establishment of separate entry points for the ureters and mesonephric ducts (Mendelsohn 2009). Retinoic acid is required for ureter insertion into the urogenital sinus (Batourina et al 2005). There is no mesodermal epithelial contribution to the bladder at the trigone. This is further supported by the observations that tissue combination of fetal urogenital sinus mesenchyme with epithelial mesoderm or endoderm produces different outcomes. Tissue recombinant with endoderm gives rise to prostatic epithelium, whereas the same mesenchyme combined with epithelial mesoderm forms seminal vesicle epithelium. Trigone epithelium differentiates into prostatic epithelium, confirming an endoderm lineage (Tanaka et al 2010).

The previous mechanism for trigone development also suggested that the muscle in that region derived from the ureter and contributed to the valve-like entry point that prevents urinary reflux. Studies have now shown that the ureter passes through a tunnel in the bladder wall in parallel with blood vessels. Such a tunnel forms even in the absence of ureters (Viana et al 2007). Study of smooth muscle progenitors shows that the bulk of the trigone derives from bladder muscle (detrusor), with a limited contribution from ureteral longitudinal smooth muscle fibres at the lateral edges. Eponymous muscle such as Mercier's bar and Bell's muscle, which were thought to arise from the ureter, are derived from bladder muscle (Viana et al 2007).

Bladder filling and emptying cycles are required for normal bladder remodelling during fetal development; in this process, detrusor smooth muscle cells undergo cyclical apoptosis and proliferation. Mechanical stretching promotes proliferation. Bladders in which the fluid is diverted do not show this cycle, and do not enlarge or undergo normal remodelling; the detrusor stops growing, producing a low-volume, lowcompliance bladder, although the serosal connective tissues continue to expand (Wei et al 2012). As yet, there is little information on the development of bladder interstitial cells of Cajal, which are present within detrusor, bladder microvessels and the mucosal lamina propria (Johnston et al 2010).

## Ultrasound antenatal imaging of the urinary system

The fetal bladder may be identified by ultrasound examination at 9-11 weeks' gestation in transverse and sagittal section. Filling and emptying over a 30-45 minute cycle can be demonstrated. The absence of a bladder image at 13 weeks or later is considered abnormal. At 20 weeks, the kidneys are best visualized in a section of the abdomen caudal to that used for abdominal circumference estimation. The diameter of the renal pelvis is reported in the anterior posterior view; 7 mm or less is considered normal at mid-gestation (To and Periera 2015).

The routine use of ultrasound as an aid to in utero diagnosis of abnormalities has revealed a prevalence of 1-2 abnormal fetuses per 1000 ultrasound procedures, of which $20-30 \%$ are anomalies of the genitourinary tract, detectable as early as 12-15 weeks' gestation. The decision to be made after such a finding is by no means clear. Urinary obstruction is considered an abnormality, yet transient modest obstruction is considered normal during canalization of the urinary tract, and has been reported in $10-20 \%$ of fetuses in the third trimester. A delay in canalization, or in the rupture of the cloacal membrane, can produce a dilation. Similarly, the closure of the urachus at 32 weeks may be associated with high-resistance outflow for the system, which again produces transient obstruction. Distension of the fetal bladder, which may indicate lower urinary tract obstruction, affects $2.2 / 10,000$ births, more commonly in males (Hodges et al 2009, Dias et al 2014). Over half of such cases are caused by the development of posterior urethral valves (a congenitally obstructing posterior urethral membrane); there may also be a dilated posterior urethra and thickened bladder wall.

## Neonatal urinary system

At full-term parturition, the two kidneys weigh approximately 23 g . They function early in development and produce the amniotic fluid that surrounds the fetus. The lobulated appearance of fetal kidneys is still

Fig. 72.8 The posterior abdominal wall of a full-term neonate. Note the lobulated kidneys and relatively wide calibre of the ureters.
present at birth (Fig. 72.8; see Fig. 14.6C). Addition of new cortical nephrons continues in the first few months of postnatal life, after which general growth of the glomeruli and tubules results in the disappearance of lobulation. The renal blood flow is lower in the neonate; adult values are attained by the end of the first year. The glomerular filtration rate at birth is approximately $30 \%$ of the adult value, which is attained by 3-5 months of age.

The neonatal urinary bladder is egg-shaped and the larger end is directed downwards and backwards (Figs 72.9-72.10; see Figs 14.6B14.7). Although described as an abdominal organ, nearly one-half of the neonatal bladder lies below a line drawn from the promontory of the sacrum to the upper edge of the pubic symphysis, i.e. within the cavity of the true pelvis. From the bladder neck, the bladder extends anteriorly and slightly upwards in close contact with the pubis, until it reaches the anterior abdominal wall. The apex of the contracted bladder lies at a point midway between the pubis and the umbilicus. When the bladder is filled with urine, the apex may extend up to the level of the umbilicus. It is therefore possible to obtain urine by inserting a needle, connected to a syringe, into the bladder through the abdominal wall about 2 cm above the pubic symphysis, and then aspirating the contents into the sterile syringe. The success rate of the procedure is variable and depends on the bladder being full; a much higher success rate has been reported by using an ultrasound scanner to locate the bladder and confirm that it contains urine prior to insertion of the needle.

There is no true fundus in the fetal bladder as there is in the adult. Although the anterior surface is not covered with peritoneum, peritoneum extends posteriorly as low as the level of the urethral orifice. Because the apex of the bladder is relatively high, pressure on the lower abdominal wall will express urine from an infant bladder. Moreover, because the bladder remains connected to the umbilicus by the obliterated remains of the urachus (see Fig. 14.7), stimulation of the umbilicus can initiate micturition in babies. The elongated shape of the bladder in neonates means that the ureters are correspondingly reduced in length and they lack a pelvic portion. The bladder does not gain its adult, pelvic, position until about the sixth year. A distinct interureteric fold is present in the contracted neonatal bladder.

## Anomalies of the urinary system

Congenital anomalies of the kidney and urinary tract are relatively common (3-6\% of live births) (Yosypiv 2012). Renal agenesis is the absence of one or both kidneys. In unilateral renal agenesis, the remaining kidney exhibits compensatory hypertrophy and produces a nearly normal functional mass of renal tissue. Atresia of the ureter during development causes a non-functional multicystic dysplastic kidney, thought to be secondary to urinary obstruction being present while the tubules are still forming. Problems with kidney ascent can result in a pelvic kidney. Alternatively, the kidneys may fuse together at their caudal poles, producing a horseshoe kidney, which cannot ascend out of the pelvic cavity because the inferior mesenteric artery prevents further migration. A duplex kidney arises when two ureteric buds meet

Fig. 72.11 Bladder exstrophy. Misalignment of the genital tubercle and urogenital swellings with the urogenital membrane during early development results in subsequent malposition of the bladder, urethra and associated sphincters. The disappearance of the urogenital membrane exposes the posterior wall of the bladder, and the urethral opening is on the superior side of the penis or clitoris. (Redrawn from Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)
the metanephros; it is characterized by two pelvicalyceal systems and is associated with ureterocele, ectopic insertion of the ureter, and vesicoureteric reflux

It was thought that renal cysts arose from clumps of vesicular cells, which persisted when the tips of branches from the ureteric diverticulum failed to fuse with metanephrogenic cap tissue. It is now believed that they are wide dilations of a part of otherwise continuous nephrons. In most cases, autosomal dominant polycystic kidney disease results from mutations of PKD1 or PKD2 genes, which are expressed in human embryos from 5-6 weeks of development within the mesonephros and later the metanephros (Chauvet et al 2002). In this condition, the cystic dilation may affect any part of the nephron, from Bowman's capsule to collecting tubules. Less common is infantile cystic renal disease, inherited as a recessive trait, in which the proximal and distal tubules are dilated to some degree but the collecting ducts are grossly affected.

There is evidence that infants born small for gestational date retain smaller kidneys throughout childhood. A causal relationship between low birth weight and later chronic kidney disease is speculated, as well as susceptibility to hypertension in adult life (White et al 2009)

Anomalies of the ventral body wall caudal to the umbilicus, especially with inappropriate siting of the genital tubercle, can result in exstrophy of the bladder (Fig. 72.11) (Suzuki et al 2009, Williams 2013). In this condition, the urorectal septum (internal) is associated with the genital tubercle (external), which means that the urogenital and anal membranes are widely separated. When the urogenital membrane involutes, the posterior surface of the bladder is exposed to the anterior abdominal wall. The lower part of the abdominal wall is, therefore, occupied by an irregularly oval area, covered with mucous membrane, on which the two ureters open. The periphery of this extroverted area, which is covered by urothelium, becomes continuous with the skin.

The volume of amniotic fluid is used as an indicator of renal function but, because other sources produce amniotic fluid in early gestation, amniotic volume does not reflect fetal urinary output until the second trimester (see p. 179). Too little amniotic fluid is termed oligohydramnios; too much, polyhydramnios. Although variation in the amount of amniotic fluid may suggest anomalies of either the gut or the kidneys, it is not always possible to correlate even severe oligohydramnios with renal dysfunction. There is an important relationship between the volume of amniotic fluid, lung development and maturity, and oligohydramnios has been shown to be associated with pulmonary hypoplasia (Ch. 52).

## REPRODUCTIVE SYSTEM

Development of the reproductive organs from the intermediate mesenchyme starts from stage 14 , about 10 days later than the urinary system. Bilateral paramesonephric (Müllerian) ducts develop alongside the mesonephric ducts, and the midportion of each mesonephros undergoes thickening to form the gonadal ridge. Although the primordial
germ cells are delineated very early in development, they are sequestered in the extraembryonic tissues until the gonadal ridge is ready to receive them. It was thought that development to one or other sexual phenotype occurred after migration of the primordial germ cells to the indifferent gonads. However, it is now recognized that the development of male or female gonads, genital ducts and external genitalia is far more complicated, and is the result of a complex interplay between genetic expression, timing of development and the influence of sex hormones. As development proceeds, a significant proportion of early embryonic urinary tissue is incorporated into the reproductive tracts, especially in the male. The earliest stage of reproductive development, prior to the arrival of the primordial germ cells into the gonad, is termed the indifferent or ambisexual stage.

## Early gonadal development (ambisexual or indifferent stage)

Essentially, four different cell lineages contribute to the gonads. Cells are derived from: proliferating coelomic epithelium on the medial side of the mesonephros; underlying mesonephric mesenchyme; invading angiogenic mesenchyme already present in the mesonephros; and primordial germ cells that arise from the epiblast very early in development and later migrate from the allantoic wall.

The formation of the gonads is first indicated by the appearance of an area of thickened coelomic epithelium on the medial side of the mesonephric ridge in the fifth week, stage 16 (Figs 72.12-72.13; see Fig. 72.16). Elsewhere on the surface of the ridge, the coelomic epithelium is one or two cells thick, but over this gonadal area it becomes multilayered. Thickening rapidly extends in a longitudinal direction until it covers nearly the whole of the medial surface of the ridge. The thickened epithelium continues to proliferate, displacing the renal corpuscles of the mesonephros in a dorsolateral direction, and forms a projection into the coelomic cavity: the gonadal ridge. Surface depressions form along the limits of the ridge, which is, thus, connected to the mesonephros by a broad mesentery, the mesogenitale. In this way, the mesonephric ridge becomes subdivided into a lateral part - the tubal fold, containing the mesonephric and paramesonephric ducts, and a medial part - the gonadal fold. The tubal fold also contains the nephric tubules and glomeruli at its base (see Fig. 72.3)

Up to the seventh week, the ambisexual gonad possesses no sexually differentiating feature. From stage 16, the proliferating coelomic epithelium forms a number of cellular epithelial cords (sometimes called primary sex cords), separated by mesenchyme. The cords remain at the periphery of the primordium and form a cortex. Proliferation and labyrinthine cellular condensation of the mesonephric mesenchyme, including angiogenic mesenchyme, produce a central medulla.

## Reproductive ducts

The paramesonephric, Müllerian, ducts develop in embryos of both sexes, but become dominant in the development of the female reproductive system. They are not detectable until the embryo reaches a length of $10-12 \mathrm{~mm}$ (early sixth week). Each begins as a linear invagination of the coelomic epithelium, the paramesonephric groove, on the

Fig. 72.13 A, The indifferent or ambisexual stage of development. B, Male. The mesonephric ducts are retained (left) and the paramesonephric ducts involute (right). C, Female. The paramesonephric (Müllerian) ducts are retained (right) and the mesonephric ducts involute (left).
lateral aspect of the mesonephric ridge near its cranial end. The blind caudal end continues to grow caudally into the substance of the ridge as a solid rod of cells, which becomes canalized as it lengthens. Throughout the extent of the mesonephros, it is lateral to the mesonephric duct, which acts as a guide for it. The paramesonephric duct reaches the
caudal end of the mesonephros in the eighth week. It turns medially and crosses ventral to the mesonephric duct to enter the genital cord, where it bends caudally in close apposition with its fellow from the opposite side (see Fig. 72.13). The two ducts reach the dorsal wall of the urogenital sinus during the third month, and their blind ends
produce an elevation called the Müllerian or sinus tubercle (see Figs 72.7F, 72.19).

At the end of the indifferent stage, each paramesonephric duct consists of vertical cranial and caudal parts and an intermediate horizontal region. The mesonephric ducts course caudally, medial to the paramesonephric ducts, and both duct systems open into the urogenital sinus. The genital ducts possess an external serosa on some surfaces, derived from coelomic epithelium; a smooth muscle muscularis, derived from underlying mesenchyme; and an internal mucosa, derived either from the mesonephric duct or from the invaginated tube of coelomic epithelium that forms the paramesonephic duct. The layers are invaded by angiogenic mesenchyme and by nerves.

## Uterus and uterine tubes

In the female, the mesonephric duct is vestigial. Cranially, it becomes the longitudinal duct of the epoophoron, while, caudally, it is referred to as Gartner's duct (Table 72.1). The cranial part of the paramesonephric ducts forms the uterine tubes, and the original coelomic invagination remains as the pelvic opening of the tube. The fimbriae become

defined as the cranial end of the mesonephros degenerates. The caudal vertical parts of the two ducts fuse with each other to form the uterovaginal primordium (Fig. 72.14). This gives rise to the lower part of the uterus, and, as it enlarges, it takes in the horizontal parts to form the fundus and most of the body of the adult uterus. A constriction between the body of the uterus and the cervix can be found at 9 weeks. The stroma of the endometrium and the uterine musculature develop from the surrounding mesenchyme of the genital cord.

Failure of fusion of the two paramesonephric ducts can lead to a range of anomalies summarized in Figure 72.15. These fusions can also contribute to anomalies of vaginal development.

At birth, the uterus is $2.5-5 \mathrm{~cm}$ long (average 3.5 cm ), 2 cm wide between the uterine tubes, and a little over 1 cm thick (see Figs 72.9, 14.6C-14.7). The body of the uterus is smaller than the uterine cervix, which forms two-thirds or more of the length. The isthmus between the body and the cervix is absent. The fetal female reproductive tract is affected by maternal hormones and undergoes some enlargement in the fetus. The endocervical glands are active before birth and the cervical canal is usually filled with mucus. The uterus is relatively large at birth and, subsequently, involutes to about one-third of its length and more than half of its weight; it does not regain its neonatal size and weight until puberty. The uterine tubes are relatively short and wide.

The position of the uterus in the pelvic cavity depends, to a great extent, on the state of the bladder anteriorly and the rectum posteriorly. If the bladder contains only a small amount of urine, the uterus may be anteverted but it is often in a direct line with the vagina (see Figs 72.9, 72.19).

## Vagina

At approximately 60 mm crown-rump (CR) length, an epithelial proliferation, the sinuvaginal bulb, arises from the dorsal wall of the urogenital sinus in the region of the sinus tubercle (see Figs 72.7F, 72.14B). Its origin marks the site of the future hymen. The proliferation gradually extends cranially as a solid, anteroposteriorly flattened plate inside the tubular condensation of the uterovaginal primordium, which will, eventually, become the fibromuscular vaginal wall. The caudal tip of the paramesonephric duct epithelium recedes until, at about 140 mm (CR), its junction with the epithelial proliferation lies in the cervical canal.

Starting from its caudal end and gradually extending cranially through its whole extent, the solid plate formed by the sinus proliferation enlarges into a cylindrical structure. After this, the central cells desquamate to establish the vaginal lumen. As the upper end of the vaginal plate enlarges, it grows up to embrace the cervix, and then is excavated to produce the vaginal fornices. The boundary of origin of the vaginal mucosa, between the epithelial contribution of the paramesonephric ducts and the sinuvaginal bulb, has been defined in the mouse (Kurita 2010, Kurita 2011). Anomalies of paramesonephric duct fusion can produce related vaginal anomalies (see Fig. 72.15). The

urogenital sinus undergoes relative shortening craniocaudally to form the vestibule, which opens on the surface through the cleft between the genital folds. The lower end of the vaginal plate grows caudally so that, in 109 mm embryos, the vaginal rudiment approaches the vestibule. In fetuses of 162 mm , the vaginal lumen is complete, except at the cephalic end, where the fornices are still solid; they are hollow by 170 mm . At approximately halfway through gestation ( 180 mm ), the genital canal is continuous with the exterior. During the later months of fetal life, the vaginal epithelium is greatly hypertrophied, apparently under the influence of maternal hormones, but, after birth, it assumes the inactive form of childhood.

In the neonate, the vagina is $2.5-3.5 \mathrm{~cm}$ long and 1.5 cm wide at the fornices, and the uterine cervix extends into the vagina for about 1 cm . The posterior vaginal wall is longer than the anterior wall, giving the vagina a distinct curve (see Figs 72.9, 72.19, 14.7). The cavity is filled with longitudinal columns covered with a thick layer of cornified, stratified, squamous epithelium. These cells slough off after birth, when the effect exerted by maternal hormones is removed.

The orifice of the vagina is surrounded by a thick, elliptical ring of connective tissue: the hymen. During childhood, the hymen becomes a membranous fold along the posterior margin of the vaginal lumen. Should the fold form a complete diaphragm across the vaginal lumen, it is termed an imperforate hymenal membrane.

## Reproductive ducts in the male

In the male, most of the paramesonephric ducts atrophy (see Fig. 72.13) under the influence of anti-Müllerian hormone (AMH; also called Müllerian inhibiting substance, or MIS), which is released into the mesonephric duct by the Sertoli cells of the testis. It is thought that the epithelial cells of the paramesonephric duct initially undergo apoptosis
and also that, once the epithelial cells no longer secrete a basal lamina, the remaining ductal epithelial cells transform into mesenchyme that remains in the vicinity of the involuting duct (Allard et al 2000). Vestigial remnants of the paramesonephric ducts are most likely to persist cranially and/or caudally, at the limits of the local exocrine effects of AMH. A vestige of the cranial end of the duct persists as the appendix testis (see Figs 72.13, 72.19; see Table 72.1). The fused caudal ends of the two ducts are connected to the wall of the urogenital sinus by a solid utricular cord of cells, which soon merges with a proliferation of sinus epithelium, the sinu-utricular cord. The latter is similar to, but less extensive than, the sinus proliferation in the female. The proliferating epithelium is claimed to be an intermingling of the endoderm of the urogenital sinus with the lining epithelia of the mesonephric and paramesonephric ducts, which have extended on to the surface of the sinus tubercle. As the sinu-utricular cord grows, so the utricular cord recedes from the tubercle. In the second half of fetal life, the composite cord acquires a lumen and becomes dilated to form the prostatic utricle, the lining of which consists of hyperplastic stratified squamous epithelium. The sinus tubercle becomes the colliculus seminalis.

The main reproductive ducts in the male are derived from the mesonephric ducts; the latter persist under the action of androgens that are probably secreted down the ducts themselves, and are subsumed into the male reproductive system as the metanephric kidney develops. The mesonephric duct gives rise to the canal of the epididymis, vas deferens and ejaculatory duct. The seminal vesicle and the ampulla of the vas deferens appear as a common swelling at the end of the mesonephric duct during the end of the third and into the fourth months. Their appearance coincides with degeneration of the paramesonephric ducts, although no causal relation between the two events has been established. Separation into two rudiments occurs at about 125 mm crownheel length. The seminal vesicle elongates, its duct is delineated and hollow diverticula bud from its wall. Around the sixth month ( 300 mm crown-heel length), the growth rate of both vesicle and ampulla is greatly increased. Figure 72.10 shows the position of the ampulla of the vas deferens in the neonate, possibly in response to increased secretion of prolactin by the fetal or maternal hypophysis, or to the effects of placental hormones. The tubules of the prostate show a similar increase in growth rate at this time.

## Primordial germ cells

The primordial germ cells are formed very early from the epiblast (see Fig. 10.3). They are larger ( $12-20 \mu \mathrm{~m}$ in diameter) than most somatic cells, and are characterized by vesicular nuclei with well-defined nuclear membranes, and by a tendency to retain yolk inclusions long after these have disappeared from somatic cells. It is not yet clear whether the primordial germ cells are derived from particular blastomeres during cleavage, if they constitute a clonal line from a single blastomere, or if they are the product of a progressive concentration of the nucleus of the fertilized ovum by unequal partition at successive mitoses. Primordial germ cells spend the early stages of development within the extraembryonic tissues near the end of the primitive streak and in the connecting stalk (see Fig. 10.4). In this situation, they are away from the inductive influences to which the majority of the somatic cells are subjected during early development.

Primordial germ cells can be identified in human embryos in stage 11 , when the number of cells is probably not more than 20-30. When the tail fold has formed, they appear within the endoderm and the splanchnopleuric mesenchyme and epithelium of the hindgut, as well as in the adjoining region of the wall of the yolk sac. They migrate dorsocranially in the mesentery, by amoeboid movements and by growth displacement, and pass around the dorsal angles of the coelom (medial coelomic bays) to reach the genital ridges from stage 15 (see Fig. 72.16). It is believed that the genital ridges exert long-range effects on the migrating primordial germ cells, in terms of controlling their direction of migration and supporting the primordial germ-cell population. Primordial germ cells contact each other via long processes and retain cytoplasmic bridges when they divide. They are usually in close proximity to somatic cells, which may modify the local environment, forming junctional complexes with them. The surface of primordial germ cells displays binding sites for extracellular matrix macromolecules. A range of molecular markers associated with the migration and proliferation of primordial germ cells has been described (Soto-Suazo and Zorn 2005, Runyan et al 2006, De Felici 2013).

Primordial germ cells proliferate both during and after migration to the mesonephric ridges. Cells that do not complete this migration mainly degenerate, but if they survive, they can give rise to germ cell tumours, usually in the midline (Runyan et al 2006). After segregation, when they are often termed primary gonocytes, they divide to form secondary gonocytes.

Fig. 72.16 The development of the gonads and associated ducts, as seen in transverse section, to show the fate of the primordial germ cells, mesonephric duct and tubules, and paramesonephric duct in males and females. (Modified with permission from Williams PL, Wendell-Smith CP, Treadgold S 1969 Basic Human Embryology, 2nd edn, London, Pitman Medical \& Scientific.)

## Development of the gonads

The factors that lead to formation of either testis or ovary are described below and in Figure 72.16. The morphological events that occur in each type of gonadal development are presented first.

## Testis

Most studies support the hypothesis that the seminiferous tubules are formed from cords of epithelial cells derived from the proliferating coelomic epithelium (see Figs 72.13, 72.16). The cords lengthen, partly by addition from the coelomic epithelium, and encroach on the medulla, where they unite with a network of cells derived from the mesonephric mesenchyme destined to become the rete testis. Primordial germ cells are incorporated into the cords, which later become enlarged and canalized to form the seminiferous tubules. The cells derived from the surface of the early gonad form the supporting Sertoli cells. The latter proliferate throughout fetal and early postnatal life (less than 6 months) and perhaps again at puberty initiation (Sharpe et al 2003); when they stop dividing, they mature and cannot be reactivated. Each Sertoli cell can only support a fixed number of germ cells during their development into spermatozoa, i.e. the number of Sertoli cells produced at this time determines the maximal limit of sperm output (Sharpe et al 2003). Because the germ cells make up the bulk of the adult testis, the number of Sertoli cells is a major determinant of the size to which the testes will grow (factors that impair the process of spermatogenesis, resulting in the loss of germ cells, will also affect testicular size). Variation in Sertoli cell number is probably the most important factor in accounting for the enormous variation in sperm counts between individual men, whether fertile or infertile. Indeed, the available data for adult men indicate that Sertoli cell numbers vary across a fifty-fold range (Sharpe et al 2003). Although some of this variation may result from attrition of Sertoli cell numbers because of ageing, the major differences in Sertoli cell numbers will have been determined by events in fetal and/or childhood life.

The interstitial cells of the testis are derived from mesenchyme and, possibly, also from coelomic epithelial cells that do not become incorporated into the tubules. Among other cell lines, they form the embryonic and fetal cells of Leydig, which secrete testosterone and insulin-like factor 3 (Insl3). A later migration of mesenchyme beneath the coelomic epithelium forms the tunica albuginea of the testis.

The cords of the rete testis become connected to the glomerular capsules in the persisting part of the mesonephros. Ultimately, they become connected to the mesonephric duct by the 5-12 most cranial persisting mesonephric tubules. These become exceedingly convoluted and form the lobules of the head of the epididymis. The mesonephric duct, which was the primitive 'ureter' of the mesonephros, becomes the canal of the epididymis and the vas deferens of the testis. The seminiferous tubules do not acquire lumina until the seventh month; the tubules of the testicular rete become canalized somewhat earlier.

Disorders of development of the testis and reproductive tract in the male fetus seem to be increasing in incidence. Testicular maldescent (cryptorchidism) and hypospadias appear to have doubled or trebled in incidence in the last 30-50 years, while testicular cancer has increased by an even greater margin and is now the most common cancer of young men. Although testicular cancer is primarily a disease of young men ( $95 \%$ of cases affect 15 - to 45 -year-old males), it is now established that this age incidence reflects activation of premalignant carcinoma-insitu (CIS) cells, which are present at birth and which almost certainly arise during fetal life. It is now accepted that CIS cells are primordial germ cells/gonocytes that have failed to complete differentiation into spermatogenic germ cells (Rajpert-De Meyts 2006). Anomalies of development of the testis and reproductive tract (e.g. gonadal dysgenesis, cryptorchidism, small testes) are important risk factors for the development of testicular germ cell cancer. However, the most dramatic change that appears to have occurred in the relatively recent past is a fall in sperm counts of around $40-50 \%$ ( $1 \%$ per year over the last 50 years). Although this dramatic decrease is obviously manifest only in adulthood, as is the case with testicular cancer there is growing evidence that it may reflect impaired testicular development during fetal or childhood life (Dean and Sharpe 2013).

## Ovary

The ovary develops from the middle part of the gonadal ridge only. The cranial part of the gonadal ridge becomes the suspensory ligament of the ovary (infundibulopelvic fold of peritoneum), and its caudal region is incorporated into the ovarian ligament.

The ovary closely resembles the testis early in development, except that its characteristically female features are slower to differentiate (see Figs 72.13, 72.16). Few, if any, of the epithelial cords invade the
medulla. The majority remain in the cortex, where they may be joined by a second proliferation from the coelomic epithelium overlying the gonad. In histological sections of ovaries from the third and subsequent months, the epithelial cords appear as clusters of cells, which may contain primitive germ cells, separated by fine septa of undifferentiated mesenchyme. An ovarian rete condenses in the medullary mesenchyme and some of its cords may join mesonephric glomeruli. The medulla subsequently regresses, and connective tissue and blood vessels from this region invade the cortex to form the ovarian stroma. During this invasion, the clusters of epithelial cortical cells break into individual groups of supporting cells (now identified as granulosa cells), which surround the primordial germ cells (now identified as primary oocytes) that have entered the prophase of the first meiotic division. Primary oocytes are derived from a mitotic division of the primordial germ cells (naked oogonia). Their epithelial capsules consist of flattened pregranulosa cells derived from proliferations of coelomic epithelium. The ovary now has its full complement of primary oocytes. The majority undergo atresia, a hormonally controlled apoptotic process, but the remainder resume development after puberty, when they complete the first meiotic division shortly before ovulation. The granulosa cells at this time enlarge and multiply to form the stratum granulosum; as they do so, they become surrounded by thecal cells, which differentiate from the stroma.

There are temporospatial changes within the developing ovary. Neurotropins and their receptors have been shown to be expressed within the fetal ovary between 13 and 21 weeks. NT4 is localized initially in epithelioid cells mingled with oogonia, then within oogonial mRNA, and finally in granulosa cells of the primordial follicles, with lesser expression in the enclosed oocytes (Anderson et al 2002).

Expression of p450c17, a steroidogenic enzyme involved in the production of androgens, has been shown in the human fetal ovary during the second and third trimesters (Cole et al 2006). Its temporospatial expression showed a movement from the cortex to the medulla, with its presence in primary interstitial cells in the cortex from 14 weeks to 23 weeks, but not in hilus interstitial cells; between 27 and 33 weeks, few cells stained for p450c17, but there was an increase after 33 weeks in theca interstitial cells associated with preantral follicles. Positivestaining hilus interstitial cells were rarely seen before 33 weeks. The temporospatial expression was similar in anencephalic fetuses of the same age, indicating that anterior pituitary function is not regulating this maturation. The authors suggest a possible role for insulin in regulating fetal ovary androgen production. It is noted that overexpression of interstitial androgen production is a component in the pathophysiology of polycystic ovary syndrome (Cole et al 2006).

## Sex determination in the embryo

It was believed that the gonads were indifferent or ambisexual until the arrival of the primordial germ cells in the gonadal ridge, at which point the sex of the embryo was 'turned on' by the presence of the male or female germ cells. It is now clear that the germ cells may be essentially irrelevant to testis determination; embryos in which the genital ridges are devoid of germ cells may still undergo otherwise normal testis development. It is not clear if the germ cells are necessary for ovarian determination. They are required for the proper organization and differentiation of the ovary, and their absence results in the development of 'streak gonads', where only lines of follicular cells can be seen, as in Turner's syndrome.

The processes of sex determination and differentiation involve interacting pathways of gene activity, which lead to the total patterning of the embryo as either male or female.

In the current, generally accepted, model of sex determination in humans, the female pathway is considered to be the 'set-up' programme; in other words, this is the course of events that will occur, unless there is modification via differentiation of Sertoli cells, which leads to testis formation. The trigger for the latter is the presence of a Y chromosome, which diverts development into the testicular pathway. The resulting cellular changes convert the indifferent gonad into a testis, which then produces three key hormones (AMH, Insl3 and testosterone), which collectively induce masculinization of the fetus and, thus, acquisition of male secondary sexual characteristics.

The possession of a Y chromosome is usually associated with a male developmental pathway. Deletion mapping of the Y chromosome in a class of XX males arising from abnormal X:Y interchange at meiosis showed that the male-determining region of the chromosome was a conserved sequence located near its tip, termed the testis-determining factor (TDF). This sequence contains a gene that is established to be the 'master switch' that programmes the direction of sexual development, the so-called SRY gene (sex-determining region on the Y chromosome). It is believed to be genetically and functionally equivalent to the TDF.

The SRY gene acts initially within the epithelial cords of cells derived from the coelomic epithelium of the ambisexual gonad. These cells can potentially differentiate into either Sertoli or granulosa cells (the supporting cells for the germ cells in the testis and ovary, respectively). Studies indicate that SRY initiates testis formation from the indifferent gonad by directing the development of supporting-cell precursors as Sertoli rather than granulosa cells (Albrecht and Eicher 2001). Gene expression is seen first in cells designated as pre-Sertoli, located centrally in the developing gonad, and then later in the cranial and caudal poles. Once the developmental pathway of Sertoli cells is directed, this influences the differentiation of the other cell types in the testicular pathway, so that Leydig cells appear later, and the connective tissue becomes organized into a male pattern. The germ cells are also affected by this environment. When they arrive, they become enclosed within the Sertoli cells and do not enter meiosis; they continue to proliferate (which is characteristic of spermatogenesis), instead of ceasing proliferation and entering meiosis and meiotic arrest, as occurs in the ovary. Thus, the development of male characteristics follows the expression of SRY, and female characteristics develop in its absence.

Studies of XY individuals with sex reversal (i.e. XY females) and corresponding gene knockout studies in mice have established that SRY initiates testis development by inducing the expression of another gene, SOX9 (SRY-like HMG-box protein 9), and expression of the latter in the absence of SRY is sufficient for male determination. It is now known that there is a multi-step cascade of gene expression changes that essentially works to reinforce SOX9 expression and, thus, to consolidate development down the male pathway; these genes include WT1 (Wilm's tumour gene), GATA4 (GATA-binding protein 4), FGF9 (fibroblast growth factor 9) and DAX-1 (orphan nuclear receptor DAX-1) (Biason-Lauber 2010, Munger et al 2013). This cascade also actively represses expression of genes that promote development along the female pathway; these include RSPO1 (R-spondin 1), WNT4 (Winglesstype MMTV integration site family member 4) and FOXL2 (Forkhead box L2). In turn, activation of the female cascade of gene expression actively suppresses expression of SOX9 and/or other genes in the 'male cascade'. Therefore, development of either a testis or an ovary results from a reinforcing programme of gene expression changes, and inactivating mutations in any one of these genes, or their aberrant expression in the wrong sex fetus, has the potential to interfere, partially or completely, with normal gonad formation and, thus, with downstream sexual development (Biason-Lauber 2010, Munger et al 2013). However fewer than $50 \%$ of disorders of sex development (DSD) in humans can be explained by alterations in the expression of known genes, such as those listed; this means that more genes and new pathways remain to be discovered, and these may involve completely new mechanisms. Very recently, the first example of sex reversal (in mice) due to an epigenetic change was reported, which resulted from the inactivating mutation of a gene (JMJD1A) involved in histone demethylation of genes, thus allowing their expression (Kuroki et al 2013). Absence of this demethylase prevented normal demethylation of the Sry gene and, thus, failure of its expression in an otherwise normal XY mouse with a normal $S r y$ gene.

Subsequent development of the male phenotype requires fetal secretion of testosterone, AMH and Insl3. Of these, testosterone is the most important, as it has body-wide effects, both on the developing reproductive system/genitalia and on numerous other organs/tissues, including the brain. Also important is the development of the appropriate cytoplasmic testosterone-binding receptor protein (the androgen receptor). Sertoli cells synthesize AMH, which causes the regression of the Müllerian ducts, and Leydig cells produce testosterone, which promotes the development of the mesonephric ducts, sets into process the development of male external genitalia, and sensitizes other tissues to testosterone. Absence of a functional androgen receptor, as occurs in the complete androgen insensitivity syndrome (CAIS), results in XY individuals who have testes and degenerated Müllerian ducts, but cannot respond to the circulating testosterone produced by their testes; they therefore develop female secondary sexual characteristics.

## Descent of the gonads

The gonads develop on the posterior abdominal wall bilaterally along the central portion of the mesonephros. This region receives a rich blood supply, which is directed to the gonads as the mesonephros involutes. Both gonads descend, the testis to lie outside the abdominal cavity, and the ovary to the pelvis; however, they both retain their early blood supply from the dorsal aorta.

## Descent of the testis

The mechanism of testicular descent is not completely understood and, to some extent, remains controversial. Recent evidence suggests that it
involves two phases - transabdominal and inguinoscrotal - which are regulated by distinct morphological and endocrine factors (Barteczko and Jacob 2000).

## Transabdominal phase

Each testis initially lies on the dorsal abdominal wall. As it enlarges, its cranial end degenerates and the remaining organ therefore occupies a more caudal position. It is attached to the mesonephric fold by the mesorchium (the mesogenitale of the undifferentiated gonad), a peritoneal fold that contains the testicular vessels and nerves, and a quantity of undifferentiated mesenchyme. It also acquires a secondary attachment to the ventral abdominal wall, which has a considerable influence on its subsequent movements. At the point where the mesonephric fold bends medially to form the genital cord (see Fig. 72.3), it becomes connected to the lower part of the ventral abdominal wall by an inguinal fold of peritoneum covering a mesenchymal cord, termed the gubernaculum or genito-inguinal ligament (see Figs 72.3, 72.13; Fig. 72.17). The distal end of this cord seems to align to the inguinal part of the milk line which extends from the axilla to the femoral region (see Fig. 53.28). It has been suggested that this line corresponds to the original lateral edge of the embryo, which expresses the apical ectodermal ridges and mesenchymal progress zones of the upper and lower limbs (Hutson 2013, Hutson et al 2014).

Up to about 10 weeks, the gubernaculum in male and female embryos is the same, but then production of Insl3 from the Leydig cells stimulates enlargement (known as the 'swelling reaction') of the gubernaculum in males. This serves to anchor the fetal testis near the future inguinal canal as the abdominal cavity enlarges between 10 and 15 weeks. By comparison, the gubernaculum in females remains thin and subsequently develops into the round ligament (see below). The cranial attachment of the urogenital ridge, known as the cranial suspensory ligament, regresses in males under the action of androgens.

After the midgut loop returns to the abdomen, the anterior abdominal wall inferior to the umbilical cord lengthens. As each umbilical artery runs ventrally from the dorsal to the ventral wall, it pulls up a falciform peritoneal fold, which forms the medial boundary of a peritoneal fossa, the saccus vaginalis of lateral inguinal fossa, into which each testis projects.

## Inguinoscrotal phase

The caudal end of the gubernaculum is initially associated with a specific portion of the milk line of the abdominal wall around which the future inguinal canal is formed by differentiating abdominal wall muscles. An interaction with the mammary line ectoderm and underlying mesenchyme may trigger gubenacular meristematic growth similar to that seen in the progress zone of the limb bud. Between 25 and 35 weeks, the male gubernaculum begins to bulge out from the abdominal muscles and elongate across the pubis and into the scrotum (see Fig. 72.17). An outpocketing of peritoneum, the processus vaginalis, extends into the gubernaculum, hollowing it out so that the proximal part is divided into a crescentic parietal layer within which the cremaster muscle develops, and a central column attached to the epididymis. Elongation of the soft, gelatinous end of the gubernaculum, which, in the early stage, is formed mainly of hyaluronic acid, is controlled by androgens. The exact mechanism mediating elongation in humans is uncertain. In rodent models, there is good evidence that androgens cause sexual dimorphism of the sensory branches of the genitofemoral nerve, which supplies the gubernaculum, the developing cremaster muscle within it, and part of the scrotum. The genital branch of the nerve releases calcitonin gene-related peptide (CGRP), which stimulates growth of the gubernacular tip along a chemotactic gradient to the scrotum.

The testis remains in apposition with the deep inguinal ring, held by the gubernaculum during the fourth to sixth months (Barteczko and Jacob 2000). From 35 weeks the extracellular matrix of the gubernaculum is resorbed and it forms a fibrous attachment to the inside of the scrotum. Testis descent during the inguinoscrotal phase occurs relatively rapidly about the seventh month, the left testis usually descending ahead of the right. It is thought that intra-abdominal pressure acting through the patent processus vaginalis contributes to this migration (Hutson 2012). In full-term male neonates, over $95 \%$ have descended testes, although, in premature babies, descent may not be complete. After descent, the distal processus vaginalis persists as a 'tiny satellite peritoneal cavity' around the testis as the tunica vaginalis, which becomes firmly attached to the surrounding scrotum within a few weeks. The proximal part of the processus vaginalis then obliterates, and there is evidence that this also is controlled by androgens indirectly via CGRP released from the genitofemoral nerve. Both exogenous CGRP and hepatocyte growth factor can cause obliteration in vitro of the

Fig. 72.17 The descent of the testis. The testis is retroperitoneal throughout development. It becomes obliquely orientated during abdominal descent. A, The gubernaculum attached to the lower part of the testis has an abdominal part covered with developing peritoneum, an interstitial part and a distal end embedded in the anterior abdominal wall at the site of the future inguinal canal. B, The gubernaculum swells, becoming similar in width to the testis. The distal-most portion of the gubernaculum bulges into abdominal wall muscles and grows $3-5 \mathrm{~cm}$ over the superior pubic ramus and into the scrotum. A crescentic column of peritoneum, the processus vaginalis, develops in the expanding gubernaculum. $\mathbf{C}$, The testis gains a crescentic covering of visceral and parietal peritoneum (which forms the tunica vaginalis) and muscle and connective tissue layers as it passes through the deep and superficial inguinal rings. The coverings remain around the ductus deferens, whereas the proximal processus vaginalis normally becomes obliterated by 3 weeks after birth. (Based on Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)
processus vaginalis in hernial sacs excised from babies with indirect inguinal hernia.

At birth, the processus vaginalis is narrowed and collapsed, but not necessarily completely obliterated. It remains patent for 2 weeks in nearly $70 \%$ of male infants but, by 3 weeks after birth, it is at least partially obliterated in $80 \%$ of male infants, the left side before the right.

Persistent patency of the processus vaginalis leads to indirect inguinal hernia (widely patent and allowing prolapse of bowel), or hydrocele (narrow patency permitting only intraperitoneal fluid to trickle down into the tunica vaginalis). During obliteration, fluid may trickle only part of the way down the processus vaginalis to produce an encysted hydrocele of the cord. This is a relatively common but transient state and usually resolves completely within a few weeks by further obliteration. Because of perinatal androgen exposure, the spermatic cord and scrotum are relatively large in the neonate, as are the seminal vesicles and adjacent ampullae of the vas deferens.

In aberrant testicular descent, the testis may remain in the abdomen, although this is thought to be uncommon because the hormonal and morphological features of the transabdominal phase are relatively simple. By contrast, the indirect endocrine regulation and complex migratory process of the gubernaculum during the inguinoscrotal phase is frequently abnormal, leading to the testis lying in the inguinal or pubic region in $2-5 \%$ of neonates. Rarely, the testis may lie in the perineum, in the upper part of the thigh or at the root of the penis. The cause for these aberrant locations is unknown but is most likely to be secondary to aberrant migration of the gubernaculum, perhaps caused by a mislocated genitofemoral nerve.

Testes that have descended may not remain within the scrotum if the spermatic cord does not double its length between birth and puberty (Hutson 2013). It is thought that the aetiology of such acquired undescended testes is also linked to that of hydrocele and hernia. Causes may be deficient prenatal and postnatal androgens and inadequate CGRP from the genitofemoral nerve.

Cryptorchidism is common in infants with abdominal wall defects such as bladder exstrophy, exomphalos ( $30 \%$ affected) and gastroschisis
( $15 \%$ affected). It is also seen in myelomeningocoele affecting the upper lumbar spinal cord ( $>30 \%$ affected), although in these latter cases it is not clear whether low abdominal pressure or genitofemoral nucleus dysplasia is the cause (Hutson 2012). Cryptorchidism used to be considered a relatively minor birth defect that was corrected surgically sometime during childhood. It is now considered to be a symptom of testicular dysgenesis syndrome, a spectrum that includes hypospadias, impaired semen quality and testicular germ cell cancer (Toppari et al 2014). Since germ cell numbers decrease rapidly in undescended testes, orchipexy is now undertaken between 6-9 months of postnatal life. Further delay results in impaired testicular catch-up growth in boys: even with early orchipexy, men with bilateral undescended testes are six times more likely to be infertile (Lee and Shortliffe 2014).

## Descent of the ovary

The relative movements of the ovary are less extensive than those of the testis and are not hormonally regulated. Like the testis, the ovary ultimately reaches a lower level than it occupies in the early months of fetal life, but it does not leave the pelvis to enter the inguinal canal, except in certain anomalies. The ovary is connected to the medial aspect of the mesonephric fold by the mesovarium (homologous with the mesorchium), and to the ventral abdominal wall by the inguinal fold (see Fig. 72.13; Fig. 72.18). A mesenchymatous gubernaculum develops in this fold but, as it traverses the mesonephric fold, it acquires an additional attachment to the lateral margin of the uterus near the entrance of the uterine tube. Its lower part, caudal to this uterine attachment, becomes the round ligament of the uterus, and the part cranial to this becomes the ovarian ligament. Collectively, these structures are homologous with the gubernaculum testis in the male (Fig. 72.19). This new uterine attachment may be correlated with the restricted ovarian descent. At first, the ovary is attached to the medial side of the mesonephric fold but, in accordance with the manner in which the two mesonephric folds form the genital cord, it is finally connected to the posterior layer of the broad ligament of the uterus. The gubernacula thus develop in the female, unlike the male, as bilateral fibrous bands or ligaments in the absence of Insl3. They do not extend into the labia

Fig. 72.18 The descent of the ovary. A, An early developing left ovary and uterine tube. B, The start of posterior movement of the ovary. C, The left ovary in its definitive posterior position. D, A sagittal section of the ligaments associated with the ovary, viewed from a left lateral position. (Based on Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)
majora, but end in the connective tissue just external to the external ring of the inguinal canal because, in the absence of androgens, there is no migratory phase analogous to inguinoscrotal migration in the male. The saccus vaginalis is present in the female. Its prolongation into the inguinal canal (sometimes termed the canal of Nuck) is normally completely obliterated, but may remain patent and form the sac of a potential indirect inguinal hernia.

In the neonate, the ovaries lie in the lower part of the iliac fossae. The long axis of the ovary is almost vertical. It becomes temporarily horizontal during descent, but regains the vertical when it reaches the ovarian fossa. The ovaries complete their descent into the ovarian fossae in early childhood. Thus, at birth, the ovary and the lateral end of the corresponding uterine tube lie above the pelvic brim. They do not sink into the lesser pelvis until the latter enlarges sufficiently to contain both of them and the other pelvic viscera, including the bladder. Neonatal ovaries are $1-3.6 \mathrm{~mm}$ long (Stranzinger and Strouse 2008) and their combined weight at birth is 0.3 g , which is relatively large, and much larger than the combined weight of the testes (see Figs 72.9, 14.6C). The ovaries double in weight during the first 6 postnatal weeks. They bear surface furrows, which disappear during the second and third postnatal months. All of the primary oocytes for the reproductive life of a female are present in her ovaries by the end of the first trimester of pregnancy. Of the 7 million primary oocytes estimated to be present at the fifth month of gestation, 1 million remain at birth and 40,000 by puberty; only 400 are ovulated during reproductive life.

## Cloaca and external genitalia

The cloaca is that region at the end of the primitive hindgut that is continuous with the allantois (see Figs 72.4, 72.7). The allantois, a ventral diverticulum, passes into the connecting stalk of the early embryo prior to tail-folding and is then drawn into the body cavity after stage 10. It retains an extension into the connecting stalk, and later into the umbilicus, throughout embryonic life. The cloaca is a slightly dilated cavity lined with endoderm. It is initially connected cranially to
the enteric hindgut, and ventrocaudally is in contact with overlying ectoderm at the cloacal membrane. Proliferation of mesenchyme at the angle of the junction of the hindgut and allantois produces a urorectal septum (intercloacal mesenchyme), which grows caudally, promoting the movement, but not the fusion, of the endodermal epithelium towards the cloacal membrane (Fig. 72.20). The cloaca becomes separated into a presumptive rectum and anal canal dorsally, and a presumptive urinary bladder and urogenital sinus ventrally; the cloacal membrane is divided into anal and urogenital parts, respectively. The nodal centre of division is the site of the future perineal body. The urogenital sinus receives the mesonephric and paramesonephric ducts.

Anomalies of cloacal development may result in a range of defects. In extroversion of the cloaca (ectopia cloacae), the urorectal septum does not develop and there is failure of mesenchymal migration around the ventral body wall to support the umbilical cord; this results in a large abdominal defect with a central colonic portion and bilateral bladder components. With only partial development of the urorectal septum, the urogenital sinus may remain with a high confluence of bladder, vagina and rectum. The cloacal membrane may be abnormally elongated and prematurely ruptured throughout its whole extent, prior to the formation of the urorectal septum, or, in some cases, there may be only a small sinus opening externally at the skin. The anal musculature is often present but not associated with the anal canal.

## Pelvic floor

The pelvic floor consists of the ligamentous supports of the cervix, and the pelvic and urogenital diaphragms, and constitutes another partition that traverses the body cavity. Little is known about pelvic floor development in the human. The striated muscle is derived from the dermomyotomes in a similar manner to the muscles of the ventrolateral body wall. Puborectalis appears in $20-30 \mathrm{~mm}$ embryos, following opening of the anal membrane, and striated muscle fibres can be seen at 15 weeks. The smooth muscle of the urethral sphincter is also present at this time.

Fig. 72.19 The development of the urogenital system from the indifferent stage to the definitive male and female states. (Modified with permission from Williams PL, Wendell-Smith CP, Treadgold S 1969 Basic Human Embryology, 2nd edn. London, Pitman Medical \& Scientific.)

## Urethra

The urethra is derived from endoderm, as are the prostate gland and vagina (both outgrowths of the lower urogenital sinus), and the other small glandular structures that develop around the caudal body orifices.

In the male, the prostatic urethra proximal to the orifice of the prostatic utricle is derived from the vesico-urethral part of the cloaca and the incorporated caudal ends of the mesonephric ducts. The remainder of the prostatic part, the membranous part, and probably the part within the bulb, are all derived from the urogenital sinus. The anterior urethra, as far as the glans, is formed by canalization of the urethral plate (see below). Secondary ingrowth of mesenchyme fuses the genital folds over the urethra (see Fig. 72.20). The short section within the glans may be formed from ectoderm, which invaginates into the glans.

In the female, the urethra is derived entirely from the vesico-urethral region of the cloaca, including the dorsal region derived from the mesonephric ducts. It is homologous with the part of the prostatic urethra proximal to the orifices of the prostatic utricle and the ejaculatory ducts. The region of the early urethra remains open to form the vestibule, into which the definitive urethra and vagina open (see Fig. 72.20). It is
believed that these regions are invaded by ectoderm because they are innervated by somatic nerves.

Urethral defects caused by anomalous development are not uncommon in the male. In epispadias, the urethra opens on the dorsal aspect of the penis at its junction with the anterior abdominal wall. This anomaly is considered to be a less severe form of exstrophy of the bladder. In the simplest form of hypospadias, related to incomplete canalization of the urethral plate, the urethra may open on the ventral (perineal) aspect of the penis at the base of the glans, and the part of the urethra that is normally within the glans is absent. In more severe cases, the genital folds fail to fuse, and the urethra opens on the ventral aspect of a malformed penis just in front of the scrotum. A still greater degree of this anomaly is accompanied by failure of the genital swellings to unite with each other. In these cases, the scrotum is divided and, since the testes are also frequently undescended, the resemblance to the labia majora is very striking, leading to genital ambiguity. In such cases, it is important to determine at the earliest time not only the chromosomal status of the infant but also the internal anatomy and state of development of the internal genital tract. Sex assignment and rearing will depend on these factors.

Fig. 72.20 The development of the external genitalia from the indifferent stage to the definitive male and female states.

The urethral sphincter first forms as a mesenchymal condensation around the urethra in $12-15 \mathrm{~mm}$ (stage 18) embryos, after division of the cloaca. The mesenchyme proliferates and becomes defined at the bladder neck in 31 mm embryos, and along the anterior part of the urethra by 69 mm . The muscle fibres differentiate after 15 weeks' development, at which time both smooth and striated fibres are present. In females, there is continuity between the smooth muscle of the urethral wall and of the bladder. In males, the muscle fibres are less abundant because of the local development of the prostate. Striated muscle fibres form around the smooth muscle, initially in the anterior wall of the urethra, and later encircle the smooth muscle layer. The origin of the striated muscle is not known; it could be derived from the myogenic cells that give rise to puborectalis. The smooth and striated components of the urethral sphincter are closely related, but there is no mixing of fibres as occurs in the anorectal sphincter.

## Prostate gland

The prostate gland arises during the third month from interactions between the urogenital sinus mesenchyme - mesenchyme that was associated with the mesonephric and paramesonephric ducts and the endoderm of the proximal part of the urethra. This region has been termed the Müllerian duct-urogenital sinus junction (Cai 2008). Early outgrowths, some 14-20 in number, arise from the endoderm around the whole circumference of the tube, but mainly on its lateral aspects and excluding the dorsal wall above the utricular plate. They give rise to the outer glandular zone of the prostate. Later outgrowths from the dorsal wall above the mesonephric ducts arise from the epithelium of mixed urogenital, mesonephric and, possibly, paramesonephric origin that covers the cranial end of the sinus tubercle. They produce the internal zone of glandular tissue that appears to be patterned by the mesenchyme that surrounded the lower end of the mesonephric and paramesonephric ducts. The developing gland is affected by the local hormonal environment, as, in response to increased androgens, recombination of female vaginal mesenchyme can direct endodermal epithelium to form prostate gland (Cai 2008). The outgrowths, which are at first solid, branch, become tubular and invade the surrounding mesenchyme. The latter differentiates into smooth muscle, associated blood and lymphatic vessels and connective tissue, and is invaded by autonomic nerves. An early surge in androgens at $8-10$ weeks is associated with endodermal growth, with mesenchymal proliferation occurring later at 12 weeks, when maternal oestrogen levels increase (Cai 2008).

Similar outgrowths occur in the female but remain rudimentary in the absence of androgenic stimulation. The urethral glands correspond to the mucosal glands around the upper part of the prostatic urethra, and the para-urethral glands correspond to the true prostatic glands of the external zone.

The bulbourethral glands in the male, and the greater vestibular glands in the female, arise as diverticula from the epithelial lining of the urogenital sinus.

## External genitalia

Patterning of the external genitalia may be achieved by mechanisms similar to those that pattern the face and limb. In the cranial region, neural crest mesenchyme makes an important contribution to the organization of the pharyngeal arches and the regions around the upper sphincters. Neural crest also arises from the tail-bud region, specifically from a population of cells termed the caudoneural hinge, which share the same molecular markers as the primitive node. The neural tube at this level is derived from a mesenchymal-epithelial transformation of caudoneural hinge cells, which form a cylinder. Neural crest cells delaminate from the dorsal surface of the cylinder in a rostrocaudal direction. It is not known whether neuronal neural crest arising from secondary neurulation processes contributes to the caudal interface between endoderm and ectoderm. Many of the genes controlling external genital development have been identified (Kojima et al 2010, Blaschko et al 2012).

The external genitalia, like the gonads, pass through an indifferent state before distinguishing sexual characters appear (see Fig. 72.20). From stage 13, primordia of the external genitalia, composed of underlying proliferating mesenchyme covered with ectoderm, arise around the cloacal membrane, between the primitive umbilical cord and the caudal limit of the embryo. During stage 15 , the cloacal membrane is divided by the urorectal septum into a cranial urogenital membrane and a caudal anal membrane (see Fig. 72.4). Local ectodermalmesenchymal interactions give rise to the anal sphincter, which will develop even without the presence of the anal canal. A surface elevation, produced by underlying pericloacal mesenchyme, the genital tubercle, appears at the cranial end of the urogenital membrane and two lateral

Fig. 72.21 Scanning electron micrographs of early human external genitalia. A, The indifferent stage in a human embryo, estimated as 42 postovulatory days. B, A human female embryo at 12 weeks' development. The genital folds are not fused. C, A human male embryo at 12 weeks. Fusion of the genital folds has occurred. (Photographs by P Collins.)
ridges, the genital or urethral folds, form each side of the membrane (see Fig. 72.20). The genital tubercle forms a distinct primordium, which will become the glans of either the penis or the clitoris. Elongation of the genital folds and urogenital membrane produces a primitive phallus. As this structure grows, it is described as having a cranial surface analogous to the dorsum of the penis, and a caudal surface analogous to the perineal surface of both sexes. The urogenital sinus, contiguous with the internal aspect of the urogenital membrane, becomes attenuated within the elongating phallus, forming the primitive urethra. The urogenital membrane breaks down at about stage 19, allowing communication of ectoderm and endoderm at the edges of the disrupted membrane and continuity of the urogenital sinus with the amniotic cavity. Urine can escape from the urinary tract from this time. The endodermal layer of the attenuated distal portion of the urogenital sinus, which is now displayed on the caudal aspect of the phallus, is termed the urethral plate. As mesenchyme proliferates within the genital folds, the urethral plate sinks into the body of the phallus, forming a primary urethral groove. The genital folds meet proximally in a transverse ridge immediately ventral to the anal membrane.

While these changes are in progress, two labioscrotal (genital) swellings appear, one on each side of the base of the phallus, and extend caudally, separated from the genital folds by distinct grooves (see Fig. 72.20; Fig. 72.21).

As a general rule, epithelium, which can be touched easily and has a somatic innervation, is derived from ectoderm. In the buccal cavity and pharynx, the ectoderm/endoderm zone is towards the posterior third of the tongue; touch here usually elicits the gag reflex. In the anal canal, the outer portion, distal to the anal valves, is derived from ectoderm and has a somatic innervation, whereas the epithelium proximal to the valves is derived from endoderm and has an autonomic innervation.

Homologies of the parts of the urogenital system are shown in Table 72.1.

## Male genitalia

The growth of male external characteristics is stimulated by androgens regardless of the genetic sex. The male phallus enlarges to form the penis. The genital swellings meet each other ventral to the anus and unite to form the scrotum (see Fig. 72.20). The genital folds fuse with each other from behind forwards, enclosing the phallic part of the urogenital sinus behind to form the bulb of the urethra, and closing the definitive urethral groove in front to form the greater part of the spongiose urethra. Fusion of the folds results in the formation of a median raphe and occurs in such a way that the lining of the postglandular urethra is mainly, perhaps wholly, endodermal in origin, formed by canalization of the urethral plate. Thus, as the phallus lengthens, the urogenital orifice is carried onwards until it reaches the base of the glans at the apex of the penis. From the tip of the phallus, an ingrowth of surface ectoderm occurs within the glans to meet and fuse with the penile urethra. Subsequent canalization of the ectoderm permits a continuation of the urethra within the glans.

The glans and shaft of the penis are recognizable by the third month. The prepuce also begins to develop in the third month, when the primary external orifice of the urethra is still at the base of the glans. A ridge consisting of a mesenchymal core covered by epithelium appears proximal to the neck of the penis and extends forwards over the glans. A solid lamella of epithelium deep to this ridge extends backwards to the base of the glans. The ventral extremities of the ridge curve back-
wards to become continuous with the genital folds at the margins of the urethral orifice. As the urethral folds meet to form the terminal part of the urethra, the ventral horns of the ridge fuse to form the frenulum. The epithelial lamella breaks down over the dorsum and sides of the glans to form the preputial sac, and thus free the prepuce from the surface of the glans. Thereafter, the prepuce grows as a free fold of skin, which covers the terminal part of the glans. Although the prepuce and glans begin to separate from the fifth month in utero, they may still be joined at birth. The preputial sac may not be complete until 6-12 months or more after birth and, even then, the presence of some connecting strands may still interfere with the retractability of the prepuce.

The mesenchymal core of the phallus is comparatively undifferentiated in the first 2 months, but the blastemata of the corpora cavernosa become defined during the third month. Nerves are present in the differentiating mesenchyme from the seventh week. Despite containing less smooth muscle and elastic tissue than the adult, the neonatal penis is capable of erection.

The scrotum is formed by proliferation of the genital swellings. The genital swellings fuse across the midline covering the base of the penis. The testes descend into the scrotum prior to birth. The gelatinous matrix of the gubernaculum is then resorbed and the tunica vaginalis becomes adherent to the connective tissue of the scrotum. In the neonate, the penis and scrotum are relatively large. The scrotum has a broad base that does not narrow until after the first year. Both the septum (i.e. the mesenchyme remaining between the tunica vaginalis on each side) and the walls of the scrotum are relatively thicker than in adults.

## Female genitalia

The female phallus, which exceeds the male in length in the early stages, becomes the clitoris. The genital swellings remain separate as the labia majora and the genital folds also remain separate, forming the labia minora (see Fig. 72.20). The perineal orifice of the urogenital sinus is retained as the cleft between the labia minora, above which the urethra and vagina open. The prepuce of the clitoris develops in the same way as its male homologue. By the fourth month, the female external genitalia can no longer be masculinized by androgens.

At birth, neonatal females have relatively enlarged labia minora, clitoris and labia majora. The labia majora are united by a posterior labial commissure. The distal end of the round ligament of the uterus, the gubernaculum ovarii, ends just outside the external inguinal ring.

There is evidence that in certain tissues, e.g. urogenital sinus and genital swellings, testosterone is converted into $5 \alpha$-dihydrotestosterone. In XY individuals with a genetic deficiency of the enzyme responsible for this conversion, not only functioning testes but also female external genitalia, with an enlarged clitoris and a small vaginal pouch, are present, suggesting that external genital development is under the control of $5 \alpha$-dihydrotestosterone (Kang et al 2014). Such individuals are often raised as girls; however, at puberty the external genitalia become responsive to testosterone, which causes masculinization at this time.

## Disorders of sex development

The acquisition of appropriate gonads, reproductive ducts, external genital structures and matching gender identity occurs through a myriad of complex processes, both local and systemic. Anomalous developmental processes, leading to differences in sex chromosomes, gonadal structure and position, retention of ductal homologues, androgen
insensitivity, androgen excess, and ambivalent external genitalia requiring gender assignment, were previously described as intersexual conditions or hermaphrodism. Such terminology is non-specific, confusing and perceived as potentially pejorative by affected individuals. Advances in the identification of molecular genetic causes of such conditions have led to proposed changes to describe them as 'disorders of sex development ${ }^{\prime}$ (DSD): congenital conditions in which development of chromosomal, gonadal or anatomical sex is atypical (Lee et al 2006). The range of anomalous development and its management by multidisciplinary teams, as well as by the affected family, are comprehensively covered by Arboleda and Vilain (2014).

## Maturation of the reproductive organs at puberty

Until the adolescent growth spurt, the reproductive organs grow very slowly. Generally, the changes occur over a time period termed puberty. The sequence of these events is much less variable than the age at which they take place. The sequence of puberty in girls and boys is shown in Figure 72.22.

In girls, the appearance of the breast bud is usually the first sign of puberty. The uterus and vagina develop simultaneously with the breast. Menarche occurs after the peak of the height spurt; onset is more closely related to radiological than to chronological age. It has been suggested that the menarche occurs as a critical weight of 50 kg is attained, and certainly sports and excessive restriction of diet, which may reduce weight below this level, can cause amenorrhoea in women who were previously menstruating normally. Tall girls reach sexual maturity earlier than short ones, but girls with a late adolescent growth spurt and later puberty are ultimately taller on the average than those who pass through the menarche early, for they have longer to grow. A girl who has begun to menstruate can be predicted to grow a further 7.5 cm at most. Menarche marks a definitive stage of uterine development but does not mean attainment of full reproductive function. Many of the early menstrual cycles may not involve ovulation.

The earliest sign of puberty in boys is the growth of the testes and scrotum. The volume of the testes may be estimated: the average adult volume is 20 ml , and a volume of 6 ml indicates that puberty has started. Later, the penis, prostate and seminal vesicles begin to enlarge. Increased testosterone levels produced by the Leydig cells of the testes promote changes in the larynx, skin and distribution of bodily hair.

Fig. 72.22 The average ages at which maturation events occur in adolescent girls and boys. The figures beneath the bars indicate the range of ages within which each event may begin and end. Figures within the bars indicate the developmental stage. The velocity of the strength spurt peaks later than the height spurt in boys, associated with testosterone and growth hormone levels. It is appreciated that the assessment and interpretation of the strength spurt during puberty is complex (De Ste Croix 2007). ## True pelvis, pelvic floor and perineum

## TRUE PELVIS AND PELVIC FLOOR

The true pelvis is a bowl-shaped structure formed from the sacrum, pubis, ilium, ischium, the ligaments that interconnect these bones, and the muscles that line their inner surfaces. The true pelvis is considered to start at the level of the plane passing through the promontory of the sacrum, the arcuate line on the ilium, the iliopectineal line and the posterior surface of the pubic crest. This plane, or 'inlet', lies at an angle of between $35^{\circ}$ and $50^{\circ}$ up from the horizontal; above this plane, the bony structures are sometimes referred to as the false pelvis. They form part of the walls of the lower abdomen. In children, the width of the pelvic inlet is an age-independent predictor of chest width and thoracic dimensions (Emans et al 2005). The 'outlet' of the true pelvis is formed by the ischiopubic rami, ischial tuberosities, sacrotuberous ligaments and distal sacrum. The bones surround a central pelvic canal that forms a ventrally concave curve (the curve of Carus); in the female, it constitutes the birth canal. The details of the topography of the bony and ligamentous pelvis are considered fully in Chapter 80.

## MUSCLES AND FASCIAE OF THE PELVIS

## Pelvic muscles

The muscles arising within the pelvis form two groups. Piriformis and obturator internus form part of the walls of the pelvis, and are considered primarily as muscles of the lower limb (Fig. 73.1). Levator ani and
ischiococcygeus form the pelvic diaphragm and delineate the lower limit of the true pelvis (Fig. 73.2). The fasciae investing the muscles are continuous with visceral pelvic fascia above, perineal fascia below, and obturator fascia laterally.

## Piriformis

Piriformis forms part of the posterolateral wall of the true pelvis and is attached to the anterior surface of the sacrum, the gluteal surface of the ilium near the posterior inferior iliac spine, the capsule of the adjacent sacroiliac joint and, sometimes, to the upper part of the pelvic surface of the sacrotuberous ligament. It passes out of the pelvis through the greater sciatic foramen above the sacrospinous ligament. Within the pelvis, the posterior surface of the muscle lies against the sacrum, and the anterior surface is related to the rectum (especially on the left), the sacral plexus of nerves and branches of the internal iliac vessels. Piriformis is described in more detail in Chapter 80.

## Obturator internus

Obturator internus and the fascia over its upper, inner (pelvic), surface form part of the anterolateral wall of the true pelvis. It is attached to the structures surrounding the obturator foramen, ischio-pubic ramus, the pelvic surface of the hip bone below and behind the pelvic brim, and the upper part of the greater sciatic foramen. It is also attached to the medial part of the pelvic surface of the obturator membrane. The muscle is covered by a fascial layer, and the muscle fibres can be seen through this semi-transparent membrane from within the pelvis. Specialized portions of the fascia give attachment to some of the fibres of levator ani (tendinous arch of levator ani), so that only the upper

Fig. 73.2 Muscles of the female pelvis. The superior gluteal and obturator vessels and nerves, as well as the pelvic viscera, have been omitted for clarity. (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

Fig. 73.3 Muscles of the female pelvis viewed from above. The sacral nerve roots have been divided close to the sacral foramina. The anorectal junction, vagina and urethra have been divided at the level of the pelvic floor.
portion of obturator internus can be seen from above. The lower portion forms part of the boundaries of the ischio-anal fossa. In the male, the upper portion lies lateral to the bladder, the obturator and vesical vessels, and the obturator nerve. In the female, the attachments of the broad ligament of the uterus, the ovarian end of the uterine tubes and the uterine vessels also lie medial to obturator internus and its fascia.

## Levator ani (pubococcygeus, iliococcygeus and puborectalis)

Levator ani is a broad muscular sheet of variable thickness attached to the internal surface of the pelvis. It forms a large portion of the pelvic floor (Fig. 73.3) (Lawson 1974a, Roberts et al 1988, Wendell-Smith and Wilson 1991). The muscle is subdivided into named portions according to their attachments and the pelvic viscera to which they are related (pubococcygeus, iliococcygeus and puborectalis). These parts are often referred to as separate muscles but the boundaries between each part cannot be easily distinguished and, moreover, they perform many similar physiological functions. Ischiococcygeus (coccygeus) lies immediately cranial to levator ani and is contiguous with it. Pubococcygeus is often subdivided into separate parts according to the pelvic viscera to which each part relates (puboperinealis, puboprostaticus or pubovaginalis, puboanalis, puborectalis). Levator ani arises from each side of the walls of the pelvis along the condensation of the obturator fascia (the tendinous arch of levator ani). Fibres from ischiococcygeus attach to the sacrum and coccyx but the remaining parts of the muscle converge in the midline. Fibres from iliococcygeus join by a partly fibrous intersection and form the iliococcygeal raphe posterior to the anorectal junction. Closer to the anorectal junction, and elsewhere in the pelvic floor, the fibres are more nearly continuous with those of the opposite side, such that the muscle forms a sling (iliococcygeus, puborectalis).

Attachments The attachments for pubococcygeus, iliococcygeus and puborectalis are as follows.

Pubococcygeus Pubococcygeus originates from the posterior aspect of the body of the pubis and passes back almost horizontally. The most medial fibres run directly lateral to the urethra and its sphincter as it passes through the pelvic floor; here, the muscle is correctly called puboperinealis, although, because of its close relationship to the upper half of the urethra in both sexes, it is often referred to as pubourethralis; despite this, no direct connection with the urethra is present. In males, some of these fibres lie lateral and inferior to the prostate and are referred to as puboprostaticus (levator prostatae). In females, fibres run further back and attach to the lateral walls of the vagina, where they are referred to as pubovaginalis. In both sexes, fibres from this part of pubococcygeus attach to the perineal body; a few elements also attach to the anorectal junction. Some fibres, sometimes called puboanalis, decussate and blend with the longitudinal rectal muscle and fascial elements to contribute to the conjoint longitudinal coat of the anal canal. Behind the rectum, other fibres of pubococcygeus form a tendinous intersection as part of the levator raphe. Elements of pubococcygeus (puboperineus, pubovaginalis/puboprostaticus and puboanalis) may collectively be referred to as 'pubovisceralis'.

Iliococcygeus Iliococcygeus is attached to the inner surface of the ischial spine below and anterior to the attachment of ischiococcygeus, and also to the tendinous arch as far forwards as the obturator canal (see Fig. 73.2). The most posterior fibres are attached to the tip of the sacrum and coccyx, but the majority join fibres from the contralateral side to form a raphe that is effectively continuous with the fibroelastic anococcygeal ligament, which is closely applied to its inferior surface; some muscle fibres may attach into the ligament. The raphe provides a strong attachment for the pelvic floor posteriorly and must be divided to allow wide excisions of the anorectal canal during abdominoperineal excisions for malignancy. An accessory slip may arise from the most posterior part and is sometimes referred to as iliosacralis.

Puborectalis Puborectalis lies lateral to pubococcygeus and cannot been seen from inside the pelvis. It originates from the inner surface of the ischiopubic rami immediately adjacent to, and sometimes arising in part from, the perineal membrane. Its fibres pass lateral to those of iliococcygeus and pubococcygeus to decussate posterior to the rectum at the anorectal junction. The border between puborectalis and some fibres of the external anal sphincter is indistinct.

Ischiococcygeus Ischiococcygeus may be referred to as a separate muscle, sometimes named coccygeus. It lies as the most posterosuperior portion of levator ani, and arises as a triangular musculotendinous sheet with its apex attached to the pelvic surface and tip of the ischial spine, and base attached to the lateral margins of the coccyx and the fifth sacral segment. Ischiococcygeus is rarely absent, but may be almost completely tendinous rather than muscular. It lies on the pelvic aspect of the sacrospinous ligament and may be fused with it, particularly if it is mostly tendinous. The sacrospinous ligament may represent either a degenerate part or an aponeurosis of the muscle, since muscle and ligament are coextensive.

Relations The superior, pelvic, surface of levator ani is separated only by fascia (superior pelvic diaphragmatic, visceral and extraperitoneal) from the urinary bladder, prostate or uterus and vagina, rectum and peritoneum. Its inferior, perineal, surface forms the medial wall of the ischio-anal fossa and the superior wall of the anterior recess of the fossa, both being covered by inferior pelvic diaphragmatic fascia. The posterior border is separated from the coccyx by areolar tissue. The medial borders of the two levator muscles and the inferior ischiopubic rami border the levator hiatus, through which pass the urethra, vagina (in the female) and anus. In the female, that portion of the hiatus that lies anterior to the perineal body is referred to as the urogenital hiatus.

Vascular supply Levator ani is supplied by branches of the inferior gluteal, inferior vesical and pudendal arteries.

Innervation The nerves to levator ani originate mainly from the third and fourth sacral spinal segments, with lesser contributions from the second segment. These nerves enter the pelvis just above, and sometimes pierce, ischiococcygeus to pass along the ventral surface of ischiococcygeus and pubococcygeus, supplying these muscles and sending fibres to puborectalis (Sato 1980, Roberts and Krishingner 1967). The
pudendal nerve also may supply pubococcygeus from its lateral surface through its inferior rectal and perineal branches.

Actions Pubococcygeus and puborectalis pull the pelvic and perineal structures ventrally and cranially, occluding the levator hiatus. In the female, this action occludes the vaginal canal and prevents prolapse of the pelvic organs through the urogenital hiatus. The constant baseline activity of the levator muscles is similar to that of the anal sphincter, modulated to adjust to the loads placed on them. The action of puborectalis and pubococcygeus also reinforces the external anal sphincter and helps to create the anorectal angle. Iliococcygeus and, to a lesser extent, the less muscular ischiococcygeus form a relatively horizontal diaphragm, especially in the dorsal half of the pelvis, that assists puborectalis in achieving anorectal and urinary continence.

Levator ani must relax appropriately to permit expulsion of urine and, particularly, faeces; it contracts with the abdominal muscles and the abdominothoracic diaphragm to raise intra-abdominal pressure. It forms much of the muscular pelvic diaphragm, which supports the pelvic viscera. Like the abdominothoracic diaphragm, but unlike the abdominal muscles, levator ani is also active in the inspiratory phase of quiet respiration. In the pregnant female, the shape of the pelvic floor may help to direct the fetal head into the anteroposterior diameter of the pelvic outlet.

## Pelvic fasciae

The pelvic fasciae may be conveniently divided into the parietal pelvic fascia, which forms the coverings of the pelvic muscles, and the visceral pelvic fascia, which forms the coverings of the pelvic organs and their neurovascular supply (Fig. 73.4).

## Parietal pelvic fascia

The parietal pelvic fascia consists of the obturator fascia, the fasciae over piriformis, and over levator ani (the pelvic diaphragm) and the presacral fascia.

## Obturator fascia

The parietal pelvic fascia on the pelvic (medial) surface of obturator internus is well differentiated. In humans, ventral to the lateral attachment of the pelvic organs, a portion of it is derived from the degener-
ated upper portion of the attachment of levator ani. It is connected to the posterior part of the arcuate line of the ilium and is continuous with iliac fascia. Anterior to this, as it follows the line of origin of obturator internus, it is gradually separated from the attachment of the iliac fascia, and a portion of the periosteum of the ilium and pubis spans between them. It arches below the obturator vessels and nerve, investing the obturator canal, and is attached anteriorly to the back of the pubis. Behind the obturator canal, the fascia is markedly aponeurotic and gives a firm attachment to the iliococcygeal portion of levator ani, usually called the tendinous arch of levator ani (arcus tendineus musculi levatoris ani) (see Figs 73.3, 73.14, 73.15). Above the attachment of levator ani, the fascia is thin and is effectively composed only of the epimysium of the muscle and overlying connective tissue; posteriorly, it forms part of the lateral wall of the ischio-anal fossa in the perineum, and anteriorly, it merges with the fasciae of the muscles of the deep perineal space, which is continuous with the ischio-anal fossa. The obturator fascia is continuous with the pelvic periosteum and, thus, the fascia over piriformis.

## Fascia over piriformis

The fascia over the inner aspect of piriformis is very thin, and fuses with the periosteum on the front of the sacrum at the margins of the anterior sacral foramina. It ensheathes the anterior primary rami of the sacral nerves that emerge from these foramina; the nerves are often described as lying behind the fascia. The internal iliac vessels lie in front of the fascia over piriformis; their branches draw out sheaths of the fascia and extraperitoneal tissue into the gluteal region, above and below piriformis.

## Fascia over levator ani (pelvic diaphragm)

Both surfaces of levator ani have a fascial covering; the combination of the two fascial layers and the intervening muscle is called the pelvic diaphragm. On the inferior surface, the thin fascia is continuous with the obturator fascia below the tendinous arch of levator ani laterally. It covers the medial wall of the ischio-anal fossa and blends below with fasciae on the urethral sphincter and the external anal sphincter. The superior fascia of the pelvic diaphragm is markedly thicker than the inferior fascia and is attached anteriorly to the posterior aspect of the body of the pubis, approximately 2 cm above its lower border. It extends laterally across the superior pubic ramus, blending with the

Fig. 73.4 Fasciae of the pelvis and perineum: median sagittal section in the male. The visceral parietal fasciae have been omitted for clarity.
obturator fascia and continuing along an irregular line to the spine of the ischium. It is continuous posteriorly with the fascia over piriformis and the anterior sacrococcygeal ligament. Medially, the superior fascia of the pelvic diaphragm blends with the visceral pelvic fascia to contribute to the endopelvic fascia.

## Tendinous arch of the pelvic fascia/white line of the parietal pelvic fascia

Low on the superomedial aspect of the upper fascia over levator ani, a thick, white band of condensed connective tissue extends from the lower part of the pubic symphysis to the superior margin of the ischial spine. It provides attachment for the condensations of visceral pelvic fascia that provide support to the urethra and bladder, and to the vagina in females (see below).

## Presacral fascia

The presacral fascia forms a hammock-like structure behind the posterior portion of the mesorectal fascia. Laterally, it extends to the origin of the fascia over piriformis and the fascia over levator ani (superior pelvic diaphragmatic fascia), with which it blends; more inferiorly, it extends between the white line of the parietal pelvic fascia on either side. Inferiorly, it extends to the anorectal junction, where it fuses with the posterior aspect of the mesorectal fascia and the iliococcygeal raphe at the level of the anorectal junction. Superiorly, it can be traced to the origin of the superior hypogastric plexus, where it becomes progressively thinner over the sacral promontory and becomes continuous with the retroperitoneal tissues. The right and left hypogastric nerves and inferior hypogastric plexuses lie on its surface, and the presacral veins lie immediately posterior to it. It forms a distinct layer that can be seen both on magnetic resonance images of the pelvis and during surgery. The presacral fascia provides an important landmark because extension of rectal tumours through it significantly reduces the possibility of curative resectional surgery. Dissection in the plane posterior to the fascia may result in bleeding from the presacral veins; because the adventitia of the veins is partly attached to the posterior surface of the fascia, the haemorrhage may be severe (as the veins are unable to contract properly). The presacral fascia is a useful structure to which the rectum may be sutured during rectopexy for rectal prolapse in children.

## Visceral pelvic fascia

The urogenital organs in both sexes are connected bilaterally to the pelvic walls by neurovascular mesenteric condensations ensheathed by a meshwork of loose connective and adipose tissue and lying above the perineal membrane (Roberts et al 1964, Ricci et al 1947, Reiffenstuhl 1982, Range and Woodburne 1964, Campbell 1950). The lateral attachments of the pelvic organs to the pelvic side walls are referred to as the endopelvic fascia. Considered as a unit, the connections provide a conduit for conducting neurovascular elements from the pelvic side wall to the organs and attachments that help to retain the pelvic organs in place; this factor is important in the female in preventing pelvic organ prolapse (DeLancey 1992). The loose connective tissue associated with these mesenteries extends to the midline, separating the bladder from the vagina, and the vagina from the rectum, in the female; it separates the bladder, prostate and seminal vesicles from the rectum in the male. The fascial tissues contain varying amounts of connective tissue and smooth muscle; where they either are unusually dense or form visible ridges, they are called 'ligaments' (e.g. cardinal ligament, uterosacral ligament). Clinically, these lateral attachments are often referred to as visceral 'ligaments', but they are mesenteric in nature and, therefore, quite unlike the bands of dense, regular, connective tissue that typify skeletal ligaments. The lateral attachments of the mesenteries sweep off the pelvic walls, arising from the superior fascia over levator ani and from part of the fascia over piriformis more superiorly and posteriorly. The mesenteries passing to the bladder in the male, or the bladder and upper vagina and uterus in the female, are relatively long, but these lateral connections become shorter towards the pelvic outlet, until at the level of the perineal membrane, there is a direct connection between the organs and the pelvic walls.

In the female, the cardinal ligament is the upper portion of this mesentery. It surrounds the cervicovaginal junction and extends down to mid-vagina, where the vagina has a more direct lateral attachment at the tendinous arch of the pelvic fascia. The portions that attach to the uterus and vagina are sometimes called the parametrium and paracolpium, respectively. Further accounts of the paravisceral portions of the visceral pelvic fascia are given in the chapters describing the organs to which the fascia relates.

The uterosacral ligament is a visible fold of tissue flanking the rectum as it descends posterior to the cervix in the female. It contains a considerable amount of smooth muscle near its attachment to the
cervix, together with some of the pelvic autonomic nerves. A similar vesicosacral fold is present in the male.

Approximately 1 cm above the inferior border of the pubic bone and 1 cm lateral to the midline, a band of dense pelvic connective tissue - the anterior end of the tendinous arch of the pelvic fascia - attaches to the paravaginal tissues in the female and the prostatic tissues in the male. This band extends on the inner surface of levator ani and joins the tendinous arch of levator ani to the ischium, just above the spine. The attachment of the paravaginal tissue to the pubic bones is sometimes called the pubourethral ligament, which is a misnomer since it is not attached to the urethra. The attachment of the anterior vaginal wall to the tendinous arch of the pelvic fascia, the paravaginal attachment, helps to provide support to the vagina, urethra and bladder.

There is much less condensation of connective tissue around the rectum. A layer presumed to be a peritoneal fusion fascia is described between the rectum and either the seminal vesicles in the male or the vagina in the female (the rectovesical septum or rectovaginal septum, respectively); it does not connect to the rectum itself. The connective tissue over the longitudinal muscles of the rectum is thickened just above the anal hiatus in levator ani and fuses with the endopelvic fascia and the anococcygeal ligament, forming a structure that is sometimes referred to as a rectosacral ligament.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE PELVIS

The true pelvis contains the internal iliac arteries and veins, and the lymphatics that drain the majority of the pelvic viscera. The common and external iliac vessels and the lymphatics that drain the lower limb lie along the pelvic brim and in the lower retroperitoneum, but are conveniently discussed together with the vessels of the true pelvis. Remarkable variation exists in the terminal branching pattern for the iliac vessels and no two individuals have quite the same anatomy. General patterns do, however, exist and this description will consider the common pattern.

## Arteries of the pelvis

## Common iliac arteries

The abdominal aorta bifurcates into the right and left common iliac arteries anterolateral to the left side of the body of the fourth lumbar vertebra (Roberts and Krishingner 1967). These arteries diverge as they descend and they divide at the level of the sacroiliac joint into external and internal iliac arteries. The external iliac artery is the principal artery of the lower limb. The internal iliac artery provides the principal supply to the walls and viscera of the pelvis, the perineum and the gluteal region.

Right common iliac artery The right common iliac artery is approximately 5 cm long. It passes obliquely across part of the bodies of the fourth and the fifth lumbar vertebrae, and is crossed anteriorly by the sympathetic rami to the pelvic plexus and, at its division into internal and external iliac arteries, by the ureter. It is covered by the parietal peritoneum, which separates it from the coils of the small intestine. Posteriorly, it is separated from the bodies of the fourth and fifth lumbar vertebrae and their intervening disc by the right sympathetic trunk, the terminal parts of the common iliac veins and the start of the inferior vena cava, the obturator nerve, lumbosacral trunk and iliolumbar artery. Laterally, the inferior vena cava and the right common iliac vein lie superiorly and the right psoas major lies inferiorly. The left common iliac vein is medial to the upper part of the right common iliac artery.

Left common iliac artery The left common iliac artery is shorter than the right and is approximately 4 cm long. Lying anterior to it are the sympathetic rami to the pelvic plexus, the superior rectal artery and, at its terminal bifurcation, the ureter. The sympathetic trunk, the bodies of the fourth and fifth lumbar vertebrae and intervening disc, the obturator nerve, lumbosacral trunk and iliolumbar artery are all posterior. The left common iliac vein is posteromedial, and the left psoas major lateral, to the left common iliac artery.

Branches In addition to the external iliac and internal iliac branches, each common iliac artery also gives small branches to the peritoneum, psoas major, ureter, adjacent nerves and surrounding areolar tissue. The common iliac artery occasionally gives rise to the iliolumbar artery and accessory or replaced renal arteries if the kidney is low-lying.

The anteroposterior diameters of the common, external and internal iliac arteries are strongly correlated to body surface area (BSA) in children, in contrast to adults, in whom the relationship is inconsistent. Vessel diameters measured by ultrasonography are significantly larger in boys than in girls. The relationship between vessel diameters and BSA is shown in Figure 73.7 (Munk et al 2002).

Fig. 73.7 The relationship between anteroposterior diameters of the right common, internal and external iliac arteries and body surface area (BSA) in boys and girls between the ages of 1 and 16 years. (With permission from Munk AL, Darge K, Wiesel M, Troeger J, Diameter of the infrarenal aorta and the iliac arteries in children: ultrasound measurements. Transplantation 2002;73:631-635.)

## Internal iliac arteries

Each internal iliac artery, approximately 4 cm long, begins at the common iliac bifurcation, level with the lumbosacral intervertebral disc and anterior to the sacroiliac joint (Figs 73.5, 73.6). It descends posteriorly to the superior margin of the greater sciatic foramen, where it divides into an anterior trunk, which continues in the same line towards the ischial spine, and a posterior trunk, which passes back to the greater sciatic foramen. The anterior trunk primarily supplies the pelvic organs, while the posterior trunk primarily supplies muscles in the hip and back. Anterior to the artery are the ureter and, in females, the ovary and fimbriated end of the uterine tube. The internal iliac vein, lumbosacral
trunk and sacroiliac joint are posterior. Laterally are the external iliac vein, between the artery and psoas major, and the obturator nerve lying inferior to the vein. The parietal peritoneum is medial, separating it from the terminal ileum on the right and the sigmoid colon on the left, and tributaries of the internal iliac vein. For details of the considerable variation in the anatomy of the internal iliac artery, see Roberts and Krishingner (1967).

In the fetus, the internal iliac artery is twice the size of the external iliac artery and is the direct continuation of the common iliac artery. The main trunk ascends on the anterior abdominal wall to the umbilicus, converging on the contralateral artery, and the two arteries run

Fig. 73.5 Arteries of the male pelvis.

Fig. 73.6 Arteries of the female pelvis.
through the umbilicus to enter the umbilical cord as the umbilical arteries. At birth, when placental circulation ceases, only the pelvic segment remains patent as the internal iliac artery and part of the superior vesical artery; the remainder becomes a fibrous medial umbilical ligament. Persistence of the umbilical artery has been described and may cause extrinsic obstruction of the distal ureter (Gupta et al 1999). In males, the patent part (commonly, the superior vesical artery) usually gives off an artery to the vas (ductus) deferens.

## Posterior trunk branches

The branches of the posterior trunk of the internal iliac artery are the iliolumbar, lateral sacral and superior gluteal arteries.
lliolumbar artery The iliolumbar artery is the first branch of the posterior trunk and ascends laterally anterior to the sacroiliac joint and lumbosacral nerve trunk. It lies posterior to the obturator nerve and external iliac vessels, and reaches the medial border of psoas major, dividing behind it into the lumbar and iliac branches. The lumbar branch supplies psoas major and quadratus lumborum, and anastomoses with the fourth lumbar artery. It sends a small spinal branch through the intervertebral foramen between the fifth lumbar and first sacral vertebrae, to supply the cauda equina. The iliac branch supplies iliacus; between the muscle and bone, it anastomoses with the iliac branches of the obturator artery. A large nutrient branch enters an oblique canal in the ilium. Other branches run around the iliac crest, contribute to the supply of the gluteal and abdominal muscles, and anastomose with the superior gluteal, circumflex iliac and lateral circumflex femoral arteries (see Fig. 80.18).

Lateral sacral arteries The lateral sacral arteries are usually double; if they are single, they divide rapidly into superior and inferior branches. The superior and larger artery passes medially into the first or second anterior sacral foramen, supplies the sacral vertebrae and contents of the sacral canal, and then leaves the sacrum via the corresponding dorsal foramen to supply the skin and muscles dorsal to the sacrum. The inferior or lateral sacral artery crosses obliquely anterior to piriformis and the sacral anterior spinal rami, and then descends lateral to the sympathetic trunk to anastomose with its fellow and the median sacral artery anterior to the coccyx. Its branches enter the anterior sacral foramina and are distributed in the same way as the branches of the superior artery.

Superior gluteal artery The superior gluteal artery is the largest branch of the internal iliac artery and, effectively, forms the main continuation of its posterior trunk. It runs posteriorly between the lumbosacral trunk and the first sacral ramus, or between the first and second rami, and then turns slightly inferiorly, leaving the pelvis by the greater sciatic foramen above piriformis and dividing into superficial and deep branches. In the pelvis, it supplies piriformis, obturator internus and a nutrient artery to the ilium. The superficial branch enters the deep surface of gluteus maximus. Its numerous branches supply the muscle and anastomose with the inferior gluteal branches (see Fig. 80.30), while others perforate the tendinous medial attachment of the muscle to supply the skin over the sacrum, where they anastomose with the posterior branches of the lateral sacral arteries. The deep branch of the superior gluteal artery passes between gluteus medius and the bone, soon dividing into superior and inferior branches. The superior branch skirts the superior border of gluteus minimus to the anterior superior iliac spine, and anastomoses with the deep circumflex iliac artery and the ascending branch of the lateral circumflex femoral artery. The inferior branch runs through gluteus minimus obliquely, supplies it and gluteus medius, and anastomoses with the lateral circumflex femoral artery. A branch enters the trochanteric fossa to join the inferior gluteal artery and ascending branch of the medial circumflex femoral artery; other branches run through gluteus minimus to supply the hip joint.

The superior gluteal artery occasionally arises directly from the internal iliac artery with the inferior gluteal artery and sometimes from the internal pudendal artery.

## Anterior trunk branches

The branches of the anterior trunk of the internal iliac artery are the superior and inferior vesical, middle rectal, vaginal, obturator, uterine, internal pudendal and inferior gluteal arteries (see Fig. 73.6). Significant variation occurs in the branching patterns of the anterior trunk; the general principles will be considered here.

Superior vesical artery The superior vesical artery is the first large branch of the anterior trunk. It lies on the lateral wall of the pelvis, just below the brim, and runs anteroinferiorly, medial to the periosteum of
the posterior surface of the pubis. It supplies the distal end of the ureter, the bladder, the proximal end of the vas deferens and the seminal vesicles. It also gives origin to the umbilical artery in the fetus, which remains as a fibrous cord - the medial umbilical ligament - in the adult. This vessel occasionally remains patent as a small artery supplying the umbilicus.

Inferior vesical artery The inferior vesical artery may arise as a common branch with the middle rectal artery. It supplies the bladder, prostate, seminal vesicles and vas deferens in the male, and the bladder in the female, where it is often replaced by the vaginal artery.

Middle rectal artery The middle rectal artery runs into the lateral fascial coverings of the mesorectum. It often consists of multiple branches, may be small, and occasionally arises either close to, or in common with, the origin of the inferior vesical artery in males.

Vaginal artery In females, the vaginal artery may replace the inferior vesical artery. It may arise from the uterine artery close to its origin and can be a single vessel or multiple branches.

Obturator artery The obturator artery runs anteroinferiorly from the anterior trunk on the lateral pelvic wall to the upper part of the obturator foramen. In the pelvis, it is related laterally to the fascia over obturator internus and is crossed on its medial aspect by the ureter and, in the male, by the vas deferens. The obturator nerve runs above the artery, the obturator vein below it. The artery provides iliac branches to the iliac fossa that supply the bone and iliacus and anastomose with the iliolumbar artery. It gives off a vesical branch that runs medially to the bladder and sometimes replaces the inferior vesical branch of the internal iliac artery. In the female, the ovary lies medial to the obturator artery. A pubic branch usually arises just before the obturator artery leaves the pelvis; it ascends over the pubis to anastomose with the contralateral artery and the pubic branch of the inferior epigastric artery.

The obturator artery leaves the pelvis via the obturator canal and divides into anterior and posterior branches that encircle the obturator foramen between obturator externus and the obturator membrane. The anterior branch curves anteriorly on the membrane and then inferiorly along its anterior margin to supply branches to obturator externus, pectineus, the femoral adductors and gracilis. It anastomoses with the posterior branch and the medial circumflex femoral artery. The posterior branch follows the posterior margin of the foramen and turns anteriorly on the ischial part to anastomose with the anterior branch. It supplies the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal artery. An acetabular branch enters the hip joint at the acetabular notch, ramifies in the fat of the acetabular fossa and sends a branch along the ligament of the femoral head.

Occasionally, the obturator artery is replaced by an enlarged pubic branch of the inferior epigastric artery that descends almost vertically to the obturator foramen. It usually lies near the external iliac vein, lateral to the femoral ring, and is rarely injured during inguinal or femoral hernia surgery. Sometimes, it curves along the edge of the lacunar part of the inguinal ligament, partly encircling the neck of a hernial sac, and may be inadvertently cut during enlargement of the femoral ring in reducing a femoral hernia.

Uterine artery The uterine artery is an additional branch in females. It is a large artery that arises below the obturator artery on the lateral wall of the pelvis and runs inferomedially into the broad ligament of the uterus (Ch. 77).

Internal pudendal artery (pelvic portion) The internal pudendal artery is the smaller terminal branch of the anterior division of the internal iliac artery. Close to its origin, it crosses anterior to piriformis, the sacral plexus and the inferior gluteal artery. It descends laterally to the inferior rim of the greater sciatic foramen, where it leaves the pelvis between piriformis and ischiococcygeus, and enters the gluteal region (see Fig. 77.3B). It next curves around the dorsum of the ischial spine and enters the ischiorectal fossa via the lesser sciatic foramen. This course effectively allows the nerve to wrap around the posterior limit of levator ani at its attachment to the ischial spine. Behind the ischial spine, the artery is covered by gluteus maximus, the pudendal nerve is medial, and the nerve to obturator internus is lateral. The artery traverses the ischiorectal fossa in Alcock's canal in the fascia covering obturator internus; it gives off an inferior rectal branch early in its course through the fossa (see Fig. 73.12). The internal pudendal artery gives off several muscular branches in the pelvis and gluteal region that supply adjacent muscles and nerves.

Inferior gluteal artery The inferior gluteal artery is the larger terminal branch of the anterior internal iliac trunk and principally supplies the buttock and thigh. It descends posteriorly, anterior to the sacral plexus and piriformis but posterior to the internal pudendal artery. It passes between either the first and second, or second and third, sacral ventral rami, then between piriformis and ischiococcygeus, before running through the lower part of the greater sciatic foramen to reach the gluteal region. The artery runs inferiorly between the greater trochanter and ischial tuberosity, together with the sciatic and posterior femoral cutaneous nerves, deep to gluteus maximus. It continues down the thigh, supplying the skin and anastomosing with branches of the perforating arteries. The inferior gluteal and internal pudendal arteries often arise as a common stem from the internal iliac artery, sometimes with the superior gluteal artery. In the pelvis, the inferior gluteal artery gives branches to piriformis, ischiococcygeus and iliococcygeus, and occasionally contributes to the middle rectal arterial supply. In the male, it may supply vessels to the seminal vesicles and prostate.

## External iliac arteries

The external iliac arteries are of larger calibre than the internal iliac arteries (see Figs 73.5, 73.6). Each artery descends laterally along the medial border of psoas major, from the common iliac bifurcation to a point midway between the anterior superior iliac spine and the pubic symphysis, and enters the thigh posterior to the inguinal ligament to become the femoral artery.

The parietal peritoneum and extraperitoneal tissue separate the right external iliac artery from the terminal ileum and, usually, the appendix, and the left external iliac artery from the sigmoid colon and coils of small intestine anteromedially. At its origin, the external iliac artery may be crossed by the ureter; it is subsequently crossed by the gonadal vessels, the genital branch of the genitofemoral nerve, the deep circumflex iliac vein, and the vas deferens (male) or round ligament (female). Posteriorly, the artery is separated from the medial border of psoas major by the iliac fascia. The external iliac vein lies partly posterior to its upper part but is more medial below. Laterally, it is related to psoas major, which is covered by the iliac and psoas fasciae. Numerous lymph vessels and nodes lie on its anterior and lateral aspects.

The external iliac artery is principally the artery of the lower limb and, as such, has few branches in the pelvis. Apart from giving off very small vessels to psoas major and neighbouring lymph nodes, the artery has no branches until it gives off the deep circumflex iliac and inferior epigastric arteries, near to the point at which it passes under the inguinal ligament.

Deep circumflex iliac artery The deep circumflex iliac artery branches laterally from the external iliac artery almost opposite the origin of the inferior epigastric artery (see Fig. 78.7A). It ascends and runs laterally to the anterior superior iliac spine behind the inguinal ligament in a sheath formed by the union of the transversalis and iliac fasciae. There, it anastomoses with the ascending branch of the lateral circumflex femoral artery, pierces the transversalis fascia and skirts the internal lip of the iliac crest. About halfway along the iliac crest, it runs through transversus abdominis, and then between transversus abdominis and internal oblique, to anastomose with the iliolumbar and superior gluteal arteries. It gives off a large ascending branch at the anterior superior iliac spine that runs between internal oblique and transversus abdominis, supplies both muscles, and anastomoses with the lumbar and inferior epigastric arteries.

Inferior epigastric artery The inferior epigastric artery originates from the external iliac artery posterior to the inguinal ligament. It curves forwards in the anterior extraperitoneal tissue and ascends obliquely along the medial margin of the deep inguinal ring; from here, it continues as an artery of the anterior abdominal wall.

## Veins of the pelvis

The true pelvis contains a large number of veins that drain the pelvic walls and most of the viscera contained within the pelvis, and also carry venous blood from the gluteal region, hip and thigh. The external iliac veins, which lie close to the brim of the pelvis, carry the venous drainage from most of the lower limb. There is considerable variation in the venous drainage of the pelvis: although the major veins frequently follow their named arterial counterparts, the small tributaries exhibit considerable inter-individual variation.

## Common iliac veins

The common iliac vein is formed by the union of the external and internal iliac veins, anterior to the sacroiliac joints (see Fig. 78.8). It
ascends obliquely to end at the right side of the fifth lumbar vertebra, uniting at an acute angle with the contralateral vessel to form the inferior vena cava. The right common iliac vein is shorter and more nearly vertical, lying posterior, and then lateral, to its artery. The right obturator nerve passes posteriorly. The left common iliac vein is longer and more oblique, and lies first medial, then posterior, to its artery. It is crossed anteriorly by the attachment of the sigmoid mesocolon and superior rectal vessels. Each vein receives iliolumbar and, sometimes, lateral sacral veins. The left common iliac vein usually drains the median sacral vein. There are no valves in these veins.

The left common iliac vein occasionally ascends to the left of the aorta to the level of the kidney, where it receives the left renal vein and crosses anterior to the aorta to join the inferior vena cava; this vessel represents the persistent caudal half of the left postcardinal or supracardinal vein.

Median sacral veins The right and left medial sacral veins accompany the corresponding arteries anterior to the sacrum, where they unite to form a single vein that usually ends in the left common iliac vein, but which sometimes ends at the common iliac junction.

Internal pudendal veins The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel that drains into the internal iliac vein. They receive veins from the inferior rectal veins and either the penile bulb and scrotum (males), or the clitoris and labia (females).

## Internal iliac vein

The internal iliac vein is formed by the convergence of several veins above the greater sciatic foramen. It does not have the predictable trunks and branches of the internal iliac artery but its tributaries drain the same territories. It ascends posteromedial to the internal iliac artery to join the external iliac vein, forming the common iliac vein at the pelvic brim, anterior to the lower part of the sacroiliac joint. It is covered anteromedially by parietal peritoneum. Its tributaries are the gluteal, internal pudendal and obturator veins, which originate outside the pelvis; the lateral sacral veins, which run from the anterior surface of the sacrum; and the middle rectal, vesical, uterine and vaginal veins, which originate in the venous plexuses of the pelvic viscera (Fig. 73.8).

The venous drainage of the leg may be blocked by thrombosis involving the external iliac systems and the inferior vena cava. Under these circumstances, the pelvic veins, particularly the internal iliac tributaries, enlarge and provide a major avenue of venous return from the femoral system. Surgical interference with these veins may seriously compromise venous drainage and precipitate oedema of one or both legs.

Superior gluteal veins The superior gluteal veins are the venae comitantes of the superior gluteal artery. They receive tributaries that correspond to the branches of the superior gluteal artery and enter the pelvis via the greater sciatic foramen, above piriformis. They join the internal iliac vein, frequently as a single trunk.

Inferior gluteal veins The inferior gluteal veins are venae comitantes of the inferior gluteal artery. They begin proximally and posterior in the thigh, where they anastomose with the medial circumflex femoral and first perforating veins, and they enter the pelvis low in the greater sciatic foramen, joining to form a vessel that opens into the distal (lower) part of the internal iliac vein. The inferior gluteal and superficial gluteal veins connect by perforating veins (Doyle 1970) analogous to the sural perforating veins. The gluteal veins probably have a venous 'pumping' role, and provide collaterals between the femoral and internal iliac veins.

Obturator vein The obturator vein begins in the proximal adductor region and enters the pelvis via the obturator foramen. It runs posteriorly and superiorly on the lateral pelvic wall below the obturator artery and between the ureter and internal iliac artery, and ends in the internal iliac vein. It is sometimes replaced by an enlarged pubic vein, which joins the external iliac vein.

Lateral sacral veins The lateral sacral veins accompany the lateral sacral arteries and are interconnected by a sacral venous plexus.

Middle rectal vein The middle rectal vein begins in the rectal venous plexus and drains the rectum and mesorectum. Variable in size, it runs laterally on the pelvic surface of levator ani to end in the internal iliac vein. The middle rectal vein often receives tributaries from the bladder

Fig. 73.8 Veins of the female pelvis.
and either the prostate and seminal vesicle (males) or the posterior aspect of the vagina (females).

## External iliac vein

The external iliac vein is the proximal continuation of the femoral vein (see Figs 78.8, 80.33). It begins posterior to the inguinal ligament, ascends along the pelvic brim, and ends anterior to the sacroiliac joint by joining the internal iliac vein to form the common iliac vein. On the right, it lies medial to the external iliac artery, gradually inclining behind it as it ascends. On the left, it is wholly medial. Disease of the external iliac artery may cause it to adhere closely to the vein at the point where it is in contact, and, particularly on the right side, the walls of the vessels may become fused, making dissection hazardous. The external iliac vein is crossed medially by the ureter and internal iliac artery. In males, it is crossed by the vas deferens, in females by the round ligament and ovarian vessels. Psoas major lies laterally, except where the artery intervenes. The vein is usually valveless but may contain a single valve. Its tributaries are the inferior epigastric, deep circumflex iliac and pubic veins. Agenesis of the external iliac vein has been reported in association with Klippel-Trenaunay syndrome (Dogan et al 2003).

Inferior epigastric vein One or two inferior epigastric veins accompany the inferior epigastric artery and drain into the external iliac vein a little above the inguinal ligament.

Deep circumflex iliac vein The deep circumflex iliac vein is formed from venae comitantes of the corresponding artery. It joins the external iliac vein a little above the inferior epigastric vein, after crossing anterior to the external iliac artery.

Pubic vein The pubic vein connects the external iliac and obturator veins. It ascends on the pelvic surface of the pubis with the pubic branch of the inferior epigastric artery and sometimes replaces the normal obturator vein.

## Lymphatic drainage of the pelvis

The lymph nodes in the pelvis are grouped around the common, external iliac and internal iliac vessels, and are named accordingly (Nesselrod 1936).

## Common iliac nodes

The common iliac nodes receive the entire lymphatic drainage of the lower limb because they drain both internal and external iliac nodes.

They usually lie in medial, lateral and anterior chains around the common iliac artery, the lateral being the main route; one or two lie inferior to the aortic bifurcation and anterior to the fifth lumbar vertebra or sacral promontory. The common iliac nodes connect to the lateral aortic nodes.

## External iliac nodes

The external iliac nodes usually form three subgroups, which are lateral, medial and anterior to the external iliac vessels (see Fig. 77.3B). The medial nodes are considered the main channel of drainage, collecting lymph from the lower limb via the inguinal nodes, the deeper layers of the infra-umbilical abdominal wall, the adductor region of the thigh, the glans penis or clitoris, the membranous urethra, prostate, fundus of the bladder, uterine cervix and upper vagina. Their efferents pass to the common iliac nodes (see Fig. 78.10).

Inferior epigastric and circumflex iliac nodes The inferior epigastric and circumflex iliac nodes are associated with their similarly named vessels and drain the corresponding areas to the external iliac nodes.

## Internal iliac nodes

The internal iliac nodes surround the branches of the internal iliac vessels. They receive afferents from most of the pelvic viscera (with the exception of the gonads and the majority of the rectum), the deeper parts of the perineum, and the gluteal and posterior femoral muscles, and drain to the common iliac nodes. The individual groups are considered in the description of the viscera. There are frequent connections between the right and left groups, particularly when they lie close to the anterior and posterior midlines (Fig. 73.9).

## INNERVATION OF THE PELVIS

The pelvis contains the lumbosacral nerve trunk, the sacral and coccygeal plexuses, and the pelvic parts of the sympathetic and parasympathetic systems. Collectively, these nerves carry the somatic and autonomic innervation to the majority of the pelvic visceral organs, and the muscles of the pelvic floor and perineum, the gluteal region and the lower limb.

The ventral rami of the sacral and coccygeal spinal nerves form the sacral and coccygeal plexuses (Fig. 73.10). The upper four sacral ventral rami enter the pelvis by the anterior sacral foramina, the fifth enters between the sacrum and coccyx, and the ventral ramus of the coccygeal nerve curves forwards below the rudimentary transverse process of the
first coccygeal segment. The first and second sacral ventral rami are large, the third to fifth diminish progressively in size, and the coccygeal ramus is the smallest. Each receives a grey ramus communicans from a corresponding sympathetic ganglion. Visceral efferent rami leave the second to fourth sacral rami as the pelvic splanchnic nerves, containing preganglionic parasympathetic fibres to minute ganglia in the walls of the pelvic viscera.

## Lumbosacral trunk and sacral plexus

The sacral plexus is formed by the lumbosacral trunk, the first to third sacral ventral rami, and part of the fourth sacral ventral ramus (the remainder of the fourth sacral ventral ramus joins the coccygeal plexus).

The lumbar part of the lumbosacral trunk contains part of the fourth and all of the fifth lumbar ventral rami; it appears at the medial margin

Fig. 73.9 Lymphatic drainage of the female pelvis and urinary bladder.
of psoas major and descends over the pelvic brim, anterior to the sacroiliac joint, to join the first sacral ramus. The greater part of the second and third sacral rami converge on the inferomedial aspect of the lumbosacral trunk in the greater sciatic foramen to form the sciatic nerve. The ventral and dorsal divisions of the nerves do not separate physically from each other but their fibres remain separate within the rami; the ventral and dorsal divisions of each contributing root join within the sciatic nerve. The fibres of the dorsal divisions will go on to form the common fibular nerve, and the fibres of the ventral division form the tibial nerve. The sciatic nerve, occasionally, divides into common fibular and tibial nerves inside the pelvis; when this occurs, the common fibular nerve usually runs through piriformis.

The sacral plexus lies against the posterior pelvic wall anterior to piriformis, posterior to the internal iliac vessels and ureter, and behind the sigmoid colon on the left. The superior gluteal vessels run either between the lumbosacral trunk and first sacral ventral ramus, or between the first and second sacral rami, while the inferior gluteal vessels lie between either the first and second, or second and third, sacral rami.

The sacral plexus is not commonly involved in malignant tumours of the pelvis because it lies behind the relatively dense presacral fascia, which resists all but locally very advanced malignant infiltration. When it occurs, there is intractable pain in the distribution of the branches of the plexus, which may be very difficult to treat. The plexus may also be involved in the reticuloses or be affected by plexiform neuromas.

## Branches of the sacral plexus <br> The branches of the sacral plexus are shown in Table 73.1.

The course and distribution of most of the branches of the sacral plexus are covered fully in Section 9 .

Table 73.1 Branches of the sacral plexus

| Nerve | Ventral divisions | Dorsal divisions |
| :--- | :--- | :--- |
| Nerve to quadratus femoris and gemellus inferior | $\mathrm{L} 4,5 ; \mathrm{S} 1$ |  |
| Nerve to obturator internus and gemellus superior | $\mathrm{L5} ; \mathrm{S} 1,2$ |  |
| Nerve to piriformis |  | $\mathrm{S} 2(\mathrm{~S} 1)$ |
| Superior gluteal nerve |  | $\mathrm{L}, 5 ; \mathrm{S} 1$ |
| Inferior gluteal nerve | $\mathrm{S} 2,3$ | $\mathrm{~L} ; \mathrm{S} 1,2$ |
| Posterior femoral cutaneous nerve | $\mathrm{L4}, 5 ; \mathrm{S} 1,2,3$ |  |
| Tibial (sciatic) nerve |  | $\mathrm{L4}, 5 ; \mathrm{S} 1,2$ |
| Common fibular (sciatic) nerve | $\mathrm{S} 2,3,4$ | $\mathrm{~S} 2,3$ |
| Perforating cutaneous nerve |  |  |
| Pudendal nerve | S 4 |  |
| Nerves to levator ani and external anal sphincter |  |  |

Fig. 73.10 The lumbosacral plexus in the pelvis.

## Pudendal nerve (in the pelvis)

The pudendal nerve arises from the ventral divisions of the second, third and fourth sacral ventral rami and is formed just above the superior border of the sacrotuberous ligament and the upper fibres of ischiococcygeus (Klink 1953, Sato 1980). It leaves the pelvis via the greater sciatic foramen between piriformis and ischiococcygeus (see Fig. 73.10), enters the gluteal region and passes dorsal to the sacrospinous ligament, close to its attachment to the ischial spine, where it lies medial to the internal pudendal vessels. It accompanies the internal pudendal artery through the lesser sciatic foramen into the pudendal (Alcock's) canal on the lateral wall of the ischio-anal fossa. In the posterior part of the canal, it gives rise to the inferior rectal and perineal nerves; the dorsal nerve of the penis or clitoris continues ventrally from this origin.

## Sacral visceral branches

Visceral branches - the pelvic splanchnic nerves - arise from the second to fourth sacral ventral rami and innervate the pelvic viscera.

## Sacral muscular branches

Several muscular branches arise from the fourth sacral ventral ramus to supply the superior surface of levator ani and the upper part of the external anal sphincter. The branches to levator ani enter the superior (pelvic) surface of the muscle whilst the branch to the external anal sphincter (also referred to as the perineal branch of the fourth sacral nerve) reaches the ischio-anal fossa by running either through ischiococcygeus, or between ischiococcygeus and iliococcygeus. It supplies the skin between the anus and coccyx via its cutaneous branches.

## Coccygeal plexus

The coccygeal plexus is formed by a small descending branch from the fourth sacral ramus and by the fifth sacral and coccygeal ventral rami. The fifth sacral ventral ramus emerges from the sacral hiatus, curves round the lateral margin of the sacrum below its cornu, and pierces ischiococcygeus from below to reach its upper, pelvic, surface. Here it is joined by a descending branch of the fourth sacral ventral ramus; the small trunk so formed descends on the pelvic surface of ischiococcy-
geus, joins the minute coccygeal ventral ramus that emerges from the sacral hiatus, and curves round the lateral coccygeal margin, piercing coccygeus to reach the pelvis. The small trunk that is formed in this way is the coccygeal plexus. Anococcygeal nerves arise from it and form a few fine filaments that pierce the sacrotuberous ligament to supply the adjacent skin.

## Pelvic part of the sympathetic system

The pelvic sympathetic trunk lies in the extraperitoneal tissue, anterior to the sacrum beneath the presacral fascia (Fig. 73.11), and supplies sympathetic innervation to the pelvic organs and vascular system. It lies medial or anterior to the anterior sacral foramina and has four or five interconnected ganglia. Above, it is continuous with the lumbar sympathetic trunk. The right and left trunks converge below the lowest ganglia and unite in the small ganglion impar anterior to the coccyx. Grey rami communicantes pass from the ganglia to sacral and coccygeal spinal nerves but there are no white rami communicantes. Medial branches connect across the midline, and twigs from the first two ganglia join the inferior hypogastric plexus or the hypogastric 'nerve'. Other branches form a plexus on the median sacral artery.

## Vascular branches

Preganglionic fibres for the vessels supplying the pelvis and lower limb are derived from the lower three thoracic and upper two or three lumbar spinal segments. They reach the lower thoracic and upper lumbar ganglia through white rami communicantes and descend through the sympathetic trunk to synapse in the lumbar ganglia. Postganglionic fibres pass from these ganglia via grey rami communicantes to the femoral nerve, which carries them to the femoral artery and its branches. Some fibres descend through the lumbar ganglia to synapse in the upper two or three sacral ganglia, from which postganglionic axons pass through grey rami communicantes to the roots of the sacral plexus. Those in the pudendal and superior and inferior gluteal nerves accompany the arteries of the same name to the gluteal and perineal tissues; branches may also supply the pelvic lymph nodes. Those joining the tibial nerve are carried to the popliteal artery and distributed via its branches to the leg and foot.

Fig. 73.11 Autonomic nerves of the pelvis.

Sympathetic denervation of vessels in the lower limb can be effected by removing or ablating the upper three lumbar ganglia and the intervening parts of the sympathetic trunk, which is used, rarely, in treating vascular insufficiency of the lower limb.

## PERINEUM

## MUSCLES AND FASCIAE OF THE PERINEUM

The perineum is an approximately diamond-shaped region that lies below levator ani, between the inner aspects of the thighs and anterior to the sacrum and coccyx. It is usually described as if from the position of an individual lying supine with the hip joints in abduction and partial flexion. The surface projection of the perineum and the form of the skin covering it vary considerably, depending on the position of the thighs, whereas the deep tissues themselves occupy relatively fixed positions. The perineum is bounded anteriorly by the pubic symphysis and its arcuate ligament, posteriorly by the coccyx, anterolaterally by the ischiopubic rami and the ischial tuberosities, and posterolaterally by the sacrotuberous ligaments. The deep limit of the perineum is the inferior surface of the pelvic diaphragm, and its superficial limit is the skin that is continuous with that over the medial aspect of the thighs and the lower abdominal wall. An arbitrary line joining the ischial tuberosities (the inter-ischial line) divides the perineum into an anterior urogenital triangle and a posterior anal triangle. The urogenital triangle faces downwards and forwards, whereas the anal triangle faces downwards and backwards at an approximate angle of $120^{\circ}$ from the plane of the urogenital triangle.

The male urogenital triangle contains the bulb and attachments of the penis (Fig. 73.12) (Ch. 76), and the female urogenital triangle contains the mons pubis, the labia majora, the labia minora, the clitoris and the vaginal and urethral orifices (Ch. 77).

## Anal triangle

The structure of the anal triangle is similar in males and females, the main difference reflecting the wider transverse dimension of the triangle in females that is associated with giving birth. The anal triangle contains the anal canal and its sphincters, and the ischio-anal fossa and its contained nerves and vessels. It is lined by superficial and deep fascia.

## Superficial fascia of the anal triangle

The superficial fascia (subcutaneous tissue; tela subcutanea) of the region is thin and is continuous with the superficial/subcutaneous fascia of the skin of the perineum, thighs and buttocks.

## Deep fascia of the anal triangle

The deep fascia (fascia musculorum) lines the inferior surface of levator ani and is continuous at its lateral origin with the fascia over obturator internus below the attachment of levator ani. It lines the deep portion of the ischio-anal fossa and its lateral walls.

## Ischio-anal fossa

The ischio-anal fossa is an approximately horseshoe-shaped region filling the majority of the anal triangle. Although often referred to as a space, it is filled with loose adipose tissue and occasional blood vessels and nerves (see Fig. 73.12). The 'arms' of the horseshoe are triangular in cross-section because levator ani slopes medially from its lateral pelvic origin towards the anorectal junction (see Fig. 66.44). The anal canal and its sphincters lie in the centre of the horseshoe. Above them, the medial limit of the fossa is formed by the deep fascia over levator ani. The outer boundary of the fossa is formed anterolaterally by the fascia over obturator internus and the periosteum of the ischial tuberosities. Posterolaterally, the outer boundary is formed by the lower border of gluteus maximus and the sacrotuberous ligament.

There is an anterior recess to the ischio-anal fossa that lies cranial to the perineal membrane and transverse perineal muscles. It extends anteriorly as far as the posterior surface of the pubis, below the attachment of levator ani. Posteriorly, the fossa contains the attachment of the external anal sphincter to the tip of the coccyx; above and below this, the adipose tissue of the fossa is uninterrupted across the midline. These continuations of the ischio-anal fossa mean that infections, tumours and fluid collections within not only may enlarge relatively freely to the side of the anal canal, but also may spread with little resistance to the contralateral side and deep to the perineal membrane. The internal pudendal vessels and accompanying nerves lie in the lateral wall of the ischio-anal fossa, enclosed in fascia forming the pudendal canal. The inferior rectal vessels and nerves cross the fossa from the pudendal canal and often branch within it.

The ischio-anal fossa is an important surgical plane during resections of the anal canal and anorectal junction for malignancy. It provides an easy, relatively bloodless, plane of dissection that encompasses all of the muscular structures of the anal canal and leads to the inferior surface of levator ani, through which the dissection is carried.

## External anal sphincter

The external anal sphincter is a band of striated muscle that surrounds the lowest part of the anal canal (Oh and Kark 1972, Dalley 1987, Lawson 1974b). The uppermost (deepest) fibres blend with the lowest fibres of puborectalis; the two are seen to be contiguous on endoanal ultrasound and magnetic resonance imaging. Anteriorly, some of these upper fibres decussate into the superficial transverse perineal muscles. Posteriorly, fibres are attached to the anococcygeal raphe. The majority

Fig. 73.12 Muscles and fasciae of the male perineum. On the left side, the skin and superficial fascia of the perineum only have been removed. The posterior scrotal (perineal) artery has been shown as it runs forwards into the scrotal tissues. On the right side, the corpora cavernosa and corpus spongiosum and their associated muscles, the superficial perineal muscles and perineal membrane have been removed to reveal the underlying deep muscles and arteries of the perineum. All veins and nerves have been omitted for clarity.
of the middle fibres of the external anal sphincter surround the lower part of the internal sphincter and are attached anteriorly in the perineal body, and posteriorly to the coccyx via the anococcygeal ligament. Some fibres from each side of the sphincter decussate in these areas to form a sort of commissure in the anterior and posterior midline. The anterior and posterior attachments of the external anal sphincter give the muscular tube an oval profile lying anteroposteriorly. A subcutaneous portion encircles the anal verge and creates the radial skin creases surrounding the anus. The lower fibres lie below the level of the internal anal sphincter and are separated from the lowest anal epithelium by submucosa. The thickness of the external anal sphincter in children is positively correlated with age (de la Portilla and López-Alonso 2009, Rehman et al 2011).

## Anococcygeal ligament and iliococcygeal raphe

The anococcygeal ligament is a musculotendinous structure running between the middle portion of the external anal sphincter and the coccyx. The iliococcygeal raphe (the decussation of the posterior fibres of iliococcygeus) lies just above the anococcygeal ligament and is separated from the rectum by presacral fascia. These structures are often referred to as the postanal plate. Division of the anococcygeal raphe may cause descent of the anal canal and a lowering of the posterior part of the anal triangle, but does not demonstrably interfere with the process of defecation.

## Urogenital triangle

The urogenital triangle is bounded posteriorly by the inter-ischial line, which usually overlies the posterior border of the transverse perineal muscles. Anteriorly and laterally, it is bounded deeply by the pubic symphysis and ischiopubic rami. In males, the urogenital triangle extends superficially to encompass the scrotum and the root of the penis. In females, it extends to the lower limit of the labia and mons pubis. The urogenital triangle is divided into two parts by a strong perineal membrane: the deep perineal space lies above the membrane, and the superficial perineal space lies below it.

The female urogenital triangle includes muscles, fasciae, erectile structures and spaces similar to those in the male. There are some differences in size and disposition caused by the presence of the vagina and female external genitalia.

## Deep perineal space

## Perineal membrane

For many years, it was thought that the anterior pelvic outlet was spanned by a triangular, trilaminar, musculofascial structure - the uro-
genital diaphragm - consisting of urogenital sphincter muscles sandwiched between two layers of fascia and connected to the perineal body, the periosteum of the ischiopubic rami and the arcuate ligament of the pubis, and perforated by the urethra and vagina. Oelrich introduced the alternative term 'perineal membrane' (Oelrich 1983). Recent detailed histological examination of serial cross-sections supports the concept of the perineal membrane as part of a larger interconnected support apparatus. It has distinct dorsal and ventral portions that are intimately connected with levator ani: the dorsal portion is related to the support of the perineal body and lateral vaginal wall by its attachment to the ischiopubic ramus, and the ventral portion is contiguous with the urethral supportive apparatus (Stein and DeLancey 2008). The perineal membrane is particularly thick where it is attached to the arcuate ligament of the pubis, and is here referred to as the transverse perineal ligament. The posterior border of the perineal membrane is continuous with the deep part of the perineal body at its dorsal margin, and is continuous with the fascia over the superficial transverse perineal muscles.

In the male, the perineal membrane is crossed by several structures: the urethra, which traverses it $2-3 \mathrm{~cm}$ behind the inferior border of the pubic symphysis; the vessels and nerves to the bulb of the penis; the ducts of the bulbourethral glands, posterolateral to the urethral orifice; the deep dorsal vessels and dorsal nerves of the penis, behind the pubic arch in the midline; and the posterior scrotal vessels and nerves, anterior to the transverse perinei.

In the female, the perineal membrane is divided almost into two halves by the vagina and urethra, such that it forms a triangle on each side of these structures. The lateral margins of the vagina are attached to the perineal membrane at the level of the hymenal ring, and levator ani lies on its cranial surface. The ducts of Bartholin's glands are at this level in the posterior lateral introitus. The deep dorsal vessels and dorsal nerves of the clitoris lie within its fibres.

## Urethral sphincter mechanism

The urethral sphincter mechanism consists of both striated and smooth muscle sphincters (Oelrich 1980, Oelrich 1983, Huisman 1983). The striated urogenital sphincter has an upper circular element that surrounds the urethra in the female and the apex of the prostate in the male, between the vesical neck and perineal membrane. In the female, at the level of the perineal membrane, it extends laterally outside of the urethra in two arch-shaped bands that lie on the cranial surface of the perineal membrane (Fig. 73.13). One, the compressor urethrae, follows the pubic arch to attached connective tissue in this area near the inner surface of the ischiopubic ramus. The other, the urethrovaginal sphincter, extends

B

Fig. 73.13 Muscles of the female perineum. A, On the right side, the membranous layer of superficial fascia has been removed (note the cut edge). On the left side, superficial perineal muscles and overlying fascia have been removed to show the deep perineal muscles. B, The continuity of the deep perineal muscles with sphincter urethrae.
caudally to surround the lateral margin of the vaginal wall. In the male, these lateral extensions are not well developed and the sphincter in this area primarily encircles the membranous urethra, forming a robust constrictor at this level. The smooth muscle sphincter consists of circularly orientated smooth muscle cells that lie between the striated sphincter and the longitudinal smooth muscle and urethral lumen. It is not well developed. In children, the inner diameter of the urethral sphincter increases with age: a cutoff value of 3 mm has been reported to predict detrusor-sphincter incoordination (Kakizaki et al 2003).

Innervation The urethral sphincter mechanism extends from the perineum through the urogenital hiatus into the pelvic cavity. It probably receives innervation via the perineal branch of the pudendal nerve from below, and direct branches from the sacral plexus and the pelvic splanchnic nerves from above. All these nerves originate in the second, third and fourth sacral spinal segments.

Actions Urinary incontinence is primarily a problem that affects women and is more common after childbirth. Continence in women is maintained by an elegantly orchestrated system of muscles and connective tissue that involves the urethral sphincters and the tissues that support them. The urethral sphincter mechanism compresses the midurethra in females and membranous urethra in males, particularly when the bladder contains fluid. Its location around the region of highest urethral closing pressure suggests that it plays an important role in the continence of urine. At rest, activity of both the smooth and striated sphincters contributes to this closure and, during times of increased need, voluntary contraction of the striated sphincter augments this closure. In the distal portion of the urethra, where it is adjacent to the perineal membrane, arch-shaped components of the striated sphincter (compressor urethrae and urethrovaginal sphincter) pass between the urethra and pubic bone, and contraction compresses the lumen until it is closed. All muscles are relaxed during micturition to aid voiding, but striated muscle contraction can help to expel final drops of urine, or of semen in the male, from the bulbar urethra.

During increases in abdominal pressure that occur, for example, during a cough, bladder pressure rises above the normal urethral closure pressure that keeps the lumen of the urethra closed. In this situation, the rise in urethral closure pressures (called pressure transmission) that prevents urine leakage occurs because the urethra is compressed against the fascial tissues that lie between it and the vaginal wall. If this layer is stable and unyielding, the urethra can be compressed closed against it, but if it is not well supported, this mechanism is less effective and leakage can occur (DeLancey 1994). Overall continence during such events is a combination of sphincter constriction due to the actions of the muscles in the urethral wall and pressure transmission; sphincter function is the predominant factor (DeLancey et al 2008).

## Superficial and deep perineal fasciae Superficial perineal fascia

The tissue commonly referred to as the superficial fascia of the perineum (Colles' fascia) forms a clear, surgically recognizable, plane beneath the skin of the anterior perineum (Tobin and Benjamin 1949). It is firmly attached posteriorly to the fascia over the superficial transverse perineal muscles and the posterior limit of the perineal membrane. Laterally, it is attached to the margins of the ischiopubic rami as far back as the ischial tuberosities. From here, it runs more superficially to the skin of the urogenital triangle, lining the skin of the external genitalia; in the male, it is also continuous with the fascial layer in the skin of the scrotum that contains the dartos muscle. In females, the fascia follows the same limits but is much less extensive in the labia majora. This layer runs anteriorly and superiorly into the skin of the lower abdominal wall where it is continuous with the membranous fascia (Scarpa's fascia). English-speaking anatomists refer to these tissue layers as a 'superficial fascia' but this is a misnomer; more accurately, they constitute the membranous layer of subcutaneous tissue (tela subcutanea).

## Deep perineal fascia (investing fascia of the superficial perineal muscles)

The tissue commonly referred to as the deep perineal fascia is a layer of fascia that overlies the superficial muscles of the perineum (bulbospongiosus, ischiocavernosus, superficial transverse perineal muscles). It is, in effect, the investing fascia of the superficial perineal muscles and, as such, is firmly attached to the borders of the muscles at attachments to the ischiopubic rami, posterior margin of the perineal membrane and perineal body. Anteriorly, it fuses with the suspensory
ligament of the penis or clitoris, and the fasciae of external oblique and the rectus sheath.

## Superficial and subcutaneous perineal pouches <br> Subcutaneous perineal pouch

The subcutaneous perineal pouch lies between the deep perineal fascia and the superficial perineal fascia. Under normal circumstances, these two layers are only separated by relatively thin subcutaneous connective tissue; the skin of the anterior perineum and external genitalia is relatively mobile over the deeper structures. However, this pouch is capable of expanding considerably in the presence of fluid accumulation; blood, urine or fluid collecting in the subcutaneous pouch following trauma or surgery on the urogenital triangle will spread throughout the tissues of the triangle, including the scrotum or labia majora, but cannot pass posteriorly into the anal triangle or laterally into the medial thigh because of the firm tethering of the posterior attachments of the subcutaneous fascia. Since the superficial perineal fascia is in continuity with the fascia of the anterior abdominal wall, fluid, blood or pus may also track freely between the subcutaneous tissues of the anterior abdominal wall and the subcutaneous perineal pouch (e.g. postsurgical haematomas of the abdominal wall readily cause discolouration of the perineal and genital skin).

## Superficial perineal pouch

The superficial perineal pouch lies below the perineal membrane and is limited superficially by the deep perineal fascia (investing fascia of the superficial perineal muscles) (Fig. 73.14). It contains the corpora cavernosa and corpus spongiosum, ischiocavernosus, bulbospongiosus and the superficial transverse perineal muscles, and branches of the pudendal vessels and nerves. In the female, it is crossed by the urethra and vagina and contains the clitoris. In the male, it contains the urethra as it runs in the root of the penis. It is a fully confined space; injuries to the contents of the space (such as bleeding into the urethra in the penile root) do not communicate with the deep or subcutaneous pouches unless the fascial coverings are also lacerated or breached.

## Perineal body

The perineal body is not a structure but an aggregation of fibromuscular tissue located in the midline at the junction between the anal and urogenital triangles, just ventral to the anal sphincter (Oh and Kark 1973). It is attached to many structures in both the deep and superficial urogenital spaces. Posteriorly, it merges with fibres from the middle part of the external anal sphincter and the conjoint longitudinal coat. Superiorly, it is continuous with the rectoprostatic or rectovaginal septum, including fibres from levator ani (puborectalis or pubovaginalis). Anteriorly, it receives a contribution from the deep and superficial transverse perineal muscles and bulbospongiosus (see Figs 73.4, 73.13). The perineal body is continuous with the perineal membrane and the superficial perineal fascia. Since the latter runs forwards into the skin of the perineum, the perineal body is tethered to the central perineal skin, which is often puckered over it. In males, this is continuous with the perineal raphe in the skin of the scrotum. In females, the perineal body lies directly posterior, and is attached, to the posterior commissure of the labia majora and the introitus of the vagina.

Spontaneous lacerations of the perineal body sustained during childbirth are often associated with damage to the anterior fibres of the external anal sphincter. The deliberate division of the perineal body to facilitate delivery (episiotomy) is sometimes angled laterally to avoid such sphincteric injuries. The perineal body is often used to position radiological markers in the assessment of pelvic floor dysfunction.

## Superficial transverse perineal muscles

The superficial transverse perineal muscles are narrow strips of muscle that run more or less transversely across the superficial perineal space anterior to the anus, from the medial and anterior aspects of the ischial tuberosities to the perineal body (see Fig. 73.13). A few fibres may also pass into the ipsilateral bulbospongiosus or external anal sphincter. They are occasionally small and may be absent.

## Bulbospongiosus

Bulbospongiosus differs between the sexes. In the male, it lies in the midline, anterior to the perineal body (see Fig. 73.12). It consists of two symmetrical parts united by a median fibrous raphe. The fibres attach to the perineal body, in which they decussate, and to the transverse superficial perinei and the external anal sphincter; they diverge like the sides of a feather from the median raphe. A thin layer of posterior fibres joins the posterior portion of the perineal membrane. The

Fig. 73.14 Muscles and fasciae of the male perineum: coronal view. The section passes through the bulb of the penis at the level of the urethra. The deep perineal space is continuous with the ischio-anal fossa posteriorly. The visceral and parietal fasciae have been omitted for clarity. The pelvic fascia over the 'pelvic' aspect of the deep transverse perinei is very thin and does not form a distinct layer: in places it blends with the parietal pelvic fascia over the inferior aspect of levator ani.
majority of the middle fibres encircle the bulb of the penis and adjacent corpus spongiosum, and attach to an aponeurosis on the dorsal surfaces. The anterior fibres spread out over the sides of the corpora cavernosa, ending partly in them, anterior to ischiocavernosus, and partly in a tendinous expansion that covers the dorsal vessels of the penis. In the female, bulbospongiosus also attaches to the perineal body, but the muscle on each side is separate and covers the superficial parts of the vestibular bulbs and greater vestibular glands (see Fig. 73.13). Fibres run anteriorly on either side of the vagina to attach to the corpora cavernosa clitoridis, and a few fibres cross over the dorsum of the body of the clitoris.

Actions In the male, bulbospongiosus helps to empty the urethra of urine after the bladder has emptied. It may assist in the final stage of erection as the middle fibres compress the erectile tissue of the bulb and the anterior fibres contribute by compressing the deep dorsal vein of the penis. It contracts six or seven times during ejaculation, assisting in the expulsion of semen. In the female, bulbospongiosus acts to constrict the vaginal orifice and express the secretions of the greater vestibular glands. Anterior fibres contribute to erection of the clitoris by compressing its deep dorsal vein.

## Ischiocavernosus

In the male, ischiocavernosus covers the crus penis. It is attached by tendinous and muscular slips to the medial aspect of the ischial tuberosity posteriorly, and to the ischial ramus on both sides of the crus (see Fig. 73.12). These fibres end in an aponeurosis that is attached to the sides and undersurface of the crus penis. In the female, ischiocavernosus is related to the crus of the clitoris but is otherwise similar to the corresponding muscle in the male (Figs 73.15-73.16).

Actions Ischiocavernosus compresses the crus penis in males and may help to maintain penile erection. The muscles form a triangle on each side of the midline with bulbospongiosus medially and the superficial transverse perineal muscles posteriorly, attached to the perineal membrane; when contracted, the two ischiocavernosi act together to stabilize the erect penis. In the female, ischiocavernosus may help to promote increased pressure in the clitoris.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE PERINEUM

## Arteries of the perineum

## Internal pudendal artery (in the perineum)

The internal pudendal artery enters the perineum around the posterior aspect of the ischial spine and runs on the lateral wall of the ischio-anal fossa in the pudendal (Alcock's) canal with the pudendal veins and the pudendal nerve. The canal lies about 4 cm above the lower limit of the ischial tuberosity and is formed by connective tissue binding the vessels and nerve to the medial surface of the fascia covering obturator internus. As the artery approaches the margin of the ischial ramus, it proceeds above or below the perineal membrane, along the medial margin of the inferior pubic ramus, en route to its target structures.

In the male, the internal pudendal artery distal to the perineal artery gives a branch to the bulb of the penis before it divides into the cavernous (deep, cavernosal) and dorsal arteries of the penis (see Fig. 73.12). Given its distribution, the internal pudendal artery distal to its perineal branch has been named the artery of the penis. The artery to the bulb supplies the corpus spongiosum, and the cavernous artery of the penis supplies the corpus cavernosum on each side. The dorsal artery runs on the dorsal aspect of the penis and supplies circumflex branches to the corpora cavernosa and corpus spongiosum that end by anastomosing in the coronal sulcus and supplying the glans penis and its overlying skin.

In the female, a similar branch of the pudendal artery is distributed to the erectile tissue of the corpus spongiosum and vagina. The cavernous artery supplies the corpora cavernosa of the clitoris; the dorsal artery supplies the glans and prepuce of the clitoris.

Branches of the internal pudendal artery are sometimes derived from an accessory pudendal artery, which is usually a branch of the pudendal artery before its exit from the pelvis; effectively, the artery is double before it leaves the pelvis.

## Inferior rectal artery

The inferior rectal artery arises just after the internal pudendal artery enters the pudendal canal on the lateral wall of the ischio-anal fossa. It

Fig. 73.15 Muscles and fasciae of the female perineum - coronal view. The section passes through the bulb of the clitoris at the level of the urethra. The deep perineal space is continuous with the ischio-anal fossa posteriorly. The visceral and parietal fasciae have been omitted for clarity. The pelvic fascia over the 'pelvic' aspect of the deep transverse perinei is very thin and does not form a distinct layer: in places it blends with the parietal pelvic fascia over the inferior aspect of levator ani.

Fig. 73.16 Muscles and fasciae of the female perineum: coronal T2-weighted magnetic resonance image. (Courtesy of Dr J Lee and Ms K Wimpey, Chelsea and Westminster Hospital, London.)
runs anteromedially through the adipose tissue of the ischio-anal fossa to reach the deep portion of the external anal sphincter, and often branches before reaching the sphincter. During dissections of the anal canal, particularly during perineal excisions of the anorectum, the inferior rectal vessels are encountered in the ischio-anal fossa and must be secured before division; otherwise, they tend to retract laterally to the canal, where they can cause troublesome bleeding.

## Perineal artery

The perineal artery is a branch of the internal pudendal artery that arises near the anterior end of the pudendal canal and runs through the perineal membrane. In the male, it approaches the scrotum in the superficial perineal space, between bulbospongiosus and ischiocavernosus (see Fig. 76.24). A small transverse branch passes medially, inferior to the superficial transverse perineal muscle, to anastomose with the
contralateral artery and with the posterior scrotal and inferior rectal arteries. It supplies the transverse perinei, the perineal body and the posterior attachment of the bulb of the penis. The posterior scrotal arteries are usually terminal branches of the perineal artery but may also arise from its transverse branch. They are distributed to the scrotal skin and dartos muscle in the male and supply the perineal muscles. In the female, the perineal artery runs an almost identical course to that in the male and gives off the posterior labial arteries (see Fig. 77.4).

## Veins of the perineum: internal pudendal veins

The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel ending in the internal iliac vein.

The perineal tributaries receive veins from the penile bulb and the scrotum (males), or clitoris and labia (females), and the inferior rectal veins join towards the posterior end of the pudendal canal.

## Lymphatic drainage of the perineum

The lymphatics from the skin of the penis and scrotum (male), or skin of the clitoris and labia (female), drain together with lymphatics from the perineal skin to the superficial inguinal nodes and, from there, to the deep inguinal nodes. The glans, corpora cavernosa and corpus spongiosum of the penis or clitoris drain directly to the deep inguinal nodes (see Fig. 78.10).

## INNERVATION OF THE PERINEUM: PUDENDAL NERVE (IN THE PERINEUM)

The pudendal nerve gives rise to the inferior rectal and perineal nerves and to the dorsal nerves of the penis or clitoris. The course of its branches parallels the pudendal vessels (see Figs 76.24, 77.4). The pudendal nerve occupies a very constant position over the ischial spine and is readily found. It may be 'blocked' by infiltration with a local anaesthetic applied via a needle passed through the lateral wall of the vagina to numb the perineal and anal skin. It may also be palpated over the ischial spine through the lateral wall of the rectum and motor terminal latencies may be measured.

## Inferior rectal nerve

The inferior rectal nerve runs through the medial wall of the pudendal canal with the inferior rectal vessels. It crosses the ischio-anal fossa to supply the external anal sphincter, the lining of the lower part of the anal canal and the circumanal skin. It frequently breaks into terminal branches before reaching the lateral border of the sphincter. Its cutaneous branches that are distributed around the anus overlap the cutaneous branches of the perineal branch of the posterior femoral cutaneous nerve and of the scrotal or labial nerves. The inferior rectal nerve occasionally arises directly from the sacral plexus and crosses the sacrospinous ligament or reconnects with the pudendal nerve. In females, the inferior rectal nerve may supply sensory branches to the lower part of the vagina.

## Perineal nerve

The perineal nerve is the inferior and larger terminal branch of the pudendal nerve in the pudendal canal. It runs forwards below the internal pudendal artery and accompanies the perineal artery, dividing into posterior scrotal or labial and muscular branches. The posterior scrotal or labial nerves are usually double; they have medial and lateral branches that run over the perineal membrane and pass forwards in the lateral part of the urogenital triangle with the scrotal or labial branches of the perineal artery. They supply the skin of the scrotum or labia majora, overlapping the distribution of the perineal branch of the posterior femoral cutaneous and inferior rectal nerves. In females, the posterior labial branches also supply sensory fibres to the skin of the lower vagina.

Muscular branches arise directly from the pudendal nerve to supply the superficial transverse perineal muscles, bulbospongiosus, ischiocavernosus, sphincter urethrae and the anterior parts of the external anal sphincter and levator ani. In males, a nerve to the bulb of the urethra leaves the nerve to the bulbospongiosus, pierces this muscle to supply the corpus spongiosum penis, and ends in the urethral mucosa.

## Dorsal nerve of the penis or clitoris

The dorsal nerve of the penis or clitoris runs anteriorly above the internal pudendal artery along the ischiopubic ramus, deep to the perineal membrane. It supplies the corpus cavernosum and accompanies the dorsal artery of the penis or clitoris between the layers of the suspensory ligament. In males, the dorsal nerve of the penis runs on the dorsum of the penis to end in the glans.

## Kidney and ureter

## CHAPTER 74

## KIDNEY

The kidneys excrete end-products of metabolism and excess water. These actions are essential for the control of concentrations of various substances in the body, maintaining electrolyte and water balance approximately constant in the tissue fluids. The kidneys also have endocrine functions, producing and releasing erythropoietin, which affects red blood cell formation; renin, which influences blood pressure; 1,25-di-hydroxycholecalciferol (the metabolically active form of vitamin D), which is involved in the control of calcium absorption and mineral metabolism; and various other soluble factors with metabolic actions.

In the fresh state, the kidneys are reddish-brown. They are situated posteriorly behind the peritoneum, on each side of the vertebral column, and are surrounded by adipose tissue. Superiorly, they are level with the upper border of the twelfth thoracic vertebra, and inferiorly, with the third lumbar vertebra. The right is usually slightly inferior to the left, reflecting its relationship to the liver. The left is a little longer
and narrower than the right and lies nearer the median plane (Fig. 74.1). The long axis of each kidney is directed inferolaterally and the transverse axis posteromedially, which means that the anterior and posterior aspects usually described are, in fact, anterolateral and posteromedial. An appreciation of this orientation is important in percutaneous and endo-urological renal surgery.

In adults, each kidney is typically 11 cm in length, 6 cm in breadth and 3 cm in anteroposterior dimension. The left kidney may be 1.5 cm longer than the right; it is rare for the right kidney to be more than 1 cm longer than the left. The average weight is 150 g in men and 135 g in women. In thin individuals with a lax abdominal wall, the lower pole of the lower right kidney may just be felt in full inspiration by bimanual lumbar examination, but this is unusual. In the fetus and the newborn, the kidney normally has 12 lobules; in the adult, these lobules are fused to present a smooth surface, although traces of lobulation may remain and can mimic a renal mass on radiographic imaging.

Absent and ectopic kidneys A single absent kidney, resulting from the failure of the metanephric blastema to join a ureteric bud on

Fig. 74.1 Relationships of the kidneys and ureters in the male retroperitoneum. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban and Fischer. Copyright 2013.)
the affected side, is seen in 1 in 1200 individuals. There are no clinical sequelae, but the ipsilateral vas (ductus) deferens and/or epididymis may also be absent and there may be other congenital anomalies, including imperforate anus, cardiac valvular anomalies and oesophageal atresia. A single kidney often shows compensatory hypertrophy but, provided the single kidney is anatomically and functionally normal, the life expectancy of individuals with a single kidney is no different from that of those with two kidneys.

Failure of the kidney to ascend into the renal fossa in utero results in renal ectopia. An ectopic kidney is found in the pelvis in 1 in 2500 live births. Kidneys so placed often have associated malrotation anomalies and may have marked fetal lobulation. Pelvic kidneys frequently become hydronephrotic as a result of an anteriorly placed ureter and an anomalous arterial supply; an associated ureteropelvic junction obstruction is often present.

Very rarely, and despite the normal location of the ureteric orifices within the bladder, the two kidneys may be on the same side (crossed renal ectopia) and are usually fused (crossed-fused ectopia). A solitary crossed renal ectopia may be associated with skeletal and other genitourinary anomalies. A number of different anatomical patterns can result, all of which are extremely rare (Fig. 74.2).

Horseshoe kidney Horseshoe kidneys are found in 1 in 400 individuals. A transverse bridge of renal tissue, the isthmus, often containing functioning renal substance, connects the two renal masses. The isthmus lies between the inferior poles, most commonly anterior to the great vessels; it is often inferior to the inferior mesenteric artery because this vessel obstructs the normal ascent of the kidney during embryologi-
cal development. The ureters curve anterior to the isthmus and often have a high insertion into the renal pelvis (Fig. 74.3).

The blood supply to horseshoe kidneys is variable. One vessel to each moiety is seen in $30 \%$ of horseshoe kidneys but multiple anomalous vessels are common; the isthmus may be supplied by a vessel directly from the aorta or from branches of the inferior mesenteric, common iliac or external iliac arteries. In view of this variable arterial anatomy, angiography or computed tomography (CT) scanning with vascular reconstruction is very helpful when planning renal surgery on horseshoe kidneys. Horseshoe kidneys may exhibit an associated congenital ureteropelvic junction obstruction in up to $30 \%$ of cases and have a chromosomal anomaly in $56 \%$ of cases (Scott 2002). Anomalous vessels crossing the ureter, and the abnormal course of the ureter as it passes over renal substance, may also cause obstruction.

## PERIRENAL FASCIA

The perirenal fascia, sometimes referred to as Gerota's fascia (p. 1084), is a dense, elastic connective tissue sheath that envelops each kidney and suprarenal gland, together with a layer of surrounding perirenal fat (Fig. 74.4; see Fig. 62.2). The kidney and its vessels are embedded in perirenal fat, which is thickest at the renal borders and extends into the renal sinus at the hilum.

The perirenal fascia was originally described as being made up of two separate entities, the posterior fascia of Zuckerkandl and the anterior fascia of Gerota, which fused laterally to form the lateroconal fascia (Burkhill and Healy 2000). According to this view, the lateroconal fascia

Fig. 74.2 Crossed renal ectopia: the possible arrangements of crossed ectopic kidneys.

Fig. 74.3 A, A horseshoe kidney. Note the ureters pass anterior to the isthmus, and the relatively high insertion of the ureters into the renal pelvis. B, Axial contrast-enhanced computed tomography (CT) image. C, Coronal maximal intensity projection (MIP) image of the abdomen. $B$ and $C$ demonstrate midline connection of the parenchyma of the two kidneys below the inferior mesenteric artery ( $B$, arrow), in a horseshoe configuration, in keeping with a horseshoe kidney. (A, With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban and Fischer. Copyright 2013.)
continued anterolaterally behind the colon to blend with the parietal peritoneum. However, work by Mitchell (1950) showed that the perirenal fascia is not made up of distinct fused fasciae but is, in fact, a single multilaminated structure that is fused posteromedially with the muscular fasciae of psoas major and quadratus lumborum. It then extends anterolaterally behind the kidney as a bilaminated sheet,

B

Fig. 74.4 A, A sagittal section through the posterior abdominal wall, showing the relations of the renal fascia of the right kidney. $\mathbf{B}, \mathbf{A}$ transverse section, showing the relations of the renal fascia.
which, at a variable point, divides into a thin anterior lamina, passing anterior to the kidney as the anterior perirenal fascia, and a thicker posterior lamina that continues anterolaterally as the lateroconal fascia and fuses with the parietal peritoneum.

Classically, the anterior perirenal fascia was thought to blend into the dense mass of connective tissue surrounding the great vessels in the root of the mesentery behind the duodenum and pancreas, thereby preventing communication between perirenal spaces across the midline. However inspection of CT images or of anatomical sections of cadavers, following injection of contrast or coloured latex, respectively, into the perirenal space, revealed that fluid could extend across the midline at the third to fifth lumbar levels through a narrow channel measuring $2-10 \mathrm{~mm}$ in anteroposterior dimension. In the midline superiorly, the anterior and posterior renal fasciae fuse and are attached to the crura of their respective hemidiaphragms. Inferiorly, the fasciae separate for a variable craniocaudal distance. The posterior perirenal fascia fuses with the muscular fascia of psoas major, while the anterior perirenal fascia extends across the midline anterior to the great vessels; communication between the two sides is permitted, although is very rarely of clinical significance. Below this level, the two fasciae once again merge
and are attached to the great vessels or iliac vessels. The containment of fluid to one side of the perirenal space that is observed in over twothirds of clinical cases is attributed to the presence of fibrous septa.

Above the suprarenal glands, the anterior and posterior perirenal fasciae were previously said to fuse with each other and to the diaphragmatic fascia. This description of a closed superior cone is not universally accepted. Cadaveric experiments have shown the superior aspect of the perirenal space to be open and in continuity with the bare area of the liver on the right and the subphrenic extraperitoneal space on the left. The posterior fascial layer blends bilaterally with the fascia of psoas major and quadratus lumborum, as well as the inferior phrenic fascia. The anterior fascial layer on the right blends with the right inferior coronary ligament at the level of the upper pole of the kidney and bare area of the liver. On the left, the anterior layer fuses with the gastrosplenic ligament at the level of the suprarenal gland.

There is some debate concerning the inferior fusion of the perirenal fascia. Many investigators believe that, inferiorly, the anterior and posterior leaves of the perirenal fascial fuse to produce an inverted cone that is open to the pelvis at its apex. Laterally, the anterior and posterior leaves fuse with the iliac fascia; medially, they fuse with the periureteric connective tissue. The inferior apex of the cone is open anatomically towards the iliac fossa but rapidly becomes sealed in inflammatory disease. An alternative view is based on the dissection of recently deceased cadavers after injections of coloured latex into the perirenal space, which have shown that the anterior and posterior perirenal fasciae merge to form a single multilaminar fascia that contains the ureter in the iliac fossa. Anteriorly, this common fascia is loosely connected to the parietal peritoneum, and so denies free communication between the perirenal space and the pelvis, and between the perirenal and pararenal spaces.

A simple nephrectomy for benign disease removes the kidney from within perirenal fascia; a radical nephrectomy (for cancer) classically removes the entire contents of the perirenal space, including the perirenal fascia and suprarenal gland, in order to give adequate clearance around the tumour.

## RELATIONS

The superior poles of both kidneys are thick and round, and related to their respective suprarenal glands (Fig. 74.5). The inferior poles are thinner and extend to within 2.5 cm of the iliac crests. The lateral borders are convex. The medial borders are convex adjacent to the poles and concave between them, and slope inferolaterally. In each, a deep vertical fissure opens anteromedially as the hilum, which is bounded by anterior and posterior lips and contains the renal vessels and nerves, and the renal pelvis. The relative positions of the main hilar structures are the renal vein (anterior), the renal artery (intermediate) and the pelvis of the kidney (posterior) (Fig. 74.6). Usually, an arterial branch from the main renal artery runs over the superior margin of the renal pelvis to enter the hilum on the posterior aspect of the pelvis, and a renal venous tributary often leaves the hilum in the same plane. Above the hilum, the medial border is related to the suprarenal gland and below to the origin of the ureter.

The convex anterior surface of the kidney actually faces anterolaterally and its relations differ on the right and left. Likewise, the posterior surface of the kidneys, in reality, faces posteromedially. Its relations are similar on both sides of the body (Fig. 74.7).

A small area of the superior pole of the right kidney is in contact with the right suprarenal gland, which may overlap the upper part of the medial border of the superior pole (Fig. 74.8). A large area below this is immediately related to the right lobe of the liver, separated by a layer of peritoneum. A narrow medial area is directly related to the retroperitoneal descending part of the duodenum. Inferiorly, the anterior surface is directly in contact laterally with the retroperitoneal right colic flexure and medially with part of the intraperitoneal small intestine.

A small medial area of the superior pole of the left kidney is related to the left suprarenal gland (see Fig. 74.8). The lateral half of the anterior surface is related to the spleen, from which it is separated by a layer of peritoneum. A central quadrilateral area lies in direct contact with the retroperitoneal pancreas and the splenic vessels. Above this, a small, variable, triangular region, between the suprarenal and splenic areas, is in contact with the stomach, separated by a layer of peritoneum. Below the pancreatic and splenic areas, a narrow lateral strip that extends to the lateral border of the kidney is directly related to the retroperitoneal left colic flexure and the beginning of the descending colon. An extensive medial area is related to intraperitoneal loops of jejunum. The gastric area is covered with the peritoneum of the lesser sac (omental bursa), and the splenic and jejunal areas are covered by the peritoneum

of the greater sac. Behind the peritoneum covering the jejunal area, branches of the left colic vessels are related to the kidney.

The posteromedial surface of the kidneys is embedded in fat and devoid of peritoneum. The right and left kidneys are related to similar structures. Superiorly are the diaphragm and the medial and lateral arcuate ligaments. More inferiorly, moving in a medial to lateral
direction，are psoas major，quadratus lumborum and the aponeurotic tendon of transversus abdominis，the subcostal vessels，and the subcos－ tal，iliohypogastric and ilioinguinal nerves．The upper pole of the right kidney is level with the twelfth rib，and that of the left with the eleventh and twelfth ribs．The diaphragm separates the kidney from the pleura， which descends to form the costodiaphragmatic recess；diaphragmatic muscle is sometimes defective or absent in a triangle immediately above the lateral arcuate ligament，and this allows perirenal adipose tissue to contact the diaphragmatic pleura．

Fig．74．6 An intraoperative view of the dissected renal hilum．The kidney is seen enveloped by Gerota＇s fascia in the superior aspect of the operative field．The renal artery（RA）is noted in its posterior location adjacent to the larger renal vein（RV）．

## INTERNAL MACROSTRUCTURE

The postnatal kidney has a thin fibrous capsule composed of collagen－ rich connective tissue with some elastic and smooth muscle fibres．In renal disease，the capsule may become adherent．

The kidney itself can be divided into an internal medulla and external cortex（Fig．74．9）．The renal medulla consists of pale，striated， conical renal pyramids；their bases are peripheral，and their apices converge to the renal sinus．At the renal sinus，they project into calyces as papillae．

The renal cortex（see Fig．74．14）is subcapsular，arching over the bases of the pyramids and extending between them towards the renal sinus as renal columns．Its peripheral regions are termed cortical arches and are traversed by radial，lighter－coloured，medullary rays，separated by darker tissue，the convoluted part．The rays taper towards the renal capsule and are peripheral prolongations from the bases of renal pyra－ mids．The cortex is histologically divisible into outer and inner zones． The inner zone is demarcated from the medulla by tangential blood vessels（arcuate arteries and veins），which lie at the junction of the two； however，a thin layer of cortical tissue（subcortex）appears on the med－ ullary side of this zone．The cortex close to the medulla is sometimes termed the juxtamedullar cortex．

## Renal pelvis and calyces

The hilum of the kidney leads into a central renal sinus，lined by the renal capsule and almost filled by the renal pelvis and vessels；the remaining space is filled by fat．Dissection into this plane can be chal－ lenging but is important in surgery on the renal pelvis，particularly open

stone surgery. Within the renal sinus, the collecting tubules of the nephrons of the kidney open on to the summits of the renal papillae to drain into minor calyces, which are funnel-shaped expansions of the upper urinary tract. The renal capsule covers the external surface of the kidney and continues through the hilum to line the sinus and fuse with the adventitial coverings of the minor calyces. Each minor calyx surrounds either a single papilla or, more rarely, groups of two or three papillae. The minor calyces unite with their neighbours to form two, or possibly three, larger chambers: the major calyces. There is wide variation in the arrangement of the calyces. As the posterior aspect of the kidney rotates laterally during its ascent in utero, the calyces that were lateral in utero become positioned anteriorly, and the medial calyces move more posteriorly. The calyces drain into the infundibula. The renal pelvis is normally formed from the junction of two infundibula - one from the upper and one from the lower pole calyces - but there may be a third, which drains the calyces in the mid portion of the kidney. The calyces are usually grouped so that three pairs drain into the upper pole infundibulum and four pairs into the lower pole infundibulum. If there is a middle infundibulum, the distribution is normally three pairs at the upper pole, two in the middle, and two at the lower pole. There is considerable variation in the arrangement of the infundibula and in the extent to which the pelvis is intrarenal or
extrarenal. The funnel-shaped renal pelvis tapers as it passes inferomedially, traversing the renal hilum to become continuous with the ureter (see Figs 74.9-74.10). It is rarely possible to determine precisely where the renal pelvis ceases and the ureter begins; the region is usually extrahilar and normally lies adjacent to the lower part of the medial border of the kidney. Rarely, the entire renal pelvis has been found to lie inside the sinus of the kidney so that the pelviureteric region occurs either in the vicinity of the renal hilum or completely within the renal sinus.

The calyces, renal pelvis and ureter are well demonstrated radiologically following an intravenous injection of radio-opaque contrast that is excreted in the urine (computed tomographic urography, CTU) (Fig. 74.10 ), or after the introduction of radio-opaque contrast into the ureter by catheterization through a cystoscope (ascending or retrograde pyelography). Normal cupping of the minor calyces by projecting renal papillae may be obliterated by conditions that cause hydronephrosis: chronic distension of the ureter and renal pelvis due to upper or lower urinary tract obstruction, resulting in elevated intrapelvic pressure. An appreciation of the rotation of the kidneys, which results in the posterior calyces lying relatively medially and the anterior calyces lying laterally, is essential when interpreting contrast imaging of the collecting system of the kidneys.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Renal arteries

The paired renal arteries take about $20 \%$ of the cardiac output to supply organs that represent less than $1 \%$ of total body weight. They branch laterally from the aorta just below the origin of the superior mesenteric artery (see Fig. 59.6; Fig. 74.11A). Both cross the corresponding crus of the diaphragm at right angles to the aorta. The right renal artery is longer and often higher, passing posterior to the inferior vena cava, right renal vein, head of the pancreas, and descending part of the duodenum. The left renal artery is a little lower and passes behind the left renal vein, the body of the pancreas, and splenic vein. It may be crossed anteriorly by the inferior mesenteric vein.

A single renal artery to each kidney is present in approximately 70\% of individuals (Fig. 74.12). The arteries vary in their level of origin and in their calibre, obliquity and precise relations (Fig. 74.11B). In its extrarenal course, each renal artery gives off one or more inferior suprarenal arteries, a branch to the ureter, and branches that supply perinephric tissue, the renal capsule and the pelvis. Near the renal hilum, each artery divides into an anterior and a posterior division, and these divide into segmental arteries supplying the renal vascular segments (Fig. 74.11C). Accessory renal arteries are common (30\% of individuals), and usually arise from the aorta above or below (most commonly, below) the main renal artery and follow it to the renal hilum (Merklin and Michels 1958). They are regarded as persistent embryonic lateral splanchnic arteries. Accessory vessels to the inferior pole cross anterior to the ureter and may, by obstructing the ureter, cause hydronephrosis (Fig. 74.13). In children with pelviureteric junction obstruction, a crossing vessel is found in $28 \%$ of cases (Veyrac et al 2003). Three anatomical variants of aberrant lower pole crossing vessels have been described: anterior to the dilated pelvis or pelviureteric junction, or inferior to the pelviureteric junction, causing kinking of the ureter
(Schneider et al 2013). Rarely, accessory renal arteries arise from the coeliac or superior mesenteric arteries near the aortic bifurcation, or from the common iliac arteries.

The subdivisions of the renal arteries are described sequentially as segmental, lobar, interlobar, arcuate and interlobular arteries, and afferent and efferent glomerular arterioles (Fig. 74.14).

## Segmental arteries

Renal vascular segmentation was originally recognized by John Hunter in 1794, but the first detailed account of the primary pattern was produced in the 1950s from casts and radiographs of injected kidneys. Five arterial segments have been identified (Fig. 74.15). The apical segment occupies the anteromedial region of the superior pole. The superior (anterior) segment includes the rest of the superior pole and the central anterosuperior region. The inferior segment encompasses the whole lower pole. The middle (anterior) segment lies between the anterior and inferior segments. The posterior segment includes the whole posterior region between the apical and inferior segments. This is the pattern most commonly seen, and although there can be considerable variation, it is the pattern that clinicians most frequently encounter when performing partial nephrectomy. Whatever pattern is present, it is important to emphasize that vascular segments are supplied by virtual end arteries. In contrast, larger intrarenal veins have no segmental organization and anastomose freely.

Brödel described a relatively avascular longitudinal zone (the 'bloodless' line of Brödel) along the convex renal border, which was proposed as the most suitable site for surgical incision (Brödel 1911). However, many vessels cross this zone, and it is far from 'bloodless'; planned radial or intersegmental incisions are preferable. Knowledge of the vascular anatomy of the kidney is important when undertaking partial nephrectomy for renal cell cancers. In this surgery, the branches of the renal artery are defined so that the surgeon may safely excise the renal substance containing the tumour while not compromising the vascular supply to the remaining renal tissue (Novick 1998).

## Lobar, interlobar, arcuate and interlobular arteries

The initial branches of segmental arteries are lobar, usually one to each renal pyramid. Before reaching the pyramid, they subdivide into two or three interlobar arteries, extending towards the cortex around each pyramid. At the junction of the cortex and medulla, interlobar arteries dichotomize into arcuate arteries, which diverge at right angles. As they arch between cortex and medulla, each divides further, ultimately supplying interlobular arteries that diverge radially into the cortex. The terminations of adjacent arcuate arteries do not anastomose but end in the cortex as additional interlobular arteries. Though most interlobular arteries come from arcuate branches, some arise directly from arcuate, or even terminal, interlobar arteries (see Fig. 74.14). Interlobular arteries ascend towards the superficial cortex or may branch occasionally en route. Some are more tortuous and recurve towards the medulla at least once before proceeding towards the renal surface. Others traverse the surface as perforating arteries to anastomose with the capsular plexus (which is also supplied from the inferior suprarenal, renal and gonadal arteries).

## Afferent and efferent glomerular arterioles

Afferent glomerular arterioles are mainly the lateral rami of interlobular arteries. A few arise from arcuate and interlobar arteries, when they vary their direction and angle of origin: deeper ones incline obliquely back towards the medulla, the intermediate pass horizontally, and the more superficial approach the renal surface obliquely before ending in a glomerulus (see Fig. 74.14). Efferent glomerular arterioles from most glomeruli (except at juxtamedullary and, sometimes, at intermediate cortical levels) soon divide to form a dense peritubular capillary plexus around the proximal and distal convoluted tubules; there are, thus, two sets of capillaries - glomerular and peritubular - in series in the main renal cortical circulation, linked by efferent glomerular arterioles. The vascular supply of the renal medulla is largely from efferent arterioles of juxtamedullary glomeruli, supplemented by some from more superficial glomeruli, and 'aglomerular' arterioles (probably from degenerated glomeruli). Efferent glomerular arterioles passing into the medulla are relatively long, wide vessels, and contribute side branches to neighbouring capillary plexuses before entering the medulla, where each divides into $12-25$ descending vasa recta. As their name suggests, these run straight to varying depths in the renal medulla, contributing side branches to a radially elongated capillary plexus applied to the descending and ascending limbs of renal loops and to collecting ducts. The venous ends of capillaries converge to the ascending vasa recta, which drain into arcuate or interlobular veins. An essential feature of the vasa recta (particularly in the outer medulla) is that both ascending and

C, An intraoperative angiogram of the left kidney, demonstrating the main renal artery (1), segmental renal arteries (2) and their subsequent branches. (B, With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban and Fischer. Copyright 2013.)
descending vessels are grouped into vascular bundles, within which the external aspects of both types are closely apposed, bringing them close to the limbs of renal loops and collecting ducts. As these bundles converge centrally into the renal medulla, they contain fewer vessels; some terminate at successive levels in neighbouring capillary plexuses. This proximity of descending and ascending vessels to each other and to adjacent ducts provides the structural basis for the countercurrent exchange and multiplier phenomena (Fig. 74.16). These complex renal vascular patterns show regional specializations that are closely adapted to the spatial organization and functions of renal corpuscles, tubules and ducts (see below).

## Renal veins

Fine radicles from the venous ends of the peritubular plexuses converge to join interlobular veins, one with each interlobular artery. Many interlobular veins begin beneath the fibrous renal capsule by the convergence of several stellate veins, which drain the most superficial zone of the renal cortex and so are named from their surface appearance. Interlobular veins pass to the corticomedullary junction and also receive some ascending vasa recta before ending in arcuate veins (which accompany arcuate arteries), and anastomose with neighbouring veins.

Arcuate veins drain into interlobar veins, which anastomose and form the renal vein.

The large renal veins lie anterior to the renal arteries and open into the inferior vena cava almost at right angles (see Fig. 59.7; Fig. 74.17). The left is three times longer than the right ( 7.5 cm and 2.5 cm , respectively), and for this reason, the left kidney is the preferred side for live donor nephrectomy. The left renal vein runs from its origin in the renal hilum, posterior to the splenic vein and the body of pancreas, and then across the anterior aspect of the aorta, just below the origin of the superior mesenteric artery. Nutcracker syndrome, characterized by left renal vein hypertension secondary to compression of the vein between the aorta and the superior mesenteric artery, has been associated with haematuria and varicocele in children. The left gonadal vein enters the left renal vein from below, and the left suprarenal vein, usually receiving one of the left inferior phrenic veins, enters it above but nearer the midline. The left renal vein enters the inferior vena cava a little superior to the right. The right renal vein is behind the descending duodenum and, sometimes, the lateral part of the head of the pancreas. It can be extremely short (less than 1 cm ), such that safe nephrectomy may require excision of a cuff of the inferior vena cava.

The left renal vein may be double, one vein passing posterior, and the other anterior, to the aorta before joining the inferior vena cava. This is sometimes referred to as persistence of the 'renal collar'. The

Fig. 74.15 The segmental arterial anatomy of the right kidney. The posterior division branches near the hilum before the anterior division divides into the other segmental arteries.
anterior vein may be absent so that there is a single retro-aortic left renal vein. The left renal vein may have to be ligated during surgery for aortic aneurysm because it has such a close relationship with the aorta; this seldom results in any harm to the kidney, provided that the ligature is placed medial to the draining gonadal and suprarenal veins, since these usually provide adequate collateral venous drainage. The right renal vein has no significant collateral drainage and cannot be ligated with impunity.

## Lymphatic drainage

Renal lymphatic vessels begin in three plexuses: around the renal tubules, under the renal capsule, and in the perirenal fat (the latter two connect freely). Collecting vessels from the intrarenal plexus form four or five trunks that follow the renal vein to end in the lateral aortic nodes; the subcapsular collecting vessels join them as they leave the hilum. The perirenal plexus drains directly into the same nodes.

## INNERVATION

Rami from the coeliac ganglion and plexus, aorticorenal ganglion, lowest thoracic splanchnic nerve, first lumbar splanchnic nerve and aortic plexus form a dense plexus of autonomic nerves around the renal artery (see Figs 59.4, 59.5).

Small ganglia occur in the renal plexus, the largest usually behind the origin of the renal artery. The plexus continues into the kidney around the arterial branches and supplies the vessels, renal glomeruli and, especially, the cortical tubules. Axons from plexuses around the arcuate arteries innervate juxtamedullary efferent arterioles and vasa recta, which control the blood flow between the cortex and medulla without affecting the glomerular circulation. Axons from the renal plexus contribute to the ureteric and gonadal plexuses.

## MICROSTRUCTURE

The kidney is composed of many tortuous, closely packed uriniferous tubules, bounded by a delicate connective tissue in which run blood vessels, lymphatics and nerves. Each tubule consists of two embryologically distinct parts, the nephron, which produces urine, and the collecting duct, which completes the concentration of urine and through which urine passes out into the calyces of the kidney, the renal pelvis, the ureter and urinary bladder.

## Nephron

The nephron consists of a renal corpuscle, concerned with filtration from the plasma, and a renal tubule, concerned with selective resorption from the filtrate to form the urine (see Fig. 74.14). Collecting ducts carry fluid from several renal tubules to a terminal papillary duct, opening into a minor calyx at the apex of a renal papilla. Papillary surfaces show numerous minute orifices of these ducts and pressure on a fresh kidney expresses urine from them.

## Renal corpuscle

Renal corpuscles are small, rounded structures averaging 0.2 mm in diameter, visible in the renal cortex deep to a narrow peripheral cortical zone (Fig. 74.18; see Fig. 74.16). Each has a central glomerulus of vessels and a glomerular (Bowman's) capsule, from which the renal tubule originates.

There are about 1 million renal corpuscles in each kidney, their number (which may be determined, in part, by intrauterine factors) decreasing with age; this process is accelerated by raised blood pressure. After birth, new nephrons cannot be developed; a lost nephron can never be replaced. The decrease in corpuscular numbers with age is reflected in a corresponding reduction in the rate of glomerular filtration from the fourth decade onwards.

## Glomerulus

A glomerulus is a collection of convoluted capillary blood vessels, united by a delicate mesangial matrix and supplied by an afferent arteriole which enters the capsule opposite the urinary pole, where the filtrate enters the tubule (Davies et al 2001). (The term glomerulus is used most frequently to describe the entire renal corpuscle.) An efferent arteriole emerges from the same point, the vascular pole of the corpuscle. Glomeruli are simple in form until late prenatal life; some remain so for about 6 months after birth, the majority maturing by 6 years and all by 12 years. Low birth weight, defined as a weight less than 2500 g at birth, is associated with a reduction in the number and volume of glomeruli (Manalich et al 2000).

## Bowman's capsule

Bowman's capsule is the blind expanded end of a renal tubule, and is deeply invaginated by the glomerulus. It is lined by a simple squamous epithelium on its outer (parietal) wall; its glomerular, juxtacapillary (visceral) wall is composed of specialized epithelial podocytes. Between the two walls of the capsule is a flattened urinary (Bowman's) space, continuous with the proximal convoluted tubule (Fig. 74.18B; see Fig. 74.16).

Podocytes are stellate cells. Their major (primary) foot processes curve around the capillary loops and branch to form secondary processes that are applied closely to the basal lamina; secondary or tertiary processes give rise to terminal pedicels (Fig. 74.19A). Pedicels of one cell alternate with those of an adjacent cell and interdigitate tightly with each other, separated by narrow ( 25 nm ) gaps: the filtration slits (Fig. 74.19 B ). The latter are covered by a dense, membranous, slit diaphragm, through which filtrate must pass to enter the urinary space. The differentiation of the adult podocyte phenotype is associated with the presence of several specific proteins, including nephrin, podocin, synaptopodin and GLEPP-1. Mutations in these proteins can cause important functional problems, e.g. the classic Finnish form of congenital nephritic syndrome is caused by a mutation of NHPS1, coding for nephrin. The luminal membrane and the slit diaphragm are covered by a dense surface coat rich in sialoglycoproteins, which gives this surface a very high negative charge and is one of the key characteristics of the perm-selectivity barrier. Differentiated podocytes cannot replicate.

The glomerular endothelium is finely fenestrated. The principal barrier to the passage of fluid from capillary lumen to urinary space is

Fig. 74.16 The regional microstructure and principal activities of a kidney nephron and collecting duct. For clarity, a nephron of the long loop (juxtamedullary) type is shown. Abbreviations: ADH, antidiuretic hormone.

Fig. 74.17 A, A coronal maximum-intensity projection contrast-enhanced magnetic resonance angiogram image obtained during the arterial phase of enhancement. It demonstrates normal-appearing single renal arteries (short arrows), normal-appearing single renal veins (long arrows), a normal-appearing abdominal aorta (A), and a normal-appearing suprarenal inferior vena cava (I). The infrarenal inferior vena cava has not yet been enhanced. B, A CT renal venogram, acquired from a multislice CT examination and reconstructed as a three-dimensional, surface-shaded reformat.
the glomerular basal lamina, the fused endothelial and podocyte basal laminae (see Fig. 74.19B). This is usually $0.33 \mu \mathrm{~m}$ thick in humans, and acts as a selective filter, allowing the passage from blood, under pressure, of water and various small molecules and ions in the circulation. Haemoglobin may cross the filter, but larger molecules and those of similar size with a negative charge are largely retained. Most protein that does enter the filtrate is selectively resorbed and degraded by cells of the proximal convoluted tubule.

The glomerular basement membrane serves as the skeleton of the glomerular tuft. Its outer aspect is completely covered by podocytes, and the interior is filled by capillaries and a delicate mesangial matrix (mesangium). The major components of the glomerular basement membrane are laminin and type IV collagen (both of which are expressed as unique isoforms), and heparin sulphate proteoglycans. The

Fig. 74.18 A, A low-power histological section of the renal cortex, containing glomeruli $(\mathrm{G})$, proximal and distal convoluted tubules and blood vessels (BV). B, A higher-power view of the section demonstrating several glomeruli (G) within a network of mesangium. The glomerular basement membrane of the capillaries is continuous with Bowman's capsule (short arrow) of the glomerulus, and is separated from it by Bowman's space (long arrow).
thickness of the glomerular basement membrane increases throughout childhood; the rate of increase decreases after the age of 11 years (Ramage et al 2002).

Irregular mesangial cells, with phagocytic and contractile properties, lie within and secrete the glomerular mesangium, a specialized connective tissue that binds the loop of glomerular capillaries and fills the spaces between endothelial surfaces that are not invested by podocytes (see Figs 74.18B, 74.16). Mesangial cells are related to vascular pericytes and are concerned with the turnover of glomerular basement membrane. They clear the glomerular filter of immune complexes and cellular debris, and their contractile properties help to regulate blood flow. Similar cells, the extraglomerular mesangial (lacis) cells, lie outside the glomerulus at the vascular pole and form part of the juxtaglomerular apparatus.

## Renal tubule

A renal, or uriniferous, tubule consists of a glomerular capsule that leads into a proximal convoluted tubule, connected to the capsule by a short neck and continuing into a sinuous or coiled convoluted part (see Fig. 74.16). This straightens as it approaches the medulla, and becomes the descending thick limb of the loop of Henle, and then the ascending limb by an abrupt U-turn. The limbs of the loop of Henle are narrower and thin-walled within the deeper medullary tissue, where they become the descending and ascending thin segments. The ascending thick limb continues into the distal tubule. The tubule wall shows a focal thickening, the macula densa, where it comes close to the vascular pole of its parent glomerulus at the start of the convoluted part of the distal tubule. The nephron finally straightens once more as the connecting tubule, which ends by joining a collecting duct.

Fig. 74.19 A, A scanning electron micrograph showing podocytes forming the visceral layer of Bowman's capsule in the renal corpuscle. Their cell bodies $(P)$ send out primary processes that branch several times and end in fine pedicels, which wrap tightly around the glomerular capillaries (C), and interdigitate with similar pedicels from a neighbouring podocyte. B, An electron micrograph demonstrating the glomerular filtration apparatus. Note the endothelial cells of fenestrated capillaries, the filtration slits between podocyte pedicels and their thick shared basal lamina. Abbreviations: BL, basal lamina; C, lumina of capillary loops; E, endothelial cell cytoplasm; F, fenestrations; FS, filtration slits; P, podocyte; $P_{1}$ and $P_{2}$, primary and secondary foot processes that rest on the glomerular basal laminae. (A, With permission from Igaku-Shoin, Tokyo, from Fujita T, Tanaka K, Tokunaga J 1981 SEM Atlas of Cells and Tissues. B, With permission from Young B, Heath JW 2000 Wheater's Functional Histology. Edinburgh: Churchill Livingstone.)

Collecting ducts originate in the cortical medullary rays and join others at intervals. They finally open into wider papillary ducts, which open on to a papilla, their numerous orifices forming a perforated area cribrosa on the surface at its tip (see Fig. 74.14).

Renal tubules are lined throughout by a single-layered epithelium (see Fig. 74.16; Fig. 74.20). The type of epithelial cell varies according to the functional roles of the different regions, e.g. active transport and passive diffusion of various ions and water into and out of the tubules; reabsorption of organic components such as glucose and amino acids; uptake of any proteins which leak through the glomerular filter.

The proximal convoluted tubule is lined by cuboidal or low columnar epithelium and has a brush border of tall microvilli on its luminal surface. The shape of the cells depends on tubular fluid pressure, which, in life, distends the lumen and flattens the cells (they become taller when glomerular blood pressure falls post mortem or at biopsy). The cytoplasm of proximal tubular cells is strongly eosinophilic and the nuclei are euchromatic and central. The basal cytoplasm is rich in mitochondria, orientated perpendicularly, and the basal plasma membrane is highly infolded. The lateral surfaces of adjacent epithelial cells interdigitate, increasing the complexity of the basolateral plasma membrane. The microvilli on the luminal surfaces significantly increase the area of plasma membrane in contact with tubular fluid and the extratubular space, facilitating the transport of ions and small molecules against steep concentration gradients. The abundant mitochondria supply the energy, as adenosine triphosphate (ATP), needed for this process. Sodium/potassium adenosine triphosphatase ( $\mathrm{Na}^{+} / \mathrm{K}^{+}$ATPase) is located in apical and basal membranes, and the cytoplasm contains

Fig. 74.20 A histological cross-section of a part of the renal medulla. Note the large collecting ducts and small, thin segments of the loop of Henle, interspersed with vasa recta (V) (trichrome-stained).
numerous other enzymes concerned with ion transport. Water and other solutes pass between cells (paracellular transport) passively, along osmotic and electrochemical gradients, probably through leaky apical tight junctions. Pinocytotic vesicles are found near the apical surface, and represent the means by which small proteins and peptides from the filtrate are internalized and degraded by associated lysosomes. Peroxisomes and lipid droplets abound in the cytoplasm.

The loop of Henle consists of a thin segment ( $30 \mu \mathrm{~m}$ in diameter), lined by low cuboidal to squamous cells, and a thick segment ( $60 \mu \mathrm{~m}$ in diameter), composed of cuboidal cells like those in the distal convoluted tubule. The thin segment forms most of the loop in juxtamedullary nephrons, which reach deep into the medulla. Few organelles appear in cells lining the thin segment, indicating that these cells play a passive, rather than an active, role in ion transport. The thick segment is composed of cuboidal epithelium with many mitochondria, deep basolateral folds and short apical microvilli, indicating a more active metabolic role. The thick limb of the loop of Henle is the source of Tamm-Horsfall protein in normal urine.

Cells of the distal tubule are cuboidal and resemble those in the proximal tubule. They have few microvilli, and so the tubular lumen has a more distinct outline. The basolateral folds containing mitochondria are deep, almost reaching the luminal aspect. Enzymes concerned with active transport of sodium, potassium and other ions are abundant. At the junction of the straight and convoluted regions, the distal tubule comes close to the vascular pole of its parent renal corpuscle. Here, tubular cells form the macula densa, a sensory structure that is concerned with the regulation of blood flow and, thus, filtration rate. Cells in the terminal part of the distal tubule have fewer basal folds and mitochondria, and constitute a connecting duct formed from metanephric mesenchyme during embryogenesis. Collecting ducts are lined by simple cuboidal or columnar epithelium. This increases in height from the cortex, where the ducts receive the contents of distal tubules, to the wide papillary ducts that discharge at the area cribrosa. The palestaining principal cells have relatively few organelles or lateral interdigitations, and only occasional microvilli. A second cell type, intercalated or dark cells (also present in smaller numbers in the distal convoluted tubule), has longer microvilli and more mitochondria, and secretes $\mathrm{H}^{+}$ into the filtrate; these cells function in the maintenance of acid-base homeostasis.

## Renal vessels

Renal, interlobar and arcuate arteries are typical large muscular arteries and the interlobular vessels resemble small muscular arteries. Afferent glomerular vessels have a typical arteriolar structure with a muscular coat 2-3 cells thick; this coat and the connective tissue components of the wall diminish near a glomerulus until a point $30-50 \mu \mathrm{~m}$ proximal to it, where arteriolar cells begin to show modifications typical of the juxtaglomerular apparatus. The efferent arterioles from most cortical glomeruli have thicker walls and a narrower calibre than corresponding afferents. Although the afferent arteriole is generally considered to be solely responsible for tubuloglomerular feedback, the peritubular and medullary capillaries possess a well-defined basal lamina and their endothelial cells have typically fenestrated cytoplasm, as do the ascending vasa recta, whereas the descending vasa recta have a thicker, continuous endothelium (Davies 1991).

## Other renal cells

Other cells essential to renal structure and function lie between the renal tubules and blood vessels. Connective tissue is inconspicuous in the cortex but prominent in the medulla, particularly in the papillae. Medullary interstitial cells, which may be modified fibroblasts, form vertical stacks of tangentially orientated cells between the more distal collecting ducts, like the rungs of a ladder. These cells secrete prostaglandins and may contribute, with cortical tubular cells, to the renal source of erythropoietin.

## Calyces and pelvis

The wall of the proximal part of the urinary tract is composed of three layers: an outer connective tissue adventitia, an intermediate layer of smooth muscle and an inner mucosa. The mucosal lining of the renal calyces and pelvis is identical in structure to that of the ureter (see below). The adventitia consists of loose fibroelastic connective tissue that merges with retroperitoneal areolar tissue. Proximally, the coat fuses with the fibrous capsule of the kidney lining the renal sinus.

The smooth muscle of the renal calyces and pelvis is composed of two distinct types of smooth muscle cell. One type of muscle cell is identical to that described for the ureter and can be traced proximally through the pelviureteric region and renal pelvis, as far as the minor calyces. The other type of cell forms the muscle coat of each minor calyx and continues into the major calyces and pelvis, where it forms a distinct inner layer. The cells also form a thin sheet of muscle that covers each minor calyx and extends across the renal parenchyma between the attachments of neighbouring minor calyces, thereby linking each minor calyx to its neighbours. This discrete inner layer of atypical smooth muscle ceases in the pelviureteric region, so that the proximal ureter lacks such an inner layer. Pacemaker cells that initiate renal pelvic and ureteric peristalsis are sited within the calyces (Gosling and Dixon 1974). These allow coordinated peristalsis of the ureter six times a minute.

## PRODUCTION OF URINE

## Glomerular filtration

Glomerular filtration (see Figs 74.14, 74.16) is the passage of water containing dissolved small molecules from the blood plasma to the urinary space in the glomerular capsule. Larger molecules, e.g. plasma proteins above 70 kilodaltons and those with a net negative charge, polysaccharides, lipids and cells, are largely retained in blood by the selective permeability of the glomerular basal lamina.

Filtration occurs along a steep pressure gradient between the large glomerular capillaries and the urinary space, the principal structure separating the two being the glomerular basal lamina (Fig. 74.19B). This gradient far exceeds the colloid osmotic pressure of blood, which opposes the outward flow of filtrate. In the peripheral renal cortex, the arteriolar pressure gradient is enhanced because afferent glomerular arterioles are wider than efferent glomerular arterioles. In all glomeruli, the rate of filtration can be altered by changes in the tone of the glomerular arterioles. When first formed, the glomerular filtrate is isotonic with glomerular blood and has an identical concentration of ions and small molecules.

The assessment of glomerular filtration is fundamental to the diagnosis of renal glomerular pathology and the management of drug therapy, where clearance depends on the glomerular filtration, and in chronic kidney disease to facilitate timely management decisions. Measurements of glomerular filtration rate (GFR) are based on the renal clearance of a marker in plasma, expressed as the volume of plasma completely cleared of the marker per unit time. Markers used to measure GFR may be endogenous (creatinine, urea) or exogenous (inulin, iothalamate) substances. The ideal marker is endogenous, freely filtered by the glomerulus, neither reabsorbed nor secreted by the renal tubule, and eliminated only by the kidney.

## Selective resorption

Selective resorption from the filtrate is an active process and occurs mainly in the proximal convoluted tubules, which resorb glucose, amino acids, phosphate, chloride, sodium, calcium and bicarbonate, and take up small proteins (e.g. albumin) by endocytosis. Cells of the proximal tubules are permeable to water, which passes out of the tubules passively, so that the filtrate remains locally isotonic with blood.

The rest of the tubule reabsorbs most of the water (to a variable extent, up to $95 \%$ ), so that, when it reaches the calyces, urine is generally much reduced in volume and hypertonic to blood. The process depends on the establishment of high osmolality in the medullary interstitium, in order to exert sufficient osmotic pressure on water-permeable regions of the tubule, and is achieved by a countercurrent multiplier mechanism.

## Countercurrent multiplier mechanism

The countercurrent multiplier mechanism is responsible for producing a high osmolality in the extratubular interstitial tissue of the renal medulla. Water passes freely from the tubular lumen into the adjacent medullary interstitium along the descending limb of the loop of Henle. This part of the tubule is less permeable to solutes. In the thick segment of the ascending limb, sodium and chloride ions are actively transported from the tubule lumen to interstitial spaces, while the tubular epithelium remains impermeable to water. The increased interstitial osmolality causes water to be withdrawn from the descending part of the loop, thus concentrating the filtrate. Tubular fluid flows in a countercurrent on its descent into and ascent out of the medulla; it is augmented by new isotonic fluid entering the loop, and depleted by hypotonic fluid leaving the loop as solutes are actively resorbed. The osmotic gradient within the interstitium is, thus, multiplied from the corticomedullary boundary to the medullary pyramids, where it reaches an equilibrium of four to five times the osmolality of plasma. Although the tonicity of the tubular fluid changes during its passage through the steep osmotic gradient within the medulla, the osmotic gradient between ascending and descending limbs at each level never exceeds $200 \mathrm{mOsm} / \mathrm{kg}$, a force that can be sustained by the cells of the tubular wall.

## Countercurrent exchange mechanism

Rapid removal of ions from the renal medulla by the circulation of blood is minimized by another looped countercurrent system. This is the countercurrent exchange mechanism, in which arterioles entering the medulla pass for long distances parallel to the venules leaving it, before ending in capillary beds around tubules. This close apposition of oppositely flowing blood allows the direct diffusion of ions from outflowing to inflowing blood, so that the vasa recta (see Fig. 74.14) conserve the high osmotic pressure in the medulla.

## Concentration of urine

Because sodium and chloride ions are selectively resorbed by the cells of the ascending limbs and distal tubules under aldosterone control, the filtrate at the distal end of the convoluted tubules is hypotonic. As it reaches the collecting ducts, fluid descends again through the medulla and, thus, re-enters a region of high osmotic pressure. The cells lining the collecting ducts are variably permeable to water, under the influence of neurohypophysial ADH. Water follows an osmotic gradient into the adjacent extratubular spaces, so that the tonicity of the filtrate gradually rises along collecting ducts, until, at the tip of the renal pyramids, it is above that of blood. This complex system is highly flexible and the balance between the rate of filtration and absorption can be varied to meet current physiological demands.

Control of hydrogen and ammonium ion concentrations is essential to the regulation of acids and bases in the blood. Secretion of various ions occurs at several sites. Over $91 \%$ of ingested potassium is excreted in urine, largely through secretion by cells of the distal tubule and collecting duct. (For further details of renal physiology, see Madias and Adrogué (2005), Tannen and Hallows (2005), Singh and Thomson (2011).)

## Juxtaglomerular apparatus

The juxtaglomerular apparatus provides a tubuloglomerular feedback system that maintains systemic arterial blood pressure during a reduction in vascular volume and decrease in filtration rate. The elements of a juxtaglomerular apparatus are juxtaglomerular and lacis cells, and the macula densa. The afferent and efferent arterioles at the vascular pole of a glomerulus and the macula densa of the distal tubule of the same nephron lie in close proximity, enclosing a small cone of tissue populated by extraglomerular mesangial (lacis) cells (see Fig. 74.16). The cells of the tunica media of afferent and, to a lesser extent, efferent, arterioles differ from typical smooth muscle cells. These juxtaglomerular cells are large, rounded, myoepithelioid cells and their cytoplasm contains many mitochondria and dense, renin-containing vesicles, $10-40 \mathrm{~nm}$ in diameter. Each macula densa of the distal tubule is a cluster of up to 40 tightly packed cells in the tubule wall; the cells have

B Fig. 74.21 Relations of the lower ureter, seen from above. A, The male pelvis. B, The female pelvis. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone.
Copyright 2010.)
large, oval nuclei and apically concentrated mitochondria. They are osmoreceptors, sensing the NaCl content of the filtrate after its passage through the loop of Henle.

When NaCl concentrations in the filtrate change, tubuloglomerular feedback mechanisms operate to maintain the inverse relationship between salt concentration and glomerular filtration rate. Juxtaglomerular cells release renin, an enzyme that acts on circulating angiotensinogen to activate the cascade whereby angiotensin II increases blood pressure (and therefore filtration rate), stimulates aldosterone and ADH release and increases sodium ion and water resorption, primarily from the distal tubule, to increase plasma volume. Macula densa cells are thought to respond to high salt concentration in the distal tubule by releasing nitric oxide, which inhibits the tubuloglomerular feedback response and reduces filtration rate. The role of macula densa cells in the stimulation of renin release to increase filtration rate is less well understood.

The third element of the juxtaglomerular apparatus is a population of extraglomerular mesangial cells that form a network (or lace; hence, their alternative name of lacis cells) of stellate cells connecting the macula densa sensory cells with the juxtaglomerular effector cells. It is likely that extraglomerular mesangial cells transmit the sensory signal, possibly through gap junctions. They may also signal to contractile glomerular mesangial cells and effect vasoconstriction directly within the glomerulus. Adrenergic nerve fibres occur in small numbers among these cells.

## URETER

The ureters are two muscular tubes whose peristaltic contractions convey urine from the kidneys to the urinary bladder (see Figs 74.1, 74.10, Fig. 74.21 ). Each measures $25-30 \mathrm{~cm}$ in length, is thick-walled and narrow, and is continuous superiorly with the funnel-shaped renal pelvis. Each descends slightly medially, anterior to psoas major, and enters the pelvic cavity, where it curves initially laterally, then medially, to open into the base of the urinary bladder. The diameter of the ureter is normally 3 mm , but is slightly less at its junction with the renal pelvis, at the brim of the lesser pelvis near the medial border of psoas major, and where it runs within the wall of the urinary bladder, which is its narrowest part. These are the most common sites for renal stone impaction.

## RELATIONS

In the abdomen, the ureter descends posterior to the peritoneum on the medial part of psoas major, which separates it from the tips of the lumbar transverse processes. During surgery on intraperitoneal structures, the ureter can be tented up as the peritoneum is drawn anteriorly, resulting in inadvertent ureteric injury. Anterior to psoas major, it crosses anterior to the genitofemoral nerve and is obliquely crossed by
the gonadal vessels. It enters the lesser pelvis either anterior to the end of the common iliac vessels or at the origin of the external iliac vessels (Fig. 74.22).

The inferior vena cava is medial to the right ureter, while the left ureter is lateral to the aorta. The inferior mesenteric vein has a long retroperitoneal course lying close to the medial aspect of the left ureter.

At its origin, the right ureter is usually overlapped by the descending part of the duodenum. It descends lateral to the inferior vena cava, and is crossed anteriorly by the right colic and ileocolic vessels. Near the superior aperture of the lesser pelvis, it passes behind the lower part of the mesentery and terminal ileum. The left ureter is crossed by the gonadal and left colic vessels. It passes posterior to loops of jejunum and sigmoid colon and its mesentery in the posterior wall of the intersigmoid recess.

In the pelvis, the ureter lies in extraperitoneal areolar tissue. At first, it descends posterolaterally on the lateral wall of the lesser pelvis along the anterior border of the greater sciatic notch. Opposite the ischial spine, it turns anteromedially into fibrous adipose tissue above levator ani to reach the base of the bladder. On the pelvic side wall, it is anterior to the internal iliac artery and the beginning of its anterior trunk, posterior to which are the internal iliac vein, lumbosacral nerve and sacroiliac joint. Laterally, it lies on the fascia of obturator internus. It progressively crosses to become medial to the umbilical, inferior vesical and middle rectal arteries.

In males, the pelvic ureter hooks under the vas deferens (Fig. 74.23); it then passes anterior and slightly superior to the upper pole of the seminal vesicle to traverse the bladder wall obliquely before opening at the ipsilateral trigonal angle. Its terminal part is surrounded by tributaries of the vesical veins. In females, the pelvic part initially has the same relations as in males but, anterior to the internal iliac artery, it is immediately behind the ovary, forming the posterior boundary of the ovarian fossa (see Fig. 77.8). In the anteromedial part of its course to the bladder, it is related to the uterine artery, uterine cervix and vaginal fornices. It is in extraperitoneal connective tissue in the inferomedial part of the broad ligament of the uterus, where it may be damaged during hysterectomy (see Fig. 77.7). In the broad ligament, the uterine artery is anterosuperior to the ureter for approximately 2.5 cm and then crosses to its medial side to ascend alongside the uterus. The ureter turns forwards slightly above the lateral vaginal fornix and is, generally, 2 cm lateral to the supravaginal part of the uterine cervix in this location. It then inclines medially to reach the bladder, with a variable relation to the anterior aspect of the vagina. As the uterus is commonly deviated to one side, one ureter, usually the left, may be more extensively apposed to the vagina, and may cross the midline.

The distal $1-2 \mathrm{~cm}$ of each ureter is surrounded by an incomplete collar of non-striated muscle (sheath of Waldeyer). The ureters pierce the posterior aspect of the bladder and run obliquely through its wall for a distance of $1.5-2.0 \mathrm{~cm}$ before terminating at the ureteric orifices (see Fig. 75.10B). This arrangement is believed to assist in the prevention of reflux of urine into the ureter, since the intramural ureters are

Fig. 74.22 Relations of male lower right ureter. (With permission from Walsh PC, Retik AB, Vaughan ED et al (eds) 2002 Campbell's Urology, 8th edn. Philadelphia:
Saunders.)
thought to be occluded during increases in bladder pressure at the time of micturition. There is no evidence of a classic ureteral sphincter mechanism in humans. The longitudinally orientated muscle bundles of the terminal ureter continue into the bladder wall and, at the ureteric orifices, become continuous with the superficial trigonal muscle. In the distended bladder, in both sexes, the ureteric openings are usually 5 cm apart, and 2.5 cm apart when the bladder is empty.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The ureter is supplied by branches from the renal, gonadal, common iliac, internal iliac, vesical and uterine arteries, and the abdominal aorta. The pattern of distribution is subject to much variation. The abdominal ureter is supplied from vessels originating medial to the ureter; the pelvic ureter is supplied by vessels lateral to the ureter (Fig. 74.24). There is a good longitudinal anastomosis between these branches on the wall of the ureter, which means that the ureter can be safely transected at any level intraoperatively, and a uretero-ureterostomy performed, without compromising its viability. The branches from the inferior vesical artery are constant in their occurrence and supply the lower part of the ureter, as well as a large part of the trigone of the bladder. The branch from the renal artery is also constant and is preserved whenever possible in renal transplantation to ensure good vascularity of the ureter.

## Veins

The venous drainage of the ureters generally follows the arterial supply.

## Lymphatic drainage

Lymph vessels draining the ureter begin in submucosal, intramuscular and adventitial plexuses, which all communicate. Collecting vessels from the upper abdominal ureter may join the renal collecting vessels
or pass directly to the lateral aortic nodes near the origin of the gonadal artery; those from the lower abdominal ureter drain to the common iliac nodes; and those from the pelvic ureter drain to common, external or internal iliac nodes.

## INNERVATION

The ureter is supplied from the lower three thoracic, first lumbar, and the second to fourth sacral segments of the spinal cord by branches from the renal and aortic plexuses, and the superior and inferior hypogastric plexuses (see Figs 59.3, 75.11). The ureteric nerves consist of relatively large bundles of axons that form an irregular plexus in the adventitia of the ureter. The plexus receives branches from the renal and aortic plexuses (in its upper part); from the superior hypogastric plexus and hypogastric nerve (in its intermediate part); and from the hypogastric nerve and inferior hypogastric plexus (in its lower part). Numerous small branches penetrate the ureteric muscle coat; some of the adventitial nerves accompany the blood vessels and branch with them as they extend into the muscle layer; others are unrelated to the vascular supply and lie free in the adventitial connective tissue around the circumference of the ureter.

The density of innervation increases gradually from the renal pelvis and upper ureter (where autonomic nerves are sparse) to a maximum density in the juxtavesical segment. At least three different neurotransmitter phenotypes - cholinergic, noradrenergic and peptidergic (substance P) - are well known and others have been reported. The functional significance of these different types of autonomic nerve fibres in relation to ureteric smooth muscle activity is not fully understood; although they are thought to influence the inherent motility of the ureter, they are not essential for the initiation and propagation of ureteric contraction waves. A branching plexus of fine cholinergic, noradrenergic and peptidergic axons occurs throughout the lamina propria and extends from the inner aspect of the muscle coat towards the base of the urothelium. Some of these axons form perivascular plexuses, while others lie in isolation from the vascular supply and may be sensory in function.

## Ureteric peristalsis

Under normal conditions, contraction waves originate in the proximal part of the upper urinary tract and are propagated in an anterograde direction towards the bladder. Atypical smooth muscle cells in the wall of the minor calyces act individually or collectively as pacemaker sites. A peristaltic wave begins at one (or possibly more) of these sites. Once

Fig. 74.25 A coronal CT urogram volume-rendered image demonstrates a duplicated right collecting system and ureter, along with dilation of the collecting system of the lower pole moiety. No urothelial lesion is seen.
initiated, the contraction is propagated through the wall of the adjacent major calyx and activates the smooth muscle of the renal pelvis. Contraction waves are propagated away from the kidney, and so undesirable pressure rises are not directed against the renal parenchyma. Since several potential pacemaker sites exist, the initiation of contraction waves is unimpaired by partial nephrectomy; the minor calyces spared by the resection remain in situ to continue their pacemaking function. Pressures within the ureter at the time of peristalsis reach $20-80 \mathrm{~cm} \mathrm{H}_{2} \mathrm{O}$.

Experimental evidence indicates that autonomic nerves do not play a major part in the propagation of peristalsis. It seems more likely that they play a modulatory role on the contractile events occurring in the musculature of the upper urinary tract. The most likely mechanism to account for impulse propagation is myogenic conduction mediated by the electrotonic coupling of one muscle cell to its immediate neighbours by means of intercellular 'gap' junctions; there are numerous regions of close approach between ureteric smooth muscle cells and also between both types of muscle cell in the renal pelvis and calyces.

Referred pain Excessive distension of the ureter or spasm of its muscle may be caused by a stone (calculus) and provokes severe pain (ureteric colic, which is commonly, but mistakenly, called renal colic). The pain is spasmodic and agonizing, particularly if the obstruction is gradually forced down the ureter by the muscle spasm. It is referred to cutaneous areas innervated from spinal segments that supply the ureter, mainly T11-L2, and shoots down and forwards from the loin to the groin and scrotum or labium majus; it may extend into the proximal anterior aspect of the thigh by projection to the genitofemoral nerve (L1, 2). The cremaster, which has the same innervation, may reflexly retract the testis.

## RENAL AND URETERIC CALCULI

An understanding of intrarenal and ureteric anatomy is essential when managing patients with calculi, particularly now that minimally invasive techniques are widely used to treat this common pathology.

## MICROSTRUCTURE

Like the calyces and the renal pelvis, the wall of the ureter is composed of an external adventitia, a smooth muscle layer and an inner mucosal layer. The mucosal layer consists of a urothelium (see Fig. 2.5D) and an underlying connective tissue lamina propria.

Smaller renal calculi are treated with extracorporeal shock wave lithotripsy. Stones in the lower pole of the kidney clear less well if the angle between the infundibulum of the calyx containing the stone and the ureter is acute, or if there is a particularly long and narrow infundibulum. Percutaneous stone extraction is most frequently achieved by puncturing a posterior calyx with a needle.

Ureteric calculi tend to be arrested in their descent in either the pelviureteric region, or the point where the ureter passes over the pelvic brim as it crosses the common iliac artery, or the vesico-ureteric junction, because these are the three areas where the ureter is narrowest. The vesico-ureteric junction is the narrowest of these areas and can be responsible for arresting the passage of stones of as little as $2-3 \mathrm{~mm}$.

The kidney and upper ureter move with respiration within the perirenal fascia, and this can affect the visualization and tracking of a stone, both at the time of extracorporeal shock wave lithotripsy and at retrograde endoscopy.

The ureteric adventitial blood vessels and connective tissue fibres are orientated parallel to the long axis of the ureter. Throughout its length, the muscle coat of the ureter is fairly uniform in thickness and, in crosssection, measures $750-800 \mu \mathrm{~m}$ in width. The muscle bundles that constitute this coat are frequently separated from one another by relatively large amounts of connective tissue. However, branches that interconnect muscle bundles are common and there is frequent interchange of muscle fibres between adjacent bundles. As a consequence of this extensive branching, individual muscle bundles do not spiral around the ureter, but form a complex meshwork of interweaving bundles. Moreover, unlike the gut (Ch. 65), the muscle bundles are so arranged that morphologically distinct longitudinal and circular layers cannot be clearly distinguished. In the upper part of the ureter, the inner muscle bundles tend to lie longitudinally while those on the outer aspect have a circular or oblique orientation. In the middle and lower parts, there are additional outer longitudinally orientated fibres, and as the ureterovesical junction is approached, the muscle coat consists predominantly of longitudinally orientated muscle bundles.

The mucosa of the ureter consists of an epithelium, the urothelium, lying on a layer of subepithelial fibroelastic connective tissue lamina propria. The latter varies in thickness from 350 to $700 \mu \mathrm{~m}$ and is a conduit for small blood vessels and bundles of unmyelinated nerve fibres. Occasional lymphocytes may be present in the lamina propria but their aggregation into definitive lymph nodules is rare. The urothelium is usually extensively folded, giving the ureteric lumen a stellate outline.

## Developmental anomalies of the ureter

Duplex ureters In 1 in 125 individuals, two ureters drain the renal pelvis on one side; this is termed a duplex system (Fig. 74.25). Bilateral duplex ureters occur in approximately 1 in 800 cases. Duplex ureters are the product of two ureteric buds arising from the mesonephric duct; they share a single fascial sheath and may either fuse at any point along their course, or remain separate until they insert through separate ureteric orifices into the bladder.

Care must be taken not to compromise the blood supply of the second ureter when excising or reimplanting a single ureter of a duplex. The ureter from the upper pole of the kidney (the longer ureter) inserts more medially and caudally in the bladder than the ureter from the lower pole (Weigert-Meyer rule). This reflects the embryological development of the ureter: the ureteric bud that is initially more proximal on the mesonephric duct has a shorter time to be pulled cranially in the bladder and so it inserts more distally in the mature bladder. The ureter from the lower pole has a shorter intramural course than the longer ureter and is prone to reflux.

Ectopic ureters Single ureters, and, more commonly, the longer ureter of a duplex system, can insert more caudally and medially than
normal in some individuals. In the male, the ureter can insert at the bladder neck or posterior urethra, or, rarely, into the seminal vesicle, but it always inserts cranial to the external urethral sphincter. In the female, ectopic insertion can be distal to the external urethral sphincter in the urethra, or into the vagina, resulting in persistent childhood incontinence.

Ureteroceles A ureterocele is a cystic dilation of the lower end of the ureter; the ureteric orifice is covered by a membrane that expands as it is filled with urine and then deflates as it empties. Ureteroceles can vary in size and usually have no influence on ureteric drainage; however, they can be a cause of obstruction in the ureter and pelvicalyceal system more proximally. Prolapsing ureteroceles, though small, prolapse from their position around the ureterovesical junction region into the urethra, causing intermittent bladder outflow obstruction.

They are identified antenatally with ultrasound (Fig. 74.26). In adults, ureteroceles tend to be bilateral and small, and are often found incidentally when the urinary tract is being imaged in the investigation of a coincidental pathology. Radiologically, they classically result in a 'cobra-head' halo around the ureteric orifice following administration of contrast on intravenous urography.

Retrocaval ureter A persistence of the posterior cardinal vein, associated with high confluence of the right and left common iliac veins or a double inferior vena cava, may result in a retrocaval (or circumcaval) ureter that passes behind the inferior vena cava, usually at the level of the inferior edge of the third part of the duodenum, before it emerges anterior to it to pass from medial to lateral. Retrocaval ureter occurs in 1 in 1500 individuals. Most commonly, it has no clinical sequelae, although it can result in upper ureteric obstruction (Fig. 74.27).

## Bladder, prostate and urethra

## Chater 75

## URINARY BLADDER

The urinary bladder is a reservoir. Its size, shape, position and relations all vary, according to its content and the state of the neighbouring viscera. When the bladder is empty, it lies entirely in the lesser pelvis, but as it distends, it expands anterosuperiorly into the abdominal cavity (Video 75.1). An empty bladder is somewhat tetrahedral and has a base (fundus), neck, apex, and a superior (dome) and two inferolateral surfaces.

## RELATIONS

The base of the bladder is triangular and located posteroinferiorly. In females, it is closely related to the anterior vaginal wall (Fig. 75.1); in males, it is related to the rectum, although it is separated from it superiorly by the rectovesical pouch, and inferiorly by the seminal vesicle and vas (ductus) deferens on each side, and by Denonvilliers' fascia (Fig. 75.2). The neck, which is most fixed, lies most inferiorly, $3-4 \mathrm{~cm}$ behind the lower part of the pubic symphysis and just above the plane of the inferior aperture of the lesser pelvis. The bladder neck is, essentially, the internal urethral orifice, which lies in a constant position that is independent of the varying positions of the bladder and rectum. In males, the neck rests on, and is in direct continuity with, the base of the prostate; in females, it is related to the pelvic fascia that surrounds the upper urethra. In both sexes, the apex of the bladder faces towards the upper part of the pubic symphysis. The median
umbilical ligament (urachus) ascends behind the anterior abdominal wall from the apex to the umbilicus, covered by peritoneum to form the median umbilical fold (Fig. 75.3, see Fig. 72.19) (see below and p. 1077).

The anterior surface of the bladder is separated from the transversalis fascia by adipose tissue in the potential retropubic space (of Retzius) (Fig. 75.4). This is more adherent to the bladder than to the anterior surface of the prostate, which aids reliable identification of the region of the bladder neck surgically. In males, each inferolateral surface is related anteriorly to the pubis and puboprostatic ligaments. In females, the relations are similar, except that the pubovesical ligaments replace the puboprostatic ligaments. The inferolateral surfaces are not covered by peritoneum. The triangular superior surface is bounded by lateral borders from the apex to the ureteric entrances, and by a posterior border that joins them. In males, the superior surface is completely covered by peritoneum, which extends slightly on to the base and continues posteriorly into the rectovesical pouch and anteriorly into the median umbilical fold; it is in contact with the sigmoid colon and the terminal coils of the ileum (see Fig. 75.2). In females, the superior surface is largely covered by peritoneum, which is reflected posteriorly on to the uterus at the level of the internal os (the junction of the uterine body and cervix), to form the vesicouterine pouch. The posterior part of the superior surface, devoid of peritoneum, is separated from the supravaginal cervix by fibroareolar tissue.

These relationships are important in managing bladder trauma. Extraperitoneal injuries can often be managed conservatively because urine is contained, whereas intraperitoneal injuries usually require surgical repair.

Fig. 75.1 The relations of the female bladder, sagittal section of the pelvis. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Fig. 75.2 A, The relationship of the bladder and prostate: sagittal section, male pelvis. The relationship of the bladder to the peritoneum and anterior abdominal wall on filling allows suprapubic cystostomy without intraperitoneal urinary leak. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

As the bladder fills, it becomes ovoid (Fig. 75.5; see Fig. 75.2 and Video 75.1). Anteriorly, it displaces the parietal peritoneum from the suprapubic region of the abdominal wall. Its inferolateral surfaces become anterior and rest against the abdominal wall without intervening peritoneum for a distance above the pubic symphysis that varies with the degree of distension, but is commonly 5-7 cm. The distended bladder may be punctured just above the pubic symphysis without traversing the peritoneum (suprapubic cystostomy) (see Fig. 75.2); surgical access to the bladder through the anterior abdominal wall is usually by this route. The summit of the full bladder points up and forwards above the attachment of the median umbilical ligament, so that the peritoneum forms a supravesical recess of varying depth
between the summit and the anterior abdominal wall; this recess often contains coils of small intestine. At birth, the bladder is higher than in the adult because the true pelvis is shallow, and the internal urethral orifice is level with the upper symphysial border. The bladder is then abdominal rather than pelvic, and extends about two-thirds of the distance towards the umbilicus.

## LIGAMENTS OF THE BLADDER

The bladder is anchored inferiorly to the pubis, lateral pelvic side walls and rectum by condensations of pelvic fascia; although these

Urine samples may, therefore, be obtained in children by performing suprapubic needle puncture. A normogram of bladder volume index (BVI $=$ length $\times$ width $\times$ depth of bladder), based on sonographic measurements in children, is shown in Figure 75.6. The bladder progressively descends with growth, and reaches the adult position shortly after puberty.

Fig. 75.6 Centiles of bladder volume index in children. (Redrawn with permission from Leung VY, Chu WC, Yeung CK et al Nomograms of total renal volume, urinary bladder volume and bladder wall thickness index in 3,376 children with a normal urinary tract, Pediatric Radiology (2007); 37:181-188.)

Fig. 75.2, cont'd B, A sagittal T2-weighted magnetic resonance image of the male pelvis, showing the bladder, prostate and relations.
condensations are not true anatomical ligaments, the term is applied in routine clinical use (see p. 1224 for a further description of the visceral pelvic fascia).

In both sexes, stout bands of fibromuscular tissue, the pubovesical ligaments, extend from the bladder neck to the inferior aspect of the pubic bones; they lie on each side of the median plane, leaving a midline hiatus through which numerous small veins pass. The pubovesical ligaments are derived from the detrusor muscle, part of the detrusor apron (Fig. 75.7). In the female, they constitute the superior extensions of the pubourethral ligaments. In the male, the detrusor apron is described as an extension of detrusor that extends over the anterior surface of the prostate, and condenses distally and anteriorly to form the puboprostatic ligaments.

Other ligaments that have been described in relation to the base of the urinary bladder are the lateral, sacrogenital/uterosacral and cardinal ligaments. The literature is sometimes confusing and even contradictory. The lateral ligament was described by Miles in 1908; although never described in anatomical cadaveric dissection studies, it is recognized clinically as an important structure in the pararectal space at operation. It is a broad band of dense connective tissue, varying in depth from 5 to 7 cm , and passing between the lateral wall of the pelvis and the base of the bladder at the point where the ureter terminates. It contains the middle rectal artery and lymphatic vessels that pass from the lower rectum to the iliac lymph nodes (Takahashi et al 2000). The apex of the bladder is connected to the umbilicus by the remains of the urachus, which forms the median umbilical ligament (see Fig. 75.3; Video 75.2). Composed of longitudinal muscle fibres derived from the detrusor, it becomes more fibrous towards the umbilicus. It usually maintains a lumen lined with epithelium that persists into adult life but is only rarely complicated by a urachal cyst, sinus, fistula or adenocarcinoma.

From the superior surface of the bladder, the peritoneum is carried off in a series of folds: the 'false' ligaments of the bladder. Anteriorly, there are three folds (Fig. 75.8): the median umbilical fold over the median umbilical ligament (urachus), and two medial umbilical folds over the obliterated umbilical arteries. The inferior epigastric vessels (Fig. 75.9) are lateral to these folds on the anterior abdominal wall and are termed lateral umbilical ligaments in descriptions of anterior abdominal wall anatomy.

Fig. 75.3 A, A view of the midline anterior abdominal wall and ligaments during laparoscopy. B, A view of the left side of the anterior abdominal wall and ligaments during laparoscopy.

## BLADDER INTERIOR

## Vesical mucosa

Almost all of the vesical mucosa (Fig. 75.10) is attached only loosely to subjacent muscle; it folds when the bladder empties, and the folds are stretched flat as it fills. Over the trigone, immediately above and behind the internal urethral orifice, it is adherent to the subjacent muscle layer and is always smooth. The anteroinferior angle of the trigone is formed by the internal urethral orifice, its posterolateral angles by the ureteric orifices. The superior trigonal boundary is a slightly curved inter-ureteric bar, which connects the two ureteric orifices and is produced by the continuation into the vesical wall of the ureteric internal longitudinal muscle. Laterally, this ridge extends beyond the ureteric openings as ureteric folds, produced by the terminal parts of the ureters, which run obliquely through the bladder wall. At cystoscopy, the inter-ureteric crest appears as a pale band and is a guide to the ureteric orifices (Fig. 75.10B).

## Trigone

The smooth muscle of the trigone consists of two distinct layers, sometimes termed the superficial trigonal muscle and deep trigonal detrusor muscle. The latter is composed of muscle cells, indistinguishable from those of the detrusor, and is simply the posteroinferior portion of the detrusor muscle proper. The superficial trigonal muscle represents a morphologically distinct component of the trigone, which, unlike the detrusor, is composed of relatively small-diameter muscle bundles that

The urachus may play a critical role in maintaining fetal life when atresia of the urethra results in complete obstruction to the flow of amniotic fluid．Anhydramnios noted at 17 weeks＇gestation has been reported to resolve by 21 weeks when the patent urachus acts as a fistula between the bladder and the amniotic space，preserving pulmonary and renal function（Stalberg and Gonzalez 2012）．

Fig. 75.4 A transperitoneal view of the male pelvis, as seen during robotic-assisted laparoscopic radical prostatectomy. The bladder is released from the anterior abdominal wall, the space of Retzius is developed and the endopelvic fascia opened.

Fig. 75.5 Laparoscopic view of the full bladder.
are continuous proximally with those of the intramural ureters. The superficial trigonal muscle is relatively thin but is generally described as becoming thickened along its superior border to form the interureteric ridge (bar). Similar thickenings occur along the lateral edges of the superficial trigone. In both sexes, the superficial trigone muscle becomes continuous with the smooth muscle of the proximal urethra, and extends in the male along the urethral crest as far as the openings of the ejaculatory ducts.

## Ureteric orifices

The slit-like ureteric orifices are placed at the posterolateral trigonal angles (Fig. 75.10A,B). In empty bladders, they are approximately 2.5 cm apart, and 2.5 cm from the internal urethral orifice; in distension, these measurements may be doubled.

## Internal urethral orifice

The internal urethral orifice is sited at the trigonal apex, the lowest part of the bladder, and is usually somewhat crescentic in section. There is often an elevation immediately behind it in adult males (particularly past middle age), which is caused by the median prostatic lobe.

## BLADDER NECK

The smooth muscle of the bladder neck is histologically, histochemically and pharmacologically distinct from the detrusor muscle proper and so the bladder neck should be considered as a separate functional

Fig. 75.7 Ligaments that anchor the neck of the bladder and pelvic part of the urethra to the pelvic bone. A, In the female. B, In the male. In males, the detrusor extends over the anterosuperior aspect of the prostate and inserts into the pubic bone. It condenses to form pubovesical/puboprostatic ligaments. (A-B, With permission from Drake RL, Vogl AW, Mitchell A, Tibbitts R, Richardson P (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)
unit. The arrangement of smooth muscle in this region is quite different in males and females, and therefore will be described separately.

## Female

In the female, the bladder neck consists of morphologically distinct smooth muscle (Fig. 75.10C). The large-diameter fasciculi characteristic of the detrusor are replaced in the region of the bladder neck by smalldiameter fasciculi that extend obliquely or longitudinally into the urethral wall. In the normal female, the bladder neck sits above the pelvic floor, supported predominantly by the pubovesical ligaments (see Fig. 75.7A), the endopelvic fascia of the pelvic floor and levator ani. These support the urethra at rest; with elevated intra-abdominal pressure, the levators contract, increasing urethral closure pressure to maintain continence. This anatomical arrangement commonly alters after parturition and with increasing age, such that the bladder neck lies beneath the pelvic floor, particularly when intra-abdominal pressure rises, which means that the mechanism described above fails to maintain continence and women may experience stress incontinence (Klutke and Siegel 1995).

## Male

In the male, the bladder neck is completely surrounded by a circular collar of smooth muscle, with its own distinct adrenergic innervation, which extends distally to surround the preprostatic portion of the urethra. These smooth muscle bundles are distinct from the smooth muscle bundles that run in continuity from the bladder neck down to the prostatic urethra, and from the smooth muscle within the prostate. The bundles that form this 'preprostatic sphincter' are small in size compared with the muscle bundles of the detrusor, and are separated by a relatively larger connective tissue component rich in elastic fibres.

The bladder neck is sometimes called the proximal or internal sphincter mechanism, to distinguish it from the distal urinary sphincter mechanism. The internal sphincter contributes to urinary continence and, in the face of distal sphincteric incompetence, can, at times, maintain continence independently. Unlike the detrusor and the rest of the

Fig. 75.10 A, A coronal section of the urinary bladder in the male. The mucosal folds are dependent on the state of filling. B, The ureteric orifice seen at endoscopy. C, A posterior view of the bladder neck in the female. (A, With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
urethral smooth muscle (common to both sexes), the preprostatic sphincter is richly supplied with sympathetic noradrenergic nerves and is almost totally devoid of parasympathetic cholinergic nerves (see below).

## Bladder outflow obstruction

In progressive chronic obstruction to micturition, e.g. as a result of prostatic enlargement or urethral stricture, or in children with congenital bladder outflow obstruction, e.g. posterior urethral valves, the muscle of the bladder hypertrophies. The muscle fasciculi increase in size and, because they interlace in all directions, a thick-walled 'trabeculated bladder' is produced. Mucosa between the fascicles forms 'diverticula'. When outflow is obstructed, emptying is not complete; some urine remains and may become infected. Back-pressure from a chronically distended bladder may gradually dilate the ureters, renal pelves and even the renal collecting tubules, which can result in progressive renal impairment.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The bladder is supplied principally by the superior and inferior vesical arteries (see Figs 77.3, 74.22), derived from the anterior trunk of the internal iliac artery, and supplemented by the obturator and inferior gluteal arteries. In the female, additional branches are derived from the uterine and vaginal arteries.

## Superior vesical artery

The superior vesical artery supplies many branches to the fundus of the bladder. The artery to the vas deferens often originates from one of these and accompanies the vas deferens to the testis, where it anastomoses with the testicular artery. Other branches supply the ureter. The initial portion of the superior vesical artery is the proximal, patent, section of the fetal umbilical artery.

## Inferior vesical artery

The inferior vesical artery often arises with the middle rectal artery from the internal iliac artery. It supplies the base of the bladder, prostate, seminal vesicles and lower ureter, and may sometimes provide the artery to the vas deferens. Prostatic branches communicate across the midline.

## Veins

The veins that drain the bladder form a complicated plexus on its inferolateral surfaces and pass backwards in the lateral ligaments of the bladder to end in the internal iliac veins (see Fig. 77.3).

## Lymphatic drainage

Lymphatics that drain the bladder begin in mucosal, intermuscular and serosal plexuses (see Fig. 77.3). There are three sets of collecting vessels; most end in the external iliac nodes. Vessels from the trigone emerge on the exterior of the bladder to run superolaterally. Vessels from the superior surface of the bladder converge to the posterolateral angle and pass superolaterally to the external iliac nodes (some may go to the internal or common iliac group). Vessels from the inferolateral surface of the bladder ascend to join those from the superior surface or run to the lymph nodes in the obturator fossa. Minute nodules of lymphoid tissue may occur along the vesical lymph vessels.

## INNERVATION

The nerves supplying the bladder arise from the pelvic plexuses, a mesh of autonomic nerves and ganglia lying on the lateral aspects of the rectum, internal genitalia and bladder base (Fig. 75.11). They consist of both sympathetic and parasympathetic components, each of which contains both efferent and afferent fibres. For further reading, see Mundy et al (1999a).

Fig. 75.11 Innervation of the lower urinary tract and male genitalia. (Redrawn with permission from Dyck P, Thomas PK, 2005, Peripheral Neuropathy, Saunders, Elsevier.)

## Efferent fibres

Parasympathetic fibres arise from the second to the fourth sacral segments of the spinal cord and enter the pelvic plexuses on the posterolateral aspects of the rectum as the pelvic splanchnic nerves. The sympathetic fibres are derived from neuronal cell bodies in the lower three thoracic and upper two lumbar segments of the spinal cord and form the coeliac and mesenteric plexuses around the great vessels in the abdomen; from here, the hypogastric plexuses descend into the pelvis as fairly discrete nerve bundles within the extraperitoneal connective tissue posterior to the ureter on each side. The anterior part of the pelvic plexus is known as the vesical plexus. Small groups of autonomic neurones occur within the plexus and throughout all regions of the bladder wall. These multipolar intramural neurones are rich in acetylcholinesterase (AChE) and occur in ganglia consisting of up to 20 neuronal cell bodies. The majority of the preganglionic nerve terminals correspond morphologically to presumptive cholinergic fibres. Noradrenergic terminals also relay on cell bodies in the pelvic plexus; it is not known whether similar nerves synapse on intramural bladder ganglia.

The urinary bladder (including the trigonal detrusor muscle) is profusely supplied with nerves, which form a dense plexus among the detrusor muscle cells. The majority of these nerves contain AChE and occur in abundance throughout the muscle coat of the bladder. Axonal varicosities adjacent to detrusor muscle cells possess features that are
considered to typify cholinergic nerve terminals, and contain clusters of small ( 50 nm diameter) agranular vesicles, occasional large ( $80-160 \mathrm{~nm}$ diameter) granulated vesicles and small mitochondria. Terminal regions approach to within 20 nm of the surface of the muscle cells and may be partially surrounded by Schwann cell cytoplasm; more often, they are naked nerve endings. The human detrusor muscle possesses a sparse but definite supply of sympathetic noradrenergic nerves that generally accompany the vascular supply and only rarely extend among the myocytes. Non-adrenergic, non-cholinergic nerves have been identified, and a number of other neurotransmitters or neuromodulators have been detected in intramural ganglia, including the peptide somatostatin. The superficial trigonal muscle is associated with more noradrenergic (sympathetic) fibres than cholinergic (parasympathetic) nerves, a difference that supports the view that the superficial trigonal muscle should be regarded as 'ureteric' rather than 'vesical' in origin. It is, however, important to emphasize that the superficial trigonal muscle forms a very minor part of the total muscle mass of the bladder neck and proximal urethra in either sex and is probably of little significance in the physiological mechanisms that control these regions.

The smooth muscle of the bladder neck in males is predominantly orientated obliquely or circularly. It is sparsely supplied with cholinergic (parasympathetic) nerves but possesses a rich noradrenergic (sympathetic) innervation. A similar distribution of autonomic nerves also
occurs in the smooth muscle of the prostate gland, seminal vesicles and vasa deferentia. Stimulation of sympathetic nerves causes contraction of smooth muscle in the wall of the genital tract, resulting in seminal emission. Concomitant sympathetic stimulation of the proximal urethral smooth muscle causes sphincteric closure of the preprostatic sphincter, thereby preventing reflux of ejaculate into the bladder.

It is extensively disrupted in the vast majority of men undergoing bladder neck surgery, e.g. transurethral resection of the prostate, which may result in retrograde ejaculation. Similarly, anejaculation can result when the sympathetic fibres are disrupted during retroperitoneal lymph node dissection surgery.

Although this genital function of the bladder neck of the male is well established, it is not known whether the smooth muscle of this region plays an active role in maintaining urinary continence. In contrast, the smooth muscle of the bladder neck of the female receives relatively few noradrenergic nerves but is richly supplied with presumptive cholinergic fibres. The sparse supply of sympathetic nerves presumably relates to the absence of a functioning 'genital' portion of the wall of the female urethra.

The lamina propria of the fundus and inferolateral walls of the bladder is virtually devoid of autonomic nerve fibres, apart from some noradrenergic and occasional presumptive cholinergic perivascular nerves. However, the density of nerves unrelated to blood vessels increases closer to the urethral orifice. At the bladder neck and trigone, a nerve plexus of cholinesterase-positive axons extends throughout the lamina propria, independent of blood vessels. Some of the largerdiameter axons are myelinated and others lie adjacent to the basal urothelial cells. In the absence of any obvious effector target sites, the subepithelial nerve plexuses of the bladder and the ureter are assumed to subserve a sensory function.

## Afferent fibres

Vesical nerves are also concerned with pain and awareness of distension, and are stimulated by distension or spasm due to a stone, inflammation or malignant disease; they travel in sympathetic and parasympathetic nerves, but predominantly in the latter. Division of the sympathetic paths (e.g. 'presacral neurectomy') or of the superior hypogastric plexus, therefore, does not materially relieve vesical pain, whereas considerable relief follows bilateral anterolateral cordotomy. Since nerve fibres mediating awareness of distension travel in the posterior columns (fasciculus gracilis), the patient still retains awareness of the need to micturate after anterolateral cordotomy. The nerve endings detecting noxious stimuli are probably of more than one type; a subepithelial plexus of fibres containing dense vesicles, which are probably afferent endings, has been described.

## MICROSTRUCTURE

The bladder consists of four layers: a lining epithelium (urothelium), lamina propria, muscularis propria and serosa.

## Lining epithelium or urothelium

Urothelium (transitional epithelium; see Fig. 2.5D) is 4-7 cells thick; it may appear to be attenuated to 2-3 cells thick when the bladder is fully distended. It contains three distinctive cell layers: a basal layer, an intermediate layer and a superficial ('umbrella' cell) layer (see Fig. 75.15). The basal layer consists of small cuboidal cells from which the upper layers arise. The intermediate layers are polygonal and possess the capacity to stretch and flatten. The superficial layer forms a protective, almost impermeable, surface for the bladder mucosa and consists of large, sometimes multinucleated, cells displaying degenerative changes in their cytoplasm; these cells are ultimately exfoliated into the urine. The apical surface of the umbrella cell layer is covered by 16 nm protein particles packed hexagonally to form two-dimensional crystals of asymmetric unit membranes (AUMs), which contribute to the permeability barrier function of the urinary bladder, preventing reabsorption of urine across the urothelium into the blood stream. Islands or nests of urothelium (von Brunn's nests) may become separated from the surface during development and are found embedded in the underlying lamina propria; they may undergo central degeneration to form cysts (cystitis cystica).

## Lamina propria

The lamina propria forms a connective tissue bed supporting the overlying urothelium, from which it is separated by a basement membrane. It is rich in capillaries, lymphatics and nerve endings, and contains elastic fibres and a thin, poorly defined, layer of smooth muscle fibres, the muscularis mucosae, which is variably distributed within the
bladder. This layer is often very superficial, lying close beneath the urothelium, but is sometimes deeper in the lamina propria, where it may be well developed; it must be distinguished from the muscularis propria. Several functions have been proposed for the lamina propria, including acting as the capacitance layer of the bladder (determining bladder compliance and enabling adaptive changes to increasing volumes); providing factors that influence the growth of the urothelium and/or detrusor; and playing a role in signal transduction (Andersson and McCloskey 2014).

## Interstitial cells of Cajal-like cells

Interstitial cells of Cajal (ICC) are a specialized population of cells involved in smooth muscle excitability that were initially described in the gastrointestinal tract (p. 1043). Cells with a similar morphology but expressing platelet-derived growth receptor alpha (PDGFR $\alpha$ ), rather than the tyrosine kinase receptor Kit that typifies ICC, and therefore designated interstitial cells of Cajal-like cells (ICC-LC), have been reported in the urethra, vas deferens, prostate, bladder, corpus cavernosum, ureter, Fallopian tube, oviduct and uterus, where they form a functional syncytium with nerves and smooth muscle cells. They may function as electrical pacemakers in the urethra and prostate. In the bladder, they are found closely apposed to detrusor smooth muscle cells, in the lamina propria and within the suburothelium; it has been tentatively suggested that one of their functions in the bladder is to act as intermediary cells transducing nerve signals to detrusor smooth muscle cells (Drumm et al 2014).

## Muscularis propria

The muscularis propria is the detrusor muscle of the bladder wall. It consists of three indistinct layers: an inner and outer longitudinal, and an intermediate circular layer. In contrast to the muscularis mucosae, which consists of small wispy fibres, the muscularis propria is made up of larger, poorly defined, bundles of smooth muscle that form welldefined inner circular and outer longitudinal layers at the neck of the bladder.

## Serosa

The serosa partially covers the bladder. It is lined externally by mesothelium, beneath which there is a variable amount of vascularized adipose tissue that frequently extends into the muscularis propria and, occasionally, into the lamina propria.

## MALE URETHRA

The male urethra (Fig. 75.12, see Fig. 75.2) is 18-20 cm long, and extends from the internal orifice in the urinary bladder to the external opening, or meatus, at the end of the penis. It may be considered in two parts. The anterior urethra is approximately 16 cm long and lies within the perineum (proximally) and the penis (distally), surrounded by the corpus spongiosum. The posterior urethra is 4 cm long and lies in the pelvis proximal to the corpus spongiosum, where it is acted on by the urogenital sphincter mechanisms. Functionally, both parts act as a conduit.

The anterior urethra is subdivided into a proximal component, the bulbar urethra, which is surrounded by bulbospongiosus and entirely within the perineum, and a pendulous or penile component, which continues to the tip of the penis. The posterior urethra is divided into preprostatic, prostatic and membranous segments. In the flaccid penis, the urethra has a double curve. The urethral canal is a mere slit, except during the passage of fluid; in transverse section, it is transversely arched in the prostatic part, stellate in the preprostatic and membranous portions, transverse in the bulbar and penile portions, and sagittal at the external orifice.

## Posterior part

## Preprostatic urethra

The preprostatic urethra is approximately 1 cm in length, and extends from the base of the bladder to the prostate (Fig. 75.12). Small periurethral glands at this site may contribute to benign prostatic hyperplasia (BPH) and symptoms of outflow obstruction in older men.

## Prostatic urethra

The prostatic urethra is $3-4 \mathrm{~cm}$ in length and tunnels through the substance of the prostate, closer to the anterior than the posterior surface of the gland (Fig. 75.13; see Fig. 75.10). It is continuous above with the preprostatic part and emerges from the prostate slightly anterior to its apex (the most inferior point of the prostate). Throughout most of its length, the posterior wall possesses a midline ridge, the urethral crest, that projects into the lumen, causing it to appear

crescentic in transverse section. On each side of the crest, the floor of a shallow depression, the prostatic sinus, is perforated by the orifices of $15-20$ prostatic ducts. An elevation, the verumontanum (seminal colliculus), occurs at about the middle of the length of the urethral crest; at this point, the urethra turns anteriorly and contains the slit-like orifice of the prostatic utricle. The extent of angulation most often approximates $30-35^{\circ}$ but can change with age and differs between individuals. The verumontanum is used as a surgical landmark for the urethral sphincter during transurethral resection for benign enlargement of the prostate.

The two small openings of the ejaculatory ducts open on both sides of, or just within, the prostatic utricle, a cul-de-sac approximately 6 mm long, that runs upwards and backwards in the substance of the prostate behind its median lobe. Its walls are composed of fibrous tissue, muscular fibres and mucous membrane, the latter pitted by the openings of numerous small glands. It develops from the paramesonephric ducts or urogenital sinus, and has been thought to be homologous with the vagina of the female so that it is sometimes called the 'vagina masculina'; the more usual view is that it is a uterine homologue - hence the name 'utricle'.

The lowermost part of the prostatic urethra is fixed by the puboprostatic ligaments and is therefore immobile.

## Membranous urethra

The membranous part of the urethra is the shortest ( $2-2.5 \mathrm{~cm}$ ), least dilatable and, with the exception of the external orifice, the narrowest section of the urethra. It descends with a slight ventral concavity from the prostate to the bulb of the penis, passing through the perineal membrane, 2.5 cm posteroinferior to the pubic symphysis. The wall of the membranous urethra consists of a muscle coat that is separated from the epithelial lining by a narrow layer of fibroelastic connective tissue. The muscle coat contains a relatively thin layer of bundles of smooth muscle, which are continuous proximally with those of the prostatic urethra, and a prominent outer layer of circularly orientated striated muscle fibres, which together form the external urethral sphincter.

Urinary continence at the level of the membranous urethra is mediated by the radial folds of urethral mucosa, the submucosal connective tissue, the intrinsic urethral smooth muscle, the striated muscle fibres and the pubourethral component of levator ani. The muscle coat of the urethra and puborectalis surround the membranous urethra and are attached to the inner surface of the ischiopubic ramus; fibres also reach up to the lowest part of the neck of the bladder and lie on the surface of the prostate. The striated external urethral sphincter has a posterior fibrous defect and is inserted throughout its length into the perineal

Cystic dilation of the prostatic utricle (Fig. 75.14) may present in childhood with urinary tract infections, recurrent epididymitis or haematuria.

Fig. 75.14 Cystic dilation of the prostatic utricle (arrow) demonstrated in an 8-month-old child during a micturating cystourethrogram. (Courtesy of Mr Alok Godse.)

Fig. 75.13 The prostatic part of the male urethra. The raised part of the urethral crest is the seminal colliculus, known clinically as the verumontanum. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
body. It is related to the dorsal vein complex anteriorly, levator ani laterally, and the perineal body and rectourethralis posteriorly; it is suspended from the pubis by fibrous tissue that extends from its anterior and lateral parts to the puboprostatic ligaments posteriorly and to the suspensory ligament of the penis anteriorly. The bulbourethral glands are invested in sphincteric muscle and drain into the membranous urethra during sexual excitement.

## Anterior part

The anterior, or spongiose, part of the urethra lies within the corpus spongiosum penis (see Fig. 76.3). In the flaccid penis, it is about 15 cm long and extends from the end of the membranous urethra to the external urethral orifice on the glans penis. It starts below the perineal membrane at a point anterior to the lowest level of the pubic symphysis as the bulbar urethra, the widest part of the urethra, surrounded by bulbospongiosus. The bulbourethral glands open into the bulbar urethra approximately 2.5 cm below the perineal membrane. The urethra next curves downwards as the penile urethra. It is a narrow, transverse slit when empty, and has a diameter of approximately 6 mm when passing urine. It is dilated at its termination within the glans penis, where it is known as the navicular fossa. The external urethral orifice is the narrowest part of the urethra and, in the adult, is a sagittal slit, about 6 mm long, bounded on each side by a small labium.

The urethral epithelium, particularly in the bulbar and distal penile segments, presents the orifices of numerous small mucous urethral glands that lie in the submucosa. It also contains a number of small pit-like recesses, or lacunae, of varying sizes with orifices directed forwards. One, the lacuna magna, is larger than the rest and is situated in the roof of the navicular fossa.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Urethral artery

The urethral artery arises from the internal pudendal artery or common penile artery just below the perineal membrane, and travels through the corpus spongiosum to reach the glans penis. It supplies the urethra and the erectile tissue around it. The urethra is also supplied by the dorsal penile artery, via its circumflex branches on each side and in a retrograde fashion from the glans, by its terminal branches. The blood supply
through the corpus spongiosum is so plentiful that the urethra can be divided without compromising its vascular supply.

## Veins

The venous drainage of the anterior urethra is to the dorsal veins of the penis and internal pudendal veins, which drain to the prostatic plexus. The posterior urethra drains into the prostatic and vesical venous plexuses, which drain into the internal iliac veins.

## Lymphatic drainage

Vessels from the posterior urethra pass mainly to the internal iliac nodes; a few may end in the external iliac nodes. Vessels from the membranous urethra accompany the internal pudendal artery. Vessels from the anterior urethra accompany those of the glans penis, most ending in the deep inguinal nodes; some may end in superficial nodes, while others may traverse the inguinal canal to end in the external iliac nodes.

## INNERVATION

The prostatic plexus supplies the smooth muscle of the prostate and prostatic urethra (see Fig. 75.11). On each side, it is derived from the pelvic plexus and lies on the posterolateral aspect of the seminal vesicle and prostate. The cavernous (deep, cavernosal) nerves, both major and minor, pierce the bulb of the corpus spongiosum to innervate the cavernous bodies of the penis. The sympathetic autonomic nerves that supply the internal urethral sphincter are derived from the pelvic plexus as it descends in the pelvis adjacent to the inferior prostatovesical pedicle and prostate, and function to prevent retrograde ejaculation. Parasympathetic preganglionic axons arise from neuronal cell bodies in the second to fourth sacral spinal segments. The nerve supply of the external urethral sphincter is controversial. It is generally believed to be supplied by neurones in Onuf's nucleus and by perineal branches of the pudendal nerve lying on the perineal aspect of the pelvic floor; in both instances, the axons arise from neurones in the second to fourth sacral spinal segments. Fibres from Onuf's nucleus (somatic) travel with the pelvic plexus on each side until they branch off to run on the pelvic aspect of the pelvic floor to enter the membranous urethra.

## MICROSTRUCTURE

The epithelium lining the preprostatic urethra and the proximal part of the prostatic urethra is a typical urothelium (Fig. 75.15). It is continuous with that lining the bladder, and with the epithelium lining the ducts of the prostate and bulbourethral glands, the seminal vesicles, and the vasa deferentia and ejaculatory ducts. These relationships are important in the spread of urinary tract infections.

The mean length of the slit is 5.4 mm in boys between the ages of 0.3 and 15 years (Hutton and Babu 2007). The width of the external urethral orifice in uncircumcised boys between the ages of 5 months and 16 years varies from 3.5 to 7.5 mm (Orkiszewski and Madej 2010).

The urethra may be ruptured by a fall-astride (straddle) injury to the bulbar urethra in the perineum, or by an injury related to a pelvic fracture. These injuries usually affect the junction of the membranous with the bulbar segments across the perineal membrane. One of the complications associated with such injuries is extravasation of urine. After an injury to the bulbar urethra, urine usually extravasates between the perineal membrane and the membranous layer of the superficial fascia (clinically, known as Colles' fascia). As both of these are attached firmly to the ischiopubic rami, extravasated fluid cannot pass posteriorly because the two layers are continuous around the superficial transverse perineal muscles. Laterally, the spread of urine is blocked by the pubic and ischial rami. Urine cannot enter the lesser pelvis through the perineal membrane if this remains intact, and so it tracks anteriorly into the loose connective tissue of the scrotum and penis, and, from there, to the anterior abdominal wall. If the posterior urethra is injured, urine is extravasated into the pelvic extraperitoneal tissue; if the perineal membrane is also torn, then urine may be extravasated into the perineum.

Hypospadias, found in 1 in 300 boys, most often results in the urethra opening in the distal penis, either on the ventral aspect of the penis or, more proximally, on to the perineum. There is also an associated abnormality of the prepuce, which is longer dorsally and lacking ventrally, and often an associated chordee, which causes a ventral curvature of the penis. The microvessel density of the prepuce is reduced in children with hypospadias and this has surgical implications when preputial flaps are used for the repair of hypospadias (Yucel et al 2004, Cagri Savas et al 2011). Anomalies of arterial vascular anatomy of the prepuce have been described in boys with hypospadias; it is, therefore, important for hypospadias to be identified prior to circumcision because the abnormal foreskin is sometimes used for surgical correction of the deformity. The anogenital distance (distance from the anus to the base of penis) is reduced in Caucasian boys with hypospadias (Hsieh et al 2012).

Epispadias occurs in approximately 1 in 100,000 boys; it is typically part of the exstrophy-epispadias complex but may occur in isolation. The urethra is either completely open dorsally or uncovered to the level of the pubic symphysis. The neurovascular bundles are anterolateral along the proximal portions, and lateral along the middle and distal portions, of the corporeal bodies (Hurwitz et al 1986). Other features of epispadias are shortened penis and dorsal chordee; the incidence of cryptorchidism is increased ten-fold.

Posterior urethral valves occur in 1 in 5000-8000 males and are the most common cause of urinary outflow obstruction in male infants. The most common type (type I) is believed to occur if the Wolffian ducts open too anteriorly on to the primitive prostatic urethra; this abnormal migration of the ducts leaves behind thick vestigial tissue that forms rigid valve cusps extending caudally from the verumontanum. Megalourethra may be associated with posterior urethral valves. Congenital anterior urethral valves are a rare cause of urethral obstruction in boys and may be associated with posterior urethral valves and hypospadias.

Very rarely, urethral duplication occurs; the two urethrae almost invariably lie on top of each other rather than side by side. One of the urethrae, usually the more dorsal, may be blind-ending. Congenital prepubic sinus consists of a midline tract in the skin passing from the suprapubic region towards the anterior bladder without communication, and is believed to be a variant of dorsal urethral duplication. Congenital urethrocutaneous fistulae are very rare anomalies in which the urethra opens on the ventral surface of the penis in the absence of chordee or hypospadias.

Congenital rectourethral fistulae may be present in children born with anorectal malformation. The prostatic or bulbar urethra is usually affected, and the rectum and urethra share a common wall immediately above the fistula site.

Fig. 75.15 The bladder is lined by urothelium with a surface 'umbrella cell' layer (U) and a layer of intermediate cells (3-5 cells thick). The lamina propria (LP) consists of stroma with blood vessels and von Brunn's nests.

The epithelium changes below the openings of the ejaculatory ducts to a pseudostratified or stratified columnar type, which lines the membranous urethra and the major part of the penile urethra. Mucussecreting cells are common throughout this epithelium and frequently occur in small clusters in the penile urethra. Branching tubular paraurethral glands secrete protective mucus on to the urethral epithelial lining and are especially numerous on its dorsal aspect. In older men, many of the deep recesses of the urethral mucosa contain concretions similar to those found within prostatic glands (see Fig. 75.23A). Towards the distal end of the penile urethra, the epithelium changes once again, becoming stratified squamous in type with well-defined connective tissue papillae. This epithelium also lines the navicular fossa and becomes keratinized at the external meatus. The epithelial cells lining the navicular fossa are glycogen-rich. This may provide a substrate for commensal lactobacilli, which, as in the female vagina, provide a defence against pathogenic organisms.

## FEMALE URETHRA

The adult female urethra is approximately 4 cm long and 6 mm in diameter. The average length of the urethra is 26 mm in girls, increasing from 23 mm at birth to 32 mm at 15 years (Hirdes et al 2010). It begins at the internal urethral orifice of the bladder, approximately opposite the middle of the pubic symphysis, and runs anteroinferiorly behind the pubic symphysis, embedded in the anterior wall of the vagina (see Fig. 75.1). It is suspended beneath the pubis by the posterior pubourethral ligaments, and anteriorly, by the suspensory ligament of the clitoris. It crosses the perineal membrane and normally ends at the external urethral orifice in the vestibule as an anteroposterior slit with rather prominent margins, directly anterior to the opening of the vagina and 2.5 cm behind the glans clitoris. It sometimes opens into the anterior vaginal wall. Except during the passage of urine, the anterior and posterior walls of the urethra are in apposition and the epithelium is thrown into longitudinal folds, one of which, on the posterior wall of the canal, is termed the urethral crest. Many small, mucous urethral glands and minute, pit-like recesses or lacunae open into the urethra and may give rise to urethral diverticula. On each side, near the lower end of the urethra, a number of these glands, Skene's glands, are grouped together and open into the paraurethral duct; each duct runs down in the submucous tissue and ends in a small aperture on the lateral margin of the external urethral orifice.

Epispadias is a rare congenital anomaly that may affect the female urethra. It may occur in isolation or as part of the exstrophy-epispadias complex. Isolated epispadias in girls is characterized by the urethra opening at the clitoris, which is typically bifid.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Urethral artery

The urethra is supplied principally by the vaginal artery, but also receives a supply from the inferior vesical artery

## Veins

The venous plexus around the urethra drains into the vesical venous plexus around the bladder neck and into the internal pudendal veins (see Fig. 77.3). An erectile plexus of veins along the length of the urethra is continuous with the erectile tissue of the vestibular bulb.

## Lymphatic drainage

The urethral lymphatics drain into the internal and external iliac nodes.

## INNERVATION

Parasympathetic preganglionic axons arise from neuronal cell bodies in the intermediolateral column of the second to fourth segments of the sacral spinal cord, run in the pelvic splanchnic nerves, and synapse in the vesical plexus in or near the bladder wall (see Fig. 77.5B). Postganglionic fibres are distributed to the smooth muscle of the urethral wall. Somatic fibres to the striated muscle are also derived from the second to fourth segments of the sacral spinal cord, and run in the pelvic splanchnic nerves but do not synapse in the vesical plexus. Sensory fibres run in the pelvic splanchnic nerves to the second to fourth segments of the sacral spinal cord. Postganglionic sympathetic fibres arise from the plexus around the vaginal arteries.

## MICROSTRUCTURE

The mucosa lining the female urethra consists of a stratified epithelium and a supporting lamina propria of loose fibroelastic connective tissue. The latter is bulky and well vascularized, and contains numerous thinwalled veins. Its abundant elastic fibres are orientated both longitudinally and circularly around the urethra. The lamina propria contains a fine nerve plexus, believed to be derived from sensory branches of the pudendal nerves. The proximal part of the urethra is lined by urothelium, identical in appearance to that of the bladder neck. Distally, the epithelium changes into a non-keratinizing stratified squamous type that lines the major portion of the female urethra. This epithelium is keratinized at the external urethral meatus, where it becomes continuous with the skin of the vestibule.

The wall of the female urethra consists of an outer muscle coat and an inner mucosa, which lines the lumen and is continuous with that of the bladder. The muscle coat consists of an outer sheath of striated muscle, together with an inner coat of smooth muscle fibres. The female external urethral sphincter is anatomically separate from the adjacent periurethral striated muscle of the anterior pelvic floor. The muscle cells forming the external urethral sphincter are all small-diameter, slowtwitch fibres.

The smooth muscle coat extends throughout the length of the urethra and consists of slender muscle bundles, the majority of which are orientated obliquely or longitudinally. A few circularly arranged muscle fibres occur in the outer aspect of the non-striated muscle layer and intermingle with the skeletal muscle fibres forming the inner part of the external urethral sphincter. Proximally, the urethral smooth muscle extends as far as the bladder neck, where it is replaced by fascicles of detrusor smooth muscle. This region in the female lacks a welldefined circular smooth muscle component comparable with the preprostatic sphincter of the male. Distally, urethral smooth muscle bundles terminate in the subcutaneous adipose tissue surrounding the external urethral meatus.

The smooth muscle of the female urethra receives an extensive presumptive cholinergic parasympathetic nerve supply but contains relatively few noradrenergic nerves. In the absence of an anatomical bladder neck sphincter, competence of the female bladder neck and proximal urethra is unlikely to be totally dependent on smooth muscle activity, and is more probably related to the support provided by the ligamentous structures that surround them. The innervation and longitudinal orientation of most of the muscle fibres suggest that urethral smooth muscle in the female is active during micturition, serving to shorten and widen the urethral lumen.

## MICTURITION AND URINARY CONTINENCE

The central integration of nervous control of the bladder and urethra is essential for normal micturition (Fig. 75.16). (For further reading, see Yoshimura and Chancellor (2012).)

Micturition consists of storage and voiding phases. During the storage phase, the bladder accommodates an increasing volume of urine

Fig. 75.16 The micturition control centre is in the paramedian pontine reticular formation on each side and consists of a medially placed micturition centre, ' $M$ ', and a laterally placed storage centre, 'L'. Neurones project from the ' M ' centre and the storage centre ' $L$ ' to parasympathetic neurones in segments 2-4 of the sacral spinal cord, and to Onuf's nucleus, which is in the same segments, and which innervates the external urethral sphincter. At higher levels, neurones in the right prefrontal and anterior cingulate cortex, right preoptic nucleus and periaqueductal grey matter are involved in the control of micturition. Vesical afferents from stretch receptors in the detrusor and trigonal mucosa relay the extent of bladder filling to the brainstem and thalamus via spinoreticulothalamic fibres (1). Activity in the sympathetic system that maintains increases in bladder compliance (via $\beta_{2}$ receptors on detrusor fibres) and parasympathetic activity is inhibited (2). Spinoreticular fibres synapsing in the ' $L$ ' nucleus in the pons activate Onuf's nucleus to increase the tone of the external sphincter (3). If micturition is deferred, fibres projecting from the inferior frontal gyrus inhibit the right anterior cingulate gyrus, preoptic area and periaqueductal grey matter (4). Voluntary contraction of the pelvic floor musculature, controlled by the prefrontal cortex driving the perineal 'area' of the motor cortex (5), cannot be long sustained once filling is complete. (With permission from FitzGerald MJT, Folan-Curren J 2001 Clinical Neuroanatomy, 4th edn. London: Saunders.)
without any change in intravesical pressure, partly because of the viscoelastic properties of its walls, and partly because a gating mechanism operates in the spinal cord that reflexively inhibits preganglionic parasympathetic activity. A gating mechanism in the pelvic ganglia prevents the activation of postganglionic parasympathetic neurones until preganglionic activity has reached a threshold level (Chancellor and Yoshimura 2002).

Mean bladder capacity in adult males varies around 400 ml but micturition commonly occurs at smaller volumes. Voluntary control is imposed from the inferior frontal gyrus of the cerebral cortex. Filling to 500 ml may be tolerated; beyond this level, pain caused by tension in the bladder wall leads to the urgent desire to micturate. The pain is referred to the cutaneous areas supplied by T10-L2 and S2-4, including the lower anterior abdominal wall, perineum and penis. Threshold afferent stimulation activates the micturition centre in the rostral pons (the ' M ' centre) (see Fig. 75.16), which drives preganglionic parasympathetic neurones in the intermediolateral grey column of the second, third and fourth sacral spinal segments via descending spinal pathways. The axons of these neurones run to the inferior hypogastric plexus in the pelvic splanchnic nerves; they synapse on postganglionic neurones in ganglia lying within the plexus and in the wall of the bladder. Postganglionic axons ramify throughout the thickness of the detrusor smooth muscle coat. When stimulated, they release acetylcholine, which activates muscarinic receptors in the detrusor layer of the bladder wall and produces the sustained bladder contraction required for micturition. The distal urethral sphincter maintains urethral closure.

## Urinary continence in the male

Urinary continence at the level of the membranous urethra is mediated by the radial folds of urethral mucosa, the submucosal connective tissue, the intrinsic urethral smooth muscle, the striated external urethral sphincter and the pubourethral component of levator ani, puboperinealis (Fig. 75.17). The external urethral sphincter represents the point of highest intraurethral pressure in the normal, contracted, state. The striated muscle component of the external urethral sphincter is devoid of muscle spindles. The striated muscle fibres themselves are unusually small in cross-section (15-20 $\mu \mathrm{m}$ in diameter), and are physiologically of the slow-twitch type, unlike the pelvic floor musculature, which is a heterogeneous mixture of slow- and fast-twitch fibres of larger diameter. The slow-twitch fibres of the external sphincter are capable of sustained contraction over relatively long periods of time and actively contribute to the tone that closes the urethra and maintains urinary continence. They are innervated by neurones that lie in Onuf's nucleus in the anterolateral grey matter of the second to fourth sacral spinal segments. Their firing is controlled centrally by a storage centre within the rostral pons (the 'L' centre) (see Fig. 75.16). Just before the onset of voiding, the external urethral sphincter is relaxed by central inhibition of Onuf's nucleus.

## Urinary continence in the female

The urethral sphincter mechanism consists of the intrinsic striated and smooth muscle of the urethra, the mucosa and submucosal connective tissue, and the puborectalis component of levator ani (which surrounds the urethra at the point of maximum concentration of those muscles).

Fig. 75.17 A, Coronal illustration of male anterior levator ani (urogenital) hiatus: prostate above, intervening striated urethral sphincter and perineal membrane with corporal bodies below. B, This coronal T2-weighted MRI includes the cephalad extension of the smooth muscle urethral sphincter, which cannot be discriminated from striated urethral sphincter; bulbourethral glands are offset from expected symmetry. (A, B Courtesy of Robert P Myers MD, Akira Kawashima MD and Bernard F King MD, used with permission of Mayo Foundation for Medical Education and Research.)

The striated muscle component of the urethral sphincter mechanism surrounds the middle and lower thirds of the urethra in the female. Proximally, it forms a complete ring around the urethra, while, more distally, it covers the anterior and lateral aspects of the urethra; it blends above with the smooth muscle of the bladder neck and below with the smooth muscle of the lower urethra and vagina. Contraction of this part of the sphincter compresses the urethra against the relatively fixed anterior vaginal wall. At its most distal point; the striated sphincter encompasses the urethra and vagina as the urethrovaginal sphincter. The mucosa and submucosa are oestrogen-dependent and atrophy postmenopausally, possibly resulting in stress incontinence.

## PROSTATE

The prostate is a globular fibromuscular gland that surrounds the prostatic urethra from the bladder base to the membranous urethra (Myers 2001). It is enclosed by firmly adherent tissue that has been variously termed the prostatic capsule or the prostatic fascia (parietal fascia covering the adjacent part of levator ani, lateral pelvic fascia, periprostatic fascia, parapelvic fascia), reflecting, in part at least, inter-individual variability and sampling site (Myers et al 2010) (Fig. 75.18). Histologically, it is a multilayered connective tissue (Hinata et al 2013). There is no true fibrous capsule at the base or apex of the prostate, and the presence of a capsule between the apex and base is variable.

The muscular tissue within the prostate is mainly smooth muscle. Anterior to the urethra, a layer of smooth muscle merges with the main mass of muscle in the fibromuscular septa; it blends superiorly with vesical smooth muscle. Anterior to the layer of smooth muscle, a transversely crescent-shaped mass of skeletal muscle is continuous inferiorly with the external urethral sphincter in the deep perineal pouch. Its fibres pass transversely internal to the capsule and are attached to it laterally by diffuse collagen bundles; other collagen bundles pass posteromedially, merging with the prostatic fibromuscular septa and the septum of the urethral crest. This muscle, supplied by the pudendal nerve, probably compresses the urethra but it may pull the urethral crest back and the prostatic sinuses forwards, dilating the urethra. Glandular contents may be expelled simultaneously into the urethra when it has expanded in this way, so that it contains $3-5 \mathrm{ml}$ seminal fluid prior to ejaculation.

The prostate lies at a low level in the lesser pelvis, behind the inferior border of the pubic symphysis and pubic arch (see Fig. 75.2A; Fig. 75.19), and anterior to rectourethralis and the rectal ampulla, through which it may be palpated. It presents a base or vesical aspect superiorly, an apex inferiorly, and posterior, anterior and two inferolateral surfaces. The prostatic base measures about 4 cm transversely. The gland is 2 cm in its anteroposterior, and 3 cm in its vertical, diameters. It weighs
about 8 g in youth but, almost invariably, enlarges with the development of BPH; it usually weighs 40 g , but sometimes as much as 150 g or even more, after the first five decades of life. The small prostate without BPH is described as a croissant shape (short anterior commissure, prominent apical notch and posterior lip of prostatic tissue), and the enlarged gland is more doughnut-shaped. The shape of the prostate affects the relationship of the prostatic apex to the external urethral sphincter. This relationship is important when removing the prostate at radical prostatectomy for cancer, and anastomosing the bladder to the urethra to maintain sphincter integrity. The external urethral sphincter is flush to a large doughnut-type gland, and so a perpendicular incision will separate the prostate and external urethral sphincter accurately. In a small prostate, the external urethral sphincter fills the defect in the anterior aspect of the prostate, and so a perpendicular incision at the level of the posterior lip of the croissant-shaped gland will excise much external urethral sphincter and leave the patient incontinent.

Superiorly, the base is largely contiguous with the neck of the bladder. The apex is inferior, surrounding the junction of the prostatic and membranous parts of the posterior urethra. The apical posterior relation of the prostate and external urethral sphincter is rectourethralis, a Y-shaped muscle that originates from the outer longitudinal coat of the rectum. The upper limbs of the Y extend from the lateral rectal wall to the midline, where rectourethralis inserts into the perineal body at the anorectal junction (Brooks et al 2002).

The anterior surface lies in the arch of the pubis, separated from it by the dorsal vascular complex (Santorini's plexus) and loosely attached adipose tissue. It is transversely narrow and convex, extending from the apex to the base. Near its superior limit, it is connected to the pubic bones by the puboprostatic ligaments. The urethra emerges from this surface anterosuperior to the apex of the gland. The anterior part of the prostate is relatively deficient in glandular tissue and is largely composed of fibromuscular tissue. The anterior and lateral aspects of the prostate are covered by a layer of fascia derived from the endopelvic fascia on each side, called the lateral prostatic fascia. This is adherent medially to the prostate, continues posteriorly over the lateral aspect of the prostate, neurovascular bundles and rectum (lateral rectal fascia), and passes distally over the urethra (see Fig. 75.18A). The prostatic venous plexus (see Fig. 75.19) lies between this extension of the endopelvic fascia and the prostate. Anteroinferiorly, the parietal and visceral fasciae of the prostate merge and blend with the puboprostatic ligaments. The anterior surface of the prostate and associated vascular plexus is covered by the detrusor apron (Myers 2002).

The inferolateral surfaces are related to the muscles of the pelvic side wall; the anterior fibres of levator ani embrace the prostate in the pubourethral sling or pubourethralis. These muscles are separated from the prostate by a thin layer of connective tissue.

Fig. 75.18 A, The endopelvic fascia. The fascia covers the pelvic viscera and continues posteriorly over the lateral aspect of the prostate, as the lateral prostatic fascia and, on the lateral aspect of the rectum, as the lateral rectal fascia. Its relationship with Denonvilliers' fascia may be visualized as an ' H '. The deep dorsal vein and lateral branches run deep to the endopelvic fascia and the lateral prostatic fascia, although communicating with perforators to the pelvic side wall. Denonvilliers' fascia is adherent to the prostate in the posterior midline but, like the lateral prostatic fascia, is separated from the prostatic tissue by the neurovascular structures and fatty tissues elsewhere. Between Denonvilliers' fascia and the rectum is a fatty potential plane, the prerectal space. B, The prostatic capsule (PC) is a condensation of connective tissue (green) on the surface of the gland and encloses the neurovascular bundle (NVB). The prostatic fibromuscular stroma and glands lie beneath the capsule.

The posterior surface of the prostate is transversely flat and vertically convex. Near its superior (juxtavesical) border is a depression where it is penetrated by the two ejaculatory ducts. Below this is a shallow, median sulcus, usually considered to mark a partial separation into right and left lateral lobes. It is separated from prerectal fat in the prerectal space (see Figs 75.2A, 75.18A) and rectum by Denonvilliers' fascia, a condensation of pelvic fascia that develops by obliteration of the rectovesical peritoneal pouch, and by loose yellow, fatty areolar tissue. The rectovesical pouch is obliterated from below upwards as fetal life progresses, forming Denonvilliers' fascia; at birth, this fascia separates the prostate, the seminal vesicles and the ampullae of the vasa deferentia from the rectum. The superior limit of Denonvilliers' fascia is the peritoneum of the rectovesical pouch. Laterally, Denonvilliers' fascia fuses with the lateral pelvic fascia; anterior to Denonvilliers' fascia, the lateral pelvic fascia is called the lateral prostatic fascia and, posterior to Denonvilliers' fascia, it is called the lateral rectal fascia.

The prostate is traversed by the urethra and ejaculatory ducts, and contains the prostatic utricle. The urethra enters the prostate near its anterior border and usually passes between its anterior and middle thirds. The ejaculatory ducts pass anteroinferiorly through its posterior region to open into the prostatic urethra.

## ZONAL ANATOMY OF THE PROSTATE

The prostate gland was once thought to be divided into five anatomical lobes, but it is now recognized that five lobes can only be distinguished in the fetal gland prior to 20 weeks' gestation. Between then and the onset of BPH , only three lobes are recognizable: two lateral and a median lobe. Clinicians refer to left and right 'lobes' when describing either what can be felt on rectal palpation, or the endoscopically visible abnormalities that are seen in the diseased state when prostatic anatomy is distorted by BPH.

From an anatomical, and particularly from a morbid anatomical, perspective, the glandular tissue may be subdivided into three distinct zones (Figs 75.20-75.22): peripheral (70\% by volume), central (25\% by volume) and transitional (5\% by volume) (Mundy et al 1999b). Non-glandular tissue (fibromuscular stroma) fills the space between the peripheral zones anterior to the preprostatic urethra. The central zone surrounds the ejaculatory ducts, posterior to the preprostatic urethra, and is more or less conical in shape, with its apex at the verumontanum. The fibromuscular stroma includes the smooth muscle detrusor apron superoanteriorly and striated urethral sphincter fibres that extend anteriorly over the anterior prostate on to the bladder neck. The transitional zone lies around the distal part of the preprostatic urethra just proximal to the apex of the central zone and the ejaculatory ducts; it includes the smooth muscle of the preprostatic urethral wall. Its ducts enter the prostatic urethra just below the preprostatic sphincter and just above the ducts of the peripheral zone. The peripheral zone is cup-shaped and encloses the central transitional zone and the preprostatic urethra, except anteriorly, where the space is filled by the anterior fibromuscular stroma. Simple mucus-secreting glands lie in the tissue around the preprostatic urethra, above the transitional zone and surrounded by the preprostatic sphincter. These simple glands are similar to those in the female urethra and unlike the glands of the prostate.

On magnetic resonance imaging (MRI), the prostate gland has a zonal anatomy on T2-weighted images (see Fig. 75.21). The normal peripheral zone has high-signal intensity, as does fluid within the seminal vesicles. The central and transitional zones have relatively low signal and are often referred to as the 'central gland'. The verumontanum may be seen as high-signal within the central gland. The relationship of the zones of the gland normally changes with age. The central zone atrophies, and the transitional zone enlarges secondary to BPH. This often produces a low-signal band at the margin of the hypertrophied transitional and compressed peripheral zones: the surgical pseudocapsule, which is well seen on T2-weighted MR images.

The zonal anatomy of the prostate is clinically important because most carcinomas arise in the peripheral zone, whereas BPH affects the transitional zone, which may grow to form the bulk of the prostate.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Arteries

The prostate is supplied by branches from the inferior vesical, internal pudendal and middle rectal arteries (see Fig. 75.19). They perforate the gland along a posterolateral line from the junction of the prostate with the bladder down to the apex of the gland.

As the transitional zone grows, it produces the appearance of 'lobes' on either side of the urethra. In due course, these lobes may compress or distort the preprostatic and prostatic parts of the urethra and produce symptoms. The central zone surrounding the ejaculatory ducts is rarely involved in any disease. It shows certain histochemical characteristics that differentiate it from the rest of the prostate; it is thought to be derived from the Wolffian duct system (much like the epididymi, vasa deferentia and seminal vesicles), whereas the rest of the prostate is derived from the urogenital sinus (p. 1218).

Fig. 75.19 A sagittal section of the male pelvis. The pelvic plexus lies with its midpoint level with the tip of the seminal vesicles. It gives branches to the prostate, bladder urethra, seminal vesicles, rectum and corpora cavernosa via the cavernous nerves. The cavernous nerves are the continuation of the neurovascular bundles, lying posterolateral to the prostate. These bundles may be damaged at radical prostatectomy, resulting in impotence.

The inferior vesical artery often arises from the internal iliac artery with the middle rectal artery. It gives rise to two groups of branches: the urethral and capsular. The urethral vessels enter at the prostatovesical junction, principally posteriorly at the 5 and 7 o'clock positions, but also anteriorly at 1 and 11 o'clock. This bladder neck arterial anatomy is always apparent at transurethral resection of the prostate and open removal of BPH adenomas. The capsular arteries run posterolaterally and inferiorly in the neurovascular bundles, providing perpendicular perforating vessels to the prostate. The most constant in position and prominence is the apical perforator at the prostatourethral junction, an important landmark for this point and for the neurovascular bundle at radical prostatectomy.

## Veins

The veins run into a plexus around the anterolateral aspects of the prostate, posterior to the arcuate pubic ligament and the lower part of pubic symphysis, anterior to the bladder and prostate. The chief tributary is the deep dorsal vein of the penis. The plexus also receives anterior vesical and prostatic rami (which connect with the vesical plexus and internal pudendal vein), and drains into vesical and internal iliac veins.

## Lymphatic drainage

Collecting vessels from the vas deferens drain into the external iliac nodes, while those from the seminal vesicle drain to the internal and external iliac nodes. Prostatic vessels end mainly in internal iliac, sacral and obturator nodes. A vessel from the posterior surface accompanies the vesical vessels to the external iliac nodes, and another from the anterior surface reaches the internal iliac group by joining vessels that drain the membranous urethra.

## INNERVATION

Commentary 8.1). The prostatic capsule is covered by numerous nerve fibres and ganglia posterolaterally, forming a crescentic periprostatic nerve plexus. The greatest density of nerves is found in the preprostatic sphincter; fewer fibres are found in the anterior fibromuscular stroma, and the peripheral zone is the least densely innervated. Nerves containing neuropeptide Y and vasointestinal polypeptide (VIP) are localized in the subepithelial connective tissue, in the smooth muscle layers of the gland, and in the walls of its blood vessels. Neurovascular bundles (Walsh and Donker 1982) containing autonomic nerves that supply the prostate, seminal vesicles, prostatic urethra, ejaculatory ducts, corpora cavernosa, corpus spongiosum, membranous and penile urethra, and bulbourethral glands are closely applied to, but separable from, the posterolateral margins of the prostate (see Commentary 8.1). They are intimately related to the prostatic fascia. These nerves may be damaged during radical prostate surgery for organ-confined prostate cancer, producing impotence, or sacrificed as part of wide local excision of the prostate (Tewari et al 2006, Pisipati et al 2014).

The somatic pudendal nerve supplies the external urethral sphincter. The branches enter at the 5 and 7 o'clock positions. Sensory branches pass through the penile hilus in association with the dorsal venous complex and dorsal vein of the penis.

## MICROSTRUCTURE

The glandular tissue consists of numerous follicles with frequent internal papillae. Follicles open into elongated canals, which join to form 12-20 main ducts. The follicles are separated by loose connective tissue, supported by extensions of the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. Follicular epithelium is variable but predominantly columnar, and either single-layered or pseudostratified.

Prostatic ducts open mainly into the prostatic sinuses in the floor of the prostatic urethra. They have a bilayered epithelium, the luminal layer is columnar, and the basal layer is populated by small cuboidal cells. Small colloid amyloid bodies (corpora amylacea) are frequent in the follicles (Fig. 75.23). Prostatic and seminal vesicular

Fig. 75.20 Ultrasound of the prostate. A, An axial view showing the hypoechoic transition zone (TZ) and the more echogenic peripheral zone (PZ). Their interface is the surgical capsule (*). B, A sagittal view showing the hypoechoic transition zone (TZ) and the more echogenic peripheral zone (PZ).
secretions form the bulk of seminal fluid. Prostatic secretions are slightly acid, and contain acid phosphatase, amylase, prostate-specific antigen, fibrinolysin and zinc. Numerous neuroendocrine cells, containing neurone-specific enolase, chromogranin and serotonin (5-hydroxtryptamine, 5-HT), are present in the glandular epithelium; their numbers decline after middle age and their function is unknown.

Histological sections just above the level of the verumontanum reveal two concentric, partially circumurethral, zones of glandular tissue. The larger outer zone is the peripheral zone and has long, branched glands, whose ducts open mainly into the prostatic sinuses. The inner zone is the transitional zone and consists of glands whose ducts open on the floor of the prostatic sinuses and colliculus seminalis, and a group of simple mucosal glands that surround the preprostatic urethra. Anteriorly, in the prostatic isthmus, the peripheral zone and submucosal glands are absent.

## AGE CHANGES IN THE PROSTATE

At birth, the prostate has a system of ducts embedded in a stroma that forms a large part of the gland. Follicles are represented by small endbuds on the ducts. Before birth, the epithelium of the ducts, seminal colliculus and prostatic utricle display hyperplasia and squamous metaplasia, possibly due to maternal oestrogens in the fetal blood. This subsides after birth and is followed by a period of quiescence lasting for 12-14 years.

At puberty, between the ages of approximately 14 and 18 years, the prostate gland enters a maturation phase and more than doubles in size during this time. Growth is almost entirely due to follicular development, partly from end-buds on ducts, and partly from modification of

Fig. 75.21 Magnetic resonance imaging (MRI) of the prostate. A, A T2-weighted MRI scan showing the normal high signal of the peripheral zone and the intermediate signal of the central and transitional zones and the verumontanum in the central gland. B, A T2-weighted coronal MRI scan of the prostate showing the zonal anatomy.
the ductal branches. Morphogenesis and differentiation of the epithelial cords starts in an intermediate part of the epithelial anlage and proceeds to the urethral and subcapsular parts of the gland; the latter is reached by the age of $17-18$ years. The glandular epithelium is initially multilayered squamous or cuboidal, and is transformed into a pseudostratified epithelium consisting of basal, exocrine secretory (including mucous) and neuroendocrine cells. The mucous cells are temporary, and are lost as the gland matures. The remaining exocrine secretory cells produce a number of products, including acid phosphatase, prostatespecific antigen and $\beta$-microseminoprotein. Growth of the secretory component is associated with condensation of the stroma, which diminishes relative to the glandular tissue. These changes are probably a response to the secretion of testosterone by the testis.

During the third decade, the glandular epithelium grows by irregular multiplication of the epithelial infoldings into the lumen of the follicles. After the third decade, the size of the prostate remains virtually

Fig. 75.22 The zonal anatomy of the prostate. (With permission from Walsh PC, Retik AB, Vaughan ED et al (eds) 2002 Campbell's Urology, 8th edition. Philadelphia: Saunders.)
unaltered until 45-50 years, when the epithelial foldings tend to disappear, follicular outlines become more regular, and amyloid bodies increase in number: all signs of prostatic involution. After 45-50 years, the prostate tends to develop BPH: an age-related condition. If a man lives long enough, then BPH is inevitable, although not always symptomatic.

## Acknowledgements

Fig. 75.9 A laparoscopic view of the left inferior epigastric vein (lateral umbilical ligament) in a 12-month-old boy.

Fig. 75.14 Cystic dilation of the prostatic utricle demonstrated in an 8 -month-old child during a micturating cystourethrogram.

Video 75.1 Laparoscopic view of bladder filling and emptying in relation to the rectovesical pouch.

Video 75.2 Laparoscopic view of anterior abdominal wall and ligaments.

BPH begins as micronodules in the transitional zone, which grow and coalesce to form macronodules around the inferior margin of the preprostatic urethra, just above the verumontanum. Macronodules, in turn, compress the surrounding normal tissue of the peripheral zone posteroinferiorly, creating a 'false capsule' around the hyperplastic tissue, which, coincidentally, provides a plane of cleavage for its surgical enucleation (for further reading see Kutikov et al (2006)).

# Male reproductive system 

## INTRODUCTION

The male reproductive system consists of the gonads (testes), spermatic cord, sex accessory glands and external genitalia. The testes perform both spermatogenic and steroidogenic functions. The unique anatomy of the reproductive tract, both gross and microscopic, is optimally suited for these functions to be carried out efficiently and effectively.

## TESTIS AND EPIDIDYMIS

## TESTIS

The testes are ovoid organs responsible for sperm and testosterone production. In adults, they typically measure $4-5 \mathrm{~cm}$ in length, $2-3 \mathrm{~cm}$ in breadth and 3-4 cm in anteroposterior diameter (Tishler 1971); their weight varies between 12 and 20 g . Average testicular volume ranges from 15 to 25 ml (Prader 1966, Goede 2011).

The testes are suspended in the scrotum by the spermatic cord (Figs 76.2, 76.3). The left testis usually lies lower than the right testis; both are positioned obliquely, such that the upper pole is tilted anterolaterally while the lower pole is tilted anteromedially. The location of the testes in the scrotum, combined with the characteristics of the scrotal skin, as well as the counter-current heat exchange mechanism of the testicular pampiniform plexus, maintains the testes at a temperature $3-4^{\circ} \mathrm{C}$ below body temperature.

The testes are enclosed in a tough capsule made up of three layers: an innermost tunica vasculosa, an intermediate tunica albuginea and an outer tunica vaginalis (Fig. 76.4). The posterior aspect of the testis is the site of attachment of the epididymis and is, therefore, only partly covered by serosa. Here, the tunica albuginea projects inwards to form the mediastinum testis, and the tunica vaginalis projects outwards to cover the epididymis. Within the scrotum, the testes are separated by a fibrous median septum.

Tunica vasculosa The tunica vasculosa contains a plexus of blood vessels and loose connective tissue. It lines the inner surface of the tunica albuginea, as well as all of the surfaces and septations within the testis.

Tunica albuginea The tunica albuginea is a dense, blue-white layer composed primarily of collagen fibres. It covers the tunica vasculosa and is surrounded by the visceral layer of the tunica vaginalis. At the posterior aspect of the testis, it projects inwards as a thick but incomplete fibrous septum - the mediastinum testis - which extends from the upper to the lower pole of the testis. It is here that vessels, nerves and testicular ducts traverse the testicular capsule (Fig. 76.5).

Tunica vaginalis The tunica vaginalis is a continuation of the peritoneal processus vaginalis, whose formation precedes the descent of the fetal testis from the abdomen to the scrotum. Following testicular migration into the scrotum, the portion of the processus vaginalis that falls between the internal inguinal ring and the testis contracts and is obliterated, leaving a distal sac containing the testis. Failure to obliterate the processus vaginalis results in a persistent communication with the scrotum and peritoneal cavity (Fig. 76.6), which can lead to hydroceles and indirect inguinal hernias.

The tunica vaginalis is reflected from the surface of the testis on to the inner surface of the scrotum, forming visceral and parietal layers that are continuous at both poles of the testis. The visceral layer covers all aspects of the testis, except the posterior aspect, where it is reflected towards the epididymis before becoming continuous with the parietal layer. The inner surface of the parietal layer has a smooth, moist,
mesothelium. The potential space between the visceral and parietal layers - the cavity of the tunica vaginalis - is normally occupied by a thin film of clear, straw-coloured fluid. The volume of this fluid can increase with obstruction of lymphatic drainage, due to inflammatory, traumatic or neoplastic conditions of the testis, resulting in a hydrocele.

## Vascular supply and lymphatic drainage

## Arteries

The arterial supply to the testis and epididymis is derived from three sources. In descending order of contribution, these are the testicular artery (supplying approximately two-thirds of the testicular blood supply), the vasal artery (artery to vas deferens, artery to ductus deferens, vasal artery, ductal artery) and the cremasteric arteries (together supplying approximately one-third of the testicular blood supply) (Fig. 76.7) (Harrison and Barclay 1948, Raman and Goldstein 2004).

## Testicular artery

The testicular artery (internal spermatic artery) arises from the abdominal aorta, inferior to the origin of the renal artery, and courses inferolaterally under the parietal peritoneum, along psoas major, towards the pelvis. On the right, it courses anterior to the inferior vena cava and posterior to the middle colic and ileocolic arteries and the terminal ileum. On the left, it courses posterior to the inferior mesenteric vein, left colic artery and the descending colon. As the right and left testicular arteries enter the pelvis, they lie anterior to the genitofemoral nerves, ureters and external iliac arteries. Both arteries then enter the deep internal inguinal ring and travel with the ipsilateral spermatic cord in the inguinal canal to the scrotum (see Figs 76.2, 76.5).

In its course to the testis, the testicular artery gives off one or more internal spermatic arteries, an inferior testicular artery, and branches supplying the caput, corpus and cauda epididymis (Macmillan 1954). The level at which this branching occurs is variable; in 31-88\% of cases, it occurs within the inguinal canal (Beck et al 1992, Jarow et al 1992). At the level of the testis, branches of the testicular artery enter the tunica albuginea in the mediastinum testis and ramify in the tunica vasculosa before reaching their distribution. Ramification of the testicular arteries occurs primarily in the anterior, medial and lateral portions of the lower pole of the testis, and in the anterior segment of the upper pole (Jarow 1991), which has important implications for planning testicular biopsies. (For further reading about variations in the origin, course and number of the testicular arteries, see Asala et al (2001), Pai et al (2008)).

## Vasal artery (artery to vas deferens, artery to ductus deferens, deferential artery, ductal artery)

The vasal artery is a branch of the superior (and, occasionally, inferior) vesical artery, which arises from the internal iliac artery.

## Cremasteric artery

The cremasteric artery (external spermatic artery) is a branch of the inferior epigastric artery. It accompanies the spermatic cord and supplies the cremaster and other coverings of the cord. Both the vasal and the cremasteric arteries enter the inguinal canal at the deep inguinal ring, and travel the length of the spermatic cord alongside the testicular artery. The testicular artery and internal spermatic veins lie within the internal spermatic fascia, whereas the vas (ductus) deferens and its vessels, as well as the cremaster muscles and its vessels, lie outside the internal spermatic fascia but within the external spermatic fascia. In the scrotum, a rich vascular anastomosis occurs at the head of the epididymis, between the testicular and epididymal arteries, and at the tail of the epididymis between the testicular, epididymal, cremasteric and vasal arteries.

The volume of the left and right testis，as measured by ultrasono－ graphy in boys between infancy and adolescence，is shown in Table 76．1；reference curves for mean testicular volume are shown in Figure 76．1．

## Veins

Pampiniform plexus
Testicular veins emerge posteriorly from the testis, drain the epididymis, and unite to form several highly anastomotic channels surrounding the testis, known as the pampiniform plexus, a major component of the spermatic cord (see Fig. 76.2). This vascular arrangement means that counterflowing arteries and veins are separated only by the thickness of
their vascular walls, permitting the exchange of heat and small molecules (Harrison 1949), and facilitating the maintenance of lower testicular temperatures. The pampiniform plexus ascends anterior to the vas deferens, and is drained by $3-4$ veins in the inguinal canal. The veins enter the abdomen through the deep inguinal ring and coalesce into a single testicular vein that drains into the inferior vena cava on the right, and into the renal vein on the left. The right testicular vein joins the inferior vena cava at an acute angle, just inferior to the level

Fig. 76.3 The external male genitalia, ventral aspect. The skin of the abdomen and parts of the skin of the scrotum have been removed, and the body of the penis has been severed, revealing the internal structure of the penis. The layers of the spermatic cord and the coverings of the testis have been dissected on the right. of the renal veins, while the left testicular vein joins the left renal vein at a right angle (Fig. 76.8). The testicular veins contain valves.

## Lymphatic drainage

Testicular lymphatic flow is abundant and consistent, and follows the general retroperitoneal scheme of vertical drainage, with lateral flow from right to left. Lymphatic vessels from the right testis drain primarily into the inter-aortocaval nodes and paracaval nodes, with some drainage into the left para-aortic nodes. Lymphatic vessels from the left testis drain into the left para-aortic and inter-aortocaval nodes.

## Innervation

The testis is innervated either by nerve fibres that arise from the tenth and eleventh thoracic spinal segments, via the renal and aortic plexuses, and accompany the testicular vessels, or by fibres that arise from the pelvic plexus and accompany the vas deferens (Rauchenwald et al 1995). Interestingly, some afferent and efferent nerves have been shown to cross over to the contralateral pelvic plexus (Taguchi et al 1999), which may be one reason why pathological processes in one testis can affect the other.

## Microstructure

The testis is enclosed within a tough, collagenous tunica albuginea, which thickens posteriorly as the mediastinum testis. Blood vessels, lymphatics and genital ducts all enter and leave the testis at the mediastinum (Fig. 76.9). Septations originating at the mediastinum testis extend internally to partition the testis into approximately 250 lobules that differ in size, the largest and longest lobules being near the centre (see Fig. 76.5). Each lobule contains 1-4 convoluted seminiferous tubules and interstitial tissue composed of Leydig cells, mast cells, macrophages, nerves and blood vessels.

Seminiferous tubules are typically long, highly coiled and looped; both ends terminate in the mediastinum testis. Spermatogenesis occurs in the highly coiled portions (Fig. 76.10). As the tubules reach the apical portion of the lobule near the mediastinum, they become much less convoluted and form short tubuli recti, which lack spermatogenic cells and are, instead, lined by cuboidal epithelium. Within the mediastinum testis, tubuli recti anastomose to form the rete testis, which is lined by a flat epithelium. Here, tubular fluid is reabsorbed and spermatozoa become concentrated. The rete testis coalesces to form 7-15 efferent ductules, which act as conduits to carry spermatozoa into the caput epididymis. The efferent ductules are lined by a ciliated columnar

Fig. 76.5 A, A vertical section through the testis and epididymis. B, The arrangement of the ducts of the testis and the mode of formation of the vas deferens. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban and Fischer. Copyright 2013.)
epithelium that also contains non-ciliated, actively endocytic cells. Outside the epithelial lining, the ductules are surrounded by a thin circular coat of smooth muscle.

There is a reduction in the diameter of the seminiferous tubules during the third trimester of pregnancy and immediately before birth, which is followed by a gradual increase in the diameter throughout childhood (Mendez and Emery 1979). Seminiferous tubules are responsible for up to $80 \%$ of the total testicular volume. It is estimated that the combined length of the 600-1200 tubules in the human testis is approximately 250 metres. Each tubule is surrounded by a basal lamina, resting on a complex, stratified epithelium. In cross-section, the lumen of the seminiferous tubule is lined by Sertoli cells, and contains spermatozoa in various stages of development, from spermatogonial stem cells near the base, to progressively mature forms (spermatogonia, spermatocytes, spermatids and spermatozoa) arranged in a systematic fashion towards the centre of the tubule. Residual bodies, spherical structures derived from surplus spermatid cytoplasm shed during spermatozoal maturation, may be found among the spermatids.

Specialized tight junctional complexes between adjacent Sertoli cells form a functional 'blood-testis barrier' that subdivides the seminiferous epithelium into basal and adluminal compartments. Spermatogonia and developing spermatocytes lie outside the blood-testis barrier, in the basal compartment, whereas mature spermatocytes and spermatids are sequestered above the blood-testis barrier, in the adluminal compartment.

The longer length of the left testicular vein and its angle of insertion into the left renal vein have been suggested as possible aetiologies for the occurrence of varicoceles. Additionally, the testicular veins may anastomose with the external pudendal, cremasteric and vasal veins, allowing varicoceles to persist or recur after ablative procedures that do not address these potential collaterals.

Fig. 76.7 The arterial blood supply and venous drainage of the testis. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban and Fischer. Copyright 2013.)

Spermatogonia Spermatogonia, the germ cells for all spermatozoa, are descended from primordial germ cells that migrate into the genital cords of the developing testis. In the fully differentiated testis, they are located along the basal laminae of the seminiferous tubules (Fig. 76.10B). Based on their cellular and nuclear dimensions, distribution of nuclear chromatin, and histochemical and ultrastructural properties, spermatogonia are characterized as either dark-type A (Ad), pale-type A (Ap) or type B. Ad spermatogonia divide mitotically to maintain their own population, and can differentiate to give rise to Ap cells, the precursors of type B cells, which are committed to the spermatogenesis cycle. Type B cells give rise to type I spermatocytes; they leave the basal compartment of the seminiferous tubule and cross the blood-testis barrier to enter the adluminal compartment in a step coordinated by Sertoli cells.

The generation of mature spermatozoa from spermatogonia takes approximately 64 days. In cross-section, a seminiferous tubule shows more than one phase of the cycle around its circumference because waves of progression through a spermatogenic cycle occur in spirals along the length of a tubule (see Fig. 76.10B).
Primary and secondary spermatocytes Primary spermatocytes have a diploid chromosome number, with duplicated sister chromatids ( 4 N DNA content). They are large cells with round nuclei, in which the chromatin is condensed into dark, thread-like, coiled chromatids. They undergo meiosis I to give rise to secondary spermatids ( 2 N ), which rapidly undergo meiosis II to form haploid spermatids (N). Theoretically, each primary spermatocyte produces four spermatids; however, a

proportion of spermatids degenerate during maturation, reducing the expected yield.

Spermatids Spermatids undergo a series of nuclear and cytoplasmic changes, termed spermiogenesis, in order to develop into mature spermatozoa. These changes take place while the spermatids are closely associated with Sertoli cells, and linked to one another by cytoplasmic bridges. Spermiogenesis includes the development of the acrosome

Fig. 76.10 A, Seminiferous tubules (ST; cut in various planes of section) and the interstitial tissue (Leydig cells, L) of the testis. The seminiferous tubules are highly convoluted and lined by a stratified epithelium, which consists of cells in various stages of spermatogenesis and spermiogenesis (collectively referred to as the spermatogenic series). Non-spermatogenic cells are the Sertoli cells. B, A human seminiferous tubule showing the differentiation sequence of spermatozoa from basally situated spermatogonia (SG). Large primary spermatocytes (SC) have characteristic thread-like chromatin in various stages of prophase of the first meiotic division. Smaller haploid spermatids (ST) have round nuclei initially, but mature to possess the dense, elongated nuclei and flagella of spermatozoa (SZ). Sertoli cells (S) are identified from their oval or pear-shaped nuclei, orientated perpendicular to the basal lamina, and from their prominent nucleoli. The tubule is surrounded by peritubular myoid cells (M). Clusters of large endocrine Leydig cells (L) are seen in the interstitial connective tissue.
from Golgi vesicles, generation of the axoneme from the centrioles, and formation of the acrosomal cap at the anterior pole of the spermatozoon. Concurrently, the nuclear chromatin condenses and the nucleus assumes a spearhead shape. The cytoplasmic volume shrinks, bringing the wall of the acrosomal vesicle into contact with the plasma membrane. A perinuclear sheath of microtubules develops from the posterior edge of the acrosome and extends towards the posterior pole of the spermatozoon. Here, the microtubules are arranged in the typical flagellar pattern of nine outer microtubules surrounding two central microtubules, the axonemal complex that extends longitudinally to form the tail of the spermatozoon. Mitochondria migrate along the axonemal complex and concentrate in the mid-piece of the tail. In the final phase of spermiogenesis, excess cytoplasm is detached from the spermatozoon as a residual body that is phagocytosed and degraded by Sertoli cells. During the formation of residual bodies, spermatids lose their cytoplasmic bridges, and separate from one another, before being released into the lumen of the seminiferous tubule.

Spermatozoa Spermatozoa released into the seminiferous tubule are structurally mature but usually non-motile. In the presence of excurrent ductal obstruction, testicular sperm can acquire motility (Jow et al 1993). The shape of the spermatozoon is ideally suited for rapid progressive motility (Fig. 76.11). Its head has minimal cytoplasm and measures approximately $4 \mu \mathrm{~m} \times 3 \mu \mathrm{~m}$. It contains an elongated, flat

Fig. 76.11 The main ultrastructural features of a mature spermatozoon.
tened nucleus with condensed, dark-staining chromatin, covered anteriorly by an acrosomal cap. The latter contains acid phosphatase, hyaluronidase and proteases necessary for oocyte fertilization. The head is connected by a short neck, approximately $0.3 \mu \mathrm{~m}$ in length, to a long tail, which is divided into middle, principal and end pieces. The midpiece of the tail is a long cylinder, approximately $7 \mu \mathrm{~m}$ in length. It consists of an axial bundle of microtubules, the axoneme, surrounded by a cylinder of nine dense outer microtubules, surrounded by a helical mitochondrial sheath. The mid-piece is the powerhouse of the spermatozoon. The principal piece of the tail is responsible for motility. With a length of $40 \mu \mathrm{~m}$ and a diameter of $0.5 \mu \mathrm{~m}$, the tail forms the majority of the volume of a spermatozoon. The axonemal complex is continuous from the neck region to the terminus of the tail, with only the axoneme persisting in the final $5-7 \mu \mathrm{~m}$.

Sertoli cells Sertoli cells have euchromatic and irregular nuclei that are aligned perpendicular to the basal lamina and contain one or two prominent nucleoli. They are variable in shape. Their basal end rests on the basal lamina, while their apical end extends into the tubule lumen. Consistent with their phagocytic function, their cytoplasm is rich in lysosomes. Sertoli cells provide key support for spermatogenesis within the seminiferous tubules. Complex recesses in their plasma membranes serve to envelop spermatogonia, spermatids and spermatozoa, until the latter are mature enough for release. Long cytoplasmic processes extend between spermatogonia in the basal compartment and spermatocytes in the adluminal compartment of the seminiferous tubule. Adjacent Sertoli cells are joined at this level by tight junctions that create a diffusion barrier between the extratubular and intratubular compartments. This so-called blood-testis barrier can be disrupted by traumatic or inflammatory events, allowing self-directed immune responses to develop against sperm antigens, potentially leading to subfertility.

In addition to their role in spermatogenesis, Sertoli cells secrete proteinaceous fluid to facilitate spermatozoal transport through the seminiferous tubules and into the excurrent ducts. They also regulate the intratesticular hormonal milieu by secreting inhibin B and androgen binding protein in response to stimulation by pituitary gonadotropins.

Leydig cells and interstitial tissue The interstitial tissue between seminiferous tubules includes peritubular myoid cells, vessels, nerves and clusters of Leydig cells. Myoid cells are contractile; their rhythmic activity helps propel non-motile spermatozoa through the seminiferous tubules towards the rete testis and excurrent ductal system. Leydig cells are large polyhedral cells with eccentric nuclei containing 1-3 nucleoli, and pale-staining cytoplasm containing smooth endoplasmic reticulum, lipid droplets, and characteristic needle-shaped, crystalloid inclusions (crystals of Reinke). In response to stimulation by pituitary gonadotropins, they synthesize and secrete testosterone.

Age-related changes Functionally, the fetal testis is primarily an endocrine organ that produces testosterone and anti-Müllerian hormone. Seminiferous tubules do not become canalized until approximately the seventh month of gestation. Fetal Leydig cells, responsible for androgen-induced differentiation of male genitalia, degenerate after birth. A second wave of Leydig cell differentiation occurs 2-3 months after birth, briefly elevating testosterone levels in male infants. The Leydig cells of early infancy subsequently regress and the testis remains in a state of dormancy during childhood. In a study of Japanese boys, gonocytes were reported to appear at about the age of 2 years, spermatocytes by 4 years and spermatids by 11 years (Yuasa et al 2001).

Puberty is associated with the development of an adult population of androgen-producing Leydig cells, which persist throughout adult life. The testes grow slowly in size until the age of 10 or 11 years, at which time there is a marked acceleration of growth rate. This increase in testicular size is largely due to the onset of spermatogenesis, characterized by proliferation and differentiation of previously dormant spermatogonial stem cells. Testicular size, sperm quality and quantity, and the numbers of Sertoli and Leydig cells have all been reported to decline with age, although no consistent or definitive age for the onset of this decline has been identified. Testicular volume occupied by seminiferous tubules decreases, whereas that occupied by interstitial tissue remains approximately constant.

The most frequently observed histological change in the ageing testis is the apparent variability in spermatogenesis; spermatogenesis is complete in some areas, and reduced in others, or absent altogether as a result of tubular sclerosis. In tubules where spermatogenesis is complete, morphological abnormalities, such as multinucleation, may be observed in the germ cells. Germ cell loss, beginning with spermatids, and progressively affecting the earlier stages of spermatogenesis, can also be seen. As a result, both sperm quality and quantity may be affected. In some men, this change is notable as early as the third or fourth decade of life.

Sertoli cells are also affected by ageing, and show a range of morphological changes including de-differentiation, mitochondrial metaplasia, and multinucleation. In Leydig cells, there is a decline in the number of mitochondria and the quantity of smooth endoplasmic reticulum, paralleled by an increase in lipid droplets, crystalline inclusions and residual bodies. Some cells may also become multinucleated. Functionally, these changes are manifested as an age-related gradual decline in circulating testosterone levels.

Sperm motility and maturation Human spermatozoa acquire an increased capacity for motility as they migrate through the epididymis, which is manifested not only as a quantitative increase in the percentage of spermatozoa with motile tails, but also as a qualitative change from an immature to a more mature pattern of motility. Spermatozoa in the proximal epididymis demonstrate high-amplitude, low-frequency tail movements, producing little motion. This is in contrast to spermatozoa in the cauda epididymis, which demonstrate low-amplitude and highfrequency tail movements, resulting in considerably greater forward progression (Bedford et al 1973).

Whether, and to what extent, sperm motility is dependent on the interaction of human spermatozoa with a particular section of the epididymis is unknown. In patients with congenital absence or obstruction of the vas deferens, spermatozoa in the distal epididymis demonstrate worse motility compared to spermatozoa in the proximal epididymis (Silber 1989, Schoysman and Bedford 1986). Therefore, intrinsic sperm processes, as well as intrinsic epididymal function, appear to play an important role in sperm maturation.

Following ejaculation, spermatozoa display their full pattern of motility. Although sperm motility is highest in the hours following ejaculation, motile human spermatozoa have been recovered from cervical mucus several days after insemination. However, this survival period may be of little relevance, given that human spermatozoa are capable of migrating to their tubal destination within an hour of insemination.

After entering the female reproductive tract, spermatozoa undergo a process known as capacitation, to render them capable of fertilizing the oocyte. Capacitation involves a number of structural and biochemical changes, including the development of hyperactivated motility and completion of the acrosome reaction. Independent of other sperm characteristics such as motility and morphology, capacitation is a necessary step for the development of functional spermatozoa.

## Developmental anomalies of the testis

Cryptorchidism Testicular descent from the abdominal cavity to the scrotum may be arrested at any point along its course at the deep
inguinal ring, in the inguinal canal, or between the superficial inguinal ring and the scrotum. Retention in the inguinal canal is associated with a patent processus vaginalis, and may be further complicated by a congenital hernia. Occasionally, the testis may migrate outside its normal path of descent, and lie in an ectopic location.

At birth, 3\% of full-term male infants have a unilateral undescended testis. By 6 months of age, this number decreases to less than $1 \%$. Undescended testes are associated with a higher risk of infertility and testicular cancer later in life.

In contrast, maldescent in children between the ages of 1 and 15 years is associated with Sertoli cell degeneration (Rune et al 1992).

## EPIDIDYMIS

The epididymis lies posterior, and slightly lateral, to the testis. Anatomically, it is divided into three sections: caput (head), corpus (body) and cauda (tail). Between 8 and 12 efferent ductules from the superior pole of the testis drain into and form the caput epididymis. Distally, the cauda epididymis becomes continuous with the convoluted portion of the vas deferens (see Fig. 76.5B). The epididymis is invested by tunica vaginalis, continuous with that covering the testis. Laterally, a deep groove, the sinus epididymis, marks the boundary between the testis and epididymis. Testis-epididymis non-fusion has been described in children with cryptorchidism; non-fusion may involve the epididymal head or tail, or the whole epididymis (Kraft et al 2011).

## Epididymal cyst and spermatoceles

Available with the Gray's Anatomy e-book

## Microstructure

The epididymal tubule is 3-4 metres in length (Turner et al 1978), and is entirely encapsulated by the tunica vaginalis. Extensions from this connective tissue sheath enter the interductal spaces, forming septa that divide the tubule into histologically similar regions (Kormano and Reijonen 1976). The caput epididymis consists of 8-12 efferent ducts and the proximal segment of the ductus epididymis. The efferent ducts become larger and more convoluted than they are in the testis. Each duct is $15-20 \mathrm{~cm}$ in length, and opens into an individual epididymal tubule. The tubules anastomose with one another along the length of the epididymis, eventually becoming a single, coiled tubule in the corpus epididymis. They are surrounded by contractile smooth muscle cells (Fig. 76.13), which increase in size and number in the distal epididymis. Peristaltic contractions generated by the smooth muscle propel the spermatozoa in an antegrade direction towards the cauda.

Epithelium The epithelial lining of the epididymal tubule contains principal, basal, apical and clear cells. Principal cells are tall columnar cells with basally located, oval nuclei. They bear long stereocilia $(15 \mu \mathrm{~m})$, and function to resorb testicular fluid; approximately $90 \%$ of

Orchidopexy is, therefore, recommended for patients with persistent cryptorchidism after 6 months of age and within 18 months of age. Available evidence suggests that orchidopexy at any age may improve spermatogenesis (Shin et al 1997), but does not decrease the risk of testicular cancer in a cryptorchid testis. An inverse relationship has been reported between age at orchidopexy and total sperm count and sperm motility. The data are in support of orchidopexy in the first year of life (Canavese et al 2009). Nevertheless, surgical correction does maximize the chance of early detection of a testicular mass, and is the only means of restoring a normal milieu for spermatogenesis to occur. Interestingly, Leydig cell function is usually unchanged by maldescent, so serum testosterone levels remain within the normal range in affected patients.

Retractile testes are seen more commonly than undescended testes in boys. A retractile testis is one that moves to and fro between the groin and the scrotum. Unlike undescended testes, retractile testes can be manipulated to the lower part of the scrotum on clinical examination. Retractile testes are smaller than normal testes, having a mean volume of 0.50 ml in children.

Testicular torsion refers to rotation of the testis around its blood supply, leading to testicular ischaemia. Torsion may be extravaginal or intravaginal, depending on whether it involves a rotation of both the testis and the tunica vaginalis, or of the testis alone, within an intact tunica vaginalis. In either case, torsion results in severe scrotal pain secondary to tissue ischaemia. Fertility can be affected by a single episode of torsion. If unrelieved within 4-6 hours, permanent tissue loss can occur. Testicular torsion is therefore considered a surgical emergency.

Other structures in the scrotum, such as the appendix testis (hydatid of Morgagni) (Fig. 76.12) and appendix epididymis (see Fig. 76.4), can also undergo torsion, resulting in scrotal pain that may be difficult to differentiate from testicular torsion. In some instances, a 'blue dot' sign is noted at the upper pole of the testis, which is diagnostic. These structures are developmental remnants of the paramesonephric (Müllerian) duct and the mesonephros, respectively. There are no associated longterm sequelae.

A patent processus vaginalis allows communication between the peritoneal cavity and the spermatic cord or scrotum. Passage of peritoneal fluid into the scrotum presents as a communicating hydrocele, and usually resolves spontaneously once the processus is obliterated, by $18-24$ months of age. Alternatively, if the processus is patent proximally but obliterated distally, a hydrocele or cyst of the cord may be noted. Surgical treatment may be indicated for persistent, non-communicating hydroceles. Hydrocele can also occur as a result of lymphatic obstruction from testicular tumour, epididymitis, orchitis or trauma. A $20 \%$ incidence of hydrocele has been reported in children having laparoscopic en bloc ligation of the spermatic vessels on the posterior abdominal wall (Palomo procedure). This complication is avoided by lymphatic-sparing surgery (Schwentner et al 2006).

Splenogonadal fusion is a rare congenital anomaly characterized by splenic tissue being connected to the gonad, resulting from an abnormal connection between the spleen and the gonad during gestation. It has a higher predominance in males and is almost invariably on the left side. It may be of the continuous type, where the testis is connected to the main spleen, or of the discontinuous type, where the testis is connected to ectopic splenic tissue.

Fig. 76.12 Gangrene of the appendix testis secondary to torsion in an 8 -year-old child.

Transverse/crossed testicular ectopia is an extremely rare condition in which both testes descend into a single inguinal canal or hemiscrotum. The origin of the spermatic cord is normally located on each side. It may occur in association with persistent Müllerian duct syndrome (Tiryaki et al 2005).

Polyorchidism is a rare congenital anomaly in which there are two or more testes. The most common type consists of three testes; cases with four testes have also been reported. The supernumerary testes may or may not be connected to a vas deferens.

Epididymal cysts arise from the epididymal tubules and may occur anywhere in the caput, corpus or cauda epididymis. If asymptomatic, removal is unnecessary, particularly given the risk of iatrogenic epididymal obstruction. Spermatoceles are cysts that are, basically, aneurysms of the efferent ducts that form the caput epididymis and contain sperm. Removal is unnecessary unless they grow to a large size and cause pain (Kaufman et al 2011). However, spermatoceles may be aspirated as a source of spermatozoa.
the total secretory fluid volume is absorbed in the epididymis. They also endocytose other components of seminal fluid and produce glycoproteins that are essential for sperm maturation. Basal cells lie between the bases of the principal cells and are thought to be precursors of principal cells. Apical and clear cells are far less common than principal and basal cells. Apical cells are rich in mitochondria and are most abundant in the caput epididymis. In contrast, clear cells are columnar and most abundant in the cauda epididymis. They have few microvilli but numerous endocytic vesicles and lipid droplets. Their functions are unknown.

## VAS DEFERENS, SPERMATIC CORD, PARADIDYMIS AND EJACULATORY'DUCT

## VAS DEFERENS

The vas deferens (ductus deferens) is a tubular structure derived from the mesonephric duct. Its primary function is the transport of sperm from the epididymis to the urethra, although absorptive and secretory functions have also been described (Hoffer 1976). As it arises from the cauda epididymis, the vas is tortuous for $2-3 \mathrm{~cm}$ (see Fig. 76.5B). Beyond this convoluted segment, it lies posterior and parallel to the vessels of the spermatic cord, passes through the inguinal canal (see Fig. 76.16), and emerges in the pelvis lateral to the inferior epigastric vessels (see Fig. 61.3). At the internal ring, the vas diverges from the testicular vessels, coursing medial to the structures of the pelvic side wall, in order to reach the base of the prostate posteriorly. Here, the vas once again becomes tortuous and dilated (the ampulla of the vas deferens), before culminating at the ejaculatory duct (see Fig. 74.23).

## Vascular supply and lymphatic drainage

The vas deferens is supplied by the vasal artery, which is usually derived from the superior vesical artery, and occasionally from the inferior vesical artery, both branches of the internal iliac artery. Rarely, it is

Fig. 76.13 The microstructure of the epididymis. Abbreviations: ET, epididymal tubule; FCT, fibromuscular connective tissue.
derived directly from the internal iliac artery. Veins from the vas and seminal vesicles drain to the pelvic venous plexus, whereas the associated lymphatic vessels drain into the external and internal iliac nodes.

## Innervation

The vasa deferentia are innervated by a rich autonomic plexus of primarily postganglionic sympathetic fibres derived from the pelvic plexus.

## Microstructure

In humans, the vas deferens is $30-35 \mathrm{~cm}$ in length and $2-3 \mathrm{~mm}$ in diameter, with a luminal diameter of $300-500 \mu \mathrm{~m}$. In cross-section, it consists of an outer adventitial sheath containing blood vessels and nerves; a thick, three-layered muscular wall of inner and outer longitudinal and middle circular smooth muscle; and an inner mucosal lining of pseudostratified columnar epithelium with non-motile cilia (Fig. 76.14). It has the greatest muscle to lumen ratio (approximately 10:1) of any hollow viscus in the body. During ejaculation, the smooth muscle layers contract reflexively, propelling the sperm in an antegrade direction (see above).

## Developmental anomalies of the vas deferens

Available with the Gray's Anatomy e-book

## SPERMATIC CORD

The spermatic cord begins at the deep or internal inguinal ring, extends the length of the inguinal canal, exits the canal at the superficial or external inguinal ring, and suspends the testis in the scrotum (Fig. 76.15; see Fig. 76.3). Between the superficial inguinal ring and the testis, the cord lies anterior to the tendon of adductor longus. It is flanked anteriorly by the superficial external pudendal artery, and posteriorly by the deep external pudendal artery. The ilioinguinal nerve lies inferior to the cord as it traverses the inguinal canal.

In addition to the artery, veins, lymphatics and nerves supplying the testis, which are contained within the internal spermatic fascia, the spermatic cord includes the ilioinguinal nerve, the genital branch of the genitofemoral nerve, the cremasteric artery, veins and lymphatics, and the vasal artery, veins and lymphatics, all of which are contained within the external spermatic fascia (Fig. 76.16; see Fig. 76.2). These fascial layers are continuous with the layers of the abdominal wall. The internal spermatic fascia is derived from the transversalis fascia, and forms a thin, loose layer around the spermatic cord. The cremasteric fascia, which contains the skeletal muscle fibres that make up the cremaster muscle, is derived from internal oblique. The external spermatic fascia is continuous with the aponeurosis of external oblique.

Ectopic suprarenal tissue (adrenal rest) is encountered within the distal end of the spermatic cord in $2 \%$ of children undergoing inguinal procedures. Adrenal rests are typically bright yellow to orange in colour, round or oval in shape, and up to 5 mm in diameter; they contain the three layers of the suprarenal (adrenal cortex) but no medulla (Savas et al 2001).

Fig. 76.14 The vas deferens. A, A low-power view, transverse section. B, A higher-power view. The convoluted lumen is lined by pseudostratified columnar epithelial cells.

The vas deferens may be congenitally absent, either unilaterally or bilaterally. When bilateral, the condition is associated with a mutation of the cystic fibrosis transmembrane conductance gene in $80 \%$ of affected men. This condition is characterized by low semen volume due to absent or hypoplastic seminal vesicles and azoospermia, although spermatogenesis is usually normal. Absent vasa is usually the only genital manifestation of cystic fibrosis.

The anatomy of the vas deferens is worthy of note in children with cryptorchidism (see above). At laparoscopic orchidopexy for intraabdominal testis, it is important to exclude a 'looping vas deferens' that enters the inguinal canal and loops back to the abdominal cavity (Shalaby et al 2011); failure to recognize this anatomical anomaly may result in iatrogenic injury to the vas deferens.

Fig. 76.16 Structures contained within the spermatic cord. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban and Fischer. Copyright 2013.)

## PARADIDYMIS

The paradidymis (organ of Giraldes) is a small collection of convoluted tubules located anteriorly in the spermatic cord, just above the caput epididymis. The tubules are lined with columnar ciliated epithelium and are likely to represent a vestigial remnant of the mesonephros.

## EJACULATORY DUCTS

The paired ejaculatory ducts are formed from the union of the duct of the seminal vesicle with the ampulla of the vas deferens. Each is approximately 2 cm in length, and extends from the base of the prostate, between the median and lateral lobes, towards its opening on the verumontanum (see Fig. 75.13). The ducts diminish in size and converge towards their ends. Ejaculatory duct obstruction, though rare, can lead to oligospermia or azoospermia. Causes include congenital cysts, such as Müllerian duct cysts, or iatrogenic injury during urethral manipulation. In contrast to the walls of the vas deferens, the walls of the ejaculatory ducts are thin. They consist of an outer fibrous layer, which decreases in thickness on their entry into the prostate; a thin layer of smooth muscle fibres; and a mucosa lined by columnar epithelium. The ducts dilate during ejaculation. Normal luminal and wall dimensions of the ejaculatory duct are remarkably uniform among men; a luminal
diameter of greater than 2.3 mm defines a dilated or obstructed efferent duct (Nguyen et al 1996).

## ACCESSORY GLANDULAR STRUCTURES

## SEMINAL VESICLES

The seminal vesicles are paired outpouchings of the terminal vas deferens, located at the base of the prostate, between the bladder and the rectum (Fig. 76.17 , see Fig. 74.23 ). In adults, the seminal vesicle measures between 5 and 10 cm in length, and 3 and 5 cm in diameter, with an average volume capacity of 13 ml (Goldstein 2012). In the majority of men, the right seminal vesicle is slightly larger than the left; the size of both glands decreases with age.

In essence, each seminal vesicle is a coiled tube with irregular diverticula, contained within a dense, fibromuscular sheath and partly covered by peritoneum. The upper pole is a cul-de-sac, while the lower pole narrows to a straight duct, which, together with the vas deferens, culminates as the ejaculatory duct. The seminal vesicles are intimately associated with the prostate and bladder anteriorly, the distal ureter superiorly, and the rectum and Denonvilliers' fascia posteriorly. The ampullae of the vas deferens lie along the medial margins of the seminal vesicles, while the veins of the prostatic venous plexus lie laterally.

Fig. 76.17 An axial magnetic resonance imaging (MRI) scan demonstrating the normal high signal in the seminal vesicles on a T2-weighted scan.

Agenesis of the seminal vesicles is a congenital anomaly, which is associated with absence of the vas deferens or vasoureteral communication (Wu et al 2005).

## Vascular supply and lymphatic drainage

The primary blood supply to the seminal vesicles is from the vesiculodeferential artery, a branch of the umbilical artery (Braithwaite 1952). An additional source of blood supply is the inferior vesical artery, which arises from the internal iliac artery or the inferior gluteal artery. Venous drainage is provided by the vesiculodeferential veins and the inferior vesical plexus. Lymphatic drainage, accordingly, occurs via the internal iliac nodes.

## Innervation

The seminal vesicles receive preganglionic parasympathetic input from the pelvic nerve, and sympathetic (postganglionic) and parasympathetic (preganglionic) input from the hypogastric nerve.

## Microstructure

After puberty, the vesicles mature into elongated, sac-like structures, produce a viscous white-yellow fluid that contributes to at least twothirds of the total ejaculate volume, and play an important role in sperm motility and metabolism. The secreted fluid is rich in fructose, coagulation proteins and prostaglandins, with a pH in the neutral to alkaline range. The wall of the seminal vesicle is composed of an external connective tissue layer, a middle smooth muscle layer (significantly thinner than the corresponding layer in the vas deferens), and an inner mucosal layer with a highly folded, labyrinthine structure (Fig. 76.18). The mucosal layer is lined by cuboidal to pseudostratified columnar epithelium, featuring typical protein-secreting cells. Contrary to the implication of their name, seminal vesicles are not reservoirs for spermatozoa, except in cases of ejaculatory duct obstruction; they contract during ejaculation to release secretions into the ejaculatory duct.

## BULBOURETHRAL GLANDS

The bulbourethral glands (Cowper's glands) are small, round, yellow, lobulated structures, measuring approximately 1 cm in diameter, and

Fig. 76.18 The microstructure of the seminal vesicles, showing the tubulo-acinar structure.
located lateral to the membranous urethra and superior to the perineal membrane. They are drained by long excretory ducts, each duct being almost 3 cm in length, which pass obliquely and anteriorly from the region of the membranous urethra, to penetrate the perineal membrane, and open on the floor of the bulbar urethra, approximately 2.5 cm below the perineal membrane. The glands are surrounded by fibres of the urinary sphincter. During sexual excitement, contraction of the muscle fibres leads to expulsion of clear mucus from the glands into the bulbar urethra. Secretions of the bulbourethral glands comprise $5-10 \%$ of the total ejaculate volume.

## Microstructure

Each bulbourethral gland consists of several lobules enclosed by a fibrous capsule. The secretory units are tubulo-alveolar in form. The glandular epithelium is columnar, and secretes acidic and neutral mucins into the urethra prior to ejaculation; the secretions primarily have a lubricating function. Diffuse mucosa-associated lymphoid tissue (MALT) is associated with the glands.

## PERIURETHRAL GLANDS

The periurethral glands (glands of Littre) are most numerous in the penile urethra. Like the bulbourethral glands, they secrete mucus into the lumen of the urethra prior to ejaculation; the secretions have a lubricating function.

## EXTERNAL GENITALIA

## PENIS

The penis consists of an attached root in the perineum (radix), and a free, pendulous body (shaft), which is completely enveloped in skin (Fig. 76.19). At its base, the penis is supported by two suspensory ligaments, which anchor it to the pubic symphysis (Fig. 76.20B). These ligaments are composed primarily of elastic fibres and are continuous with Buck's fascia of the penis. The penile shaft contains three erectile columns - the paired corpora cavernosa and the corpus spongiosum; the urethra; and the investing fasciae, blood vessels and nerves associated with these structures (Fig. 76.20A).

The corpora cavernosa lie in intimate apposition with one another along the length of the penile shaft (Fig. 76.21); the corpus spongiosum lies in the ventral groove between the cavernous bodies. Proximally, posterior to the suspensory ligaments, the right and left corpora cavernosa diverge to form two tapering processes, the crura penis, which are firmly anchored to the ischiopubic rami (see Fig. 76.20B). The corpus spongiosum broadens between the two crura to form the bulbospongiosus muscle (see Fig. 76.20C). At the distal end of the penis, the corpus spongiosum again enlarges and assumes a bulbous shape to form the glans penis. The rounded base of the glans, the corona, separates the glans from the penile shaft. The glans is covered by the foreskin (prepuce), which is a loose fold of retractable skin attached to the ventral surface of the glans penis, under the corona, at the frenulum. Cutaneous sensitivity is greatest over the glans penis.

Fig. 76.19 Structures in the male urogenital triangle. A, An inferior view. B, The ventral surface of the body of the penis. C, A lateral view of the body of the penis and glans. D, An inferior view of the urogenital triangle of a male, with the erectile tissues of the penis indicated with overlays. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray’s Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

Skin The skin of the penile shaft is thin, highly elastic and devoid of appendages (hair or glandular elements), with the exception of smegmaproducing glands located at the base of the corona. It is also devoid of fat and quite mobile because of loose attachments between the dartos fascia and the underlying Buck's fascia. In contrast, the skin of the glans is immobile, as a result of its direct attachment to the underlying tunica albuginea. Blood supply to the penile skin is independent of the erectile bodies, and is derived from the external pudendal branches of the femoral vessels that enter the base of the penis and run longitudinally within the dartos fascia, forming a rich anastomotic network. Thus, it is possible to mobilize penile shaft skin on a vascular pedicle for surgical procedures such as urethral reconstruction.

The superficial penile fascia is devoid of fat, and consists of loose connective tissue interspersed by fibres of the dartos muscle from the scrotum; it is commonly referred to as the dartos layer. In contrast, the deep penile fascia is a denser fascial sheath, known as Buck's fascia, which envelops both corpora cavernosa and splits to envelop the corpus spongiosum (Fig. 76.22B). Distally, it blends with the tunica albuginea covering all three corporal bodies. Proximally, it is continuous with the dartos muscle and the deep perineal fascia. Bleeding from a tear in the corporal bodies is usually contained within Buck's fascia, and ecchymosis is limited to the penile shaft.

Root The root (radix) of the penis consists of three masses of erectile tissue in the urogenital triangle: namely, the two crura and the bulb, firmly attached to the pubic arch and the perineal membrane, respectively. The crura are the posterior extensions of the corpora cavernosa, while the bulb is the dilated posterior end of the corpus spongiosum. The urethra enters the bulb via its posterior surface and travels the length of the penile shaft within the corpus spongiosum.

Shaft The major portion of the penile shaft consists of the paired corpora cavernosa. These contain erectile tissue, enclosed within a dense fibroelastic sheath of connective tissue, the tunica albuginea (see Figs 76.21E, 76.22). The outer longitudinal and inner circular fibres of the tunica form an undulating meshwork when the penis is flaccid but become tightly stretched on erection. The circular fibres surround each corpus separately and the corpora are then surrounded as a unit by the outer longitudinal fibres. Smooth muscle bundles traverse the erectile bodies to form endothelium-lined cavernous sinuses, which give the erectile tissue a spongy appearance on gross examination. Blood flow into the sinuses leads to penile engorgement and compression of venous outflow channels, resulting in penile erection.

The corpora cavernosa are not distinct, separate structures but are divided in the midline by a fibrous septum that is continuous with the deep circular fibres of the tunica albuginea. The septum is complete and thick proximally, but incomplete distally, permitting communication and exchange of blood flow between the corporal bodies. The wide median groove along the ventral aspect of the corpora cavernosa is occupied by the corpus spongiosum, containing the urethra. Dorsally, a similar, but narrower, groove contains the dorsal neurovascular bundle. The corpora cavernosa end distally within the glans penis as individual, rounded cones (see Fig. 76.19D). The corpus spongiosum contains less erectile tissue than the corpora cavernosa, and is enclosed by a thinner layer of tunica albuginea. The urethra traverses the length of the corpus spongiosum, terminating at a slitlike meatus on the tip of the glans penis, which is, itself, an expansion of the corpus spongiosum. Numerous small preputial glands secreting sebaceous smegma line the corona along the base of the glans penis.

## Vascular supply and lymphatic drainage

## Arteries

Blood supply to the corporal bodies is derived from the internal pudendal artery, a branch of the internal iliac artery, which travels within Alcock's canal before reaching the penis and perineum (Fig. 76.23). As it emerges from Alcock's canal, the internal pudendal artery gives off the perineal artery, to supply ischiocavernosus and bulbospongiosus, and the posterior surface of the scrotum, as well as the common penile artery that supplies the deep structures of the penis (Fig. 76.24).

The common penile artery has three main branches: the bulbourethral artery, the dorsal penile artery and the cavernous (deep, cavernosal) artery (Fig. 76.25).

Bulbourethral artery The bulbourethral artery penetrates the perineal membrane to enter the spongiosum from above its posterolateral border and supplies the penile bulb and the urethra, in addition to the corpus spongiosum and glans penis.

Dorsal artery of the penis The dorsal artery of the penis passes between the crus penis and the pubis to reach the dorsal surface of the corporal bodies. It runs alongside the dorsal vein and the dorsal penile nerve, and is attached, together with these structures, to the underside of Buck's fascia. As it courses to the glans penis, it gives off circumfer-
ential branches to the corpus spongiosum and urethra. The rich blood supply to the spongiosum allows safe division of the urethra during stricture repair.

Cavernous (deep, cavernosal) artery of the penis The cavernous (deep, cavernosal) artery of the penis is usually a paired vessel that pierces the tunica albuginea of the corpora cavernosa at the hilum of the penis and then travels near the centre of the corporal bodies in the direction of the glans penis. Along its course, it gives off several straight and helicine branches at regular intervals; they open directly into the sinusoidal spaces of the corporal bodies.

Variations in penile vascular anatomy are common, and may include a single or absent cavernous artery or the presence of accessory pudendal arteries (Bare et al 1994, Matin 2006). While penile arterial supply is commonly derived from both accessory and internal pudendal arteries, it may be derived exclusively from either the internal pudendal arteries or the accessory pudendal arteries (Droupy et al 1997). Recognizing such variation is extremely important for any surgeon contemplating penile revascularization surgery.

## Veins

Blood leaving the penis is drained by one of three venous systems: superficial, intermediate or deep (see Figs 76.22B, 76.23). The superficial veins are contained within the dartos fascia on the dorsolateral

surface of the penis. They receive blood from the penile shaft skin and prepuce, and coalesce at the base of the penis to form a single superficial dorsal vein that drains into the great saphenous vein via the superficial external pudendal veins.

The intermediate drainage system contains the circumflex and deep dorsal veins, which lie within and beneath Buck's fascia. This system receives blood from the glans, corpus spongiosum and the distal twothirds of the penis. Circumflex veins originate in the corpus spongiosum, and course around the corpora cavernosa to meet the deep dorsal vein perpendicularly. They are only present in the distal two-thirds of the penile shaft, and range between 3 and 10 in number. Intermediate venules in the erectile tissue of the corpora cavernosa arise from the cavernous sinuses and drain into a subtunical capillary plexus. This plexus gives rise to emissary veins that course obliquely through the tunica albuginea, and drain either into the circumflex veins, or directly into the deep dorsal vein. The deep dorsal vein lies in the midline
groove between the two corpora cavernosa. It passes inferior to the pubic symphysis at the level of the suspensory ligament, leaving the shaft of the penis at the crus, and drains into the prostatic plexus.

Deep venous drainage occurs via the crural and cavernous (deep, cavernosal) veins, which receive blood from the proximal third of the penis. The emissary veins consolidate into $2-5$ veins on the dorsomedial surface of the corpora cavernosa. Crural veins arise in the midline, in the space between the crura, and join the cavernous veins at the hilum of the penis, ultimately draining into the internal pudendal vein.

## Lymphatic drainage

The penile and perineal skin is drained by lymphatic vessels that accompany the external pudendal veins to the superficial inguinal nodes. Lymphatics from the glans penis pass to the deep inguinal and external iliac nodes, and those from the erectile tissue and penile urethra pass to the internal iliac nodes.

Fig. 76.23 The perineal vessels. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

## Innervation

A rich sensory innervation to the glans penis is provided by the dorsal nerve, a division of the pudendal nerve; it follows the course of the dorsal penile arteries (Fig. 76.26, see also Fig. 76.2). Small branches from the perineal nerve provide additional innervation to the skin on the ventrum of the penis, as far distally as the glans (Uchio et al 1999).

Sympathetic and parasympathetic input to the corpora cavernosa is provided by the cavernous (deep, cavernosal) nerve, which originates in the pelvic plexus. It courses along the posterolateral aspect of the prostate before exiting the pelvis, together with the urethra, and entering the corpora cavernosa at the crus. Before entering the cavernous bodies, the cavernous nerve sends branches to the corpus spongiosum. Parasympathetic input to the penis (excitatory) originates in the neurones of the first four sacral segments of the spinal cord and travels via the pelvic splanchnic nerves (nervi erigentes) to the pelvic plexus (see Fig. 76.26), where preganglionic fibres synapse on postganglionic neurons that give rise to the cavernous nerve. Sympathetic input to the penis (inhibitory) originates in the intermediolateral columns of the eleventh and twelfth thoracic, and first lumbar segments of the spinal cord, and travels through the sympathetic trunk before descending to the pelvic plexus. Parasympathetic stimulation produces vasodilation, while sympathetic innervation causes vasoconstriction, contraction of the seminal vesicles and prostate, and seminal emission.

## Microstructure

The corpora cavernosa are cylinders of spongy erectile tissue, composed of interconnected endothelium-lined sinusoids, separated by smooth muscle trabeculae, and surrounded by elastic fibres, collagen and loose areolar tissue. The sinusoids are larger in the centre. Terminal cavernous
nerves and helicine arteries are intimately associated with smooth muscle. The helicine arteries are contracted and tortuous in the flaccid state, and straight and dilated in the erect state.

The tunica albuginea surrounding the corpora consists of an inner circular and outer longitudinal layer of elastic fibres arranged in a latticed network. Venous drainage from the corpora cavernosa originates in the trabeculae between the peripheral sinusoids and the tunica albuginea (the subtunical venous plexus) before exiting the corpora via the emissary veins.

Emissary veins travel between the two layers of the tunica albuginea, and exit the outer layer in an oblique fashion. The outer layer compresses the emissary veins when the penis becomes engorged with blood, preventing venous outflow, and thereby maintains the erection.

The structure of the corpus spongiosum is similar to that of the corpora cavernosa, with the exception of larger sinusoids and a thinner tunica albuginea. The glans has no tunical covering.

## ERECTION AND EJACULATION

Penile erection is a neurovascular process, initiated by sexual stimulation and relaxation of the smooth muscle of the corpora cavernosa and mediated by various neurotransmitters produced by the parasympathetic nerves and the endothelium. The most important neurotransmitter is nitric oxide, which acts via the cyclic guanosine monophosphate (cGMP) second messenger system. Following smooth muscle relaxation, there is rapid influx of blood flow from the helicine arteries, filling the cavernous spaces and leading to penile tumescence. The resulting distension compresses the emissary veins, preventing venous outflow. This so-called 'veno-occlusive mechanism' converts tumescence into an erection. Continuing cutaneous stimulation of the glans and frenulum contributes significantly towards maintaining an erection and initiating orgasm and ejaculation. Erection, therefore, depends on a variety of factors, including a normal psychogenic response to stimulation, intact parasympathetic nerves, healthy corporal smooth muscle capable of relaxation, patent arteries capable of delivering blood at the required rate, and a normal venous system. Following ejaculation, the sequence just described is reversed; smooth muscle contraction in response to sympathetic stimulation leads to penile detumescence.

Emission and ejaculation are separate, but related, processes. Emission is the transmission of seminal fluid from the vas deferens, prostate and seminal vesicles into the prostatic urethra and is under sympathetic control. Ejaculation is the expulsion of seminal fluid from the prostatic urethra to the exterior and has both autonomic and somatic components. The first discernible event during ejaculation is contraction of bulbospongiosus, which occurs approximately six times and is under somatic control. Antegrade ejaculation requires concomitant bladder neck closure and periurethral muscle contraction (Ch. 75). Relaxation of the external urethral sphincter, under autonomic control, permits expulsion of seminal fluid from the prostatic to the bulbar urethra, and from there to the exterior. The timing of this process is such that the ejaculate is expelled from the external urethral meatus between the second and final contraction of bulbospongiosus; in some men, ejaculation may be pulsatile.

## Erectile dysfunction and priapism

Available with the Gray's Anatomy e-book

## SCROTUM

The scrotum is composed of multiple layers of tissues, including skin, dartos muscle and external spermatic, cremasteric and internal spermatic fasciae (see Fig. 76.3). The internal spermatic fascia is loosely attached to the parietal layer of the tunica vaginalis.

Scrotal skin is thin, pigmented, devoid of fat, hair-bearing, and rich in sebaceous and sweat glands. It is also richly innervated by sensory nerves that respond to stimulation of the skin and hairs, and to changes in temperature. The appearance of the scrotal skin may vary from smooth to rugated, depending on the degree of contraction of the underlying dartos muscle. A midline raphe extends from the urethral meatus, down the ventral penile shaft and to the anus, signifying the line of fusion of the genital tubercles (see Fig. 72.20). It is a relatively avascular plane and, therefore, a popular location for incisions used to access both scrotal compartments. Deep to the raphe, the scrotum is separated into two compartments by a septum composed of all the

Erectile dysfunction is the inability to achieve tumescence despite adequate sexual stimulation. The pathophysiology of erectile dysfunction is complex, and involves vascular, neurogenic and psychogenic components. Common aetiologies underlying a diagnosis of erectile dysfunction include: inability to relax the cavernous smooth muscle; arterial insufficiency due to atheromatous disease; neurogenic dysfunction due to diabetes or surgery; and radiation therapy.

A prolonged erection that fails to subside after ejaculation is called priapism. Priapism can, broadly, be classified as being high-flow (nonischaemic) or low-flow (ischaemic). Low-flow priapism, which is due to impaired efflux of venous blood from the penis, is characterized by significant pain and is a medical emergency. If untreated, priapism leads to ischaemia of the corporal smooth muscle and irreversible erectile dysfunction. The aetiology of low-flow priapism includes conditions such as sickle-cell disease and leukaemia, and the use of intracavernosal injection therapy with medications such as prostaglandin. In contrast, high-flow priapism is the consequence of excessive blood flow into the penis, usually secondary to a fistula between the cavernous arteries and sinusoidal spaces.

Fig. 76.24 The blood vessels and nerves of the perineal region and external genitalia in the adult male. Fig. 76.25 The arterial blood supply to the body of the penis.
layers of the scrotal wall except the skin. The testes are suspended by the spermatic cords within these compartments.

The dartos layer of smooth muscles is continuous with Colles', Scarpa's and the dartos fascia of the penis. The external spermatic, cremasteric and internal spermatic layers of the scrotum are continuous with the corresponding layers in the spermatic cord, and arise from the aponeuroses of external oblique and internal oblique and the transversalis fascia of the abdominal wall, respectively. The testis is also fixed to the scrotal wall at its lower pole by a fibrous band of tissue known as the gubernaculum.

Developmental anomalies of the scrotum Congenital agenesis of the scrotum is a very rare anomaly characterized by the absence of the scrotum; no rugae are noted in the perineum (Yilmaz et al 2013). Penoscrotal transposition, in which the scrotum is located superior and anterior to the penis, is a consequence of abnormal genital tubercle development and is associated with hypospadias, renal agenesis and dysplasia, and imperforate anus.

## Vascular supply and lymphatic drainage

Arterial supply to the scrotum includes external pudendal branches of the femoral artery, scrotal branches of the internal pudendal artery, and a cremasteric branch from the inferior epigastric artery. Of note, the anterior scrotal wall is supplied primarily by branches of the external pudendal artery, which run parallel to the rugae and do not cross the raphe; this anatomical detail is important for planning appropriate incisions during scrotal surgery.

The scrotal vessels are arranged in a dense subcutaneous network, which facilitates heat loss and regulation of scrotal temperature. Venous drainage follows the arterial network, and simple arteriovenous anastomoses are common.

Fig. 76.26 The nerve supply to the penis. The corpus cavernosum of penis receives both a parasympathetic and a sympathetic innervation from the cavernous nerves. It should be noted that, in life, multiple cavernous nerves emanate from the prostatic plexus and intertwine with both dorsal sensory nerves. The afferent fibres from the glans pass via the dorsal nerves of the penis and via the pudendal nerve. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray’s Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

Scrotal lymphatics do not cross the median raphe. Therefore, lymphatic drainage from the scrotum is always routed to the ipsilateral superficial inguinal nodes.

## Innervation

The scrotum is innervated by the ilioinguinal nerve, the genital branch of the genitofemoral nerve, two posterior scrotal branches of the perineal nerve, and the perineal branch of the posterior femoral cutaneous nerve (see Fig. 76.24). Innervation of the anterior third of the scrotum is primarily derived from the first lumbar spinal segment, by way of the ilioinguinal and genitofemoral nerves (see Fig. 76.2). Innervation of the posterior two-thirds of the scrotum is primarily derived from the third sacral spinal segment, via the perineal and posterior femoral cutaneous nerves. In order to anaesthetize the scrotum, spinal anesthesia must, therefore, be injected higher than the L1 level.

## Female reproductive system

The female reproductive system consists of the lower genital tract (vulva and vagina) and the upper tract (uterus and cervix with associated uterine (Fallopian) tubes and ovaries).

## LOWER GENITAL TRACT

## VULVA

The female external genitalia or vulva include the mons pubis, labia majora, labia minora, clitoris, vestibule, vestibular bulb and the greater vestibular glands (Fig. 77.1).

## Mons pubis

The mons pubis is the rounded, hair-bearing area of skin and adipose tissue over the pubic symphysis and adjacent pubic bone. Before puberty, the mons pubis is relatively flat and hairless, and the labia minora are poorly formed. Through adolescence and into adult life, the
mons becomes prominent with coarse hair and atrophies slightly after menopause.

## Labia majora

The labia majora are two prominent, longitudinal folds of skin that extend back from the mons pubis to the perineum (Fig. 77.1B). They form the lateral boundaries of the vulva. Each labium has an external, pigmented surface covered with hairs and a smooth, pink internal surface with large sebaceous follicles. Between these surfaces there is loose connective and adipose tissue, intermixed with smooth muscle (resembling the scrotal dartos muscle), vessels, nerves and glands. The subcutaneous layer consists of a superficial fatty layer similar to Camper's fascia, and a deep membranous layer - Colles' fascia - continuous with Scarpa's fascia of the anterior abdominal wall (p. 1069). The uterine round ligament may end in the adipose tissue and skin in the anterior part of the labium. A patent processus vaginalis may also reach a labium. The labia join anteriorly to form the anterior commissure. Posteriorly, they do not join, but instead merge into neighbouring skin,

D

Fig. 77.1 A, The superficial features of the perineum. B, The labia majora and surrounding external genitalia. C, The labia minora. D, An inferior view of the vestibule with the left labium minus pulled to one side to show the regions of the vestibule into which the greater vestibular and para-urethral glands open. (A, With permission from Drake RL, Vogl AW, Mitchell A, Tibbitts R, Richardson P (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008. B-D, With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray’s Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
ending near and almost parallel to each other. The connecting skin between them posteriorly forms a ridge, the posterior commissure, which overlies the perineal body and is the posterior limit of the vulva. The distance between the posterior vulva and the anus is $2.5-3 \mathrm{~cm}$ and is termed the 'gynaecological' perineum.

## Labia minora

The labia minora are two small cutaneous folds, devoid of fat, that lie between the labia majora. They extend from the clitoris obliquely down, laterally and back, flanking the vaginal orifice. Anteriorly, each labium minus bifurcates. The upper layer of each side passes above the clitoris to form the hood or prepuce, while the lower layer passes below the clitoris to form the frenulum of the clitoris (Fig. 77.1A-C). Sebaceous follicles are numerous on the medial surfaces. Sometimes, an extra labial fold (labium tertium) is found on one or both sides between the labia minora and majora. Adhesions between the labia minora are common in prepubertal girls and may predispose to urinary infections (Leung and Robson 1992).

## Vestibule

The vestibule is the cavity that lies between the labia minora. It contains the vaginal and external urethral orifices and the openings of the two greater vestibular (Bartholin's) glands and of numerous mucous, lesser vestibular glands. There is a shallow vestibular fossa between the vaginal orifice and the frenulum of the labia minora. The posterior part of the vestibule is a classic site where a fistulous opening of the rectum may be located in girls born with an imperforate anus (Bill et al 1975).

## Urethra

The urethra opens into the vestibule about 2.5 cm below the clitoris and above the vaginal opening via a short, sagittal cleft with slightly raised margins: the urethral meatus. The meatus is very distensible and varies in shape; the aperture may be rounded, slit-like, crescentic or stellate. The ducts of the para-urethral glands (Skene's glands) open on each side of the lateral margins of the urethra.

## Bulbs of the vestibule

The bulbs of the vestibule lie on each side of the vestibule (Fig. 77.2B). They are two elongated masses of erectile tissue, 3 cm long, which flank the vaginal orifice and unite anterior to it by a narrow commissura bulborum (pars intermedia). Their posterior ends are expanded and are in contact with the greater vestibular glands. Their anterior ends taper and are joined by a commissure, and also to the clitoris by two slender bands of erectile tissue. Their deep surfaces contact the inferior aspect of the perineal membrane; superficially, each is covered posteriorly by bulbospongiosus (Fig. 77.2A) (Delancey 2011).

## Greater vestibular glands (Bartholin's glands)

The greater vestibular glands are homologues of the male bulbourethral glands. They consist of two small, round or oval, reddish-yellow bodies that flank the vaginal orifice, in contact with, and often overlapped by, the posterior end of the vestibular bulb. Each opens into the vestibule by a 2 cm duct, situated in the groove between the hymen and the labium minus at approximately the 5 and 7 o'clock positions (Corton 2012) (see Fig. 77.1D). The glands are composed of tubulo-acinar tissue; the secretory cells are columnar and secrete a clear or whitish mucus for lubrication during sexual arousal.

## Clitoris

The clitoris is an erectile structure, partially enclosed by the anterior bifurcated ends of the labia minora. It has a root, a body and a glans (see Fig. 77.2). The body can be palpated through the skin. It contains two corpora cavernosa, composed of erectile tissue and enclosed in dense fibrous tissue, and separated medially by an incomplete fibrous pectiniform septum. The fibrous tissue forms a suspensory ligament that is attached superiorly to the pubic symphysis. Each corpus cavernosum is attached to its ischiopubic ramus by a crus that extends from the root of the clitoris. The glans clitoris is a small, round tubercle of spongy erectile tissue at the end of the body, connected to the bulbs of the vestibule by thin bands of erectile tissue. It is exposed between the anterior ends of the labia minora. Its epithelium has high cutaneous sensitivity, important in sexual responses. Congenital absence of the clitoris is very rare.

## Vascular supply and lymphatic drainage of the vulva

## Arteries

The arterial blood supply of the female external genitalia is derived from the superficial and deep external pudendal branches of the femoral artery superiorly and the internal pudendal artery inferiorly on each side (Figs 77.3A, 77.4).

Fig. 77.3 A, The vessels of the female pelvis: sagittal view. B, The nerves and lymphatics of the female pelvis: sagittal view. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

This blood supply to the labial fat must be carefully preserved during vaginal surgery, e.g. in creating a Martius fat pad flap to repair a vesicovaginal fistula where blood supply has already been compromised by radiation or fibrosis (Delancey 2011).

## Veins

Venous drainage of the vulval skin is via external pudendal veins to the long saphenous vein. Venous drainage of the clitoris is via deep dorsal veins to the internal pudendal vein, and via superficial dorsal veins to the external pudendal and long saphenous veins.

## Lymphatic drainage

A meshwork of connecting vessels from the skin of the labia, clitoris and perineum join to form three or four collecting trunks that drain to superficial inguinal nodes lying on the cribriform fascia covering the femoral artery and vein; these nodes drain through the cribriform fascia to the deep inguinal nodes lying medial to the femoral vein (Corton 2012). The deep inguinal nodes drain via the femoral canal to the pelvic nodes (Table 77.1). The last of the deep inguinal nodes lies under the inguinal ligament within the femoral canal and is often called Cloquet's node. Lymph vessels from the clitoris drain directly to the deep inguinal nodes, and direct clitoral lymphatics may pass to the internal iliac nodes (Fig. 77.3B). Lymph vessels in the perineum and lower part of the labia majora drain to the rectal lymphatic plexus.

## Innervation

The main nerve supply of the vulva is the pudendal nerve (S2, 3 and 4) through its inferior rectal and perineal branches and the dorsal nerve of the clitoris (Table 77.2; Figs 77.4, 77.5). Shoja et al 2013). The sensory innervation of the anterior and posterior parts of the labium majus differs. The anterior third of the labium majus is supplied by the ilioinguinal nerve (L1), the posterior two-thirds are supplied by the pudendal nerve through the posterior labial branches of the perineal nerve (S3), and the lateral aspect is also innervated by the perineal branch of the posterior cutaneous nerve of the thigh (S2). Vulvar nerves are susceptible to trauma and inflammation, leading to vulvar pain syndromes or vulvodynia (Shoja et al 2013).

## VAGINA

The vagina is a fibromuscular tube lined by non-keratinized stratified epithelium. It extends from the vestibule (the opening between the labia minora) to the uterus. The upper end of the vagina surrounds the vaginal projection of the uterine cervix. The anular recess between the cervix and vagina is the fornix; the different parts of the fornix are given separate names, i.e. anterior, posterior and right and left lateral, but they are continuous (Fig. 77.6).

In the standing position, the vagina ascends posteriorly and superiorly, forming an angle of $60-70^{\circ}$ with the horizontal plane (Corton 2012). The vagina forms an angle of over $90^{\circ}$ to the uterine axis (see Fig. 77.12); this angle varies with the contents of the bladder and rectum. The apex of the vagina is directed posteriorly towards the ischial spines. The width of the vagina increases as it ascends. The inner surfaces of the anterior and posterior vaginal walls are in contact with each other, forming a transverse slit. The vaginal mucosa is attached to the uterine cervix higher on the posterior cervical wall than on the anterior; the anterior wall is approximately 7.5 cm long and the posterior wall is approximately 9 cm long. The fibromuscular anterior wall of the vagina supports the base of the bladder in its middle and upper portions, and the urethra (which is embedded in it) inferiorly. The fibromuscular posterior wall of the vagina supports the rectum. The upper quarter of the posterior vagina is separated from the rectum by the peritoneum of the recto-uterine pouch, and by moderately dense fibromuscular tissue (Denonvilliers's fascia) in its middle half (Delancey 2011). In its lower quarter, it is separated from the anal canal by the fibromuscular perineal body. The upper part of the vagina is supported laterally by levator ani, together with the transverse cervical, pubocervical and uterosacral ligaments. Pubovaginalis provides a U-shaped muscular sling around the mid-vagina. The lower vagina is surrounded by the skeletal muscle fibres of bulbospongiosus (see Fig. 77.4). As the ureters pass anteromedially to reach the fundus of the bladder, they pass close to the lateral fornices, where care must be taken to avoid damage during hysterectomy (Fig. 77.7). As they enter the bladder, the ureters are usually anterior to the vagina; at this point, each ureter is crossed transversely by a uterine artery (Fig. 77.8).

Table 77.1 Lymphatic drainage of the female genitalia

| Structure | Nodes |
| :--- | :--- |
| Vulva |  |
| $\quad$ Labia, clitoris, and perineum | Superficial inguinal nodes |
| Perineum and lower labia majora | Rectal Iymphatic plexus |
| Clitoris | Superficial inguinal nodes |
|  | Direct to deep inguinal nodes |
| Vagina | Direct to internal iliac nodes |
| Upper vagina | Internal and external iliac nodes |
| Mid-vagina | Internal iliac nodes |
| Lower vagina | Superficial inguinal nodes |
| Uterus | Para-aortic nodes |
| Fundus | Superficial inguinal nodes |
| Isthmus of tube and round ligament | External iliac nodes |
| Body of uterus, including cervix | Internal iliac nodes |
|  | Obturator nodes |
| Uterine (Fallopian) tubes | Para-aortic nodes |
|  | Internal iliac nodes |
| Ovaries | Superficial inguinal nodes |

Fig. 77.5 The autonomic innervation of the female reproductive system. (Based on Barucha AE 2006 Pelvic floor: anatomy and function. Neurogastroenterol Motil 18:507-19.)

The vagina opens externally via a sagittal introitus positioned below the urethral meatus (see Fig. 77.1C). The size of the introitus varies; it is capable of great distension during childbirth and, to a lesser degree, during sexual intercourse. The hymen is a thin fold of mucous membrane situated just within the vaginal orifice. The internal surfaces of the folds are normally in contact with each other and the vaginal opening appears as a cleft between them. The hymen varies greatly in shape and dimensions. When stretched, it is anular and widest posteriorly; it may also be semilunar and concave towards the mons pubis, cribriform, fringed, absent or complete and imperforate. The hymenal ring normally ruptures after first sexual intercourse, but can rupture earlier during non-sexual physical activity. Small round carunculae hymenales (also known as carunculae myrtiformis) are its remnants
after it has been ruptured. It has no established function. The hymen may be imperforate; this is usually detected in adolescence.

Remnants of the duct of Gartner (embryologically, the caudal end of the mesonephric duct) (see Figs 72.13, 72.19) are occasionally seen protruding through the lateral fornices or lateral parts of the vagina and may cause cysts (Gartner's cysts). Prepubertal distal longitudinal folds are common within the vagina and they disappear during puberty (Altchek et al 2008).

## Vascular supply and lymphatic drainage

## Arteries

The arterial supply of the vagina is derived from the internal iliac arteries by two median longitudinal vessels, the azygos arteries of the vagina, which descend anterior and posterior to the vagina; they also supply the vestibular bulb, fundus of the bladder, and adjacent part of the rectum (see Fig. 77.3A). The uterine, internal pudendal and middle rectal branches of the internal iliac artery may contribute to the blood supply of the vagina.

## Veins

The vaginal veins, one on each side, arise from lateral plexuses that connect with uterine, vesical and rectal plexuses and drain to the internal iliac veins. The uterine and vaginal plexuses may provide collateral venous drainage to the lower limb.

## Lymphatic drainage

Vaginal lymphatic vessels link with those of the cervix, rectum and vulva. They form three groups but the regions drained are not sharply demarcated. Upper vessels accompany the uterine artery to the internal and external iliac nodes; intermediate vessels accompany the vaginal artery to the internal iliac nodes; and vessels draining the vagina below the hymen, and from the vulva and perineal skin, pass to the superficial inguinal nodes (see Table 77.1).

Fig. 77.7 The most common sites of ureteric injury during hysterectomy. Key: 1, distal ureter at the level of the uterine artery; 2, dorsal to the infundibulopelvic ligament, near the pelvic bone; 3 , intramural portion of ureter at the angle of the vaginal cuff.

Fig. 77.8 The relationship of the ureter to the uterine and vaginal arteries. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

## Innervation

The lower vagina is supplied by the pudendal nerve ( $\mathrm{S} 2, \mathrm{~S} 3$ and S 4 ). The upper vagina is supplied by the pelvic splanchnic nerves (S2, S3 and, sometimes, S4) (see Fig. 77.5 and Table 77.2).

## Developmental anomalies of the vagina

Congenital anomalies of the vagina are vaginal agenesis, absent hymen, transverse vaginal septum and persistent cloaca. Vaginal agenesis, in the presence of other Müllerian duct anomalies and renal agenesis, is termed Mayer-Rokistansky-Kuster-Hauser syndrome. An absent hymen in patients with vaginal agenesis is associated with renal agenesis (Kimberley et al 2012). A congenital transverse septum may be present within the vagina and manifests clinically in adolescence with primary amenorrhoea and haematocolpos. Children with a persistent cloaca have a congenital defect characterized by fusion of the rectum, vagina and urethra into a single common channel that varies in length from 1 to 7 cm .

## Microstructure

The vagina has an inner mucosal and an external muscular layer. The mucosa adheres firmly to the muscular layer. There are two median longitudinal ridges on its epithelial surface: one anterior and the other posterior. Numerous transverse bilateral rugae extend from these vaginal columns, divided by sulci of variable depth, giving an appearance of conical papillae. These transverse rugosities are most numerous on the posterior wall and near the orifice; they increase under the influence of oestrogen during puberty and pregnancy, are especially well developed before parturition, and decrease after the menopause (Corton 2012). The epithelium is non-keratinized, stratified, squamous similar to, and continuous with, that of the ectocervix. After puberty, it thickens and its superficial cells accumulate glycogen, which gives them a clear appearance in histological preparations.

The vaginal epithelium does not change markedly during the menstrual cycle, but its glycogen content increases after ovulation and then diminishes towards the end of the cycle. Natural vaginal bacteria, particularly Lactobacillus acidophilus, break down glycogen in the desquamated cellular debris to lactic acid. This produces a highly acidic ( pH 3 ) environment that inhibits the growth of most other microorganisms. The amount of glycogen is less before puberty and after the menopause, when vaginal infections are more common. There are no mucous glands, but a fluid transudate from the lamina propria and mucus from the cervical glands lubricate the vagina (Fig. 77.9). The muscular layers are composed of smooth muscle and consist of a thick outer longitudinal and an inner circular layer; the two layers are not distinct but are

Fig. 77.9 Stratified squamous non-keratinizing epithelium (E) covering the ectocervix and vagina. The cells of the middle and upper layers appear clear due to their glycogen content. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

C, Abbreviations: B, bladder; C, cervix (which, from external to internal, has several layers, as seen on T2-weighted images: a high-signal-intensity outer cervical stroma (contiguous with the outer myometrium); a low-signal-intensity inner cervical stroma (contiguous with the inner myometrium); high-signal-intensity endocervical glands (contiguous with endometrium); and a very high-signal-intensity endocervical canal (contiguous with the endometrial canal); R, rectum. D, Abbreviations: A, anus; I, ischio-anal fossa; S, pubic symphysis; U, urethra; V, vagina.
connected by oblique interlacing fibres. The longitudinal fibres are continuous with the superficial muscle fibres of the uterus. A layer of loose connective tissue, containing extensive vascular plexuses, surrounds the muscle layers.

## UPPER GENITAL TRACT

## UTERUS

The uterus is a thick-walled, muscular organ situated in the pelvis between the urinary bladder and the rectum (Figs 77.10-77.12). It lies posterior to the bladder and uterovesical space, and anterior to the rectum and recto-uterine pouch; it is mobile, which means that its position varies with distension of the bladder and rectum. The broad ligaments are lateral.

The uterus is divided structurally and functionally into two main regions: the muscular body of the uterus (corpus uteri) forms the upper two-thirds, and the fibrous cervix (cervix uteri) forms the lower third.

In the adult nulliparous state, the cervix usually tilts forwards relative to the axis of the vagina (anteversion), and the body of the uterus tilts forwards relative to the cervix (anteflexion) (see Fig. 77.12). In $10-15 \%$ of women, the whole uterus leans backwards at an angle to the vagina and is said to be retroverted. A uterus that angles backwards on the cervix is described as retroflexed.

## Body

The body of the uterus is pear-shaped and extends from the fundus superiorly to the cervix inferiorly. The uterine tubes enter the uterus on both sides at the uterine cornua. The round and ovarian ligaments are inferoanterior and inferoposterior, respectively, to each cornu. The dome-like fundus is superior to the entry points of the uterine tubes and covered by peritoneum that is continuous with that of neighbouring surfaces. The fundus is in contact with coils of small intestine and, occasionally, by distended sigmoid colon. The lateral margins of the body are convex; on each side, their peritoneum is reflected laterally to form the broad ligament, which extends as a flat sheet to the pelvic wall

Table 77.2 Innervation of the female genitalia

With permission from Shoja MM, Sharma A, Mirzaya N, Groat C, Watanabe K, Loukas M and Tubbs RS. Neuroanatomy of the Female Abdominoplevic Region: A Review with Application to Pelvic Pain Syndromes. Clinical Anatomy 26:66-76, 2013.)

Fig. 77.11 A, Anatomical relations of the female genital tract, bladder and rectum. B, Pelvic peritoneal reflections, showing the broad ligament and its contents. (A, With permission from Drake RL, Vogl AW, Mitchell A, Tibbitts R, Richardson P (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008. B, With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
(see Figs $77.11 \mathrm{~B}, 77.15$ ). The anterior surface of the uterine body is covered by peritoneum reflected on to the bladder at the uterovesical fold (see Fig. 77.14). This normally occurs at the level of the internal os, the most inferior margin of the body of the uterus. The vesicouterine pouch, between the bladder and uterus, is obliterated when the bladder is distended, but may be occupied by small intestine when the bladder is empty. The posterior surface of the uterus is convex transversely. Its peritoneal covering continues down to the cervix and upper vagina, and is then reflected back to the rectum along the surface of the recto-uterine pouch, which lies posterior to the uterus (see Fig. 77.16). The sigmoid colon, and occasionally the terminal ileum, lie posterior to the uterus.

The cavity of the uterine body usually measures 6 cm from the external os of the cervix to the wall of the fundus and is flat in its anteroposterior plane (Salardi et al 1985). In coronal section, it is triangular, broad above where the two uterine tubes join the uterus, and narrow below at the internal os of the cervix. There is no change in the

Fig. 77.12 Angles of anteflexion and anteversion. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
size of the uterus until approximately 7 years of age, when there is greater enlargement of the body of the uterus than the cervix.

Developmental anomalies of the uterus There may be failure in fusion of the paramesonephric (Müllerian) ducts, which results in a uterus that is not pear-shaped. There may only be a septum (septate uterus) or partial clefting of the uterus (bicornuate uterus); the most extreme example is a septate vagina, two cervices and two discrete uteri, each with one uterine tube (uterus didelphys) (Minto et al 2001) (see Fig. 72.15).

## Cervix

The adult, non-pregnant cervix is narrower and more cylindrical than the body of the uterus and is typically 2.5 cm long. The upper end communicates with the uterine body via the internal os, and the lower end opens into the vagina at the external os (see Fig. 77.6). In nulliparous women, the external os is usually a circular aperture, whereas, after childbirth, it is a transverse slit. Two longitudinal ridges, one each on its anterior and posterior walls, give off small, oblique, palmate folds that ascend laterally like the branches of a tree (arbor vitae uteri); the folds on opposing walls interdigitate to close the canal. The narrower isthmus forms the upper third of the cervix. Although unaffected in the first month of pregnancy, it is gradually taken up into the uterine body during the second month to form the 'lower uterine segment' (see below). In nonpregnant women, the isthmus undergoes menstrual changes, although these are less pronounced than those occurring in the uterine body. The external end of the cervix enters the upper end of the vagina, thereby dividing the cervix into supravaginal and vaginal parts. The supravaginal part is separated anteriorly from the bladder by cellular connective tissue: the parametrium, which also passes to the sides of the cervix and laterally between the two layers of the broad ligaments.

## Peritoneal folds and ligaments of the pelvis

The uterus is connected to a number of 'ligaments'. Some are true ligaments, in that they have a fibrous composition and provide support to the uterus; some provide no support to the uterus; and others are simply folds of peritoneum.

## Peritoneal folds

The parietal peritoneum is reflected over the upper genital tract to produce anterior (uterovesical), posterior (rectovaginal) and lateral peritoneal folds. The lateral folds are commonly called the broad ligaments (Fig. 77.13).

Fig. 77.13 A laparoscopic view of the uterus. The patient is tilted head down so that the small bowel is moved away from the uterus to give this view.

Fig. 77.14 A laparoscopic view of the anterior part of the pelvis, showing the uterovesical fold anterior to the uterus.

## Uterovesical and rectovaginal folds

The anterior, or uterovesical, fold consists of peritoneum reflected on to the bladder from the uterus at the junction of its cervix and body (Fig. 77.14). The posterior or rectovaginal fold extends lower than the anterior fold and consists of peritoneum reflected from the posterior vaginal fornix on to the front of the rectum, thereby creating the deep recto-uterine pouch (pouch of Douglas). The recto-uterine pouch is bounded anteriorly by the uterus, supravaginal cervix and posterior vaginal fornix; posteriorly, by the rectum; and laterally, by the uterosacral ligaments.

## Broad ligament

The lateral folds, or broad ligaments, extend on each side from the uterus to the lateral pelvic walls, where they become continuous with the peritoneum covering those walls (Figs 77.15, 77.17-77.18). The upper border is free and the lower border is continuous with the peritoneum over the bladder, rectum and side wall of the pelvis. The borders are continuous with each other at the free edge via the uterine fundus, and diverge below near the superior surfaces of levatores ani. A uterine tube lies in the upper free border on either side. The broad ligament is divided into an upper mesosalpinx, a posterior mesovarium and an inferior mesometrium.

Fig. 77.15 A laparoscopic view of the broad ligament.

Fig. 77.16 A laparoscopic view of the posterior pelvis, showing the recto-uterine pouch (pouch of Douglas) with the sigmoid colon descending towards the rectum.

## Mesosalpinx

The mesosalpinx is attached above to the uterine tube and posteroinferiorly to the mesovarium (see Fig. 77.17). Superior and laterally, it is attached to the suspensory ligament of the ovary; medially, it is attached to the ovarian ligament. The fimbria of the tubal infundibulum projects from its free lateral end. Between the ovary and uterine tube, the mesosalpinx contains vascular anastomoses between the uterine and ovarian vessels, the epoophoron and the paroophoron. The mesovarium projects from the posterior aspect of the broad ligament, of which it is the smaller part. It is attached to the hilum of the ovary and carries vessels and nerves to the ovary.

## Mesometrium

The mesometrium is the largest part of the broad ligament, and extends from the pelvic floor to the ovarian ligament and uterine body. The uterine artery passes between its two peritoneal layers typically 1.5 cm lateral to the cervix; it crosses the ureter shortly after its origin from the internal iliac artery and gives off a branch that passes superiorly to the uterine tube, where it anastomoses with the ovarian artery (Fig. 77.19). Between the pyramid formed by the infundibulum of the tube, the

Fig. 77.18 The ovaries and broad ligament: superior view with the uterus lifted away from the bladder. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
upper pole of the ovary, and the lateral pelvic wall, the mesometrium contains the ovarian vessels and nerves lying within the fibrous suspensory ligament of the ovary (infundibulopelvic ligament). This ligament continues laterally over the external iliac vessels as a distinct fold. The mesometrium also encloses the proximal part of the round ligament of the uterus, as well as smooth muscle and loose connective tissue.

## Ligaments of the pelvis

The ligaments of the pelvis consist of the round, uterosacral, transverse cervical and pubocervical ligaments.

## Round ligament

Each round ligament is a narrow smooth muscle band $10-12 \mathrm{~cm}$ long, which extends from the lateral cornu of the uterus through the broad ligament to enter the deep inguinal ring lateral to the inferior epigastric artery (see Figs $77.13,77.15,77.18$ ). Although conventionally described as ending in the labium majus, a cadaveric dissection study found that, in girls, the round ligament ended just outside the external ring, with
neither attachment nor extension to the caudal labium (the homologue of the hemiscrotum) (Attah and Hutson 1991). Near the uterus, the round ligament contains a considerable amount of smooth muscle but this gradually diminishes and the terminal portion is purely fibrous. The round ligament also contains striated muscle, blood vessels, nerves and lymphatics. The latter drain the uterine region around the entry of the uterine tube to the superficial inguinal lymph nodes.

In the fetus, a projection of peritoneum (processus vaginalis) is carried with the round ligament for a short distance into the inguinal canal. This is generally obliterated in adults, although it is sometimes patent even in old age. A patent processus vaginalis in the inguinal canal in females is often referred to as the canal of Nuck; it may be asymptomatic or it may give rise to an inguinal hernia or hydrocele of the canal of Nuck. In the canal, the ligament receives the same coverings as the spermatic cord, although they are thinner and blend with the ligament itself, which may not reach the mons pubis. The round and ovarian ligaments both develop from the gubernaculum and are continuous.

## Uterosacral, transverse cervical and pubocervical ligaments

The uterosacral, transverse cervical and pubocervical ligaments are condensations of the visceral or endopelvic connective tissue that connect the pelvic viscera to the side wall of the pelvis; they radiate like the spokes of a wheel around the hub of the cervix, providing it with considerable support (see Figs 77.13-16) (Delancey 2011). The connective tissue lateral to the uterus and the cervix - the parametrium - continues down along the vagina as the paracolpium. The uterosacral ligaments contain fibrous tissue and smooth muscle. They pass back from the cervix and uterine body on both sides of the rectum, and are attached to the anterior aspect of the sacrum. They can be palpated laterally on rectal examination and can be felt as thick bands of tissue passing downwards on both sides of the posterior fornix on vaginal examination. The transverse cervical ligaments (cardinal ligaments, ligaments of Mackenrodt) (Fig. 77.20) extend from the side of the cervix and lateral fornix of the vagina, and are attached extensively on the pelvic wall. The lower parts of the ureters and pelvic blood vessels traverse the transverse cervical ligaments. Fibres of the pubocervical ligament pass forwards from the anterior aspect of the cervix and upper vagina to diverge around the urethra, and are attached to the posterior aspect of the pubic bones.

The transverse cervical and uterosacral ligaments are almost vertically orientated in the standing position and maintain the near-

Fig. 77.19 The broad ligament (left), and blood supply to the uterus and ovaries (right). (With permission from Drake RL, Vogl AW, Mitchell A, Tibbitts R, Richardson P (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)
horizontal axis of the upper vagina. The uterus and vagina are supported by the close interaction of the uterosacral and transverse cervical ligaments with the muscles of the pelvic floor, including the levatores ani and coccygei, the perineal membrane and the perineal body. The support of the pelvic floor has been reviewed in detail by Delancey (2011) (see also Ch. 73).

## Vascular supply and lymphatic drainage

## Arteries

The arterial supply to the uterus comes from the uterine artery (see Fig. 77.19; Fig. 77.21), which arises as a branch of the anterior division of the internal iliac artery. From its origin, the uterine artery crosses the ureter anteriorly in the broad ligament before branching as it reaches the uterus at the level of the cervico-uterine junction (see Fig. 74.21B). One major branch ascends the uterus tortuously within the broad ligament until it reaches the region of the ovarian hilum, where it anastomoses with branches of the ovarian artery. Another branch descends to supply the cervix and anastomoses with branches of the vaginal artery to form two median longitudinal vessels: the azygos arteries of the vagina, which descend anterior and posterior to the vagina. Although there are anastomoses with the ovarian and vaginal arteries, the dominance of the uterine artery is indicated by its marked hypertrophy during pregnancy.

The tortuosity of the vessels as they ascend in the broad ligaments is repeated in their branches within the uterine wall. Each uterine artery gives off numerous branches. These enter the uterine wall, divide and run circumferentially as groups of anterior and posterior arcuate arteries. They ramify and narrow as they approach the anterior and posterior midline so that no large vessels are present in these regions. However, the left and right arterial trees anastomose across the midline and unilateral ligation can be performed without serious effects. Terminal branches in the uterine muscle are tortuous and are called helicine arterioles. They provide a series of dense capillary plexuses in the myometrium and endometrium. From the arcuate arteries, many helical arteriolar rami pass into the endometrium. Their detailed appearance changes during the menstrual cycle. In the proliferative phase, helical arterioles are less prominent, whereas they grow in length and calibre, becoming even more tortuous in the secretory phase.

## Veins

The uterine veins extend laterally in the broad ligaments, running adjacent to the arteries and passing over the ureters. They drain into the internal iliac veins (see Fig. 77.3). The uterine venous plexus anastomoses with the vaginal and ovarian venous plexuses.

## Lymphatic drainage

Uterine lymphatics exist in the superficial (subperitoneal) and deep parts of the uterine wall. Collecting vessels from the body of the uterus and cervix pass laterally in the parametrium to three main groups of lymph nodes: the external and internal iliac and the obturator nodes

Fig. 77.20 The supporting ligaments of the pelvis, showing the transverse cervical ligaments. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \&
Fischer. Copyright 2013.)

Fig. 77.21 A, The normal arterial supply to the uterus and ovary. B-D, Variations in arterial blood supply to the ovary. E-F, Variations in arterial blood supply to the fundus of the uterus. (A, With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
(see Table 77.1). The external and internal iliac nodes surround their corresponding arteries. The obturator nodes lie in the obturator fossa between the external and internal iliac vessels; the obturator nerve passes through the lower part of this group of lymph nodes.

Lymph vessels from the fundus of the uterus and the uterine tubes may accompany the lymph drainage of the ovaries to para-aortic nodes (see Fig. 77.3B). The region surrounding the isthmus of the uterine tube may drain along the round ligament to the superficial inguinal nodes.

## Innervation

The nerve supply to the uterus is predominantly from the inferior hypogastric plexus (see Fig. 77.5) (Shoja et al 2013). Some branches ascend with, or near, the uterine arteries in the broad ligament. They supply the uterine body and tubes, and connect with tubal nerves from the inferior hypogastric plexus and with the ovarian plexus. The uterine nerves terminate in the myometrium and endometrium, and usually accompany the vessels (see Table 77.2). Nerves to the cervix form a plexus that contains small paracervical ganglia. Sometimes, one ganglion is larger and is termed the uterine cervical ganglion. Branches may pass directly to the cervix uteri or may be distributed along the vaginal arteries.

Efferent preganglionic sympathetic fibres are derived from neurones in the last thoracic and first lumbar spinal segments; the sites where they synapse on their postganglionic neurones are unknown but are presumably in the superior and/or inferior hypogastric plexuses (Lee et al 1973). Preganglionic parasympathetic fibres arise from neurones in the second to fourth sacral spinal segments and relay in the paracervical ganglia. Sympathetic activity may produce uterine contraction and vasoconstriction, and parasympathetic activity may produce uterine inhibition and vasodilation, but these activities are complicated by hormonal control of uterine functions.

## Microstructure

## Body of the uterus

The uterus is composed of three main layers. From its lumen outwards, these are the endometrium (mucosa), myometrium (smooth muscle layer) and serosa (or adventitia) (Fig. 77.22).

## Endometrium

The endometrium is formed by a layer of connective tissue, the endometrial stroma, which supports a single-layered columnar epithelium. Before puberty, the epithelium is ciliated and cuboidal. It contains glands that are composed largely of columnar cells secreting glycoproteins and glycogen. After puberty, the structure of the endometrium varies with the stage of the menstrual cycle (see below). The glands are tubular, run perpendicular to the luminal surface and penetrate up to the myometrial layer. The stroma consists of a highly cellular connective tissue between the endometrial glands, and contains blood and lymphatic vessels.

## Myometrium

The myometrium is composed of smooth muscle and loose connective tissue, and contains blood vessels, lymphatic vessels and nerves. It is dense and thick at the uterine midlevel and fundus but thin at the tubal orifices. The body of the uterus has four muscular layers. The submucosal (innermost) layer is composed of longitudinal and some oblique smooth muscle fibres. Where the lumen of the uterine tube passes through the uterine wall, this layer forms a circular muscle coat. The vascular layer is external to the submucosal layer and is rich in blood vessels, as well as longitudinal muscle; it is succeeded by a layer of predominantly circular muscle, the supravascular layer. The outer, thin, longitudinal muscle layer, the subserosal layer, lies adjacent to the serosa.

The muscular fibres of the outer two layers converge at the lateral angles of the uterus and continue into the uterine tubes. Some fibres enter the broad ligaments as the round and ovarian ligaments; others turn back into the uterosacral ligaments. At the junction between the body and the cervix, the smooth muscle merges with dense, irregular connective tissue containing both collagen and elastin, and forms the majority of the cervical wall. Bilateral longitudinal fibres extend in the lateral submucosal layer from the fundal angle to the cervix. Their muscle fibres differ structurally from those of typical myometrium, and they may provide fast-conducting pathways that coordinate the contractile activities of the uterine wall.

## Serosa

The uterine body is covered by peritoneal serosa, which continues downwards posteriorly to cover the supravaginal cervix. The anterior

Fig. 77.23 The endocervical glands. These are are deep infoldings of the lining of the endocervical canal (EC). The epithelium (E) is simple columnar and mucus-secreting. The underlying lamina propria (LP) is richly supplied with blood vessels (BV) and lymphatics (L). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
cervix and the lateral surfaces of the uterine body and cervix are not covered by peritoneum.

## Cervix uteri

The cervix consists of fibroelastic connective tissue and contains relatively little ( $10 \%$ ) smooth muscle. The elastin component of the cervical stroma is essential to the stretching capacity of the cervix during childbirth. The cervical canal is lined by a deeply folded mucosa with a surface epithelium of columnar mucous cells (Fig. 77.23). There are branched tubular glands present within the mucosa, which are lined by a similar secretory epithelium. The glands extend obliquely upwards and outwards from the canal. They secrete clear, alkaline mucus, which is relatively viscous except at the midpoint of the menstrual cycle, when it becomes more copious and less viscous to encourage the passage of sperm. At the vaginal end of the cervix, the aperture of a gland may block and it then fills with mucus to form a Nabothian follicle (or cyst). None of the mucosa is shed during menstruation and so, unlike the body of the uterus, it is not divided into functional and basal layers, and lacks spiral arteries. The surface of the intravaginal part of the cervix (ectocervix) is covered by non-keratinizing stratified squamous epithelium, which contains glycogen.

Fig. 77.24 The transformation zone of the uterine cervix. The singlelayered columnar epithelium lining the endocervical canal (EC) and its endocervical glands (EG) changes abruptly (arrow) to the stratified squamous non-keratinizing epithelium of the external os and ectocervix (below arrow).

The squamocolumnar junction, where the columnar secretory epithelium of the endocervical canal meets the stratified squamous covering of the ectocervix, is located at the external os before puberty. As oestrogen levels rise during puberty, the cervical os opens, exposing the endocervical columnar epithelium on to the ectocervix. This area of columnar cells on the ectocervix forms an area that is red and raw in appearance, called an ectropion (cervical erosion). It is then exposed to the acidic environment of the vagina and, through a process of squamous metaplasia (p. 40), transforms into stratified squamous epithelium. This area is thus known as the 'transformation zone' (Fig. 77.24). Other hyperoestrogenic states, such as pregnancy and the use of oral contraceptive pills, can also result in an ectropion. This area is the most usual site of cervical intraepithelial neoplasia (CIN), which may progress to malignancy. In postmenopausal women, the squamocolumnar junction recedes into the endocervical canal.

## Magnetic resonance imaging of the uterus and vagina

On T2-weighted magnetic resonance imaging (MRI), the uterus displays a zonal anatomy, with three distinct zones: the endometrium, junctional zone and myometrium (Fig. 77.25) (Minto et al 2011). The endometrium and uterine cavity appear as a high-signal stripe; the thickness varies with the stage of the menstrual cycle. In the early proliferative phase, it measures up to 5 mm , and widens to up to 1 cm in the mid-secretory phase. A band of low signal, the junctional zone, borders the endometrium. It represents the inner myometrium and is of constant thickness and signal throughout the menstrual cycle; it usually measures 5 mm . The outer myometrium is of medium-signal intensity in the proliferative phase, and of high-signal intensity in the mid-secretory phase as a result of the increased vascularity and prominence of the arcuate vessels.

Fig. 77.25 T2-weighted MRI scans of the uterus and ovaries. A, A coronal T2-weighted MRI through a female pelvis showing the uterus and both ovaries with the high-signal central stroma and lower-signal outer stroma. B, A sagittal T2-weighted MRI through a female pelvis, showing the zonal anatomy of the uterus.

In prepubertal females, the uterus is smaller (only 4 cm in length), and on T2-weighted images, the endometrium is minimal or absent, and the junctional zone is indistinct. In postmenopausal women, the corpus decreases in size and the zonal anatomy is indistinct.

On T2-weighted MRI, the cervix has an inner, low-signal stroma continuous with the junctional zone of the uterus. Often, this is surrounded by an outer zone of intermediate signal intensity, which is continuous with the outer myometrium. The appearances do not change with the menstrual cycle or oral contraceptive pill use. The central stripe is very high-signal and is a consequence of the secretions produced by the endocervical glands.

The vagina is best seen on T2-weighted MRI as a thin layer of highsignal intensity of the mucosa and an outer, low-signal layer of the submucosa and muscularis (see Fig. 77.25). MRI accurately demonstrates congenital and acquired Müllerian anomalies, including uterine and vaginal aplasia, duplication and septa (Grant et al 2010). Vaginal and perivaginal cysts are well visualized with T2-weighted MRI.

## UTERINE (FALLOPIAN) TUBES

The uterine tubes are attached to the upper part of the body of the uterus, and their ostia open into the uterine cavity (Figs 77.26, 77.27, 77.28). The medial opening of the tube (the uterine os) is located at the superior angle of the uterine cavity. The tube passes laterally and superiorly, and consists of four main parts: intramural, isthmus, ampulla and fimbria (see Fig. 77.22). The intramural part is 0.7 mm wide and 1 cm long, and lies within the myometrium. It is continuous laterally with the isthmus, which is $1-5 \mathrm{~mm}$ wide and 3 cm long; it is rounded, muscular and firm. The isthmus is continuous laterally with the ampulla, the widest portion of the tube with a maximum luminal diameter of 1 cm . The ampulla is 5 cm long and has a thin wall and a tortuously folded luminal surface. Typically, fertilization takes place in its lumen. The ampulla opens into the trumpet-shaped infundibulum at the abdominal os. Fimbriae, numerous mucosal finger-like folds 1 mm wide, are attached to the ends of the infundibulum and extend from its inner circumference beyond the muscular wall of the tube. One of these, the ovarian fimbria, is longer and more deeply grooved than the others, and is typically applied to the tubal pole of the ovary. At the time of ovulation, the fimbriae swell and extend as a result of engorgement of the vessels in the lamina propria, which aids capture of the released oocyte. All fimbriae are covered, like the mucosal lining throughout the tube, by a ciliated epithelium whose cilia beat towards the ampulla.

## Vascular supply and lymphatic drainage

## Arteries

The blood supply to the uterine tubes is derived from ovarian and uterine arteries (see Fig. 77.21A). The lateral third of the tube is supplied by the ovarian artery, which continues in the mesosalpinx to anastomose with branches from the uterine artery. The medial two-thirds of the tube are supplied by the uterine artery.

Ostium of left uterine tube
Fundus
Ostium of right uterine tube

Fig. 77.26 A hysteroscopic view of the endometrial cavity of the uterus.

Fig. 77.27 A digitally subtracted hysterosalpingogram. Radiopaque contrast is introduced via a catheter inserted through the cervical os; the catheter is introduced using a vaginal speculum. The contrast fills the triangular uterine cavity. The lumina of the narrow intramural and isthmic parts of the uterine tubes may be traced inferolaterally from the superior angles as they expand into the wider ampullae. Some contrast media has escaped into the pelvic cavity from the abdominal ostia. (Courtesy of Dr Julia Hillier, Chelsea and Westminster Hospital, London.)

Fig. 77.28 A laparoscopic view of the origin of the uterine tube from the uterus.

## Veins

Venous drainage is similar to the arterial supply. The venous drainage of the lateral two-thirds of the uterine tube is via the pampiniform plexus to the ovarian veins, which open into the inferior vena cava on the right side and the renal vein on the left side. The medial two-thirds of the tube drain via the uterine plexus to the internal iliac vein.

## Lymphatic drainage

Lymph drainage is via ovarian vessels to the para-aortic nodes and uterine vessels to the internal iliac chain. It is possible for lymph to reach the inguinal nodes via the round ligament (see Table 77.1).

Fig. 77.29 The uterine tube (ampulla) with the mucosal lining thrown into extensive folds that fill the lumen. The superficial epithelium includes both secretory and ciliated cells, covering a lamina propria (LP). Smooth muscle (SM) occupies the wall of the tube. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

## Innervation

The uterine tube is innervated by autonomic fibres that are distributed mainly with the ovarian and uterine arteries. Most of the tube has a dual sympathetic and parasympathetic supply (see Table 77.2). Preganglionic parasympathetic fibres are derived from the vagus for the lateral half of the tube, and pelvic splanchnic nerves for the medial half. Preganglionic sympathetic supply is derived from neurones in the intermediolateral column of the tenth thoracic to the second lumbar spinal segments; postganglionic sympathetic fibres are most likely derived from the superior hypogastric plexus, via the superior hypogastric and hypogastric nerves (see Fig 77.5) (Chen et al 2014). Visceral afferent fibres travel with the sympathetic nerves and enter the cord through corresponding dorsal roots; they may also travel with parasympathetic fibres. The ampullary submucosa contains modified Pacinian corpuscles.

## Microstructure

The walls of the uterine tubes show typical visceral mucosal, muscular and serosal layers (Fig. 77.29). The mucosa is thrown into longitudinal folds, which are most pronounced distally at the infundibulum and decrease to shallow bulges in the intrauterine (intramural) portion. The mucosa is lined by a single-layered, tall, columnar epithelium, which contains mainly ciliated cells and secretory (peg) cells (so called because they project into the lumen further than their ciliated neighbours), and occasional intraepithelial lymphocytes. In the tube, ciliated cells predominate distally and secretory cells proximally. Their activities vary with the stage in the menstrual cycle and with age. Secretory cells are most active around the time of ovulation. Their secretions include nutrients for the gametes and aid capacitation of the spermatozoa. Ciliated cells increase in height and develop more cilia in the oestrogenic first half of the menstrual cycle. Their cilia waft the oocyte from the open-ended infundibulum towards the uterus in fluids secreted by the peg cells. The epithelium regresses in height towards the end of the cycle and postmenopausally, when ciliated cells are reduced in number.

The lamina propria provides vascular connective tissue support and abundant lymphatic drainage vessels. The smooth muscle of the muscularis is arranged as an inner circular, or spiral, layer and an outer, thinner, longitudinal layer. Together, their contractile activity produces peristaltic movements of the tube, which assist propulsion of the gametes and the fertilized ovum. The uterine tubes are covered externally by a highly vascular serosa.

## OVARIES

In the adult, non-pregnant state, the ovaries lie on each side of the uterus close to the lateral pelvic wall, suspended in the pelvic cavity by
a double fold of peritoneum, the mesovarium, which is attached to the upper limit of the posterior aspect of the broad uterine ligament. They are dull white in colour and consist of dense fibrous tissue, in which ova are embedded. Before regular ovulation begins, they have a smooth surface but, thereafter, their surfaces are distorted by scarring that follows the degeneration of successive corpora lutea (Speroff and Fritz 2004) (Fig. 77.30). Their average dimensions are $4 \times 2 \times 3 \mathrm{~cm}$ in reproductively mature women; they more than double their size during pregnancy. In the neonate, their dimensions are $1.3 \times 0.6 \times 0.4 \mathrm{~cm}$. Prior to the first menstrual period (menarche), the ovaries are about onethird of the normal reproductive adult size; they gradually increase in size with body growth (Sforza et al 1993, Badouraki et al 2008) and decrease significantly after the menopause.

The lateral surface of the ovary contacts parietal peritoneum in the ovarian fossa. Behind the ovarian fossa are retroperitoneal structures, including the ureter, internal iliac vessels, obturator vessels and nerve, and the origin of the uterine artery (Fig. 77.31). The medial surface faces the uterus and uterine vessels in the broad ligament, and the peritoneal recess here is termed the ovarian bursa. Above the superior extremity are the fimbria and distal section of the uterine tube. The

Fig. 77.30 A laparoscopic view of the right ovary, showing its distorted surface.

Fig. 77.31 The broad ligament dissected and pelvic lymph nodes removed to reveal the structures of the right-hand pelvic side wall.
inferior extremity points downwards towards the pelvic floor. The anterior border faces the posterior leaf of the broad ligament and contains the mesovarium. The posterior border is free and faces the peritoneum, which overlies the upper part of the internal iliac artery and vein, and the ureter. On the right side, superior and lateral to the ovary, are the ileocaecal junction, caecum and appendix. On the left side, the sigmoid colon passes over the superior pole of the ovary and joins the rectum, which lies between the medial surfaces of both ovaries. The mesosalpinx lies below the uterine tube. The ovarian ligament is inferior and medial. The mesovarium and ovary lie inferiorly at its fimbrial end. The round ligament is anterior to the tube. The superior and posterior surfaces of the tube lie free in the peritoneal cavity.

In embryonic and early fetal life, the ovaries are situated in the lumbar region near the kidneys. They gradually descend along the gubernaculum, stopping at the lesser pelvis. The relationship between the location of the ovaries and surface landmarks is important in order to enable shielding of the ovaries from exposure to radiation during radiological procedures. In girls, the ovaries lie at or below the iliac crest, just medial to the anterior superior iliac spine, and above the pubic symphysis at all ages (Bardo et al 2009). Accessory ovarian tissue may occur in the mesovarium or along the course of the gubernacula; rarely, the ovaries may descend along the whole course of the gubernacula and are found in the labia majora. During pregnancy, the ovaries are lifted high in the pelvis; by 14 weeks of gestation, they become partly abdominal structures, and by the third trimester, they are totally abdominal structures and lie vertically behind and lateral to the parous uterus.

## Peritoneal and ligamentous supports of the ovary

The peritoneal and ligamentous supports of the ovary consist of the infundibulopelvic and ovarian ligaments and the mesovarium.

## Infundibulopelvic (suspensory) ligament

The suspensory or infundibulopelvic ligament of the ovary is a peritoneal fold attached to the upper part of the lateral surface of the ovary, which contain the ovarian vessels and nerves (see Fig. 77.18). On the right side, the infundibulopelvic ligament is attached to a fold of peritoneum that is posterior and inferior to the caecum and appendix. On the left side, the peritoneal attachment is higher than on the right, and is lateral to the junction of the descending and sigmoid colons. As it joins the peritoneum covering psoas major, the suspensory ligament of the ovary passes superiorly over the external iliac vessels, genitofemoral nerve and ureter.

## Ovarian ligament (ligament of the ovary)

The ovarian ligament (ligament of the ovary) attaches the uterine (inferomedial) extremity of the ovary to the lateral angle of the uterus, posteroinferior to the uterine tube (see Fig. 77.22). It lies in the posterior leaf of the broad ligament and contains some smooth muscle cells. It is continuous with the medial border of the round ligament. Both ligaments are remnants of the gubernaculum.

## Mesovarium

The mesovarium is a short peritoneal fold that attaches the ovary to the back of the broad ligament. It carries blood vessels and nerves to the ovarian hilum. The uterine tube arches over the ovary and ascends in relation to its mesovarian border, then curves over its tubal end and passes down on its posterior, free, border and medial surface.

## Vascular supply and lymphatic drainage

## Arteries

The ovarian arteries are branches of the abdominal aorta and originate below the renal arteries. Each descends behind the peritoneum and, at the brim of the pelvis, crosses the external iliac artery and vein to enter the true pelvic cavity. Here, the artery turns medially in the ovarian suspensory ligament and splits into a branch to the mesovarium that supplies the ovary, and a branch that continues into the uterine broad ligament, below the uterine tube, and supplies the tube. There are variations in the site of the division to the ovary and tube (see Fig. 77.21). On each side, a branch passes lateral to the uterus to unite with the uterine artery. Other branches accompany the round ligaments through the inguinal canal to the skin of the labium majus and the inguinal region. Early in intrauterine life, the ovaries flank the vertebral column inferior to the kidneys, and so the ovarian arteries are relatively short; they gradually lengthen as the ovaries descend into the pelvis.

## Veins

The ovarian veins emerge from the ovary as a plexus (pampiniform plexus) in the mesovarium and suspensory ligament (see Fig. 77.3A). Two veins emerge from the plexus and ascend with the ovarian artery; they usually merge into a single vessel before entering either the inferior vena cava on the right side, or the renal vein on the left side.

## Lymphatic drainage

The main lymphatic drainage of the ovaries is along vessels that follow the ovarian veins to para-aortic nodes situated near the origin of the renal arteries (see Table 77.1). Drainage may also occur via pelvic nodes into lower para-aortic nodes and, rarely, may follow the round ligament to the inguinal nodes.

## Innervation

The ovarian innervation is derived from autonomic plexuses (see Table 77.2). The upper part of the ovarian plexus is formed from branches of the renal and aortic plexuses, and the lower part is reinforced from the superior and inferior hypogastric plexuses. These plexuses consist of postganglionic sympathetic fibres, preganglionic parasympathetic fibres from the sacral outflow, and visceral afferent fibres (Lee et al 1973). The efferent preganglionic sympathetic fibres are derived from the tenth and eleventh thoracic spinal segments.

## Microstructure

In young females, the surface of the ovary is covered by a single layer of cuboidal epithelium, which contains some flatter cells. It appears dull white, in contrast to the shiny, smooth peritoneal mesothelial covering of the mesovarium, with which it is continuous. A white line around the anterior mesovarian border usually marks the transition between peritoneum and ovarian epithelium. The surface epithelium is also termed the germinal epithelium, but this is a misnomer because it is not the source of germ cells. Immediately beneath the epithelium, there is a tough collagenous coat, the tunica albuginea. The ovarian tissue it surrounds is divisible into a cortex, containing the ovarian follicles, and a medulla, which receives the ovarian vessels and nerves at the hilum.

## Ovarian cortex

Before puberty, the cortex forms 35\%, the medulla $20 \%$ and interstitial cells up to $45 \%$ of the volume of the ovary. After puberty, the cortex forms the major part of the ovary, enclosing the medulla, except at the
hilum. It contains the ovarian follicles at various stages of development, and corpora lutea and their degenerative remnants, depending on age or stage of the menstrual cycle. The follicles and the structures derived from them are embedded in a dense stroma composed of a meshwork of thin collagen fibres and fusiform fibroblast-like cells, arranged in characteristic whorls. Stromal cells differ from fibroblasts in general connective tissue in that they contain lipid droplets, which accumulate in pregnancy. Stromal cells give rise to the thecal layers of maturing ovarian follicles.

## Ovarian follicles

## Primordial follicles

The development of ovarian follicles can be divided into different stages (Fig. 77.32). At birth, the ovarian cortex contains a superficial zone of primordial follicles. These consist of primary oocytes $25 \mu \mathrm{~m}$ in diameter, each surrounded by a single layer of flat follicular cells. The oocyte nuclei are slightly eccentric and have a characteristically prominent nucleolus. They contain the diploid number of chromosomes (duplicated as sister chromatids), arrested at the diplotene stage of meiotic prophase since 16-20 weeks of fetal life (Speroff and Fritz 2004) (Fig. 77.33). Many follicles degenerate either during prepubertal (including prenatal) life, or through atresia at some stage after beginning the process of cyclical maturation during the child-bearing period. Their remnants are visible as atretic follicles, the remains of which accumulate throughout the period of reproductive life. After puberty, cohorts of up to 20 primordial follicles become activated in each menstrual cycle (fewer are activated with advancing age). Their development takes a number of cycles. Of the follicles activated in each cohort, usually only one follicle from one or other ovary becomes dominant, reaches maturity and releases its oocyte at ovulation.

Abnormal, non-growing follicles with indistinct germinal vesicle membranes and absent nucleoli are sometimes found in prepubertal ovaries and, occasionally, in pubertal ovaries, but are not found in adult ovaries (Anderson et al 2014).

## Primary follicles

Primary follicles develop from primordial follicles. The first sign is a change in the follicle cells from flattened to cuboidal, followed by their proliferation to give rise to a multilayered follicle consisting of granulosa cells surrounded by a thick basal lamina (Fig. 77.34). Stromal cells immediately surrounding the follicle begin to differentiate into spindleshaped cells, which constitute the theca folliculi that will become the theca interna. They are later surrounded by a more fibrous layer, the theca externa. At the same time, the oocyte increases in size and secretes

Fig. 77.33 Ovarian cortex with primordial (p) and early primary ( P ) follicles within the stroma (S); stimulated primary follicles have cuboidal cells forming their wall. A large oocyte nucleus is visible in the plane of section of most of the follicles (arrow). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 77.34 A high-magnification micrograph of a primary follicle in a human ovarian cortex. The pale oocyte, with its eccentric nucleus $(N)$, is separated from the follicle (F) by the zona pellucida (arrow). Cells of the follicle wall are in the early stages of proliferation to form a multilayered, late primary follicle. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
a thick layer of extracellular proteoglycan-rich material - the zona pellucida - between its plasma membrane and the surrounding granulosa cells of the early follicle; this is important for the process of fertilization. The granulosa cells in contact with the zona pellucida send cytoplasmic processes radially inwards; these contact and communicate with oocyte microvilli at gap junctions (Motta et al 2003). The follicular cells - in particular, the granulosa cells - continue to proliferate and so the thickness of the late primary follicle wall increases.

## Secondary (antral) follicles

Secondary (antral) follicles develop from primary follicles. The number of granulosa cells continues to increase. Cavities begin to form between them and are filled with a clear fluid (liquor folliculi) containing hyaluronate, growth factors, and steroid hormones secreted by the granulosa cells. The follicle is now about $200 \mu \mathrm{~m}$ in diameter and usually lies deep in the cortex. The cavities coalesce to form one large, fluid-filled space - the antrum - which is surrounded by a thin, uniform layer of granulosa cells, except at one pole of the follicle where a thickened granulosa layer envelops the eccentrically placed oocyte, to form the cumulus oophorus. The oocyte has now reached its maximum size of about $80 \mu \mathrm{~m}$ and the inner and outer thecae are clearly differentiated (Fig. 77.35). As follicles mature, the theca interna becomes more prominent and its cells more rounded and typical of steroid-secreting endocrine cells. They produce androstenedione, from which the granulosa

Fig. 77.35 An antral (secondary) follicle, showing the layers of the developing follicle wall. Granulosa cells (GC) enclose the antrum (A), filled with liquor folliculi, and surround the oocyte (not seen in the plane of section) within an eccentric cellular mass (right). The outer theca interna (TI) is a highly vascular layer that develops steroid secretory activity and is enclosed by the outermost theca externa (TE). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 77.36 A low-power view of a section of a human ovary, containing a corpus luteum (C). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
cells synthesize oestrogens (primarily oestradiol). Follicular development is stimulated by follicle-stimulating hormone (FSH).

## Tertiary (Graafian) follicle

Although a number of follicles may progress to the secondary stage by about the first week of a menstrual cycle, usually only one tertiary follicle develops; the remainder become atretic. The surviving follicle increases considerably in size as the antrum takes up fluid from the surrounding tissues and expands to a diameter of 2 cm . The term Graafian follicle is often used to describe this mature follicular stage. The oocyte and a surrounding ring of tightly adherent cells, the corona radiata, breaks away from the follicle wall and floats freely in the follicular fluid. The primary oocyte, which has remained in the first meiotic prophase (see Fig. 1.16) since fetal life, completes its first meiotic division to produce the almost equally large secondary oocyte and a small first polar body with very little cytoplasm. The secondary haploid oocyte immediately begins its second meiotic division, but when it reaches metaphase, the process is arrested until fertilization has occurred. The follicle moves to the superficial cortex, causing the surface of the ovary to bulge. The tissues at the point of contact (the stigma) with the tough tunica albuginea and ovarian surface epithelium are eroded until the follicle ruptures and its contents are released into the peritoneal cavity for capture by the fimbria of the uterine tube. The oocyte at ovulation is still surrounded by its zona pellucida and corona radiata of granulosa cells. If fertilization does not occur, it begins to degenerate after 24-48 hours.

## Corpus luteum

After ovulation, the remainder of the follicle becomes the corpus luteum (Fig. 77.36). The walls of the empty follicle collapse and fold. The granulosa cells increase in size and synthesize a cytoplasmic
carotenoid pigment (lutein), giving them a yellowish colour (hence, corpus luteum). These large ( $30-50 \mu \mathrm{~m}$ ) granulosa lutein cells form most of the corpus luteum. The basal lamina surrounding the follicle breaks down, and numerous smaller theca lutein cells infiltrate the folds of the cellular mass, accompanied by capillaries and connective tissue. Extravasated blood from thecal capillaries accumulates in the centre as a small clot, but this rapidly resolves and is replaced by connective tissue. All lutein cells have a cytoplasm filled with abundant smooth endoplasmic reticulum, characteristic of steroid-synthesizing endocrine cells. Granulosa lutein cells secrete progesterone and oestradiol (from aromatization of androstenedione synthesized by theca lutein cells). The two cell types also respond differently to circulating gonadotropins: theca lutein cells respond to luteinizing hormone (LH) and granulose lutein cells respond to FSH. Theca lutein cells express receptors for human chorionic gonadotrophin (hCG). If the oocyte is not fertilized, the corpus luteum (of menstruation) functions for 12-14 days after ovulation, then atrophies. The lutein cells undergo fatty degeneration, autolysis, removal by macrophages and gradual replacement with fibrous tissue. Eventually, after 2 months, a small, whitish, scar-like corpus albicans is all that remains

If fertilization does occur, implantation of the blastocyst into the uterine endometrium usually begins 7 days later and the embryonic trophoblast then starts to produce hCG. The chorionic gonadotrophin stimulates the corpus luteum of menstruation to grow, and it becomes a corpus luteum of pregnancy. It normally increases in size from 10 mm in diameter to 25 mm at 8 weeks of gestation and can be seen clearly on ultrasound. It secretes progesterone, oestrogen and relaxin, and functions throughout pregnancy, although it gradually regresses as its endocrine functions are largely replaced by the placenta after 8 weeks gestation. Its diameter is reduced by the end of pregnancy to 1 cm . In the next few months, it degenerates, like the corpus luteum of menstruation, to form a corpus albicans.

## Ovarian medulla

The medulla is highly vascular. It contains numerous veins and spiral arteries that enter the hilum from the mesovarium and lie within a loose connective tissue stroma. Small numbers of cells (hilus cells) with characteristics similar to interstitial (Leydig) cells in the testis are found in the medulla at the hilum; they may be a source of androgens.

## Menopause

At the menopause, ovulation ceases and various microscopic changes ensue within the ovarian tissues. The stroma becomes denser, the tunica albuginea thickens and the ovarian surface epithelium thins. However, many follicles persist within the cortex.

## MENSTRUAL CYCLE

The onset of menstruation (menarche) occurs between the tenth and seventeenth years of life, with a peak between 12 and 14 years. The uterus, ovaries and vagina undergo changes during the menstrual cycle, which normally lasts approximately 28 days. A follicle begins a period of development in the ovary during the first days of the cycle, and matures and ruptures mid-cycle (approximately day 14 of a 28-day cycle) to release a secondary oocyte. The wall of the follicle is then transformed into the corpus luteum, which secretes progesterone (luteal phase). About 10 days after ovulation, the corpus luteum begins to regress, then ceases to function and is replaced by fibrous tissue. The breakdown of the endometrium that follows this cessation of function is due to the reducing levels of progesterone and oestrogen as the corpus luteum degenerates.

The changes that occur in the endometrium during the menstrual cycle may be divided into three phases: proliferative, secretory and menstrual (Fig. 77.37)

## PROLIFERATIVE PHASE

In the early proliferative phase, even before the menstrual flow ceases, the epithelium from the persisting basal parts of the uterine glands grows over the surface of the endometrium, which has been denuded by menstruation. Re-epithelialization is complete 5-6 days after the start of menstruation. Initially, the tissue is only $1-2 \mathrm{~mm}$ thick and is lined by low cuboidal epithelium. The glands are straight and narrow, and their lining cells are short columnar. The apical cell surface contains microvilli; some cells are ciliated. The stroma is dense and contains small numbers of lymphocytes. During days 10-12 of the proliferative phase, the endometrium thickens. Cells divide in response to rising
levels of oestrogen, which is produced by the ovary and which acts through receptors present on both the stromal and the epithelial cells. The glands become tortuous and their lining epithelial cells become tall columnar in nature (Speroff and Fritz 2004).

## SECRETORY PHASE

The secretory phase coincides with the luteal phase of the ovarian cycle. The endometrial changes are driven by progesterone and oestrogen, secreted by the corpus luteum. Steroid receptors in the endometrium activate a programme of new gene expression that produces, in the following 7 days, a highly regulated sequence of differentiative events, presumably required to prepare the tissue for blastocyst implantation. Part of the response is direct, but there is evidence that some of the effects may be mediated through growth factors (Speroff and Fritz 2004). The first morphological effects of progesterone are evident 24-36 hours after ovulation (which occurs approximately 14 days before the next menstrual flow). In the early secretory phase, glycogen masses accumulate in the basal cytoplasm of the epithelial cells lining the glands, where they are often associated with lipid. Giant mitochondria appear and are associated with semi-rough endoplasmic reticulum. There is an obvious increased polarization of the gland cells: nuclei are displaced towards the centre of the cells, and Golgi apparatus and secretory vesicles accumulate in the supranuclear cytoplasm. The nuclear channel system is prominent and nuclei enlarge. Nascent secretory products may be detected immunohistochemically within the cells. Progestational effects on the stroma (known as the decidual reaction) are also evident in the early secretory phase. Nuclear enlargement occurs and the packing density of the resident stromal cells increases, due, in part, to the increase in volume of gland lumina and onset of secretory activity in the epithelial compartment.

By the mid-secretory phase, the endometrium may be up to 6 mm deep. The basal epithelial glycogen mass is progressively transferred to the apical cytoplasm, and nuclei return to the cell bases. The Golgi apparatus becomes dilated and products, including glycogen, mucin and other glycoproteins, are released from the glandular epithelium into the lumen by a combination of apocrine and exocrine mechanisms; this activity reaches a maximum 6 days after ovulation. These secretory changes are considerably less pronounced in the basal gland cells and the luminal epithelium than in the glandular cell population of the stratum functionalis. There is a notable stromal oedema and a corresponding decrease in the density of collagen fibrils. At the same time, the endoplasmic reticulum and Golgi apparatus become more prominent; there is evidence for collagen synthesis and degradation, presumably reflecting ongoing matrix remodelling.

In the late secretory phase, glandular secretory activity declines. Decidual differentiation occurs in the superficial stromal cells that surround blood vessels; this transformation includes nuclear rounding and an increased cytoplasmic volume, reflecting an increase in and dilation of the rough endoplasmic reticulum and Golgi systems, and cytoplasmic accumulation of lipid droplets and glycogen. The cells begin to produce basal lamina components, including laminin and type IV collagen.

Ultrasound is frequently used in the clinical evaluation of the endometrium. In the early secretory phase, the endometrium is identified as a thin echogenic line, a consequence of specular reflection from the interface between opposing surfaces of endometrium. During the late proliferative phase, the endometrium appears as a triple layer: a central echogenic line (due to the apposed endometrial surfaces), surrounded by a thicker hypoechoic functional layer, and bounded by an outer echogenic basal layer. During the secretory phase, the functional layer surrounding the echogenic line becomes more hyperechoic as a result of the increased mucus and glycogen within the glands and the increased number of interfaces caused by the development of tortuous spiral arteries (Fig. 77.38).

## MENSTRUAL PHASE

Prior to menstruation, three layers can be recognized in the endometrium: the strata compactum, spongiosum and basale. In the stratum compactum, which is next to the free surface, the necks of the glands are only slightly expanded and the stromal cells show a distinct decidual reaction. In the stratum spongiosum, the uterine glands are tortuous, dilated and, ultimately, only separated from one another by a small amount of interglandular tissue. The stratum basalis, next to the uterine muscle, is thin and contains the tips of the uterine glands embedded in an unaltered stroma.

Fig. 77.37 Stages in the menstrual cycle with concomitant changes in the endometrium. Note that developing antral follicles are selected from cohorts of follicles recruited in earlier cycles. The ten lower panels are histological sections of endometrium at the cycle times indicated (low magnification on top and high magnification below in each case).

Fig. 77.38 Transvaginal ultrasound of the uterus, showing the triplelayered endometrium. The central echogenic line is produced by the interface of the opposing surfaces of the endometrium. The functional layer of the endometrium surrounding the echogenic line is hypoechoic on the left, in keeping with late proliferative phase, but is becoming more hyperechoic on the right, indicating the early secretory phase.

The two upper strata are often grouped together as the functional layer, stratum functionalis, of the endometrium; the lower (basal) layer is called the stratum basalis. As regression of the corpus luteum occurs, those parts of the stroma showing a decidual reaction, together with the glandular epithelium, undergo degenerative changes and the
endometrium often diminishes in thickness. Blood escapes from the superficial vessels of the endometrium, forming small haematomata beneath the surface epithelium (see below). The stratum functionalis, next to the free surface, is shed piecemeal, leaving mainly the stratum basalis, adjacent to the uterine muscle; 65-75\% of the thickness of the endometrium may be shed. Blood and necrotic endometrium then begin to appear in the uterine lumen, to be discharged from the uterus through the vagina as the menstrual flow, which usually lasts 3-6 days. The amount of tissue lost is variable, but usually the stratum compactum and most of the spongiosum are desquamated.

## VASCULAR CHANGES WITHIN THE UTERUS DURING THE MENSTRUAL CYCLE

The vascular bed of the endometrium undergoes significant changes during the menstrual cycle. The arteries to the endometrium arise from a myometrial plexus and consist of short, straight vessels to the basal portion of the endometrium, and more muscular spiral arteries to its superficial two-thirds. The venous drainage, consisting of narrow perpendicular vessels that anastomose by cross-branches, is common to both the superficial and the basal layers of the endometrium. The capillary bed consists of an endothelium with a basal lamina that is discontinuous in the proliferative phase, but becomes more distinct by the mid-secretory phase. Pericytes are present, some of which resemble smooth muscle cells, and these are sometimes enclosed within the basal lamina. The pericytes make contact with the endothelial cells by means of cytoplasmic extensions that project through the basal lamina. Enlargement of the pericytes starts in the early secretory phase, and leads to a conspicuous cuff of cells in the mid- and late secretory phases. The arterial supply to the basal part of the endometrium remains
unchanged during the menstrual cycle. However, the spiral arteries to the superficial strata lengthen disproportionately. They become increasingly coiled and their tips approach the uterine epithelium more closely. This leads to a slowing of the circulation in the superficial strata with some vasodilation. Immediately before the menstrual flow, these vessels begin to constrict intermittently, causing stasis of the blood and anaemia of the superficial strata. During the periods of relaxation of the vessels, blood escapes from the devitalized capillaries and veins, causing the menstrual blood loss. The breakdown of the endometrium is a consequence of the reducing levels of progesterone and oestrogen as the corpus luteum degenerates.

## PREGNANCY AND PARTURITION

During pregnancy, many morphological changes occur in the female reproductive system and associated abdominal structures. The uterus enlarges to accommodate the developing fetus and placenta, and various alterations take place in the pelvic walls, floor and contents that allow for this expansion, and which anticipate parturition. At the end of gestation, dramatic changes occur that facilitate the passage of the baby through the birth canal and, subsequently, allow the pelvic organs to return to the non-pregnant state (involution).

On average, human gestation is approximately 280 days (or 40 weeks) from the date of the last menstrual period (LMP) (Ch. 14). However, as the menstrual history can often be inaccurate due to cycle irregularity or inaccurate recollection, an accurate gestational age can be calculated by ultrasound measurement of the fetal crown-rump length in the first trimester (Fig. 77.39). A discrepancy of more than 5-7 days from the LMP-estimated age is usually cause to revise the estimated date of confinement. For women presenting after the first trimester, gestational dating can be based on other sonographically obtained fetal biometric measurements, such as the fetal biparietal diameter, head circumference and femur length, although precision gradually decreases later in pregnancy (see Fig. 14.4). The increased accuracy of gestational dating using sonographic fetal biometry rather than menstrual history alone has significantly reduced the number of pregnancies requiring induction of labour for post-term women.

## UTERUS IN PREGNANCY

The function of the uterus in pregnancy is to retain the developing fetus and to provide a protected environment until a stage at which the fetus is capable of surviving ex utero. The uterus must grow, facilitate delivery of the fetus and then involute.

The uterus grows dramatically during pregnancy, increasing in weight from about 50 g at the beginning of pregnancy to up to 1 kg at term. Most of the weight gain is the result of increased vascularity and fluid retention in the myometrium. The increased growth of the uterine wall is driven by a combination of mechanical stretching and endocrine input. The mechanical load that increasing gestation imposes on the uterine wall induces hypertrophy of uterine smooth muscle cells and is the major stimulus that increases smooth muscle mass. Some hyperplasia occurs early on in pregnancy, mainly from the growth of the media of the myometrial arteries and veins. The myometrium is relatively unresponsive to additional endocrine stimulation during most of pregnancy, a relative quiescence that is, in part, attributed to progesterone.

Fig. 77.39 Transabdominal ultrasound at 12 weeks, showing measurement of the crown-rump length to calculate the gestational age

However, a number of growth factors, e.g. insulin-like growth factor-1 (IGF-1), have been identified, which interact with oestrogen in promoting uterine growth. The myometrium thins with advancing gestation from $2-3 \mathrm{~cm}$ thick in early pregnancy to $1-2 \mathrm{~cm}$ at term.

The upper third of the cervix (isthmus) is gradually taken up into the uterine body during the second month to form the 'lower segment' (Fig. 77.40). The isthmus hypertrophies like the uterine body during the first trimester and triples in length to about 3 cm . From the second trimester, the wall of the isthmus and that of the body are the same thickness and their junction is no longer visible externally. This condition persists until the middle of the third trimester, when the lower uterine segment thins considerably to less than 1 cm in thickness. The thicker myometrium above this transition is the main contractile portion of the uterus that will generate the expulsive forces during labour; the thin lower uterine segment, which begins just below the vesico-uterine pouch and is thought to correspond to the level of the anatomical internal os, is more compliant and allows for the descent of the fetus in late pregnancy and during labour. As the lower uterine segment is thinner and less vascular than the upper uterus, it is the preferred site of incision during a caesarean section. In addition, because it is less contractile, there is a lower risk of uterine rupture in subsequent pregnancies, compared with an incision made in the body of the uterus during a 'classic' caesarean section.

The growing uterus generally emerges from the pelvis by the twelfth week of pregnancy and can be palpated on the maternal abdomen just above the pubic symphysis. By the twentieth week of pregnancy, the uterine fundus is at the level of the umbilicus and reaches the xiphisternum by 36 weeks. After 24 weeks of gestation, the distance between the pubic symphysis and the uterine fundus generally corresponds to the number of gestational weeks and is often used in clinical care as a screening method to detect a pregnancy that is measuring suspiciously larger or smaller than expected. If there is more than a 2 cm discrepancy, a more accurate, sonographic assessment of fetal size and amniotic fluid volume is indicated.

## Cervix and pregnancy

During pregnancy, the uterine cervix is a relatively rigid, fibromuscular structure that retains the developing fetus within the uterus. The rigidity of the cervix appears to be related to the orientation of its collagen fibres within a regular connective tissue matrix. The cervix gradually softens and shortens in the weeks preceding labour. During active labour, the cervix dilates to allow the fetus to descend through the birth canal. The exact processes that allow softening, effacement and dilation of the cervix are unclear, but are believed to include remodelling of the connective tissue matrix, probably mediated by an increase in the activity of enzymes such as matrix metalloproteinase 1, a reduction in collagen concentration, a significant increase in the water content in the cervix, an infiltration of macrophages and neutrophils, and an increased level of apoptosis.

Transvaginal ultrasound examination allows for a robust evaluation of the cervix during pregnancy. Cervical length, dilation of the internal os and bulging of the membranes into the canal can all be assessed (Fig. 77.41). Detection of a shortened cervical length in mid-gestation using transvaginal ultrasound is a strong risk factor for premature delivery and has been used clinically to identify women at high risk of preterm delivery in order to plan appropriate management (Fonseca et al 2007, Hassan et al 2011, Owen et al 2009). Emerging sonographic and MRI technologies are being used to investigate both the biomechanical properties and the microstructure of the cervix in pregnancy and promise to shed light on the poorly understood mechanisms involved in both normal and pathological cervical shortening in human pregnancy (Feltovich et al 2012, House et al 2013).

## Relations of the uterus in pregnancy

With uterine expansion, the ovaries and uterine tubes are displaced upwards and laterally. The round ligaments become hypertrophied and their course from the cornual regions of the uterus down to the internal inguinal ring becomes more vertical. The broad ligament tends to open out to accommodate the massive increase in the sizes of the uterine and ovarian vessels. The uterine veins, in particular, can reach about 1 cm in diameter and they appear to act as a significant reservoir for blood during uterine contractions. Lymphatics and nerves expand their territories (the significance of this increased innervation is not clear because paraplegic women are able to labour normally, albeit painlessly). Later in pregnancy, the increase in intra-abdominal pressure produced by the gravid uterus may produce eversion of the umbilicus. On the skin over

Fig. 77.40 A frontal view of the uterus, showing the location and extent of the body, isthmus and cervix in the non-gravid and gravid uterus at different stages in gestation. The isthmus forms the lower uterine segment with advancing gestation.

Fig. 77.41 Transvaginal ultrasound at 36 weeks. A, Measurement of cervical length. B, Posterior placenta praevia 18.5 mm from the internal os. C, A placenta completely covering the internal cervical os, consistent with a complete placenta praevia.
the abdomen, a combination of stretching and hormonal changes may produce stretch marks (striae gravidarum). In multiparous patients, diastasis (diverification) of right and left rectus abdominis may occur to accommodate the enlarging uterine fundus further. In the supine position, the gravid uterus can cause aortocaval compression, leading to reduced venous return to the heart and decreased cardiac output. In some women, this can lead to symptomatic hypotension and symptoms of nausea and faintness. These symptoms are minimized if the woman lies on her left side, thereby deviating the gravid uterus and reducing compression of the inferior vena cava.

The jejunum, ileum and transverse colon tend to be displaced upwards by the enlarging uterus, whereas the caecum and appendix are displaced to the right, and the sigmoid colon posteriorly and to the left. Upward and lateral displacement of the appendix in later pregnancy can cause difficulties in the diagnosis of appendicitis. The ureters are pushed laterally by the enlarging uterus and, in late pregnancy, can be compressed at the level of the pelvic brim, resulting in hydronephrosis and loin pain. However, mild ureteric dilation is normal in pregnancy, and is caused by progesterone-induced relaxation of smooth muscle in the ureteric walls. The axis of the uterus is often dextrorotated by the presence of the sigmoid colon; this rotation must be considered when performing a hysterotomy at the time of caesarean section to avoid injuring the large uterine vessels located bilaterally.

## PELVIC CHANGES IN PREGNANCY

The presence of a pregnant uterus results in a change in the centre of gravity of the body, especially in late pregnancy. In order to compensate for this, the mother tends to straighten her cervical and thoracic spine, and throw her shoulders back, resulting in a compensatory lumbar lordosis. There is also a softening of the pubic symphysis and sacroiliac joints, caused by production of relaxin and other pregnancy hormones, leading to mild pelvic instability that may result in a waddling gait. Softening also produces an increase in pelvic diameter, which is of benefit during the time of labour. Significant joint relaxation may lead to pubic symphysis diastasis, which, in severe cases, may produce debilitating pain during walking.

Advances in three-dimensional ultrasound imaging permit the realtime visualization of the anatomical relationships and adaptations of the pelvic floor in pregnancy. They also enable detection of pelvic floor injury that might lead to symptomatic postpartum pelvic floor prolapse (Dietz and Lanzarone 2005, Shek et al 2012).

## PLACENTAL DEVELOPMENT

Placental attachment to the uterus occurs at the point where the blastocyst becomes embedded, and is determined by a multitude of molecular signalling pathways. In early pregnancy, the placental disc occupies a large proportion of the uterine cavity and will often appear to be situated near the internal os. In the majority of cases, growth and stretching of the uterus will usually draw the placenta upwards, away from the cervix, by the end of pregnancy.

In about $1 \%$ of pregnancies, the position of the placenta will remain over, or in close proximity to, the internal cervical os at the end of pregnancy (see Fig. 77.41B; Fig. 77.42). This condition is called placenta praevia and can be associated with vaginal bleeding during pregnancy and labour. If the placenta covers the internal os, or the lower edge is less than $1-2 \mathrm{~cm}$ from the internal os, delivery by caesarean section is generally indicated.

Normal trophoblastic development includes the remodelling of maternal spiral arterioles to allow for low-resistance flow into the intervillous space. Thus, the uteroplacental vasculature is a low-resistance, high-capacitance system. Antenatal ultrasound Doppler velocimetry can be used during pregnancy to evaluate the resistance to flow in both the uterine and the umbilical arteries, and may be helpful in the management of high-risk pregnancies (Fig. 77.43)

Abnormally invasive placentation can occur when trophoblastic tissue invades through the decidua basalis and reaches the myometrium; this can lead to a morbidly adherent placenta and significant maternal morbidity. This condition, placenta accreta, occurs in approximately 3 per 1000 births. When the trophoblastic tissue invades the myometrium, it is referred to as placenta increta; if the placental tissue reaches the uterine serosa, it is called a placenta percreta. In extreme cases, a placenta percreta can also invade into the maternal bladder mucosa. These conditions often require a hysterectomy. Prior uterine surgery, especially multiple prior caesarean sections, is the most significant risk factor (Fig. 77.44).

Fig. 77.43 Doppler examination of the maternal and fetal circulation in pregnancy. A pulsed Doppler showing normal waveforms in the umbilical arteries at 28 weeks.

## LABOUR

The onset of labour is defined as the combination of regular uterine contractions that are of sufficient intensity to produce progressive effacement and dilation of the cervix. The process of labour is described in three main stages.

## First stage

The first stage of labour is the period during which the cervix progressively dilates until the fetus is able to descend into the birth canal and there is no longer any cervix palpable on vaginal examination. There is little change in the uterine volume because myometrial contractions are

Fig. 77.44 A gross photograph taken at the time of caesarean section in a patient with a placenta accreta. Note the hypervascularity caused by the placental tissue invading into, and almost through, the myometrial layer of the lower uterine segment, which is still covered with its serosal layer.
isometric, and so there is minimal shortening of the muscle fibres. Progress is determined by the equilibrium between forces generated by myometrial contractions, especially from the fundus, and the resistance of the cervix.

## Second stage

The second stage of labour begins once the cervix is fully dilated, and ends with the delivery of the fetus. Cervical resistance is lost and myometrial activity results in isometric contractions that aid descent of the fetus in the birth canal. The head of the fetus usually enters the pelvis with the occiput facing laterally. As the head descends further, the occiput contacts the gutter-shaped pelvic floor formed by levator ani and this promotes flexion and rotation of the occiput to the anterior position. With further descent, the occiput escapes under the pubic symphysis and the head is born by extension. At this point, the head of the fetus regains its normal relationship with its shoulders, and slight rotation (or restitution) of the head is seen. Further external rotation occurs as the leading shoulder is directed medially by the maternal pelvic floor. The body of the fetus is now born by lateral flexion as one shoulder slips underneath the symphysis and the posterior shoulder is drawn over the frenulum.

## Third stage

The third stage of labour is the time from delivery of the fetus until delivery of the placenta. Prior to separation of the placenta, a large proportion of the mother's cardiac output passes through the uterine circulation. After separation in the third stage of labour, maternal exsanguination is only prevented by marked uterine contraction; the crisscrossing myometrial fibres act as a tourniquet, restricting blood flow to the area that was the placental site. This process is usually expedited clinically by the administration of oxytocic drugs in an attempt to limit maternal blood loss. Any condition that predisposes to poor uterine contraction, such as retained placental tissue, will increase the likelihood of postpartum haemorrhage.

## Placenta after delivery

Separation of the placenta from the uterine wall takes place along the plane of the stratum spongiosum and extends beyond the placental area, detaching the villous placenta, with associated fibrinoid matrix and small amounts of decidua basalis; the chorio-amnion, together with a superficial layer of the fused decidua capsularis; and the decidua parietalis. When the placenta and membranes have been expelled, a thin layer of stratum spongiosum is left lining the uterus; it soon degenerates and is cast off in the early part of the puerperium. A new epithelial lining is regenerated from the remaining stratum basalis. The expelled placenta is a flattened discoid mass with an approximately circular or oval outline (Fig. 77.45). It has an average volume of 500 ml (range 200-950 ml), a weight of 470 g (range 200-800 g), a diameter of 185 mm (range $150-200 \mathrm{~mm}$ ), a thickness of 23 mm

Fig. 77.45 The fetal surface of a recently delivered placenta. The spiral umbilical vessels in the umbilical cord and their radiating branches are seen through the transparent amnion. The maternal surface is exposed in the lower and right corner of the figure. Note the fringes of amnion and chorion, the majority of which have been cut away near the placental margin.
(range $10-40 \mathrm{~mm}$ ), and a surface area of approximately $30,000 \mathrm{~mm}^{2}$. It is thickest at its centre (the original embryonic pole), and rapidly thins towards its periphery, where it continues as the chorion laeve. The size of the placenta correlates well with the birth weight of the neonate.

Macroscopically, the fetal or inner surface, covered by amnion, is smooth, shiny and transparent, so that the mottled appearance of the subjacent chorion, to which it is closely applied, can be seen. The umbilical cord is usually attached near the centre of the fetal surface, and branches of the umbilical vessels radiate out under the amnion from this point; the veins are deeper and larger than the arteries. The maternal surface of the placenta is finely granular and mapped into some 15-30 lobes by a series of fissures or grooves. The placental lobes, which are often somewhat loosely termed cotyledons, correspond, in large measure, to the major branches of the umbilical vessels. The grooves correspond to the bases of incomplete placental septa, which become increasingly prominent from the third month onwards. They extend from the maternal aspect of the intervillous space (the basal plate) towards the chorionic plate (see Fig. 9.5) but do not quite reach it. The septa are complex structures composed of components of the cytotrophoblastic shell and residual syncytium, together with maternally derived material, including decidual cells, occasional blood vessels and gland remnants, collagenous and fibrinoid extracellular matrix, and, in the later months of pregnancy, foci of degeneration.

In multiple pregnancies, the number of placentas is determined by the zygosity; for example, in twin gestations, dizygotic pregnancies will always have two placentas (dichorionic). Monozygotic pregnancies usually have a single placenta (monochorionic), but about one-third will have two placentas; the number is determined by the timing of splitting of the embryonic mass (see Ch. 8 and Fig. 8.9). If the split occurs within 3 days of fertilization, each fetus will have its own placenta and amniotic sac (dichorionic diamniotic); splitting after the third day following fertilization results in a monochorionic diamniotic pregnancy (two amniotic sacs) and vascular communication within the two placental circulations (Fig. 77.46); splitting after the ninth day results in a single placenta and single amniotic sac (monochorionic monoamniotic); and splitting after the twelfth day results in conjoined twins.

## Placental variations

The umbilical cord is usually attached near the centre of the placenta, although it can occasionally insert more laterally and closer to the placental margin; this condition is known as a battledore placenta (Fig. 77.47). Occasionally, the cord fails to reach the placenta itself and ends in the membranes as a velamentous insertion. When insertion of the cord is velamentous, the larger branches of the umbilical vessels traverse the membranes before they reach and ramify on the placenta

Fig. 77.46 A vascular cast from a monochorionic diamniotic twin pregnancy, showing vascular communications between both placentas. (Courtesy of Dr Ling Wee, University College London Hospital.)

Fig. 77.47 A battledore placenta showing the marginal insertion of the umbilical cord into the placenta. (Courtesy of Dr Michael Ashworth, Consultant Histopathologist, Great Ormond Street Hospital for Children, London.)
(Fig. 77.48). They travel unprotected through the membranes to the placenta, and this puts the fetus at risk because compression or tearing of the vessels can disrupt blood flow to and from the fetus. This can be particularly problematic when the vessels present themselves across the cervical os, a condition called vaso praevia. An accessory (succenturiate) placental lobe is occasionally present, connected to the main organ by membranes and blood vessels. If it is inadvertently retained in utero after delivery of the main placental mass, it can cause postpartum haemorrhage or infection. Other variations include placenta membranacea, in which villous stems and their branches persist over the whole chorion; and placenta circumvallata, where the placental margin is undercut by a deep groove caused by an abnormally central insertion of the membranes (Fig. 77.49).

# The neurovascular bundles of the prostate 

Robert P Myers

The neurovascular bundles are discrete anatomical structures flanking the posterolateral surfaces of the prostate. They contain autonomic nerves that become cavernous nerves once they enter the corpora cavernosa and corpus spongiosum more distally. The neurovascular bundles are so named because, where they course along the prostate, the bundles, which serve as a visual marker in radical prostatectomies, contain small arteries and veins, as well as nerves (Walsh et al 1983). They extend distally from the vascular pedicle at the vesicoprostatic junction and base of the prostate, and reach all the way to the prostatic apex. Nerves in the neurovascular bundles are derived from the pelvic plexus.

The pelvic plexus consists of sympathetic and parasympathetic components (Fig. 8.1.1). A major portion of the plexus consists of the inferior hypogastric plexus, where the sympathetic innervation is centred on the lateral surfaces of the rectum, superior and posterior to the seminal vesicles. Nerve roots comprising the parasympathetic portion exit sacral foramina S2-4 and join and intermix with the hypogastric plexus. Both sympathetic and parasympathetic nerve fibres entering the neurovascular bundles emerge from the pelvic plexus to embrace both the lateral surfaces of the seminal vesicles and the posterolateral surfaces of the prostate. Proximal to the vascular pedicle to the prostate, the nerves course particularly close to the lateral surfaces

Fig. 8.1.1 Pelvic plexus origins with ramifications distally into the prostatic and cavernous plexuses, with autonomic nerves to seminal vesicles, bladder and rectum. Variable configurations include prostate shape with blunt apex to accentuate the inward turn of the neurovascular bundle towards the prostato-urethral junction, and anterior $90^{\circ}$ prostatic urethral angulation into the vesical neck. Inset: radical prostatectomy specimen. (Used with permission of Mayo Foundation for Medical Education and Research.)
of the seminal vesicles (Lunacek et al 2005, Schlegel and Walsh 1987), and thus mobilization of the seminal vesicles during radical prostatectomy is of potential risk to nerve integrity. On occasion, nerves run in a mass anterior to the seminal vesicles (van der Zypen 1988). As nerves from the pelvic plexus run distally, branches are given off to the bladder, ureters, seminal vesicles, vasa deferentia, levator ani, rectum, prostate and membranous urethra (Walsh et al 1983, Costello et al 2004, Durward 1953, Arai 2006). Individual variation in the distribution of pelvic plexus nerves relative to where they join the neurovascular bundle is well recognized, and four distribution types have been identified by intraoperative nerve stimulation and measurement of concomitant intracavernosal corporal body pressures (Takenaka et al 2011). These four tentative nerve distribution types have not yet been corroborated by gross dissection specimens.

Residual autonomic branches of the neurovascular bundles pass beneath the pubic arch to innervate the corpora cavernosa and corpus spongiosum as the cavernous nerves (Walsh et al 1983, Durward 1953, Paick et al 1993, Alsaid et al 2011, Müller 1836). Nerves branch both posteriorly, into the corpus spongiosum, and anterolaterally, to intermesh with the dorsal sensory nerves of the penis; the latter act as a scaffold for both proximal and distal entry of cavernous nerve fibres into the cavernous bodies.

After radical prostatectomy with prostate removed, the preserved neurovascular bundles sit prominently on the rectal surface and course distally from the bladder to embrace either side of the protruding membranous urethra and external striated urethral sphincter (rhabdosphincter) (Fig. 8.1.2).

Within neurovascular bundles next to the prostate, the major nerves vary in their distance from the underlying prostatic fascia or capsule. If they are close, they are more easily injured in the lateral dissection of the neurovascular bundles during radical prostatectomy. If they run next to a bleeding vessel that needs to be secured, there is greater likelihood that an adjacent nerve may be injured in the process. Within the neurovascular bundles, cross-sectional nerve diameters of $0.04-0.37 \mathrm{~mm}$ have been measured with a cross-reference human hair 0.02 mm in diameter (Myers 2002a). The periprostatic fascia is multilayered, and compartmentalizes the neurovascular bundles on cross-section; proerectile nerves are situated more posteriorly (Costello et al 2004).

With the posterior Denonvilliers' fascia removed, cadaveric dissection shows the prostate situated literally in a basket of autonomic nerves (Costello et al 2004). The disposition of this basket may be altered as a consequence of the development of benign prostatic hyperplasia, which tends to favour a more posterolateral displacement of the neurovascular bundles. Anteriorly, the top edges of the basket abut the lateral aspect of the dorsal vascular (venous) complex and the detrusor apron (Myers 2002b), both of which cover the anterolateral prostate. Gross dissection demonstrates the rich abundance of nerves both laterally and posteriorly, with evident decussation of some nerves at the prostato-urethral junction posteriorly (Costello et al 2004, Takenaka
et al 2005). This point of decussation is in proximity to the triangular tip of Denonvilliers' fascia as it merges to join the posterior median raphe of the urethra. On the basis of anatomical study, passing a needle posteriorly close to this junction of the neurovascular bundles (Rocco stitch; Rocco et al 2007) must be done carefully because there is certain risk of nerve entrapment. The basket configuration makes the intrafascial dissection and removal of the prostate the most nerve-preserving technique (Walz et al 2010).

In an anatomical study of transverse prostate sections, Kiyoshima and colleagues (2004) found that, in approximately half of prostates, the nerves were in the typical bundle configuration dominant at the 4 and 5 o'clock and the 7 and 8 o'clock positions, as was originally described. However, in the other half of the specimens, the nerves were more evenly distributed on the posterolateral surfaces of the prostate. This finding has affected the conduct of nerve-sparing radical retropubic prostatectomies calling for mobilization of the nerves with initial high lateral prostate fascial incision and release (Montorsi et al 2005). This manœeuvre allows as many nerves as possible to be mobilized laterally away from the prostate, even if the major nerves are still found at the 4 and 5 o'clock positions, as based on stimulation study (Kaiho et al 2009). While dominance of nerves is demonstrated rectolaterally, onefifth to one-fourth of nerves have been found along the ventral circumference of the prostate (Eichelberg et al 2007).

As autonomic nerves pass the prostato-urethral junction with a medial swing inwards, hugging the prostate apex at the prostatourethral junction, they approach very close to the rhabdosphincter and membranous urethra; anterolateral fibres extend as far anteriorly as the 10 and 2 o'clock positions en route to becoming true cavernous nerves (Costello et al 2004, Lepor et al 1985). In radical retropubic prostatectomies, exceptional care must be taken to secure and transect the dorsal vascular complex without trapping these anteriorly directed nerve fibres with suture material or transecting them with blunt dissection manœeuvres and instruments passed distal to the prostato-urethral junction. An immunohistochemical study found $15 \%$ of sympathetic and $6.8 \%$ of parasympathetic fibres disposed anterolaterally at the prostate apex; the distribution distal to the apex was not detailed (Costello et al 2011). Beyond the prostatic plexus, a cavernous plexus has been described that is mixed within the anterior rhabdosphincter, distal to which fibres pass under the symphysis embedded in fibrous tissue connecting the penile crura with the pubic arcuate ligament (Müller 1836).

For years, patients undergoing radical prostatectomy for localized prostate cancer were almost always rendered impotent. Interest in preserving potency was clear but the success rate was virtually nil; when it was reported, e.g. in radical perineal prostatectomy, the reason was elusive (Finkle 1975). When surgery was the chosen method of treatment, patients generally knew that erectile dysfunction or loss would be likely to be an outcome in the quest to cure their cancer. This sad situation was to be reversed in the 1980s.

Fig. 8.1.2 A-B, With the prostate removed, two neurovascular bundles (NVB), left and right, are shown as gross anatomical structures, isolated on the rectal surface (R) as they course distally to embrace the transected striated sphincter (SS) and membranous urethra (U). Other abbreviations: B, bladder; LA, levator ani; NVT, neurovascular triangle. (A, Adapted with permission from Myers RP, Cheville JC, Pawlina W; Making anatomic terminology of the prostate and contiguous structures clinically useful: historical review and suggestions for revision in the 21st century. Clinical Anatomy. 2010 Jan;23(1):18-29. B, Used with permission of Mayo Foundation for Medical Education and Research.)

Fig. 8.1.3 A-B, After haemostatic clips are applied to secure the prostate vascular pedicle, a scissor cut releases the left neurovascular bundle (NVB) isolated by combined retrograde and anterograde dissection during robotic-assisted laparoscopic prostatectomy. Other abbreviations: B, bladder; NVT, neurovascular triangle; P, prostate; SV, seminal vesicle. (A, Video frame courtesy of V. Patel, MD, FACS, University of Central Florida, Altamonte Springs, Florida. Used with permission. B, Used with permission of Mayo Foundation for Medical Education and Research.)

Finding the reason for the dysfunction and the means of preventing it was the focus of attention of Walsh and Donker (1982), who independently reported the course of autonomic nerves running distally from the pelvic plexus, some of which became cavernous nerves of the penis. Their work corroborated that of Müller (1836), who, on the basis of dissecting two male cadavers, described a cavernous plexus that was a continuation of the prostatic plexus; major and minor cavernous nerves infiltrated the corpora cavernosa and corpus spongiosum, ultimately and intimately connecting in their terminal distribution to the penile helicine arteries that are responsible for erection.

In surgery devised to preserve potency successfully (Quinlan et al 1991), the neurovascular bundles must be dissected bilaterally away from the posterolateral aspects of the prostate (Fig. 8.1.3). As originally defined and emphasized by Walsh and colleagues (1983), the critical technical step in preservation of the neurovascular bundles in radical prostatectomy is to ligate the vascular pedicles to the inferior bladder and prostate in a line anterior to the course of the neurovascular bundles. When the procedure is done correctly, the result is a neurovascular triangle on each side in the region of the vascular pedicle at the junction of the prostate and the seminal vesicles (see Figs 8.1.2 and 8.1.3) (Tewari et al 2006).

Any role of nerves within the neurovascular bundles controlling urinary continence is controversial. Nerve fibres from the neurovascular bundles that enter the striated urethral sphincter may be simply passing through the sphincter to innervate the smooth muscle sphincter (lissosphincter) of the membranous urethra. The idea that autonomic nerves would ever innervate the specialized striated and slow-twitch rhabdosphincter is particularly contentious. The fact that patients who have surgery with preservation of neurovascular bundles seem to do better has never been separated from the confounder that they are left
with more functional profile, membranous urethral sphincteric length (Presti et al 1990). Pudendal innervation of the sphincter complex from below is well recognized (Hollabaugh et al 1997), and patients undergoing prostate removal with no preservation of their neurovascular bundles can experience perfect urinary control.

The neurovascular bundles are important. In surgery, patients subjected to the least injury by virtue of maintaining the full number and integrity of all neurovascular bundle-related autonomic nerves, as well as those disposed to be cavernous in destination, will do best in terms of recovery of their erectile function and, possibly, urinary control. Despite universal recognition by the urological community, neurovascular bundles have yet to be recognized in official anatomical nomenclature (International Anatomical Nomenclature Committee 1989, Federative Committee on Anatomical Terminology 1998). With this in mind, a suggestion has been offered to update terminology with the Latin fasciculus neurovascularis prostatae [dexter et sinister] and, in English, neurovascular bundle of prostate [right and left] (Myers et al 2010). Official recognition of these grossly reproducible structures would put anatomists, urologists, surgical pathologists and other students of anatomy on the same page.

## Acknowledgement

# Real-time microscopy of the upper and lower gastrointestinal tract and the hepatobiliarypancreatic system during endoscopy 

## Introduction

Real-time histology during ongoing endoscopy has been a goal of endoscopists since the very beginning of modern endoscopy. Technological advancements have brought forward endomicroscopy and endocytoscopy, two microscopic techniques that provide high-resolution (sub) cellular images of the mucosa with approximately 1000 -fold magnification in vivo (Goetz et al 2014). These novel techniques have been extensively studied for diseases of the upper gastrointestinal tract and the lower gastrointestinal tract, and also, more recently, for intrabiliary and intrapancreatic imaging. Imaging relies on the application of fluorescent agents (mostly fluorescein) for endomicroscopy or of topical dyes for endocytoscopy.

Real-time virtual histology ('optical biopsy') serves several needs in clinical medicine: first, it provides an immediate diagnosis for the welltrained endoscopist. This limits the need for biopsies and helps to minimize sampling error. Second, microscopic imaging can predict depth of invasion of lesions or assist in guiding immediate endoscopic resection. Third, endomicroscopy has also been successfully evaluated for functional and molecular imaging of the gastrointestinal mucosa, providing deep insights into normal tissue function and disease pathology in translational research.

## Technology and devices

For confocal laser endomicroscopy (CLE), two devices are available for clinical use: in an endoscope-based approach (eCLE), a miniaturized confocal scanner is integrated into the distal end of a dedicated endoscope, whereas in probe-based CLE (pCLE), a flexible probe can be introduced into the working channel of different endoscopes (Fig. 8.2.1). eCLE provides images with higher resolution and user-adaptable imaging plane depth. pCLE is more flexible for use 'on demand', and thin probes can be introduced into the bile or pancreatic duct. Fluorescein is the contrast agent most commonly used ( $5 \mathrm{ml} / 10 \%$ intravenously), together with blue laser light excitation, but - since fluorescein does not stain nuclei - acriflavine and cresyl violet have also been studied for topical application. CLE provides transverse optical sections, i.e. orientated at $90^{\circ}$ to conventional histopathology, at the tissue surface or below (up to $250 \mu \mathrm{~m}$ ).

Endocytoscopy is an adaption of contact white light microscopy with lens-based magnification ('ultrahigh zoom-endoscopy'). After intravital tissue staining, high-resolution images of the uppermost mucosal layer (including nuclei) are visible. Systems are currently not marketed, limiting the broad clinical application of endocytoscopy.

## Upper gastrointestinal tract

In the healthy upper gastrointestinal tract, squamous epithelium of the oesophagus, gastric mucosa and duodenal villi can be easily visualized and differentiated with CLE by their characteristic structural features, even without visualization of nuclei (Fig. 8.2.2). In Barrett's oesophagus, the visualization of goblet cells is the hallmark of intestinal metaplasia. Barrett's-associated neoplasia was diagnosed in a pilot trial with high accuracy (Kiesslich et al 2006) (Fig. 8.2.3). When compared to untargeted quadrant biopsies, the yield per biopsy was significantly higher when eCLE was used, and two-thirds of patients did not need any biopsy based on normal optical biopsies (Dunbar et al 2009). Similarly, pCLE had a high negative predictive value for Barrett's oesophagus (Pohl et al 2008). Since pan-endomicroscopy of larger mucosal regions is not feasible, CLE is often used in conjunction with chromoendoscopy to pinpoint the region of interest to be examined subsequently by CLE. In squamous cell carcinoma, eCLE was able to predict malignant histology in unstained regions after chromoendoscopy with Lugol's solution (Pech et al 2008).

Fig. 8.2.1 For endomicroscopy, two systems are available: for probebased imaging (right), a thin confocal probe is used together with a conventional endoscope; for endoscope-integrated imaging (left), a miniaturized scanner is integrated into a dedicated endoscope (protruding tip). See text for details.

In the stomach, studies have addressed the use of CLE to diagnose gastritis (Wang et al 2010), Helicobacter pylori (Kiesslich et al 2005), intestinal metaplasia (Guo et al 2008), and gastric hyperplastic and adenomatous polyps (Li et al 2010). In a large trial, eCLE was able to diagnose high-grade neoplasia and superficial gastric cancer in a highrisk population of 1786 patients (Li et al 2011). CLE can also help to guide intervention and minimize sampling error prior to resection

Fig．8．2．2 Normal microscopic anatomy of the gastrointestinal tract．A，In the squamous cell lining of the oesophagus，intrapapillary capillary loops （arrows）are orientated perpendicular to the tissue surface in a corkscrew fashion．Bright vessel contrast is found after intravenous fluorescein injection； black dots within the vessel lumen correspond to unstained red blood cells．B，The gastric mucosa（antrum）typically shows a cobblestone－like surface pattern；in subsurface sections，capillaries become visible（arrows）．C，In the terminal ileum，the villi are easily seen．Below the columnar epithelium with goblet cells（arrowheads），separated by the basal membrane，hairpin－like capillaries（arrows）can be seen within the lamina propria．D，The normal colon shows crypts of fairly even size with an unstained（black）central lumen（arrows），surrounded by goblet cells with dark mucin inclusions（arrowheads）that can be optically sectioned parallel（drop－like shape）or vertical（round shape）to the mucosa．Original magnification $\times 1000$ ．
（Jeon et al 2011）or surveillance and reintervention after resection（Ji et al 2011）．

## Lower gastrointestinal tract

The first study with eCLE in patients was performed in screening colon－ oscopy，establishing criteria for normal mucosa，hyperplasia and neo－ plasia（Kiesslich et al 2004）that were followed by a similar classification system for pCLE（Kuiper et al 2011）（see Fig．8．2．2）．In ulcerative colitis， combination of eCLE with chromoendoscopy found a four－fold increase in the number of intraepithelial neoplasias with a 10 －fold reduction in biopsies compared to a quadrant biopsy protocol（Kiesslich et al 2007a），corroborating the concept of targeted，＇smart＇biopsies for optimized surveillance．CLE competes with non－microscopic tech－
niques for prediction of histology，such as virtual chromoendoscopy and high－definition endoscopy，but shows higher accuracy（Buchner et al 2010）．

Endocytoscopy has mostly been studied in the lower gastrointestinal tract．A high accuracy and kappa agreement with histology have been found for the diagnosis of colorectal lesions（Sasajima et al 2006）． Endocytoscopy was non－inferior to histopathology but results were available immediately（Mori et al 2013）．

## Hepatobiliary and pancreatic system

Indeterminate biliary strictures pose a clinical dilemma and the approach to obtain specimens for histopathology is often limited．CLE probes that are advanced into the bile duct via duodenoscopes have

Fig. 8.2.3 A, In Barrett's oesophagus, the normal squamous epithelium is replaced by specialized intestinal metaplasia that resembles mucosa of the small intestine (compare Fig. 8.2.2C). The double lining at the surface of the villi (arrows) corresponds to the brush border, while black dots (arrowheads) indicate mucin inclusions in goblet cells, establishing the diagnosis of Barrett's oesophagus during endoscopy. B, In Barrett's-associated neoplasia (same patient), the tissue structure is progressively lost. Residual gland structures are visible (arrows), and white contrast extravasation into the solid tissue indicates increased vessel leakiness of tumour-associated neoangiogenesis. Original magnification $\times 1000$.
demonstrated increased sensitivity in a first trial (Meining et al 2008). Such thin CLE probes were also used for imaging in the pancreatic duct (Meining et al 2012) and were advanced through needles targeted by endoscopic ultrasonography to pancreatic cystic lesions (Konda et al 2011). Rigid laparoscopic CLE devices have been used for microscopic liver imaging (Goetz et al 2010a). Interpretation of images from the hepatobiliary and pancreatic systems is less straightforward since structural resolution is lower than in the gastrointestinal tract. The final clinical significance, therefore, remains to be established in larger trials.

## Perspective

The introduction of CLE has augmented translational research. To date, no other device is able to study microscopic events dynamically in the natural micromilieu, free of artefacts and without disrupting tissue integrity or perfusion. CLE was able to visualize intramucosal bacteria in patients with inflammatory bowel diseases (IBD) (Moussata et al 2011), exemplifying the high resolution that can be obtained in vivo. Gaps smaller than a single cell, punctuating the epithelial barrier of the healthy gut mucosa can be visualized, and probably correspond to residual microlesions after normal cell shedding (Kiesslich et al 2007b). Increased shedding was found in IBD (Liu et al 2011). Functional impairment of such gaps in endoscopically and histopathologically normal mucosa predicted IBD flares (Kiesslich et al 2012), potentially constituting the microarchitectural correlate of the impaired barrier
function. Similarly, in patients with H. pylori-associated gastritis, epithelial barrier damage was predominant: failure to reverse barrier function indicated complications despite H. pylori clearance (Ji et al 2012).

CLE has also been used for molecular imaging (Atreya and Goetz 2013). Fluorescent labelling of single molecules highlighted adenomatous lesions in patients (Hsiung et al 2008, Liu et al 2013). Targeting of specific surface receptors overexpressed on malignant cells has been used as a molecular beacon for colorectal (Goetz et al 2010b) and gastric cancers (Hoetker et al 2012) in murine models, and has been linked to predicting response to targeted therapy (Goetz et al 2013). It is too early to integrate these results into routine clinical protocols. However, they indicate a way to individualizing therapy based on functional and molecular microscopic imaging.

## Summary

In the past 10 years, microscopic imaging during endoscopy has become possible, and multiple trials have evaluated its relevance in imaging in the upper and lower gastrointestinal tracts and, recently, within the hepatobiliary and pancreatic systems. Optical biopsies by microscopic imaging have not replaced (or aimed at replacing) tissue sampling, but can help to target, complement or avoid conventional biopsies, decide on and guide endoscopic resection and, broaden our understanding of microarchitectural and molecular processes within the mucosa of the gastrointestinal tract.

1446Innervation

The structure of the lower limb is specialized for support of the body's weight, locomotion, and maintenance of body stability (balance). Indeed, adaptations for weight-bearing and stability account for the major structural and functional differences between the upper and lower limbs. The inguinal (pelvicrural) and gluteal (buttock) regions are important anatomical junctional zones between the trunk and the lower limb through which longitudinally running nerves and vessels travel (Fig. 78.1). The inguinal region includes the transitional zones between the lower limb and abdominal cavity via the myopectineal orifice (the gap between the inguinal ligament and hip joint) and inguinal canal, and provides a gateway for the passage of various structures. Similarly, the obturator canal allows for the obturator nerve and vessels to traverse between the pelvis and thigh. The gluteal region communicates with the lower limb and the abdominopelvic cavity via the greater sciatic foramen, and with the lower limb and pelvic cavity and perineum via the lesser sciatic foramen.

This chapter will provide general information on the lower limb in two sections. The first section is an overview of the general organization of the lower limb, with particular emphasis on the fasciocutaneous system, distribution of the major blood vessels and lymphatic channels, and the branches of the lumbar and sacral plexuses; it is intended to complement the detailed regional anatomy described in Chapters $80-84$. The second section describes the surface anatomy of the lower
limb, which is especially important to physicians during various surgical and clinical procedures.

## SKIN, FASCIA AND SOFT TISSUES

In the young adult and as an adaptation to weight-bearing, the skin of the lower limb is generally stronger and thicker than that of the upper limb. The soft tissues of the sole of the foot are particularly thickened in order to support weight during standing. The skin of the buttocks and posterior thigh bears weight in the sitting position, and consequently is relatively thick. The skin over the anteromedial aspect of the leg is particularly fragile and vulnerable in the elderly.

## Subcutaneous tissue (tela subcutanea)

The subcutaneous tissue (tela subcutanea; hypodermis) of the lower limb becomes thinner peripherally. It participates in the integrity of the skin and provides support for subcutaneous structures such as superficial veins and cutaneous nerves. It is connected to the adventitia of the superficial veins by thin bands that prevent the displacement of the veins during movement. The hypodermal plexus of arteries and veins

Fig. 78.1 Gateways from the abdomen, pelvis and perineum to the lower limb. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
controls blood flow through the skin, thus helping to regulate body temperature (Sterzi 1910).

The deep fascia of the lower limb is a well-defined layer that forms a tough circumferential 'stocking-like' structure that constrains the musculature (Fig. 78.2). Septa pass from the deep surface of this fascial sheath to the bones within, confining the functional muscle groups within osteofascial compartments. The tough fascia gives additional areas of attachment to the muscles and ensures maximal function. According to Cruveilhier (1841), all aponeurotic fasciae are put under tension by specific myofascial expansions or dedicated muscles. Such thickenings may act functionally as additional tendons. Elsewhere, thickenings in the fascial skeleton form fibrous retinacula where tendons cross joints. The pattern of soft tissue organization has a bearing on the physiological effects of the muscles and is crucial for efficient venous return from the limb. The fascial planes also control and direct the spread of pathological fluids (blood, pus) within the limb and play an important part in determining the degree and direction of displacement seen in long bone fractures.

## Fasciocutaneous system

The fascial septa dictate the pathways of cutaneous arteries, which subsequently perforate and ramify on the fascial 'stocking' before supplying the skin.

## Osteofascial compartments in the lower limb

The muscles of the thigh may be grouped into three compartments according to their function: namely, anterior (extensor), posterior (flexor) and medial (adductor). Only the anterior and posterior compartments possess distinct fascial boundaries. A very definite fascial separation into anterior (extensor), posterior (flexor) and lateral (evertor) compartments exists in the leg, and compartment syndrome is most common in this region (see below). Osteofascial compartments in the foot are described on page 1420 .

Vessels and nerves run through all the osteofascial compartments and supply the muscles contained within them. The muscles acting within these closed compartments assist in maintaining the anti-gravity flow of venous blood.

Fig. 78.2 The deep fascia of the lower limb. A, Anterior view. B, Posterior view. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Compartment syndrome The fascial boundaries that limit the osteofascial compartments are largely inelastic, which means that any condition that leads to an increase in the volume of the compartmental contents, e.g. muscle swelling caused by trauma, haemorrhage or local infection, is likely to cause an increase in intracompartmental pressure. If unrelieved, this increased pressure will lead to compressive occlusion of the vessels in the compartment and consequent ischaemic damage to the nerves and muscles of the compartment, a phenomenon known as compartment syndrome. The normal compartmental pressure of the leg is significantly higher in children than in adults: the average pressure in the compartments varies between 13.3 and 16.6 mmHg in children, compared with 5.2 and 9.7 mmHg in adults (Staudt et al 2008).

The treatment of compartment syndrome relies on reducing abnormally elevated tissue pressure. Surgical decompression of the restricting compartment's fasciae may be necessary; in order to prevent neurovascular injury during a fasciotomy, the exact course of the nerves and vessels within the affected compartment must be known (Apaydin et al 2008).

## BONES AND JOINTS

The bones of the lower limb are the three fused components of the pelvic girdle; the femur and patella (thigh); the tibia and fibula (leg); and the tarsus, metatarsus, phalanges and sesamoid bones (foot) (Fig. 78.3). The pelvic bones (especially the ilium and ischium), femur, tibia and bones of the hindfoot are strong and their external (cortical) and internal (trabecular) structure is adapted for weight-bearing.

The pelvic girdle connects the lower limb to the axial skeleton via the sacroiliac joint, a plane synovial type of joint in which mobility has been sacrificed for stability and strength, to allow for effective weight transmission from the trunk to the lower limb. Anteriorly, the pelvic girdle articulates with the contralateral girdle at the pubic symphysis, a secondary cartilaginous joint that may display a slight degree of mobility during hip and sacroiliac movement, and during childbirth. The hip joint, a synovial ball-and-socket joint, exhibits a very effective compromise between mobility and stability that allows movement in all three orthogonal planes. The more distal joints have gained mobility the expense of stability. The knee joint is a bicompartmental synovial articulation, which occurs mainly between the femur and the tibia, and allows flexion, extension and some medial and lateral rotation of the leg. It is not a true hinge joint because its axes of flexion and extension are variable and there is coupled rotation. The knee joint also includes the articulation between the patella and femur. The tibia and fibula articulate with each other at the superior and inferior tibiofibular joints. The superior joint, a plane synovial joint, allows slight gliding movement only. The inferior joint, a fibrous joint, lies just above the ankle and allows a degree of fibular rotation linked to ankle motion. The ankle (talocrural) joint is formed by the distal ends of the tibia and fibula 'gripping' the talus, and allows dorsiflexion and plantar flexion. There are multiple joints in the foot that may be classified topographically on the basis of whether they are in the hindfoot, midfoot or forefoot. Collectively, these joints allow the complex movements required as the foot fulfils its functional roles as a platform for standing and for shock absorption and propulsion in gait.

Both the knee and ankle are commonly subject to closed injuries, and the relatively superficial location of the knee renders it susceptible to open injury and infection. Although the ankle is frequently injured and is a major load-bearing joint, the incidence of clinically significant degenerative arthritis is surprisingly low when compared with that found in the hip and knee joints.

## MUSCLES

The effects of extension and medial rotation of the limb that occur during fetal development are manifest in the relative positions of the muscle groups in the thigh and the leg, and in the adult pattern of segmental cutaneous innervation (dermatomes). The role of the muscles of the lower limb in the maintenance of equilibrium during locomotion and in stance is rarely emphasized sufficiently. Many of the muscles act frequently or predominantly from their distal attachments. During both stance and locomotion, the distal attachment is often fixed and the proximal attachment is mobile, e.g. the predominant action of gluteus medius is as a pelvic stabilizer rather than as a hip abductor. In contrast, in the upper limb, the proximal muscle attachments are usually fixed and the distal attachments are mobile, an arrangement that is consistent with the prehensile function of the hand. The lower

Fig. 78.3 An overview of the bones of the lower limb. A, Posterior aspect. B, Anterior aspect.
limb contains many muscles that act on more than one joint, and it is unusual for any joint of the lower limb to move in isolation.

Muscles of the lower limb may be subdivided into those of the iliac and gluteal regions, and those of the thigh, leg and foot. Note that in anatomical nomenclature, 'leg' refers to that part of the lower limb between the knee and ankle. The main muscles of the posterior abdominopelvic region are psoas major and iliacus (together called iliopsoas), the major flexors of the hip that run from the lumbar spine and inner surface of the ilium, respectively, to attach distally on to the lesser trochanter of the femur. When present, the much less important psoas minor runs from the lumbar spine to the pubis. The muscles of the gluteal region include the three named gluteal muscles and the deeper short lateral rotators of the hip joint. Gluteus maximus lies most superficially, running from the posterior pelvis to the proximal femur and fascia lata. It is a powerful extensor of the hip joint, acting more often to extend the trunk on the femur than to extend the limb on the trunk. Gluteus medius and minimus, attaching proximally to the outer surface of the ilium and distally to the greater trochanter of the femur, are abductors of the hip; their most important action is to stabilize the pelvis on the femur during locomotion, and they are helped in this
function by tensor fasciae latae, a more anteriorly placed muscle that arises from the anterolateral ilium and inserts via the iliotibial tract on to the proximal tibia. Two of the short lateral rotators of the hip, piriformis and obturator internus, arise from within the pelvis, while the others, obturator externus, the gemelli and quadratus femoris, originate externally; all of these muscles are attached distally to the proximal femur.

The muscles of the thigh lie in three functional compartments. The anterior or extensor compartment includes sartorius and the quadriceps femoris. Sartorius and rectus femoris are attached proximally to the pelvis and can thus act on the hip joint as well as on the knee, whereas the vasti are attached proximally to the femoral shaft and, acting as a unit, are powerful knee extensors. The medial or adductor compartment contains the named adductor muscles and gracilis; pectineus may also be included. These muscles are attached proximally to the anterior aspect of the pelvis, and distally to the femur; gracilis has no femoral attachment, being attached distally to the proximal tibia, while a part of adductor magnus has a proximal attachment to the ischial tuberosity. The posterior compartment includes semitendinosus, semimembranosus and biceps femoris. These muscles are attached proximally to the ischial tuberosity and act both to extend the trunk on the femur and to flex and rotate the knee. Adductor magnus, as may be inferred from the extent of its proximal attachment and its dual innervation, shares the first of these functions with the hamstrings. Biceps femoris is the only muscle of the thigh that is attached distally to the fibula, and has no tibial attachment.

In the leg, the anterior or extensor compartment includes the extensors (dorsiflexors) of the foot and the extrinsic extensors of the toes. Tibialis anterior, the main foot dorsiflexor, also inverts the foot at the subtalar joint, while the smallest muscle of the compartment, fibularis (peroneus) tertius, is a dorsiflexor that everts the foot. The posterior or flexor (plantar flexor) compartment has superficial and deep components. The superficial component contains gastrocnemius and soleus, powerful plantar flexors of the foot, and the small plantaris with its long slender tendon. Gastrocnemius and soleus are attached distally to the foot via the calcaneal (Achilles) tendon. The deep component of the flexor compartment contains popliteus, a rotator of the knee; the extrinsic flexors of the toes; and tibialis posterior, the main invertor of the foot. The lateral compartment contains the main evertors of the foot, fibularis (peroneus) longus and brevis; both muscles are also plantar flexors of the foot. Gastrocnemius and plantaris are attached proximally to the femur and distally to the calcaneus; these two muscles can therefore act on the knee as well as at the ankle. The intrinsic muscles of the sole of the foot are arranged in four layers. They facilitate the actions of the extrinsic flexors of the toes, and provide subtle changes in the shape of the foot, thereby contributing to the control of foot posture in stance and locomotion.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES

The femoral artery (the continuation of the external iliac artery) provides the principal arterial supply to the lower limb distal to the inguinal ligament and the gluteal fold (Figs 78.4-78.5). The femoral artery courses within the subsartorial (adductor) canal, which is located on the anteromedial aspect of the thigh. It passes through the adductor hiatus to become the popliteal artery on entering the posterior compartment of the thigh and soon thereafter divides into the anterior and posterior tibial arteries. The obturator and inferior gluteal vessels also contribute to the supply of the proximal part of the limb. In the embryo, the inferior gluteal artery supplied the main axial artery of the limb, which is represented in the adult by the artery to the sciatic nerve.

The bones of the lower limb receive their arterial supply from nutrient vessels, metaphysial arterial branches of the peri-articular anastomoses, and the arteries supplying the muscles that attach to their periosteum. The pattern of arterial supply is particularly relevant to fracture healing, the spread of infection and malignancy, and the planning of reconstructive surgical procedures. For further details, consult Cormack and Lamberty (1984), Taylor and Razaboni (1994) and Crock (1996).

Ischaemia of the lower limb due to peripheral vascular disease is a tremendous burden on healthcare resources. Many diseases contribute to this pathology and include diabetes, hypertension and atherosclerosis. Obesity and smoking also increase the risk of developing peripheral vascular disease. Symptoms include intermittent claudication and wounds that do not heal well. Physical examination of such patients
may reveal decreased distal pulses (e.g. of the posterior tibial artery), pallor or a cool extremity.

## Arterial perforators of the lower limb and surgical flaps

Achieving adequate and aesthetically satisfactory skin and soft tissue cover for large, superficial tissue defects is a perennial challenge in the field of plastic and reconstructive surgery, and accounts for a substantial part of the plastic surgeon's workload. Generally, split-thickness and full-thickness skin grafts are suitable only for very superficial defects. To achieve tissue coverage for deeper and larger tissue defects, the plastic surgeon employs one of a variety of autologous tissue flaps. A fasciocutaneous flap is composed of skin, fat and deep fascia (fascia musculorum); a lower-extremity fasciocutaneous flap (Pontén 1981) is very useful in the repair of soft tissue defects of the leg.

The viability of a flap transplanted from one part of the body to another is crucially dependent on the flap's blood supply. An appreciation of the angiosome concept, coupled with technological advances in reconstructive microsurgery, has stimulated the development and use of perforator (or perforator-based) flaps. These are flaps of skin or subcutaneous tissue supplied by one or more fascial 'perforators', i.e. arteries, which reach the suprafascial plexus either directly from a source vessel, or indirectly from some other neighbouring tissue (Harry et al 2009) (Fig. 78.6). Perforator-based flaps are typically harvested with sparing of underlying muscle tissue and minimal trauma; their use is said to reduce postoperative pain, donor site morbidity and functional loss.

The lower limb is the largest donor site in the body for perforatorbased flaps. Commonly used flaps include anterolateral thigh flaps, which provide a large amount of skin; superior and inferior gluteal artery perforator flaps used in breast reconstruction; vascularized fibular flaps for reconstruction of deficient bone; vascularized tensor fasciae latae flaps for tendon reconstruction; vascularized sural nerve flaps for nerve reconstruction; and the gracilis muscle flap, used in, for example, reanimation of paralysed muscle.

In the context of perforator flap surgery, the lower limb may be considered in terms of four anatomic regions: gluteal; anterior hip and thigh; knee and leg; and ankle and foot. Each lower limb accounts for approximately $23 \%$ of the total body surface area (thigh $10.5 \%$, leg $6.5 \%$, buttock $2.5 \%$ and foot $3.5 \%$ ) and contains an average of 90 arterial perforators (Fig. 78.7).

## VEINS

The veins of the lower limb can be subdivided, like those of the upper limb, into superficial and deep groups (Figs 78.8-78.9). The superficial veins lie in the subcutaneous tissue; the deep veins (deep to the deep fascia) accompany the major arteries. Valves are present in both groups, but are more numerous in the deep veins and are more numerous in the veins of the lower versus the upper limb. Venous plexuses occur within and between some of the lower limb muscles. The two principal superficial veins are the long and short saphenous veins; their numerous tributaries are mostly unnamed; however, changes in clinical practice are driving a revision of the terminology. For further reading, see Caggiati et al $(2002,2005)$. The long saphenous vein can be harvested and used as a graft for peripheral vascular surgery, including coronary artery bypass (Kosinski 1926).

Deep veins of the lower limbs accompany the arteries and their branches. Plantar digital veins arise from plexuses in the plantar regions of the toes, connect with dorsal digital veins and unite to form four plantar metatarsal veins. These run in the intermetatarsal spaces and connect with dorsal veins by means of perforating veins. They then connect with each other to constitute a deep plantar venous arch adjacent to the deep plantar arch. From this venous arch, medial and lateral plantar veins run near the corresponding arteries; they communicate with the long and short saphenous veins before forming the posterior tibial veins posterior to the medial malleolus. The posterior tibial veins accompany the posterior tibial artery. They receive veins from the calf muscles, especially the venous plexus in soleus, and connect with superficial veins and with the fibular veins. The latter, running with their artery, receive tributaries from soleus and from superficial veins.

The anterior tibial veins are continuations of the venae comitantes of the dorsalis pedis artery. They leave the extensor region between the tibia and fibula, pass through the proximal end of the interosseous membrane, and unite with the posterior tibial veins, at the distal border of popliteus, to form the popliteal vein.

Fig. 78.4 An overview of the arteries of the lower limb. A, Anterior aspect. B, Posterior aspect.

## Venous (muscle) pumps

While standing, venous return from the lower limb depends largely on muscular activity, especially contraction of the calf and foot muscles, known as the 'muscle pump', whose efficiency is aided by the tight sleeve of deep fascia (Ricci 2011). 'Perforating' veins connect the long saphenous vein with the deep veins, particularly near the ankle, distal calf and knee. Their valves are arranged so as to prevent flow of blood from the deep to the superficial veins. At rest, pressure in a superficial vein is equal to the height of the column of blood extending from that vein to the heart. When the posterior leg muscles contract, blood is pumped proximally into the deep veins and is normally prevented from flowing into the superficial veins by the valves in the perforating veins. During muscular relaxation, blood is drawn into the deep veins from the superficial veins. If the valves in the perforating veins become incompetent, these veins become sites of 'high-pressure leaks' during muscular contraction, and the superficial veins become dilated and varicose. Similar perforating connections occur in the anterolateral region, where varicosities may also occur. Incompetence of the valves
in the connecting veins between the long saphenous vein and femoral vein in the adductor canal may predispose to superficial varicosities along the medial aspect of the thigh (Dodd and Cockett 1976).

## Venous plexuses

Venous plexuses may be intramuscular (soleus) or intermuscular (in the foot and gluteal region). The plexuses communicate with the axially running deep veins and are components of the 'muscle pump' mechanism.

## LYMPHATIC DRAINAGE

Most lymph from the lower limb traverses a large intermediary inguinal group of nodes (Fig. 78.10). Peripheral nodes are few and all are deeply sited. Except for an inconsistent node lying proximally on the interosseous membrane near the anterior tibial vessels, they occur only in the popliteal fossa. Enlarged popliteal nodes may be palpated along the line of the popliteal vessels while the passively supported knee is

Fig. 78.5 The anatomical territories served by the cutaneous blood supply to the lower limb.

Fig. 78.6 Types of arterial perforators.
gradually moved from extension to semi-flexion. These are often due to inflammation, malignancy or injury to the lateral side of the foot. Inguinal lymph nodes are found superficial and deep to the deep fascia. The deep nodes are few and lie alongside the medial aspect of the femoral vein. The superficial nodes may be divided into a lower vertical group that clothe the proximal part of the long saphenous vein, and an upper group that lie parallel to, but below, the inguinal ligament and which are related laterally to the superficial circumflex iliac and medially to the superficial external pudendal vessels. Lymph from the lower limb passes from the inguinal lymph nodes to the external and common iliac nodes, and ultimately drains to the lateral aortic nodes. Deep gluteal lymph reaches the same group through the internal and common iliac lymphatic vessels.

## Superficial tissues

The superficial lymph vessels begin in subcutaneous plexuses. Collecting vessels leave the foot medially, along the long saphenous vein, or laterally with the short saphenous vein. Medial vessels are larger and more numerous; they start on the medial side of the dorsum of the foot, ascend anterior or posterior to the medial malleolus and accompany the long saphenous vein. They drain to the distal superficial inguinal nodes. Lateral vessels begin on the fibular side of the dorsum of the foot; some cross anteromedially in the leg to join the medial vessels and so pass to the distal superficial inguinal lymph nodes, while others accompany the short saphenous vein and drain to the popliteal nodes. Superficial lymph vessels from the gluteal region run anteriorly to the proximal superficial inguinal nodes.

## Deeper tissues

The deep lymph vessels accompany the anterior and posterior tibial, fibular, popliteal and femoral vessels. Popliteal nodes interrupt the deep vessels from the foot and leg; those from the thigh pass to the deep inguinal nodes. The deep lymphatic vessels of the gluteal region follow their corresponding blood vessels. Those accompanying the superior gluteal vessels end in a node near the intrapelvic part of the superior gluteal artery, adjacent to the superior border of the greater sciatic foramen, while those that follow the inferior gluteal vessels traverse one or two of the small nodes inferior to piriformis and then pass to the internal iliac nodes.

## INNERVATION

## OVERVIEW OF THE LUMBAR AND SACRAL PLEXUSES

Nerves derived from the lumbar and sacral plexuses innervate the lower limb (Fig. 78.11). The lumbar plexus lies deep within psoas major, anterior to the transverse processes of the first three lumbar vertebrae. The sacral plexus lies in the pelvis on the anterior surface of piriformis, external to the pelvic fascia, which separates it from the inferior gluteal and internal pudendal vessels. The lumbosacral trunk (L4 and L5) emerges medial to psoas major on the posterior abdominal wall and lies on the ala of the sacrum before crossing the pelvic brim to join the ventral ramus of S1. Contributions to the lumbosacral trunk may also be derived from the third lumbar nerve (Bergman et al 1988).

## Lesions of the lumbar and sacral plexuses

The deep and protected situation of the plexuses means that lesions are not common. The lumbar plexus may be involved in retroperitoneal pathology, and the sacral plexus may be invaded by pelvic malignancies. Both may be involved in the reticuloses, affected by plexiform neuromas, or damaged in fractures of the lumbar spine and pelvis or in other conditions that cause severe retroperitoneal and pelvic haemorrhage. Temporary lesions may occur after pregnancy and childbirth, e.g. after difficult forceps delivery of a large baby. Pain, which may be diffuse, is the most common feature.

Sciatica is pain in the lower back and hip region, which radiates inferiorly along the posterior thigh to the leg. It is often caused by a herniated intervertebral disc, compressing the L5 or S1 ventral rami. The so-called piriformis syndrome, which may result from a variant or anomalous relationship between piriformis and the sciatic nerve, may also produce hip pain that radiates inferiorly along the course of the sciatic nerve.

Fig. 78.7 The source and location of the arterial perforators of the lower limb. A, Anterior aspect. B, Posterior aspect.

## OVERVIEW OF THE PRINCIPAL NERVES OF THE LOWER LIMB

## Femoral nerve (L2-4)

The femoral nerve is the nerve of the anterior compartment of the thigh. It arises from the posterior divisions of the second to fourth lumbar ventral rami, descends through psoas major and emerges on its lateral border to pass between it and iliacus. It enters the thigh behind the inguinal ligament and lateral to the femoral sheath. Its terminal branches form in the femoral triangle about 2 cm distal to the inguinal ligament. In the abdomen, the nerve supplies small branches to iliacus and a branch to the proximal part of the femoral artery. It subsequently supplies a large cutaneous area on the anterior and medial thigh, medial leg and foot, and gives articular branches to the hip, knee and ankle. The femoral nerve is described in detail on page 1372.

## Obturator nerve (L2-4)

The obturator nerve is the nerve of the medial compartment of the thigh. It arises from the anterior divisions of the second to fourth lumbar ventral rami, descends through psoas major and emerges from its medial border at the pelvic brim. It crosses the sacroiliac joint behind the common iliac artery and lateral to the internal iliac vessels, runs along the lateral pelvic wall medial to obturator internus, and enters the thigh through the upper part of the obturator foramen. Near the foramen, it divides into anterior and posterior branches, which are separated at first by part of obturator externus and more distally by adductor brevis. It provides articular branches to the hip and knee, and may supply skin on the medial thigh and leg. The obturator nerve is described in detail on page 1372. An accessory obturator nerve may also be present and leaves the pelvis anterior to the pubis.

Fig. 78.8 An overview of the veins of the lower limb.

## Sciatic nerve (L4, L5, S1-3)

The sciatic nerve travels in the posterior compartment of the thigh and, via its major branches, supplies the leg and foot. Formed in the pelvis from the ventral rami of the fourth lumbar to third sacral spinal nerves, it is typically 2 cm wide at its origin and is the thickest nerve in the body. It enters the lower limb via the greater sciatic foramen inferior to piriformis and descends between the greater trochanter and ischial tuberosity. In its descent along the posterior thigh, it is crossed by the long head of biceps femoris and divides into the tibial and common fibular (peroneal) nerves proximal to the knee; however, the level of bifurcation can be variable. Prior to diverging, the tibial and common fibular nerves are structurally separate and only loosely held together as the sciatic nerve. The tibial nerve is derived from the anterior divisions of the sacral plexus, and the common fibular nerve is made up of the posterior divisions of the plexus. The sciatic nerve sends articular branches to the hip joint through its posterior capsule (these are sometimes derived directly from the sacral plexus) and to the knee joint. The posterior thigh muscles, including the ischial part of adductor magnus

A

Fig. 78.9 A, The long saphenous vein and its tributaries. B, The short saphenous vein and its tributaries.
but not the short head of biceps femoris, are supplied by the medial (tibial) component of the sciatic nerve. The short head of biceps femoris is supplied by the lateral (common fibular) component. The common variations of the sciatic nerve have been well described and have been classified into six types (Beason and Anson 1937). The sciatic nerve is described in detail on page 1373.

Fig. 78.10 An overview of the lymphatics of the lower limb.

## Tibial nerve (L4, L5, S1-3)

The tibial nerve is derived from the anterior divisions of the sacral plexus. It descends along the posterior thigh and popliteal fossa to the distal border of popliteus, then passes anterior to the soleus with the popliteal artery and continues into the leg. In the popliteal fossa, it lies lateral to the popliteal vessels, becomes superficial to them at the knee and crosses to the medial side of the artery. In the leg, it is the nerve of the posterior compartment and descends with the posterior tibial vessels to lie between the heel and the medial malleolus. It ends deep to the flexor retinaculum by dividing into the medial and lateral plantar nerves. The tibial nerve supplies articular branches to the knee and ankle joints. Its cutaneous supply, including its terminal branches, supplies the back of the calf, the sole, the lateral border of the foot and the medial and lateral sides of the heel. The tibial nerve is described in detail on page 1415.

## Common fibular nerve (L4, L5, S1, S2)

The common fibular nerve (common peroneal nerve) is derived from the posterior divisions of the sacral plexus. In the leg, it is the nerve of
the anterior and lateral compartments. It descends obliquely along the lateral side of the popliteal fossa to the fibular head, lying between the tendon of biceps femoris and the lateral head of gastrocnemius; it then curves lateral to the neck of the fibula, lying on the bone deep to fibularis longus, and divides into superficial and deep fibular (peroneal) nerves. Before it divides, it gives branches to the knee and superior tibiofibular joints, and to the skin. The cutaneous area supplied by the common fibular nerve and its terminal branches includes the anterolateral leg and most of the dorsum of the foot. The common fibular nerve is described in detail on page 1415.

## Gluteal nerves (L4, L5, S1, S2)

The gluteal nerves arise from the posterior divisions of the sacral plexus. The superior gluteal nerve (L4, L5, S1) leaves the pelvis through the greater sciatic foramen superior to piriformis and supplies gluteus medius, gluteus minimus, tensor fasciae latae and the hip joint. The inferior gluteal nerve (L5, S1, S2) passes through the greater sciatic foramen inferior to piriformis and supplies gluteus maximus. The gluteal nerves are described in detail on page 1374.

## CUTANEOUS INNERVATION

The cutaneous nerves supplying the skin of the lower limb are all branches of the lumbar and sacral plexuses, with the exception of some proximal nerves. The areas of distribution and spinal segments of origin of the cutaneous nerves of the lower limb are illustrated in Figure 78.12. Variations in the composition and course of the cutaneous nerves of the lower limb are common.

## Dermatomes

Our knowledge of the extent of individual dermatomes, especially in the limbs, is largely based on clinical evidence (Ladak et al 2014). The dermatomes of the lower limb are innervated by spinal nerves T12 to S3 (see Fig. 78.12; Figs 78.13-78.14).

## AUTONOMIC INNERVATION

The autonomic nerve supply to the limbs is exclusively sympathetic. Preganglionic sympathetic fibres to the lower limb are derived from neurones in the lateral horn of the lower thoracic (T10, T11 and T12) and upper lumbar (L1, L2) spinal cord segments. Fibres pass in white rami communicantes to the sympathetic trunk and synapse in the lumbar and sacral ganglia. Postganglionic fibres pass in grey rami communicantes to enter the lumbar and sacral plexuses; many are distributed to the skin via the cutaneous branches of the nerves derived from these plexuses. The blood vessels to the lower limb receive their sympathetic nerve supply via adjacent peripheral nerves. Postganglionic fibres accompanying the iliac arteries are destined mainly for the pelvis but may supply vessels in the proximal thigh.

## MOVEMENTS, MUSCLES AND SEGMENTAL INNERVATION

Most limb muscles are innervated by neurones derived from more than one segment of the spinal cord. The predominant segmental origin of the nerve supply for each of the muscles of the lower limb and for the movements that take place at the joints of the lower limb is summarized in Tables 78.1-78.4 (Sharrard 1955).

Movements At the central nervous level of control, muscles are not recognized as individual actuators but as components of movement, and may therefore contribute to several types of motion, acting variously as prime movers, antagonists, fixators or synergists. Some muscles have been included in more than one place in Table 78.3 on the basis that a muscle that acts across one joint can produce a combination of movements (e.g. flexion with medial rotation, or extension with adduction) and a muscle that crosses two joints can produce more than one movement. It is also important to remember that these listings are not exhaustive.

Spinal nerves There is no universal consensus concerning the contribution that individual spinal nerves make to the innervation of individual muscles; the most positive identifications, which are limited,

For example, the ilioinguinal and iliohypogastric nerves may arise from a common trunk or the ilioinguinal nerve may be absent. The ilioinguinal nerve may also join the iliohypogastric nerve at the iliac crest. When the obturator nerve makes a more significant contribution to the cutaneous innervation, the medial cutaneous branch of the femoral nerve is relatively small. Alternatively, the cutaneous branch of the obturator nerve may be absent. The lateral femoral cutaneous nerve normally arises from L2 and L3, but L1 may also contribute. Although it usually bifurcates after it exits the pelvis, it may bifurcate within the pelvic cavity. The nerve may be absent on one side and/or may be replaced by the ilioinguinal nerve or a branch of the anterior femoral cutaneous nerve. The genital and femoral branches of the genitofemoral nerve may arise as separate offshoots of the lumbar plexus. The genital branch may receive fibres from the twelfth thoracic nerve or may be completely absent, while the femoral branch may have an extensive distribution to the skin of the upper two-thirds of the thigh. The sural nerve is subject to wide variation and may supply the dorsal cutaneous aspect of the lateral two-and-a-half toes, or may terminate in the foot without any digital branches.

The preaxial border starts near the midpoint of the thigh and descends to the knee. It then curves medially, descending to the medial
malleolus and the medial side of the foot and hallux. The postaxial border starts in the gluteal region and descends to the centre of the popliteal fossa, then deviates laterally to the lateral malleolus and the lateral side of the foot. The ventral and dorsal axial lines exhibit corresponding obliquity. The ventral axial line starts proximally at the medial end of the inguinal ligament and descends along the posteromedial aspect of the thigh and leg to end proximal to the heel. The dorsal axial line begins in the lateral gluteal region and descends posterolaterally in the thigh to the knee; it inclines medially and ends proximal to the ankle. Considerable overlap exists between adjacent dermatomes innervated by nerves derived from consecutive spinal cord segments.

Surgical or chemical lumbar sympathectomy may be indicated in arterial disease and in the management of plantar hyperhidrosis, and may be used to treat rest pain or other troublesome sensory symptoms of arterial disease or in causalgia. A segment of the sympathetic trunk including the second and third lumbar ganglia is removed; preservation of the first lumbar ganglion is said to lessen the risk of ejaculatory problems.

Table 78.2 Segmental innervation of joint movements of the lower limb

| Region | Muscles supplied | Segment |
| :--- | :--- | :--- |
| Hip | Flexors, adductors, medial rotators | $\mathrm{L} 1-3$ |
|  | Extensors, abductors, lateral rotators | $\mathrm{L} 5, \mathrm{~S} 1$ |
| Knee | Extensors | $\mathrm{L} 3,4$ |
|  | Flexors | $\mathrm{L} 5, \mathrm{~S} 1$ |
| Ankle | Dorsiflexors | $\mathrm{L4}, 5$ |
|  | Plantar flexors | $\mathrm{S} 1,2$ |
| Foot | Invertors | $\mathrm{L4}, 5$ |
|  | Evertors | $\mathrm{L5}, \mathrm{~S} 1$ |
|  | Intrinsic muscles | $\mathrm{S} 2,3$ |

Table 78.1 Segmental innervation of the muscles of the lower limb

| Great toe extension | Extensor hallucis longus |  | L5 |  | Deep fibular |

*The muscles listed in the 'Upper motor neurone' column are those that are preferentially affected in upper motor neurone lesions. The root level is the principal supply to a muscle.

Fig. 78.11 The nerves of the lower limb, with their cutaneous and muscular branches. A, Anterior aspect. B, Posterior aspect. Adductor magnus has dual innervation.
have been obtained by electrically stimulating spinal nerves and recording the evoked electromyographic activity in the muscles. Much of the information in Tables 78.1-78.4 is based on the clinical appreciation of deficits following lesions to various nerves.

## Reflexes

Knee reflex (L2-4) With the patient sitting and the knee supported and partially flexed, the patellar ligament is struck with a finger or percussion hammer, resulting in extension of the knee joint.

Ankle reflex $(\mathrm{S} 1,2)$ With the patient sitting and the lower limb laterally rotated and partially flexed at the hip and knee, the foot is dorsiflexed by the examiner and the calcaneal tendon struck with a percussion hammer. This results in plantar flexion of the foot.

Plantar reflex The plantar reflex is an important part of the clinical examination of the central nervous system. With the foot relaxed, the outer edge of the sole is stroked longitudinally with a blunt object such
as the tip of the handle of a percussion hammer. Normally, this action elicits flexion of the toes. However, in patients with upper motor neurone lesions, the response includes extension of the great toe (Babinski's sign).

## Neurological localization of a lesion

Available with the Gray's Anatomy e-book

## SURFACE ANATOMY

## SKELETAL LANDMARKS

## Pelvis

The inguinal or groin skin crease marks the junction of the anterior thigh with the anterior abdominal wall. It lies distal to the inguinal

In clinical practice, it is only necessary to test a relatively small number of muscles in order to determine the location of a lesion. Any muscle to be tested must satisfy a number of criteria. It should be visible, so that wasting or fasciculation can be observed, and the muscle consistency with contraction can be felt. It should have an isolated action, so that its function can be tested separately. It should help to differentiate between lesions at different levels in the neural axis and in the peripheral nerve, or between peripheral nerves. It should be tested in such a way that normal can be differentiated from abnormal, so that slight weakness can be detected early with reliability. Some preference should be given to muscles with an easily elicited reflex. Table 78.4 gives a list of movements and muscles chosen according to these criteria; in practice, these tests would be combined with tests of sensory function. Knowledge of the sequence in which motor branches leave a peripheral nerve to innervate specific muscles is very helpful in localizing the level of a lesion.

Fig. 78.15 The inguinal region and femoral triangle. Key: 1, anterior superior iliac spine; 2, lateral femoral cutaneous nerve and its zone of emergence into femoral triangle (white): range $0.3-7.3 \mathrm{~cm}$ (mean $2.1-3.5 \mathrm{~cm}$ ) from anterior superior iliac spine; 3 , inguinal ligament; 4, femoral artery and zone of emergence into femoral triangle (white): mid-inguinal point $\pm 1 \mathrm{~cm}$ either side, femoral nerve (yellow cross) and vein (blue cross) sit lateral and medial, respectively, to the femoral artery; 5 , femoral head: located $2-4 \mathrm{~cm}$ above the midpoint of the greater trochanter to pubic tubercle line; 6, pubic tubercle; 7, greater trochanter to pubic tubercle line; 8, profunda femoris artery: almost always arises $6.5 \pm 1.5 \mathrm{~cm}$ distal to the mid-inguinal point, or superior to or at the level of the inguinal/groin crease; 9, zone of saphenofemoral junction location: almost always sits within a $3 \mathrm{~cm} \times 3 \mathrm{~cm}$ zone situated $1-4 \mathrm{~cm}$ lateral and $0-3 \mathrm{~cm}$ inferior to the pubic tubercle; 10, sartorius; 11, inguinal/groin crease; 12, adductor longus. (Adapted from Drake R, Vogl AW, Mitchell AW, et al, Gray's Atlas of Anatomy, Elsevier 2008, Churchill Livingstone.)
ligament by a mean of $6.7 \pm 1.9 \mathrm{~cm}$ (Lechner et al 1988) (Fig. 78.15). The inguinal crease sits more distal to the inguinal ligament in females than in males ( $7.5 \pm 1.9 \mathrm{~cm}$ versus $6.3 \pm 1.9 \mathrm{~cm}$ ) (Lechner et al 1988). The anterior superior iliac spine lies superior to the lateral end of the fold, and from this point, the iliac crest is palpable along its entire length. A line (Tuffier's) joining the most superior aspects of the iliac crests almost always crosses the L4 body or L4/L5 intervertebral disc (Render 1996, Walsh et al 2006, Chakraverty et al 2007) (Fig. 78.16). This line is used as a landmark when performing a lumbar puncture; localization via palpation, especially in females and patients with a greater body mass index (BMI), often places it at a higher vertebral level, up to the L2-L3 interspace (Chakraverty et al 2007, Kim et al 2007, Hale et al 2010). Vertebral column flexion in the adult has little effect on the level of Tuffier's line (Kim et al 2003). In neonates, Tuffier's line sits at the L4/L5 interlaminar space level whilst prone, moving to the upper third of L5 during vertebral column flexion (van Schoor et al 2014). The iliac crest terminates posteriorly as the posterior superior iliac spine, which is marked superficially by the gluteal dimples (dimples of Venus). Palpation places the posterior superior iliac spines in the range of the L5-S1 vertebral junction to the S2 spinous process level (Kim et al 2007), whereas radiographic assessment shows their inferior margin to mark vertebral level S2 almost always (McGaugh et al 2007). The caudal limit of the dura mater ranges from the L5-S1 junction to S4 (Hansasuta et al 1999, Binokay et al 2006, Senoglu et al 2013), with the majority sitting at the lower S1 to the S2 level (Senoglu et al 2013) and the mean position being lower in males versus females (Binokay et al 2006). The ischial tuberosity is covered by gluteus maximus and is palpable during hip flexion. The coccyx is palpable in the superior part of the intergluteal cleft, the deep vertical groove between the buttocks extending to the S3-S4 bony sacral segments. The sacral hiatus sits superior to the tip of the coccyx at a mean of $57.5 \pm 8.7 \mathrm{~mm}$ and is flanked by the raised palpable sacral cornua, which serve as reliable landmarks (Aggarwal et al 2009). The hiatus can also be located at the apex of an inverted equilateral triangle

Fig. 78.16 The gluteal region and sciatic nerve. Key: 1, zone of supracristal plane intersection with vertebrae (white): ranges from the L2-L3 to the L4-L5 junction/interspinous space; 2, highest point of iliac crests (supracristal plane or Tuffier's line): most commonly intersects the L4 vertebra to the L4/5 junction; 3, zone of intersection between the vertebrae and a horizontal plane between the posterior superior iliac spines (white): ranges from the L5-S1 junction/interspinous space to S2 when determined via palpation, located at S2 via radiographs; 4, posterior superior iliac spine and interspinous plane: marked by a skin indentation (dimple of Venus); 5, safe zone (white) for gluteal region injection (upper lateral quadrant), determined via a vertical line from the highest point of the iliac crest to ischial tuberosity level, and a horizontal line passing through its midpoint; 6, zone of termination of dural sac (blue): ranges from L5-S1 to S4, most commonly sitting from the lower part of S1 to the S2 level; 7, sacral hiatus bordered by sacral cornua, located at the apex of an approximately equilateral triangle with baseline measurement taken between the posterior superior iliac spines; 8, course of sciatic nerve: from approximately one third of the way down a line joining the posterior superior iliac spine to the ischial tuberosity (black $X$ and white zone) to the midpoint or middle third of a line joining the ischial tuberosity to the upper greater trochanter (blue $X$ and white zone); 9, tip of coccyx within intergluteal cleft; 10, greater trochanter; 11, ischial tuberosity; 12, gluteal fold. (Adapted from Drake R, Vogl AW, Mitchell AW, et al, Gray's Atlas of Anatomy, Elsevier 2008, Churchill Livingstone.)
whose base is measured between the posterior superior iliac spines (Senoglu et al 2005), although this arrangement may not always be observed (Aggarwal et al 2009). The termination of the dural sac is located a mean of $31.6 \pm 11.8 \mathrm{~mm}$ from the sacral hiatus apex (Aggarwal et al 2009), a point relevant to caudal anaesthetic administration.

## Femur

The greater trochanter of the femur sits on the upper lateral thigh, inferior to the midpoint of the iliac crest and approximately level with a horizontal plane passing through the pubic tubercle (see Fig. 78.15). It can be used to guide surgeons during anterolateral approaches to the hip joint. A line (Nelaton's/Roser-Nelaton's) drawn from the anterior superior iliac spine to the ischial tuberosity passes superior to or over the greater trochanter. In a patient with hip dislocation or femoral neck fracture, the greater trochanter can be palpated superior to this line. The femoral shaft is not directly palpable but runs inferomedially from a point $2-3 \mathrm{~cm}$ medial to the lateral aspect of the greater trochanter to the midpoint of the patella. The femoral head sits $2-4 \mathrm{~cm}$ superior to the midpoint of a line between the superior margin of the greater trochanter and the pubic tubercle.

When the knee is flexed, the medial surface of the medial condyle and the lateral surface of the lateral condyle of the femur may both be palpated, and portions of the femoral condylar articular surface can be examined on each side of the patellar ligament.

## Patella

The entire patella is palpable except for its articular surface. When the quadriceps femoris is relaxed in the fully extended knee, the patella can be tilted and moved on the distal aspect of the femur. The inferior limit of the patella is located superior to the knee joint line by $1-2 \mathrm{~cm}$ (Fig. 78.17).

## Knee

The patella and the femoral condyles have been described above. The tibial condyles form visible and palpable landmarks on the medial and lateral sides of the patellar ligament (see Fig. 78.17). The latter may be traced inferiorly from the apex of the patella to the tibial tuberosity, which is both visible and palpable. When the knee is flexed, the anterior margins of the tibial condyles can be felt: each forms the lower boundary of a depression at the side of the patellar ligament. The lateral condyle is the more prominent of the two. The joint line of the knee (tibiofemoral joint) corresponds to the upper margins of the tibial condyles and can be represented by a line drawn round the limb at this level. The anterior horns of the menisci lie in the angles between this
line and the edges of the patellar ligament. The iliotibial tract is attached to a prominence, Gerdy's tubercle, on the anterior aspect of the lateral condyle that is usually approximately 1 cm inferior to the joint line and about 2 cm superolateral to the tibial tuberosity.

The head of the fibula forms a slight surface elevation on the posterior part of the proximal lateral leg. It lies vertically below the posterior part of the lateral condyle of the femur, $1-2 \mathrm{~cm}$ inferior to the knee joint line.

## Leg and ankle

The subcutaneous medial surface of the tibia corresponds to the flat anteromedial aspect of the leg. Superiorly, this surface merges with the medial condyle of the tibia, and inferiorly, it is continuous with the visible prominence of the medial malleolus of the tibia (see Fig. 78.17; Figs 78.18-78.19). The anterior border of the tibia can be palpated distinctly throughout most of its extent, but inferiorly, it is somewhat masked by the tendon of tibialis anterior, which lies to its lateral side. The lateral malleolus of the fibula forms a conspicuous projection on the lateral side of the ankle; it descends to a more distal level than the medial malleolus and is located on a more posterior plane. The lateral aspect of the lateral malleolus is continuous superiorly with an elongated, subcutaneous, triangular area of the inferior shaft of the fibula. The lateral part of the anterior margin of the inferior end of the tibia can be palpated immediately anterior to the base of the lateral malleolus; the line of the ankle joint can be gauged from it.

Fig. 78.17 The anterior aspect of the knee and leg. Key: 1, vastus lateralis; 2, vastus medialis; 3 , iliotibial tract; 4, quadriceps tendon overlying suprapatellar bursa; 5 , sartorius; 6 , anterior horns of menisci: located above knee joint line (dotted line) and either side of patellar ligament; 7, Gerdy's tubercle; 8, fibular head; 9, patellar ligament insertion into tibial tuberosity; 10, anterior tibial artery and deep fibular nerve: pass from halfway between fibular head and tibial tuberosity to a point halfway between the malleoli; 11, soleus and long saphenous vein (blue); 12, medial tibial border (subcutaneous); 13, medial malleolus: long saphenous vein and saphenous nerve pass anterior; 14, lateral malleolus; 15 , tendon of tibialis anterior. (Adapted from Drake R, Vogl AW, Mitchell AW, et al, Gray's Atlas of Anatomy, Elsevier 2008, Churchill Livingstone.)

Fig. 78.18 The posterior aspect of the knee and leg. Key: 1, popliteal artery: passing from a point (black X) 2.5 cm medial to the posterior midline of the thigh at the junction of its middle and lower thirds to a point halfway between the femoral condyles/the midaxial line of the calf (blue X); 2, iliotibial tract; 3, tendon of biceps femoris and common fibular nerve located medially; 4, semimembranosus and semitendinosus; 5 , gracilis; 6 , popliteal fossa; 7 , head of fibula; 8 , gastrocnemius, lateral head; 9 , gastrocnemius, medial head; 10, soleus; 11, posterior tibial artery and tibial nerve: run from the midaxial line of the calf at the fibular neck level to a point one-third of the way from the posterior border of the medial malleolus to the calcaneal tendon; 12, medial malleolus; 13, lateral malleolus and short saphenous vein passing posteriorly; 14, calcaneal tendon insertion into calcaneus. (Adapted from Drake R, Vogl AW, Mitchell AW, et al, Gray's Atlas of Anatomy, Elsevier 2008, Churchill Livingstone.)

Fig. 78.19 The dorsal aspect of the foot and ankle. Key: 1, long saphenous vein and saphenous nerve; 2, medial malleolus; 3, lateral malleolus; 4, dorsalis pedis artery and deep fibular nerve: located immediately lateral to the tendon of extensor hallucis longus; 5 , intermediate dorsal cutaneous nerve: visible passing towards the fourth digit during digit and ankle plantar flexion; 6 , extensor digitorum brevis; 7 , tendon of extensor hallucis longus; 8 , tendon of tibialis anterior: insertion into medial cuneiform; 9, tuberosity of fifth metatarsal; 10, dorsal venous arch of foot; 11, tendon of extensor digitorum longus (to digit two). (Adapted from Drake R, Vogl AW, Mitchell AW, Gray's Anatomy for Students, 2nd ed, Elsevier 2010, Churchill Livingstone.)

## Foot

The anterior part of the upper surface of the calcaneus can be identified slightly anterior to the lateral malleolus on the dorsum of the foot. When the foot is passively inverted, the upper and lateral parts of the head of the talus can be both seen and palpated approximately 3 cm anterior to the distal end of the tibia; the extensor tendons obscure them when the toes are extended. Regional tenderness can indicate a talar neck fracture.

The dorsal aspects of the bodies of the metatarsals can be felt more or less distinctly, although they are partly obscured by the extensor tendons of the toes. The tuberosity on the base of the fifth metatarsal forms a distinct palpable and visible projection on the lateral border of the foot.

The flat lateral surface of the calcaneus can be palpated on the lateral aspect of the heel and can be traced anteriorly and inferior to the lateral malleolus, where the tendons of fibularis longus and brevis hide it. The fibular (peroneal) tubercle, when sufficiently large, can be palpated 2 cm inferior to the tip of the lateral malleolus. A palpable depression just anterior to the lateral malleolus leads to the lateral end of the tarsal sinus.

On the medial side of the foot, the sustentaculum tali can be felt approximately 2 cm inferior to the medial malleolus, with the tendon of flexor hallucis longus located inferiorly (Fig. 78.20). The navicular tuberosity is palpable and usually visible approximately 2.5 cm anterior to the sustentaculum tali. Anterior to this, the medial cuneiform can be identified, with the tendon of tibialis anterior inserting on to it. The upper and medial parts of the joint between the medial cuneiform and the first metatarsal can be felt as a narrow groove.

When the foot is placed on the ground, it rests on the posterior part of the inferior surface of the calcaneus, the heads of the metatarsals and, to a lesser extent, on its lateral border. The medial longitudinal arch of the foot, the instep, is elevated from the ground. The medial and lateral

Fig. 78.20 The medial aspect of the foot and ankle. Key: 1, long saphenous vein and saphenous nerve; 2, medial malleolus; 3, posterior tibial artery and tibial nerve: located approximately one-third of the distance along a line passing from the posterior border of the medial malleolus to the calcaneal tendon; 4, tendon of tibialis anterior: insertion into medial cuneiform; 5 , navicular tuberosity and tibialis posterior insertion; 6, sustentaculum tali; 7, dorsal venous arch; 8, region of the posterior tibial artery bifurcation into medial and lateral plantar arteries; 9 , medial border of plantar aponeurosis; 10, medial calcaneal tubercle covered by fibro-fatty heel pad. Fig. 78.21 The anterolateral aspect of the foot and ankle. Key: 1, tendons of fibularis longus and brevis; 2, tendons of extensor digitorum longus and fibularis tertius; 3, inferior extensor retinaculum; 4, lateral malleolus; 5 , fibular tubercle/trochlea; 6 , tendon of fibularis tertius; 7, calcaneocuboid joint and transverse tarsal joint line; 8, tuberosity of fifth metatarsal and tarsometatarsal (Lisfranc) joint line (dotted). (Adapted from Drake R, Vogl AW, Mitchell AW, Gray's Anatomy for Students, 2nd ed, Elsevier 2010, Churchill Livingstone.)
tubercles of the calcaneus can be palpated on its inferior surface via the anterior region of the fibro-fatty heel pad, which covers and obscures them. The heads of the metatarsals are similarly covered by a fibro-fatty pad on the plantar surface of the foot and can be palpated on the dorsal foot, with the digits in flexion.

The calcaneocuboid joint is about 2 cm posterior to the tuberosity on the base of the fifth metatarsal and is almost in line with the talonavicular joint, whose position may be gauged from the talar head (Fig. 78.21). The tarsometatarsal (Lisfranc) joints lie on a line joining the tuberosity of the fifth metatarsal to the tarsometatarsal joint of the great toe, which is located $2-3 \mathrm{~cm}$ anterior to the navicular tuberosity and is palpable. The joint between the second metatarsal and the intermediate cuneiform is located $2-3 \mathrm{~mm}$ posterior to the line of the other
tarsometatarsal joints. The metatarsophalangeal joints lie about 2.5 cm behind the web spaces of the toes and are palpable on the dorsal foot, where they are accessible via needle.

## MUSCULOTENDINOUS AND <br> LIGAMENTOUS LANDMARKS

See Video 78.1.

## Buttock and hip

The bulky prominence of the buttock is formed by gluteus maximus, a variable amount of subcutaneous fat and the normal alignment of the pelvis, which angles the ischium posteriorly (see Fig. 78.16).

The horizontal gluteal fold marks the upper limit of the posterior aspect of the thigh. It does not correspond to the lower border of gluteus maximus but is formed by fibrous connections between the skin and the deep fascia. The intergluteal cleft, which separates the buttocks inferiorly, begins superiorly at the S3 or S4 vertebrae. The superior border of gluteus maximus begins on the iliac crest $5-7 \mathrm{~cm}$ superolateral to the posterior superior iliac spine and runs inferiorly and laterally towards the apex of the greater trochanter. Its lower border corresponds to a line drawn from the ischial tuberosity, through the midpoint of the gluteal fold, to a point approximately 9 cm below the greater trochanter. Although gluteus maximus overlaps the ischial tuberosity in the standing position, on sitting, it slides superiorly posterior to the tuberosity, leaving it free to bear weight. Gluteus maximus can be felt to contract when the hip is extended against resistance.

Gluteus medius completely covers the underlying gluteus minimus. Both muscles lie in a slight depression superolateral to gluteus maximus and inferior to the anterior portion of the iliac crest and both pass inferiorly to insert into the greater trochanter. They constitute the major abductors of the hip and are demonstrated by asking the subject to stand on one limb. The ipsilateral muscles contract to stabilize the centre of gravity and maintain a relatively horizontal pelvic position. Paresis or paralysis causes pelvic tilt towards the unsupported, contralateral side (Trendelenburg's sign).

## Thigh

The inguinal ligament can be felt running between the anterior superior iliac spine and the pubic tubercle, especially when the thigh is abducted and laterally rotated (see Fig. 78.15). The groin/inguinal crease (Holden's line), where the deep layer of the subcutaneous tissue of the anterior abdominal wall meets the fascia lata of the thigh, is distal to the inguinal ligament and runs obliquely. It lies a mean of $6.7 \pm 1.9 \mathrm{~cm}$ distal to the inguinal ligament (Lechner et al 1988).

The femoral triangle is located on the proximal anterior thigh. It is bounded superiorly by the inguinal ligament and laterally by the straplike sartorius, which can be both seen and felt in a reasonably thin and muscular subject when the hip is flexed in the sitting position, while the knee is kept extended and the thigh is slightly abducted and rotated laterally. Sartorius can be traced inferomedially from the anterior superior iliac spine to approximately halfway down the medial side of the thigh; distally, it may be identified as a soft longitudinal ridge passing towards the posterior part of the medial femoral condyle. The adductor group of muscles forms the bulky, fleshy mass at the upper part of the medial thigh. The medial boundary of adductor longus forms the medial boundary of the femoral triangle and can be felt as a distinct ridge when the thigh is adducted against resistance. At its superior end, its prominent tendon of origin can be seen and palpated immediately inferior to the pubic tubercle, which is a useful guide to this bony landmark.

The forward convexity of the anterior thigh is caused by the curvature of the femur covered by the muscle mass of quadriceps femoris. Rectus femoris appears as a raised ridge passing down the anterior aspect of the thigh to the patellar base, when the sitting subject flexes the hip with the knee extended. Vastus medialis constitutes a bulge that is both superior and medial to the patella (see Fig. 78.17). Vastus lateralis forms an elevation superior and lateral to the patella that is more proximal and less pronounced than that of vastus medialis. Vastus intermedius is covered by the three other muscles in the group. The thick tendon of adductor magnus can be palpated on the distal medial thigh, deep within the indentation formed between vastus medialis anteriorly and gracilis and sartorius posteriorly.

The iliotibial tract, a thickened portion of the deep fascia of the thigh (fascia lata), runs from the lateral aspect of the iliac crest to Gerdy's
tubercle and produces the flattened appearance of the lateral thigh. It forms a defined ridge that is visible on the lateral aspect of the knee either when the knee is extended against gravity or when the opposite limb is lifted from the floor while standing.

The muscles of the posterior thigh may be palpated from the ischial tuberosity inferiorly along the lateral (biceps femoris) and medial (semitendinosus and semimembranosus) aspects of the thigh.

## Knee

The large depression visible posterior to the knee when the joint is actively flexed against resistance corresponds to the popliteal fossa. The transverse skin crease of the popliteal fossa is located $2-3 \mathrm{~cm}$ superior to the knee joint line. The fossa is bounded on the superolateral side by the prominent tendon of biceps femoris, which can be palpated between the finger and thumb and traced inferiorly to the head of the fibula. Three tendons, of semitendinosus, gracilis and semimembranosus, can be felt on the superomedial side of the fossa. Semitendinosus is the most lateral and posterior, while gracilis is the most medial and anterior; both tendons stand out sharply and can be seen when the knee is flexed against resistance and the limb actively adducted. The tendon of semimembranosus may be palpated deeply in the interval between the tendons of semitendinosus and gracilis. It is much thicker than the other two tendons and broadens rapidly as it is traced proximally. The upper borders of the two heads of gastrocnemius form the inferomedial and inferolateral boundaries of the popliteal fossa.

The cord-like fibular collateral ligament may be felt passing from the apex of the fibular head to the lateral epicondyle of the femur when the knee is flexed and laterally directed pressure (valgus force) is applied to the medial side of the knee. The medial patellar retinaculum may be felt as a flat, broad band overlying the medial femoral condyle in the flexed knee, running between the midpoint of the medial side of the patella and the medial femoral epicondyle.

## Leg

The muscles in the anterior osteofascial compartment of the leg form a gentle prominence over the upper two-thirds of its anterolateral aspect; this prominence is accentuated when the foot is actively dorsiflexed. These muscles are replaced by their tendons in the lower third of the leg. The tendon of tibialis anterior can be seen just lateral to the anterior border of the tibia and traced inferiorly and medially across the anterior aspect of the ankle to the medial cuneiform (see Figs 78.17, 78.19). The other tendons cannot be examined satisfactorily superior to the ankle. Immediately superior to the posterior border of the medial malleolus and close to the medial border of the tibia, the tendons of tibialis posterior and flexor digitorum longus can be felt (rather indistinctly) when the foot is actively inverted and plantar flexed.

On the lateral aspect of the leg, fibularis longus can be seen as a narrow ridge following the line of the lateral aspect of the fibula during active eversion and plantar flexion of the foot. It covers and hides fibularis brevis. The shaft of the fibula can only be palpated indistinctly between its neck and the area above the lateral malleolus.

The bulky prominence of the posterior leg is formed by gastrocnemius and soleus, both of which can be identified either when the foot is plantar flexed against resistance, or when the heel is raised from the ground by standing on tiptoes (see Fig. 78.18). The two heads of gastrocnemius unite to form the inferior borders of the popliteal fossa. The medial head of gastrocnemius descends to a more inferior level than the lateral head. Soleus lies deep to gastrocnemius; when tensed, it bulges from under the medial and lateral margins of gastrocnemius, particularly on the lateral side, and its fleshy belly extends to a more distal level. Both muscles end inferiorly in the conspicuous calcaneal tendon, which can be palpated between the finger and thumb and followed inferiorly to its insertion into the posterior aspect of the calcaneus.

## Foot

When the toes are actively extended, the bellies of extensor digitorum brevis and extensor hallucis brevis form a small elevation on the dorsal foot, just anterior to the lateral malleolus (see Fig. 78.19). During ankle inversion and extension of the toes, the prominent tendon of tibialis anterior is visible on the medial side of the dorsal foot, passing inferiorly and medially to the medial cuneiform. The tendon of extensor hallucis longus can be identified laterally; the tendons of extensor digitorum longus and fibularis tertius are further lateral as they pass deep
to the inferior extensor retinaculum and immediately anterior to the lateral part of the distal tibia. More distally, the tendons of extensor digitorum longus and fibularis tertius diverge and may be traced to their insertions.

The tendon of tibialis posterior winds posterior to the medial malleolus and then curves anteriorly in the interval between this bony landmark and the sustentaculum tali to reach the tuberosity of the navicular (see Fig. 78.20). The tendon is visible and palpable posterior to the malleolus when the foot is forcibly plantar flexed and inverted. The tendon of flexor digitorum longus lies immediately posterolateral to that of tibialis posterior. It curves forwards inferior to tibialis posterior and lies on the medial aspect of the sustentaculum tali. From there, it passes anteriorly and laterally to the centre of the plantar foot, where it divides into four tendons that pass to the lateral four toes. The tendon of flexor hallucis longus lies inferior to, and grooves, the sustentaculum tali. As it passes towards the great toe, it crosses the line of the flexor digitorum longus opposite the interval between the sustentaculum tali and the tuberosity of the navicular. Abductor hallucis may be seen in some subjects as a fleshy mass along the medial border of the foot, passing from the medial calcaneal tubercle to the first metatarsophalangeal joint.

When the toes are maximally dorsiflexed, the plantar aponeurosis is easily palpated along the medial border of the foot, from just distal to the heel pad as far as the first metatarsophalangeal joint. It originates from the calcaneal tubercles, which may be palpable via the anterior aspect of the heel pad.

## VESSELS, PULSES AND NERVES

## Arteries

The femoral artery normally enters the anterior thigh at the midinguinal point $\pm 1 \mathrm{~cm}$ either side (medial to lateral) (Hale et al 2010) (see Fig. 78.15). The midinguinal point is halfway between the anterior superior iliac spine and the pubic symphysis. The artery normally passes directly anterior to the hip joint; its course may be represented by the upper two-thirds of a line joining its entry point into the thigh with the adductor tubercle, when the thigh is flexed, slightly abducted and rotated laterally. It travels deep to sartorius from the apex of the femoral triangle to the adductor hiatus. The profunda femoris artery (deep artery of the thigh) normally arises from the lateral side of the femoral artery, $6.5 \pm 1.5 \mathrm{~cm}$ distal to the mid-inguinal point (Choy et al 2013), which is most commonly at or superior to the level of the inguinal/groin crease (Lechner et al 1988).

The popliteal artery may be represented by a line extending from the junction of the middle and lower thirds of the thigh, 2.5 cm medial to its posterior midline, to a point halfway between the femoral condyles, and continuing inferolaterally to the level of the tibial tuberosity, medial to the fibular neck, where it bifurcates into the anterior and posterior tibial arteries (see Fig. 78.18).

The anterior tibial artery may be represented by a line extending from a point halfway between the tibial tuberosity and the fibular head to a point midway between the anterior borders of the two malleoli (see Fig. 78.17). It passes on to the dorsal foot lateral to the tendon of extensor hallucis longus, as the dorsalis pedis artery. The latter gives off a medial branch that travels toward the first intermetatarsal space.

The posterior tibial artery may be represented by a line drawn from a midaxial point on the calf (approximately midway between the tibial condyles) at the level of the neck of the fibula, to a point onethird of the way between the posterior border of the medial malleolus and the calcaneal tendon (see Fig. 78.18). The same line represents the course of the tibial nerve. At first, the nerve lies lateral to the popliteal artery but gradually crosses the vessel to gain its medial side. The posterior tibial artery bifurcates into the plantar arteries halfway between the medial malleolus and the medial calcaneal tubercle (see Fig. 78.20).

The medial plantar artery passes anteriorly towards the great toe. The lateral plantar artery passes obliquely towards a point approximately 2.5 cm medial to the tuberosity of the fifth metatarsal, after which it enters the proximal part of the fourth intermetatarsal space. Digital arteries and nerves pass along the medial and lateral sides of the toes.

## Pulses

Femoral artery The pulsations of the femoral artery can be felt at its entry point into the proximal femoral triangle, where it can be compressed against either the superior pubic ramus or the hip joint. The pulse of the femoral artery is of value in assessing whether there is any
significant cardiac output in cases of circulatory collapse. It is a common site for catheter insertion for radiological examinations such as cardiac angiography and for arterial puncture for blood gas analysis.

Popliteal artery The pulse of the popliteal artery is the most difficult of the peripheral pulses to feel because the artery lies deep in the popliteal fossa. It is best examined with the subject lying supine or prone, with the knee flexed in order to relax the tense popliteal fascia that roofs the popliteal fossa. The popliteal pulse is then felt over the midline of the fossa by deep pressure against the popliteal surface of the femur.

Posterior tibial artery The pulse of the posterior tibial artery can be felt by gentle palpation posterior to the medial malleolus as the artery lies between the tendons of flexor hallucis longus and flexor digitorum longus, approximately one-third of the way along a line connecting the posterior border of the medial malleolus to the calcaneal tendon.

Dorsalis pedis artery The dorsalis pedis arterial pulse is found by palpation against the underlying tarsals, immediately lateral to the tendon of extensor hallucis longus, from the midpoint between the malleoli to the proximal end of the first intermetatarsal space.

## Veins

The femoral vein is located immediately medial to the femoral artery pulse, where it can be accessed (see Fig. 78.15). While femoral vein puncture is relatively easy and supplies ready access to the right atrium, the use of this approach is relatively unpopular for long-term cannulation because of a greater incidence of thrombosis and sepsis. However, it is a useful site for venous sampling in a patient with collapsed veins. For femoral vein cannulation, the skin puncture site is approximately 1 cm medial to the femoral artery and just inferior to the inguinal ligament.

The dorsal venous arch of the foot is visible and curves across the metatarsals (see Fig. 78.19). The long saphenous vein arises from the medial end of the arch, and the short saphenous vein arises from the lateral end. The long saphenous vein can be seen and palpated anterior to the medial malleolus, after which it runs superiorly and posteriorly across the distal medial surface of the tibia: this is a useful site for surgical venous access (cut-down) or venous harvesting for cardiac bypass surgery (see Figs $78.17,78.19$ ). The vein then runs proximally along the posterior aspect of the medial border of the tibia, where it is accompanied by the saphenous nerve, to reach a point a hand's breadth $(7-10 \mathrm{~cm})$ posterior to the medial patellar border. From here, the vein ascends the thigh to the saphenous opening, where it passes deep to enter the femoral vein. An image-based study found that the saphenofemoral junction almost always occupied a $3 \times 3 \mathrm{~cm}$ zone located $1-4 \mathrm{~cm}$ lateral and $0-3 \mathrm{~cm}$ inferior to the pubic tubercle (Mirjalili et al 2014) (see Fig. 78.15). The junction was nearer to the pubic tubercle in younger and thinner subjects.

The course of the short saphenous vein may be represented by a line from the posterior surface of the lateral malleolus superiorly along the midline of the calf to the popliteal fossa; together with the sural nerve, this vein is the key anatomical guide to surgical dissection of the popliteal fossa (see Fig. 78.18).

## Nerves

In the proximal femoral triangle, the femoral nerve is located immediately lateral to the femoral artery pulse.

The surface marking for the course of the saphenous nerve in the leg matches that of the long saphenous vein (see above). The lateral femoral cutaneous nerve enters the femoral triangle 2.1-3.5 cm (range $0.3-7.3 \mathrm{~cm}$ ) from the anterior superior iliac spine (see Fig. 78.15) (Grothaus et al 2005, Bjurlin et al 2007, Ropars et al 2009). It then passes over the lateral border of sartorius up to 11.3 cm distal to the anterior superior iliac spine (Grothaus et al 2005, Ropars et al 2009), and over the anterior border of tensor fasciae latae between 2.4 and 9.2 cm distal to the anterior superior iliac spine (Ropars et al 2009). The nerve is at risk of damage during anterolateral surgical approaches to the hip.

The course of the sciatic nerve can be represented by a curved line that starts at a point $0.3 \pm 0.05$ of the distance down a line drawn from the posterior superior iliac spine to the ischial tuberosity, and passes to a point $0.5 \pm 0.05$ of the distance along a line drawn from the ischial tuberosity to the greater trochanter (see Fig. 78.16). It then continues vertically and inferiorly in the midline of the posterior aspect of the
thigh, deep to biceps femoris, to the upper angle of the popliteal fossa, where it divides into the tibial and common fibular nerves (if it has not already done so at a more superior level).

The surface marking for the course of the tibial nerve in the leg matches that of the posterior tibial artery (see above). The course of the sural nerve at the ankle can be represented by a line running parallel to the calcaneal tendon that is situated halfway between the tendon and the lateral malleolus: this position is variable and the sural nerve is at risk from surgery in this region.

The course of the common fibular nerve can be indicated by a line that runs from the superior angle of the popliteal fossa, along the medial side of the tendon of biceps femoris (see Fig. 78.18) and then curves inferiorly and anteriorly around the neck of the fibula approximately 3 cm distal to the superior tip of the fibula. The common fibular nerve is palpable medial and distal to the tendon of biceps femoris and over the neck of the fibula, although here it becomes less distinct as it passes deep to the origin of fibularis longus. At the neck of the fibula, the nerve is at particular risk of damage either from a tightly applied plaster cast or from a fracture.

The deep fibular nerve starts on the lateral aspect of the neck of the fibula, passes downwards and medially, and rapidly becomes associated with the anterior tibial artery, with which it is landmarked (see Fig. 78.18). The superficial fibular nerve also begins on the lateral aspect of the neck of the fibula. It descends to a point on the anterior border of fibularis longus, at the junction of the middle and lower thirds of the leg, where it pierces the deep fascia and divides into intermediate and medial dorsal cutaneous branches. The intermediate dorsal cutaneous branch is normally both visible and palpable over the dorsolateral aspect of the ankle and foot toward the fourth toe (see Fig. 78.19). The medial dorsal cutaneous branch is rarely visible and passes towards the second toe. These superficial nerves are at risk from surgery in the anterior ankle region (especially during arthroscopy).

## CLINICAL PROCEDURES

## Nerve anaesthesia (nerve blocks)

Nerves can be effectively anaesthetized with local anaesthetic injection for surgical or post-injury pain relief. Common injection sites for the lower limb are around the hip for thigh and knee pain, and around the ankle for foot surgery. For the deeper nerves around the hip, the use of a nerve stimulator is very helpful in localizing the target nerve precisely before infiltration of local anaesthetic. For example, blockade of the sciatic nerve in the buttock, femoral nerve in the anterior thigh, and obturator nerve in the medial thigh may be undertaken to provide pain relief for total knee replacement; the tibial nerve at the posteromedial ankle, the sural nerve at the posterolateral ankle and the superficial fibular nerves at the anterior ankle may all be anaesthetized at the ankle to allow 'awake foot surgery'.

## Intramuscular injection

Intramuscular injections into the buttock should be avoided to prevent iatrogenic damage to the sciatic nerve. If the buttock is to be used, a relatively safe area is the true upper and outer quadrant, which is identified with the whole buttock exposed. The injection is then given mainly into gluteus medius rather than into gluteus maximus, provided a sufficiently long needle is used; most so-called 'intramuscular' injections given into the buttock are actually given into the fat. A safe alternative is to inject into the lateral aspect of the thigh (vastus lateralis).

## Joint injection and aspiration

Careful aseptic technique is essential for all joint aspirations and injections.

Hip Intra-articular hip injections are typically performed under fluoroscopic or ultrasonographic guidance. With the patient lying supine, and after the positions of the femoral artery and the anterior superior iliac spine have been marked out, the needle is introduced anteriorly, approximately 5 cm distal to the anterior superior iliac spine and 4 cm lateral to the femoral artery pulse, and passed posteriorly, a little proximally and medially. An alternative technique that is dependent on relative distances from surface landmarks, rather than imaging guidance, utilizes the site of the proximal anterolateral portal for hip arthroscopy as the point of needle insertion (Masoud and Said 2013).

Knee The lateral retropatellar approach is used. With the patient supine and the knee extended, the needle is introduced at the level of the superior border of the patella and guided towards the suprapatellar bursa.

Popliteal fossa Sciatic nerve blocks at the popliteal fossa in infants and children can be effectively performed above the popliteal skin crease by correcting the adult landmark of 10 cm by the ratio of the calculated child femoral shaft length over the adult femoral shaft length (Bernière et al 2008).

Ankle The anterior approach entails introducing the needle between the tendons of tibialis anterior and extensor hallucis longus with the foot partially plantar flexed.

## Arthroscopy portals

The placement of portals for arthroscopy is important for maximizing surgical access for visualization and for surgical instruments, and also for avoiding damage to structures such as nerves and blood vessels.

Hip Arthroscopy of the hip is not yet a common procedure but is increasingly being used. A variety of entry portals have been described. The anterolateral portal is sited on the skin approximately 4 cm lateral to the femoral artery pulse and 4 cm inferior to the inguinal ligament. Under fluoroscopy, a needle traversing the skin 30-45 degrees proximally is advanced into the joint. Other more lateral portals can be used; the lateral femoral cutaneous nerve and the sciatic nerve are potentially at risk.

Knee The knee is the joint most frequently examined with arthroscopy. The standard portals are placed anteriorly. When the knee is flexed at a right angle, 'soft triangles' bordered by the patellar ligament, the femoral condyles and the tibia and anterior horns of the menisci are palpable on either side of the superior third of the patellar ligament. Small incisions can be made in the apices of these triangular areas at about the level of the inferior pole of the patella for the anterolateral portal, and slightly lower for the anteromedial portal. These portals will allow passage of an arthroscope and instruments, with good access to most of the joint. The patellar ligament and the infrapatellar branch of the saphenous nerve are at risk from the skin incisions. The nerve is less vulnerable than the ligament; its position is variable but it usually lies below the appropriate portal sites. In the days of open meniscal surgery, the nerve was usually divided and painful neuroma formation was not uncommon.

Posteromedial and posterolateral portals are useful when better access to the posterior knee is required. The saphenous and common fibular nerves, respectively, are at risk with these approaches, and anatomical knowledge is vital to ensure safe portal placement. Laterally, the incision should be anterior to the tendon of biceps femoris, which can easily be palpated. Medially, the situation is more difficult because the saphenous nerve and long saphenous vein travel superficial to the medial epicondylar region of the knee, approximately a hand's breadth posterior to the medial border of the patella. It is essential that sharp incision includes the skin only, and that dissection down to the joint capsule is undertaken bluntly. If the medial meniscus is sutured, the capsule must be exposed before tying off sutures to avoid ensnaring the nerve.

Ankle The use of ankle arthroscopy is well established, especially in treating sports-related injuries. Anterior portals are standard. The anteromedial portal can be placed just medial to the tendon of tibialis anterior, in the palpable soft spot. However, this comes close to the long saphenous vein and saphenous nerve; limiting the sharp incision to the skin, followed by blunt deeper dissection, reduces the risk. Alternatively, the anteromedial portal can be chosen to pass between the lateral edge of tibialis anterior and extensor hallucis longus. The anterolateral portal is placed with the help of the arthroscope in the joint to check the position of a preliminary needle passed into it. The portal should pass lateral to fibularis tertius and extensor digitorum longus. The intermediate dorsal cutaneous branch of the superficial fibular nerve is at risk as it crosses the ankle anterior to the lateral malleolus, and therefore it is wise to mark the positions of the nerves and blood vessels with a pen before making any incision. The nerves can usually be felt at the front of the ankle, even in obese patients. They are often seen if the ankle is maximally pulled into plantar flexion. Posterior ankle arthroscopy is controversial: there is a view that the proximity of the neurovascular bundle (medially) and the sural nerve (laterally) renders it too
hazardous．Keeping lateral to the tendon of flexor hallucis longus will safeguard the medial neurovascular bundle．

## Placement of surgical incisions

Hip Surgery of the hip joint is usually undertaken for congenital issues， slipped capital femoral epiphysis in children，trauma or arthroplasty． Anterior and anterolateral approaches，often used in children，put the lateral femoral cutaneous nerve at considerable risk．Even in more lateral approaches，the lateral femoral cutaneous nerve and the femoral and sciatic nerves are all at risk through traction．A popular anterolateral approach to the hip joint involves splitting and separating forwards the anterior part of gluteus medius and vastus lateralis as a single sheet of tissue for subsequent reattachment to the greater trochanter．This tech－ nique relies on the anatomical continuity of the tissue．If the splitting of gluteus medius is more than a few centimetres superior to the tip of the greater trochanter，then the superior gluteal nerve and vessels are at risk，and weakness of hip abduction and a limp may result．In the posterior approach to the hip joint，gluteus maximus is incised in the line of its fibres．This is followed by division of the tendons of the short lateral rotators（piriformis，obturator internus and externus and gemelli）near their trochanteric attachments to reveal the joint capsule．Reflecting these cut tendons medially protects the sciatic nerve． The inferior and superior gluteal nerves are at risk during posterior approaches to the hip．

Knee Most open knee surgery can be undertaken through an anterior midline longitudinal incision，which gives good access and means that any future surgery can usually be undertaken via the same wound．New incisions run the risk of skin necrosis and poor wound healing as a consequence of interfering with the cutaneous blood supply．Inevitable interruption of cutaneous nerves，including the infrapatellar branch of
the saphenous nerve，means that there is always numbness lateral to a longitudinal incision．

The extensile approach to the posterior knee is extensive．The key is to expose the sural nerve and short saphenous vein and to trace them proximally．This will lead the surgeon into the popliteal fossa and，after opening the deep fascia，safely to the neurovascular bundle．The wound crosses a flexure crease．A scar perpendicular to the crease might induce a fixed flexion contracture of the joint and therefore an S－shaped inci－ sion is employed where the transverse segment runs in the line of the flexure crease．

Ankle and foot Incisions around the foot and ankle frequently put cutaneous nerves at risk and such an injury can result in a neuroma． The sural nerve at the ankle has a notorious tendency to form neuromas if transected，often after repair of a ruptured calcaneal tendon．

## Development of the pelvic girdle and lower limb

## PELVIC GIRDLE DEVELOPMENT

The pelvic girdle develops in close proximity to cloacal structures. The anterior portion of the pelvic girdle is intimately associated with the normal development of the caudal part of the urogenital system and the anterior body wall. Studies on the development of the lower limb in avian species and the mouse show that the perineal muscles, including the sphincters, derive from somitic myoblasts that have previously entered the hindlimb bud. Similar to the developmental process seen in the upper limb, somitic myoblasts originating from the dorsoventral edge of the dermomyotome migrate into the somatopleuric mesenchyme of the early lower limb bud. The myoblasts coalesce into a single entity before dividing into dorsal and ventral muscle masses. The cells of the ventral muscle mass then divide again, with one population continuing to develop within the limb and the other migrating ventrally towards the genital tubercle (Valasek et al 2005). In the avian embryo, myoblasts from somites 26-29 enter the limb only, and those from somites 30-33 form both cloacal and limb muscles, whereas those from somite 34 form cloacal muscles solely. Within pelvic girdle development, myoblasts do not attain their position by somitic hypaxial domain extension; all myoblasts migrate into the region. Interestingly, the population of myoblasts giving rise to perineal muscles are innervated by axons derived from neurones located in Onuf's nucleus, whereas those that remain in the limb bud gain innervation from anterior horn cells (Valasek et al 2005).

The bony pelvis forms from two hemipelves, each of which develops from one cartilaginous focus. Ossification of the pelvis starts with the ilium, which undergoes endochondral ossification at 9.5 weeks. Development of trabecular bone in the ilium is evident from about 22 weeks gestation and a mature trabecular morphology is present at birth (Cunningham and Black 2009a, Cunningham and Black 2009b). It is suggested that the trabecular pattern, previously assumed to develop consequent to weight bearing and bipedal gait, is initiated through genetic patterning plus intrauterine muscular movements which confer biomechanical loading onto the ilium and pelvis.

The development of the superior pubic rami is related to the normal development of the cloacal membrane. In cases of bladder exstrophy (see Fig. 72.11), the superior pubic rami are shortened and do not meet at the pubic symphysis. There is a 4 cm pubic diastasis at birth, which increases to 8 cm at age 10 years, compared with a mean normal width of the pubic symphysis of 0.6 cm at all ages (Wild et al 2011). The ischiopubic segment of the pelvis is $30 \%$ shorter, the iliac wings are externally rotated and the acetabuli are retroverted (Wild et al 2011). The mechanisms suggested for this are premature rupture of an abnormally cranially placed cloacal membrane, obstruction of medial migration of somatopleuric mesenchyme, and local apoptosis of ventral mesenchyme (Stec 2011). It is thought that some combination of the three is likely.

The sacroiliac joint can be recognized from 7 weeks; its development is slightly different from that of other synovial joints in that the development of the ilium is ahead of that of the sacrum. Reconsideration of the role of the sacroiliac joint in the transfer of load from axial to appendicular skeleton has been prompted by study of the relative growth of regional surface areas of the ilium from birth to adulthood (Yusof et al 2013). Cavitation of the hip joint has been reported at 7-8 weeks.

## LOWER LIMB DEVELOPMENT

The lower limb is first recognizable as a laterally projecting thickening in the body wall opposite somites 24-29 at stage 13 (28 days); by stage 14 , it is closely associated with the wide umbilical cord. During stages $15-17$, the limb projects laterally and outgrowth is fairly symmetrical. The core of mesenchymal cells is derived from both somatopleuric and paraxial mesenchyme.

By stage 17, the lower limb still has a flattened foot plate and, although a hip region can be identified, there is no true knee as yet. In stage 18, the lower limb appears to be flexed and abducted at the hip with the knee bent, giving the appearance that the knee is facing laterally. The femur and tibia form in cartilage, and the sciatic nerve extends distally to the tibia by stage 18 . Very little skin of the thigh is visible. The soles of the feet face the umbilical cord, and the foot plate has digit rays. During stages 20-23, the digit rays separate and toes are clearly defined by stage 23 . The feet can finally touch at stage 21 , when the umbilical cord becomes proportionally smaller and the embryo larger. For more details, see O'Rahilly and Gardner (1975).

## VESSELS

## Arteries

The blood supply to the lower limb is derived from the lateral branch of the fifth lumbar intersegmental artery, which arises from the dorsal root of the umbilical artery passing to the placenta, and continues into the limb bud as the axial artery. The arterial supply to the developing lower limb is thus far less oxygenated than the arterial supply to the upper limb, which receives blood directly from the heart via the subclavian artery. It is possible that the development of several arteries, some of which subsequently regress, in the distal part of the leg in the embryonic period, is a reflection of the lower oxygenation of these tissues. During development, the lower limb undergoes medial rotation and extension, so that the original dorsal (extensor) portion of the limb becomes directed ventrally. This relative movement suggests that very different patterning mechanisms operate in the lower limb compared to those in the upper limb: an early, complex vasculature may be a product of that difference.

There have been relatively few studies on the early development of the vasculature of the lower limb (Senior 1991a,b, Mandell et al 1985, Levinsohn et al 1991). The terminology used to describe the developing vessels is specific and will be used here: descriptions of developmental vascular anomalies retain the original terminology. Table 79.1 describes and illustrates the changes to the axial artery, the new vessels that arise and the vessels that regress, during stages 13-19 (corresponding to weeks 5-7 of development). The mature vascular pattern is established by the end of the embryonic period.

## Veins

The superficial veins of the lower limb are derived from the marginal vein which runs along the periphery of the extending limb bud beneath the pre- and post-axial limb borders. The preaxial vein becomes the long saphenous vein, which drains into the femoral vein the saphenous opening. The postaxial vein becomes the short saphenous vein, which passes deep and joins the popliteal vein. The earliest valves in the short saphenous vein are noted at 13 weeks' gestation. The number of valves increases from 1 to 8 between 13 and 18 weeks' gestation; there are more valves present in the upper than in the lower portion of the short saphenous vein (Czarniawska-Grzesińska and Bruska 2002).

## ULTRASOUND ANTENATAL IMAGING

Femur length is routinely measured to assess growth velocity (along with head circumference and abdominal circumference) and to predict the expected date of delivery. The longest axis of the ossified diaphysis is identified with soft tissue noted beyond both ends. The distal epiphysis is excluded (Fig. 79.1). Fetal femur length is related to ethnicity, and appropriate fetal biometry comparison charts are necessary for accurate evaluation; whether such data can be extrapolated to mixed ethnicity fetal populations has been questioned (Ogasawara 2009).

Fig. 79.1 An ultrasound image showing femur length. (With permission from To M, Pereira S 2015 Routine fetal anomaly scan, in Coady AM (ed) Twining's Textbook of Fetal Abnormalities, 3rd edition, Churchill Livingstone.)

Identification of short femur length is associated with a higher risk of chromosomal abnormalities (Mathiesen et al 2014) and a significantly higher likelihood of the fetus being small for gestational age and at risk of early preterm delivery (Mathiesen et al 2014, Özlü and Ozcan 2013). It has been estimated that identification of isolated short femur length below the tenth or fifth percentile at mid-gestation is associated with more than a three-fold risk of the development of fetal growth retardation and increased risk of early preterm birth before 37 and 34 weeks (Goetzinger et al 2012). Although the cause of this relationship must be multifactorial, it is suggested that changes in placentation and chronic fetal hypoxia may lead to a fetal adaptive response in which highly oxygenated blood is diverted to the brain and heart at the expense of the extremities.

## NEONATAL LOWER LIMB

In the neonate, the pelvis is cone-shaped. The transverse diameter of the true pelvis is 2.2 cm , its anteroposterior diameter is 2.8 cm , and the length between the inlet and outlet is 2 cm . The sacrum is proportionately larger than in the adult and the sacral promontory is higher. When walking begins, the sacrum descends between the ilia and the promontory develops. The ilia, ischia and pubic bones are variably ossified at
birth; they meet at the acetabulum, which in the neonate is cartilaginous, relatively large and shallow.

The lower limbs are underdeveloped in the neonate when compared to the upper limbs. They are retained in a flexed position and the lower leg is proportionately shorter than the thigh. Although the legs appear to be bowed, the tibia and fibula are straight; the illusion of bow legs is caused by the shape of the soft tissues and the slightly more advanced development of the lateral head of gastrocnemius compared to its medial head. The femoral neck is much shorter and forms an acute angle with the shaft. The latter is quite straight because the adult curvature is acquired with walking. The head of the femur is larger than the acetabular fossa and nearly one-third remains external, which means that the ligament of head of femur is relatively very long. Dislocation of the hip joint is relatively easy; the femoral head can be removed from the acetabular fossa laterally but not posteriorly. The calcaneus and the talus have an ossification centre at birth, and a centre is present in the cuboid in half of neonates.

The muscles of the lower limb are much less developed than those in the upper limb. The fetal position often assumed by postnatal babies keeps the thighs in continuous abduction, stretching the adductors. The muscles that will be used for walking are weak; the lack of gluteal development, in particular, gives the typically diminutive buttocks of the neonate

In neonates, the feet are usually inverted and they have a greater degree of dorsiflexion, caused by the relatively greater area of the trochlea of the talus. Plantar flexion is limited, in part reflecting the shortness of the extensor muscles of the foot. At birth, the footprint outlines the whole plantar surface, reflecting the deposition of subcutaneous fat beneath the longitudinal and transverse arches, and so most babies appear flat-footed.

## DEVELOPMENTAL ANOMALIES OF THE LOWER LIMB

The categories of limb defects described by Swanson (1976) are given on page 796. Although devised for the upper limb, they similarly apply to the lower limb.

Developmental dysplasia of the hip (previously known as congenital dislocation of the hip) refers to an abnormal configuration of, or relationship between, the femoral head and the acetabulum that occurs either before or after birth in approximately 1 in 100 live births with a female: male ratio of $6: 1$. (In $2 \%$ of cases, hip dislocation is not evident at birth but manifests in the first few months of the life.) It covers a continuum of disorders that ranges from shallowness of the acetabulum to instability and subluxation of the femoral head and, ultimately, to frank dislocation. Acetabular anteversion may occur (Li et al 2009). The aetiology is considered to be multifactorial and is associated with first pregnancies, suggesting that both maternal and uterine musculature restricts fetal movement and puts postural strain on the fetal hips.

Developmental dysplasia of the hip is seen more frequently in breech delivery, especially if the child's knees are extended. The incidence is similar in preterm and term infants born in the breech position (Quan et al 2013). The left hip is more frequently affected than the right, possibly because, in breech presentation, the fetus lies with the right shoulder anterior and the left thigh closest to the maternal sacrum. The physiological effects that cause the maternal ligaments to become temporarily lax prior to delivery are also considered to affect the fetus and to contribute to laxity of the hip capsule. Risk factors are breech delivery, female sex, a positive family history and clicking hips at clinical examination (de Hundt et al 2012). Ultrasound is beneficial in the early detection and assessment of children with developmental dyspla-
sia of the hip; magnetic resonance imaging (MRI) may be beneficial in identifying the underlying bony and soft tissue anatomy.

The collodiaphysial angle (CDA; neck-shaft angle, Mikulicz angle) is the angle between the long axis of the femoral shaft and the head and neck of the femur; the normal range varies between $125^{\circ}$ and $140^{\circ}$ (see Fig. 81.10). Where the CDA is enhanced, usually above $135^{\circ}$, a coxa valga deformity occurs. Where CDA is decreased (usually defined as less than $120^{\circ}$ ), a coxa vara deformity occurs; the mechanism is thought to be a failure of medial growth of the physial plate. The resulting lower limb is shortened and abduction is restricted. In both coxa valga and coxa vara, the long-term unequal weight distribution may result in excessive wear of articular cartilage.

The femur normally aligns on the tibia obliquely, creating an angle of $174^{\circ}$ facing laterally. A medial angulation of the leg in relation to the thigh is a deformity called genu varum, whereas a lateral angulation is called genu valgum. The hip-knee (femoral-tibial) angle in children is $+3.6^{\circ}$ (varum) between the ages of 1 and 2 years, and $-2.5^{\circ}$ (valgum) between the ages of 2 and 3 years. The prevalence of lower limb deformities physiologically decreases after 5 years of age; the angle is $+0.3^{\circ}$ after the age of 7 years, which is within $1^{\circ}$ of adult reference values (Sabharwal and Zhao 2009). Both deformities cause unequal weight distribution that hastens destruction of knee cartilages; persistence of genu varum/valgum until late childhood may require correction in order to prevent arthrosis. (For further reading, see Goldman and Green (2010).)

The patella may be absent or hyoplastic, a malformation that may be isolated or may be associated with other defects (Mizobuchi et al 2007).

Congenital talipes equinovarus, or club foot, derives its name from a combination of talus and pes, together with terms describing an elevated heel resembling that of a horse (equino), which is also turned inwards (varus). It is a common neonatal anomaly and occurs in approximately 1 per 1000 live births, with males affected twice as often as females. There is some degree of inheritance, so it is not entirely an effect of intrauterine positioning or of oligohydramnios (abnormally little amniotic fluid). Both bones and soft tissues are affected and it is difficult to tell which are primary effects and which are secondary. A number of theories have been proposed to explain the underlying pathogenetic mechanism(s), including abnormal tendon and ligament attachments, defective development of the talus and delayed muscle maturation. One theory is that the talus undergoes defective development and that all the other deformities arise as a consequence of this initial defect. The talus is decreased in size by up to $25 \%$. It has a foreshortened neck and decreased body/neck angle, and the subtalar facets are medially rotated. The navicular is small and medially deviated relative to the talus. The calcaneus is also small and shows varus displacement and equinus tilt; the anterior facets correspond to those of the talus (Barlow and Clarke 1994). The entire affected foot and calf are smaller than their normal counterparts. The foot is inverted and supinated, and the forefoot is adducted. The heel is small, rotated inwards and elevated. The calcaneus is inverted beneath the talus. MRI analysis of the lower legs of patients who had been treated for idiopathic congenital talipes equinovarus showed that leg muscle volume was consistently reduced (Duce et al 2013). Treatment varies between splintage and repeated complex surgery, which reflects the highly variable severity of the condition and individual response to therapy.
'Flat feet' are common in childhood. The majority are 'flexible' and simply related to posture, whereas 'rigid' flat feet are caused by structural abnormalities. The description of 'rocker bottom' foot is associated with many congenital syndromes. The foot is flat and rigid, and the plantar surface appears curved with the apex of the curve at the mid-tarsal joint. The condition shows an equinus position of the hindfoot. The talus may be vertical and palpable on the plantar surface. A majority of infants with this condition have neurological abnormalities.

# Pelvic girdle, gluteal region and thigh 

The pelvic girdle consists of the paired hip bones (each composed of the ilium, ischium and pubis) and the sacrum. The two pubic bones articulate anteriorly at the pubic symphysis and the sacrum articulates posteriorly with the two iliac bones at the sacroiliac joint; the bones are virtually incapable of independent movement, except in the female during parturition or as a result of pathological change. The pelvic girdle is massively constructed and serves as a weight-bearing and protective structure, as an attachment for trunk and lower limb muscles, and as the skeletal framework of a birth canal capable of accommodating passage of the fetus.

The gluteal region or buttock is an area demarcated by the gluteal fold inferiorly, a line joining the greater trochanter and the anterior superior iliac spine laterally, the iliac crest superiorly and the midline medially. It contains a large bulk of skeletal muscle that covers several vulnerable neurovascular structures, and incorporates junctional zones between the lower limb, pelvis and perineum at the sciatic foramina. Direct and indirect musculoskeletal injuries in this region may damage the sciatic nerve and gluteal vessels.

The thigh consists of a cylinder of compact bone, the femoral shaft, surrounded by muscle groups traversed by important neurovascular structures. The muscles are grouped according to function and lie within osteofascial compartments that are defined by fascial septa running between the femur and an enveloping tube of thick fascia, the fascia lata. The femoral artery gives off its major branch, the profunda femoris artery (deep artery of the thigh), in the anterior compartment, and the sciatic nerve usually divides into its main branches, the tibial and common fibular nerves, as it passes through the posterior compartment of the thigh. The femoral nerve divides soon after entering the anterior compartment of the thigh beneath the inguinal ligament; the obturator nerve enters the medial thigh proximally and medially from the pelvis and divides into its main branches, which run anterior and posterior to adductor brevis.

## SKIN AND SOFT TISSUES

## SKIN

See also Chapter 78 (p. 1316).

## Cutaneous vascular supply and Iymphatic drainage

## Buttock

Most of the skin of the buttock is supplied by musculocutaneous perforating vessels from the superior and inferior gluteal arteries. There are also small peripheral contributions from similar branches of the internal pudendal, iliolumbar and lateral sacral arteries.

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic drainage is to the superficial inguinal nodes.

## Thigh

The skin of the thigh distal to the inguinal ligament and gluteal fold is supplied mainly by branches of the femoral and profunda femoris arteries. There is some contribution from the obturator, inferior gluteal and popliteal arteries, and from direct cutaneous, musculocutaneous and fasciocutaneous vessels. For further details, consult Cormack and Lamberty (1994).

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic drainage is to the superficial inguinal nodes, mainly via collecting trunks accompanying the long saphenous vein.

## Innervation

For the dermatomes and cutaneous nerves, see Figures 78.12B, 78.13, 78.14.

## SOFT TISSUES

## Subcutaneous tissue

The subcutaneous tissue (tela subcutanea) of the thigh and buttock consists, as elsewhere in the limbs, of loose areolar tissue containing a variable quantity of fat. In some regions, particularly near the inguinal ligament, it splits into recognizable layers, between which may be found the branches of superficial vessels and nerves. It is thick in the inguinal region, where its two layers enclose the superficial inguinal lymph nodes, long saphenous vein and other smaller vessels. Here, the superficial layer is continuous with that of the abdominal fascia. The deep layer, a thin fibroelastic stratum, is most marked medial to the long saphenous vein and inferior to the inguinal ligament, and is interposed between the subcutaneous vessels and nerves and the deep fascia, fusing with the latter a little below the ligament. This membranous layer of subcutaneous tissue overlies the saphenous opening, blending with its circumference and with the femoral sheath. Over the opening, it is perforated by the long saphenous vein, by the superficial branches of the femoral artery other than the superficial circumflex iliac branch (which perforates the fascia lata separately), and lymphatic vessels; hence the term cribriform fascia. The subcutaneous tissue of the buttock is continuous superiorly with that over the low back and contains a variable quantity of fat.

## Deep fascia

The deep fascia (fascia musculorum) covering the gluteal muscles varies in thickness. Over gluteus maximus it is thin, but over the anterior twothirds of gluteus medius it forms the thick, strong gluteal aponeurosis. This is attached to the lateral border of the iliac crest superiorly, and splits anteriorly to enclose tensor fasciae latae and posteriorly to enclose gluteus maximus.

## Fascia lata

The fascia lata, the wide, deep fascia of the thigh, is thicker in the proximal and lateral parts of the thigh where tensor fasciae latae and an expansion from gluteus maximus are attached to it. It is thin posteriorly and over the adductor muscles, but thicker around the knee, where it is strengthened by expansions from the tendon of biceps femoris laterally, sartorius medially and quadriceps femoris anteriorly. The fascia lata is attached superiorly and posteriorly to the back of the sacrum and coccyx, laterally to the outer margin of the iliac crest, anteriorly to the inguinal ligament and superior ramus of the pubis, and medially to the inferior ramus of the pubis, the ramus and tuberosity of the ischium, and the lower border of the sacrotuberous ligament. From the iliac crest, it descends as a dense layer over gluteus medius to the upper border of gluteus maximus, where it splits into two layers, one passing superficial and the other deep to the muscle, the layers reuniting at the lower border of the muscle.

## Iliotibial tract

Over the flattened lateral surface of the thigh, the fascia lata thickens to form a strong band, the iliotibial tract. The upper end of the tract splits into two layers, where it encloses and anchors tensor fasciae latae and receives, posteriorly, most of the tendon of gluteus maximus. The superficial layer ascends lateral to tensor fasciae latae to the iliac crest; the deeper layer passes up and medially, deep to the muscle, and blends with the lateral part of the capsule of the hip joint. Distally, the iliotibial
tract is attached to a smooth, triangular facet (Gerdy's tubercle) on the anterolateral aspect of the lateral condyle of the tibia, where it is superficial to, and blends with, an aponeurotic expansion from vastus lateralis. When the knee is extended against resistance, it stands out as a strong, visible ridge on the anterolateral aspect of the thigh and knee.

Distally, the fascia lata is attached to all exposed bony points around the knee joint, such as the condyles of the femur and tibia, and the head of the fibula. On each side of the patella, the deep fascia is reinforced by transverse fibres, which receive contributions from the lateral and medial vasti. The stronger lateral fibres are continuous with the iliotibial tract.

## Intermuscular septa

The deep surface of the fascia lata yields two intermuscular septa, which are attached to the whole of the linea aspera and to its proximal and distal prolongations. The lateral septum, thicker and stronger than the medial one, extends from the attachment of gluteus maximus to the lateral femoral condyle; it lies between vastus lateralis in front and the short head of biceps femoris behind, and provides partial attachment for them. The medial, thinner and weaker septum lies between vastus medialis and the adductors and pectineus. Numerous smaller septa, such as that separating the thigh adductors and flexors, pass between the individual muscles, ensheathing them and sometimes providing partial attachment for their fibres.

## Saphenous opening

The saphenous opening is an aperture in the deep fascia, inferolateral to the medial end of the inguinal ligament, which allows passage for the long saphenous vein and other smaller vessels (Fig. 80.1). The cribriform fascia, which is pierced by these structures, fills in the aperture and must be removed to reveal it. Adjacent subsidiary openings may exist to transmit venous tributaries. In the adult, the approximate centre of the saphenous opening is 3 cm lateral to a point just distal to the pubic tubercle. The length and width of the opening vary considerably. The fascia lata in this part of the thigh displays superficial and deep strata (not to be confused with the superficial and deep layers of the subcutaneous tissue described above). They lie, respectively, anterior and posterior to the femoral sheath, with the saphenous opening situated where the two layers are in continuity. This serves to explain the somewhat oblique and spiral configuration of the saphenous opening.

The superficial layer, lateral and superior to the saphenous opening, is attached, in continuity, to the crest and anterior superior spine of the ilium, to the whole length of the inguinal ligament, and to the pecten pubis and lacunar ligament. It is reflected inferolaterally from the pubic tubercle as the arched falciform margin, which forms the superior, lateral and inferior boundaries of the saphenous opening; this margin adheres to the anterior layer of the femoral sheath, and the cribriform fascia is attached to it. The falciform margin is considered to have superior and inferior horns. The inferior horn is well defined, and is continuous behind the long saphenous vein with the deep stratum of the fascia lata.

The deep layer is medial to the saphenous opening and is continuous with the superficial stratum at its lower margin. Traced upwards, it covers pectineus, adductor longus and gracilis, passes behind the femoral sheath, with which it blends, and continues to the pecten pubis.

## Fascial compartments

There are three functional groups of muscle in the thigh: namely, anterior (extensor), posterior (flexor) and medial (adductor). The anterior and posterior groups occupy separate osteofascial compartments that are limited peripherally by the fascia lata and separated from each other by the femur and the medial and lateral intermuscular septa (Fig. 80.2). The adductor muscles do not possess a separate compartment limited by fascial planes. Nevertheless, it is customary to speak of three compartments: anterior, posterior and medial. The muscles of the three compartments are described below. Adductor magnus, adductor longus and pectineus could each be considered to be constituents of two compartments, i.e. adductor magnus in the posterior and the medial compartments, and adductor longus and pectineus in the anterior and the medial compartments.

The nerve supply to the compartments of the thigh mainly follows the 'one compartment - one nerve' principle. Thus, the femoral nerve supplies the anterior compartment muscles, the obturator nerve supplies the medial compartment muscles, and the sciatic nerve supplies those in the posterior compartment. The dual functional and compartmental attribution of adductor magnus, adductor longus and pectineus are reflected in their dual nerve supplies.

In contrast to the motor innervation, the arterial supply to the compartmental muscle groups does not exhibit such a direct relationship. All groups receive a supply from the femoral system, particularly from the profunda femoris artery and its branches. The adductors receive a contribution from the obturator artery, and the hamstrings receive a proximal supply from the inferior gluteal artery. Further details are given in the descriptions of the individual muscles.

## Femoral sheath

The femoral sheath is a funnel-shaped distal prolongation of extraperitoneal fascia, formed of transversalis fascia anterior to the femoral vessels, and of the iliac fascia posteriorly. It is wider proximally and its tapered distal end fuses with the vascular adventitia 3 or 4 cm distal to the inguinal ligament. At birth the sheath is shorter; it elongates when extension at the hips becomes habitual. The femoral branch of the genitofemoral nerve perforates its lateral wall. The medial wall slopes laterally and is pierced by the long saphenous vein and lymphatic vessels. Like the carotid sheath, the femoral sheath encloses a mass of connective tissue in which the vessels are embedded. Three compartments are described: a lateral one containing the femoral artery; an intermediate one for the femoral vein; and a medial compartment, the femoral canal, which contains lymph vessels and an occasional lymph node embedded in areolar tissue. The presence of this canal allows the femoral vein to distend. The canal is conical and approximately 1.25 cm in length. Its proximal (wider) end, termed the femoral ring, is bounded in front by the inguinal ligament, behind by pectineus and its fascia and the pectineal ligament, medially by the crescentic, lateral edge of the lacunar ligament and laterally by the femoral vein. The spermatic cord, or the round ligament of the uterus, is just above its anterior margin, while the inferior epigastric vessels are near its anterolateral rim. It is larger in women than in men: this is due partly to the relatively greater width of the female pelvis and partly to the smaller size of the femoral vessels in women. The ring is filled by condensed extraperitoneal tissue, the femoral septum, which is covered on its proximal aspect by the parietal peritoneum. Numerous lymph vessels that connect the deep inguinal to the external iliac lymph nodes traverse the femoral septum (Fig. 80.3).

## Femoral hernia

Femoral hernia is described with other groin hernias on page 1081.

## lliac fascia

The iliac fascia covers psoas and iliacus. It is thin above but thickens progressively towards the inguinal ligament. The part covering psoas is thickened above as the medial arcuate ligament. Medially, the fascia over psoas is attached by a series of fibrous arches to the intervertebral discs, the margins of vertebral bodies, and the upper part of the sacrum. Laterally, it blends with the fascia anterior to quadratus lumborum above the iliac crest, and with the fascia covering iliacus below the crest.

The iliac part is connected laterally to the whole of the inner lip of the iliac crest and medially to the pelvic brim, where it blends with the periosteum. It is attached to the iliopubic ramus, where it receives a slip from the tendon of psoas minor, when this muscle is present. The external iliac vessels are anterior to the fascia but the branches of the lumbar plexus are posterior to it. The fascia is separated from the peritoneum by loose extraperitoneal tissue. Lateral to the femoral vessels, the iliac fascia is continuous with the posterior margin of the inguinal

Fig. 80.2 A transverse (axial) section through the thigh. A, At the level of the apex of the femoral triangle. B, At the level of the mid-thigh.
ligament and the transversalis fascia. Medially, it passes behind the femoral vessels to become the pectineal ligament, attached to the pecten pubis. At the junction of its lateral and medial parts, it is attached to the iliopubic ramus and the capsule of the hip joint. It thus forms a septum between the inguinal ligament and the hip bone, dividing the space here into a lateral part, the muscular space, containing psoas major, iliacus and the femoral nerve, and a medial part, the vascular space, transmitting the femoral vessels (see Fig. 80.3). The iliac fascia continues downwards to form the posterior wall of the femoral sheath.

## Obturator membrane

The obturator membrane (Fig. 80.4) is a thin aponeurosis that closes (obturates) most of the obturator foramen, leaving a superolateral aperture, the obturator canal, through which the obturator vessels and nerve leave the pelvis and enter the thigh. The membrane is attached to the sharp margin of the obturator foramen except at its inferolateral angle, where it is fixed to the pelvic surface of the ischial ramus, i.e. internal to the foramen. Its fibres are arranged mainly transversely in interlacing bundles; the uppermost bundle, which is attached to the obturator tubercles, completes the obturator canal. The outer and inner surfaces of the obturator membrane provide attachment for the obturator externus and internus, respectively. Some fibres of the pubofemoral ligament of the hip joint are attached to the outer surface.

## BONES

The pelvic girdle is an entity consisting of the two hip bones and the sacrum (strictly speaking, the sacrum is part of the vertebral column). The pelvic girdle is massively constructed and serves as a weight-bearing and protective structure, an attachment for trunk and limb muscles, and as the skeletal framework of the birth canal.

## HIP BONE

The hip bone is large, irregular, constricted centrally and expanded above and below (Fig. 80.5). Its lateral surface has a deep, cup-shaped acetabulum, articulating with the femoral head, anteroinferior to which is the large, oval or triangular obturator foramen. Above the acetabulum, the bone widens into an undulant plate surmounted by a sinuously curved iliac crest.

The bone articulates in front with its fellow and posteriorly with the side of the sacrum to form the pelvic girdle. Each hip bone has three parts - ilium, ischium and pubis, connected to each other by cartilage in youth but united as one bone in adults. The principal union is in the acetabulum. The ilium includes the upper acetabulum and expanded

passing beneath the inguinal ligament. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Fig. 80.4 An anterolateral view of left bony pelvis, showing associated ligaments and the obturator membrane.
area above it; the ischium includes the posteroinferior acetabulum and bone posteroinferior to it; the pubis forms the anteroinferior acetabulum.

## Acetabulum

The acetabulum (Fig. 80.5A,C) is an approximately hemispherical cavity situated about the centre of the lateral aspect of the hip bone. It faces anteroinferiorly and is circumscribed by an irregular margin deficient inferiorly at the acetabular notch. The acetabular fossa forms the central floor and is rough and non-articular. The articular lunate surface is widest above (the 'dome'), where weight is transmitted to the femur. Consequently, fractures through this region tend to be associated with unsatisfactory outcomes. All three components of the hip bone contribute to the acetabulum, although unequally. The pubis forms the anterosuperior fifth of the articular surface, the ischium forms the floor of the fossa and rather more than the posteroinferior two-fifths of the articular surface, and the ilium forms the remainder. Occasionally, a linear defect may be seen to cross the acetabular surface from the superior border to the acetabular fossa. This does not correspond to any junction between the main morphological parts of the hip bone.

## Obturator foramen

The obturator foramen lies below and slightly anterior to the acetabulum, between the pubis and ischium. It is bordered above by the grooved obturator surface of the superior pubic ramus, medially by the pubic body and its inferior ramus, below by the ischial ramus, and laterally by the anterior border of the ischial body, including the margin of the acetabulum. The foramen is almost closed by the obturator membrane (see above), which is attached to its margins, except superolaterally, where a communication remains between the pelvis and thigh. This free edge of the membrane is attached to an anterior obturator tubercle at the anterior end of the inferior border of the superior pubic ramus, and a posterior obturator tubercle on the anterior border of the acetabular notch; these tubercles are sometimes indistinct. Since the tubercles lie in different planes and the obturator groove crosses the upper border of the foramen, the acetabular margin is in fact a spiral. The foramen is large and oval in males, but smaller and nearly triangular in females.

## Structure

The thicker parts of the hip bone are trabecular, encased by two layers of compact bone, while the thinner parts, as in the acetabulum and central iliac fossa, are often translucent and consist of a single lamina of compact bone. In the upper acetabulum and along the arcuate line, i.e. the route of weight transmission from the sacrum to the femur, the amount of compact bone is increased and the subjacent trabecular bone displays two sets of pressure lamellae. These start together near the upper auricular surface and diverge to meet two strong buttresses of compact bone, from which two similar sets of lamellar arches start and converge on the acetabulum. The anterior part of the iliac crest has been much studied with regard to distribution of cortical and trabecular bone. Whitehouse (1977) described the cortical bone as very porous, being only $75 \%$ bone, decreasing to $35 \%$ near the anterior superior iliac spine.

Studies of the internal stresses within the hip bone have revealed a pattern of trabeculae that corresponds well with the theoretically expected patterns of stress trajectories (Holm 1980). These patterns are considerably more complex than in any other major bone. Stresses are higher in the acetabular than in the iliac region. In the ilium, the pelvic surface is subjected to considerably less stress than is the gluteal surface.

## Muscle attachments

See individual bones.

## Vascular supply

In the infant, nutrient arteries are clearly demonstrable for each component of the hip bone. Each nutrient artery branches in a fan-like fashion within its bone of supply (Crock 1996). Later, a periosteal arterial network develops, with contributions from numerous local arteries (see under individual bones).

## Innervation

Periosteal innervation is by a network of nerves derived from branches of local nerves. These nerves also supply muscles attaching to the periosteum and the joints involving the hip bone. Autonomic nerves accompany nutrient arteries and branch within the bone.

## Ossification

Ossification (Figs 80.6-80.7) is by three primary centres: one each for the ilium, ischium and pubis. The iliac centre appears above the greater sciatic notch prenatally at about the ninth week; the ischial centre in its body in the fourth month; and the pubic centre in its superior ramus between the fourth and fifth months. The pubis is often not recovered from prenatal remains due to its size and fragility and because it is the last of the hip bones to begin ossification (Scheuer and Black 2004). At birth the whole iliac crest, the acetabular floor and the inferior margin are cartilaginous. Gradual ossification of the three components of the acetabulum results in a triradiate cartilaginous stem extending medially to the pelvic surface as a Y-shaped epiphysial plate between the ilium, ischium and pubis, and including the anterior inferior iliac spine. Cartilage along the inferior margin also covers the ischial tuberosity, forms

Unossified (cartilaginous) regions
Fig. 80.6 The hip bone. A, At birth. B, In adolescence; more heavily stippled areas indicate the secondary centres of ossification.

Fig. 80.7 An anteroposterior radiograph of the pelvis of a boy aged 7 years. Key: 1, ilium; 2, part of triradiate growth cartilage; 3, superior femoral epiphysis; 4, cartilaginous growth plates; 5, ossifying greater trochanter; 6, ischium; 7, pubis; 8, cartilage between inferior pubic and ischial rami.
conjoined ischial and pubic rami, and continues to the pubic symphysial surface and along the pubic crest to the pubic tubercle.

The ossifying ischium and pubis fuse to form a continuous ischiopubic ramus at the seventh or eighth year. Secondary centres, other than for the acetabulum, appear at about puberty and fuse between the fifteenth and twenty-fifth years. There are usually two for the iliac crest (which fuse early), and single centres for the ischial tuberosity (in cartilage close to the inferior acetabular margin and spreading forwards), anterior inferior iliac spine (although it may ossify from the triradiate cartilage) and symphysial surface of the pubis (the pubic tubercle and crest may have separate centres). Progression of ossification of the iliac crest in girls is an index of skeletal maturity and is useful in determining the optimal timing of surgery for spinal deformity.

Between the ages of 8 and 9 years, three major centres of ossification appear in the acetabular cartilage. The largest appears in the anterior wall of the acetabulum and fuses with the pubis, the second in the iliac acetabular cartilage superiorly, fusing with the ilium, and the third in the ischial acetabular cartilage posteriorly, fusing with the ischium. At puberty, these epiphyses expand towards the periphery of the acetabulum and contribute to its depth (Ponseti 1978). Fusion between the three bones within the acetabulum occurs between the sixteenth and eighteenth years. Delaere et al (1992) have suggested that ossification of the ilium is similar to that of a long bone, possessing three cartilaginous epiphyses and one cartilaginous process, although it tends to undergo osteoclastic resorption comparable with that of cranial bones. During development, the acetabulum increases in breadth at a faster rate than it does in depth.

Avulsion fractures of pelvic apophyses may occur from excessive pull on tendons, usually in athletic adolescents. The most frequent examples of such injuries are those to the ischial tuberosity (hamstrings) and anterior inferior iliac spine (rectus femoris).

## Pubis

The pubis (see Figs 80.5-80.6) is the ventral part of the hip bone and forms a median cartilaginous pubic symphysis with its fellow. The body of the pubis occupies the anteromedial part of the bone, and from the body a superior ramus passes up and back to the acetabulum and an inferior ramus passes back, down and laterally to join the ischial ramus inferomedial to the obturator foramen.

## Body

The body, anteroposteriorly compressed, has anterior, posterior and symphysial (medial) surfaces and an upper border, the pubic crest. The anterior surface also faces inferolaterally; it is rough superomedially and smooth elsewhere, giving attachment to medial thigh muscles. The smooth posterior surface faces upwards and backwards as the oblique anterior wall of the lesser pelvis and is related to the urinary bladder. The symphysial surface is elongated and oval, united by cartilage to its fellow at the pubic symphysis. Denuded of cartilage, it has an irregular surface of small ridges and furrows or nodular elevations, varying considerably with age, features that are of forensic interest. The pubic crest is the rounded upper border of the body and overhangs the anterior surface; the pubic tubercle is a small rounded eminence on its lateral end. Both crest and tubercle are palpable; the latter partly is obscured in males by the spermatic cord that crosses above it from the scrotum to the anterior abdominal wall. The pubic rami diverge posterolaterally from the superolateral corners of the body.

The anterior surface of the pubic body faces the adductor region. The anterior pubic ligament attaches to its medial part along a rough strip, which is wider in females. The posterior surface is separated from the urinary bladder by retropubic fat. The puboprostatic ligaments are attached to this surface medial to levator ani.

## Superior pubic ramus

The superior pubic ramus passes upwards, backwards and laterally from the body, superolateral to the obturator foramen, to reach the acetabulum. It is triangular in section and has three surfaces and borders. Its anterior, pectineal surface, tilted slightly up, is triangular in outline and extends from the pubic tubercle to the iliopubic ramus. It is bounded in front by the rounded obturator crest and behind by the sharp pecten pubis (pectineal line), which, with the crest, is the pubic part of the linea terminalis (i.e. anterior part of the pelvic brim). The posterosuperior, pelvic surface, medially inclined, is smooth and narrows into the posterior surface of the body, which is bounded above by the pecten pubis and below by a sharp inferior border. The obturator surface, directed down and back, is crossed by the obturator groove sloping down and forwards. Its anterior limit is the obturator crest and its posterior limit is the inferior border.

## Inferior pubic ramus

The inferior pubic ramus, an inferolateral process of the body, descends inferolaterally to join the ischial ramus medial to, and below, the obturator foramen. The union may be locally thickened, but not obviously so in adults. The ramus has two surfaces and borders. The anterolateral surface, continuous above with that of the pubic body, faces the thigh and is marked by muscles. It is limited laterally by the margin of the obturator foramen, and medially by the rough anterior border. The posteromedial surface is continuous above with that of the body and is transversely convex; its medial part is often everted in males and gives attachment to the crus of the penis. This surface faces the perineum medially, its smooth lateral part tilted up towards the pelvic cavity.

The internal surface is indistinctly divided into medial, intermediate and lateral areas. The medial area faces inferomedially in direct contact with the crus of the penis or clitoris and is limited above and behind by an indistinct ridge for attachment of the fascia overlying the superficial perineal muscles. The medial margin of the ramus, strongly everted in males, provides attachment for the fascia lata and the stratum membranosum perinei.

## Pubic tubercle

The pubic tubercle provides attachment to the medial end of the inguinal ligament. It forms part of the floor of the superficial inguinal ring and is crossed by the spermatic cord.

## Pecten pubis

The pecten pubis is the sharp, superior edge of the pectineal surface. The conjoint tendon (inguinal falx) and lacunar ligament are attached at its medial end and a strong, fibrous pectineal ligament is attached along the rest of its surface. The smooth pelvic surface is separated from parietal peritoneum only by areolar tissue, in which the lateral umbilical ligament descends forwards across the ramus and, laterally, the vas deferens (ductus deferens) passes backwards. The obturator groove, which is converted to a canal by the upper borders of the obturator membrane and obturator muscles, transmits the obturator vessels and nerve from the pelvis to the thigh. Some fibres of the pubofemoral ligament are attached to the lateral end of the obturator crest.

## Muscle attachments

The tendon of adductor longus is attached on the anterior (external) surface of the body, below the pubic crest. Below adductor longus, gracilis is attached to a line near the lower margin extending down on to the inferior ramus. Above gracilis, adductor brevis is attached to the body and inferior ramus. Above again, obturator externus is attached to the anterior surface, spreading on to inferior pubic and ischial rami. Adductor magnus usually extends from the ischial ramus on to the lower part of the inferior pubic ramus between adductor brevis and obturator externus. Pectineus is attached to the pectineal surface of the superior ramus along its upper part. Ascending loops of cremaster are attached to the pubic tubercle. The lateral part of rectus abdominis and, inferiorly, pyramidalis, are attached lateral to the tubercle, on the pubic crest. Medially, the crest is crossed by the medial part of rectus abdominis, ascending from ligamentous fibres that interlace in front of the pubic symphysis. Anterior fibres of levator ani are attached on the posterior (internal) surface of the body near its centre. More laterally, obturator internus is attached on this surface, extending on to both rami. Psoas minor, when present, is attached near the centre of the pecten pubis.

## Vascular supply

The pubis is supplied by a periosteal anastomosis of branches from the obturator, inferior epigastric and medial circumflex femoral arteries. The superficial and deep external pudendal arteries may also contribute. Multiple vascular foramina are present, mainly at the lateral (acetabular) end of the bone, but there is no consistently placed nutrient foramen.

## Innervation

The pubic periosteum is innervated by branches of the nerves that supply muscles attached to the bone, the hip joint and the symphysis pubis.

## Ossification

Ossification of the pubis is described on page 1342.

## Ilium

The ilium has upper and lower parts and three surfaces (see Figs 80.5, 80.6). The smaller, lower part forms a little less than the upper two-fifths of the acetabulum. The upper part is much expanded, and has gluteal,
sacropelvic and iliac (internal) surfaces. The posterolateral gluteal surface is an extensive rough area; the anteromedial iliac fossa is smooth and concave; and the sacropelvic surface is medial and posteroinferior to the fossa, from which it is separated by the medial border.

## Iliac crest

The iliac crest is the superior border of the ilium. It is convex upwards but sinuous from side to side, being internally concave in front and convex behind. Its ends project as anterior and posterior superior iliac spines. The anterior superior iliac spine is palpable at the lateral end of the inguinal fold; the lateral end of the inguinal ligament is attached to the anterior superior iliac spine. The posterior superior iliac spine is not palpable but is often indicated by a dimple, approximately 4 cm lateral to the second sacral spinous process, above the medial gluteal region.

The iliac crest has ventral and dorsal segments. The ventral segment occupies slightly more than the anterior two-thirds of the iliac crest and its prominence is associated with changes in iliac form as a result of the emergence of the upright posture. It has internal and external lips and a rough intermediate zone that is narrowest centrally. The dorsal segment, which occupies approximately the posterior one-third in humans, is a feature of all land vertebrates. It has two sloping surfaces separated by a longitudinal ridge ending at the posterior superior spine. The interosseous and posterior sacroiliac ligaments arise from the medial margin of the dorsal segment. The tubercle of the iliac crest projects outwards from the outer lip approximately 5 cm posterosuperior to the anterior superior spine. The summit of the iliac crest, a little behind its midpoint, is level with the fourth lumbar vertebral body in adults and with the fifth lumbar vertebral body in children aged 10 years or less (Tame and Burstal 2003).

## Anterior border

The anterior border descends to the acetabulum from the anterior superior spine. Superiorly it is concave forwards. Inferiorly, immediately above the acetabulum, is a rough anterior inferior iliac spine, which is divided indistinctly into an upper area for the straight head of rectus femoris and a lower area extending laterally along the upper acetabular margin to form a triangular impression for the proximal end of the iliofemoral ligament.

## Posterior border

The posterior border is irregularly curved and descends from the posterior superior spine, at first forwards, with a posterior concavity forming a small notch. At the lower end of the notch is a wide, low projection: the posterior inferior iliac spine. Here the border turns almost horizontally forwards for approximately 3 cm , then down and back to join the posterior ischial border. Together these borders form a deep notch, the greater sciatic notch, which is bounded above by the ilium and below by the ilium and ischium. The upper fibres of the sacrotuberous ligament are attached to the upper part of the posterior border. The superior rim of the notch is related to the superior gluteal vessels and nerve. The lower margin of the greater sciatic notch is covered by piriformis and is related to the sciatic nerve.

## Medial border

The medial border separates the iliac fossa and the sacropelvic surface. It is indistinct near the crest, rough in its upper part, then sharp where it bounds an articular surface for the sacrum, and finally rounded. The latter part is the arcuate line, which inferiorly reaches the posterior part of the iliopubic ramus, marking the union of the ilium and pubis.

## Gluteal surface

The gluteal surface, facing inferiorly in its posterior part and laterally and slightly downwards in front, is bounded above by the iliac crest, and below by the upper acetabular border and by the anterior and posterior borders. It is rough and curved, convex in front, concave behind, and marked by three gluteal lines. The posterior gluteal line is shortest, descending from the external lip of the crest approximately 5 cm in front of its posterior limit and ending in front of the posterior inferior iliac spine. Above, it is usually distinct, but inferiorly it is poorly defined and frequently absent. The anterior gluteal line, the longest, begins near the midpoint of the superior margin of the greater sciatic notch and ascends forwards into the outer lip of the crest, a little anterior to its tubercle. The inferior gluteal line, seldom well marked, begins posterosuperior to the anterior inferior iliac spine, curving posteroinferiorly to end near the apex of the greater sciatic notch. Between the inferior gluteal line and the acetabular margin is a rough, shallow groove. Behind the acetabulum, the lower gluteal surface is continuous
with the posterior ischial surface, the conjunction marked by a low elevation.

The articular capsule is attached to an area adjoining the acetabular margin, most of which is covered by gluteus minimus. Posteroinferiorly, near the union of the ilium and ischium, the bone is related to piriformis.

## Iliac fossa

The iliac fossa, the internal concavity of the ilium, faces anterosuperiorly. It is limited above by the iliac crest, in front by the anterior border and behind by the medial border, separating it from the sacropelvic surface. It forms the smooth and gently concave posterolateral wall of the greater pelvis. Below it is continuous with a wide shallow groove, bounded laterally by the anterior inferior iliac spine and medially by the iliopubic ramus.

The converging fibres of iliacus occupy the wide groove between the anterior inferior iliac spine and the iliopubic ramus laterally and the tendon of psoas major medially; the tendon is separated from the underlying bone by a bursa. The right iliac fossa contains the caecum, and often the vermiform appendix and terminal ileum. The left iliac fossa houses the terminal part of the descending colon and the proximal sigmoid colon.

## Sacropelvic surface

The sacropelvic surface, the posteroinferior part of the medial iliac surface, is bounded posteroinferiorly by the posterior border, anterosuperiorly by the medial border, posterosuperiorly by the iliac crest and anteroinferiorly by the line of fusion of the ilium and ischium. It is divided into iliac tuberosity and auricular and pelvic surfaces. The iliac tuberosity, a large, rough area below the dorsal segment of the iliac crest, shows cranial and caudal areas separated by an oblique ridge and connected to the sacrum by the interosseous sacroiliac ligament. The sacropelvic surface gives attachment to the posterior sacroiliac ligaments and, behind the auricular surface, to the interosseous sacroiliac ligament. The iliolumbar ligament is attached to its anterior part. The auricular surface, immediately anteroinferior to the tuberosity, articulates with the lateral sacral mass. Shaped like an ear, its widest part is anterosuperior, and its 'lobule' posteroinferior and on the medial aspect of the posterior inferior spine. Its edges are well defined but the surface, though articular, is rough and irregular. It articulates with the sacrum and is reciprocally shaped. The anterior sacroiliac ligament is attached to its sharp anterior and inferior borders. The narrow part of the pelvic surface, between the auricular surface and the upper rim of the greater sciatic notch, often shows a rough pre-auricular sulcus (that is usually better defined in females) for the lower fibres of the anterior sacroiliac ligament. For the reliability of this feature as a sex discriminant, refer to Finnegan (1978) and Brothwell and Pollard (2001). The pelvic surface is anteroinferior to the acutely curved part of the auricular surface, and contributes to the lateral wall of the lesser pelvis. Its upper part, facing down, is between the auricular surface and the upper limb of the greater sciatic notch. Its lower part faces medially and is separated from the iliac fossa by the arcuate line. Anteroinferiorly, it extends to the line of union between the ilium and ischium. Though usually obliterated, it passes from the depth of the acetabulum to approximately the middle of the inferior limb of the greater sciatic notch.

## Muscle attachments

The attachment of sartorius extends down the anterior border below the anterior superior iliac spine. The iliac crest gives attachment to the anterolateral and dorsal abdominal muscles, and to the fasciae and muscles of the lower limb. The fascia lata and iliotibial tract are attached to the outer lip and tubercle of its ventral segment. Tensor fasciae latae is attached anterior to the tubercle. The lower fibres of external oblique and, just behind the summit of the crest, the lowest fibres of latissimus dorsi are attached to its anterior two-thirds. A variable interval exists between the most posterior attachment of external oblique and the most anterior attachment of latissimus dorsi, and here the crest forms the base of the lumbar triangle through which herniation of abdominal contents may rarely occur. Internal oblique is attached to the intermediate area of the crest. Transversus abdominis is attached to the anterior two-thirds of the inner lip of the crest, and behind this to the thoracolumbar fascia and quadratus lumborum. The highest fibres of gluteus maximus are attached to the dorsal segment of the crest on its lateral slope. Erector spinae arises from the medial slope of the dorsal segment. The straight head of rectus femoris is attached to the upper area of the anterior inferior spine. Some fibres of piriformis are attached in front of the posterior inferior spine on the upper border of the greater sciatic foramen.

The gluteal surface is divided by three gluteal lines into four areas. Behind the posterior line, the upper rough part gives attachment to the
upper fibres of gluteus maximus and the lower, smooth region to part of the sacrotuberous ligament and iliac head of piriformis. Gluteus medius is attached between the posterior and anterior lines, below the iliac crest, and gluteus minimus is attached between the anterior and inferior lines. The fourth area, below the inferior line, contains vascular foramina.

The reflected head of rectus femoris attaches to a curved groove above the acetabulum. Iliacus is attached to the upper two-thirds of the iliac fossa and is related to its lower one-third. The medial part of quadratus lumborum is attached to the anterior part of the sacropelvic surface, above the iliolumbar ligament. Piriformis is sometimes partly attached lateral to the pre-auricular sulcus, and part of obturator internus is attached to the more extensive remainder of the pelvic surface.

## Vascular supply

Branches of the iliolumbar artery run between iliacus and the ilium; one or more enter large nutrient foramina lying posteroinferiorly in the iliac fossa. The superior gluteal, obturator and superficial circumflex iliac arteries contribute to the periosteal supply. The obturator artery may supply a nutrient branch. Vascular foramina on the ilium underlying the gluteal muscles may lead into large vascular canals in the bone.

## Innervation

The periosteum is innervated by branches of nerves that supply muscles attached to the bone, the hip joint and the sacroiliac joint.

## Ossification

Ossification of the ilium is described on page 1342.

## Ischium

The ischium, the inferoposterior part of the hip bone, has a body and ramus. The body has upper and lower ends and femoral, posterior and pelvic surfaces (see Figs 80.5-80.7). Above, it forms the posteroinferior part of the acetabulum; below, its ramus ascends anteromedially at an acute angle to meet the inferior pubic ramus, thereby completing the boundary of the obturator foramen. The ischiofemoral ligament is attached to the lateral border below the acetabulum (Fuss and Bacher 1991).

The femoral surface faces downwards, forwards and laterally towards the thigh. It is bounded in front by the margin of the obturator foramen. The lateral border, indistinct above but well defined below, forms the lateral limit of the ischial tuberosity. At a higher level, the femoral surface is covered by piriformis, from which it is partially separated by the sciatic nerve and the nerve to quadratus femoris. The posterior surface, facing superolaterally, is continuous above with the iliac gluteal surface, and here a low convexity follows the acetabular curvature. Inferiorly, this surface forms the upper part of the ischial tuberosity, above which is a wide, shallow groove on its lateral and medial aspects. Above the ischial tuberosity, the posterior surface is crossed by the tendon of obturator internus and the gemelli. The nerve to quadratus femoris lies between these structures and the ischium. The ischial tuberosity is a large, rough area on the lower posterior surface and inferior extremity of the ischium. Though obscured by gluteus maximus in hip extension, it is palpable in hip flexion. It is 5 cm from the midline and about the same distance above the gluteal fold. It is elongated and widest above, and tapers inferiorly. The ischial posterior aspect lies between the lateral and posterior borders. The posterior border blends above with that of the ilium, helping to complete the inferior rim of the greater sciatic foramen, the posterior end of which has a conspicuous ischial spine. Below this, the rounded border forms the floor of the lesser sciatic foramen, between the ischial spine and tuberosity. The pelvic surface is smooth and faces the pelvic cavity; inferiorly, it forms part of the lateral wall of the ischio-anal fossa.

## Ischial ramus

The ischial ramus has anteroinferior and posterior surfaces continuous with the corresponding surfaces of the inferior pubic ramus. The anteroinferior surface is roughened by the attachment of the medial thigh muscles. The smooth posterior surface is partly divided into perineal and pelvic areas, like the inferior pubic ramus. The upper border completes the obturator foramen; the rough lower border, together with the medial border of the inferior pubic ramus, contributes to the pubic arch. The fascia overlying the superficial muscles of the perineum is attached below the ridge between the perineal and pelvic areas of the posterior surface of the ischial ramus. Above the ridge, areas give attachment to the crus of the penis or clitoris and the external urethral sphincter. The lower border of the ramus provides an attachment for the fascia lata and the stratum membranosum perinei.

## Ischial tuberosity

The ischial tuberosity is divided nearly transversely into upper and lower areas. The upper area is subdivided by an oblique line into superolateral and inferomedial parts. The lower area, narrowing as it curves on to the inferior ischial aspect, is subdivided by an irregular vertical ridge into lateral and medial areas. The medial area is covered by fibroadipose tissue that usually contains the sciatic bursa of gluteus maximus, which supports the body in sitting. Medially, the tuberosity is limited by a curved ridge that passes on to the ramus and which gives attachment to the sacrotuberous ligament and its falciform process.

## Ischial spine

The ischial spine projects downwards and a little medially (see Fig. $80.5 \mathrm{~A}, \mathrm{~B})$. The sacrospinous ligament is attached to its margins, separating the greater from the lesser sciatic foramen. The ligament is crossed posteriorly by the internal pudendal vessels, pudendal nerve and the nerve to obturator internus.

## Muscle attachments

Part of obturator externus is attached to the lower femoral surface of the ischial body. Part of obturator externus, the anterior fibres of adductor magnus and, near the lower border, gracilis are all attached to the anterior surface of the ischial ramus. Between adductor magnus and gracilis, the attachment of adductor brevis may descend from the inferior pubic ramus. The posterior surface is divided into pelvic and perineal areas. The pelvic area, facing back, has part of obturator internus attached to it. The perineal area faces medially; its upper part is related to the crus of the penis or clitoris, and its lower part gives attachment to sphincter urethrae, ischiocavernosus and the superficial transverse perineal muscle.

The ischial tuberosity gives attachment to the posterior thigh muscles. Quadratus femoris is attached along the upper part of its lateral border. The upper area of the tuberosity is subdivided by an oblique line into a superolateral part for semimembranosus and an inferomedial part for the long head of biceps femoris and semitendinosus. The lower area is subdivided by an irregular vertical ridge into lateral and medial areas. The larger lateral area is for part of adductor magnus. Superomedial to the tuberosity, the posterior surface has a wide, shallow groove, usually covered by hyaline cartilage, with a bursa between it and the tendon of obturator internus. Gemellus inferior is attached to the lower margin of the groove, near the tuberosity. Gemellus superior is attached to the upper margin, near the ischial spine. Forceful contraction of the hamstrings can result in an avulsion fracture of the ischial tuberosity.

The pelvic surface of the ischial spine gives attachment to coccygeus and to the most posterior fibres of levator ani. Obturator internus is attached to the upper part of the smooth pelvic ischial surface and converges on the bony part of the lesser sciatic foramen, covering the rest of this surface other than the pelvic aspect of the ischial spine; the muscle and its fascia separate the bone from the ischio-anal fossa.

## Vascular supply

There are multiple vascular foramina at the acetabular margins and a few are usually present on the pelvic surface. Branches of the obturator, medial circumflex femoral and inferior gluteal arteries supply the ischium.

## Innervation

The periosteum is innervated by branches of nerves that supply the hip joint and muscles attached to the bone.

## Ossification

Ossification of the ischium is described on page 1342.

## SACRUM

See page 726 .

## COCCYX

See page 729 .

## BONY PELVIS AS A WHOLE

The term pelvis ('basin') is applied variously to the skeletal ring formed by the hip bones and the sacrum, the cavity therein, and even the entire

Fig. 80.8 Anterior (A) and posterior (B) views of the female pelvis, upper femur and lower lumbar spine, using three-dimensional computed tomography. (Courtesy of Dr Yoginder Vaid and Mr Jon C Betts, Jr.)
region where the trunk and lower limbs meet (Fig. 80.8). It is used here in the skeletal sense, to describe the irregular osseous girdle between the femoral heads and fifth lumbar vertebra. It is large because its primary function is to withstand the forces of body weight and musculature. In this section, its obstetric, forensic and anthropological significance will be considered.

The pelvis can be regarded as having greater and lesser segments, the true and false pelves. The segments are arbitrarily divided by an oblique plane passing through the sacral promontory posteriorly and the lineae terminales elsewhere. Each linea terminalis includes the iliac arcuate line, pectineal line (pecten pubis) and pubic crest.

## Greater pelvis

The greater pelvis consists of the ilium and pubis above the lineae terminales and the base of the sacrum. This junctional zone is structurally massive and forms powerful arches from the acetabular fossae to the vertebral column around the visceral cavity, which is part of the abdomen. It has little anterior wall because of the pelvic inclination.

## Pelvic inlet (superior pelvic aperture)

The pelvic inlet or brim may be round or oval in shape, and is indented posteriorly by the sacral promontory. The pelvic brim is obstetrically important and has also long been measured for anthropological reasons, as has the pelvic cavity.

By convention, the pelvic inlet is described in three dimensions. The anteroposterior diameter (true conjugate) is measured between the
midpoints of the sacral promontory and upper border of the pubic symphysis, and on average is 10 cm in the adult male and 11.2 cm in the adult female. The transverse diameter is the maximum distance between similar points (assessed by eye) on opposite sides of the pelvic brim, and is on average 12.5 cm in the adult male and 13.1 cm in the adult female. The oblique diameter is measured from the iliopubic ramus to the opposite sacroiliac joint, and is on average 12 cm in the adult male and 12.5 cm in the adult female. These measurements vary with the individual and with racial group. In children, dimensions of the thorax and spine are significantly correlated with the width of the pelvic inlet, which are age-independent predictors of paediatric chest width and may be useful in assessing growth of the thorax and spine in children with early-onset spinal deformity (Emans et al 2005).

## Articulated bony pelvis

The lesser pelvis encloses a true basin when soft tissues of the pelvic floor are in place. Skeletally, it is a narrower continuation of the greater pelvis, with irregular but more complete walls around its cavity. Of obstetric importance, it has a curved median axis, and superior and inferior openings. The superior opening is occupied by viscera. The pelvic floor, viscera and subjacent perineal sphincters close the inferior opening.

## Cavity of the lesser pelvis

The cavity of the lesser pelvis is short, curved, and markedly longer in its posterior wall. Anteroinferiorly, it is bounded by pubic bones, their rami and symphysis. Posteriorly, it is bounded by the concave anterior sacral surface and coccyx. Laterally on each side, its margins are the smooth quadrangular pelvic aspect of the fused ilium and ischium. The region so enclosed is the pelvic cavity proper, through which pass
the rectum, urinary bladder and parts of the reproductive organs. The cavity in females must also permit passage of the fetus.

The pelvic cavity diameters are measured at approximately the midlevel. The anteroposterior diameter is measured between the midpoints of the third sacral segment and posterior surface of the pubic symphysis, and is about 10.5 cm in the adult male and 13 cm in the adult female. The transverse diameter is the widest transverse distance between the side walls of the cavity, and often the greatest transverse dimension in the whole cavity. It measures about 12 cm in the adult male and 12.5 cm in the adult female. The oblique diameter is the distance from the lowest point of one sacroiliac joint to the midpoint of the contralateral obturator membrane, and measures about 11 cm in the adult male and 13.1 cm in the adult female. All measurements vary with the individual and with racial group.

## Pelvic outlet (inferior pelvic aperture)

Less regular in outline than the pelvic inlet, the pelvic outlet is indented behind by the coccyx and sacrum, and bilaterally by the ischial tuberosities. Its perimeter thus consists of three wide arcs. Anteriorly is the pubic arch, between the converging ischiopubic rami. Posteriorly and laterally on both sides are the sciatic notches between the sacrum and ischial tuberosities. The sciatic notches are divided by the sacrotuberous and sacrospinous ligaments into greater and lesser sciatic foramina (Fig. 80.9).

With ligaments included, the pelvic outlet is rhomboidal. Its anterior limbs are the ischiopubic rami (joined by the inferior pubic ligament) and its posterior margins are the sacrotuberous ligaments, with the coccyx in the midline. The outlet is thus not rigid in its posterior half, being limited by ligaments and the coccyx, all slightly yielding. Even with the sacrum taken as the posterior midline limit (more reliable for

Fig. 80.9 Joints and ligaments of the pelvis.
A, Anterior aspect. Note the arrows indicating vascular and muscular spaces. B, Posterior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
measurement), there may be slight mobility at the sacroiliac joints. Note also that a plane of the pelvic outlet is merely conceptual. The anterior, ischiopubic part has a plane that is inclined down and back to a transverse line between the lower limits of the ischial tuberosities, and the posterior half has a plane approximating to the sacrotuberous ligaments, sloping down and forwards to the same line.

Three measurements are made for the pelvic outlet. The anteroposterior diameter is usually measured from the apex of the coccyx to the midpoint of the lower rim of the pubic symphysis. The lowest sacral point may also be used (on average: male 8 cm , female 12.5 cm ). The transverse (bituberous) diameter is measured between the ischial tuberosities at the lower borders of their medial surfaces (on average: male 8.5 cm , female 11.8 cm ). The oblique diameter extends from the midpoint of the sacrotuberous ligament on one side to the contralateral ischiopubic junction (on average: male 10 cm , female 11.8 cm ). All measurements vary among individuals and racial groups.

## Other measurements

Apart from these main measurements, by consensus the basis of pelvic osteometry, other planes and measurements are used in obstetric practice. The plane of greatest pelvic dimensions is an obstetric concept. It represents the most capacious pelvic level, between the pelvic brim and midlevel plane, and corresponds with the latter anteriorly at the middle part of the pubic symphysis and posteriorly at the level of the second and third sacral segments.

The plane of least dimensions is said to be at about mid-pelvic level. Its transverse diameter is between the apices of the ischial spines. This measurement is about 9.5 cm in an adult female and is just wide enough to allow passage of the biparietal diameter of a fetal head (about 9 cm ). Not surprisingly, most difficulty in parturition occurs here.

The above measurements are sometimes made in clinical practice using radiographs or magnetic resonance imaging (MRI) pelvimetry. Precise measurement is not possible without radiological techniques, and even these do not take into account the adjacent soft tissues. In the past, measurements were made at physical (e.g. vaginal) examinations. However, these manual measurements have proved to be of little clinical value and are now more or less obsolete.

## Morphological classification of pelves

Available with the Gray's Anatomy e-book

## Pelvic axes and inclination

The axis of the superior pelvic aperture traverses its centre at right angles to its plane, directed down and backwards (Fig. 80.10). When prolonged (projected), it passes through the umbilicus and mid-coccyx. An axis is similarly established for the inferior aperture: projected upwards, it impinges on the sacral promontory. Axes can likewise be constructed for any plane, and one for the whole cavity is a concatenation of an infinite series of such lines (see Fig. 80.10). The fetal head, however,

Fig. 80.10 A median sagittal section through the female pelvis, showing the planes of the inlet and outlet and the axis of the pelvic cavity.
descends in the axis of the inlet as far as the level of the ischial spines; it is then directed forwards into the axis of the vagina at right angles to that axis. The form of this pelvic axis and the disparity in depth between the anterior and posterior contours of the cavity are prime factors in the mechanism of fetal transit in the pelvic canal.

In the standing position, the pelvic canal curves obliquely backwards relative to the trunk and abdominal cavity. The whole pelvis is tilted forwards, the plane of the pelvic brim making an angle of 50-60 ${ }^{\circ}$ with the horizontal. The plane of the pelvic outlet is tilted to about $15^{\circ}$. Strictly, the pelvic outlet has two planes: an anterior passing backwards from the pubic symphysis and a posterior passing forwards from the coccyx, both descending to meet at the intertuberous line. In standing, the pelvic aspect of the pubic symphysis faces nearly as much upwards as backwards and the sacral concavity is directed anteroinferiorly. The front of the pubic symphysis and anterior superior iliac spines are in the same vertical plane. While sitting, body weight is transmitted through the inferomedial parts of the ischial tuberosities, with variable soft tissues intervening. The anterior superior iliac spines are in a vertical plane through the acetabular centres, and the whole pelvis is tilted back with the lumbosacral angle somewhat diminished at the sacral promontory.

## Pelvic mechanism

The skeletal pelvis supports and protects the contained viscera but is primarily part of the lower limbs, affording wide attachment for muscles of the thigh, leg and trunk. It constitutes the major mechanism for transmitting the weight of the head, trunk and upper limbs to the lower limbs. It may be considered as two arches divided by a coronal transacetabular plane. The posterior arch, chiefly concerned in transmitting weight, consists of the upper three sacral vertebrae and strong pillars of bone from the sacroiliac joints to the acetabular fossae. The anterior arch, formed by the pubic bones and their superior rami, connects these lateral pillars as a tie beam to prevent separation; it also acts as a compression strut against medial femoral thrust. The sacrum, as the summit of the posterior arch, is loaded at the lumbosacral joint. Theoretically, this force has two components: one thrusting the sacrum downwards and backwards between the iliac bones, the other thrusting its upper end downwards and forwards. Sacral movements are regulated by osseous shape and massive ligaments. The first component therefore acts against the wedge, its tendency to separate iliac bones resisted by the sacroiliac and iliolumbar ligaments and pubic symphysis.

Vertical coronal sections through the sacroiliac joints suggest division of the (synovial) articular region of the sacrum into three segments. In the anterosuperior segment, involving the first sacral vertebra, the articular surfaces are slightly sinuous and almost parallel. In the middle segment, the posterior width between the articular markings is greater than the anterior, and centrally a sacral concavity fits a corresponding iliac convexity, an interlocking mechanism relieving the strain on the ligaments produced by body weight. In the posteroinferior segment, the anterior sacral width is greater than the posterior and here its sacral surfaces are slightly concave. Anteroinferior sacral dislocation by the second component (of force) is prevented, therefore, mainly by the middle segment, owing to its cuneiform shape and interlocking mechanism. However, some rotation occurs, in which the anterosuperior segment tilts down and the posteroinferior segment up. 'Superior' segmental movement is limited to a small degree by wedging but primarily by tension in the sacrotuberous and sacrospinous ligaments. In all movements, the sacroiliac and iliolumbar ligaments and pubic symphysis resist separation of the iliac bones.

## SEXUAL DIFFERENCES IN THE PELVIS

The pelvis provides the most marked skeletal differences between male and female. Distinction can be made even during fetal life, particularly in the subpubic arch. In infancy, dimensions of the whole pelvis are greater in males than in females, but the size of the pelvic cavity is usually greater in females. This distinction prevails in childhood but the difference is maximal at about 22 months. Sexual differences in adults are divisible into metrical and non-metrical features; the range of most features overlaps between the sexes.

Differences are inevitably linked to function. While the primary pelvic function in both sexes is locomotor, the pelvis, particularly the lesser pelvis, is adapted to parturition in females, and these changes variably affect the proportions and dimensions of the greater pelvis. Since males are distinctly more muscular and therefore more heavily built, overall pelvic dimensions, such as the intercristal distance (distance between the iliac crests), are greater, markings for muscles and ligaments more pronounced, and general architecture more robust. The

Interest in the dimensions described above is primarily obstetric and, less frequently, forensic. All pelvic measurements display individual variation and the values quoted are means from limited surveys. These measurements have been analysed by many anatomists, anthropologists, obstetricians and radiologists in attempts to classify human pelves, especially female. The four most common terms used today are gynaecoid, anthropoid, platypelloid and android. The gynaecoid pelvis is the traditional Western female pelvis with a heart-shaped brim and the range of measurements quoted above. An anthropoid pelvis has a larger mid-cavity and a wide anteroposterior inlet, which is oval in shape; it is more common in women of African origin and may be associated with a 'high-assimilation' pelvis where there is an additional lumbar vertebra. A platypelloid pelvis is flat and oval from side to side at the brim; it is a contracted pelvis that is rarely seen nowadays, having previously been associated with rickets. An android pelvis has a triangular brim and is the shape of a male pelvis.
male iliac crest is more rugged and more medially inclined at its anterior end; in females the iliac crests are less curved in all parts. The iliac alae are more vertical in females but do not ascend so far; the iliac fossae are therefore shallower. These iliac peculiarities probably account for the greater prominence of female hips.

The male is relatively and absolutely more heavily built above the pelvis, with consequent differences at the lumbosacral and hip joints. The sacral basal articular facet for the fifth lumbar vertebra and intervening intervertebral disc is more than one-third of the total sacral basal width in males but less than one-third in females, in whom the sacrum is also relatively broader, accentuating this difference. The female has relatively broader sacral alae. The male acetabulum is absolutely larger, and its diameter is approximately equal to the distance between its anterior rim and pubic symphysis. In females, acetabular diameter is usually less than this distance, not only because it is absolutely smaller but also because the anterolateral wall of the cavity is comparatively and often absolutely wider. The height of the female pubic symphysis and adjoining parts of the pubis and ischium, which form the anterior pelvic wall, are also absolutely less, producing a somewhat triangular obturator foramen, which is more ovoid in males. Differing pubic growth is also expressed in the pubic arch below the pubic symphysis and between the inferior pubic rami. It is more angular in males, being $50-60^{\circ}$; in females it is rounded, less easy to measure and usually $80-85^{\circ}$. A greater separation of the pubic tubercles in females contributes to the pubic width. The ischiopubic rami are also much more lightly built and narrowed near the symphysis; in males they bear a distinctly rough, everted area for attachment of the penile crura, the corresponding attachment for the clitoris being poorly developed. The ischial spines are closer in males and are more inturned. The greater sciatic notch is usually wider in females: mean values for males and females are $50.4^{\circ}$ and $74.4^{\circ}$, respectively. The greater female values for angle and width are associated with increased backward sacral tilt and greater anteroposterior pelvic diameter, especially at lower levels.

The sacrum also displays metrical sexual differences. Female sacra are less curved, the curvature being most marked between the first and second segments and the third and fifth, with an intervening flatter region. Male sacra are more evenly curved, and relatively long and narrow, and more often exceed five segments (by addition of a lumbar or coccygeal vertebra). The sacral index compares sacral breadth (between the most anterior points on the auricular surfaces) with length (between midpoints on the anterior margins of the promontory and apex): average values for males and females are $105 \%$ and $115 \%$, respectively. Auricular surfaces are relatively smaller and more oblique in females, but extend on to the upper three sacral vertebrae in both sexes. The dorsal auricular border is more concave in females. Many differences may be summarized in the generalization that the pelvic cavity is longer and more conical in males, and shorter and more cylindrical in females; the axis is curved in both. Differences are greater at the inferior aperture than at the brim, where in absolute measurements males are not as different from females as sometimes stated.

In forensic practice, identification of human skeletal remains (which are sometimes fragmentary) usually involves determination of sex, and this is most reliably established from an examination of the pelvis. Even fragments of the pelvis may be useful in this respect. Several studies of metrical characteristics in various pelvic regions have been made, leading to the establishment of various indices. The ilium has received particular attention, e.g. one index compares the pelvic and sacroiliac parts of the bone. A line is extended back from the iliopubic ramus to the nearest point on the anterior auricular margin and thence to the iliac crest. The auricular point divides this chilotic line into anterior (pelvic) and posterior (sacral) segments, each expressed as a percentage of the other. Chilotic indices display reciprocal values in the sexes: the pelvic part of the chilotic line is predominant in females, and the sacral part in males. Detailed metrical studies of the ilium have indicated its limited reliability in 'sexing' pelves. However, the higher incidence and definition of the female pre-auricular sulcus is recognized. The desirability of correlating all available metrical data is to be emphasized; when a range of pelvic data can be combined, especially if they are metrical, 95\% accuracy should be achieved. Complete accuracy has been claimed when the rest of the skeleton is available. Assessment of sex from isolated and often incomplete human remains is less reliable. For further details, consult Mays (1998) and Brothwell and Pollard (2001).

## FEMUR

The femur is the longest and strongest bone in the human body (Figs 80.11-80.12). Its length is associated with a striding gait, and its
strength with the weight and muscular forces it is required to withstand. Its shaft, almost cylindrical along most of its length, is bowed forwards. It has a proximal rounded, articular head projecting medially from its short neck, which, in turn, is a medial extension of the proximal shaft. The distal extremity is wider and more substantial, and presents a double condyle that articulates with the tibia. In standing, the femoral shafts show an inclination upwards and outwards from their tibial articulations, with the femoral heads being separated by the pelvic width. Since the tibia and fibula descend vertically from the knees, the ankles are also in the line of body weight in standing or walking. The degree of femoral obliquity varies between individuals but is generally greater in women, reflecting the relatively greater pelvic breadth and shorter femora. Proximally, the femur consists of a head, neck and greater and lesser trochanters.

## Femoral head

The femoral head faces anterosuperomedially to articulate with the acetabulum (Fig. 80.13). The head, often described as rather more than half a 'sphere', is not part of a true sphere but is spheroidal. Its smoothness is interrupted posteroinferior to its centre by a small, rough fovea. The head is intracapsular and is encircled, distal to its equator, by the acetabular labrum. Its articular margin is distinct, except anteriorly, where the articular surface extends on to the neck. The ligamentum teres is attached to the fovea. The anterior surface of the head is separated inferomedially from the femoral artery by the tendon of psoas major, the iliopectineal bursa and the articular capsule.

## Femoral neck

The femoral neck (see Fig. 80.13) is approximately 5 cm long, narrowest in its mid part and widest laterally, and connects the head to the shaft at an average angle of $127^{\circ}$ (Gilligan et al 2013) (angle of inclination; neck-shaft angle): this facilitates movement at the hip joint, enabling the limb to swing clear of the pelvis. The neck also provides a lever for the action of the muscles acting about the hip joint, which are attached to the proximal femur. The neck-shaft angle is widest at birth and diminishes gradually until the age of 10 years (Birkenmaier et al 2010); it is smaller in females. The neck is laterally rotated with respect to the shaft (angle of anteversion) some $10-15^{\circ}$, although values of this angle vary between individuals and between populations (Eckhoff et al 1994). The contours of the neck are rounded; the upper surface is almost horizontal and slightly concave, while the lower is straighter but oblique, directed inferolaterally and backwards to the shaft near the lesser trochanter. On all aspects the neck expands as it approaches the articular surface of the head. The anterior surface of the neck is flat and marked at the junction with the shaft by a rough intertrochanteric line. The posterior surface, facing posteriorly and superiorly, is transversely convex, and concave in its long axis; its junction with the shaft is marked by a rounded intertrochanteric crest. There are numerous vascular foramina, especially anteriorly and posterosuperiorly.

The anterior surface is intracapsular, the capsule attaching laterally to the intertrochanteric line. Facets, often covered by extensions of articular cartilage, and various imprints frequently occur here. These facets may sometimes be associated with squatting. On the posterior surface the capsule does not reach the intertrochanteric crest; little more than the medial half of the neck is intracapsular. The anterior surface adjoining the head and covered by cartilage is related to the iliofemoral ligament. A groove, produced by the tendon of obturator externus as it approaches the trochanteric fossa, spirals across the posterior surface of the neck of the femur in a proximolateral direction.

## Greater trochanter

The greater trochanter is large and quadrangular, projecting up from the junction of the neck and shaft (see Fig. 80.13). Its posterosuperior region projects superomedially to overhang the adjacent posterior surface of the neck and here its medial surface presents the rough trochanteric fossa. The proximal border of the trochanter lies approximately a hand's breadth below the iliac tuberculum, level with the centre of the femoral head. It has an anterior rough impression. Its lateral surface, continuous distally with the lateral surface of the femoral shaft, is crossed anteroinferiorly by an oblique, flat strip, which is wider above. This surface is palpable, especially when the muscles are relaxed. The trochanteric fossa occasionally presents a tubercle or exostosis.

## Lesser trochanter

The lesser trochanter is a conical posteromedial projection of the shaft at the posteroinferior aspect of its junction with the neck. Its summit and anterior surface are rough, but its posterior surface, at the distal end of the intertrochanteric crest, is smooth. It is not palpable.

Fig. 80.11 The femur, anterior aspect. A, Osseous features. B, Muscle attachments. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

## Intertrochanteric line

The intertrochanteric line, a prominent ridge at the junction of the anterior surfaces of the neck and shaft, descends medially from a tubercle on the upper part of the anterior aspect of the greater trochanter to a point on the lower border of the neck, anterior to the lesser trochanter, where there may also be a tubercle. This line is the lateral limit of the hip joint capsule anteriorly. The upper and lower bands of the iliofemoral ligament are attached to its proximal and distal ends and the associated tubercles. Distally, it is continuous with the spiral line.

## Intertrochanteric crest

The intertrochanteric crest, a smooth and prominent ridge at the junction of the posterior surface of the neck with the shaft, descends medially from the posterosuperior angle of the greater trochanter to the lesser trochanter. A little above its centre is a low, rounded quadrate tubercle. It is covered by gluteus maximus, from which it is separated, medial to the tubercle, by quadratus femoris and the upper border of adductor magnus.

## Gluteal tuberosity

The gluteal tuberosity may be an elongated depression or a ridge. It may at times be prominent enough to merit the title of a third trochanter.

## Shaft

The shaft is surrounded by muscles and is impalpable (see Figs 80.1180.12). The distal anterior surface, for $5-6 \mathrm{~cm}$ above the patellar articular surface, is covered by a suprapatellar bursa, between bone and muscle. The distal lateral surface is covered by vastus intermedius. The medial surface, devoid of attachments, is covered by vastus medialis.

The shaft is narrowest centrally, expanding a little at its proximal end, and substantially more at its distal end. Its long axis makes an angle of approximately $10^{\circ}$ with the vertical, and diverges $5-7^{\circ}$ from the long axis of the tibia. Its middle one-third has three surfaces and borders. The extensive anterior surface, smooth and gently convex, is between the lateral and medial borders, which are both round and
indistinct. The posterolateral surface is bounded posteriorly by the broad, rough linea aspera, usually a crest with lateral and medial edges. Its subjacent compact bone is augmented to withstand compressive forces, which are concentrated here by the anterior curvature of the shaft. The linea aspera gives attachment to adductor longus, intermuscular septa and the short head of biceps femoris, all inseparably blended at their attachments. Perforating arteries cross the linea aspera laterally under tendinous arches in adductor magnus and biceps femoris. Nutrient foramina, directed proximally, appear in the linea aspera, varying in number and site, one usually near its proximal end, a second usually near its distal end. The posteromedial surface, smooth like the others, is bounded in front by the indistinct medial border and behind by the linea aspera. In its proximal third the shaft has a fourth, posterior surface, bounded medially by a narrow, rough spiral line that is continuous proximally with the intertrochanteric line and distally with the medial edge of linea aspera. Laterally, this surface is limited by the broad, rough gluteal tuberosity, ascending a little laterally to the greater trochanter and descending to the lateral edge of the linea aspera. In its distal one-third, the posterior surface of the shaft presents a further surface, the popliteal surface (see below) between the medial and lateral supracondylar lines. These lines are continuous above with the corresponding edges of the linea aspera. The lateral line is most distinct in its proximal two-thirds, where the short head of biceps femoris and lateral intermuscular septum are attached. Its distal third has a small, rough area for the attachment of plantaris, often encroaching on the popliteal surface. The medial line is indistinct in its proximal twothirds, where vastus medialis is attached. Distally, the femoral vessels entering the popliteal fossa from the adductor canal cross the medial line obliquely. Further distally, the line is often sharp for 3 or 4 cm proximal to the adductor tubercle.

The popliteal surface, triangular in outline, lies between the medial and lateral supracondylar lines. In its distal medial part, it is rough and slightly elevated. Forming the proximal part of the floor of the popliteal fossa, the popliteal surface is covered by a variable amount of fat that separates the popliteal artery from bone. The superior medial genicular

Fig. 80.12 The femur, posterior aspect. A, Osseous features. B, Muscle attachments. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

artery, a branch of the popliteal artery, arches medially above the medial condyle. It is separated from bone by the medial head of gastrocnemius. The latter is attached a little above the condyle; further distally, there may be a smooth facet underlying a bursa for the medial head of gastrocnemius. More medially, there is often an imprint proximal to the articular surface; in flexion, this is close to a rough tubercle on the medial tibial condyle for the attachment of semimembranosus. The superior lateral genicular artery arches up laterally proximal to the

Fig. 80.14 The distal end of the femur, articular surface. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
lateral condyle but is separated from bone by the attachment of plantaris to the distal part of the lateral supracondylar line.

## Distal end

The distal end of the femur is widely expanded as a bearing surface for transmission of weight to the tibia (Fig. 80.14). It bears two massive condyles, which are partly articular. Anteriorly, the condyles are confluent and continue into the shaft; posteriorly, they are separated by a deep intercondylar fossa and project beyond the plane of the popliteal surface. The articular surface is a broad area, like an inverted $U$, for the patella and the tibia. The patellar surface extends anteriorly on both condyles, especially the lateral. It is transversely concave, vertically convex and grooved for the posterior patellar surface. The tibial surface is divided by the intercondylar fossa but is anteriorly continuous with the patellar surface. Its medial part is a broad strip on the convex
inferoposterior surface of the medial condyle, and is gently curved with a medial convexity. Its lateral part covers similar aspects of the lateral condyle but is broader and passes straight back. The tibial surfaces are convex in all directions. The medial and lateral tibial surfaces have dissimilar anteroposterior curvatures. However, views differ as to the exact representation of these differences. One view holds that in both tibial portions of the femoral condyles, the sagittal radius of curvature is everdecreasing (a 'closing helix'). More recently, it has been suggested that the medial articular surface describes arcs of two circles. The more posterior has a smaller radius. Laterally, there may only be one arc of fixed curvature with a radius similar to that of the posterior arc of the medial femoral articular surface. These differences are believed to be important determinants of knee joint motion.

## Patellar surface

The patellar surface extends more proximally on the lateral side. Its proximal border is therefore oblique and runs distally and medially, separated from the tibial surfaces by two faint grooves that cross the condyles obliquely. The lateral groove is the more distinct. It runs laterally and slightly forwards from the front of the intercondylar fossa and expands to form a faint triangular depression, resting on the anterior edge of the lateral meniscus when the knee is fully extended. The medial groove is restricted to the medial part of the medial condyle and rests on the anterior edge of the medial meniscus in full extension. Where it ceases, the patellar surface continues back to the lateral part of the medial condyle as a semilunar area adjoining the anterior region of the intercondylar fossa. This area articulates with the medial vertical facet of the patella in full flexion; its outline is indistinct in most femora. In habitual squatters articular cartilage may extend to the lateral aspect of the lateral condyle under vastus lateralis.

## Intercondylar fossa

The intercondylar fossa separates the two condyles distally and behind. In front, the distal border of the patellar surface limits it, and behind an intercondylar line limits it, separating it from the popliteal surface. It is intracapsular but largely extrasynovial. Its lateral wall, the medial surface of the lateral condyle, bears a flat posterosuperior impression that spreads to the floor of the fossa near the intercondylar line for the proximal attachment of the anterior cruciate ligament. The medial wall of the fossa, i.e. the lateral surface of the medial condyle, bears a similar larger area, but far more anteriorly, for the proximal attachment of the posterior cruciate ligament. Both impressions are smooth and largely devoid of vascular foramina, whereas the rest of the fossa is rough and pitted by vascular foramina. A bursal recess between the ligaments may ascend to the fossa. The capsular ligament and, laterally, the oblique popliteal ligament are attached to the intercondylar line. The infrapatellar synovial fold is attached to the anterior border of the fossa.

## Lateral condyle

The lateral condyle (see Fig. 80.14) is larger anteroposteriorly than the medial. Its most prominent point is the lateral epicondyle to which the fibular collateral ligament is attached (Fig. 80.15). A short groove, deeper in front, separates the lateral epicondyle inferiorly from the articular margin. This groove allows the tendon of popliteus to run deep to the fibular collateral ligament and insert inferior and anterior to the ligament insertion. Adjoining the joint margin is a strip of condyle, 1 cm broad. It is intracapsular and covered by synovial membrane except for the attachment of popliteus.

The medial surface is the lateral wall of the intercondylar fossa. Its lateral surface projects beyond the shaft. Part of the lateral head of gastrocnemius is attached to an impression posterosuperior to the lateral epicondyle.

## Medial condyle

The medial condyle has a bulging, convex medial aspect, which is easily palpable. Proximally, its adductor tubercle, which may only be a facet rather than a projection, receives the tendon of adductor magnus. The medial prominence of the condyle, the medial epicondyle, is anteroinferior to the tubercle. The lateral surface of the condyle is the medial wall of the intercondylar fossa. The condyle projects distally so that, despite the obliquity of the shaft, the profile of the distal end is almost horizontal. A curved strip, 1 cm wide and adjoining the medial articular margin, is covered by synovial membrane and is inside the joint capsule. Proximal to this, the medial epicondyle receives the tibial collateral ligament.

## Structure

The femoral shaft is a cylinder of compact bone with a large medullary cavity. The wall is thick in its middle third, where the femur is narrowest

Fig. 80.15 The distal end of the femur, lateral aspect. Key: 1, attachment of plantaris; 2, attachment of lateral head of gastrocnemius; 3, lateral epicondyle; 4, attachment of fibular collateral ligament; 5, groove for popliteus in full flexion; 6, attachment of popliteus.
and the medullary cavity most capacious. Proximally and distally, the compact wall becomes progressively thinner, and the cavity gradually fills with trabecular bone. The extremities, especially where articular, consist of trabecular bone within a thin shell of compact bone, their trabeculae being disposed along lines of greatest stress. At the proximal end, the main trabeculae form a series of plates orthogonal to the articular surface, converging to a central dense wedge, which is supported by strong trabeculae passing to the sides of the neck, especially along its upper and lower profiles (Fig. 80.16). Force applied to the femoral head is therefore transmitted to the wedge and from there to the junction of the neck and shaft. This junction is strengthened by dense trabeculae extending laterally from the lesser trochanter to the end of the superior aspect of the neck, thus resisting tensile or shearing forces applied to the neck through the head (Fig. 80.17). Tensile and compressive tests indicate that axial trabeculae of the femoral head withstand much greater stresses than peripheral trabeculae. A smaller bar across the junction of the greater trochanter with the neck and shaft resists shearing produced by muscles attached to it. These two bars are proximal layers of arches between the sides of the shaft and transmit to it forces applied to the proximal end. A thin vertical plate, the so-called calcar femorale, ascends from the compact wall near the linea aspera into the trabeculae of the neck (see Fig. 80.17). Medially, it joins the posterior wall of the neck; laterally, it continues into the greater trochanter, where it disperses into general trabecular bone. It is thus in a plane anterior to the trochanteric crest and base of the lesser trochanter. Dixon (1910) demonstrated that the trabecular framework of the proximal femur was spiral, and that the 'arches' were simplified sectional profiles of this spiral. At the distal end of the femur, trabeculae spring from the entire internal surface of compact bone, descending perpendicular to the articular surface. Proximal to the condyles these are strongest and most accurately perpendicular. Horizontal planes of trabecular bone, arranged like crossed girders, form a series of cubical compartments.

## Muscle attachments

The greater trochanter provides attachment for gluteus minimus and medius. Gluteus minimus is attached to its rough anterior impression and gluteus medius to its lateral oblique strip. The bone is separated from the tendon of gluteus medius by a bursa. The area behind it is covered by deep fibres of gluteus maximus, with part of its trochanteric bursa interposed. The tendon of piriformis is attached to the upper border of the trochanter and the common (tricipital) tendon of obturator internus and the gemelli is attached to its medial surface. The trochanteric fossa receives the tendon of obturator externus. Psoas major is attached to the summit and anteromedial surface of the lesser trochanter. Iliacus is attached to the medial or anterior surface of its base, descending a little behind the spiral line as its tendon fuses with that of psoas major. Adductor magnus (upper part) passes over its posterior surface, sometimes separated by an interposed bursa.

Fig. 80.17 A coronal section through the proximal end of the femur showing the trabecular architecture, calcar femorale and variations in cortical thickness. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The most proximal fibres of vastus lateralis are attached to the proximal end of the intertrochanteric line, and those of vastus medialis to the distal end. Quadratus femoris is attached to the quadrate tubercle and the immediately distal bone. Vastus intermedius is attached to the anterior and lateral surfaces of the proximal three-quarters of the femoral shaft. Slips of articularis genus are attached distal to this.

The gluteal tuberosity receives the deeper fibres of the distal half of gluteus maximus and, at its medial edge, the uppermost fibres of adduc-
tor magnus. Distal to this, adductor magnus is attached to the linea aspera and, by an aponeurosis, to the proximal part of the medial supracondylar ridge. Its remaining fibres form a large tendon attached to the adductor tubercle, with an aponeurotic expansion to the distal part of the medial supracondylar ridge.

Pectineus and adductor brevis are attached to the posterior femoral surface between the gluteal tuberosity and spiral line. The pectineal attachment is a line, sometimes slightly rough, from the base of the lesser trochanter to the linea aspera. Adductor brevis is attached lateral to pectineus and beyond this to the proximal part of the linea aspera, medial to adductor magnus. Adductor longus, intermuscular septa and the short head of biceps femoris are attached to the linea aspera. Vastus lateralis has a linear attachment from the anterior surface of the base of the greater trochanter to the proximal end of the gluteal tuberosity, and along the lateral margin of the latter to the proximal half of the lateral edge of the linea aspera. Vastus medialis is attached from the distal end of the intertrochanteric line along the spiral line to the medial edge of the linea aspera and thence to the medial supracondylar line, which also receives many fibres from the aponeurotic attachments of adductor magnus.

The medial head of gastrocnemius is attached to the posterior surface a little above the medial condyle. The short head of biceps femoris is attached to the proximal two-thirds of the lateral supracondylar line. Plantaris attaches to the line distally. Vastus medialis is attached to the proximal two-thirds of the medial supracondylar line.

Part of the lateral head of gastrocnemius is attached posterosuperiorly to the lateral epicondyle. Popliteus is attached anteriorly in the groove on the outer aspect of the lateral epicondyle. Its tendon passes deep to the fibular collateral ligament (see Fig. 80.15). The tendon lies in the groove in full knee flexion; in extension it crosses the articular margin and may form an impression on it.

## Vascular supply

The blood supply of the femoral head is derived from an arterial ring around the neck, just outside the attachment of the fibrous capsule, constituted by the medial and lateral circumflex femoral arteries with minor contributions from the superior and inferior gluteal vessels (see 'Trochanteric anastomosis') (Fig. 80.18). From this ring, ascending cervical branches pierce the capsule (under its zona orbicularis) to ascend the neck beneath the reflected synovial membrane. These vessels become the retinacular arteries and form a subsynovial intracapsular anastomosis. Here the vessels are at risk with a displaced fracture of the femoral neck. Interruption of blood supply in this way can lead to avascular necrosis of the femoral head. If the fracture is intracapsular, not only is the intraosseous blood supply damaged but the retinacular vessels are also vulnerable. If the fracture is extracapsular, the retinacular vessels will remain intact and avascular necrosis of the femoral head is much less likely. The ascending cervical vessels give off metaphysial branches that enter the neck, while the intracapsular ring gives off lateral and inferior epiphysial branches. A small medial epiphysial supply, of importance in early childhood, reaches the head along the ligament of the head of femur by the acetabular branches of the obturator and medial circumflex femoral arteries, which anastomose with the other epiphysial vessels. During growth, the epiphysial plate separates the territories of the metaphysial and epiphysial vessels; these vessels anastomose freely after osseous union of the head and neck.

Fig. 80.18 The collateral circulation around the hip and upper thigh, anterior aspect.

Observations of developmental patterns of this supply in late fetal and early postnatal periods have revealed that although medial and lateral circumflex femoral arteries at first contribute equally, two major branches of the medial provide the final supply, both posterior to the neck. The supply from the lateral circumflex artery diminishes and the arterial ring is interrupted. As the femoral neck elongates, the extracapsular circle becomes more distant from the epiphysial part of the head.

The trochanteric regions and subtrochanteric shaft are supplied by the trochanteric and cruciate arterial anastomoses. More distally in the shaft, nutrient foramina, directed proximally, are found in the linea aspera, varying in number and site: one is usually near its proximal end and a second usually near its distal end. The main nutrient artery is usually derived from the second perforating artery (see 'Profunda femoris artery'). If two nutrient arteries occur, they may branch from the first and third perforators. Periosteal vessels arise from the perforators and from the profunda femoris artery, and run circumferentially rather than longitudinally. The distal metaphysis has many vascular foramina. Arterial supply here is from the genicular anastomosis. For further details, consult Crock $(1980,1996)$.

In general, the pattern of venous drainage of the head and neck corresponds to that of the arteries, though there may be a single large cervical vein posteroinferiorly.

## Innervation

The periosteal innervation is derived proximally from nerves that supply the hip joint, distally from those supplying the knee, and in all areas from nerves that innervate muscles attached to the bone.

## Ossification

The femur ossifies from five centres: in the shaft, head, greater and lesser trochanters and the distal end (Fig. 80.19). Other than the clavicle, it is the first long bone to ossify. The process starts in the mid-shaft in the seventh prenatal week and extends to produce a miniature shaft that is largely ossified at birth. Secondary centres appear in the distal end (from which the condyles and epicondyles are formed) during the ninth month, in the head during the first six months after birth (Fig. 80.20), in the greater trochanter during the fourth year and in the lesser trochanter between the twelfth and fourteenth years. In the infant, the femoral head is entirely cartilaginous; it cannot be seen on plain radiographs and is best visualized using ultrasound (Fig. 80.21). The centre in the cartilaginous head is restricted to it until the tenth year, so that the epiphysial line (see Fig. 80.7) is horizontal and the

Fig. 80.19 Stages in ossification of the femur (not to scale).
inferomedial part of the articular surface is on the neck. The medial epiphysial margin later grows over this part of the articular surface. Thus, the mature epiphysis is a hollow cup on the summit of the neck. The epiphysial line follows the articular margin except where it is separated superiorly from the articular surface by a non-articular area where blood vessels enter the head (Trueta 1957). The epiphyses fuse independently: the lesser trochanter soon after puberty, followed by the greater trochanter. The capital epiphysis fuses in the fourteenth year in females and seventeenth year in males. The epiphysis at the distal end fuses in the sixteenth year in females, and eighteenth year in males. The distal epiphysial plate traverses the adductor tubercle.

## Growth plate considerations

Trauma to any epiphysial plate can lead to bony union between epiphysis and metaphysis, and so cause premature cessation of growth. Any surgery in the hip region in children can injure the growth plate, resulting in abnormal proximal femoral development. In the case of fractures involving the epiphysis, expeditious restoration of normal bony alignment is essential in order to minimize the risk of subsequent abnormal growth.

The growth plate represents a line of weakness and predisposes to fracture from injury. Such acute injuries affecting the capital epiphysis are uncommon. However, a more chronic fracture through the capital epiphysis occurs in slipped capital femoral epiphysis (SCFE) (see Fig. 81.9). The condition affects pubescent adolescents, especially males. Endocrinological abnormality may be related. The femoral head epiphysis displaces posteriorly off the femoral neck. If it heals in this position, lower limb deformity and restricted hip movement occur. A classic hallmark is obligatory lateral rotation of the femur as the hip is flexed. Treatment varies according to the time taken for the 'slip' to occur. Normal anatomical restoration is not attempted because of an increased incidence of avascular necrosis. The position of the femoral head may be accepted as it is and fixed with screws in this position to stop further displacement. This treatment will deliberately cause premature growth plate fusion and so prevent future 'slippage'. Since the distal femoral growth plate accounts for most of the normal increase in longitudinal growth of the femoral shaft, an acceptable limb length difference usually results.

Infection of bone in neonates and young children tends to arise via bacteria in the blood stream that usually 'seed' in the metaphysial region, probably as a consequence of the vascular 'arcade' arrangement of arteries in this part of the bone. The proximal femoral growth plate is intra-articular. As a result, infection in the proximal femoral metaphysis can spread into the joint and result in a septic arthritis that can destroy the hip joint permanently.

The distal end of the femur is the only epiphysis in which ossification consistently starts just before birth; the phenomenon therefore serves as a reliable indicator of the gestational maturity of a stillborn baby. Since the epiphysial plate is level with the adductor tubercle, the epiphysis is partly extra-articular. Operations here may damage the distal epiphysial cartilage in children and result in subsequent shortening of the leg.

## JOINTS

## PUBIC SYMPHYSIS

The pubic bones meet in the midline at the pubic symphysis, a secondary cartilaginous joint (see Fig. 80.4).

Fig. 80.20 A radiograph of the pelvis of a 9-month-old infant showing the centre of ossification of the femoral epiphysis (arrow). (Courtesy of Mr Christopher Edward Bache.)

Fig. 80.21 An ultrasound image of a 4-week-old baby taken in the lateral position and demonstrating the cartilaginous femoral head (yellow arrow) and edge of the acetabulum (red arrow). (Courtesy of Mr Christopher Edward Bache.)

Articulating surfaces The articulating surfaces are the medial (symphysial) surfaces of the pubic bones, each covered by a thin layer of tightly adherent hyaline cartilage (surface growth cartilage in the young). The junction is not flat but is marked by reciprocal crests and papillae. Theoretically, this would resist shearing. The surfaces of hyaline cartilage are connected by fibrocartilage, varying in thickness and constituting the interpubic disc. The symphysis often contains a cavity, probably due to absorption. It rarely appears before the tenth year and is non-synovial. The cavity, which is better developed in females, is usually posterosuperior but may reach the front or even occupy most of the cartilage.

Ligaments The interpubic disc is strengthened anteriorly by several interlacing collagenous fibrous layers, passing obliquely from bone to bone, decussating with fibres of the external oblique aponeuroses and the medial tendons of the recti abdominis. These layers constitute the anterior pubic ligament. There are less well developed posterior fibres, sometimes named the posterior pubic ligament. The main ligaments of the joint are the superior and arcuate pubic ligaments. The superior pubic ligament connects the bones above, extending to the pubic tubercles. The arcuate pubic ligament, a thick arch of fibres, connects the lower borders of the symphysial pubic surfaces bounding the pubic arch. It blends superiorly with the interpubic disc and extends laterally attached to the inferior pubic rami. Its inferior edge is separated from the anterior border of the perineal membrane by an opening, which is traversed by the deep dorsal vein of the penis or clitoris.

Vascular supply The pubic symphysis is supplied by pubic branches of the obturator, superficial external pudendal and inferior epigastric arteries.

Innervation The pubic symphysis is innervated by branches from the iliohypogastric, ilioinguinal and pudendal nerves.

Factors maintaining stability The interpubic disc and the superior and arcuate ligaments are the main stabilizing factors of the pubic symphysis.

Movements Angulation, rotation and displacement are possible but slight, and are likely during movement at the sacroiliac and hip joints. The movements at the pubic symphysis range between 0.1 and 2 mm and are higher along the vertical axis than along the sagittal and transverse axes (Walheim et al 1984). Excessive movement may occur following an injury. Some separation occurs late in gestation and during childbirth; on occasion, this is considerable.

Relations Anteriorly, the pubic symphysis is related to subcutaneous tissue and skin. Because of the obliquity of the joint, the proximal ends of the penile or clitoral shafts lie anterior to the lower half of the joint. Inferiorly, the urethra lies about 2.5 cm away in the male, and somewhat closer in the female, as it passes through the perineal membrane. Closer to the joint, the deep dorsal vein of the penis or clitoris passes between the arcuate ligament and the anterior border of the perineal membrane. Posteriorly, the upper part of the joint is separated from the inferolateral surfaces of the urinary bladder by the retropubic fat pad. Inferiorly in the male, the prostatic venous plexus separates the prostate from the lower part of the joint. The region is sometimes termed the retropubic space (of Retzius). These relationships explain why traumatic disruption of the anterior bony pelvis may be associated with serious urogenital injury.

## SACROILIAC JOINT

The sacroiliac joint occurs between the sacral and iliac auricular surfaces and, in essence, is a stress-relieving joint (Bogduk 1997) (see Fig. 80.8A). The joint consists of syndesmotic and synovial parts. Fibrous adhesions and gradual obliteration occur in both sexes, earlier in males, and after menopause in females. Radiological evidence of obliteration in normal subjects is occasionally seen before 50 years but is not uncommon thereafter; in old age, the joint may be completely fibrosed and occasionally even ossified.

Articulating surfaces The surfaces are nearly flat in infants, whereas in adults they are irregular, often markedly so, and sometimes undulant. The curvatures and irregularities, greater in males, are reciprocal; they restrict movements and contribute to the considerable strength of the joint in transmitting weight from the vertebral column to the lower limbs. The sacral surface is covered by hyaline cartilage, which is thicker
anteriorly than posteriorly in adults. The thinner cartilage on the iliac surface is also hyaline in type, as confirmed by the presence of type II collagen.

Fibrous capsule The capsule is attached close to both articular margins.

Ligaments The ligaments of the sacroiliac joint are the anterior, interosseous and posterior sacroiliac, iliolumbar, sacrotuberous and sacrospinous ligaments.

Anterior sacroiliac ligament The anterior sacroiliac ligament (see Fig. 80.9A), an anteroinferior capsular thickening, is particularly well developed near the arcuate line and the posterior inferior iliac spine, where it connects the third sacral segment to the lateral side of the preauricular sulcus. It is thin elsewhere.

Interosseous sacroiliac ligament The interosseous sacroiliac ligament is the major bond between the bones, filling the irregular space posterosuperior to the joint. The posterior sacroiliac ligament covers it superficially. Its deeper part has superior and inferior bands passing from depressions posterior to the sacral auricular surface to those on the iliac tuberosity. These bands are covered by, and blend with, a more superficial fibrous sheet connecting the posterosuperior margin of a rough area posterior to the sacral auricular surface to the corresponding margins of the iliac tuberosity. This sheet is often partially divided into superior and inferior parts, the former uniting the superior articular process and lateral crest on the first two sacral segments to the neighbouring ilium as a short posterior iliac ligament (see Fig. 43.68).

Posterior sacroiliac ligament The posterior sacroiliac ligament (see Fig. 80.9B) overlies the interosseous ligament: the dorsal rami of the sacral spinal nerves and vessels intervene. It consists of several weak fasciculi connecting the intermediate and lateral sacral crests to the posterior superior iliac spine and posterior end of the internal lip of the iliac crest. Inferior fibres, from the third and fourth sacral segments, ascend to the posterior superior iliac spine and posterior end of the internal lip of the iliac crest; they may form a separate long posterior sacroiliac ligament. This ligament is continuous laterally with part of the sacrotuberous ligament and medially with the posterior lamina of the thoracolumbar fascia.

## Iliolumbar ligament See page 738.

Sacrotuberous ligament The sacrotuberous ligament (see Figs 80.9, 43.68) is attached by its broad base to the posterior superior iliac spine, the posterior sacroiliac ligaments (with which it is partly blended), lateral sacral crest, and the lateral margins of the lower sacrum and upper coccyx. Its oblique fibres descend laterally, converging to form a thick, narrow band that widens again below and is attached to the medial margin of the ischial tuberosity. It then spreads along the ischial ramus as the falciform process, whose concave edge blends with the fascial sheath of the internal pudendal vessels and pudendal nerve. The lowest fibres of gluteus maximus are attached to the posterior surface of the ligament; superficial fibres of the lower part of the ligament continue into the tendon of biceps femoris. The coccygeal branches of the inferior gluteal artery, the perforating cutaneous nerve and filaments of the coccygeal plexus pierce the ligament.

Sacrospinous ligament The thin, triangular sacrospinous ligament (see Fig. 80.9) extends from the ischial spine to the lateral margins of the sacrum and coccyx anterior to the sacrotuberous ligament, with which it blends in part. Its anterior surface is in fact the coccygeus muscle, i.e. muscle and ligament are coextensive. The sacrospinous ligament is often regarded as a degenerate part of coccygeus.

Sciatic foramina The sacrotuberous and sacrospinous ligaments convert the sciatic notches into foramina (see Fig. 80.9).

Greater sciatic foramen The greater sciatic foramen is bounded anterosuperiorly by the greater sciatic notch, posteriorly by the sacrotuberous ligament and inferiorly by the sacrospinous ligament and ischial spine (see Fig. 80.9). It is partly filled by the emerging piriformis, above which the superior gluteal vessels and nerve leave the pelvis. Below it, the inferior gluteal vessels and nerve, internal pudendal vessels and pudendal nerve, sciatic and posterior femoral cutaneous nerves and the nerves to obturator internus and quadratus femoris all leave the pelvis.

Lesser sciatic foramen The lesser sciatic foramen is bounded anteriorly by the ischial body, superiorly by its spine and sacrospinous ligament, and posteriorly by the sacrotuberous ligament (see Fig. 80.9A). It transmits the tendon of obturator internus, the nerve to obturator internus, and the internal pudendal vessels and pudendal nerve.

Vascular supply The arterial supply of the sacroiliac joint is derived from the iliolumbar, superior gluteal and superior lateral sacral arteries, with corresponding venous drainage. Lymphatic drainage follows the arteries, reaching the iliac and lumbar nodes.

Innervation Nerve fibres ramify within the joint capsule and adjoining ligaments, but their source is uncertain. It is thought that the joint probably receives branches from the anterior and posterior rami of the first two sacral spinal nerves, and from the superior gluteal nerve, and that there may also be contributions from the obturator nerve and the lumbosacral trunk.

The sacroiliac joint has sometimes been implicated as the source of pain in the lower back and buttocks. Diagnosing sacroiliac jointmediated pain is difficult because the presenting complaints are similar to those seen with other causes of back pain. Patients with sacroiliac joint-mediated pain rarely report pain above the level of L5; most localize their pain to the area around the posterior superior iliac spine.

Factors maintaining stability The sacroiliac joint is one of the most stable joints in the body and supports the weight of the trunk. The reciprocal irregularity of the joint surfaces allows very little movement. The tendency of the sacrum to be forced downwards by the trunk is resisted by the extremely strong posterior ligaments, while the iliolumbar ligaments help to resist displacement of the fifth lumbar vertebra over the sacrum. The sacrotuberous and sacrospinous ligaments oppose upward tilting of the lower part of the sacrum when downward thrust is applied at its upper end.

Movements Primary movement of the sacroiliac joint is minimal. All muscles that cross the joint act on the lumbar spine or on the hip. Such movements as do occur are secondarily imposed on the joint as the pelvis moves. Data from living subjects are technically difficult to obtain, and those based on plain radiographs are unreliable. Studies using implanted tantalum spheres and biplanar radiography have shown mean rotational ranges of less than $2^{\circ}$. Even when there is recordable movement, the direction of movement is irregular. Biplanar radiography has also shown that the axes of movement of the sacroiliac joint during hip movement are oblique, and that the axes differ in flexion and extension.

During pregnancy, the pelvic joints and ligaments loosen under the influence of the hormone relaxin. Movements in the joints increase. Relaxation renders the sacroiliac locking mechanism less effective, permitting greater rotation and perhaps allowing alterations in pelvic diameters at childbirth, although the effect is probably small. The impaired locking mechanism diverts the strain of weight-bearing to the ligaments, with frequent sacroiliac strain after pregnancy.

Relations The sacroiliac joints have many important anterior relations. The internal and external iliac veins join to form the common iliac veins immediately anteriorly, separating the joints from the bifurcations of the common iliac arteries and, more anteriorly, the ureters. The lumbosacral trunk and the obturator nerve cross the anterior aspect of the joint behind the vessels. Piriformis partly attaches to the anterior capsule, separating the joint from the upper part of the sacral plexus.

Variants Accessory sacroiliac articulations are not uncommon. They develop behind the articular surface between the lateral sacral crest and posterior superior iliac spine and iliac tuberosity, and are acquired fibrocartilaginous joints resulting from the stresses of weight-bearing. They have a joint capsule, are saddle-shaped, and may be single, double, unilateral or bilateral (Weisl 1954).

## MUSCLES

## MUSCLES OF THE ILIAC REGION

Although there is no 'iliac region' as such, this heading conveniently describes a group of three muscles that originate from the lumbar vertebral column (psoas major and minor) and the ilium (iliacus). Psoas major and iliacus are attached together on the femur as flexors of the hip joint and are often considered as a functional unit, iliopsoas. Psoas minor only reaches the pubis, and acts on the spine and sacroiliac joint.

## Psoas major

Attachments Psoas major is a long muscle that lies on either side of the lumbar vertebral column and the pelvic brim (Fig. 80.22, see Fig. 62.7). Its proximal attachments are complex. They include the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebrae. There are five digitations, each from the bodies of two adjoining vertebrae and their intervertebral disc. The highest of these arises from the lower margin of the body of the twelfth thoracic vertebra, the upper margin of the body of the first lumbar vertebra and the interposed intervertebral disc. The lowest arises from the adjacent margins of the bodies of the fourth and fifth lumbar vertebrae and the interposed disc. A series of tendinous arches extend across the narrow parts of the bodies of the lumbar vertebrae between the digitations already described. The lumbar arteries and veins, and filaments from

Fig. 80.22 The hip flexors and superficial muscles of the thigh.
the sympathetic trunk, pass medial to these arches. The upper four lumbar intervertebral foramina bear important relations to these attachments of the muscle. The foramina lie anterior to the transverse processes and posterior to the attachments to vertebral bodies, intervertebral discs and tendinous arches. Thus, the roots of the lumbar plexus enter the muscle directly, the plexus is lodged within it, and its branches emerge from its borders and surfaces.

The muscle descends along the pelvic brim, continues posterior to the inguinal ligament and anterior to the capsule of the hip joint, and converges to a tendon that, having received on its lateral side nearly all the fibres of iliacus, becomes attached to the lesser trochanter of the femur. The large subtendinous iliac bursa, which occasionally communicates with the cavity of the hip joint, separates the tendon from the pubis and the capsule of the joint.

The complex vertebral attachments of psoas major sometimes display minor numerical variations.

Relations The upper limit of psoas major is posterior to the diaphragm in the lowest part of the posterior mediastinum. It may be in contact with the posterior extremity of the pleural sac. In the abdomen, its anterolateral surface is related to the medial arcuate ligament (a linear, arched thickening in the psoas fascia), extraperitoneal tissue and peritoneum, the kidney, psoas minor, renal vessels, ureter, testicular or ovarian vessels and the genitofemoral nerve. Anteriorly, the right psoas is overlapped by the inferior vena cava and crossed by the terminal part of the ileum; the colon crosses the left psoas. Its posterior surface is related to the transverse processes of the lumbar vertebrae and the medial edge of quadratus lumborum. The lumbar plexus is embedded posteriorly in the substance of psoas major. Medially, the muscle is related to the bodies of the lumbar vertebrae and lumbar vessels. Along its anteromedial margin, it is in contact with the sympathetic trunk, aortic lymph nodes and, along the pelvic brim, with the external iliac artery. This margin is covered by the inferior vena cava on the right side, and lies posterior and lateral to the abdominal aorta on the left side. In the thigh, iliopsoas is related anteriorly to the fascia lata and the femoral artery, and posteriorly to the capsule of the hip joint, from which it is separated by a bursa. At its medial border, it is related to pectineus and the medial circumflex femoral artery, and to the femoral vein, which may overlap it slightly. At its lateral border, it is related to the femoral nerve and iliacus. The femoral nerve descends at first through the fibres of psoas major, and then in the furrow between it and iliacus.

Branches of the lumbar plexus diverge from the abdominal part of psoas major. Emerging from the lateral border, from above downwards, are the iliohypogastric, ilioinguinal and lateral femoral cutaneous and femoral nerves. Emerging from the anterolateral surface is the genitofemoral nerve. The obturator and accessory obturator nerves (when present) and the upper root of the lumbosacral trunk all emerge from the medial border.

Vascular supply Psoas major is supplied by a rich network of arteries derived from the lumbar, iliolumbar, obturator, external iliac and femoral arteries. In general terms, the upper part of the muscle is supplied by the lumbar arteries, the mid part by the anterior branch of the iliolumbar artery (the main artery to the muscle) with contributions from the deep circumflex and external iliac arteries, and the distal part by the femoral artery and its branches. The psoas sheath has an arterial supply independent from that of the muscle, though the same vessels contribute.

Innervation Psoas major is innervated by the ventral rami of the lumbar spinal nerves, mainly L1 and 2 with some contribution from L3.

Actions Psoas major acts together with iliacus; the combination is referred to as iliopsoas. See below ('Iliacus').

Testing See below (after 'Iliacus').

## Psoas minor

Attachments Psoas minor (see Fig. 80.22) is sometimes absent. When present, it lies anterior to psoas major, entirely within the abdomen. It arises from the sides of the bodies of the twelfth thoracic and first lumbar vertebrae, and from the intervertebral disc between them. It ends in a long, flat tendon that is attached to the pecten pubis, iliopubic ramus and, laterally, to the iliac fascia.

Relations Psoas minor lies on psoas major, and its proximal anterior relations are those of the anterior or anteromedial surface of that muscle.

Vascular supply The main arterial supply to psoas minor is from the lumbar arteries, though there may be minor contributions from other vessels of the network that supplies psoas major.

Innervation Psoas minor is innervated by a branch from L1.
Actions Psoas minor is probably a weak flexor of the trunk.
Testing Psoas minor cannot be tested clinically.

## Iliacus

Attachments Iliacus (see Figs 80.22, 62.7) is a triangular sheet of muscle that arises from the superior two-thirds of the concavity of the iliac fossa, the inner lip of the iliac crest, the ventral sacroiliac and iliolumbar ligaments, and the upper surface of the lateral part of the sacrum (see Fig. 43.49). In front, it reaches as far as the anterior superior and anterior inferior iliac spines, and receives a few fibres from the upper part of the capsule of the hip joint (iliocapsularis, p. 1377). Most of its fibres converge into the lateral side of the strong tendon of psoas major, and the muscles then insert together into the lesser trochanter, but some fibres are attached directly to the femur 2.5 cm below and in front of the lesser trochanter.

Relations In the abdomen, the anterior surface of iliacus is related to its fascia (which separates the muscle from extraperitoneal tissue and peritoneum), the lateral femoral cutaneous nerve, the caecum (on the right) and the iliac part of the descending colon (on the left). On its posterior surface is the iliac fossa, and at its medial border, psoas major and the femoral nerve. In the thigh, its anterior surface is in contact with the fascia lata, rectus femoris, sartorius and the profunda femoris artery, and its posterior surface is in contact with the capsule of the hip joint, from which it is partially separated by a bursa it shares with psoas major.

Vascular supply Iliacus is supplied by the same arterial network as psoas major, and there is mutual overlap of the arterial territories of each muscle. The main supply is from the iliac branches of the iliolumbar artery, with contributions from the deep circumflex iliac and obturator arteries, and branches of the femoral artery.

Innervation Iliacus is innervated by branches of the femoral nerve, L2 and 3.

Actions Psoas major, acting from above together with iliacus, flexes the thigh on the pelvis. Electromyographic studies do not support the common view that psoas major acts as a medial rotator of the hip joint, but activity has been described in lateral rotation, particularly in the young. When psoas major and iliacus of both sides act from below, they contract powerfully to bend the trunk and pelvis forwards against resistance, as in raising the trunk from the recumbent to the sitting posture when undertaking a 'sit-up' exercise.

Electromyography does not support the commonly held belief that unilateral action of psoas major causes lateral and forward flexion of the trunk to that side (Joseph 1975).

In symmetrical upright stance, iliopsoas has some action from below to maintain the vertebral column upright. Psoas major is active in balancing the trunk while sitting.

Testing Both psoas and iliacus may be the sites of pathological collections of fluid. An abscess (typically tuberculous) of vertebral origin may track down through psoas and present as a mass in the thigh. Haematoma or infection within the iliacus fascia may present as a mass or as a flexion deformity of the hip.

Iliopsoas may be tested clinically by actively flexing the hip against resistance, in the supine position with the hip and knee flexed.

## MUSCLES OF THE GLUTEAL REGION

## Tensor fasciae latae

Attachments Tensor fasciae latae (see Fig. 80.22) arises from the anterior 5 cm of the outer lip of the iliac crest, from the lateral surface of the anterior superior iliac spine and part of the border of the notch below it, between gluteus medius and sartorius, and from the deep surface of the fascia lata. Proximal attachments may extend to the aponeurotic fascia superficial to gluteus medius. It descends between, and is attached to, the two layers of the iliotibial tract of the fascia lata and usually ends approximately one-third of the way down the thigh,
although it may occasionally extend as far as the lateral femoral condyle.

Vascular supply The muscle itself is supplied mainly by a large ascending branch of the lateral circumflex femoral artery. The tensor fasciae latae musculocutaneous flap is raised on this pedicle. The superior part of the muscle receives branches from the superior gluteal artery. The fascia surrounding the muscle is supplied on its superficial aspect by the superficial circumflex iliac artery and on its deep surface by the lateral circumflex femoral artery.

Innervation Tensor fasciae latae is innervated by the superior gluteal nerve, L4, 5 and S1.

Actions Tensor fasciae latae, acting through the iliotibial tract, extends the knee with lateral rotation of the leg; it may also assist in abduction and medial rotation of the thigh, though its role as an abductor is debatable. The muscle helps to maintain upright posture while minimizing energy expenditure on muscle activity: when the subject is standing it acts from below to steady the pelvis on the head of the femur and, through the iliotibial tract, to steady the condyles of the femur on the tibial condyles while the knee extensors are relaxed. The muscle aids gluteus medius in postural abduction at the hip. Postural control is its main function.

In the last $20^{\circ}$ or so of extension, the pull of the iliotibial tract is anterior to the flexion axis of the knee and so the tensor fasciae latae is a weak extensor. Flexion of greater than $20^{\circ}$ leads to the iliotibial tract passing posterior to the axis of flexion so that the muscle becomes a weak flexor.

Testing When the thigh is flexed against gravity and the knee is extended, an angular depression appears immediately below the anterior superior iliac spine; its lateral boundary is tensor fasciae latae. If the thigh is then abducted against resistance, the muscle can be felt and sometimes seen.

## Gluteus maximus

Attachments Gluteus maximus (Fig. 80.23) is the largest and most superficial muscle in the gluteal region. It is a broad, thick, quadrilateral mass, which, with its overlying adipose fascia, forms the familiar prominence of the buttock. Gluteus maximus is thicker and more extensive in humans than in any non-human primate, features that presumably correlate with the evolutionary transition to bipedality and a permanently upright posture. The muscle has a coarse fascicular architecture, with large bundles of fibres separated by fibrous septa. It arises from the posterior gluteal line of the ilium and the rough area of bone, including the crest, immediately above and behind it; from the aponeurosis of erector spinae; the dorsal surface of the lower part of the sacrum and the side of the coccyx; the sacrotuberous ligament; and the fascia (gluteal aponeurosis) that covers gluteus medius. There may be additional slips from the lumbar aponeurosis or ischial tuberosity. The muscle may also be bilaminar. The fibres descend laterally; the upper part of the muscle, together with the superficial fibres of the lower part, ends in a thick tendinous lamina that passes lateral to the greater trochanter and is attached to the iliotibial tract of the fascia lata. The deeper fibres of the lower part of the muscle are attached to the gluteal tuberosity between vastus lateralis and adductor magnus.

Relations A thin fascia separates the superficial surface of gluteus maximus from the overlying thick, adipose subcutaneous tissue. The deep surface of the muscle is related to the ilium, sacrum, coccyx, sacrotuberous ligament, part of gluteus medius, piriformis, the gemelli, obturator internus, quadratus femoris, the ischial tuberosity, greater trochanter, and the attachments of biceps femoris, semitendinosus, semimembranosus and adductor magnus to the ischial tuberosity. Three bursae lie deep to gluteus maximus: trochanteric, over the greater trochanter; gluteofemoral, between the tendon of gluteus maximus and that of vastus lateralis; and ischiofemoral, over the gluteal tuberosity, which is less commonly present.

The superficial division of the superior gluteal artery reaches the deep surface of the muscle between piriformis and gluteus medius. The inferior gluteal and internal pudendal vessels, the sciatic, pudendal and posterior femoral cutaneous nerves, muscular branches from the sacral femoral cutaneous nerves, and muscular branches from the sacral plexus all leave the pelvis below piriformis. The first perforating artery and the terminal branches of the medial circumflex femoral artery are also deep to the lower part of gluteus maximus. Its upper border is thin and overlies gluteus medius. Its prominent lower border is free and slopes downwards and laterally. It is crossed by the horizontal gluteal

Fig. 80.23 Gluteus maximus, posterior view with the posterior thigh muscles seen through the overlying fascia lata.
fold (the posterior flexure line of the hip joint), which marks the upper limit of the back of the thigh on the surface.

Vascular supply The dominant vascular pedicle is usually that of the inferior gluteal artery, which supplies approximately two-thirds of the muscle. The remainder is supplied mainly by the superior gluteal artery, though this may sometimes be the dominant vessel. The lateral and distal borders of the muscle receive a supply from the first perforator given off from the profunda femoris artery and from the medial circumflex femoral artery. Minor branches may be derived from the lateral circumflex femoral, lateral sacral and internal pudendal arteries.

Gluteus maximus musculocutaneous flaps may be based on either of the gluteal vessels or on the first perforator given off from the profunda femoris artery, depending on the site and size of the defect requiring coverage.

Innervation Gluteus maximus is innervated by the inferior gluteal nerve, L5, S1 and S2.

Actions Acting from the pelvis, gluteus maximus can extend the flexed thigh and bring it into line with the trunk. Acting from its distal attachment, it may prevent the forward momentum of the trunk from producing flexion at the supporting hip during bipedal gait. The muscle is inactive during standing, when swaying forwards at the ankle joints, or when bending forwards at the hip joints to touch the toes. However, it acts with the hamstrings in raising the trunk after stooping, by rotating the pelvis backwards on the head of the femur. It is intermittently active in the walking cycle and in climbing stairs, and continuously active in strong lateral rotation of the thigh. Its upper fibres are active in powerful abduction of the thigh. It is a tensor of the fascia lata, and through the iliotibial tract it stabilizes the femur on the tibia when the extensor muscles of the knee are relaxed.

Fig. 80.24 A, Gluteus medius, posterior view. B, Gluteus minimus and short lateral rotators of the hip, posterior view.

Testing Gluteus maximus may be tested by extension of the hip against resistance, in the supine or prone position.

## Gluteus medius

Attachments Gluteus medius is a broad, thick muscle (see Fig. 80.23; Fig. 80.24A). It arises from the outer surface of the ilium between the iliac crest and posterior gluteal line above, and the anterior gluteal line below, and also from the strong fascia superficial to its upper part. The fibres converge to a flat tendon that attaches to a ridge that slants downwards and forwards on the lateral surface of the greater trochanter.

A deep slip of the muscle may be attached to the upper border of the trochanter. The posterior edge of gluteus medius sometimes blends with piriformis.

Relations The posterior third of gluteus medius is covered by gluteus maximus but it is superficial in its anterior two-thirds, where a strong layer of deep fascia covers it. Its deep surface is related to gluteus minimus. Branches of the deep divisions of the superior gluteal nerve and artery run between the medius and minimus muscles, and are vulnerable during anterolateral and lateral approaches to the hip that involve splitting gluteus medius. Where the tendon glides on the anterosuperior part of the lateral surface of the trochanter, a bursa (trochanteric bursa of gluteus medius) separates it from the bone.

Vascular supply The main supply to gluteus medius is from the deep branch of the superior gluteal artery (Fig. 80.25A). The distal part of the muscle is supplied by the trochanteric anastomosis.

Innervation Gluteus medius is innervated by the superior gluteal nerve, L4, 5 and S1.

Actions These are considered below with gluteus minimus.
Testing This is considered below with gluteus minimus.

## Gluteus minimus

Attachments Gluteus minimus lies deep to gluteus medius (see Fig. 80.24B). The fan-shaped muscle arises from the outer surface of the ilium between the anterior and inferior gluteal lines and, behind, from the margin of the greater sciatic notch. The fibres converge below to the deep surface of an aponeurosis that ends in a tendon attached to an anterolateral ridge on the greater trochanter and contributes an expansion to the capsule of the hip joint.

The muscle may divide into anterior and posterior parts. Separate slips may pass to piriformis, gemellus superior or vastus lateralis.

Relations Branches of the deep division of the superior gluteal artery and nerve run on the superficial surface of the muscle. The reflected tendon of rectus femoris and the capsule of the hip joint are deep to gluteus minimus. A bursa (trochanteric bursa of gluteus minimus) separates the tendon from the medial part of the anterior surface of the greater trochanter.

Vascular supply Gluteus minimus is supplied from both its surfaces, from the main trunk and the deep branch of the superior gluteal artery, with a contribution at its femoral attachment from the trochanteric anastomosis (see Fig. 80.25).

Innervation Gluteus minimus is innervated by the superior gluteal nerve, L4, 5 and S1.

## Actions of gluteus medius and minimus

Both gluteus medius and minimus, acting from the pelvis, abduct the thigh, and their anterior fibres rotate it medially. Acting from the femur, they play an essential part in maintaining the trunk upright when the foot of the opposite side is raised from the ground in walking and running. In this phase, the body weight tends to make the pelvis sag downwards on the unsupported side. This is counteracted by the gluteus medius and minimus of the supporting side, which, acting from below, exert such powerful traction on the hip bone that the pelvis is actually raised a little on the unsupported side. In symmetrical standing with the feet somewhat separated, the abductor muscles are usually 'silent' on electromyography, but with the feet placed parallel and close together they are active.

Testing The supportive effect of the glutei (medius and minimus) on the pelvis when the contralateral foot is raised depends on the following conditions. The two muscles, and their innervation, must be functioning normally. The components of the hip joint, which forms the fulcrum, must be in their usual relation. The neck of the femur must be intact, with its normal angulation to the shaft.

When any one of these conditions is not fulfilled, e.g. in paralysis of the glutei, developmental dysplasia of the hip or coxa vara, the supporting mechanism is upset and the pelvis sinks on the unsupported side when the patient tries to stand on the affected limb. This is known clinically as Trendelenburg's sign. Individuals with paralysis of gluteus medius and minimus have a characteristic lurching gait. Provided that these two muscles are intact, paralysis of other muscles acting on the hip joint produces remarkably little deficit in walking, or even in running.

Gluteus medius and minimus may be tested together by medial rotation of the thigh against resistance, in the supine position with hip and knee flexed. Both muscles may be tested together with tensor fasciae latae by abduction of the lower limb against resistance, in the supine position with the knee extended.

## Piriformis

Attachments Piriformis (see Figs 80.24B, 80.25A) occupies a central position in the buttock, where it lies in the same plane as gluteus medius. It arises from the anterior surface of the sacrum by three digitations, which are attached to the portions of bone between the pelvic sacral foramina, and to the grooves leading from the foramina (see Fig. 43.49). It also arises from the gluteal surface of the ilium near the

Fig. 80.25 The arteries and muscles of the left gluteal and femoral regions. A, Posterior aspect. B, Anterior aspect. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
posterior inferior iliac spine, from the capsule of the adjacent sacroiliac joint, and sometimes from the upper part of the pelvic surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, which it substantially fills. Here it constitutes an important surgical landmark in the identification of structures that emerge above and below it. It inserts into the medial side of the upper border of the greater trochanter of the femur via a rounded tendon that lies behind and above, but is often partially blended with, the common tendon of obturator internus and the gemelli. The muscle itself may be fused with gluteus medius.

Relations Within the pelvis, the anterior surface of piriformis is related to the rectum (especially on the left), the sacral plexus of nerves and branches of the internal iliac vessels. The posterior surface lies against the sacrum. Outside the pelvis, its anterior surface is in contact with the posterior surface of the ischium and capsule of the hip joint, and its posterior surface with gluteus maximus. Its upper border is in contact with gluteus medius and the superior gluteal vessels and nerve, its lower border with coccygeus and gemellus superior. The inferior gluteal and internal pudendal vessels, the sciatic, posterior femoral cutaneous and pudendal nerves, and muscular branches from the sacral plexus appear in the buttock in the interval between piriformis and gemellus superior. The relationship between piriformis and the sciatic nerve is variable. The undivided nerve may emerge above the muscle or through the muscle. The major divisions of the nerve may lie either side of the muscle, or (the most common variant) one division passes between the heads of a divided muscle and one division either above or below.

Piriformis can occasionally cause entrapment of the sciatic nerve in the buttock, giving rise to the so-called 'piriformis syndrome'.

Vascular supply In the buttock, piriformis is supplied mainly from the superior gluteal artery, with contributions from the gemellar branches of the internal pudendal. There may be a separate branch from
the inferior gluteal artery (see Fig. 80.25A). In the pelvis, the main supply is from the lateral sacral artery, with contributions from both gluteal vessels.

Innervation Piriformis is innervated by branches from S1 and 2 (sometimes only from S2). It may also contain fibres from L5.

Actions Piriformis rotates the extended thigh laterally, but abducts the flexed thigh.

Testing Clinically, it is not possible to test piriformis alone; however, for suspected injury to piriformis the best provocative test is to ask the seated subject to abduct the thighs. Buttock pain suggests piriformis injury.

## Obturator internus

Attachments Obturator internus (see Figs 80.24B, 80.27) is situated partly within the true pelvis and partly posterior to the hip joint. It arises from the internal surface of the anterolateral wall of the lesser pelvic cavity. Its attachments, which almost surround the obturator foramen, are to the inferior ramus of the pubis, the ischial ramus, and the pelvic surface of the hip bone below and behind the pelvic brim, to the upper part of the greater sciatic foramen above and behind, to the obturator foramen below and in front. It also arises from the medial part of the pelvic surface of the obturator membrane, from the tendinous arch that completes the obturator canal, and, to a small extent, from the obturator fascia that covers the muscle. The fibres converge towards the lesser sciatic foramen and end in four or five tendinous bands on the deep surface of the muscle. These bands make a lateral right-angled turn around the grooved surface of the ischium between its spine and tuberosity. The grooved surface is covered with a smooth layer of hyaline cartilage and is separated from the tendon by a bursa; ridges on the surface correspond to furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic
foramen and unite to form a single flattened tendon that passes horizontally across the capsule of the hip joint. The gemelli fuse with this tendon before it inserts on to an anterior impression on the medial surface of the greater trochanter anterosuperior to the trochanteric fossa. A long, narrow bursa is usually interposed between the tendon and the capsule of the hip joint, and occasionally communicates with the bursa between the tendon and the ischium.

Relations Within the pelvis, the anterolateral surface of the muscle is in contact with the obturator membrane and inner surface of the lateral wall of the pelvis. Its posteromedial surface is related to the obturator fascia, the origin of levator ani, and the sheath that surrounds the internal pudendal vessels and pudendal nerve, and forms the lateral wall of the ischio-anal fossa. Outside the pelvis, the muscle is covered by gluteus maximus, is crossed posteriorly by the sciatic nerve and passes behind the hip joint. As the tendon of obturator internus emerges from the lesser sciatic foramen, it is overlapped both above and below by the two gemelli, which form a muscular canal for it. Near its termination, the gemelli pass anterior to the tendon and form a groove in which it lies.

Vascular supply The main arterial supply of the extrapelvic part of obturator internus is from the gemellar branches of the internal pudendal artery. Intrapelvic and extrapelvic parts are supplied by the branches of the obturator artery.

Innervation Obturator internus is innervated by the nerve to obturator internus, L5 and S1.

## Actions See below actions of obturator externus.

## Obturator externus

Attachments Obturator externus (Figs 80.26-80.29; see Fig. 80.16) is a flat, triangular muscle covering the external surface of the anterior pelvic wall. It arises from the anteromedial two-thirds of the external surface of the obturator membrane, and from the adjacent bone of the pubic and ischial rami, extending for a short distance on to their pelvic surfaces between the margin of the obturator foramen and the obturator membrane. The whole muscle, and the tendon into which its fibres converge, spiral backwards, laterally and upwards, and thus cross the inferior aspect and then the back of the neck of the femur and lower part of the capsule of the hip joint to end in the trochanteric fossa of the femur.

Fig. 80.26 Obturator externus, anterior aspect. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

Relations A bursa, which communicates with the hip joint, may be interposed between the tendon and the hip joint capsule and femoral neck. The obturator vessels lie between the muscle and the obturator membrane. The anterior branch of the obturator nerve reaches the thigh by passing in front of the muscle, and the posterior branch by piercing it.

Vascular supply Obturator externus receives a variable pattern of supply from the obturator and medial circumflex femoral arteries.

Innervation Obturator externus is innervated by the posterior branch of the obturator nerve, L3 and 4.

Actions It has been suggested that the short muscles around the hip joint (pectineus, piriformis, obturator externus and internus, the gemelli and quadratus femoris) are more important as postural muscles than as prime movers, acting as adjustable ligaments to maintain the stability and integrity of the hip. However, these muscles are largely inaccessible to direct observation, and, because of the hazards presented by their close relationship to important neurovascular structures, there is a lack of electromyographic data in humans. In both bipedal walking and vertical climbing, obturator externus is recruited during the early part of the swing phase; in climbing it effects lateral rotation of the thigh, and in walking it probably counteracts the tendency to medial rotation produced by the anterior adductor muscles at this stage of the cycle. Obturator internus differs from obturator externus in its pattern of use but its role in bipedal walking remains unclear. Its attachments suggest

Fig. 80.27 The posterior thigh and gluteal muscles with gluteus maximus and medius partially removed. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
that it, like the gemelli, is a lateral rotator of the extended thigh and an abductor of the flexed thigh. These actions may be used to antagonize unwanted components of movement produced by the primary locomotor muscles.

Testing The short rotators cannot be tested individually, but lateral rotation of the extended hip and abduction of the flexed hip against resistance tests them as a group.

## Gemellus inferior and gemellus superior

Attachments Gemellus inferior arises from the upper part of the lateral surface of the ischial tuberosity, immediately below the groove for the tendon of obturator internus (Fig. 80.27). It blends with the lower border of this tendon, and inserts with it into the medial surface of the greater trochanter.

Gemellus superior, the smaller of the two gemelli, arises from the dorsal surface of the ischial spine, blends with the upper border of the tendon of obturator internus, and inserts with it into the medial surface of the greater trochanter. It is sometimes absent.

The two gemelli can be regarded as accessory to obturator internus (see Fig. 80.24B).

Relations The relations of the gemelli are as described for the extrapelvic part of obturator internus.

Vascular supply Gemellus superior is supplied by the internal pudendal artery and its gemellar branches; by the inferior gluteal artery; and sometimes also by the superior gluteal artery. Gemellus inferior is supplied mainly by the medial circumflex femoral artery.

Innervation Gemellus superior is innervated by the nerve to obturator internus, L5, S1 and S2. Gemellus inferior is innervated by the nerve to quadratus femoris, L4, L5 and S1.

Actions The gemelli rotate the extended thigh laterally and abduct the flexed thigh.

Testing See testing of obturator externus above.

## Quadratus femoris

Attachments Quadratus femoris (see Fig. 80.24B) is a flat, quadrilateral muscle lying between gemellus inferior and the upper margin of adductor magnus, from which it is separated by the transverse branch of the medial circumflex femoral artery. It arises from the upper part of the external aspect of the ischial tuberosity and inserts on to a small tubercle a little above the middle of the trochanteric crest of the femur and into the bone for a short distance below. It may be absent.

Relations The muscle passes behind the hip joint and the neck of the femur, separated from them by the tendon of obturator externus and the ascending branch of the medial circumflex femoral artery (which may cause troublesome bleeding if injured during the posterior approach to the hip). The sciatic nerve crosses the muscle posteriorly. A bursa is often present between the muscle and the lesser trochanter.

Vascular supply Branches pass to the superficial surface of the muscle from the inferior gluteal artery and from the medial circumflex femoral artery, which also supplies the deep surface.

Innervation Quadratus femoris is innervated by the nerve to quadratus femoris, L5 and S1.

Actions Quadratus femoris produces lateral rotation of the thigh.
Testing See testing of obturator externus.

## MUSCLES OF THE THIGH

The presence and position of the femoral neck cause the femoral shaft to lie obliquely; consequently, the anterior (extensor) muscle group, quadriceps femoris, runs obliquely distally and medially and so applies a pull to the patella that is both laterally and proximally directed. The adductor muscles occupy the region between quadriceps femoris and the medial margin of the thigh. They are attached distally to the posterior surface of the femur and lie more posteriorly than quadriceps femoris. The posterior muscle group, the hamstrings, lie behind the adductors. The attachments of these muscles determine the nature and direction of displacement of femoral shaft fractures.

## Anterior compartment

The muscles of the anterior compartment (see Figs 80.2, 80.22) include sartorius and rectus femoris, which can act at both the hip and knee joints, and vasti medialis, lateralis and intermedius, which act only at the knee. Articularis genus completes the group: it retracts the synovial capsule of the knee joint. Rectus femoris and the vasti extend the knee joint through a common tendon and hence are collectively termed quadriceps femoris. Adductor longus and pectineus are sometimes considered to be part of both the anterior and the adductor compartments.

## Sartorius

Attachments Sartorius is a narrow strap muscle and is the longest muscle in the body (see Fig. 80.31). It arises by tendinous fibres from the anterior superior iliac spine and the upper half of the notch below it. It crosses the thigh obliquely over to the medial side and then descends more vertically to the medial side of the knee. The muscle fibres terminate at this point and a thin, flattened tendon curves obliquely forwards and expands into a broad aponeurosis. The aponeurosis is attached to the proximal part of the medial surface of the tibia in front of gracilis and semitendinosus, together forming the so-called pes anserinus (Fig. 80.28). A slip from its upper margin blends with the capsule of the knee joint, and another from its lower margin merges with the superficial layer of the deep fascia on the medial side of the leg. This sheet of tissue passes inferiorly to lie superficial to and over the distal insertions of gracilis and semitendinosus. It has to be split by sharp dissection to reveal these two tendons if they need to be harvested, e.g. in cruciate ligament surgery.

In some cases, sartorius is absent, while in others, the muscle may possess an extra head; when the latter occurs, the extra head is attached to the pectineal line or to the femoral sheath. Variations in the distal attachment of sartorius, in the vicinity of the knee, have been described.

Relations The relations of sartorius are described in the femoral triangle (see below).

Vascular supply The main arterial supply to sartorius is derived from multiple branches of the femoral system and enters the medial half of the muscle from its deep surface. Vessels supplying the proximal third of sartorius may arise from the femoral artery, the profunda femoris artery, the 'artery of the quadriceps' or the lateral circumflex femoral artery. There may be an additional proximal supply from the superficial circumflex iliac artery. Those vessels supplying the middle third of the

Fig. 80.28 The distal attachment of muscles of the thigh, medial aspect.
muscle arise from the femoral artery. The distal vessels arise from the femoral artery within the adductor canal and from the descending genicular artery.

## Innervation Sartorius is innervated by the femoral nerve, L2 and 3.

Actions Sartorius assists in flexing the leg, and the thigh on the pelvis, particularly when these two movements are combined. It also helps to abduct the thigh and to rotate it laterally. Together with inversion of the foot, these movements bring the sole of the foot into direct view. The fact that sartorius represents only $1 \%$ of the physiological crosssectional area of all muscles that cross the hip or knee joint would appear to suggest that its role in walking is a minor one. In a subject ascending steps, electromyographic activity of sartorius increases during lateral rotation of the thigh at the end of the swing phase immediately preceding heel strike, which presumably decelerates the limb. Sartorius may therefore have a significant involvement in climbing.

Testing When it contracts against gravity, as it usually does, sartorius can be both seen and felt in the living subject.

## Femoral triangle

The femoral triangle is a depressed, intermuscular space in the anteromedial aspect of the proximal thigh, lying immediately distal to the inguinal ligament. The latter constitutes the base of the femoral triangle's inverted triangular outline. Its lateral boundary is the medial margin of sartorius. Its medial boundary is the medial margin of adductor longus. Its distal extremity, the apex, is where sartorius overlaps adductor longus (see Fig. 80.31). Its floor is provided laterally by iliacus and psoas major, and medially by pectineus and adductor longus. Its roof is the overlying fascia lata. The femoral vessels, passing from midbase to apex, are in the deepest part of the triangle. Lying lateral to the artery and outside the femoral sheath is the femoral nerve, which, on entering the femoral triangle divides into multiple branches. The triangle also contains fat and lymph nodes.

## Quadriceps femoris

Quadriceps femoris (see Figs 80.2, 80.22, 80.31), the great extensor muscle of the leg, covers almost all of the front and sides of the femur. It can be divided into four parts, each named individually. One, rectus femoris, arises from the ilium and travels straight down the middle of the thigh, its shape and path determining its name. The other three arise from the shaft of the femur and surround it (apart from the linea aspera) from the trochanters to the condyles: vastus lateralis is lateral to the femur, vastus medialis is medial to it, and vastus intermedius lies anterior to the femur. Rectus femoris crosses both hip and knee joints, while the three vasti only cross the knee joint.

The tendons of the four components of quadriceps femoris unite in the lower part of the thigh to form a single strong tendon attached to the base of the patella, and some fibres continue over it to blend with the patellar ligament. The patella is a sesamoid bone in the quadriceps femoris tendon, and the patellar ligament, which extends from the patellar apex to the tibial tuberosity, is the continuation of the main tendon. The medial and lateral patellar retinacula are expansions from its borders. The suprapatellar bursa (a synovial extension of the knee joint) lies between the femur and the suprapatellar part of the quadriceps femoris tendon. The deep infrapatellar bursa lies between the patellar ligament and the proximal end of the tibia.

The arterial supply to the quadriceps femoris has been traditionally ascribed to a single branch of either the profunda femoris artery or the lateral circumflex femoral artery, the 'artery of the quadriceps'. This vessel, which may be large, occasionally arises directly from the femoral artery. However, according to Taylor and Razaboni (1994), this artery does not supply all four components of quadriceps femoris; vastus medialis is supplied directly from the femoral artery. The supply of the individual muscle components is described below; their sheaths may have an additional and variable supply.

Quadriceps femoris as a group shows little anatomical variation.

## Rectus femoris

Attachments Rectus femoris is fusiform. Its superficial fibres are bipennate, the deep fibres parallel. It has a double origin on the ilium: a straight tendon arises from the anterior inferior iliac spine, and a thinner, flatter reflected tendon from a groove above the acetabulum and from the fibrous capsule of the hip joint. The two unite at an acute angle and spread into an aponeurosis that is prolonged downwards on the anterior surface of the muscle; the muscular fibres arise from this aponeurosis. The fibres end in a broad, thick aponeurosis that forms over the lower two-thirds of its posterior surface and gradually narrows
into the thick, flat tendon by which it is attached to the base of the patella. This constitutes the superficial central part of the quadriceps femoris tendon. A third head of rectus femoris may exist; it attaches deeply to the iliofemoral ligament and superficially to the tendon of gluteus minimus as it attaches on to the femur (Tubbs et al 2006). Rectus femoris may also arise from the anterior superior iliac spine, and its reflected head may be absent.

Relations Proximally, the muscle is covered by tensor fasciae latae, iliacus and sartorius. The reflected head lies beneath gluteus minimus. The capsule of the hip joint, vastus intermedius, the anterior borders of vasti lateralis and medius, the lateral circumflex femoral artery and some branches of the femoral nerve all lie deep to rectus femoris.

Vascular supply There are two main vascular pedicles: a superior and an inferior. The superior enters rectus femoris at the junction of its upper and middle thirds, and arises from the 'artery of the quadriceps'. The inferior and larger branch arises from the 'artery of the quadriceps' at about mid-thigh level and enters the muscle a few centimetres more distally. There are additional contributions from the lateral circumflex femoral artery and, less often, from the superficial circumflex iliac artery.

## Vastus medialis and vastus medialis obliquus

Attachments Vastus medialis arises from the lower part of the intertrochanteric line, spiral line, medial lip of the linea aspera, proximal part of the medial supracondylar line, the tendons of adductor longus and magnus, and the medial intermuscular septum. Its fibres pass downwards and forwards at an average angle of $15^{\circ}$ to the long axis of the femur, most of them into an aponeurosis on the deep surface of the muscle that is attached to the medial border of the patella and to the quadriceps femoris tendon. An expansion from this aponeurosis reinforces the capsule of the knee joint and is attached below to the medial condyle of the tibia.

The lowest fibres are nearly horizontal and form a bulge in the living subject, medial to the upper half of the patella. Some authors distinguish this part of the muscle as the vastus medialis obliquus, with fibres that originate largely from the tendon of adductor magnus and insert into the medial border of the patella. It plays an important role in the function of patellofemoral joint.

Relations Vastus medialis is partly covered by rectus femoris and sartorius. In the central part of the thigh it forms the lateral wall of the adductor (Hunter's) canal.

Vascular supply Vastus medialis is supplied by three branches of the femoral artery. The superior and middle branches arise, sometimes from a common trunk, proximal to the adductor canal, while the inferior arises within the canal. There may also be minor branches from the profunda femoris artery and descending genicular arteries.

## Vastus lateralis

Attachments Vastus lateralis is the largest component of quadriceps femoris. It arises by a broad aponeurosis from the upper part of the intertrochanteric line, the anterior and inferior borders of the greater trochanter, the lateral lip of the gluteal tuberosity, and the proximal half of the lateral lip of the linea aspera. This aponeurosis covers the proximal three-quarters of the muscle; many additional fibres arise from its deep surface. A few fibres also arise from the tendon of gluteus maximus and the lateral intermuscular septum between vastus lateralis and the short head of biceps femoris. The muscular mass thus formed is attached to a strong aponeurosis on the deep surface of the lower part of the muscle. This narrows to a flat tendon, which is attached to the base and lateral border of the patella and blends into the compound quadriceps femoris tendon. It contributes an expansion to the capsule of the knee joint that descends to the lateral condyle of the tibia and blends with the iliotibial tract.

Relations Vastus lateralis is covered laterally by the fascia lata and the aponeurotic insertions of tensor fasciae latae and gluteus maximus. It is separated from vastus intermedius by branches of the femoral nerve and the lateral circumflex femoral artery. Posteriorly, it is separated from biceps femoris by the lateral intermuscular septum.

Vascular supply There are three main arteries of supply: the superior medial artery arises directly from the lateral circumflex femoral artery; the inferior medial (the largest of the three) from the 'artery of the quadriceps'; and the lateral from the first perforating branch given off from the profunda femoris artery.

## Vastus intermedius

Attachments Vastus intermedius arises from the anterior and lateral surfaces of the upper two-thirds of the femoral shaft, and from the lower part of the lateral intermuscular septum. Its fibres end on the anterior surface of the muscle in an aponeurosis that forms the deep part of the quadriceps femoris tendon and is attached to the lateral border of the patella and the lateral condyle of the tibia.

Vastus intermedius appears to be inseparable from vastus medialis. However, when rectus femoris is reflected, a narrow cleft can be seen extending upwards from the medial border of the patella between the two muscles, sometimes as far as the lower part of the intertrochanteric line; proximal to this, the two muscles are frequently fused.

Relations Vastus intermedius is almost completely covered by the other components of quadriceps femoris, except laterally, where a small part becomes superficial behind vastus lateralis.

Vascular supply Vastus intermedius receives a lateral artery of supply, which arises from the 'artery of the quadriceps', and a medial artery that arises directly from the profunda femoris artery. Arteries to the other components of quadriceps femoris may also contribute. There is an anastomotic network deep to the muscle that supplies the suprapatellar bursa and articularis genus, and may form a collateral pathway when the femoral artery is blocked.

## Articularis genus

Articularis genus is a small muscle, usually distinct from vastus intermedius but occasionally blending with it. It consists of several muscular bundles that arise from the anterior surface of the lower part of the femoral shaft and are attached to a proximal reflection of the synovial membrane of the knee joint. It is visible during knee arthroscopy when viewed looking superiorly from within the suprapatellar bursa (see
Commentary 9.3).

## Innervation of quadriceps femoris

Quadriceps femoris and articularis genus are supplied by the femoral nerve, L2, 3 and 4.

## Actions of quadriceps femoris

Quadriceps femoris extends the knee. Rectus femoris helps to flex the thigh on the pelvis; if the thigh is fixed, it helps to flex the pelvis on the thigh. Rectus femoris can flex the hip and extend the knee simultaneously. Electromyographic studies indicate that the three vasti are not equally active in different phases of extension or rotation. There is little or no activity in quadriceps femoris during standing. Rectus femoris pulls the patella along the line of the mechanical axis of the lower limb (i.e. the line connecting the centres of the hip, knee and ankle) because its attachment is anterior to the hip joint. The remaining muscles in the group are attached to the shaft of the femur and their pull is lateral as well as proximal. An extremely important dynamic function of vastus medialis obliquus is to counter this lateral vector on the patella during knee motion. Other static factors that help are the depth of the femoral patellar surface, the buttressing effect of the lateral femoral condyle in the groove, and the restraining action of the medial patellofemoral ligament. Inadequacy of vastus medialis obliquus is a factor in producing patellar instability and pain. Strengthening of this muscle to improve patellar 'tracking' on the femur is an important part of physiotherapy regimens for patellofemoral problems.

Articularis genus retracts the synovial suprapatellar bursa proximally during extension of the leg, presumably to prevent interposition of redundant synovial folds between patella and femur.

Testing The quadriceps femoris is tested by extending the knee against resistance, in the supine position with the hip flexed.

## Adductor compartment

The muscles of the adductor compartment - gracilis, pectineus, adductor longus, adductor brevis, and adductor magnus (Fig. 80.29) - have evolved, as their nerve supply suggests, from both flexor and extensor columns. All five muscles cross the hip joint but only gracilis reaches beyond the knee. They are known collectively as the adductors of the thigh, although their actions are more complex than this, e.g. acting from below they have important roles in balancing the trunk on the lower limb during walking.

Their blood supply is derived from the profunda femoris artery, medial circumflex femoral, femoral and obturator arteries. The profunda femoris artery (or sometimes the first perforator) supplies a large branch, the 'artery of the adductor muscles'.

Fig. 80.29 The adductor muscles of the thigh, anterior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

## Gracilis

Attachments Gracilis (see Figs 80.2, 80.29) is the most superficial of the adductor group. It is thin and flat, broad above, and narrow and tapering below. It arises by a thin aponeurosis from the medial margins of the lower half of the body of the pubis, the whole of the inferior pubic ramus, and the adjoining part of the ischial ramus. The fibres descend vertically into a rounded tendon, often harvested as a knee ligament graft, which passes across the medial condyle of the femur posterior to the tendon of sartorius. It then curves around the medial condyle of the tibia, where it fans out and is attached to the upper part of the medial surface of the tibia, just below the condyle, forming part of the pes anserinus (see Fig. 80.28). A few fibres from the lower part of the tendon continue into the deep fascia of the lower leg. Often there is a slip that blends with the tendon of the medial head of gastrocnemius. Unless divided, this can lead to problems during surgical harvesting of the gracilis tendon.

Relations The muscle is covered medially by the fascia lata throughout most of its length. Deep to gracilis lie adductor brevis and adductor magnus. The tibial attachment is immediately proximal to that of semitendinosus, and the tendon of sartorius, with which it is partly blended, overlaps its upper edge. It is separated from the tibial collateral ligament of the knee joint by the anserine bursa.

Vascular supply The arterial supply to gracilis enters via its lateral surface. The main pedicle arises from the 'artery to the adductors', a branch of the profunda femoris artery, and enters at the junction of the upper and middle thirds of the muscle. The gracilis musculocutaneous flap is based on this pedicle. A less important artery enters the distal third of the muscle from the femoral artery. There is a minor proximal supply from the medial circumflex femoral artery.

Innervation Gracilis is innervated by the obturator nerve, L2 and 3.
Actions Gracilis flexes the leg and rotates it medially. It may also act as an adductor of the thigh. When the foot is fixed, gracilis rotates the femur and pelvis laterally on the tibia, and helps balance the trunk during walking.

Testing While palpating over the tendon posteromedially at the flexed knee, the knee is actively further flexed and the leg actively rotated medially. Gracilis can also be tested with the other adductors of the hip.

## Adductor longus

Attachments Adductor longus (see Figs 80.2, 80.22), the most anterior of the three adductors, is a large, fan-shaped muscle that lies in the same plane as pectineus. It arises by a narrow tendon with a flattened (sometimes C-shaped) cross-section, which is attached to the front of the pubis in the angle between the crest and the symphysis. It expands into a broad fleshy belly that descends posterolaterally and inserts by an aponeurosis into the linea aspera in the middle third of the femur, between vastus medialis and adductors magnus and brevis, usually blending with all of them. Its proximal attachment is vulnerable to overload from sporting activity: this is one cause of sport-related groin pain.

Adductor longus is occasionally double.
Relations Anterior to adductor longus are the spermatic cord, fascia lata (which separates it from the long saphenous vein) and, near its attachment, the femoral artery and vein and sartorius. Posterior to it are adductor brevis and adductor magnus, the anterior branch of the obturator nerve and, near its attachment, the deep artery and vein of the thigh. Lateral and medial to adductor longus are, respectively, pectineus and gracilis.

Vascular supply The main supply to adductor longus is to the central part of the muscle from the 'artery to the adductors', a branch of the profunda femoris artery. There is an additional proximal supply from the medial circumflex femoral artery, and a more distal supply from the femoral artery and sometimes the descending genicular artery.

Innervation Adductor longus is innervated by the anterior division of the obturator nerve, L2, 3 and 4.

Actions The actions of the named adductors as a group are discussed below, after each muscle has been described.

Testing The adductors are tested as a group by adduction of the thigh against resistance, in the supine position and with the knee extended.

## Adductor brevis

Attachments Adductor brevis (see Fig. 80.2A; Fig. 80.25B) lies posterior to pectineus and adductor longus. It arises by a narrow attachment from the external aspect of the body and inferior ramus of the pubis, between gracilis and obturator externus. Like adductor longus, it is somewhat triangular, and expands as it descends posterolaterally to insert via an aponeurosis into the femur, along a line from the lesser trochanter to the linea aspera, and on the upper part of the linea immediately behind pectineus and the upper part of adductor longus.

Adductor brevis often has two or three separate parts, or may be integrated into adductor magnus.

Relations Anteriorly lie pectineus, adductor longus, the profunda femoris artery and the anterior branch of the obturator nerve; posteriorly are adductor magnus and the posterior branch of the obturator nerve. The upper border of adductor brevis is related to the medial circumflex femoral artery, obturator externus, and the conjoined tendon of psoas major and iliacus. Its lower border is related to gracilis and adductor magnus. The second perforating artery, or first and second perforating arteries, pierces it near its femoral attachment.

Vascular supply The vascular supply to adductor brevis is variable. Usually the main supply is directly from the profunda femoris artery distally and from the 'artery to the adductors' more proximally. There is an additional proximal supply from the medial circumflex femoral artery. The deep surface receives branches from the obturator artery.

Innervation Adductor brevis is innervated by the obturator nerve, L2 and 3 .

Actions The actions of the named adductors as a group are discussed below, after each muscle has been described.

Testing Adductor brevis is tested in the same way as adductor longus.

## Adductor magnus

Attachments Adductor magnus (see Figs 80.2, 80.25A, 80.29, 80.30), a massive triangular muscle, arises from a small part of the inferior ramus of the pubis, from the conjoined ischial ramus, and from the inferolateral aspect of the ischial tuberosity. The short, horizontal fibres from the pubic ramus are inserted into the medial margin of the gluteal tuberosity of the femur, medial to gluteus maximus; this part of the muscle, in a plane anterior to the rest, is sometimes called adductor minimus. The fibres from the ischial ramus fan out downwards and laterally, to insert via a broad aponeurosis into the linea aspera and the proximal part of the medial supracondylar line. The medial part of the muscle, composed mainly of fibres from the ischial tuberosity, is a thick mass that descends almost vertically, and ends in the lower third of the thigh in a rounded tendon, which can be palpated proximal to its attachment to the adductor tubercle on the medial condyle of the femur. The tendon is connected by a fibrous expansion to the medial supracondylar line.

The long, linear attachment of the muscle is interrupted by a series of osseo-aponeurotic openings, bridged by tendinous arches attached to the bone. The upper four are small and transmit the perforating branches and the termination of the profunda femoris artery. The lowest is large and allows the femoral vessels to cross to the popliteal fossa.

The vertical, ischiocondylar part of the muscle varies in its degree of separation from the rest. The upper border of adductor magnus may fuse with quadratus femoris.

Relations Anteriorly lie pectineus, adductor brevis and adductor longus, the femoral and deep femoral vessels, and the posterior branch of the obturator nerve. A bursa separates the proximal part of the muscle from the lesser trochanter of the femur. Posteriorly are the sciatic nerve, gluteus maximus, biceps femoris, semitendinosus and semimembranosus. The superior border is parallel with quadratus femoris, and the transverse branch of the medial circumflex femoral artery passes between the muscles. The medial border is related to gracilis, sartorius and the fascia lata.

Vascular supply As expected from its position, adductor magnus is supplied from both its anterior and its posterior aspects. The contribution from the anterior compartment is the more important. The profunda femoris artery, obturator artery and femoral artery all contribute; the main supply comes directly from the distal part of the profunda femoris artery. Distally, there may be contributions from the femoral and descending genicular arteries. Posteriorly, there are branches from the medial circumflex femoral, the first and second perforating and the popliteal vessels.

Innervation Adductor magnus is composite and is doubly innervated by the obturator nerve and by the tibial division of the sciatic nerve (L2, 3 and 4), which supplies the ischiocondylar part. Both nerves are derived from anterior divisions in the lumbosacral plexus, indicating a primitive flexor origin for both parts of the muscle.

## Actions of the adductors

Extensive or forcible adduction of the femur is not often required. Although the adductors can act in this way, they more commonly act as synergists in the complex patterns of gait activity, and to some degree as controllers of posture. They are active during flexion and extension of the knee. Adductors magnus and longus are probably medial rotators of the thigh. The adductors are inactive during adduction of the abducted thigh in the erect posture (when gravity assists), but active in other postures, such as the supine position, or during adduction of the flexed thigh when standing. They are also active during flexion (longus) and extension (magnus) of the thigh at the hip joint. In symmetrical easy standing their activity is minimal.

Testing of the adductors The adductors are usually tested as a group by adduction of the thigh against resistance, in the supine position with the knee extended. The tendon of adductor magnus can be felt just proximal to the adductor tubercle on the medial condyle of the femur. Clinical testing of the other actions mentioned above is not feasible for the individual muscles.

Fig. 80.30 The posterior thigh and gluteal regions with associated neurovascular structures. (With permission from Netter, FH, Atlas of Human Anatomy, 5th ed, Elsevier, Saunders. Copyright 2011.)

Relations Pectineus is related anteriorly to the deep lamina of the fascia lata, which separates it from the femoral vessels and long saphenous vein; posteriorly, to the capsule of the hip joint, adductor brevis, obturator externus and the anterior branch of the obturator nerve;

## Pectineus

Attachments Pectineus (see Fig. 80.22) is a flat, quadrangular muscle in the femoral triangle. It may also be considered as part of the anterior compartment of the thigh. It arises from the pecten pubis, from the bone anterior to it between the iliopubic ramus and the pubic tubercle, and from the fascia on its own anterior surface. The fibres descend, initially posteromedially and then posterolaterally, to be attached along a line from the lesser trochanter to the linea aspera. Proximally, it may be partially or wholly attached to the capsule of the hip joint.
laterally, to psoas major and the medial circumflex femoral vessels; and medially, to the lateral margin of adductor longus.

Vascular supply The main arterial supply to pectineus is derived from the medial circumflex femoral artery, which enters the superficial surface of the muscle. There may be a branch from the femoral artery more proximally, and a deep supply from the obturator artery.

Innervation Pectineus is innervated by the femoral nerve, L2 and 3, and the accessory obturator nerve, L3 (when present). Occasionally, it receives a branch from the obturator nerve. The muscle may be incompletely divided into dorsal and ventral layers, which are supplied by the obturator and femoral (or rarely, accessory obturator) nerves, respectively.

Actions Pectineus adducts the thigh and flexes it on the pelvis. -

Testing The action of pectineus cannot be tested clinically in isolation.

## Adductor canal

The adductor canal (Hunter's canal; subsartorial canal) is a troughshaped intermuscular tunnel occupying the distal two-thirds of the medial aspect of the thigh (see Fig. 80.2B). It starts at the apex of the femoral triangle and extends distally as far as the distal attachment of the tendon of adductor magnus. It is triangular in section and is bounded anterolaterally by vastus medialis; posteromedially by adductor longus; and distal to adductor longus, by adductor magnus. Its anteromedial boundary (often referred to as the roof) is a strong and dense fascia that extends from the medial surface of vastus medialis to the medial edge of the adductors longus and magnus, overlapping in its stride the femoral vessels in the adductor canal. This fascia, on account of being overlain by sartorius, is termed the subsartorial fascia.

The adductor canal contains the femoral artery and vein, the descending genicular and muscular branches of the femoral artery and their corresponding venous tributaries, the saphenous nerve, and the nerve to vastus medialis (until it enters its muscle). The femoral vessels pass from the adductor canal into the popliteal fossa via the adductor hiatus, an opening in the tendon of adductor magnus adjacent to the femoral shaft, two-thirds of the way down the adductor canal.

## Posterior compartment

The posterior thigh muscles, biceps femoris, semitendinosus and semimembranosus, are colloquially termed the 'hamstrings'. They cross both hip and knee joints, and integrate extension at the hip with flexion at the knee. As the muscles span the back of the knee, they form the proximal lateral and medial margins of the popliteal fossa. The actions of these muscles and their clinical anatomy will be considered as a group after they have been described individually.

The muscles of the posterior compartment (see Figs 80.2, 80.25A, 80.27) receive their blood supply from the perforating branches of the profunda femoris artery, most importantly through the first perforator given off from this artery. This vessel has important anastomoses with the inferior gluteal artery (on or within semitendinosus) and with the medial circumflex femoral artery, while the third perforator anastomoses with the superior medial genicular artery within the short head of biceps femoris. This anastomotic chain forms an important collateral arterial pathway when the femoral artery is blocked

## Semitendinosus

Attachments Semitendinosus (see Figs 80.2B, 80.30), notable for the length of its tendon, lies posteromedial in the thigh. It arises from an inferomedial impression on the upper area of the ischial tuberosity (see Fig. 80.5), by a tendon it shares with the long head of biceps femoris, and from an aponeurosis connecting the adjacent surfaces of the two muscles for 7.5 cm from their common origin. The belly is fusiform and ends a little below mid-thigh in a long, rounded tendon that runs on the posterior surface of semimembranosus. The tendon curves around the medial condyle of the tibia, passes over the tibial collateral ligament (from which it is separated by the anserine bursa), and inserts into the upper part of the medial surface of the tibia behind the attachment of sartorius and distal to that of gracilis (see Fig. 80.28). At its termination, it is united with the tendon of gracilis and gives off a prolongation to the deep fascia of the leg and to the medial head of gastrocnemius. A tendinous intersection is usually present near the midpoint of the muscle, which may also receive a muscular slip from the long head of biceps femoris. These connections with the medial head of gastrocnemius and biceps femoris can cause difficulty when harvesting the tendon surgically for a graft.

Relations Semitendinosus lies on semimembranosus throughout its length. The relations of the distal part of the muscle are described above and with the pes anserinus.

Vascular supply The two main arteries of supply to semitendinosus are superior and inferior. The superior is derived from either the medial circumflex femoral artery or the first perforating artery. The inferior and larger branch arises from the first perforator distal to the origin of the superior branch. An accessory supply at the ischial attachment is derived from the inferior gluteal artery, and at the tibial attachment from the inferior medial genicular artery.

Innervation Semitendinosus is innervated by the sciatic nerve, L5, S1 and 2, through its tibial division (see Fig. 80.30).

## Semimembranosus

Attachments Semimembranosus (see Figs 80.2, 80.30), so named because of the flattened form of its upper attachment, is posteromedial in the thigh. It arises by a long, flat tendon from a superolateral impression on the ischial tuberosity (see Fig. 80.5). Inferomedially, the tendinous fibres intermingle to some extent with those of biceps femoris and semitendinosus. The tendon receives, from the ischial tuberosity and ramus, two fibrous expansions that flank adductor magnus. It then broadens and descends deep to semitendinosus and the long head of biceps femoris. Muscle fibres arise from the tendon at about mid-thigh and converge to a second aponeurosis on the posterior aspect of the lower part of the muscle, which tapers to the heavy, rounded tendon of the distal attachment. The tendon divides at the level of the knee into five components. The main one is attached to a tubercle (sometimes called the tuberculum tendinis) on the posterior aspect of the medial tibial condyle. The others are: a series of slips to the medial margin of the tibia, immediately behind the tibial collateral ligament; a thin fibrous expansion to the fascia over popliteus; a cord-like tendon to the inferior lip and adjacent part of the groove on the back of the medial tibial condyle, deep to the tibial collateral ligament; and a strong expansion that passes obliquely upwards to the femoral intercondylar line and lateral femoral condyle, and forms much of the oblique popliteal ligament of the knee joint.

Semimembranosus varies considerably in size and may be absent. It may be double, and arise mainly from the sacrotuberous ligament. Slips to the femur or to adductor magnus may occur.

Relations Semimembranosus overlaps the popliteal vessels and is itself partly overlapped by semitendinosus throughout its extent (see Fig. 80.2). Its deep surface lies on adductor magnus. The sciatic nerve lies laterally and surprisingly close to the surface. The distal end of the muscle partially overlies the medial head of gastrocnemius before passing anteromedially to it. An important bursa lies between the semimembranosus tendon and gastrocnemius, and often communicates with the knee joint and with a smaller bursa between the tendon and the posterior tibial margin.

Vascular supply Semimembranosus is supplied from the perforating arteries, usually from all, though predominantly from the first. Sometimes the predominant artery arises from the fourth perforator. A branch of the femoral or popliteal artery supplies the distal part of the muscle, and there may be a contribution from the inferior gluteal artery at the proximal attachment.

Innervation Semimembranosus is innervated by the sciatic nerve, L5, S1 and 2, through its tibial division.

## Biceps femoris

Attachments Biceps femoris (see Figs 80.2, 80.30) occupies a posterolateral position in the thigh. It has two proximal attachments. One, the long head, arises from an inferomedial impression on the upper area of the ischial tuberosity (see Fig. 80.5), via a tendon that it shares with semitendinosus, and from the lower part of the sacrotuberous ligament. The other, the short head, arises from the lateral lip of the linea aspera, between adductor magnus and vastus lateralis. This attachment extends proximally almost to gluteus maximus and distally along the lateral supracondylar line to within 5 cm of the lateral femoral condyle, and from the lateral intermuscular septum. The long head forms a fusiform belly that descends laterally across the sciatic nerve. The fibres end in an aponeurosis that covers the posterior surface of the muscle. This aponeurosis receives on its deep surface the fibres of the short head, and gradually narrows to a tendon (the lateral hamstring). The main part of the tendon splits round the fibular collateral ligament and is attached to the head of the fibula. The remainder splits into three laminae. The intermediate lamina fuses with the fibular collateral ligament, while the others pass superficial and deep to the ligament to attach to the lateral condyle of the tibia.

The short head may be absent. Additional slips may arise from the ischial tuberosity, linea aspera or medial supracondylar line.

Relations Proximally, biceps femoris is covered by gluteus maximus, but elsewhere it lies relatively superficially. Deep to it lie semimembranosus proximally, and the sciatic nerve, adductor magnus and the lateral head of gastrocnemius more distally. Semitendinosus and semimembranosus lie medially. A bursa may lie between the tendon and the fibular collateral ligament. The common fibular nerve descends along the medial border of the tendon of biceps femoris, separating it distally from the lateral head of gastrocnemius.

As a guide during surgery, it is safest to find a nerve proximally and dissect it free distally. The common fibular nerve is found emerging posterior to the biceps femoris tendon, which is a useful guide to locating the nerve and avoiding iatrogenic injury. The nerve is adherent to the tendon; if part of the fibular head or the attachment of the tendon of biceps femoris, usually with the insertion of the fibular collateral ligament, is avulsed, then the tendon will exert proximal traction on the nerve, which may contribute to common fibular nerve traction injury. When the lateral meniscus is sutured arthroscopically, care must be taken that all needle passages are anterior to biceps femoris. A proximal fibular fracture may result in the nerve being trapped in the fracture line.

Vascular supply The long head of biceps femoris is supplied by the first and second perforating arteries. There are accessory supplies at the ischial attachment from the inferior gluteal and medial circumflex femoral arteries, and in the distal quarter from the superior lateral genicular artery. The short head is supplied superiorly by the second or third perforating artery and inferiorly by the superior lateral genicular artery.

Innervation Biceps femoris is innervated by the sciatic nerve, L5, S1 and 2: the long head through the tibial division and the short head through the common fibular division, a distribution that reflects the composite derivation from flexor and extensor musculature.

## Actions of posterior thigh muscles

Acting from above, the posterior thigh muscles flex the knee. Acting from below, they extend the hip joint, pulling the trunk upright from a stooping posture against the influence of gravity, biceps femoris being the main agent. When the knee is semi-flexed, biceps femoris can act as a lateral rotator and semimembranosus and semitendinosus as medial rotators of the lower leg on the thigh at the knee. When the hip is extended, biceps femoris is a lateral rotator and semimembranosus and semitendinosus are medial rotators of the thigh. As is the case with quadriceps femoris, the adductors and gluteus maximus, the hamstrings are quiescent in easy symmetrical standing. However, any action that takes the centre of gravity in front of a transverse axis through the hip joints, e.g. forward reaching, forward sway at the ankle joints or forward bending at the hips, is immediately accompanied by strong contraction of the hamstrings. This is in marked contrast to gluteus maximus, which contracts only when there is a call for powerful extension at the hip joint.

When the knee is flexed against resistance, the tendon of biceps femoris can be felt lateral to the popliteal fossa. Medial to the fossa, the tendons of gracilis (which is the more medial) and semitendinosus stand out sharply. The semimembranosus tendon is just palpable in the interval between them (and also by deep pressure from a 'pincer' grip beyond their margins). There is some evidence that semimembranosus, semitendinosus and biceps femoris, although they cross both hip and knee joints, may produce movement at one of these joints without resisting antagonists at the other. Usually, however, each of these muscles contracts as a whole, and whether or not movement takes place at hip or knee is determined by other muscles that act as fixators of these joints.

Testing The posterior thigh muscles are tested clinically by active knee flexion against resistance in the supine or prone position. In the prone position, the individual hamstring tendons can be identified more easily.

When relaxed, these muscles show considerable variation in length; in some individuals, the muscles are so short as to impose a serious limitation on flexion of the trunk at the hip joints when the knees are kept extended. Movements such as stooping must then be accomplished by flexing the vertebral column or squatting. Perhaps the need for more stress on the lumbar spine accounts for the occurrence of hamstring tightness in adolescents who develop spondylolysis. These muscles are prone to tearing, which may be related to the relative complexity of muscles that cross two joints, or to the fact that they are subject to large forces including eccentric contractions.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## Iliac vessels and external iliac arteries and veins

The iliac vessels are described on page 1224, and the external iliac arteries and veins on pages 1227 and 1228, respectively.

## ARTERIES

## Gluteal vessels

The superior and inferior gluteal arteries (see Fig. 80.30) are described on pages 1226 and 1227, respectively.

## Arteria comitans nervi ischiadici (artery to sciatic nerve)

The arteria comitans nervi ischiadici is a direct or indirect branch of the internal iliac artery, and runs on the surface of, or within, the sciatic nerve. It represents the primitive axial artery of the lower limb. The artery is usually a very small vessel; occasionally, it persists as a large vessel, in which case the femoral artery is correspondingly reduced in size. The artery may participate in collateral circulatory pathways.

## Femoral artery

The femoral artery (see Figs 78.4, 80.2-80.3; Figs 80.31-80.32) is a continuation of the external iliac artery (Benninger 2014). It begins behind the inguinal ligament, midway between the anterior superior

Fig. 80.31 The left femoral triangle. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Fig. 80.32 The neurovascular structures of the anteromedial thigh. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
iliac spine and the pubic symphysis, descends along the anteromedial part of the thigh in the femoral triangle, enters and passes through the adductor (subsartorial) canal, and becomes the popliteal artery as it passes through an opening in adductor magnus near the junction of the middle and distal thirds of the thigh. Its first 3 or 4 cm are enclosed, with the femoral vein, in the femoral sheath. The femoral artery gives off several branches in the proximal thigh, including the superficial epigastric, superficial circumflex iliac, superficial external pudendal, deep external pudendal and the profunda femoris artery. It gives off the descending genicular artery within the adductor canal.

Rarely, the femoral artery divides, distal to the origin of the profunda femoris artery, into two trunks that reunite near the adductor opening. The inferior gluteal artery, accompanying the sciatic nerve to the popliteal fossa and representing a persistence of the original axial artery, may replace it. The external iliac artery is then small, ending as the deep artery of the thigh.

## Relations

Anterior to the artery in the femoral triangle are the skin, subcutaneous tissue, superficial inguinal lymph nodes, fascia lata, femoral sheath, superficial circumflex iliac vein (crossing in the subcutaneous tissue) and the femoral branch of the genitofemoral nerve (which is at first lateral and then anterior). Near the apex of the triangle, the medial femoral cutaneous nerve crosses in front of the artery from the lateral

Fig. 80.33 The neurovascular structures of the anterior thigh. This is a deeper dissection than is shown in Figure 80.32. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
to the medial side. Posteriorly, the posterior wall of the femoral sheath separates the artery from the tendons of psoas, pectineus and adductor longus. The artery is separated from the hip joint by the tendon of psoas major, from pectineus by the femoral vein and deep femoral vessels, and from adductor longus by the femoral vein. Proximally, the nerve to pectineus passes medially behind the artery. The femoral nerve lies lateral to the artery, outside the femoral sheath. The femoral vein is medial to the artery in the proximal part of the triangle and becomes posterior distally at the apex.

Within the adductor canal, the artery is covered by skin, subcutaneous tissue, deep fascia, sartorius and the fibrous roof (subsartorial fascia) of the canal. The saphenous nerve lies at first lateral, then anterior and finally medial to the artery. Adductor longus and adductor magnus are posterior, vastus medialis and its nerve are anterolateral, and the femoral vein is also posterior proximally but it becomes lateral distally (see Figs 80.31-80.32; Fig. 80.33).

Compression of the femoral artery is most effective just distal to the inguinal ligament, where it is superficial and separated from the bone (iliopubic ramus) only by the psoas tendon. For this reason, arterial injury proximal to the inguinal ligament, such as laceration by a knife, cannot be controlled simply by compression. Gaining proximal control of bleeding involves major exposure of the more proximal arteries as a life-saving manœuvre.

## Branches

The branches of the femoral artery include the superficial epigastric, superficial circumflex iliac, superficial external pudendal, deep external pudendal arteries, muscular branches, the profunda femoris artery and the descending genicular artery (see Fig. 78.4).

## Superficial epigastric artery

The superficial epigastric artery arises anteriorly from the femoral artery approximately 1 cm distal to the inguinal ligament, and traverses the cribriform fascia to ascend anterior to the ligament and run in the abdominal subcutaneous tissue almost to the umbilicus. It supplies the superficial inguinal lymph nodes, subcutaneous tissue and skin, and anastomoses with branches of the inferior epigastric artery and its contralateral fellow.

## Superficial circumflex iliac artery

The superficial circumflex iliac artery is the smallest superficial branch of the femoral artery and arises near or with the superficial epigastric artery. It usually emerges through the fascia lata, lateral to the saphenous opening, and turns laterally distal to the inguinal ligament towards the anterior superior iliac spine. It supplies the skin, subcutaneous tissue and superficial inguinal lymph nodes, anastomosing with the deep circumflex iliac, superior gluteal and lateral circumflex femoral arteries.

The superficial circumflex iliac artery is the basis for the important axial-pattern pedicled groin skin flap. Free flaps based on the vessel may also be raised.

## Superficial external pudendal artery

The superficial external pudendal artery arises medially from the femoral artery, close to the preceding branches. Emerging from the cribriform fascia, it passes medially, usually deep to the long saphenous vein, across the spermatic cord (or round ligament) to supply the lower abdominal, penile, scrotal or labial skin, and anastomoses with branches of the internal pudendal artery.

## Deep external pudendal artery

The deep external pudendal artery passes medially across pectineus and anterior or posterior to adductor longus, covered by fascia lata, which it pierces to supply the skin of the perineum and scrotum or labium majus. Its branches anastomose with the posterior scrotal or labial branches of the internal pudendal artery.

## Muscular branches

These branches supply sartorius, vastus medialis and the adductors.

## Profunda femoris artery (deep artery of the thigh)

The profunda femoris artery (see Figs $80.2 \mathrm{~B}, 80.25,80.32-80.33$ ) is a large branch that arises posterolaterally from the femoral artery about 3.5 cm distal to the inguinal ligament. At first lateral to the femoral artery, it spirals posterior to this and the femoral vein to reach the medial side of the femur. It passes between pectineus and adductor longus, then between the latter and adductor brevis, before it descends between adductor longus and adductor magnus. It pierces adductor magnus and anastomoses with the upper muscular branches of the popliteal artery. This terminal part is sometimes named the fourth perforating artery.

The profunda femoris artery is the main supply to the adductor, extensor and flexor muscles, and also anastomoses with the internal and external iliac arteries above and with the popliteal artery below. It is a major collateral artery of the lower limb in patients with femoropopliteal arterial occlusive disease (see Fig. 80.33) (Shakeri et al 2010).

The profunda femoris artery sometimes arises from the posterior aspect of the femoral artery, and more rarely from the medial aspect. If it arises posteriorly, it may cross anterior to the femoral vein and then pass backwards around its medial side.

## Relations

Posteriorly, in proximodistal order, lie iliacus, pectineus, adductor brevis and adductor magnus. Anteriorly, the femoral and deep femoral veins, and distally, adductor longus, separate the profunda femoris artery from the femoral artery. Laterally, vastus medialis separates the proximal part of the artery from the femur.

## Branches

The profunda femoris artery gives off the lateral and medial circumflex arteries in the proximal thigh, and perforating and muscular branches more distally.

Lateral circumflex femoral artery The lateral circumflex femoral artery (see Figs 80.32-80.33) is a laterally running branch given off near the root of the profunda femoris artery. It passes between the divisions of the femoral nerve, posterior to sartorius and rectus femoris, and divides into ascending, transverse and descending branches. The ascending branch ascends along the intertrochanteric line, under tensor fasciae latae, lateral to the hip joint. It anastomoses with the superior gluteal and deep circumflex iliac arteries, supplying the greater trochanter, and, with branches of the medial circumflex femoral, forms an anastomotic ring round the femoral neck, from which the femoral neck and head are supplied. The ascending branch forms the pedicle of the tensor fasciae latae musculocutaneous flap. The descending branch descends posterior to rectus femoris, along the anterior border of vastus lateralis, which it supplies; a long branch descends in vastus lateralis to the knee, anastomosing with the superior lateral genicular branch of the popliteal artery, accompanied by the nerve to vastus lateralis. The fasciocutaneous perforators that arise from the descending branch supply the anterolateral thigh fasciocutaneous flap. The transverse branch, the smallest, passes laterally anterior to vastus intermedius and pierces vastus lateralis to wind round the femur, just distal to the greater trochanter. It anastomoses with the medial circumflex, inferior gluteal and first perforating arteries, forming a cruciate anastomosis.

The lateral circumflex femoral artery may arise from the femoral artery or as a common trunk with the profunda femoris artery and the medial circumflex femoral artery. The ascending and descending branches may occasionally arise separately (Siddharth et al 1985).

Medial circumflex femoral artery The medial circumflex femoral artery (see Figs 80.32-80.33) usually originates from the posteromedial aspect of the profunda femoris artery, but sometimes originates from the femoral artery itself or as a common trunk with either the profunda femoris artery or the lateral circumflex femoral artery or both (Siddharth et al 1985). It supplies the adductor muscles and curves medially round the femur between pectineus and psoas major and then obturator externus and adductor brevis, finally appearing between quadratus femoris and the upper border of adductor magnus, dividing into transverse and ascending branches. The transverse branch takes part in the cruciate anastomosis. The ascending branch ascends on the tendon of obturator externus, anterior to quadratus femoris, to the trochanteric fossa, where it anastomoses with branches of the gluteal and lateral circumflex femoral arteries. An acetabular branch at the proximal edge of adductor brevis enters the hip joint under the transverse acetabular ligament with one from the obturator artery. It supplies the fat in the fossa and reaches the femoral head along its ligament. For details of the blood supply of the proximal end of the femur, consult Crock (1996).

Perforating arteries The perforating arteries (see Fig. 80.25) perforate the femoral attachment of adductor magnus to reach the flexor aspect of the thigh. There are three perforating branches, and the terminal part of the profunda femoris artery itself becomes the fourth perforator. They pass close to the linea aspera under small tendinous arches and give off muscular, cutaneous and anastomotic branches. Diminished, they pass deep to the short head of biceps femoris (the first usually through the attachment of gluteus maximus), traverse the lateral intermuscular septum and enter vastus lateralis. The first arises proximal, the second anterior, and the third distal to adductor brevis. The first perforating artery passes back between pectineus and adductor brevis (sometimes through the latter), pierces adductor magnus near the linea aspera to supply adductor brevis, adductor magnus, biceps femoris and gluteus maximus, and anastomoses with the inferior gluteal, medial and lateral circumflex femoral and second perforating arteries. The larger second perforating artery, often arising with the first, pierces the attachments of adductor brevis and magnus, divides into the ascending and descending branches supplying the posterior thigh muscles and anastomoses with the first and third perforating arteries. The femoral nutrient artery usually arises from it. When two nutrient arteries exist, they usually arise from the first and third perforators. The third perforating artery starts distal to adductor brevis, pierces the attachment of adductor magnus and divides into branches to the posterior thigh muscles. It anastomoses proximally with the perforating arteries, and distally with the end of the profunda femoris artery and muscular branches of the popliteal. The femoral nutrient artery may arise from it. Side branches of the diaphysial nutrient and other branches of the profunda femoris artery provide subsidiary cortical arteries.

The perforating arteries form a double chain of anastomoses, initially in the adductor muscles and subsequently near the linea aspera.

Muscular branches Numerous muscular branches arise from the profunda femoris artery. Some end in the adductors, and others pierce adductor magnus, supply the flexors and anastomose with the medial circumflex femoral artery and superior muscular branches of the popliteal artery. The profunda femoris artery is thus the main supply to the thigh muscles.

## Descending genicular artery

The descending genicular artery (see Figs 82.1, 80.32-80.33), the distal branch of the femoral artery, arises just proximal to the adductor opening and immediately supplies a saphenous branch. It then descends in vastus medialis, anterior to the tendon of adductor magnus, to the medial side of the knee, where it anastomoses with the superior medial genicular artery. Muscular branches supply vastus medialis and adductor magnus, and give off articular branches that anastomose round the knee joint. One articular branch crosses above the femoral patellar surface, forming an arch with the superior lateral genicular artery and supplying the knee joint. The saphenous branch (saphenous artery) emerges distally through the roof of the adductor canal to accompany the saphenous nerve to the medial side of the knee. It passes between sartorius and gracilis, and supplies the skin of the proximomedial area of the leg; it anastomoses with the inferior medial genicular artery.

## Arterial anastomoses around the hip

In the fetus, a peri-acetabular vascular circle formed by the superior and inferior gluteal, internal pudendal and obturator arteries reduces the risk of bony necrosis of this region in children. However, there is a zone at the anterior portion of the acetabulum where the blood supply is less abundant (Damsin et al 1992).

## Anastomoses on the back of the thigh

An important chain of anastomoses extends on the back of the thigh from the gluteal region to the popliteal fossa. It is formed in proximodistal order by anastomoses between the gluteal arteries and terminal branches of the medial circumflex femoral artery; the circumflex femoral arteries and the first perforating artery; the perforating arteries themselves; and between the fourth perforating artery and the superior muscular branches of the popliteal artery (see Fig. 80.18). The trochanteric and cruciate anastomoses are the proximal elements of this chain.

## Trochanteric anastomosis

The so-called trochanteric anastomosis lies near the trochanteric fossa of the femur and is an anastomosis between the ascending branch of the medial circumflex femoral artery and descending branches of the superior and inferior gluteal arteries (see Fig. 80.18). The lateral circumflex femoral artery and the first perforating artery from the profunda femoris artery may also contribute, creating an extracapsular 'arterial ring of the femoral neck' (Crock 1996). Branches from this ring, the retinacular vessels, pierce the capsule and ascend along the femoral neck to give the main blood supply to the head of the femur.

## Cruciate anastomosis

The cruciate anastomosis lies at the level of the lesser trochanter, near the lower edge of the femoral attachment of quadratus femoris, and is an anastomosis between the transverse branches of the medial and lateral circumflex femoral arteries, a descending branch of the inferior gluteal artery and an ascending branch from the first perforating artery.

## Collateral circulation in proximal femoral artery occlusion

After occlusion of the femoral artery proximal to the origin of the profunda femoris artery, five main anastomotic channels are available. These are between branches of the superior and inferior gluteal arteries, the medial and lateral circumflex femoral arteries and the first perforating branch of the profunda femoris artery; the obturator branch of the internal iliac artery and the medial circumflex femoral artery; the internal pudendal branch of the internal iliac artery and the superficial and deep external pudendal branches of the femoral artery; a deep circumflex iliac branch of the external iliac artery, the lateral circumflex femoral branch of the deep artery of the thigh and the superficial circumflex iliac branch of the femoral artery; and the inferior gluteal branch of the internal iliac artery and perforating branches of the profunda femoris artery.

## Perforator flaps in the hip and thigh

## Gluteal region

The gluteal region of the lower limb has an average of 21 perforators, which arise from three main source arteries: namely, the superior and inferior gluteal and the internal pudendal arteries (see Fig. 78.7). The flaps based on these perforators are used as free flaps for breast reconstruction and as local flaps for covering defects in the sacral and perineal region.

## Hip and thigh region

The hip and thigh region has six source arteries and an average of 50 arterial perforators. The thigh can be divided into four areas: anteromedial; anterolateral and trochanteric; posteromedial; and posterolateral. The perforators that supply the anteromedial thigh are derived from the femoral artery, and those for the anterolateral thigh are derived from branches of the lateral circumflex femoral artery. Perforators that supply the skin over the posteromedial and posterolateral thigh regions are derived from the profunda femoris artery and the popliteal arteries. Skin flaps based on the superficial circumflex iliac, superficial external pudendal and superficial inferior epigastric arteries have been used as local flaps, tube pedicles and free tissue transfers. Other popular skin flaps are TFL (tensor fasciae latae) perforator flaps, ALT (anterolateral thigh) and AMT (anteromedial thigh) flaps, gracilis perforator flap and posterior thigh flaps.

## VEINS

## Femoral vein

The femoral vein accompanies its artery, beginning at the adductor opening as the continuation of the popliteal vein, and ending posterior to the inguinal ligament as the external iliac vein (see Figs 78.8, 80.1$80.3,80.31$ ). The vein is posterolateral to the femoral artery in the distal adductor canal. More proximally in the canal, and in the distal femoral triangle (i.e. at its apex), the vein lies posterior to the artery and proximally, at the base of the triangle, the vein lies medial to the artery. The vein occupies the middle compartment of the femoral sheath, between the femoral artery and femoral canal; fat in the canal permits expansion of the vein.

The femoral vein has numerous muscular tributaries. The profunda femoris vein (deep vein of the thigh, deep femoral vein) joins the femoral vein posteriorly $4-12 \mathrm{~cm}$ distal to the inguinal ligament, and the long saphenous vein then enters anteriorly. Veins accompanying the superficial epigastric, superficial circumflex iliac and external pudendal arteries join the long saphenous vein before it enters the saphenous opening. Lateral and medial circumflex femoral veins are usually tributaries of the femoral vein. There are usually four or five valves in the femoral vein; the two most constant are just distal to the entry of profunda femoris and near the inguinal ligament.

## Profunda femoris vein (Deep vein of the thigh)

Profunda femoris lies anterior to its artery and receives tributaries corresponding to the branches of the artery. Through these tributaries it connects distally with the popliteal vein and proximally with the inferior gluteal veins. It sometimes drains the medial and lateral circumflex femoral veins and has a valve just before it empties into the femoral vein.

## Long saphenous vein

The long saphenous vein (great saphenous vein) (see Fig. 78.9A), the longest vein in the body, starts distally as a continuation of the medial marginal vein of the foot, and ends in the femoral vein a short distance distal to the inguinal ligament. It ascends immediately anterior to the tibial malleolus, crosses the distal third of the medial surface of the tibia obliquely in an anteroposterior direction to reach its medial border, and then ascends a little behind the border to the knee. Proximally, it is posteromedial to the medial tibial and femoral condyles (lying the breadth of the subject's hand posterior to the medial edge of the patella), and then ascends the medial aspect of the thigh. It passes through the saphenous opening and finally opens into the femoral vein. The 'centre' of the opening is often said to be $2.5-3.5 \mathrm{~cm}$ inferolateral to the pubic tubercle, and the vein is then represented by a line drawn from this point to the adductor tubercle. However, the saphenous opening varies greatly in size and disposition so that this 'centre' is not a reliable surface marking for the saphenofemoral junction.

In its course through the thigh, the long saphenous vein is accompanied by the medial branches of the anterior cutaneous branches of the femoral nerve. At the knee, the saphenous branch of the descending genicular artery (the saphenous artery) and, in the leg and foot, the saphenous nerve all lie anterior to the vein. The vein is often duplicated, especially distal to the knee. It has $10-20$ valves, which are more numerous in the leg than in the thigh. One is present just before the vein pierces the cribriform fascia, another at its junction with the femoral vein. In almost its entire extent the vein lies in subcutaneous tissue, but it has many connections with the deep veins, especially in the leg.

## Tributaries

At the ankle, the long saphenous vein drains the sole by medial marginal veins. In the leg, it often connects with the short saphenous vein and with deep veins via perforating veins. Just distal to the knee, it usually receives three large tributaries from the front of the leg, the tibial malleolar region (connecting with some of the 'perforating' veins) and the calf (communicating with the short saphenous vein). The tributary draining the tibial malleolar region is formed distally from a fine network or 'corona' of delicate veins over the medial malleolus, and then ascends the medial aspect of the calf as the posterior arch vein (Dodd and Cockett 1976). This vein was first illustrated by Leonardo da Vinci, whose name is sometimes given to it. It connects with posterior tibial venae comitantes by a series of perforating (communicating) veins. There are usually three, equally spaced between the medial malleolus and the mid-calf. More than three such perforators are uncommon, and an arch vein perforator above mid-calf is only very rarely found.

Above the posterior crural arch vein, perforating veins join the long saphenous vein or one of its main tributaries at two main sites. The first is at a level in the upper calf indicated by its name, the tibial tubercle perforator; the second is in the lower/intermediate third of the thigh, where it perforates the deep fascia roof of the subsartorial canal to join the femoral vein.

In the thigh, the long saphenous vein receives many tributaries. Some open independently, while others converge to form large named channels that frequently pass towards the basal half of the femoral triangle before joining the long saphenous near its termination. These may be grouped as follows: one or more large posteromedial tributaries, one or more large anterolateral tributaries, and four or more periinguinal veins. The posteromedial vein of the thigh, large and sometimes double, drains a large superficial region indicated by its name; it has (as have the other tributaries) radiological and surgical significance. One of its lower radicles is often continuous with the short saphenous vein. The posteromedial vein is sometimes named the accessory saphenous vein, though some restrict the term accessory to a lower (more distal) posteromedial tributary when two (or more) are present. Another large vessel, the anterolateral vein of the thigh (anterior femoral cutaneous vein), usually commences from an anterior network of veins in the distal thigh and crosses the apex and distal half of the femoral triangle to reach the long saphenous vein. As the latter traverses the saphenous opening, it is joined by the superficial epigastric, superficial circumflex iliac and superficial external pudendal veins. Their mode of union varies. Superficial epigastric and circumflex iliac veins drain the inferior abdominal wall, the latter also receiving tributaries from the proximolateral region of the thigh. The superficial epigastric or the femoral vein may connect with the lateral thoracic veins by means of a thoracoepigastric vein that runs superficially on the anterolateral aspect of the trunk. This vein connects the inferior and superior caval areas of drainage and may be dilated and visible in cases of inferior caval obstruction. Superficial external pudendal veins drain part of the scrotum/labia; one is joined by the superficial dorsal vein of the penis/ clitoris. The deep external pudendal veins join the long saphenous vein at the saphenous opening.

The long saphenous vein is often harvested for grafts used in both peripheral and coronary arterial surgery.

## LYMPHATIC DRAINAGE

## Superficial inguinal nodes

The superficial inguinal nodes form proximal and distal groups. The proximal group usually consists of five or six nodes just distal to the inguinal ligament. Its lateral members receive afferent vessels from the gluteal region and the adjoining infra-umbilical anterior abdominal wall. Medial members receive superficial vessels from the external genitalia (including the inferior vagina), inferior anal canal and perianal region, adjoining abdominal wall, umbilicus and vessels accompanying the round ligament. The distal group usually consists of four or five
nodes along the termination of the long saphenous vein. They receive all the superficial vessels of the lower limb, except those from the posterolateral calf. All superficial inguinal nodes drain to the external iliac nodes, some via the femoral canal and others anterior or lateral to the femoral vessels. Numerous vessels interconnect individual nodes.

Superficial inguinal nodes are frequently enlarged in disease or injury in their region of drainage. Thus the proximal inguinal nodes are almost invariably affected in malignant or infective disease of the prepuce, penis, labia majora, scrotum, perineum, anus and lower vagina, or in diseases affecting the skin and superficial structures in these regions, in the infra-umbilical part of the abdominal wall or in the gluteal region. The distal group is implicated only in disease or injury of the limb.

## Deep inguinal nodes

The deep inguinal nodes vary from one to three, and are situated medial to the femoral vein. One lies just distal to the saphenofemoral junction, another in the femoral canal, and the most proximal node lies laterally in the femoral ring. The middle node is the most inconstant and the proximal node is often absent. All receive deep lymphatics that accompany the femoral vessels, lymph vessels from the glans penis or clitoris and a few efferents from the superficial inguinal nodes. Their own efferents traverse the femoral canal to the external iliac nodes.

## INNERVATION

## LUMBAR PLEXUS AND BRANCHES

The lumbar plexus is formed by the first three and most of the fourth lumbar ventral rami (see Fig. 62.15). The iliohypogastric, ilioinguinal and genitofemoral nerves are described on pages 1094-1096.

## Lateral femoral cutaneous nerve

The lateral femoral cutaneous nerve (lateral cutaneous nerve of the thigh) arises from the dorsal branches of the second and third lumbar ventral rami and emerges from the lateral border of psoas major, crossing iliacus obliquely towards the anterior superior iliac spine. It supplies the parietal peritoneum in the iliac fossa. The right nerve passes posterolateral to the caecum, separated from it by the fascia iliaca and peritoneum; the left passes behind the lower part of the descending colon. Both pass behind or through the inguinal ligament, variably medial to the anterior superior iliac spine (commonly 1 cm ) and anterior to or through sartorius into the thigh, where they divide into anterior and posterior branches. The anterior branch becomes superficial approximately 10 cm distal to the anterior superior iliac spine and supplies the skin of the anterior and lateral thigh as far distally as the knee. It connects terminally with the cutaneous branches of the anterior division of the femoral nerve and the infrapatellar branch of the saphenous nerve, forming the peripatellar plexus. The posterior branch pierces the fascia lata higher than the anterior, and divides to supply the skin on the lateral surface from the greater trochanter to about mid-thigh. It may also supply skin of the gluteal region.

## Lesions of the lateral femoral cutaneous nerve

The lateral femoral cutaneous nerve may become entrapped at three sites along its course: close to the vertebral column; within the abdominal cavity as the nerve travels across the pelvis; and as it leaves the pelvis. This last site is where the nerve is most commonly damaged, and entrapment is thought to occur as the nerve passes through or deep to the inguinal ligament just medial to the anterior superior iliac spine. The angulation of the nerve as it crosses the iliac crest means that it is vulnerable to compression during movement, e.g. hip extension may increase angulation and tension on the nerve.

Injury produces an area of impaired sensation, often with pain and paraesthesia on the anterolateral aspect of the thigh (meralgia paraesthetica) in the distal cutaneous distribution of the nerve. This area does not extend across the midline anteriorly, it does not extend below the knee and it does not extend behind the hamstring tendons laterally. Symptoms may be exacerbated when wearing tight belts or tight-waisted clothes or as a result of a recent weight gain or pregnancy. Exceptionally, the posterior branch of the lateral femoral cutaneous nerve, which supplies a thin strip from the greater trochanter of the femur down about two-thirds of the way to the knee, may be affected separately. This branch leaves the main trunk of the nerve, usually distal to the inguinal ligament, and it then turns laterally to pierce tensor fasciae latae, where it may become entrapped.

## Femoral nerve

The femoral nerve is the largest branch of the lumbar plexus and arises from the dorsal branches (posterior divisions) of the second to fourth lumbar ventral rami (see Figs 78.11A, 80.31-80.33). It descends through psoas major, emerging low on its lateral border, and then passes between psoas and iliacus, deep to the iliac fascia. Passing behind the inguinal ligament into the thigh, it is split into anterior and posterior divisions by the lateral circumflex femoral artery. Behind the inguinal ligament, it is separated from the femoral artery by part of psoas major. In the abdomen, the nerve supplies small branches to iliacus and pectineus and a branch to the proximal part of the femoral artery; the latter branch sometimes arises in the thigh.

## Nerve to pectineus

The nerve to pectineus branches from the medial side of the femoral nerve near the inguinal ligament. It passes behind the femoral sheath and enters the anterior aspect of the muscle.

## Anterior division of the femoral nerve

The anterior division of the femoral nerve supplies intermediate and medial femoral cutaneous nerves and branches to sartorius.

Medial femoral cutaneous nerve of the thigh The medial femoral cutaneous nerve (medial cutaneous nerve of the thigh) is at first lateral to the femoral artery. It crosses anterior to the artery at the apex of the femoral triangle and divides into anterior and posterior branches. Before doing so, it sends a few rami through the fascia lata to supply the skin of the medial side of the thigh, near the long saphenous vein; one ramus emerges via the saphenous opening, while another becomes subcutaneous about mid-thigh. The anterior branch descends on sartorius, perforates the fascia lata beyond mid-thigh, and divides into a branch that supplies the skin as low as the medial side of the knee, and another that runs lateral to the former and connects with the infrapatellar branch of the saphenous nerve. The posterior branch descends along the posterior border of sartorius to the knee, pierces the fascia lata, connects with the saphenous nerve and gives off several cutaneous rami, some as far as the medial side of the leg. The nerve contributes to the subsartorial plexus (see below).

Intermediate cutaneous nerve of the thigh The intermediate femoral cutaneous nerve (intermediate cutaneous nerve of the thigh) usually pierces the fascia lata some 8 cm below the inguinal ligament, either as two branches or as one trunk that quickly divides into two. These descend on the front of the thigh, supplying the skin as far as the knee and ending in the peripatellar plexus. The lateral branch of the intermediate cutaneous nerve communicates with the femoral branch of the genitofemoral nerve, frequently piercing sartorius and sometimes supplying it.

Nerve to sartorius The main nerve to sartorius arises from the femoral nerve in common with the intermediate cutaneous nerve of the thigh.

## Posterior division of the femoral nerve

The branches of the posterior division of the femoral nerve are the saphenous nerve and branches to quadriceps femoris and the knee joint.

## Saphenous nerve See page 1399.

Muscular branches The muscular branches of the posterior division of the femoral nerve supply quadriceps femoris. A branch to rectus femoris enters its proximal posterior surface and also supplies the hip joint. A larger branch to vastus lateralis forms a neurovascular bundle with the descending branch of the lateral circumflex femoral artery in its distal part and also supplies the knee joint. A branch to vastus medialis descends through the proximal part of the adductor canal, lateral to the saphenous nerve and femoral vessels, and enters the muscle at about its midpoint, sending a long articular filament distally along the muscle to the knee. Two or three branches to vastus intermedius enter its anterior surface about mid-thigh; a small branch from one of these descends through the muscle to supply articularis genus and the knee joint.

## Vascular branches

Vascular branches of the femoral nerve supply the femoral artery and its branches.

## Lesions of the femoral nerve

The main trunk of the femoral nerve is not subject to an entrapment neuropathy, but it may be compressed by retroperitoneal tumours or retroperitoneal haemorrhage in patients on anticoagulants or with a bleeding diathesis. A localized lesion of the femoral nerve may occur in diabetes mellitus (one of the forms of diabetic amyotrophy). The most striking feature of femoral neuropathy is wasting and weakness of quadriceps femoris, which results in considerable difficulty in walking and a tendency for the leg to collapse. Pain and paraesthesia may occur on the anterior and medial aspect of the thigh, extending down the medial aspect of the leg in the distribution of the saphenous branch of the femoral nerve.

## Obturator nerve

The obturator nerve arises from the ventral branches of the second to fourth lumbar ventral rami. The branch from the third is the largest while that from the second is often very small. The nerve descends in psoas major, emerging from its medial border at the pelvic brim to pass behind the common iliac vessels and lateral to the internal iliac vessels. It then descends forwards along the lateral wall of the lesser pelvis on obturator internus, anterosuperior to the obturator vessels, to the obturator foramen, entering the thigh by its upper part. Near the foramen, it divides into anterior and posterior branches, separated at first by part of obturator externus and lower down by adductor brevis.

## Anterior branch

The anterior branch (see Fig. 80.33) leaves the pelvis anterior to obturator externus, descending in front of adductor brevis, behind pectineus and adductor longus. At the lower border of adductor longus it communicates with the medial cutaneous and saphenous branches of the femoral nerve, to form a subsartorial plexus that supplies the skin on the medial side of the thigh (see below). It descends on, and supplies, the femoral artery. Near the obturator foramen, the anterior branch supplies the hip joint. Behind pectineus it supplies adductor longus, gracilis, usually adductor brevis and often pectineus, and connects with the accessory obturator nerve (when present). Occasionally, the communicating branch to the femoral medial cutaneous and saphenous branches continues as a cutaneous branch to the thigh and leg. When this occurs, the nerve emerges from behind the distal border of adductor longus to descend along the posterior margin of sartorius to the knee, where it pierces the deep fascia and connects with the saphenous nerve to supply the skin halfway down the medial side of the leg.

Subsartorial nerve plexus The medial cutaneous nerve of the thigh forms a subsartorial plexus with branches of the saphenous and obturator nerves, deep to the fascia lata, at the lower border of adductor longus. When the communicating branch of the obturator nerve is large and reaches the leg, the posterior branch of the medial cutaneous nerve is small, and ends in the plexus from which it gives rise to a few cutaneous filaments.

## Posterior branch

The posterior branch pierces obturator externus anteriorly, supplies it and passes behind adductor brevis to the front of adductor magnus, dividing into branches to this and adductor brevis when the latter is not supplied by the anterior division. It usually sends an articular filament to the knee joint, which either perforates adductor magnus distally or traverses its opening with the femoral artery to enter the popliteal fossa. Within the fossa, the nerve descends on the popliteal artery to the back of the knee, pierces its oblique posterior ligament and supplies the articular capsule. It gives filaments to the popliteal artery.

## Lesions of the obturator nerve

Isolated lesions of the obturator nerve are extremely rare, but may occasionally occur as a result of direct trauma (sometimes during parturition) or in anterior dislocations of the hip. The nerve may also be damaged by an obturator hernia, or be involved together with the femoral nerve in retroperitoneal lesions that occur close to the origins of the lumbar plexus. Compression of the nerve by herniated bowel loops at the obturator foramen can result in pain referred to the hip, medial thigh and knee, the so-called Howship-Romberg sign. A more distal nerve entrapment syndrome causing chronic medial thigh pain has been described in athletes with large adductor muscles.

## Accessory obturator nerve

Occasionally present, the accessory obturator nerve is small and arises from the ventral branches of the third and fourth lumbar ventral rami.

Table 80.1 The branches of the sacral plexus

|  | Ventral divisions | Dorsal divisions |
| :---: | :---: | :---: |
| Nerve to quadratus femoris and gemellus inferior | L4, 5, S1 |  |
| Nerve to obturator internus and gemellus superior | L5, S1, 2 |  |
| Nerve to piriformis |  | (L5), S1, 2 |
| Superior gluteal |  | L4, 5, S1 |
| Inferior gluteal |  | L5, S1, 2 |
| Posterior femoral cutaneous | S2, 3 | S1, 2 |
| Tibial (sciatic) | L4, 5, S1, 2, 3 |  |
| Common fibular (sciatic) |  | L4, 5, S1, 2 |
| Perforating cutaneous |  | S2, 3 |
| Pudendal | S2, 3, 4 |  |
| Branches to levator ani, coccygeus and external anal sphincter | S4 |  |

It descends along the medial border of psoas major, crosses the superior pubic ramus behind pectineus and divides into branches; one branch enters the deep surface of pectineus, another supplies the hip joint, and a third connects with the anterior branch of the obturator nerve. Sometimes the accessory obturator nerve is very small and only supplies pectineus. Any branch may be absent and others may occur; an additional branch sometimes supplies adductor longus.

## SACRAL PLEXUS AND BRANCHES

The branches of the sacral plexus (see Fig. 78.11B) are shown in Table 80.1.

## Sciatic nerve

The sciatic nerve is 2 cm wide at its origin and is the thickest nerve in the body. It leaves the pelvis via the greater sciatic foramen below piriformis and descends between the greater trochanter and ischial tuberosity, along the back of the thigh, dividing into the tibial and common fibular nerves at a varying level proximal to the knee (Fig. 80.34; see Fig. 78.11B). Superiorly, it lies deep to gluteus maximus, resting first on the posterior ischial surface with the nerve to quadratus femoris between them. It then crosses posterior to obturator internus, the gemelli and quadratus femoris, separated by the latter from obturator externus and the hip joint. It is accompanied medially by the posterior femoral cutaneous nerve and the inferior gluteal artery. More distally, it lies behind adductor magnus and is crossed posteriorly by the long head of biceps femoris. Its course corresponds to a line drawn from just medial to the midpoint between the ischial tuberosity and greater trochanter to the apex of the popliteal fossa.

Articular branches arise proximally to supply the hip joint through its posterior capsule; these are sometimes derived directly from the sacral plexus. Muscular branches are distributed to biceps femoris, semitendinosus, semimembranosus and the ischial part of adductor magnus.

The point of division of the sciatic nerve into its tibial and common fibular components is very variable. The common site is at the junction of the middle and lower thirds of the thigh, near the apex of the popliteal fossa, but the division may occur at any level above this point and, rarely, may occur below it.

## Blood supply to the sciatic nerve

In the gluteal region, the sciatic nerve is supplied by the inferior gluteal artery and cruciate anastomosis (the medial and lateral circumflex femoral arteries, inferior gluteal artery and the first perforating branch of the profunda femoris artery) (see Fig. 80.30). On rare occasions, it is supplied by branches from the superior gluteal or internal pudendal arteries, which reach the nerve on its medial side. Lower in the thigh, arterial branches derived from the perforating branches of the profunda femoris artery or the anastomotic chain between them or, occasionally, from the popliteal artery, enter the nerve on its lateral or anterolateral side (Sunderland 1945). The numerous arterial branches to the sciatic nerve anastomose with each other to form extraneural and intraneural arterial chains (Sunderland 1945, Ugrenovic et al 2013).

## Lesions of the sciatic nerve

The sciatic nerve supplies the knee flexors and all the muscles below the knee, which means that a complete palsy of the sciatic nerve results in a flail foot and severe difficulty in walking. Fortunately, complete

Fig. 80.34 The sciatic nerve and its branches, posterior view.
sciatic nerve palsy is very rare. The nerve is vulnerable in posterior dislocation of the hip. As it leaves the pelvis, it passes either behind piriformis or sometimes through the muscle, and at that point it may very rarely become entrapped or tethered; the piriformis syndrome is a controversial condition in which an anomalous relationship between piriformis and the sciatic nerve is thought to cause pain in the buttocks and along the course of the sciatic nerve. External compression over the buttock, e.g. in patients who lie immobile on a hard surface for a considerable length of time, can injure the nerve. However, the most common cause of serious sciatic nerve injury (and of the resulting major medicolegal claims) is iatrogenic (Dillow et al 2013). The nerve may be damaged in misplaced therapeutic injections into gluteus maximus. Sciatic nerve palsy occurs after total hip replacement or similar surgery in $1 \%$ of cases, and may be caused by sharp injury, burning from bone cement, traction from instruments, manipulation of the hip, inadvertent lengthening of the femur, or haematoma surrounding the nerve. For some reason, possibly anatomical, the common fibular component of the sciatic nerve is more usually affected; the patient has a foot drop and a high-stepping gait.

## Inferior gluteal nerve

The inferior gluteal nerve arises from the dorsal branches of the fifth lumbar and first and second sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, and divides into branches that enter the deep surface of gluteus maximus (see Fig. 80.30).

## Superior gluteal nerve

The superior gluteal nerve arises from the dorsal branches of the fourth and fifth lumbar and first sacral ventral rami. Accompanied by the superior gluteal vessels, the nerve leaves the pelvis via the greater sciatic foramen above piriformis, and divides into superior and inferior branches (see Fig. 80.30). The superior branch accompanies the upper branch of the deep division of the superior gluteal artery to supply gluteus medius and occasionally gluteus minimus. The inferior branch runs with the lower ramus of the deep division of the superior gluteal artery across gluteus minimus, supplies the glutei medius and minimus, and ends in tensor fasciae latae.

## Pudendal nerve

See Figure 62.15 and pages 1230 and 1236.

## Perforating cutaneous nerve

The perforating cutaneous nerve usually arises from the posterior aspects of the second and third sacral ventral spinal rami. It pierces the sacrotuberous ligament, curves round the inferior border of gluteus maximus and supplies the skin over the inferomedial aspect of this muscle. The nerve may arise from the pudendal nerve or it may be absent, in which case it may be replaced either by a branch from the posterior femoral cutaneous nerve or from the third and fourth, or fourth and fifth, sacral ventral rami.

## Nerve to quadratus femoris

The nerve to quadratus femoris arises from the ventral branches of the fourth lumbar to the first sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, descends on the ischium deep to the sciatic nerve, the gemelli and the tendon of obturator internus, and supplies gemellus inferior, quadratus femoris and the hip joint.

## Nerve to obturator internus

The nerve to obturator internus arises from the ventral branches of the fifth lumbar and first and second sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, supplies a branch to the upper posterior surface of gemellus superior, crosses the ischial spine lateral to the internal pudendal vessels, re-enters the pelvis via the lesser sciatic foramen, and enters the pelvic surface of obturator internus.

## Posterior femoral cutaneous nerve (posterior cutaneous nerve of the thigh)

The posterior femoral cutaneous nerve (posterior cutaneous nerve of the thigh) arises from the dorsal branches of the first and second, and the ventral branches of the second and third sacral rami. It leaves the pelvis via the greater sciatic foramen below piriformis and descends under gluteus maximus with the inferior gluteal vessels, lying posterior or medial to the sciatic nerve (see Fig. 80.30). It descends in the back of the thigh superficial to the long head of biceps femoris, deep to the fascia lata. It pierces the deep fascia behind the knee and accompanies the short saphenous vein to mid-calf, its terminal twigs connecting with the sural nerve. Its branches are cutaneous and are distributed to the gluteal region, perineum, posterior thigh and proximal posterior leg.

Three or four gluteal branches (inferior clunial nerves) curl round the lower border of gluteus maximus to supply the skin over the inferolateral portion of the muscle. The perineal branch supplies the superomedial skin in the thigh, curves forwards across the hamstrings below the ischial tuberosity, pierces the fascia lata and then runs in the superficial perineal fascia to the scrotal or labial skin. It communicates with the inferior rectal and posterior scrotal or labial branches of the perineal nerve, and gives numerous branches to the skin of the back and medial side of the thigh, the popliteal fossa and the proximal part of the back of the leg. One study found the perineal branch of the posterior cutaneous nerve of the thigh in about one-half of specimens (Tubbs et al 2009).

## Nerve to piriformis

The nerve to piriformis usually arises from the dorsal branches of the first and second sacral ventral rami (sometimes only the second) and enters the anterior surface of piriformis.

## Visceral and pelvic muscular branches of sacral plexus

Visceral branches of the sacral plexus are described on page 1229. Pelvic muscular branches are described on page 1221.

## TOPOGRAPHY

The hip joint is a synovial joint of ball-and-socket (multiaxial spheroidal) type between the head of the femur and the cup-shaped (cotyloid) acetabulum; its centre lies a little inferior to the middle one-third of the inguinal ligament.

## Articular surfaces

The femoral head can be landmarked from the surface roughly $2-4 \mathrm{~cm}$ superior to an approximate midpoint of a line joining the superior margin of the greater trochanter to the pubic tubercle. The articular surfaces of the femoral head and the acetabulum are reciprocally curved but neither coextensive nor completely congruent (Fig. 81.1; see Fig. 80.16). The close-packed position of the hip joint is one of full extension, with slight abduction and medial rotation (see also Table 5.4). This position winds up most of the joint's capsular ligaments, which can provide an important element of articular stability. The femoral head is covered by articular cartilage, except over the rough pit where the ligament of the head of the femur is attached. Anteriorly, the cartilage extends laterally over a small area on the adjoining neck. Articular cartilage is, generally, thicker centrally than peripherally. Cartilage thickness is maximal anterosuperiorly in the acetabulum and anterolaterally on the femoral head, the two areas that correspond to the principal load-bearing areas within the joint. The acetabular articular surface, the lunate surface, is an incomplete ring, broadest anterosuperiorly where the pressure of body weight falls in the erect posture, and narrowest in its pubic region. It is deficient inferiorly opposite the acetabular notch. The lunate surface is covered by articular cartilage, which is thickest where the surface is broadest. The acetabular fossa, the central nonarticular area in the floor of the acetabulum, is devoid of cartilage but contains fibroelastic fat largely covered by synovial membrane. The acetabular labrum, a fibrocartilaginous rim attached to the acetabular margin, serves to deepen the acetabulum and bridges the acetabular notch by attaching to the peripheral edge of the transverse acetabular
ligament. The acetabular labrum is triangular in section, attached by its base to the acetabular margin and blending with adjacent articular cartilage; its acute free edge projects beyond the acetabular margin. The diameter of the acetabular cavity is constricted by the labral rim, which embraces the femoral head, thereby contributing to the stability of the articulation. The acetabular labrum increases the surface area for joint contact as well as sealing the joint, allowing optimal intra-articular distribution of synovial fluid (Ferguson et al 2003, Cadet et al 2012). It thus facilitates nutrition of the articular cartilage and helps to reduce intra-articular friction (Safran et al 2011, Song et al 2012). Nerve endings found within the labrum suggest this structure may be a source of proprioception or, when injured, of pain (Kim and Azuma 1995). A torn acetabular labrum can be detected using MRI, to identify the site and severity of the lesion (Fig. 81.2).

## Acetabular labrum and impingement injury

## Fibrous capsule

The fibrous capsule of the hip joint is strong and dense (Fig. 81.4). It is attached superiorly to the acetabular margin $5-6 \mathrm{~mm}$ medial to the labral attachment, anteriorly to the outer labral aspect and, near the acetabular notch, to the transverse acetabular ligament and the adjacent rim of the obturator foramen. From its acetabular attachment, it extends laterally to surround the femoral head and neck, and is attached anteriorly to the intertrochanteric line, superiorly to the base of the femoral neck, posteriorly 1 cm superomedial to the intertrochanteric crest, and inferiorly to the femoral neck near the lesser trochanter. Anteriorly, many fibres ascend along the neck as longitudinal retinacula, containing blood vessels for both the femoral head and the neck. The capsule is thicker anterosuperiorly, where maximal stress occurs, particularly while standing with the hip extended. Posteroinferiorly, it is relatively thin and loosely attached. The capsule as a whole has two sets of fibres,

The shape of the bones of the hip normally limits large and potentially damaging contact stress on adjacent connective tissues, especially during the extremes of movement. Consider, for example, the normal shape of the femoral head and neck region. Similar to the shape of a light bulb, the spherical femoral head narrows gradually at its junction with the neck of the femur. This tapering limits large contact stress between the femoral neck and the margin of the acetabulum. However, tapering may be lost as a result of natural variation or underlying pathology, resulting in a specific deformity that has been referred to as a cam deformity because the head and neck of the femur, together, resemble a camshaft. Although often subtle, this deformity may be detected radiographically (see arrow in Fig. 81.3). In some patients with a cam deformity, extreme and repeated motions of the hip, typically involving combinations of flexion, medial rotation and adduction, can

Fig. 81.3 Pre-surgical radiograph of a hip with a cam deformity of the femoral head-neck junction (arrow). Note the loss of sphericity in the femoral head and the loss of the tapering of the neck. (Image courtesy of John T Heinrich MD, Milwaukee Orthopaedic Group Limited, Milwaukee, WI, USA.)
create damaging impingement between the hard and bulbous femoral neck and the softer acetabular labrum. The anterosuperior section of the labrum is particularly vulnerable to this type of injury, which is a painful and often motion-limiting condition referred to as femoralacetabular impingement syndrome. The repeatedly traumatized section of the labrum can become enlarged, fragmented or torn. When the acetabular labrum is torn, a hip joint may become unstable as a consequence of the loss of the natural suction seal around the joint. In some advanced cases, the impingement trauma may create lesions at the chondrolabral junction, resulting in damage to the adjacent articular cartilage, potentially predisposing the hip joint to degenerative arthritis (osteoarthrosis). Treatment may involve arthroscopic repair of the acetabular labrum and cartilage, as well as reshaping the area of the femoral head and neck responsible for the impingement.
circular and longitudinal. The circular fibres (zona orbicularis) are internal and form a collar round the femoral neck; although partly blended with the pubofemoral and ischiofemoral ligaments, these fibres are not directly attached to bone (see Fig. 81.4). Externally, longitudinal fibres are most numerous in the anterosuperior region, where

Fig. 81.4 Synovial cavity of the left hip joint (distended): posterior aspect.
they are reinforced by the iliofemoral ligament. The capsule is also strengthened inferiorly by the pubofemoral ligament, and posteriorly by the ischiofemoral ligament. Externally the capsule is rough, covered by muscles and tendons, and separated anteriorly from psoas major and iliacus by a bursa. The capsular attachment to the femur lies well distal to the growth plate of the femoral head both anteriorly and posteriorly, and so the upper femoral epiphysis is entirely intracapsular. The capsular attachment intersects the growth plate of the greater trochanter on the superior surface of the base of the neck.

## Iliocapsularis

## Available with the Gray's Anatomy e-book

Relations The joint capsule is surrounded by muscles (Fig. 81.5). Anteriorly, lateral fibres of pectineus separate the capsule from the femoral vein. Lateral to this, the tendon of psoas major, with iliacus lateral to it, descends en route to the lesser trochanter, partly separated from the capsule by a bursa. The femoral artery is anterior to the tendon of psoas major, and the femoral nerve lies deep in a groove between the tendon and iliacus. More laterally, the straight head of rectus femoris crosses the joint with a deep layer of the iliotibial tract, which blends with the capsule under the lateral border of the muscle. Superiorly, the reflected head of rectus femoris contacts the capsule medially, while gluteus minimus covers it laterally, being closely adherent. Inferiorly, medial fibres of pectineus adjoin the capsule and, more posteriorly, obturator externus spirals obliquely to its posterior aspect. Posteroinferiorly, the capsule is covered by the tendon of obturator externus, separating it from quadratus femoris and accompanied by an ascending branch of the medial circumflex femoral artery. Superior to this, the tendon of obturator internus and the gemelli contact the joint capsule, separating it from the sciatic nerve. The nerve to quadratus femoris is deep to the obturator internus tendon and descends medially on the capsule. Superior to this, the posterior surface of the joint is crossed by piriformis.

Fig. 81.5 Schematic dissection to display the structures surrounding the hip joint. The femoral head has been disarticulated and removed.

Iliocapsularis (also called iliacus minor or iliotrochantericus) is a littleknown but constant muscle that lies immediately deep to the tendon of iliopsoas and overlies the anterior hip capsule (Babst et al 2011, Ward et al 2000). Typically present as just a few strands of fibres, it originates from the anteromedial hip capsule and anteroinferior iliac spine, and is attached just distal to the lesser trochanter. Although the function of the muscle is uncertain, it may draw the capsule taut as a way of reducing its impingement during hip flexion.

Fig. 81.6 Ligaments of the hip joint. A, Anterior aspect; B, Posterior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

## Ligaments

The ligaments of the hip joint are the iliofemoral, pubofemoral, ischiofemoral and transverse acetabular ligaments, and the ligament of the head of the femur (Fig. 81.6). As the hip moves, the capsular ligaments wind and unwind, tightening around the hip, and affecting stability, excursion and joint capacity (Fuss and Bacher 1991). Joint capacity is maximal when the hip joint is held in a partially flexed and abducted position; a patient with an effusion in the hip joint is therefore most comfortable when the joint is held in this position.

Iliofemoral ligament The iliofemoral ligament is very strong and is shaped like an inverted Y, lying anteriorly and intimately blended with the capsule. Its apex is attached between the anterior inferior iliac spine and acetabular margin, its base to the intertrochanteric line. It is composed of a medially placed, thicker descending part and a laterally placed, transverse part, which is typically distinguishable anteriorly. The obliquely disposed transverse part is attached to a tubercle at the superolateral end of the intertrochanteric line, while the vertically oriented descending part reaches the inferomedial end of the line.

Pubofemoral ligament The pubofemoral ligament is triangular, with a base that is attached to the iliopubic ramus, superior pubic ramus, obturator crest and membrane. It blends distally with the capsule and deep surface of the descending part of the iliofemoral ligament and has been described as consisting of multiple crura (Fuss and Bacher 1991).

Ischiofemoral ligament The ischiofemoral ligament thickens the posterior aspect of the capsule. The central part spirals superolaterally from the ischium, where it is attached posteroinferior to the acetabulum, then courses posterior to the femoral neck to attach distally to the greater trochanter deep to the iliofemoral ligament. Some fibres blend with the zona orbicularis. Some of the more inferior fibres of the ischiofemoral ligament embrace the posterior circumference of the femoral neck.

Transverse acetabular ligament The transverse acetabular ligament (see Fig. 80.4) is continuous peripherally with the labrum but does not possess any cartilage cells. Its strong, flat fibres cross the acetabular notch, forming a foramen through which vessels and nerves pass to enter the joint.

Fig. 81.7 Interior aspect of the hip joint to show the ligament of the head of the femur. (With permission from Drake RL, Vogl AW, Mitchell A, et al (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)

Ligament of the head of the femur The ligament of the head of the femur is a triangular and somewhat flattened band of connective tissue (see Fig. 81.5, Fig. 81.7). Its apex is attached anterosuperiorly in the fovea for the ligament of the head of the femur while its base is attached principally to both edges of the acetabular notch, between which it blends with the transverse acetabular ligament. It also receives weaker contributions from the margins of the acetabular fossa, is ensheathed by synovial membrane and varies in strength. Occasionally, the synovial sheath exists by itself in the absence of the ligament; rarely, both the ligament and sheath are absent.

Although the ligament of the head of the femur is known primarily for lending structural support to the blood vessels that travel to and
from the femoral head, speculation exists that it may also have a role in stabilizing the hip joint in utero. In the adult, it is mostly elongated and assumed to be taut when the hip joint is semi-flexed, laterally rotated, and adducted, the position where the capsular ligaments, as a whole, offer least stability to the joint (Martin et al 2012). The degree to which the ligament of the head of the femur offers functional stability to the adult hip is uncertain, although it is likely to be secondary to that provided by the capsular ligaments and muscle activation.

Medical interest in the ligament of the head of the femur has increased with the advancing technology associated with medical imaging and arthroscopic hip surgery (Botser et al 2011, Gray and Villar 1997; Fig. 81.8). Free nerve endings have been identified within this ligament, suggesting that this structure may be a source of pain when it is injured or degenerating (Leunig et al 2000). The afferent innervation in the healthy state may serve as a source of proprioception or protection of the joint (Bardakos and Villar 2009).

## Synovial membrane

Starting from the femoral articular margin, the synovial membrane covers the intracapsular part of the femoral neck, and then passes to the internal surface of the capsule to cover the acetabular labrum, the ligament of the head of femur and fat in the acetabular fossa. It is thin on the deep surface of the iliofemoral ligament where it is compressed against the femoral head, and sometimes is even absent here.

## Bursae

The hip joint may communicate with the subtendinous iliopectineal bursa through a circular aperture between the pubofemoral ligament and the descending part of the iliofemoral ligament. More distant bursae are associated with the tendons of distal attachment of glutei medius and minimus at the greater trochanter, and between gluteus maximus and vastus lateralis.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Articular arteries are branches from the obturator, medial circumflex femoral, and superior and inferior gluteal arteries; they form the cruciate and trochanteric anastomoses (see Fig. 80.18). There is a corresponding venous drainage.

Lymphatics from the anterior aspect of the hip joint drain to the deep inguinal nodes, while those from the medial and posterior aspects of the joint travel with the obturator and gluteal arteries, respectively, to reach the internal iliac nodes.

## INNERVATION

The anterior capsule of the hip joint is innervated by the femoral, obturator and accessory obturator (when present) nerves. The posterior capsule is innervated by the sciatic and superior gluteal nerves, and by the nerve to quadratus femoris (Birnbaum et al 1997, Gardner 1948).

## Hip and groin pain

Pain emanating from the hip and groin has many possible causes. True pain from the hip joint is typically felt deep in the crease of the groin. Pain over the lateral aspect of the hip usually suggests a local problem such as trochanteric bursitis. Pain in the buttock is only occasionally derived from the hip joint; most frequently, it is referred from the lumbosacral spine or may be caused by vascular claudication. Pain in the groin may be associated with inguinal or femoral hernias. In the younger age group, it afflicts those engaged in sports, especially running ball sports; the pain is sometimes due to femoro-acetabular impingement or to hernia but most often is related to adductor longus tendinitis ('groin strain'). Attritional chronic overload of the anterior abdominal wall at its attachments to the pubis and inguinal ligament, or of external oblique at the superficial inguinal ring, is a common occurrence. Rarely, problems may occur at the pubic symphysis.

## FACTORS MAINTAINING STABILITY

The hip joint is normally very stable. The femoral head is closely fitted to the acetabulum in an area exceeding half a sphere, and is embraced
closely by the acetabular labrum, which restrains it in the socket. In addition, a 'vacuum effect' is present. The thick capsule is reinforced by the three major ligaments: iliofemoral, pubofemoral and ischiofemoral. The iliofemoral ligament is the strongest, and is progressively tightened when the femur extends to the line of the trunk. The pubofemoral and ischiofemoral ligaments also tighten when this happens and, as the joint approaches the close-packed position, resistance to an extending torque increases rapidly. The transverse acetabular ligament and ligament of the head of the femur also contribute to stability. Only slight separation of the articular surfaces can be achieved by strong traction on the joint. To aid insertion of an arthroscope, a needle is first inserted into the joint to eliminate the suction effect; the joint will subsequently open sufficiently with traction. Traumatic dislocation usually occurs only when the joint is subjected to extreme force.

## BIOMECHANICS OF THE HIP JOINT

The transition from quadrupedal to bipedal gait was a considerable biomechanical milestone in the evolution of Homo sapiens. The biomechanical features of the human lower limb, whose function is primarily to allow stance and bipedal propulsion, are very different from those of the quadruped lower limb, and these differences are reflected in the anatomy and biomechanics of the human hip, knee, ankle and foot joints.

The acetabulum and femoral head form a multiaxial spheroidal ('ball and socket') joint, which allows relatively unhindered motion in three degrees of freedom, i.e. flexion/extension, abduction/adduction and medial/lateral rotation. This articulation is innately limited in its capacity for translational motion in anteroposterior, transverse and vertical directions.

## Femur

The femur is essentially a tubular structure with distortions that consist of bows and twists. The most notable is the anterior bow in its mid portion, where the radius of curvature is relatively constant along the length of the femoral shaft. In the coronal (frontal) plane, the femoral neck is inclined obliquely to the shaft at an angle of about $135^{\circ}$ (range $120-140^{\circ}$; Fig. 81.10). Although the neck-shaft angle (collo-diaphyseal angle; Mikulicz angle) and neck length are variable, the centre of the neck in the coronal plane is at the level of the apex of the greater trochanter. In the axial (transverse) plane, the femoral neck is anteverted, i.e. rotated anteriorly relative to the posterior surfaces of the femoral condyles; in the adult, this angle is $10-15^{\circ}$ (Fig. 81.11A). Excessive anteversion may exist when this angle is significantly greater than $10-15^{\circ}$ (Fig. 81.11B). At birth, the angle of anteversion is typically about $35-40^{\circ}$. As the child develops, forces from muscles and gravity cause the angle of anteversion to decrease gradually, approaching $15^{\circ}$ by young adulthood. Excessive anteversion usually persists beyond

Fig. 81.10 The neck-shaft angle (NSA) between the long axis of the femoral shaft ( S ) and the axis of the femoral neck $(\mathrm{N})$ is on average $135^{\circ}$ (range $125-140^{\circ}$ ). In addition, in most hips, a line nearly perpendicular to $S$ from the tip of the greater trochanter (B) passes through the centre of the femoral head. This approximation can be utilized in judging the position of the femoral osteotomy in hip arthroplasty.

The blood supply to the hip in the child is different from that in the adult and this has very important implications clinically．Since the growth plate is avascular，the only blood supply to the femoral head is conveyed through the retinacular vessels，which are mainly tributaries of the medial circumflex femoral artery．These retinacular arteries enter the joint capsule in the trochanteric fossa and ascend the femoral neck on its outer aspect superiorly and posteriorly．They pass around the edge of the growth plate（physis）and enter the femoral head（Fig．81．9）．A minor contribution to the vascular supply comes from the ligament of
the head of the femur．Any damage to these vessels（e．g．trauma，infec－ tion）can result in the devastating complication of avascular necrosis of the femoral head．The growth plate represents a line of weakness and predisposes to fracture from injury．Acute injuries affecting the capital epiphysis are uncommon．A more chronic fracture through the capital epiphysis resulting in slipped capital femoral epiphysis，where the femoral head epiphysis displaces posteriorly off the femoral neck， occurs in pubescent adolescents，especially males（see Fig． 81.9 and p．1353）．

Fig. 81.11 A, Superior view of a proximal femur with normal anteversion. B, Superior view of a proximal femur with excessive anteversion. (With permission from Neumann D, Kinesiology of the Musculoskeletal System, 2nd ed, Elsevier, Mosby. Copyright 2010.)
childhood in cases of abnormal motor development, such as can be seen with cerebral palsy.

The degree of anteversion affects many aspects of lower limb biomechanics, including the moment (lever) arms of the hip abductor and medial rotator muscles (the perpendicular distance from the centre of rotation of the femur to the line of action of the resultant muscle force); patellar tracking (the motion of the patella relative to the femur); and foot orientation.

## Acetabulum

The acetabulum consists of the confluence of the ilium, ischium and pubis at the triradiate cartilage. By itself, the acetabulum covers an area slightly less than a hemisphere; it is deepened by the acetabular labrum. The degree of acetabular anteversion is about $17^{\circ}\left(16^{\circ}\right.$ males and $18^{\circ}$ females) (Reikeras et al 1983). In the coronal plane, the acetabular axis is inclined inferiorly approximately $45^{\circ}$ from the horizontal.

## MOVEMENTS

Available with the Gray's Anatomy e-book

## Muscles producing hip joint movements

Flexion is primarily produced by psoas major, iliacus and rectus femoris, assisted by pectineus, tensor fasciae latae and sartorius. The adductors, particularly adductor longus and brevis, also assist, especially when the hip is near full extension. Effective action of the hip flexor muscles requires strong synergistic activation of the abdominal muscles to stabilize the pelvis.

Extension is produced by gluteus maximus, biceps femoris, semitendinosus, semimembranosus and adductor magnus. The posterior fibres of gluteus medius assist with this action (Neumann 2010a). In the fully erect posture, a vertical line through the centre of gravity of
the body passes posterior to a line joining the centres of the femoral heads. The body therefore tends to incline posteriorly but this is counterbalanced by ligamentous tension and congruence and compression of the articular surfaces within the hip joints in the close-packed position. Under increased loading of the trunk or leaning posteriorly, these resistive but passive factors are assisted by active force produced by the hip joint flexors. In swaying anteriorly at the ankles, or when the arms are stretched forwards, and also in forward-bending at the hip, the line of body weight moves anterior to the medial-lateral axis of rotation through the hip joints. The posture adopted, or the rate of change of posture, is largely controlled by the hamstrings, which, besides being powerful flexors of the knee, are strong extensors of the hip. Gluteus maximus becomes particularly active when the thigh is extended against resistance, as in rising from a bending position or during climbing.

Abduction is produced by glutei medius and minimus, assisted by tensor fasciae latae, piriformis and sartorius. The motion is limited by adductor muscle tension, the pubofemoral ligament and the extreme medial bands of the descending part of the iliofemoral ligament. The abductor muscles, most notably glutei medius and minimus, are active periodically at precise phases of the walking or running cycle to ensure coronal plane stability of the pelvis.

Adduction is produced by adductors longus, brevis and magnus and by gracilis assisted by pectineus, quadratus femoris and the inferior fibres of gluteus maximus. The range of adduction is limited by the increasing tension in the abductor muscles, the transverse part of the iliofemoral ligament and the fascia lata of the thigh.

Medial rotation is produced by the anterior fibres of glutei minimus and medius, and assisted by tensor fasciae latae and most adductor muscles. The strength of medial rotation naturally increases as the hip is flexed because this position increases the moment arm of most medial rotator muscles (Delp et al 1999). Medial rotation is limited by tension in lateral rotator muscles such as piriformis, the ischiofemoral ligament and the adjacent posterior joint capsule (Wagner et al 2012).

Lateral rotation is produced by gluteus maximus, obturator internus, superior and inferior gemelli, quadratus femoris and piriformis, and it is assisted by obturator externus and sartorius. Lateral rotation, a stronger motion than medial rotation, is limited by tension in the medial rotator muscles and the transverse part of the iliofemoral ligament (Myers et al 2011).

## Forces acting on the hip

In quiet upright standing, the femoral heads support the weight of the trunk, upper limbs and head. About two-thirds of body weight is located above the hips, and so each femoral head normally accepts about one-third of body weight. This force is compressive in nature, as gravity pulls the acetabula against the femoral heads. When viewed in the sagittal plane, minimal muscle forces suffice to maintain equilibrium as long as the weight of the upper body is directed over the femoral heads. If the upper body leans anteriorly, shifting the upper body weight vector anteriorly beyond the femoral heads and thereby producing a hip flexion moment, posterior thigh muscles can counter such rotation. As the capsular ligaments of the hip slacken in flexion, none of them is able to resist the forward lean.

During walking, hip joint compression force varies from one-third of body weight, when both feet are on the ground, to some four times body weight when the other foot is lifted. The large compression forces generated while walking originate primarily from two sources: gravity and muscle activation. During the stance phase, gravity pulls the upper body and acetabulum inferiorly on the femoral heads (as described above for quiet standing). More significantly, each femoral head is pushed superiorly against its socket as the foot strikes and then pushes against the ground. Although activation of muscles is responsible for a greater portion of joint compression at the hip, the influences of gravity and of capsular tension (when the hip joint is extended) should not be ignored.

As the lower limb is swinging anteriorly and free of contact with the ground, hip joint compression force is estimated to be at about $50 \%$ of body weight (Correa et al 2010). Such joint force is essentially myogenic. Consider, for example, a contracting iliopsoas pulling the femoral head against the acetabulum as it simultaneously advances the lower limb in walking.

In contrast, during the stance phase of walking, hip joint forces may reach four times body weight. These forces are mainly caused by the pull of the hip abductor muscles (primarily gluteus medius, gluteus minimus and tensor fasciae latae). This muscular action, essential to

Two terms can conveniently describe the kinematics (movements) at the hip. Femoral-on-pelvic hip kinematics describes the rotation of the femur about a relatively fixed pelvis. Conversely, pelvic-on-femoral (hip) kinematics describes the rotation of the pelvis, and often the superimposed trunk, over a relatively fixed femur or set of femurs. Regardless of whether the femur or the pelvis is the moving segment, kinematics are described for all three cardinal planes on the assumption that movements are initiated from the anatomical position.

Flexion and extension are motions that occur in the sagittal plane. To appreciate the hip joint arthrokinematics that accompany the associated femoral-on-pelvic motions, the length and angulation of the femoral neck in relation to the shaft must be considered. As the hip (femur) is flexed about $120^{\circ}$ towards the anterior thoracic wall, or extended $10-20^{\circ}$ beyond the plane of the trunk, the femoral head 'spins' in the acetabulum about a side-to-side (medial-lateral) axis of rotation. Conversely, from a pelvic-on-femoral perspective, the acetabula rotate around a similar axis in flexion and extension relative to

B

Fig. 81.12 Hip flexion shown from two kinematic perspectives, as indicated by the green curved arrows. A, Femoral-on-pelvic flexion. B, Pelvic-on-femoral flexion. Note the directional-specific motion of the lumbar spine in $\mathbf{B}$; this is a necessity, assuming the trunk remains upright. Tissues that are elongated or pulled taut are indicated by orange arrows; tissues slackened are indicated by blue wavy arrows. In all cases, muscles are assumed to be inactive but stretched. The red circle indicates the axis of rotation at the hip. (With permission from Neumann D, Kinesiology of the Musculoskeletal System, 2nd ed, Elsevier, Mosby. Copyright 2010.)
stationary femoral heads (compare Figs 81.12A and B). Depending on the accompanying trunk movement, the lumbar vertebrae will either flex or extend in rhythm with the rotating pelvis. Consider, for example, a short-arc anterior rotation (or tilt) of the pelvis over both femurs while the upper trunk remains stationary. During this motion, the lumbar vertebrae extend slightly towards greater lordosis. By comparison, rotating both the pelvis and the trunk over both femurs (as in reaching towards the ground with knees held extended), the pelvis and the thoracolumbar vertebrae both flex, thereby augmenting the overall forward motion of the body as a whole.

Abduction and adduction of the hip joint occur in the coronal plane about an anterior-to-posterior axis of rotation through the femoral head. With the pelvis fixed, the femur abducts about $40^{\circ}$ (Fig. 81.13A). Conversely, pelvic-on-femoral (hip) motions that occur in the coronal

Fig. 81.14 Hip adduction shown from a pelvic-on-femoral perspective, as indicated by the green curved arrow. Note the directional-specific motion of the lumbar spine; this is a necessity, assuming the trunk remains upright. Tissues that are elongated or pulled taut are indicated by orange arrows. In all cases, muscles are assumed to be inactive but stretched. The red circle indicates the axis of rotation at the hip. (With permission from Neumann D, Kinesiology of the Musculoskeletal System, 2nd ed, Elsevier, Mosby. Copyright 2010.)
plane are best described assuming a person is bearing weight firmly on one lower limb, referred to hereafter as the 'support' hip. Abduction at the support hip occurs by raising the contralateral side of the pelvis a few degrees (Fig. 81.13B). Marked tightness in hip adductor muscles or medial capsule of the hip on the support hip can limit this pelvic motion. Adduction at the support hip occurs by lowering the contralateral side of the pelvis (Fig. 81.14). Assuming that the trunk remains nearly stationary during these short-arc pelvic-on-femoral motions, the lumbar spine laterally bends slightly as a way to offset undesired thoracic motion. The lumbar vertebrae, therefore, act to decouple motion of the pelvis (moving on the femur) from undesired motions between the thorax and pelvis (Neumann 2010b). This decoupling function of the lumbar vertebrae is especially useful during walking as a way of partially fixing the spatial orientation of the upper thorax, as well as the associated craniocervical region and the embedded senses of vision and equilibrium. This kinematic linkage between the spine, pelvis and femur exists in essentially all hip motions to varying degrees, and is an essential characteristic of normal walking.

Medial and lateral rotation of the hip joint occurs in the transverse (horizontal) plane about a vertical axis of rotation. With the pelvis

Fig. 81.15 The right lateral rotator muscles of the hip contract to produce lateral rotation of the right hip, from a pelvic-on-femoral perspective. Back extensor muscles are also shown active, rotating the lower trunk to the left. (With permission from Neumann D, Kinesiology of the Musculoskeletal System, 2nd ed, Elsevier, Mosby. Copyright 2010.)
fixed, the femur rotates medially about $35^{\circ}$. The extended hip rotates laterally about $45^{\circ}$. Transverse plane movements of the hip joint from a pelvic-on-femoral perspective, as explained above, are best described assuming a person is bearing weight over a given 'support' hip. Consider, for example, running and rapidly changing directions while one lower limb is securely planted on the ground. During lateral rotation of the support hip, the iliac crest located contralateral to the support limb rotates posteriorly in the transverse plane, an action driven strongly by gluteus maximus (Fig. 81.15). Conversely, pelvic-on-femoral (hip) medial rotation occurs as the contralateral iliac crest region rotates anteriorly.

As stated above, the axis of rotation for transverse plane motions at the hip joint occurs about a vertical axis of rotation. The slight anterior bowing for the femoral shaft, coupled with the natural angle between the femoral shaft and neck, means that this axis is not intramedullary; rather it passes just posterior and slightly medial to the shaft. The position of this 'mechanical' (versus medullary) axis becomes biomechanically relevant when considering the actions and moment arms of certain hip muscles, most notably for adductor muscles that also function as medial rotators.

Fig. 81.16 While standing on one (left) lower limb, body weight (BW) line of force, i.e. total body weight minus the weight of the left lower limb, passes just lateral to the midline, exerting a counterclockwise moment about the stance hip $(B W \times b)$. An equal but clockwise moment is required about the stance hip for mechanical equilibrium: a moment produced by the force of the abductors (Ab), whose lever arm (a) is approximately half that of the lever arm (b). The two moments are in balance when ( $\mathrm{Ab} \times \mathrm{a}=\mathrm{BW} \times \mathrm{b}$ ). The abductor force required to maintain equilibrium is approximately twice that of BW, resulting in a joint reaction force (JRF) about 2.5 times that of total weight of the subject's body.
normal bipedal gait, provides the necessary coronal plane stabilization of the pelvis relative to the femoral head of the stance limb.

The importance of hip abductor muscle activation during the stance phase of walking can be well appreciated by understanding the simple mechanics of standing on one limb (Fig. 81.16). The lever arm (a) of
left hip abductor force $(\mathrm{Ab})$ is about half the length of the lever arm (b) associated with body weight (BW). To balance the competing (coronal plane) gravitational moments about the stance hip, the hip abductors must produce a force about twice superincumbent body weight. Thus, the acetabulum is pulled inferiorly against the femoral head not only by the body weight but also by the force created by the activated hip abductor muscles. The sum of the muscular and gravitational forces equals about 2.5 times the total weight of the person. These downward forces on the head of the femur are counteracted by an upward joint reaction force of equal magnitude (JRF in Fig. 81.16). Both magnitude and direction of the joint reaction force are strongly influenced by the pull of the hip abductor muscles.

The above analysis is for standing quietly on one limb. During walking, however, the joint reaction force routinely reaches at least four times body weight, reflecting both the high ground reaction forces and the need for the hip abductor muscles to decelerate rotations of the pelvis (Bergmann et al 1993). Hip joint forces reach still greater values during running or stair-climbing (see review in Stansfield and Nicol 2002).

Compression forces produced by the gluteus medius during stance phase are directed superiorly and slightly anteromedially within the acetabulum (Correa et al 2010), a region naturally protected by thick articular cartilage. In the healthy hip joint, the muscular-based compressive forces serve important functions, such as helping to stabilize the articulation and stimulate the morphological development of the growing hip. Forces that cross the hip typically do not harm the joint because they are absorbed by healthy articular cartilage and congruent joint surfaces. Failure of these conditions to absorb forces in the joint may predispose to osteoarthritis of the hip.

The three factors that influence both the magnitude and the direction of compressive forces acting on the hip are the position of the centre of gravity; the abductor moment arm, which is a function of neck length (offset) and neck-shaft angle; and the amount of body weight. Shortening of the lever arm of the abductors, such as occurs in coxa valga or excessive femoral anteversion, or in a remodelled proximal femur in advanced hip osteoarthritis, would increase abductor muscle demand and thus increase joint reaction force as well. If the muscles cannot meet this demand, the pelvis cannot be held level in standing on one limb, a problem known as either a compensated or an uncompensated Trendelenburg sign. The Trendelenburg sign is said to be compensated if the pelvis is brought towards the affected stance limb as a way of shortening the body weight's lever arm. Conversely, the Trendelenburg sign is said to be uncompensated if the pelvis drops away from the affected stance limb uncontrollably.

The knee is the largest synovial joint in the body. It consists of three functional compartments that collectively form a dynamic, specialized hinge joint. During propulsion, the knee is able to withstand impressive weight-bearing loads while conducting precision movements, providing a stable yet fluid mechanism for relatively efficient bipedal locomotion. The complex arrangement of intra- and extracapsular ligaments that helps to counter the considerable biomechanical demands that are imposed on the joint can also be involved in disease (i.e. tricompartment disease).

## SKIN AND SOFT TISSUES

## SKIN

## Innervation

## Infrapatellar branch of the saphenous nerve

The infrapatellar branch of the saphenous nerve reaches the anterior aspect of the knee from the medial side. It is invariably divided in the medial surgical approaches to the knee, which accounts for the numbness that inevitably occurs following such procedures. A painful neuroma may form if the nerve is partially sectioned, e.g. by the incision for an arthroscopy portal or a small medial arthrotomy. Unfortunately, the position of the nerve relative to the line of the joint is variable. In most cases, it crosses just below the joint line, passing over the patellar ligament at its insertion on to the tibia. For further details, see Tennant et al (1998).

## Peripatellar plexus

Proximal to the knee, the infrapatellar branch of the saphenous nerve connects with branches of the medial and intermediate femoral cutaneous nerves, and lateral femoral cutaneous nerve. Distal to the knee, it connects with other branches of the saphenous nerve. This fine, subcutaneous network of communicating nerve fibres over and around the patella is termed the peripatellar plexus.

## Cutaneous vascular supply and lymphatic drainage

The arterial supply of the skin covering the knee is derived from genicular branches of the popliteal artery, the descending genicular branch of the femoral artery, and the anterior recurrent branch of the anterior tibial artery, with small contributions from muscular branches to vastus medialis and the posterior thigh muscles (Fig. 82.1). For further details, consult Cormack and Lamberty (1994).

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic drainage is initially to the superficial inguinal nodes, possibly also to the popliteal nodes, and then to the deep inguinal nodes.

## SOFT TISSUES

## Popliteal fossa

The popliteal fossa (Figs 82.2-82.3) is a diamond-shaped region posterior to the knee, bordered by posterior compartment muscles of the thigh and leg. The boundaries are biceps femoris proximolaterally; semimembranosus and the overlying semitendinosus proximomedially; the lateral head of gastrocnemius with the underlying plantaris distolaterally; and the medial head of gastrocnemius distomedially. The anterior boundary (or floor) of the fossa is formed, in proximodistal sequence, by the popliteal surface of the femur, the oblique popliteal
ligament (overlying the posterior surface of the capsule of the knee joint), and the posterior aspect of the proximal tibia covered by popliteus and its fascia. The deep fascia (fascia musculorum) acts as the roof of the fossa and is continuous with the fascia lata proximally and with the deep fascia of the leg distally. It is a dense layer that is strongly reinforced by transverse fibres and is often perforated by the short saphenous vein and medial and lateral sural cutaneous nerves; these structures are useful landmarks in the direct posterior approach to the knee joint.

The popliteal fossa is approximately 2.5 cm wide. Distally, its contents are protected and hidden by the heads of gastrocnemius, which contact each other. The fossa contains the popliteal vessels (see Fig. 82.2; Fig. 82.4), tibial and common fibular nerves, short saphenous vein, medial and lateral sural cutaneous nerves, posterior femoral cutaneous nerve, articular branch of the obturator nerve, lymph nodes, fat and a variable number of bursae. The tibial nerve descends centrally immediately anterior to the deep fascia, crossing the vessels posteriorly from lateral to medial. The common fibular nerve descends laterally immediately medial to the tendon of biceps femoris. When the popliteal vessels enter the proximal region of the popliteal fossa, they maintain a side-by-side relationship, which shifts to an over-under relationship as they descend through the fossa and are held together by dense areolar tissue within the fossa. This may potentially compromise the popliteal artery in distal femoral fractures. The popliteal vein is generally located posterior to the artery. Proximally, the vein lies lateral to the artery, crossing to its medial side distally. At times, the popliteal vein may be duplicated, so that the artery lies between the veins, which are usually bridged by connecting channels. An articular branch from the obturator nerve descends along the artery to the knee. Six or seven popliteal nodes are embedded in the fat, one under the deep fascia near the termination of the short saphenous vein, one between the popliteal artery and knee joint, and the others intimate with the popliteal vessels.

## BONES

## FEMUR, TIBIA AND FIBULA

The femur is described on pages 1348-1353 and the tibia and fibula are described on pages 1401-1405 and 1405, respectively.

## PATELLA

The patella is the largest sesamoid bone in the body (Figs 82.5-82.6) and is embedded in the tendon of quadriceps femoris, lying anterior to the distal femur (femoral condyles). It is flat, distally tapered and proximally curved, and has anterior and articular surfaces, three borders and an apex, which is the distal end of the bone. Most surfaces and borders are palpable. With the knee in extension, the apex is positioned proximal to the line of the knee joint by $1-2 \mathrm{~cm}$.

The subcutaneous, convex anterior surface is perforated by numerous nutrient vessels. It is longitudinally ridged, separated from the skin by the subcutaneous prepatellar bursa, and covered by an expansion from the tendon of quadriceps femoris, which blends distally with superficial fibres of the patellar ligament (inaccurately named because this structure is the continuation of the tendon of quadriceps femoris). The posterior surface has a proximal smooth, oval articular area, crossed by a smooth vertical ridge, which fits the intercondylar groove on the femoral patellar surface and divides the patellar articular area into medial and lateral facets; the lateral is usually larger. Each facet is divided by faint horizontal lines into approximately equal thirds. A seventh 'odd' facet is present as a narrow strip along the medial border of the patella; it contacts the medial femoral condyle in extreme knee flexion. Distal to the articular surface, the apex is roughened by the attachment of the patellar ligament. Proximal to this, the area between the roughened apex and the articular margin is covered by an infrapatellar fat pad. The patellar articular cartilage is the thickest in the body, reflecting the magnitude of the stresses to which it is subjected.

The thick superior border (surface) slopes anteroinferiorly. The medial and lateral borders are thinner and converge distally; the expansions of the tendons of vasti medialis and lateralis (medial and lateral patellar retinacula, respectively) are attached to them. The lateral

Fig. 82.3 Muscles of the calf, superficial view including the boundaries of the popliteal fossa. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
retinaculum receives contributions from the iliotibial tract. Ossification occasionally extends from the lateral margin of the patella into the tendon of vastus lateralis.

The shape of the patella can vary and certain configurations are associated with patellar instability. Not infrequently, a bipartite and, less commonly, a tripartite patella are seen on imaging. The bone seems to be in separate parts, usually with a smaller superolateral fragment: this has long been attributed to the presence of a separate ossification centre but, in some cases, could represent failed union following either a stress fracture or a violent contraction of quadriceps femoris (e.g. landing on the feet after jumping from a substantial height) resulting in a traumatic fracture.

Structure The patella consists of more or less uniformly dense trabecular bone, covered by a thin compact lamina. Trabeculae beneath the anterior surface are parallel to the surface; elsewhere, they radiate from the articular surface into the substance of the bone.

Muscle attachments Quadriceps femoris is attached to the superior surface, except near its posterior margin; the attachment extends distally on to the anterior surface. The attachment for rectus femoris is anteroinferior to that for vastus intermedius. Rough markings can be traced in continuity around the periphery of the bone from the anterosuperior surface to the deep surface of the apex. Those at the lateral and medial

Fig. 82.4 The left popliteal, posterior tibial and fibular arteries, posterior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
borders represent the attachments of vasti lateralis and medialis, and those at the apex represent the attachment of the patellar ligament.

Vascular supply The arterial supply of the patella is derived from the genicular anastomosis, particularly from the genicular branches of the popliteal artery and from the anterior tibial recurrent artery. An anatomical study in children and fetuses confirmed that this network is already well developed in these age groups (Hamel et al 2012).

Ossification Several centres appear during the third to sixth years and these coalesce rapidly. Accessory marginal centres appear later and fuse with the central mass.

## JOINTS

## SUPERIOR TIBIOFIBULAR JOINT

The superior (proximal) tibiofibular joint is a synovial joint (plane variety) between the lateral tibial condyle and head of the fibula.

Articulating surfaces The articulating surfaces vary in size, form and inclination. The joint line may be transverse or oblique (in the

Fig. 82.5 A, Left patella, anterior aspect. Key: 1, area of attachment of rectus femoris; 2, medial border: attachment of medial retinaculum (expansion); 3, apex; 4, area of attachment of vastus intermedius; 5 , markings of attachment of tendon of quadriceps femoris; 6, lateral border: attachment of lateral retinaculum (expansion). B, Left patella, articular (posterior) surface. Key: 1, upper lateral facet: in contact with femur in flexion of the knee; 2, lower lateral facet: in contact with femur in extension of the knee; 3, area overlain by edge of circumferential fat pad; 4, upper medial facet: in contact with femur in flexion of the knee; 5 , medial vertical ('odd') facet: in contact with femur in extreme flexion of the knee; 6 , lower medial facet: in contact with femur in extension of the knee; 7, ridge; 8, area covered by infrapatellar fat pad; 9, area for attachment of patellar ligament.
latter case, the joint surfaces are inclined at an angle of greater than $20^{\circ}$ ). The fibular facet is usually elliptical or circular, and almost flat or slightly grooved. The surfaces are covered with hyaline cartilage.

The volume of articular cartilage peaks at Tanner stage 2; boys gain articular cartilage faster than girls. The rate of cartilaginous volume development is $+233 \mu \mathrm{l} /$ year for the patella, $+350 \mu \mathrm{~L} /$ year for the medial tibial compartment and $+256 \mu \mathrm{~L} /$ year for the lateral tibial compartment (Jones et al 2003).

Fibrous capsule The capsule is attached to the margins of the articular surfaces of the tibia and fibula, and is thickened anteriorly and posteriorly.

Ligaments The ligaments of the superior tibiofibular joint are not entirely separate from the capsule. The anterior ligament is made up of two or three flat bands, which pass obliquely up from the fibular head to the front of the lateral tibial condyle in close relation to the tendon of biceps femoris. The posterior ligament is a thick band that ascends

Fig. 82.6 Anteroposterior (A) and lateral (B) radiographs of the knee of a boy aged 14 years. Key: 1, patella; 2, cartilaginous growth plates; 3 , intercondylar eminence; 4, prolongation of proximal tibial epiphysis and growth plate forming the tibial tuberosity.
obliquely between the posterior aspect of the fibular head and the lateral tibial condyle, covered by the popliteal tendon.

Synovial membrane The synovial membrane of the superior tibiofibular joint is occasionally continuous with that of the knee joint via the subpopliteal recess.

Vascular supply and lymphatic drainage The superior tibiofibular joint receives an arterial supply from the anterior and posterior tibial recurrent branches of the anterior tibial artery. Lymphatics follow the arteries and drain to the popliteal nodes.

Innervation The superior tibiofibular joint is innervated by branches from the common fibular nerve and from the nerve to popliteus.

Factors maintaining stability Stability of the superior tibiofibular joint is maintained by the fibrous capsule and the anterior and posterior ligaments, assisted by the biceps femoris tendon and the interosseous membrane of the leg.

Movements Very little movement other than limited gliding takes place at the superior tibiofibular joint. Some movement must occur in conjunction with movement at the inferior tibiofibular joint; however, surgical fusion (arthrodesis) of the superior tibiofibular joint seems to have no effect on movements of the ankle joint.

Relations The common fibular nerve runs posterior to the head of the fibula, medial to the tendon of biceps femoris, which is closely associated with the anterior capsule. The anterior and posterior tibial branches of the popliteal artery, and the fibular artery are all vulnerable inferomedial to the joint.

## PATELLOFEMORAL JOINT

The patellofemoral joint is a synovial joint and is part of the knee joint.
Articulating surfaces The articular surface of the patella is adapted to that of the femur. The latter extends on to the anterior surfaces of both femoral condyles like an inverted U. Since the whole area is concave transversely and convex in the sagittal plane, it is an asymmetrical sellar surface. The 'odd' facet on the articular surface of the patella contacts the anterolateral aspect of the medial femoral condyle in full
flexion, when the highest lateral patellar facet contacts the anterior part of the lateral femoral condyle. As the knee extends, the middle patellar facets contact the lower half of the femoral surface; in full extension, only the lowest patellar facets are in contact with the femur. In summary, on flexion, the patellofemoral contact point moves proximally and the contact area broadens to cope with the increasing stress that accompanies progressive knee flexion.

Patellar ligament sheath and patellar ligament The patellar ligament is a continuation of the tendon of quadriceps femoris and therefore is inaccurately named. It continues from the patella to the tibial tuberosity (see Figs $80.28,80.31$ ). It is strong, flat and $6-8 \mathrm{~cm}$ in length. Proximally, it is attached to the apex of the patella and adjoining margins, to roughened areas on the anterior surface and to a depression on the distal posterior patellar surface. Distally, it is attached to the superior smooth area of the tibial tuberosity. This attachment is oblique, and is more distal laterally. Its superficial fibres are continuous over the patella with the tendon of quadriceps femoris, the medial and lateral parts of which descend, flanking the patella, to the sides of the tibial tuberosity, where they merge with the fibrous capsule as the medial and lateral patellar retinacula. The patellar ligament is separated from the synovial membrane by a large infrapatellar fat pad and from the tibia by a bursa, and lies within its own well-defined sheath.

In the procedure of tibial osteotomy, the tibia is cut transversely just above the insertion of the patellar ligament. Failure to appreciate the obliquity of the tibial attachment of the tendon may lead to inadvertent division of the tendon during this procedure. The middle third of the patellar ligament may be harvested for surgical repair of a cruciate ligament.

All other aspects of the patellofemoral joint are described with the tibiofemoral joint.

## TIBIOFEMORAL JOINT

The tibiofemoral joint is a complex synovial joint and is part of the knee joint.

## Articulating surfaces

## Proximal tibial surface

The proximal tibial surface (unofficially referred to as the tibial plateau) slopes posteriorly and downwards relative to the long axis of the shaft (Fig. 82.7). The tilt, which is maximal at birth, decreases with age, and

Fig. 82.7 The left tibial plateau. Key: 1, tibial tuberosity; 2, attachment of anterior horn, lateral meniscus; 3, lateral condyle; 4, attachment of posterior horn, lateral meniscus; 5, attachment of anterior horn, medial meniscus; 6, attachment of anterior cruciate ligament; 7, medial condyle; 8 , intercondylar eminence; 9 , attachment of posterior horn, medial meniscus; 10, attachment of posterior cruciate ligament.
is more marked in habitual squatters. The tibial plateau presents medial and lateral articular surfaces (facets) for articulation with the corresponding femoral condyles. The posterior surface, distal to the articular margin, displays a horizontal, rough groove to which the capsule and posterior part of the tibial collateral ligament are attached. The anteromedial surface of the medial tibial condyle is a rough strip, separated from the medial surface of the tibial shaft by an inconspicuous ridge. The medial patellar retinaculum is attached to the medial tibial condyle along its anterior and medial surfaces, which are marked by vascular foramina.

The medial articular surface is oval (long axis anteroposterior) and longer than the lateral articular surface. Around its anterior, medial and posterior margins, it is related to the medial meniscus; the meniscal imprint, wider posteriorly and narrower anteromedially, is often discernible. The surface is flat in its posterior half and the anterior half slopes superiorly about $10^{\circ}$. The meniscus covers much of the posterior surface so that, overall, a concave surface is presented to the medial femoral condyle. Its lateral margin is raised as it reaches the intercondylar region.

The lateral tibial condyle overhangs the shaft of the tibia posterolaterally above a small circular facet for articulation with the fibula. The lateral articular surface is more circular and coapted to its meniscus. In the sagittal plane, the articular surface is fairly flat centrally, and anteriorly and posteriorly the surface slopes inferiorly. Overall, this creates a rather convex surface so that, with the lateral femoral condyle in contact, there are anterior and posterior recesses (triangular in section), which are occupied by the anterior and posterior meniscal 'horns'. Elsewhere, the surface has a raised medial margin that spreads to the lateral intercondylar tubercle. Its articular margins are sharp, except posterolaterally, where the edge is rounded and smooth: here the tendon of popliteus is in contact with bone.

## Intercondylar area

The rough-surfaced area between the condylar articular surfaces is narrowest centrally where there is an intercondylar eminence, the edges of which project slightly proximally as the lateral and medial intercondylar tubercles. The intercondylar area widens behind and in front of the eminence as the articular surfaces diverge (see Fig. 82.7; Fig. 82.8).

The anterior intercondylar area is widest anteriorly. Anteromedially, anterior to the medial articular surface, a depression marks the site of attachment of the anterior horn of the medial meniscus. Behind this, a smooth area receives the anterior cruciate ligament. The anterior horn of the lateral meniscus is attached anterior to the intercondylar eminence, lateral to the anterior cruciate ligament. The eminence, with medial and lateral tubercles, is the narrow central part of the area. The raised tubercles are thought to provide a slight stabilizing influence on the femur. It is believed that the eminence becomes prominent once walking commences and that the tibial condyles transmit the weight of the body through the tibia.

The posterior horn of the lateral meniscus is attached to the posterior slope of the intercondylar area. The posterior intercondylar area inclines down and backwards behind the posterior horn of the lateral meniscus.

Fig. 82.8 The superior aspect of the left tibia, showing the menisci and the attachments of the cruciate ligaments. (With permission from Drake RL, Vogl AW, Mitchell A, et al (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)

Fig. 82.9 Left knee joint, T1-weighted coronal magnetic resonance image (MRI). Key: 1, posterior cruciate ligament; 2, tibial collateral ligament; 3, medial meniscus; 4, lateral meniscus; 5, fibular collateral ligament; 6 , anterior cruciate ligament.

A depression behind the base of the medial intercondylar tubercle is for the attachment of the posterior horn of the medial meniscus. The rest of the area is smooth and provides attachment for the posterior cruciate ligament, spreading back to a ridge to which the capsule is attached.

In a study of Nigerian children, the mean intercondylar distance was 0.2 cm at 1 year of age and there was no significant increase in this distance by the age of 10 years (Omololu et al 2003).

## Femoral surface

The femoral condyles, bearing articular cartilage, are almost wholly convex. Opinions as to the contours of their sagittal profiles tend to vary. One view is that they are spiral with a curvature increasing posteriorly ('a closing helix'), that of the lateral condyle being greater. An alternative view is that the articular surface for contact with the tibia on the medial femoral condyle describes the arcs of two circles. According to this view, the anterior arc makes contact with the tibia near extension and is part of a virtual circle of larger radius than the more posterior arc, which makes contact during flexion. The lateral femoral condyle is believed to describe a single arc and thus to possess a single radius of curvature.

Tibiofemoral congruence is improved by the menisci, which are shaped to produce concavity of the surfaces presented to the femur; the combined lateral tibiomeniscal surface is deeper. The lateral femoral condyle has a faint groove anteriorly, which rests on the peripheral edge of the lateral meniscus in full extension. A similar groove appears on the medial condyle but does not reach its lateral border, where a narrow strip contacts the medial patellar articular surface in full flexion. These grooves demarcate the femoral patellar and condylar surfaces. The differences between the shapes of the articulating surfaces correlate with the movements of the knee joint.

## Menisci

The menisci (semilunar cartilages) are crescentic, intracapsular, fibrocartilaginous laminae (see Fig. 82.8; Fig. 82.9). They serve to widen, deepen and prepare the tibial articular surfaces that receive the femoral condyles. Their peripheral attached borders are thick and convex, and their free, inner borders are thin and concave. Their peripheries are
vascularized by capillary loops from the fibrous capsule and synovial membrane, while their inner regions are less vascular. Tears of the menisci are common. Peripheral tears (e.g. in the vascularized zone) have the potential to heal satisfactorily, especially with surgical intervention. Tears in the less vascular or inner zones seldom heal spontaneously; if surgery is indicated, these menisci are often resected. The meniscal horns are richly innervated compared with the remainder of the meniscus. The central one-third is devoid of innervation (Gronblad et al 1985). The proximal surfaces are smooth and concave, and in contact with the articular cartilage on the femoral condyles. The distal surfaces are smooth and flat, resting on the tibial articular cartilage. Each covers approximately two-thirds of its tibial articular surface. Canal-like structures open on to the surface of the menisci in infants and young children, and may transport nutrients to deeper, less vascular areas

Two structurally different regions of the menisci have been identified. The inner two-thirds of each meniscus consist of radially organized collagen bundles, and the peripheral one-third consists of larger circumferentially arranged bundles (Ghadially et al 1983). Thinner collagen bundles parallel to the surface line the articular surfaces of the inner part, while the outer portion is covered by synovium. This structural arrangement suggests specific biomechanical functions for the two regions: the inner portion of the meniscus is suited to resisting compressive forces while the periphery is capable of resisting tensional forces. With ageing and degeneration, compositional changes occur within the menisci, which reduce their ability to resist tensional forces. Outward displacement of the menisci by the femoral condyles is resisted by firm anchorage of the peripheral circumferential fibres to the intercondylar bone at the meniscal horns.

The menisci spread load by increasing the congruity of the articulation, provide stability by their physical presence and proprioceptive feedback, and may cushion the underlying bone from the considerable forces generated during extremes of flexion and extension of the knee.

## Medial meniscus

The medial meniscus is broader posteriorly and is almost a semicircle in shape (see Fig. 82.8). It is attached by its anterior horn to the anterior tibial intercondylar area in front of the anterior cruciate ligament; the posterior fibres of the anterior horn are continuous with the transverse ligament of the knee (when present). The anterior horn is in the floor of a depression medial to the upper part of the patellar ligament. The posterior horn is fixed to the posterior tibial intercondylar area, between the attachments of the lateral meniscus and posterior cruciate ligament. Its peripheral border is attached to the fibrous capsule and the deep surface of the tibial collateral ligament. The tibial attachment of the meniscus is known as the 'coronary or meniscotibial ligament'. Collectively, these attachments ensure that the medial meniscus is relatively fixed and moves much less than the lateral meniscus.

## Lateral meniscus

The lateral meniscus forms approximately four-fifths of a circle and covers a larger area than the medial meniscus (see Fig. 82.8). Its breadth, except at its short tapered horns, is more or less uniform. It is grooved posterolaterally by the tendon of popliteus, which separates it from the fibular collateral ligament. Its anterior horn is attached in front of the intercondylar eminence, posterolateral to the anterior cruciate ligament, with which it partly blends. Its posterior horn is attached behind this eminence, in front of the posterior horn of the medial meniscus. Its anterior attachment is contorted so that the free margin faces posterosuperiorly, and the anterior horn rests on the anterior slope of the lateral intercondylar tubercle. Near its posterior attachment, it commonly sends a posterior meniscofemoral ligament superomedially behind the posterior cruciate ligament to the medial femoral condyle. An anterior meniscofemoral ligament may also connect the posterior horn to the medial femoral condyle anterior to the posterior cruciate ligament. The meniscofemoral ligaments are often the sole attachments of the posterior horn of the lateral meniscus. More laterally, part of the tendon of popliteus is attached to the lateral meniscus, and so mobility of its posterior horn may be controlled by the meniscofemoral ligaments and by popliteus. A meniscofibular ligament occurs in most knee joints. As with the medial meniscus, there is a tibial attachment via the so-called coronary ligament, but the meniscus has no peripheral bony attachment in the region of popliteus; in the surgical literature, this gap is referred to as the popliteus hiatus.

Discoid lateral meniscus A discoid lateral meniscus occasionally occurs, often bilaterally. The distinguishing features of a discoid lateral meniscus are its shape and posterior ligamentous attachments. The following classification of the abnormality is based on the work of

Watanabe et al (1979). In its mildest form, the partial discoid meniscus is simply a wider form of the normal lateral meniscus. The acute, medial free edge is interposed between the femoral and tibial condyles but it does not completely cover the tibial plateau. A complete discoid meniscus appears as a biconcave disc with a rolled medial edge and covers the lateral tibial plateau. The Wrisberg type of meniscus has the same shape as a complete discoid meniscus but its only peripheral posterior attachment is by the meniscofemoral ligaments. In this case, the normal tibial attachment of the posterior horn of the lateral meniscus is lacking but the posterior meniscofemoral ligament persists. As a result, this type of meniscus is attached anteriorly to the tibia and posteriorly to the femur, which renders the posterior horn unstable. Under these circumstances, the meniscus is liable to become caught between the femur and tibia: this accounts for the classic presenting symptom of the 'clunking knee' in some patients. The aetiology of discoid meniscus is not clear. Most are asymptomatic and are often found by chance at arthroscopy. However, they may cause difficulty in gaining access to the lateral compartment at arthroscopy. A discoid medial meniscus is extremely rare.

## Transverse ligament of the knee

The transverse ligament of the knee connects the anterior convex margin of the lateral meniscus to the anterior horn of the medial meniscus (see Fig. 82.8). It varies in thickness and is often absent. Its exact role is conjectural, although one study found that the ligament was slightly taut in knee extension (Tubbs et al 2008); presumably, it helps to decrease tension generated in the longitudinal circumferential fibres of the menisci when the knee is subjected to load. A posterior meniscomeniscal ligament is sometimes present.

## Meniscofemoral ligaments

The two meniscofemoral ligaments connect the posterior horn of the lateral meniscus to the inner (lateral) aspect of the medial femoral condyle (Figs 82.10-82.11). The anterior meniscofemoral ligament (ligament of Humphrey) passes anterior to the posterior cruciate ligament. The posterior meniscofemoral ligament (ligament of Wrisberg) passes behind the posterior cruciate ligament and attaches proximal to the margin of attachment of the posterior cruciate.

2, tendon of quadriceps femoris; 3, patellar articular cartilage; 4, patella; 5 , femoral articular cartilage; 6, patellar ligament; 7, infrapatellar fat pad; 8 , medial meniscus.

Anatomical studies found that at least one meniscofemoral ligament was almost always present in the cadaveric knees examined, while both sometimes coexisted (Gupte et al 2003). Biomechanical studies have revealed the cross-sectional area and strength of the meniscofemoral ligaments to be comparable to those of the posterior fibre bundle of the posterior cruciate ligament.

The meniscofemoral ligaments are believed to act as secondary restraints, supporting the posterior cruciate ligament in minimizing displacement caused by posteriorly directed forces on the tibia. These ligaments are also involved in controlling the motion of the lateral meniscus in conjunction with the tendon of popliteus during knee flexion.

## Soft tissues

Recent advances in imaging and surgery of knee ligaments have contributed to an improved understanding of the anatomy of the medial and lateral soft tissues of the knee.

## Capsule and retinacula

The joint capsule is a fibrous membrane of variable thickness. Anteriorly, it is replaced by the patellar ligament and does not pass proximal to the patella or over the patellar area. Elsewhere, it lies deep to expansions from vasti medialis and lateralis, separated from them by a plane of vascularized loose connective tissue. The expansions are attached to the patellar margins and patellar ligament, extending back to the corresponding collateral (tibial and fibular) ligaments and distally to the tibial condyles. They form medial and lateral patellar retinacula, the lateral being reinforced by the iliotibial tract.

Posteriorly, the capsule contains vertical fibres that arise from the articular margins of the femoral condyles and intercondylar fossa, and from the proximal tibia. The fibres mainly pass downwards and somewhat medially. The oblique popliteal ligament is a well-defined thickening across the posteromedial aspect of the capsule, and is one of the major extensions from the tendon of semimembranosus.

## Medial soft tissues

The medial soft tissues (see Fig. 80.28; Fig. 82.12) are arranged in three layers (Warren and Marshall 1979).

Layer 1 Layer 1 is the most superficial and is the deep fascia that invests sartorius. The saphenous nerve and its infrapatellar branch are superficial to the deep fascia of the leg. Sartorius inserts into the fascia as an expansion rather than as a distinct tendon. The fascia spreads inferiorly and anteriorly to lie superficial to the distinct and readily identifiable tendons of gracilis and semitendinosus and their insertions. The latter two tendons are commonly harvested for surgical reconstruction of damaged cruciate ligaments. To gain access to them, the upper edge of sartorius can be identified. The sartorius (layer 1) fascia is then incised to reveal the tendons. Deep to the tendons is the anserine bursa, which overlies the superficial part of the tibial collateral ligament; this bursa sometimes becomes inflamed, especially in track and field athletes. Posteriorly, layer 1 overlies the tendons of gastrocnemius and the structures of the popliteal fossa. Anteriorly, layer 1 blends with the anterior limit of layer 2 and the medial patellar retinaculum. More inferiorly, layer 1 blends with the periosteum.

A condensation of tissue passes from the medial border of the patella to the medial epicondyle of the femur (the medial patellofemoral ligament), the anterior horn of the medial meniscus (the meniscopatellar ligament), and the medial tibial condyle (the patellotibial ligament).

Layer 2 Layer 2 is the plane of the superficial part of the tibial collateral ligament, which means that the tendons of gracilis and semitendinosus lie between layers 1 and 2. The superficial part of the tibial collateral ligament has vertical and oblique portions. The former contains vertically orientated fibres that pass from the medial epicondyle of the femur to a large insertion on the medial surface of the proximal end of the tibial shaft. It extends to an area about 5 cm distal to the joint line. Its anterior edge is rolled and easily seen just posterior to the insertions of gracilis and semitendinosus once layer 1 has been opened. The posteriorly placed oblique fibres run posteroinferiorly from the medial epicondyle of the femur to blend with the underlying layer 3 (capsule), effectively to insert on the posteromedial tibial articular margin and posterior horn of the medial meniscus. This area is reinforced by a part of the insertion of semimembranosus. There is a vertical split in layer 2 anterior to the superficial part of the tibial collateral ligament. The fibres anterior to the split pass superiorly to blend with vastus medialis fascia and layer 1 in the medial patellar retinaculum. The fibres posterior to the split pass superiorly to the medial epicondyle and thence anteriorly as the medial patellofemoral ligament.

Layer 3 Layer 3 is the capsule of the knee joint and can be separated from layer 2 everywhere except anteriorly close to the patella, where it blends with the more superficial layers. Deep to the superficial part of the tibial collateral ligament it is thick and has vertically orientated fibres that make up the deep medial part of the tibial collateral ligament. It sends fibres to the medial meniscus. Anteriorly, the separation of the superficial and deep parts of the tibial collateral ligament is distinct. Posteriorly, layers 2 and 3 blend to form a conjoined posteromedial capsule.

## Lateral soft tissues

The lateral soft tissues (see Fig. 82.12; Fig. 82.13) are also arranged in three layers (Seebacher et al 1982), which collectively have been referred to as the lateral collateral ligamentous complex (Nissman et al 2008) The most superficial layer is the lateral patellar retinaculum. The middle layer consists of the fibular collateral popliteofibular, fabellofibular and arcuate ligaments. The recently described anterolateral ligament of the knee may exist in this layer (Claes et al 2013). The deep layer is the lateral part of the capsule.

The lateral patellar retinaculum consists of superficial oblique and deep transverse portions. The former runs from the iliotibial tract to the

Fig. 82.13 The left knee joint, lateral aspect. The synovial cavity is distended and the synovial membrane appears grey. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
patella. The latter is thicker and subdivided into three parts: the lateral patellofemoral ligament, running from the lateral patellar border to the lateral epicondyle of the femur; the transverse retinaculum, running from the iliotibial tract to the mid-patella; and the patellotibial band, running from the patella to the lateral tibial condyle.

The fascia lata and the iliotibial tract lie posterior to the lateral retinaculum. They come together distally to insert on to the tibia at a tubercle (Gerdy's tubercle) on the anterolateral proximal tibia; some fibres continue to insert on the tibial tuberosity. Proximally, the fascia lata merges with the lateral intermuscular septum. Posteriorly, it blends with the fascia over biceps femoris. Here, as it emerges from behind the biceps femoris tendon, the common fibular nerve lies in a thin layer of fat bound by the fascia.

The fibular collateral ligament arises from the lateral epicondyle of the femur posterior to the popliteus insertion and just proximal to the groove for popliteus. It is a cord-like structure that passes distally, superficial to the popliteus tendon and deep to the lateral retinaculum, to attach to the fibular head, where it blends with the biceps femoris tendon just anterior to the apex of the head of the fibula. It is separated from the capsule by a thin layer of fat and the inferior lateral genicular vessels.

The single most important stabilizer of the posterolateral knee is the popliteofibular (short external lateral) ligament. It passes from the popliteus tendon at a level just below the joint line, posteriorly, laterally and inferiorly, to the apex of the head of the fibula. As a passive 'tether' combined with the popliteus tendon proximal to it, it resists lateral rotation of the tibia. Its connection to the tendon of popliteus also allows 'dynamic' tensioning.

The fabellofibular ligament is a condensation of fibres that runs either from the fabella (a sesamoid bone sometimes found within the tendon of the lateral head of gastrocnemius) or from the lateral head of gastrocnemius (if the fabella is absent), to the apex of the head of the fibula. The arcuate ligament is a condensation of fibres that runs from the apex of the head of the fibula, posteromedially over the emerging tendon of popliteus below the level of the tibial joint surface, to the tibial intercondylar area. The lateral joint capsule is thin and blends posteriorly with the arcuate ligament. Anteriorly, it forms the weak, lax coronary or meniscotibial ligament, which attaches the inferior border of the meniscus to the lateral tibia.

## Ligaments

## Cruciate ligaments

The cruciate ligaments, so named because they cross each other, are very strong, richly innervated intracapsular structures. The point of crossing is located a little posterior to the articular centre. They are named anterior and posterior with reference to their tibial attachments (Figs 82.14-82.15; see Fig. 82.17). A synovial membrane almost surrounds the ligaments but is reflected posteriorly from the posterior cruciate ligament to adjoining parts of the capsule; the intercondylar part of the posterior region of the fibrous capsule therefore has no synovial covering.

Fig. 82.14 The left knee joint. A, Anterior aspect in full flexion.
B, Posterior aspect in extension. (With permission from Drake RL, Vogl AW, Mitchell A, et al (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)

Fig. 82.15 The intercondylar notch at arthroscopy, showing the anterior cruciate and transverse ligaments of the knee. (Courtesy of Smith and Nephew Endoscopy.)

Anterior cruciate ligament The anterior cruciate ligament is attached to the anterior intercondylar area of the tibia, just anterior and slightly lateral to the medial intercondylar tubercle, partly blending with the anterior horn of the lateral meniscus (see Fig. 82.8). It ascends posterolaterally, twisting on itself and fanning out to attach high on the posteromedial aspect of the lateral femoral condyle (Girgis et al 1975). The average length and width of an adult anterior cruciate ligament are 38 mm and 11 mm , respectively. It is formed of two, or possibly three, functional bundles that are not apparent to the naked eye but can be demonstrated by microdissection techniques. The bundles are named anteromedial, intermediate and posterolateral, according to their tibial attachments (Amis and Dawkins 1991).

Posterior cruciate ligament The posterior cruciate ligament is thicker and stronger than the anterior cruciate ligament (see Fig. 82.8), the average length and width of an adult posterior cruciate ligament being 38 mm and 13 mm , respectively. It is attached to the lateral surface of the medial femoral condyle and extends up on to the anterior part of the roof of the intercondylar fossa, where its attachment is extensive in the anteroposterior direction. Its fibres are adjacent to the articular surface. They pass distally and posteriorly to a fairly compact attachment posteriorly in the intercondylar region and in a depression on the adjacent posterior tibia. This gives a fan-like structure in which fibre orientation is variable. Anterolateral and posteromedial bundles have been defined; they are named (against convention) according to their femoral attachments. The anterolateral bundle tightens in flexion while the posteromedial bundle is tight in extension of the knee. Each bundle slackens as the other tightens. Unlike the anterior cruciate ligament, it is not isometric during knee motion, i.e. the distance between attachments varies with knee position. The posterior cruciate ligament ruptures less commonly than the anterior cruciate ligament and rupture is usually better tolerated by patients than rupture of the anterior cruciate ligament.

## Synovial membrane, plicae and fat pads

The synovial membrane of the knee is the most extensive and complex in the body. It forms a large suprapatellar bursa between quadriceps femoris and the lower femoral shaft proximal to the superior patellar border (Fig. 82.16). The bursa is an extension of the joint cavity. The attachment of articularis genus to its proximal aspect prevents the bursa from collapsing into the joint. Alongside the patella, the membrane extends beneath the aponeuroses of the vasti, especially under vastus medialis. It extends proximally a hand's breadth above the superior pole of the patella. Distal to the patella, the synovial membrane is separated from the patellar ligament by an infrapatellar fat pad. Where it lies beneath the fat pad, the membrane projects into the joint as two fringes, alar folds, which bear villi. The folds converge posteriorly to form a single infrapatellar fold or plica (ligamentum mucosum), which curves posteriorly to its attachment in the femoral intercondylar fossa (Fig. 82.17). This fold may be a vestige of the inferior boundary of an originally separate femoropatellar joint. The extent of the infrapatellar plica ranges from a thin cord to a complete sheet that can obstruct the passage of instruments during knee arthroscopy. When substantial, it has been mistaken for the anterior cruciate ligament, which is directly posterior to it. The medial plica extends in the midline anteriorly from the medial alar fold medially to the suprapatellar bursa. Occasionally,

Fig. 82.16 A sagittal section through the left knee joint, lateral aspect.

Fig. 82.17 The left knee joint in full flexion. The tendon of quadriceps femoris has been sectioned and the patella retracted distally. Compare with Figure 82.14A.
it can be thickened and inflamed, usually following acute or chronic trauma.

The suprapatellar plicae are remnants of an embryonic septum that completely separates the suprapatellar bursa from the knee joint. Occasionally, a septum persists, either in its entirety or perforated by a small peripheral opening.

The infrapatellar fat pad is the largest part of a circumferential extrasynovial fatty ring that extends around the patellar margins (Newell 1991).

At the sides of the joint, the synovial membrane descends from the femur and lines the capsule as far as the menisci, whose surfaces have no synovial covering. Posterior to the lateral meniscus, the membrane forms a subpopliteal recess between a groove on the meniscal surface and the tendon of popliteus, which may connect with the superior tibiofibular joint. The relationship of the synovial membrane to the cruciate ligaments is described above.

## Bursae

Numerous bursae are associated with the knee. Anteriorly, there is a large subcutaneous prepatellar bursa between the lower half of the patella and skin; a small, deep infrapatellar bursa between the tibia and patellar ligament; a subcutaneous infrapatellar bursa between the distal
part of the tibial tuberosity and skin; and a large suprapatellar bursa, which is the superior extension of the knee joint cavity (see Fig. 82.16) Posterolaterally, there are bursae between the lateral head of gastrocnemius (lateral subtendinous bursa of gastrocnemius) and the joint capsule (this bursa is sometimes continuous with the joint cavity); the fibular collateral ligament and the tendon of biceps femoris; the fibular collateral ligament and the tendon of popliteus; and the tendon of popliteus and the lateral femoral condyle, which is usually an extension of the synovial cavity of the joint. The last two bursae may communicate with each other.

Medially, the arrangement of the bursae is complex. The bursa between the medial head of gastrocnemius and the fibrous capsule is prolonged between the medial tendon of gastrocnemius and the tendon of semimembranosus (the semimembranosus bursa), and usually communicates with the joint. The bursa between the tendon of semimembranosus and the medial tibial condyle and the medial head of gastrocnemius may communicate with this bursa. The anserine bursa is located between the tibial collateral ligament and the tendons of sartorius, gracilis and semitendinosus. Bursae that vary in both number and position lie deep to the tibial collateral ligament between the joint capsule, femur, medial meniscus, tibia or tendon of semimembranosus. Occasionally, there may be a bursa between the tendons of semimembranosus and semitendinosus. Posteriorly, bursae associated with the knee are variable.

The clinically important bursae are the anterior group, the anserine bursa and the semimembranosus bursa. Inflammation of the subcutaneous prepatellar bursa and infrapatellar bursa are referred to colloquially as 'housemaid's knee' and 'clergyman's knee', respectively. The anserine bursa can become inflamed, especially in athletes. In adults, bursal inflammation producing a popliteal fossa swelling commonly occurs secondary to degeneration within the knee joint; regardless of its size and position, it almost always arises from the plane between semimembranosus and the tendon of the medial head of gastrocnemius.

## Relations and 'at risk' structures

The tendon of quadriceps femoris (which encloses and is attached to the non-articular surfaces of the patella), the patellar ligament, tendinous expansions from vasti medialis and lateralis (which extend over the anteromedial and anterolateral aspects of the capsule, respectively), and the patellar retinacula all lie anterior to the knee joint. Posteromedially are sartorius and the tendon of gracilis (which lies along its posterior border); both descend across the joint. Posterolaterally, the tendon of biceps femoris and the common fibular nerve (which lies medial to the tendon) are in contact with the capsule, and thereby separated from the tendon of popliteus. Posteriorly, the popliteal artery and associated lymph nodes lie posterior to the oblique popliteal ligament; the popliteal vein is posteromedial or medial, and the tibial nerve is posterior to both. The nerve and vessels are overlapped by both heads of gastrocnemius and laterally by plantaris. Gastrocnemius contacts the capsules on either side of the vessels. Semimembranosus lies between the capsule and semitendinosus, medial to the medial head of gastrocnemius.

## Movements at the knee

Movements at the knee are customarily described as flexion, extension, medial (internal) and lateral (external) rotation. Flexion and extension differ from true hingeing, in that the articular surface profiles of the femoral and tibial articular surfaces produce a variably placed axis of rotation during the flexion arc, and when the foot is fixed, flexion entails corresponding conjunct (coupled) lateral rotation. These conjunct rotations are a product of the complex geometry of the articular surfaces and, to an extent, the disposition of the associated ligaments. There is differential motion in the medial and lateral tibiofemoral compartments. Laterally, there is considerable displacement of the femur on the tibia, with rolling as well as sliding at the joint surface. In contrast, medially, for most of the flexion arc there is minimal relative motion of the femur and tibia, and the motion almost exclusively involves one joint surface sliding on the other. In full flexion, the lateral femoral condyle is close to posterior subluxation off the lateral tibial articular surface. Medially, significant posterior femoral displacement only occurs when flexion exceeds $120^{\circ}$. The menisci move with the femoral condyles, the anterior horns more than the posterior, and the lateral meniscus considerably more than the medial.

The axial rotations have a smaller range than the arc of flexion and extension. These rotations are conjunct, and integral with flexion and
extension, i.e. they are obligatory. They can also be adjunct and independent, i.e. voluntary, and are best demonstrated with the knee semiflexed. The degree of axial rotation therefore varies with flexion and extension.

The range of extension is $5-10^{\circ}$ beyond the 'straight position'. Active flexion is approximately $120^{\circ}$ with the hip extended, $140^{\circ}$ when it is flexed, and $160^{\circ}$ when aided by a passive element, e.g. sitting on the heels. Voluntary rotation is $60-70^{\circ}$ but conjunct rotation only $20^{\circ}$

Conjunct medial rotation of the femur on the tibia in the later stages of extension is part of a 'locking' mechanism, the so-called 'screw-home movement', which is an asset when the fully extended knees are subjected to strain. Full extension results in the close-packed position, with maximal spiralization and tightening of the ligaments. The roles of the articular surfaces, musculature and ligaments in generating conjunct rotations remain controversial (Girgis et al 1975, Rajendran 1985) but the following points can be made. The lateral combined meniscotibial 'receiving surface' is smaller, more circular and more deeply concave. Since the articular surface is virtually convex in sagittal section, the depth of the receiving surface is largely due to the presence of the lateral meniscus. The lateral femoral articular surface is also smaller. Consequently, the lateral femoral condyle approaches full congruence with the opposed surface some $30^{\circ}$ before full extension (well before the medial condyle). Simple extension cannot continue, but medial rotation of the femur occurs on a vertical axis through its head and medial condyle; the medial femoral condyle moves very little in the sagittal plane and is stabilized by the 'upslope' of the anterior half of the medial tibia, while rotation of the lateral femoral condyle and meniscus brings the anterior horn of the latter on to the anterior 'downslope' of the lateral tibial condyle. Rotation and extension follow simultaneously and smoothly until final close packing of both condyles is accomplished. At the beginning of flexion from full extension (with the foot fixed), lateral femoral rotation occurs, which 'unlocks' the joint. While joint surfaces and many ligaments are involved, electromyographic evidence reveals that contraction of popliteus is important, and that it pulls down and backwards on the lateral femoral condyle, lateral to the axis of femoral rotation. It also retracts the posterior horn during lateral rotation and continuing flexion, via its attachment to the lateral meniscus, and so prevents traumatic compression.

Any position of extension adopted is a balance between forces (torque) extending the joint and passive mechanisms resisting them. The range near to close packing is functionally important. In symmetrical standing, the line of the body's weight is anterior to the transverse axes of the knee joints, but the passive mechanisms noted above preserve posture with minimal muscular effort (Joseph 1960). Active contraction of quadriceps femoris and a close-packed position only occurs in asymmetrical postures, e.g. in leaning forward, during heavy loading, or when powerful thrust is needed.

In knee extension, parts of the cruciate ligaments, the tibial and fibular collateral ligaments, the posterior capsular region, the oblique popliteal ligament, skin and fasciae are all taut. Passive and sometimes active tension exists in the posterior thigh muscles and gastrocnemius, and the anterior part of the medial meniscus is compressed between the femoral and tibial condyles. During extension, the patellar ligament is tightened by quadriceps femoris but is relaxed in the erect attitude. When the knee flexes, the fibular collateral ligament and the posterior part of the tibial collateral ligament relax but the cruciate ligaments and the anterior part of the tibial collateral ligament remain taut; the posterior parts of the menisci are compressed between the femoral and tibial condyles. Flexion is checked by quadriceps femoris, anterior parts of the knee joint capsule, posterior cruciate ligament and compression of soft tissues behind the knee. In extreme passive flexion, contact of the calf with the thigh may be the limiting factor and parts of both cruciate ligaments are also taut. In addition to conjunct rotation with terminal extension or initial flexion, relaxed collateral ligaments also allow independent medial and lateral rotation (adjunct rotation) when the joint is flexed.

## Accessory movements

Wider rotation can be obtained by passive movements when the knee is semi-flexed. To a limited extent, the tibia can also be translated backwards and forwards on the femur. Abduction and adduction are prevented in full extension by the collateral ligaments and secondary restraints such as the cruciate ligaments. With the knee slightly flexed, limited adduction and abduction are possible, both passive and active. Slight separation of the femur and tibia can be achieved by strong traction on the leg with countertraction applied to the thigh.

Physiological knee joint laxity may occur during puberty. Increased knee joint flexibility is seen more frequently in adolescent girls than boys. There is an inverse relationship between Tanner stage and the
degree of laxity with a progressive decrease of sagittal laxity at the onset of Tanner stage 2 (Falciglia et al 2009).

## Muscles producing movements

Flexion Flexion is produced by biceps femoris, semitendinosus and semimembranosus, assisted by gracilis, sartorius and popliteus. With the foot stationary, gastrocnemius and plantaris also assist (see Fig. 82.3).

Extension Extension is produced by quadriceps femoris, assisted by tensor fasciae latae.

Medial rotation of the flexed leg Medial rotation of the flexed leg is produced by popliteus, semimembranosus and semitendinosus, assisted by sartorius and gracilis.

Lateral rotation of the flexed leg Lateral rotation of the flexed leg is produced by biceps femoris.

Patellofemoral joint The alignment of the femoral and tibial shafts is such that the pull of quadriceps femoris on the patella imparts a force on the patella that is directed both superiorly and laterally. The static bony factors that counter this tendency to move laterally are the congruity of the patellofemoral joint and the buttressing effect of the larger lateral part of the patellar surface of the femur, which, clinically, is often referred to as the trochlear groove. Instability of the patella may result if the patella is small or if the patellar surface of the femur is too shallow. The static ligamentous factors are the medial patellofemoral ligament and medial patellar retinaculum.

Dynamic neuromuscular control is important. The most distal part of vastus medialis (vastus medialis obliquus) consists of transverse fibres that are attached directly to the medial edge of the patella: these pull the patella medially, countering the tendency to move laterally. This is the muscle that is preferentially strengthened in a physical therapy programme aimed at treating patellofemoral conditions often associated with patella tracking problems such as those seen in growing adolescents.

Tibiofemoral joint The tibiofemoral joint surfaces are inherently mobile, especially laterally. Medially, some stability is afforded by the relatively concave tibial surface and the relatively fixed posterior horn of the medial meniscus. Both medially and laterally the menisci are helpful, particularly as they move with the femoral condyles. Ligaments play a major role in constraining mobility because they bind the bones in positions of extreme stress and also provide proprioceptive feedback, aiding coordination of stabilizing muscle activity. To take a somewhat 'two-dimensional' view, the tibial and fibular collateral ligaments may be considered as sensors (resistors) of valgus and varus forces on the knee, respectively, and the anterior and posterior cruciate ligaments as sensors (resistors) of anterior and posterior tibial translation, respectively. However, in reality the situation is more complex than this. The stresses are rarely applied in orthogonal planes and so a combination of forces, especially rotational, is involved. Moreover, many structures other than the collateral and cruciate ligaments are involved in stabilizing the joint. The 'posterolateral corner', which resists tibial lateral rotation, consists of the popliteofibular, fabellofibular, arcuate and fibular collateral ligaments and iliotibial tract, together with popliteus, the lateral head of gastrocnemius and biceps femoris. The 'posteromedial corner', which resists tibial rotation, consists of the posterior oblique portion of the superficial part of the tibial collateral ligament, the capsule including the oblique popliteal ligament and semimembranosus. Since stresses are often a combination of force plus rotation, structures usually operate together rather than in isolation.

## Loading at the knee

During level walking, the force across the tibiofemoral joint for most of the cycle is between two and four times body weight, and can be more. In contrast, the force across the patellofemoral joint is no more than $50 \%$ of body weight. Peak force transmission across the joint increases sequentially as the menisci, articular cartilage and subchondral bone are damaged or removed. Walking up or down stairs has little influence on tibiofemoral forces, but significantly increases patellofemoral forces to two (walking up) or three (walking down) times body weight, reflecting the changed angle of the tendon of quadriceps femoris and patellar ligament during flexion. There are two mechanisms for ameliorating forces transmitted across the patella: the extensor lever arm is lengthened as the axis of rotation moves posteriorly during flexion, and the contact area between the patella and femur almost triples between $30^{\circ}$ and $90^{\circ}$. To cope with the potential large forces
generated by activities such as running, the patella has the thickest articular cartilage in the body.

## BIOMECHANICS OF THE KNEE

The knee joint is a complex synovial joint consisting of the tibiofemoral and patellofemoral articulations. It functions to control the centre of body mass and posture in the activities of daily living. This necessitates a large range of movement in three dimensions coupled with the ability to withstand high forces. These conflicting parameters of mobility and stability are only achieved by the interactions between the articular surfaces, the passive stabilizers and the muscles that cross the joint.

The relatively incongruent nature of the joint surfaces makes the knee joint inherently mobile. In addition, because it acts as a pivot between the longest bones in the body, and is subjected to considerable loads in locomotion, the joint is also potentially at risk of injury if any of the multiple factors providing joint stability are compromised. The long bones may act as levers, increasing the stresses on the stabilizing ligaments.

## KNEE JOINT KINEMATICS

The surfaces of the tibia and femur are not as conforming as those of the relatively congruent hip joint. Although this variation in geometry permits motion to occur in six degrees of freedom (Fig. 82.18), the primary motion of the knee occurs in the sagittal plane, and a relatively minor degree of movement occurs in the transverse plane. The knee joint may therefore be described simplistically as a modified hinge joint allowing flexion-extension and a measure of rotatory motion. Knee motion is normally defined as starting from $0^{\circ}$ (the neutral position), when the tibia and femur are in line in the sagittal plane. Biomechanically, it is important that the knee reaches the neutral position in extension because that allows the leg to support the body weight like a simple strut when the subject is standing still. When the subject is standing upright, if the knee is flexed, the vertical line of action of the body weight passes posterior to the centre of rotation of the knee, tending to cause the body to tilt posteriorly. To counterbalance this, continuous quadriceps femoris contraction is required, causing expenditure of energy.

CHAPTER 82
Fig. 82.18 The knee joint motion in three dimensions, described using six independent variables (degrees of freedom).

Active knee flexion leads to approximately $130^{\circ}$ flexion. The active motion is limited by apposition of the soft tissue masses (posterior thigh and calf). Passive flexion may reach $160^{\circ}$. This is required in people who habitually kneel as part of daily life, and is a challenge for designers of knee prostheses. It can be observed that such deep flexion is often accompanied by tibial medial rotation, so that, when the subject is kneeling, the buttocks can rest on the feet. This movement carries the lateral tibial plateau anteriorly, so that it does not engage with the femoral lateral condyle in deep knee flexion. The femoral condyle passes posteriorly and rides over the horn of the lateral meniscus.

The most frequently employed knee movement occurs when walking (Fig. 82.19). When the leg is swinging past the supporting leg, the knee must be flexed in order to avoid dragging the toes on the ground; this requires approximately $67^{\circ}$ knee flexion. When the swinging leg approaches the first contact with the ground, the knee extends, to move the foot forwards for heel strike. If the knee remained extended, this would then cause the body to move in a circular arc, centred at the ankle, causing the centre of gravity to move upwards and then back down again, leading to more energy expenditure. It would also increase the forces on the knee because the leg would act more like a rigid strut, unable to dissipate the impact forces when the foot hit the ground. All these problems are overcome by flexing the knee $15^{\circ}$ in the mid-stance phase; the centre of gravity of the body can move forwards at approximately constant height, and the impact energy is absorbed by stretching quadriceps femoris (see Fig. 82.19).

Tibial medial-lateral rotation also occurs during gait: the tibia rotates laterally during terminal extension, a phenomenon known as 'screw-home' (Fig. 82.20). It is surmised that this rotation helps to lock
the geometry and tighten the soft tissues, thereby maintaining the knee in a stable position prior to the impact load of weight-bearing. The knee acts as one link in a chain of limb segments, and this screw-home relates to rotation of both the foot and hip. When the foot is swung forwards for heel strike, the pelvis rotates so that the hip is moved forwards, a movement that entails lateral rotation of the hip. During stance, the femur is medially rotated against the locked knee. Tibial lateral rotation also causes inversion of the foot at the subtalar joint, raising the arch and locking the structure of the foot. The knee flexion that occurs after the impact on the ground allows the tibia to rotate medially so that the foot everts, softening its structure and allowing it to deform and absorb energy. Conversely, towards toe-off, the knee extends, rotating the tibia laterally, so the foot is again a rigid lever with which to push the body forwards.

## Articular kinematics

We now consider knee motion at a smaller scale, within the joint. This, of course, is difficult to separate from the actions of the ligaments that act as passive restraints to tibiofemoral joint movements, and are discussed below.

Sagittal sections of the knee reveal that the arcs of the femoral condyles are much longer than the anterior-posterior length of the tibial plateau. This means that if the knee flexed with a purely rolling motion, then the femur would roll off the back of the tibia long before the knee reaches full flexion (see Fig. 82.20). This does not happen because the femur slides anteriorly at the same time as it rolls posteriorly, and thus remains in correct articulation. If the knee were to possess a fully conforming roller-in-trough geometry, as in the humero-ulnar joint, then flexion would occur by pure sliding movement between the joint

Fig. 82.19 Knee flexion-extension motion during gait.

Fig. 82.20 Knee joint kinematics during gait: rolling and sliding (flexion, anterior translation).
surfaces. This conformity is not possible at the knee because it would inhibit the tibial medial-lateral rotation that is needed during locomotion.

In the locked, fully extended knee, the anterodistal femoral articular surfaces press on to the anterior horns of the menisci. This tends to cause the femur to slide posteriorly, tensing the anterior cruciate ligament and slackening the posterior cruciate ligament. With knee flexion, the femur lifts off the anterior horns of the menisci, leading to contact between the smaller radii of the posterior parts of the femoral condyles and the tibial plateau plus the posterior horns of the menisci. This means that the centre of contact moves posteriorly in early knee flexion. After this, the femoral condyles have approximately circular sagittal sections. The femur is now prevented from rolling back any further by tension in the anterior cruciate ligament.

## Articular mechanics

The combined effect of the external and internal loads on the knee is to impose considerable forces on the articular cartilage. This may be analysed as a vertical (compressive) component and a horizontal (shear or friction) component. The friction component is a combination of the compressive force and the friction characteristics of the joint surfaces.

## Compression

The compressive force is distributed over an area to produce a contact pressure (contact stress). The contact pressure is, therefore, dependent on the area of contact as well as the load itself. Fully conforming articular surface geometry would allow the greatest area of contact, and thus would minimize contact pressure; however, this is not present in the knee. The medial compartment of the knee is semi-conforming with a convex femoral condyle articulating over a concave medial tibial plateau. The lateral compartment has less conformity; the lateral tibial plateau is flat or slightly convex in sagittal sections. These different shapes reflect the differential movement of the medial and lateral compartments. In normal movement, the screw-home rotation of the tibia occurs about a medial axis, which means that most of the rotation of the tibia is due to an anterior-posterior translation of the lateral compartment (Fig. 82.21).

In order to maintain some degree of conformity, and also to minimize contact pressure between the femur and tibia, the menisci are wedge-shaped in cross-section, thereby increasing the area over which the compressive force on the knee is distributed. In the absence of the menisci, the load is carried by a much smaller area of cartilage, resulting in higher contact stresses on the articular cartilage. This helps to explain the prevalence of osteoarthrosis following meniscectomy (Fig. 82.22).

The menisci are most firmly attached at the intercondylar eminence of the tibia, which means that they can translate anteriorly and posteriorly to 'follow' the femoral rollback. The lateral meniscus is more mobile because it is attached to the capsule less tightly than the medial meniscus. The anterior-posterior movement of the menisci is approximately half the magnitude of the anterior-posterior movement of the femur, suggesting that the conformity of the joint changes during flexion of the knee joint.

The distal aspect of the femur, resting on the menisci in the extended knee, has a large radius of curvature and thus fits against the entire area of the menisci. However, as the knee flexes, the smaller radii of the posterior parts of the femoral condyles cause the femur to lift off the

Fig. 82.21 The shape of the articular surfaces providing mobility of the lateral compartment.
anterior horns of the menisci, and the femoral contact is now solely on the posterior horns in the flexed knee. This, combined with the large joint forces that are generated when arising from a seated position, explains why there are often spontaneous tears of the posterior horns in older patients, when standing up from a squatting position.

The load-carrying mode of the menisci is shown in Figure 82.23. When the femoral condyle presses down on the meniscus, it tends to squeeze the meniscus out of the joint because of its tapered crosssection. This causes the diameter of the circular shape of the meniscus (and therefore the meniscal circumference) to increase. This is resisted by 'hoop tension' in strong fibres that pass around the periphery of the meniscus, and transmit the tension to the tibial plateau via strong insertional ligaments. As the tissue is adapted to resist hoop stresses, it has much greater hoop strength (approximately 100 MPa ) than radial strength (approximately 3 MPa ), which explains why bucket handle tears occur. It also explains why a circumferential tear does not have such a serious effect on meniscal function because the circumferential fibres can still transmit the loads, whereas a radial tear breaks the loadcarrying fibres.

## Friction

The knee acts as a bearing that transmits forces and movements between the limb segments. Load-bearing synovial joints move with remarkably little friction and their surfaces must withstand many millions of impact loads, which tend to cause fatigue failure and breakdown of the surfaces.

During walking, every step involves phases of action that vary the loading and velocity conditions at the knee joint. A variety of lubrication mechanisms normally prevent joint surface damage. Thus, in the swing phase, when the foot is off the ground, the joint surfaces are

Fig. 82.22 The function of the menisci in increasing articular conformity, with increased peak pressure before and after meniscectomy.

Fig. 82.23 The load-carrying mode of the menisci. Conversion of axial load into meniscal hoop stresses.

Fig. 82.24 The different modes of knee joint motion and lubrication when walking.
loaded lightly, and have high relative velocity while the knee flexes and extends. This allows the synovial fluid to separate the surfaces, giving fluid film lubrication, with very low friction and no wear (Fig. 82.24). At the time of heel strike, a large impact load acts to compress the surfaces together. At a microscopic level, the surfaces do not come into contact because of the squeeze-film effect: in essence, the impact occurs so rapidly (less than 0.1 sec ) that the synovial fluid cannot all be squeezed out of the joint space because of its viscosity and the narrowness of the space. In the mid-stance phase, the flexion-extension motion again entrains the synovial fluid in between the joint surfaces, producing what is known as a hydrodynamic effect: the fluid is trapped between the surfaces by the motion and therefore it acts to separate them. Finally, when the foot is pushing off the body weight, there is little motion and the thin fluid film diminishes under the compressive load. If the squeeze-film effect were insufficient, then the joint surfaces would come into direct contact were it not for the fact that the synovial fluid contains large protein molecules that are trapped on the cartilage surfaces when the fluid is expelled. This molecular layer acts as a boundary lubricant, protecting the cartilage in the same way that grease protects a synthetic bearing.

Many aspects of the arthritic breakdown of the cartilage can be explained on the basis of lubrication biomechanics. Thus, in joints affected by osteoarthrosis, synovial fluid is known to have a lower viscosity than that in normal joints. The viscosity is lower still in joints afflicted with rheumatoid arthritis and is unable to prevent attritional damage to the cartilage surfaces.

## SOFT TISSUE MECHANICS

The knee joint relies on active (musculotendinous) and passive (ligamentous) restraints to maintain its stability. The muscles provide the loading to move the joint: quadriceps femoris, hamstrings and gastrocnemius control both flexion/extension and medial-lateral rotation. However, they also cause anterior-posterior shear forces that are resisted primarily by the cruciate ligaments. This tethering effect is critical in allowing the joint to move physiologically, maintaining congruency and stability.

The passive stabilizers of the joint act by resisting unwanted displacements between the bones. This may be to control the path of motion or to limit the range of motion. When the muscles or some other external force (due to body weight or impact) cause the bones to displace, the ligaments are stretched, and so develop tensile forces that resist the
displacement and allow the joint to maintain its stability. Disruption of any of these passive restraints may cause a mechanical instability, which is an abnormally increased displacement due to an applied force (in biomechanical terms this is called excess laxity).

## Primary and secondary restraints

On testing the laxity in any of the degrees of freedom of the joint (e.g. in the anterior drawer test, a bedside clinical test in which the subject is placed in the supine position with the knee to be tested flexed to $80-90^{\circ}$ before passive forward traction is applied to the tibia), there are usually combinations of ligaments that are tensed. Some of these are better aligned to resist the applied load or displacement. These are termed primary restraints, and are exemplified by the cruciate ligaments and the tibial and fibular collateral ligaments. Secondary restraints are less well aligned but still have a significant restraining effect. These are exemplified by the menisci and by the meniscofemoral ligaments. In the example in Figure 82.25, the anterior cruciate ligament is well aligned to resist the applied anterior force. With an absent anterior cruciate ligament, the tibial collateral ligament can resist the applied force; however, it does so by being loaded to a much higher level than the original loading on the anterior cruciate ligament. The size of the lines in the vector diagram demonstrate this principle: although joint laxity may remain normal initially following rupture of a primary restraint, it may subsequently result in the overload of a secondary restraint and, ultimately, in further soft tissue failure.

The patellofemoral joint is most heavily loaded during weightbearing activities when the knee is flexed. Analyses of rising from a chair have predicted that the patellar ligament tension at $90^{\circ}$ of knee flexion may be greater than the tibiofemoral joint, which is loaded at the same time (Amis and Farahmand 1996).

In the frontal plane, quadriceps femoris and the patellar ligament tensions combine to cause a lateralizing force vector termed the Q-angle effect. The Q angle is defined as the difference between the resultant force vector of quadriceps femoris, which is normally parallel to the femoral shaft, and the patellar ligament (Fig. 82.26). Clinically, the Q angle is changed by the position of hip rotation, tibial rotation and quadriceps femoris tension. The clinical Q angle is $12-15^{\circ}$ (males) and $15-18^{\circ}$ (females), which means that there is a greater lateralizing force vector on the patellofemoral joint in females. Contraction of quadriceps femoris, therefore, tends to displace the patella laterally, which is resisted by the geometry of the joint and by the ligaments. Vastus medialis obliquus acts medially and posteriorly as much as it acts proximally, and so its tension helps to resist the Q-angle effect.

Fig. 82.25 Primary and secondary restraints to anteroposterior forces. The example shows the anterior cruciate ligament (ACL) and superficial part of the tibial collateral ligament (sTCL).

PL = Patellar ligament force PF = Patellofemoral joint reaction force $\mathbf{Q}=$ Quadriceps femoris traction force

Fig. 82.26 The patellofemoral joint force with knee extension (A) and with $90^{\circ}$ of knee flexion (B).

## MUSCLES

The majority of muscles that act on the knee joint are described in either Chapter 80 (quadriceps femoris, semimembranosus, biceps femoris, semitendinosus, articularis genus) or on page 1409 (gastrocnemius). Popliteus is described below.

## Popliteus

Attachments Popliteus is a flat muscle that forms the floor of the lower part of the popliteal fossa (see Figs 82.12A, 83.4B, 83.9A). It arises within the capsule of the knee joint by a strong tendon, 2.5 cm long, which is attached to a depression at the anterior end of the groove (groove for popliteus) on the lateral aspect of the lateral condyle of the femur. Medially, this tendon is joined by collagenous fibres arising from the arcuate popliteal ligament; the fibrous capsule adjacent to the lateral meniscus; and the outer margin of the meniscus.

Popliteus is attached to the medial aspect of the head of the fibula by the popliteofibular ligament, which passes laterally and inferiorly from the popliteus tendon in a sheet of tissue that is normally about $2 \mathrm{~cm}^{2}$. This ligament is the single most important stabilizer of the posterolateral region of the knee and resists lateral rotation of the tibia on the femur. Failure to recognize and reconstruct damage to this ligament and to the related ligamentous structures is the most common reason for a poor result from an otherwise well-performed operation for repair of ruptured cruciate ligaments.

Fleshy fibres expand from the inferior limit of the tendon to form a somewhat triangular muscle that descends medially to be inserted into the medial two-thirds of the triangular area above the soleal line on the posterior surface of the tibia, and into the tendinous expansion that covers its surface.

An additional head may arise from the sesamoid bone in the lateral head of gastrocnemius. Very rarely, two other muscles may be found deeply situated behind the knee. Popliteus minor runs from the posterior surface of the lateral tibial condyle, medial to plantaris, to the oblique popliteal ligament. Peroneotibialis runs deep to popliteus from the medial side of the fibular head to the upper end of the soleal line.

Relations Popliteus is covered posteriorly by a dense aponeurotic expansion, which is largely derived from the tendon of semimembranosus. Gastrocnemius, plantaris, the popliteal vessels and the tibial nerve all lie posterior to the expansion. The popliteal tendon is intracapsular and is deep to the fibular collateral ligament and the tendon of biceps femoris. It is invested on its deep surface by synovial membrane, and grooves the posterior border of the lateral meniscus and the adjoining part of the tibia before it emerges inferior to the posterior band of the arcuate ligament. This region is called the 'popliteus hiatus'; the lateral meniscus has no peripheral bony attachment here and is therefore rather mobile.

Vascular supply The arterial supply of popliteus is derived mainly from the inferior medial and lateral genicular arteries. The latter may cross either superficial or deep to the muscle. There are additional contributions from the nutrient artery of the tibia (from the posterior tibial artery), the proximal part of the posterior tibial artery, and the posterior tibial recurrent artery.

Innervation Popliteus is innervated by a branch of the tibial nerve (L4, 5 and S1), which winds around the distal border of popliteus and enters the anterior surface of the muscle; this nerve also innervates the superior tibiofibular joint and the interosseous membrane of the leg.

Actions Popliteus rotates the tibia medially on the femur or, when the tibia is fixed, rotates the femur laterally on the tibia. It is usually regarded as the muscle that 'unlocks' the joint at the beginning of flexion of the fully extended knee; electromyography supports this view. Its connection with the arcuate popliteal ligament, fibrous capsule and lateral meniscus has led to the suggestion that popliteus may retract the posterior horn of the lateral meniscus during lateral rotation of the femur and flexion of the knee joint, thus protecting the meniscus from being crushed between the femur and the tibia during these movements. The muscle is markedly active in crouching, perhaps to provide stability as the tibia rotates medially during flexion of the knee. However, the main function is likely to be provision of dynamic stability to the posterolateral part of the knee by preventing excessive lateral rotation of the tibia, partly by its direct action, but more significantly by tensing the popliteofibular ligament.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES

There is an intricate arterial anastomosis around the patella and the femoral and tibial condyles (see Fig. 78.4). A superficial arterial network spreads between the fascia and skin around the patella and in the fat deep to the patellar ligament. A deep arterial network lies on the femur and tibia near the adjoining articular surfaces, and supplies the bone, articular capsule, synovial membrane and cruciate ligaments (see Fig. 82.1). The vessels involved are the superior, middle and inferior genicular branches of the popliteal artery; descending genicular branches of the femoral artery and descending branch of the lateral circumflex femoral artery; circumflex fibular artery; and anterior and posterior tibial recurrent arteries. For details, consult Scapinelli (1968).

## Variations in the arterial anatomy of the lower limb

Most anatomical variations in the arterial pattern of the lower limb arteries cause no symptoms. They are usually incidental findings in the dissection room, or may come to light in the course of angiographic examination. Some variations in vascular anatomy may be symptomatic and may necessitate surgical correction; other variations, while asymptomatic, may influence technical considerations during vascular surgical procedures.

Anatomical variations of the femoral, profunda femoris, anterior and posterior tibial and fibular arteries have been described elsewhere in this Section.

## Popliteal artery

The popliteal artery is the continuation of the femoral artery and crosses the popliteal fossa (see Figs 82.2, 82.4). It descends laterally from the opening in adductor magnus to the femoral intercondylar fossa, inclining obliquely to the distal border of popliteus, where it divides into the anterior and posterior tibial arteries. This division usually occurs at the proximal end of the interosseous space between the wide tibial metaphysis and the slender fibular metaphysis. The artery is relatively tethered at the adductor hiatus and again distally by the fascia related to soleus, and is therefore susceptible to damage following knee injuries, e.g. dislocation. Aneurysms of the popliteal artery are not uncommon.

## Variations in the popliteal artery

The popliteal artery may occasionally bifurcate more superiorly and divide into its terminal branches proximal to popliteus, or it may trifurcate into anterior and posterior tibial and fibular arteries. Either the anterior tibial or the posterior tibial artery may be reduced or increased in size. The size of the fibular artery is usually inversely related to the size of the anterior and posterior tibial arteries. Rarely, the anterior tibial artery is the source of the fibular artery, a variation that is almost always associated with a high bifurcation of the popliteal artery.

The popliteal and inferior gluteal arteries may be joined by a large anastomotic vessel; in such cases, the femoral artery is hypoplastic (Kawashima and Sasaki 2010). When this occurs, the popliteal artery usually has an abnormal relationship to popliteus, running deep to the muscle before dividing into its terminal branches. The popliteal artery may pass medially beneath the medial head of gastrocnemius, or may pass beneath an aberrant band of muscle in the popliteal fossa; in either case, contraction of the muscles may occlude the artery - a condition that may present with claudication on exertion. The popliteal vein is usually superficial and adjacent to the artery, but it may run deep to the artery, or be separated from it by a slip of muscle derived from the medial head of gastrocnemius.

## Relations

Anteriorly, from proximal to distal, are fat covering the femoral popliteal surface, the capsule of the knee joint, and the fascia of popliteus. Posteriorly are semimembranosus (proximally) and gastrocnemius and plantaris (distally). In between, the artery is separated from the skin and fasciae by fat and crossed from its lateral to its medial side by the tibial nerve and popliteal vein; the vein lies between the nerve and artery and is adherent to the latter. Laterally are biceps femoris, the tibial nerve, popliteal vein and lateral femoral condyle (all proximal), and plantaris and the lateral head of gastrocnemius (distal). Medially are semimembranosus and the medial femoral condyle (proximal), and the tibial nerve, popliteal vein and medial head of gastrocnemius (distally). The relations of the popliteal nodes are described below.

## Branches (other than terminal)

Genicular anastomosis There is an intricate arterial anastomosis around the patella and femoral and tibial condyles (see Fig. 82.1). A superficial network spreads between the fascia and skin around the patella and in the fat deep to the patellar ligament. A deep network lies on the femur and tibia near their adjoining articular surfaces, and supplies the bone, articular capsule and synovial membrane. The vessels involved in this anastomosis are superior medial and lateral genicular; inferior medial and lateral genicular; descending genicular; descending branch of the lateral circumflex femoral; circumflex fibular; and anterior and posterior tibial recurrent arteries.

Superior genicular arteries The superior genicular arteries branch from the popliteal artery, curving round proximal to both femoral condyles to reach the anterior aspect of the knee. The superior medial genicular artery lies under semimembranosus and semitendinosus,
proximal to the medial head of gastrocnemius and deep to the tendon of adductor magnus. It divides into a branch to vastus medialis that anastomoses with the descending genicular and inferior medial genicular arteries, and a branch that ramifies on the femur and anastomoses with the superior lateral genicular artery. Its size varies inversely with that of the descending genicular artery. The superior lateral genicular artery passes under the tendon of biceps femoris, pierces the lateral intermuscular septum and divides into superficial and deep branches. The superficial branch supplies vastus lateralis and anastomoses with the descending branch of the lateral circumflex femoral and inferior lateral genicular arteries, while the deep branch anastomoses with the superior medial genicular artery, forming an anterior arch across the femur with the descending genicular artery. The superficial branch is vulnerable if the lateral patellar retinaculum is divided surgically.

Middle genicular artery The middle genicular artery is small. It arises from the popliteal artery near the midpoint of the posterior aspect of the knee joint. It pierces the oblique popliteal ligament to supply the cruciate ligaments and synovial membrane.

Inferior genicular arteries The inferior medial and lateral genicular arteries arise from the popliteal artery deep to gastrocnemius. The inferior medial genicular artery is deep to the medial head of gastrocnemius. It descends along the proximal margin of popliteus, which it supplies; passes inferior to the medial tibial condyle, under the tibial collateral ligament; and then ascends anteromedial to the knee joint at the anterior border of the tibial collateral ligament. It supplies the joint and the tibia, and anastomoses with the inferior lateral and superior medial genicular arteries and with the anterior tibial recurrent artery and saphenous branch of the descending genicular artery. The inferior lateral genicular artery runs laterally across popliteus and forwards over the head of the fibula to the front of the knee joint, passing under the lateral head of gastrocnemius, the fibular collateral ligament and the tendon of biceps femoris. Its branches anastomose with the inferior medial and superior lateral genicular arteries; anterior and posterior tibial recurrent arteries; and the circumflex fibular branch of the posterior tibial artery.

Cutaneous branches: the superficial sural arteries The superficial sural arteries are three vessels that leave the popliteal artery, or its side branches, descend between the heads of gastrocnemius and perforate the deep fascia to supply the skin on the back of the leg. The central or median vessel is usually larger than the medial or lateral vessels, and usually accompanies the sural nerve.

Fasciocutaneous free and pedicled flaps may be raised on the superficial sural arteries.

Superior muscular branches The superior muscular branches are two or three vessels that arise proximally and pass to adductor magnus and the posterior thigh muscles. They anastomose with the termination of the profunda femoris artery.

Sural arteries The two sural arteries are large and arise behind the knee joint to supply gastrocnemius, soleus and plantaris. They are used in gastrocnemius musculocutaneous flaps.

## VEINS

The veins draining the knee correspond in name to the arteries and run with them; the named smaller veins drain into the popliteal and femoral veins.

## Popliteal vein

The popliteal vein ascends through the popliteal fossa to the opening in adductor magnus, where it becomes the femoral vein (see Figs 78.8, $78.9 \mathrm{~B}, 80.30$ ). Its relationship to the popliteal artery changes as the vein ascends: distally, it is medial to the artery; between the heads of gastrocnemius, it is superficial (posterior) to the artery; and proximal to the knee joint, it is posterolateral to the artery. Its tributaries are the short saphenous vein; veins corresponding to branches of the popliteal artery; and muscular veins, including a large branch from each head of gastrocnemius. There are usually four or five valves in the popliteal vein.

## Long saphenous vein

The course of the long saphenous vein is described on pages 1370-1371.

## Short saphenous vein

The short saphenous vein（small saphenous vein）begins posterior to the lateral malleolus as a continuation of the lateral marginal vein（see Fig．78．9B）．In the lower third of the calf，it ascends lateral to the cal－ caneal tendon，lying on the deep fascia and covered only by subcutan－ eous tissue and skin．Inclining medially to reach the midline of the calf， it penetrates the deep fascia，within which it ascends on gastrocnemius， only emerging between the deep fascia and gastrocnemius gradually at about the junction of the middle and proximal thirds of the calf（usually well below the lower limit of the popliteal fossa）．Continuing its ascent， it passes between the heads of gastrocnemius and proceeds to its termi－ nation in the popliteal vein， $3-7.5 \mathrm{~cm}$ above the knee joint．

## Tributaries

The short saphenous vein connects with deep veins on the dorsum of the foot，receives many cutaneous tributaries in the leg，and sends several communicating branches proximally and medially to join the long saphenous vein．Sometimes a communicating branch ascends medially to the accessory saphenous vein：this may be the main con－ tinuation of the short saphenous vein．In the leg，the short saphenous vein lies near the sural nerve and contains 7－13 valves，with one near its termination．Its mode of termination is variable：it may join the long saphenous vein in the proximal thigh or it may bifurcate，one branch joining the long saphenous vein and the other joining the popliteal or deep posterior femoral veins．Sometimes it drains distal to the knee in the long saphenous or sural veins．

## LYMPHATIC DRAINAGE

Lymphatic drainage is to the popliteal nodes（see Fig．78．10）．Most of the lymph vessels accompany the genicular arteries；some vessels from the joint drain directly into a node between the popliteal artery and the posterior capsule of the knee joint．

## Popliteal nodes

There are usually six small lymph nodes embedded in the fat of the popliteal fossa．One，near the termination of the short saphenous vein， drains the superficial region served by this vessel．Another lies between the popliteal artery and the posterior aspect of the knee，receiving direct vessels from the knee joint and those accompanying the genicular
arteries．The remainder flank the popliteal vessels，receiving trunks that accompany the anterior and posterior tibial vessels．Popliteal lymphatic vessels ascend close to the femoral vessels to reach the deep inguinal nodes；some may accompany the long saphenous vein to the superficial inguinal nodes．

## INNERVATION

The knee joint is innervated by branches from the obturator，femoral， tibial and common fibular nerves（see Fig．78．11）（Freeman and Wyke 1967）．The articular branch of the obturator nerve is the terminal branch of its posterior division．Muscular branches of the femoral nerve， especially to vastus medialis，supply articular branches to the knee joint． Genicular branches from the tibial and common fibular nerves accom－ pany the genicular arteries，and those from the tibial nerve travel with the medial and middle genicular arteries，while those from the common fibular nerve travel with the lateral genicular and anterior tibial recur－ rent arteries．

The femoral and obturator nerves are described on page 1372， and the tibial and common fibular nerves are described on page 1415 ．

## Saphenous nerve

The saphenous nerve is the largest and longest cutaneous branch of the femoral nerve and the longest nerve in the body（see Figs 78．11，80．32）． It descends lateral to the femoral artery in the femoral triangle and enters the adductor canal，where it crosses anterior to the artery to lie medial to it．At the distal end of the canal，it leaves the artery and emerges through the aponeurotic covering with the saphenous branch of the descending genicular artery．As it leaves the adductor canal，it gives off an infrapatellar branch that contributes to the peripatellar plexus and then pierces the fascia lata between the tendons of sartorius and gracilis，becoming subcutaneous to supply the skin anterior to the patella．It descends along the medial border of the tibia with the long saphenous vein and divides distally into a branch that continues along the tibia to the ankle and a branch that passes anterior to the ankle to supply the skin on the medial side of the foot，often as far as the first metatarsophalangeal joint．The saphenous nerve connects with the medial branch of the superficial fibular nerve．Near the mid－thigh，it provides a branch to the subsartorial plexus．The nerve may become entrapped as it leaves the adductor canal．

This chapter describes the shafts of the tibia and fibula, the soft tissues that surround them and the interosseous membrane between them. The superior (proximal) and inferior (distal) tibiofibular joints are described on pages 1385 and 1433, respectively.

## SKIN AND SOFT TISSUES

## SKIN

## Vascular supply and lymphatic drainage

The cutaneous arterial supply is derived from branches of the popliteal, anterior tibial, posterior tibial and fibular vessels (see Fig. 78.5). Multiple fasciocutaneous perforating branches from each vessel pass along intermuscular septa to reach the skin; musculocutaneous perforators traverse muscles before reaching the skin. In some areas, there is an additional, direct cutaneous supply from vessels that accompany cutaneous nerves, e.g. the descending genicular artery (saphenous artery) and superficial sural arteries. Fasciocutaneous and direct cutaneous arterial branches have a longitudinal orientation in the skin, whereas the musculocutaneous branches are more radially oriented. For further details, consult Cormack and Lamberty (1994).

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic vessels running on the medial side of the leg accompany the long saphenous vein and drain to the superficial inguinal nodes, while those from the lateral and posterior sides of the leg accompany the short saphenous vein and pierce the deep fascia to drain into the popliteal nodes.

## Innervation

The skin of the leg is supplied by branches of the saphenous, posterior femoral cutaneous, common fibular and tibial nerves (see below and Figs 78.11, 78.12, 78.17, 78.18).

## SOFT TISSUES

## Deep fascia

The deep fascia of the leg is continuous with the fascia lata and is attached around the knee to the patellar margin, the patellar ligament, the tuberosity and condyles of the tibia, and the head of the fibula. Posteriorly, where it covers the popliteal fossa as the popliteal fascia, it is strengthened by transverse fibres and is perforated by the short saphenous vein and sural nerve. It receives lateral expansions from the tendon of biceps femoris and multiple medial expansions from the tendons of sartorius, gracilis, semitendinosus and semimembranosus. The deep fascia blends with the periosteum on the subcutaneous surface of the tibia and the subcutaneous surfaces of the fibular head and lateral malleolus, and is continuous below with the extensor and flexor retinacula. It is thick and dense in the proximal and anterior part of the leg, where fibres of tibialis anterior and extensor digitorum longus are attached to its deep surface, and is thinner posteriorly, where it covers gastrocnemius and soleus. On the lateral side, it is continuous with the anterior and posterior intermuscular septa of the leg, which are attached to the anterior and posterior borders of the fibula, respectively.

## Transverse intermuscular septum

The transverse intermuscular septum of the leg is a fibrous stratum between the superficial and deep muscles of the calf. It extends transversely from the medial margin of the tibia to the posterior border of the fibula. Proximally, where it is thick and dense, it is attached to the
soleal ridge of the tibia and to the fibula, inferomedial to the fibular attachment of soleus. Between these bony attachments, it is continuous with the fascia covering popliteus, which is, in effect, an expansion from the tendon of semimembranosus. At intermediate levels it is thin but distally, where it covers the tendons behind the malleoli, it is thick and continuous with the flexor and superior fibular retinacula.

## Interosseous membrane

The interosseous membrane connects the interosseous borders of the tibia and fibula (Fig. 83.1). It is interposed between the anterior and

Fig. 83.1 The posterior aspect of the interosseous membrane. Note the contrasting direction of the fibre bundles around the vascular openings.

Fig. 83.2 A, A transverse (axial) section through the left leg, approximately 10 cm distal to the knee joint. B, Colour-coded axial magnetic resonance imaging (MRI) of the leg. Observe the anterior (blue), lateral (red) and posterior (deep part yellow and superficial part green) compartments of the leg. (C, continued online)
posterior groups of crural muscles; some members of each group are attached to the corresponding surface of the interosseous membrane. The anterior tibial artery passes forwards through a large oval opening near the proximal end of the membrane, and the perforating branch of the fibular artery pierces it distally. An associated ligament (ligament of Barkow), in the same plane as the interosseous membrane, may be found uniting the proximal tibiofibular joint; when present, it forms the upper half of this oval opening (see Fig. 83.1) (Tubbs et al 2009). Its fibres are predominantly oblique and most descend laterally; those that descend medially include a bundle at the proximal border of the proximal opening. The thickness of the interosseous membrane differs between its thin centre and thick tibial and fibular borders. The membrane is continuous distally with the interosseous ligament of the distal tibiofibular joint.

## Retinacula

The retinacula at the ankle joint are described on page 1418.

## Osteofascial compartments

The compartments of the leg are particularly well defined and are the most common sites at which osteofascial compartment syndromes occur. The three main compartments are anterior (extensor), lateral (fibular) and posterior (flexor). The posterior compartment is divided into deep and superficial parts by the transverse intermuscular septum (Fig. 83.2). These compartments are enclosed by the unyielding deep fascia and separated from each other by the bones of the leg and interosseous membrane, and by the anterior and posterior intermuscular septa that pass from the deep fascia to the fibula. The anterior compartment, the least expansile of the three, is bounded by the deep fascia, the interosseous surfaces of the tibia and fibula, the interosseous membrane and the anterior intermuscular septum. The lateral compartment lies between the anterior and posterior intermuscular septa, and is bordered laterally by the deep fascia and medially by the lateral surface of the fibula. The posterior compartment is bounded by the deep fascia, the posterior intermuscular septum, the fibula and tibia, and the interosseous membrane. Its relatively expansile superficial component is separated from the compacted deep component by the transverse intermuscular septum, reinforced by the deep aponeurosis of soleus. Knowledge of the compartmental anatomy of the leg is important in planning the treatment of compartment syndromes and for soft tissue tumour resections of the leg.

The nerve supply of the muscles in the compartments follows the 'one compartment - one nerve' principle: the deep fibular nerve supplies the anterior compartment, the superficial fibular nerve supplies the lateral compartment, and the tibial nerve supplies the posterior compartment. Magnetic resonance imaging (MRI) is the best imaging modality for evaluating the soft tissues of the leg. Most of the muscle in the anterior compartment is supplied by the anterior tibial artery,
with an additional contribution from the fibular artery to extensor hallucis longus. The muscles of the posterior compartment are supplied by the popliteal, posterior tibial and fibular arteries. The muscles of the lateral compartment are supplied by the anterior tibial and fibular arteries, and to a lesser extent proximally, by a branch from the popliteal artery.

## Trauma and soft tissues of the leg

The relative paucity of soft tissue in the shin region and the subcutaneous position of the medial surface of the tibia means that even trivial soft tissue injury may lead to serious problems such as ulceration and osteomyelitis. In the elderly, these soft tissues are often especially thin and unhealthy, reflecting the effects of ageing and venous stasis (see below). Tibial fractures are common in the young and, partly as a result of poor soft tissue coverage, they are often open injuries. Diminished blood supply to the bone, caused by traumatic stripping of attached soft tissues, and the risk of contamination add greatly to the risk of non-union and infection of the fracture. Healing of fractures at the junction of the middle and lower thirds of the tibia is compromised by the relatively poor blood supply to this region. Injury to the leg may result in elevated pressures of one or more compartments (so-called compartment syndrome); this clinical scenario is manifested by the 'six Ps': pain, paraesthesias, pallor, paralysis, pulselessness and poikilothermia (differing temperatures in the affected and unaffected limbs).

## BONES

## TIBIA

The tibia lies medial to the fibula and is exceeded in length only by the femur (Figs 83.3-83.4). The tibial shaft is triangular in section and has expanded ends; a strong medial malleolus projects distally from the smaller distal end. The anterior border of the shaft is sharp and curves medially towards the medial malleolus. Together with the medial and lateral borders, it defines the three surfaces of the bone. The exact shape and orientation of these surfaces show individual and racial variations. In children, the mean tibial length is greater in males than in females (Oeffinger et al 2010).

## Proximal end

The expanded proximal end bears the weight transmitted through the femur. It consists of medial and lateral condyles, an intercondylar area and the tibial tuberosity.

Condyles The tibial condyles overhang the proximal part of the posterior surface of the shaft. Both condyles have articular facets on their

Fig. 83.2 C, An axial T2-weighted MRI of the leg in a patient with anterior compartment denervation (arrow).

superior surfaces, separated by an irregular, non-articular intercondylar area. The condyles are visible and palpable at the sides of the patellar ligament, the lateral being more prominent. In the passively flexed knee, the anterior margins of the condyles are palpable in depressions that flank the patellar ligament.

The fibular articular facet on the posteroinferior aspect of the lateral condyle faces distally and posterolaterally. The angle of inclination of the superior tibiofibular joint varies between individuals, and may be horizontal or oblique. Superomedial to it, the condyle is grooved on its posterolateral aspect by the tendon of popliteus; a synovial recess intervenes between the tendon and bone. The anterolateral aspect of the condyle is separated from the lateral surface of the shaft by a sharp margin for the attachment of deep fascia. The distal attachment of the iliotibial tract makes a flat and usually definite marking (Gerdy's tubercle) on its anterior aspect. This tubercle, which is triangular and facetlike, is usually palpable through the skin.

The anterior condylar surfaces are continuous with a large triangular area whose apex is distal and formed by the tibial tuberosity. The lateral
edge is a sharp ridge between the lateral condyle and lateral surface of the shaft. The condyles, their articular surfaces and the intercondylar area are described on pages 1386-1387.

Tibial tuberosity The tibial tuberosity is the truncated apex of a triangular area where the anterior condylar surfaces merge. It projects only a little, and is divided into distal rough and proximal smooth regions. The distal region is palpable and is separated from skin by the subcutaneous infrapatellar bursa. A line across the tibial tuberosity marks the distal limit of the proximal tibial growth plate (see Fig. 83.3). The patellar ligament is attached to the smooth bone proximal to this, its superficial fibres reaching a rough area distal to the line. The deep infrapatellar bursa and fibroadipose tissue intervene between the bone and tendon proximal to its site of attachment. The latter may be marked distally by a somewhat oblique ridge, on to which the lateral fibres of the patellar ligament are inserted more distally than the medial fibres. This knowledge is necessary for avoiding damage to this structure when performing an osteotomy just above the tibial tuberosity in a lateral to

medial direction. In habitual squatters, a vertical groove on the anterior surface of the lateral condyle is occupied by the lateral edge of the patellar ligament in full flexion of the knee.

## Shaft

The shaft is triangular in section and has (antero)medial, lateral and posterior surfaces separated by anterior, lateral (interosseous) and medial borders. It is narrowest at the junction of the middle and distal thirds, and expands gradually towards both ends. The anterior border descends from the tuberosity to the anterior margin of the medial malleolus and is subcutaneous throughout. Except in its distal quarter, where it is indistinct, it is a sharp crest. It is slightly sinuous, and turns medially in the distal quarter. The interosseous border begins distal and anterior to the fibular articular facet and descends to the anterior border of the fibular notch; it is indistinct proximally. The interosseous membrane is attached to most of its length, connecting the tibia to the fibula. The medial border descends from the anterior end of the groove on the medial condyle to the posterior margin of the medial malleolus. Its proximal and distal quarters are ill defined but its central region is sharp and distinct.

The anteromedial surface, between the anterior and medial borders, is broad, smooth and almost entirely subcutaneous. The lateral surface, between the anterior and interosseous borders, is also broad and smooth. It faces laterally in its proximal three-quarters and is transversely concave. Its distal quarter bends to face anterolaterally, on account of the medial deviation of the anterior and distal interosseous borders. This part of the surface is somewhat convex. The posterior surface, between the interosseous and medial borders, is widest above, where it is crossed distally and medially by an oblique, rough soleal line. A faint vertical line descends from the centre of the soleal line for a short distance before becoming indistinct. A large vascular groove adjoins the end of the line and descends distally into a nutrient foramen. Deep fascia and, proximal to the medial malleolus, the medial end of the superior extensor retinaculum are attached to the anterior border. Posterior fibres of the tibial collateral ligament and slips of semimembranosus and the popliteal fascia are attached to the medial border proximal to the soleal line, and some fibres of soleus and the fascia covering the deep calf muscles are attached distal to the line. The distal medial border runs into the medial lip of a groove for the tendon of tibialis posterior. The interosseous membrane is attached to the lateral
border, except at either end of this border. It is indistinct proximally where a large gap in the membrane transmits the anterior tibial vessels. Distally, the border is continuous with the anterior margin of the fibular notch, to which the anterior tibiofibular ligament is attached.

The anterior part of the tibial collateral ligament is attached to an area approximately 5 cm long and 1 cm wide near the medial border of the proximal medial surface. The remaining medial surface is subcutaneous and crossed obliquely by the long saphenous vein. Tibialis anterior is attached to the proximal two-thirds of the lateral surface. The distal third, devoid of attachments, is crossed in mediolateral order by the tendons of tibialis anterior (lying just lateral to the anterior border), extensor hallucis longus, the anterior tibial vessels and deep fibular nerve, extensor digitorum longus and fibularis tertius.

On the posterior surface, popliteus is attached to a triangular area proximal to the soleal line, except near the fibular articular facet. The popliteal aponeurosis, soleus and its fascia, and the transverse intermuscular septum are all attached to the soleal line; the proximal end of the line does not reach the interosseous border, and is marked by a tubercle for the medial end of the tendinous arch of soleus. Lateral to the tubercle, the posterior tibial vessels and tibial nerve descend on tibialis posterior. Distal to the soleal line, a vertical line separates the attachments of flexor digitorum longus and tibialis posterior. Nothing is attached to the distal quarter of this surface, but the area is crossed medially by the tendon of tibialis posterior travelling to a groove on the posterior aspect of the medial malleolus. Flexor digitorum longus crosses obliquely behind tibialis posterior; the posterior tibial vessels and nerve and flexor hallucis longus contact only the lateral part of the distal posterior surface.

## Distal end

The slightly expanded distal end of the tibia has anterior, medial, posterior, lateral and distal surfaces. It projects inferomedially as the medial malleolus. The distal end of the tibia, when compared to the proximal end, is laterally rotated (tibial torsion). The torsion begins to develop in utero and progresses throughout childhood, mainly during the first four years of life (Kristiansen et al 2001), until skeletal maturity is attained. Some of the femoral neck anteversion seen in the newborn may persist in adult females: this causes the femoral shaft and knee to be medially rotated, which may lead the tibia to develop a compensatory external torsion to counteract the tendency of the feet to turn inwards. Tibial torsion is approximately $30^{\circ}$ in Caucasian and Asian populations, but is significantly greater in Africans (Eckhoff et al 1994).

The smooth anterior surface projects beyond the distal surface, from which it is separated by a narrow groove. The capsule of the ankle joint is attached to an anterior groove near the articular surface. The medial surface is smooth and continuous above and below with the medial surfaces of the shaft and medial malleolus, respectively; it is subcutaneous and visible. The posterior surface is smooth except where it is crossed near its medial end by a nearly vertical but slightly oblique groove, which is usually conspicuous and extends to the posterior surface of the malleolus. The groove is adapted to the tendon of tibialis posterior, which usually separates the tendon of flexor digitorum longus from the bone. More laterally, the posterior tibial vessels, tibial nerve and flexor hallucis longus contact this surface. The lateral surface is the triangular fibular notch; its anterior and posterior edges project and converge proximally to the interosseous border. The floor of the notch is roughened proximally by a substantial interosseous ligament but is smooth distally and is sometimes covered by articular cartilage. The anterior and posterior tibiofibular ligaments are attached to the corresponding edges of the notch. The distal surface articulates with the talus and is wider in front, concave sagittally and slightly convex transversely, i.e. saddle-shaped. Medially, it continues into the malleolar articular surface, which may extend into the groove that separates it from the anterior surface of the shaft. Such extensions, medial or lateral or both, are squatting facets, and they articulate with reciprocal talar facets in extreme dorsiflexion. These features have been used in the field of forensic medicine to identify the race of skeletal material.

Medial malleolus The short, thick medial malleolus has a smooth lateral surface with a crescentic facet that articulates with the medial surface of the talus. Its anterior aspect is rough and its posterior aspect features the continuation of the groove from the posterior surface of the tibial shaft for the tendon of tibialis posterior. The distal border is pointed anteriorly, posteriorly depressed, and gives attachment to the deltoid ligament. The tip of the medial malleolus does not project as far distally as the tip of the lateral malleolus, the latter also being the more posteriorly located of the two malleoli. The capsule of the ankle joint is attached to the anterior surface of the medial malleolus, and the flexor retinaculum is attached to its prominent posterior border.

## Muscle attachments

The patellar ligament is attached to the proximal half of the tibial tuberosity. Semimembranosus is attached to the distal edge of the groove on the posterior surface of the medial condyle; a tubercle at the lateral end of the groove is the main attachment of the tendon of this muscle. Slips from the tendon of biceps femoris are attached to the lateral tibial condyle anteroproximal to the fibular articular facet (see Fig. 83.3B). Proximal fibres of extensor digitorum longus and (occasionally) fibularis longus are attached distal to this area. Slips of semimembranosus are attached to the medial border of the shaft posteriorly, proximal to the soleal line. Some fibres of soleus attach to the posteromedial surface distal to the line. Semimembranosus is attached to the medial surface proximally, near the medial border, behind the attachment of the anterior part of the tibial collateral ligament. Anterior to this area (in anteroposterior sequence) are the linear attachments of the tendons of sartorius, gracilis and semitendinosus; these rarely mark the bone. Tibialis anterior is attached to the proximal two-thirds of the lateral (extensor) surface. Popliteus is attached to the posterior surface in a triangular area proximal to the soleal line, except near the fibular articular facet (see Fig. 83.4B). Soleus and its associated fascia are attached to the soleal line itself. Flexor digitorum longus and tibialis posterior are attached to the posterior surface distal to the soleal line, medial and lateral, respectively, to the vertical line (see above).

## Vascular supply

The proximal end of the tibia is supplied by metaphysial arteries from the genicular anastomosis. The nutrient foramen usually lies near the soleal line and transmits a branch of the posterior tibial artery; the nutrient vessel may also arise at the level of the popliteal bifurcation or as a branch from the anterior tibial artery. On entering the bone, the nutrient artery divides into ascending and descending branches. The periosteal supply to the shaft arises from the anterior tibial artery and from muscular branches. The distal metaphysis is supplied by branches from the arterial anastomosis around the ankle.

## Innervation

The proximal and distal ends of the tibia are innervated by branches from the nerves that supply the knee joint and ankle joint, respectively. The periosteum of the shaft is supplied by branches from the nerves that innervate the muscles attached to the tibia.

## Ossification

The tibia ossifies from three centres: one in the shaft and one in each epiphysis. Ossification (see Figs 83.3-83.4; Fig. 83.5) begins in midshaft at about the seventh intrauterine week. The proximal epiphysial centre is usually present at birth: at approximately 10 years, a thin anterior process from the centre descends to form the smooth part of the tibial tuberosity. A separate centre for the tuberosity may appear at about the twelfth year and soon fuses with the epiphysis. Distal strata of the epiphysial plate are composed of dense collagenous tissue in which the fibres are aligned with the patellar ligament. Exaggerated traction stresses may account for Osgood-Schlatter disease, in which

Fig. 83.5 Stages in the ossification of the tibia (not to scale).
fragmentation of the epiphysis of the tibial tuberosity occurs during adolescence and produces a painful swelling around it. Healing occurs once the growth plate fuses, leaving a bony protrusion. Prolonged periods of traction with the knee extended, both in children and adolescents, can lead to growth arrest of the anterior part of the proximal epiphysis, which results in bowing of the proximal tibia as the posterior tibia continues to grow. The proximal epiphysis fuses in the sixteenth year in females and the eighteenth in males. The distal epiphysial centre appears early in the first year and joins the shaft at about the fifteenth year in females and the seventeenth in males. The medial malleolus is an extension from the distal epiphysis and starts to ossify in the seventh year; it may have its own separate ossification centre. An accessory ossification centre sometimes appears at the tip of the medial malleolus, more often in females than in males. It fuses during the eighth year in females and the ninth year in males; it should not be confused with an os subtibiale, which is a rare accessory bone found on the posterior aspect of the medial malleolus. The average growth rate of the distal tibia decreases from a plateau of about 11 years of age in boys and 10 years of age in girls (Kärrholm et al 1984).

## FIBULA

The fibula (see Figs 83.3-83.4) is much more slender than the tibia and is not directly involved in transmission of weight. It has a proximal head, a narrow neck, a long shaft and a distal lateral malleolus. The shaft varies in form, being variably moulded by attached muscles; these variations may be confusing.

## Head

The head of the fibula is irregular in shape and projects anteriorly, posteriorly and laterally. A round facet on its proximomedial aspect articulates with a corresponding facet on the inferolateral surface of the lateral tibial condyle. It faces proximally and anteromedially, and has an inclination that may vary among individuals from almost horizontal to an angle of up to $45^{\circ}$. A blunt apex projects proximally from the posterolateral aspect of the head and is often palpable approximately 2 cm distal to the knee joint. The fibular collateral ligament is attached in front of the apex, embraced by the main attachment of biceps femoris. The tibiofibular joint capsule is attached to the margins of the articular facet. The common fibular nerve crosses posterolateral to the neck and can be rolled against the underlying bone at this location.

## Shaft

The shaft has three borders and surfaces, each associated with a particular group of muscles. The anterior border ascends proximally from the apex of an elongated triangular area that is continuous with the lateral malleolar surface, to the anterior aspect of the fibular head. The posterior border, continuous with the medial margin of the posterior groove on the lateral malleolus, is usually distinct distally but often rounded in its proximal half. The interosseous border is medial to the anterior border and somewhat posterior. Over the proximal two-thirds of the fibular shaft the two borders approach each other, with the surface between the two being narrowed to 1 mm or less.

The lateral surface, between the anterior and posterior borders and associated with the fibular muscles, faces laterally in its proximal threequarters. The distal quarter spirals posterolaterally to become continuous with the posterior groove of the lateral malleolus. The anteromedial (sometimes simply termed anterior, or medial) surface, between the anterior and interosseous borders, usually faces anteromedially but often directly anteriorly. It is associated with the extensor muscles. Though wide distally, it narrows in its proximal half and may become a mere ridge. The posterior surface, between the interosseous and posterior borders, is the largest and is associated with the flexor muscles. Its proximal two-thirds are divided by a longitudinal medial crest, separated from the interosseous border by a grooved surface that is directed medially. The remaining surface faces posteriorly in its proximal half; its distal half curves on to the medial aspect. Distally, this area occupies the fibular notch of the tibia, which is roughened by the attachment of the principal interosseous tibiofibular ligament. The triangular area proximal to the lateral surface of the lateral malleolus is subcutaneous; muscles cover the rest of the shaft.

The anterior border is divided distally into two ridges that enclose a triangular subcutaneous surface. The anterior intermuscular septum is attached to its proximal three-quarters. The lateral end of the superior extensor retinaculum is attached distally on the anterior border of the triangular area and the lateral end of the superior fibular retinaculum is attached distally on the posterior margin of the triangular area. The interosseous border ends at the proximal limit of the rough area for the
interosseous ligament. The interosseous membrane attached to this border does not reach the fibular head, which leaves a gap through which the anterior tibial vessels pass. The posterior border is proximally indistinct, and the posterior intermuscular septum is attached to all but its distal end. The medial crest is related to the fibular artery. A layer of deep fascia separating the tendon of tibialis posterior from flexor hallucis longus and flexor digitorum longus is attached to the medial crest.

## Lateral malleolus

The distal end of the fibula forms the lateral malleolus, which projects distally and posteriorly (see Figs 83.3-83.4). Its lateral aspect is subcutaneous while its posterior aspect has a broad groove with a prominent lateral border. Its anterior aspect is rough, round and continuous with the tibial inferior border. The medial surface has a triangular articular facet, vertically convex, its apex distal, which articulates with the lateral talar surface. Behind this facet is a rough malleolar fossa pitted by vascular foramina. The posterior tibiofibular ligament and, more distally, the posterior talofibular ligament, are attached in the fossa. The anterior talofibular ligament is attached to the anterior surface of the lateral malleolus; the calcaneofibular ligament is attached to the notch anterior to its apex. The tendons of fibularis brevis and longus groove its posterior aspect; the latter is superficial and covered by the superior fibular retinaculum.

## Muscle attachments

The main attachments of biceps femoris embrace the fibular collateral ligament in front of the apex of the fibular head. Extensor digitorum longus is attached to the head anteriorly, fibularis longus anterolaterally, and soleus posteriorly. Extensor digitorum longus, extensor hallucis longus and fibularis tertius are attached to the anteromedial (extensor) surface. Fibularis longus is attached to the whole width of the lateral (fibular) surface in its proximal third, but in its middle third only to its posterior part, behind fibularis brevis. The latter continues its attachment almost to the distal end of the shaft.

Muscle attachments to the posterior surface, which is divided longitudinally by the medial crest, are complex. Between the crest and interosseous border, the posterior surface is concave. Tibialis posterior is attached throughout most (the proximal three-quarters) of this area; an intramuscular tendon may ridge the bone obliquely. Soleus is attached between the crest and the posterior border on the proximal quarter of the posterior surface; its tendinous arch is attached to the surface proximally (see Fig. 83.4B). Flexor hallucis longus is attached distal to soleus on the posterior surface and almost reaches the distal end of the shaft.

## Vascular supply

A little proximal to the midpoint of the posterior surface (14-19 cm from the apex), a distally directed nutrient foramen on the fibular shaft receives a branch of the fibular artery. An appreciation of the detailed anatomy of the fibular artery in relation to the fibula is fundamental to the raising of osteofasciocutaneous free flaps. Free vascularized diaphysial grafts may also be taken on a fibular arterial pedicle. The proximal and distal ends receive metaphysial vessels from the arterial anastomoses at the knee and ankle, respectively (Taylor and Razaboni 1994).

## Innervation

The proximal and distal ends of the bone are supplied by branches of nerves that innervate the knee and superior tibiofibular joint, and the ankle and inferior tibiofibular joints, respectively. The periosteum of the shaft is supplied by branches from the nerves that innervate the muscles attached to the fibula.

## Ossification

The fibula ossifies from three centres: one each for the shaft and the extremities. The process begins in the shaft at about the eighth week in utero; in the distal end in the first year; and in the proximal end at about the third year in females and the fourth year in males. The distal epiphysis unites with the shaft at about the fifteenth year in females and the seventeenth year in males, whereas the proximal epiphysis does not unite until about the seventeenth year in females and the nineteenth year in males. A longitudinal radiographic study of children has shown that the proximal growth plate of the fibula contributes more to growth than the proximal growth plate of the tibia, their growth contributions being $61 \%$ and $57 \%$, respectively (Pritchett and Bortel 1997).

## MUSCLES

The muscles of the leg consist of an anterior group of extensor muscles, which produce dorsiflexion (extension) of the ankle; a posterior group

An os subfibulare is an occasional and separate entity and lies posterior to the tip of the fibula, whereas the distal fibular apophysis lies anteriorly. An os retinaculi is rarely encountered; if present, it overlies the bursa of the distal fibula within the fibular retinaculum. Fibular dimelia is characterized by duplication of the fibula, tibial aplasia and partial duplication of the foot with mirror polydactyly, and may be associated with ulnar dimelia and calcaneal duplication. It has been postulated that a re-establishment of limb polarity during embryogenesis may account for this condition (Bayram et al 1996, Ganey et al 2000).

of flexor muscles, which produce plantar flexion (flexion); and a lateral group of muscles, which evert the ankle and which are derived, embryologically, from the anterior muscle group. The greater bulk of the muscles in the calf is commensurate with the powerful propulsive role of the plantar flexors in walking and running.

## ANTERIOR OR EXTENSOR COMPARTMENT

The anterior compartment contains muscles that dorsiflex the ankle when acting from above (see Fig. 83.2A, B; Fig. 83.6). When acting from below, they pull the body forwards on the fixed foot during walking. Two of the muscles, extensor digitorum longus and extensor hallucis longus, also extend the toes, and two muscles, tibialis anterior and fibularis tertius, have the additional actions of inversion and eversion, respectively.

## Tibialis anterior

Attachments Tibialis anterior is a superficial muscle and is therefore readily palpable lateral to the tibia. It arises from the lateral condyle and proximal one-half to two-thirds of the lateral surface of the tibial shaft; the adjoining anterior surface of the interosseous membrane; the deep surface of the deep fascia; and the intermuscular septum between itself and extensor digitorum longus. The muscle descends vertically and ends in a tendon on its anterior surface in the lower third of the leg. The tendon passes through the medial compartments of the superior and inferior retinacula, inclines medially, and is inserted on to the medial and inferior surfaces of the medial cuneiform and the adjoining part of the base of the first metatarsal.

Fig. 83.6 Muscles of the left leg and foot. The fasciae have been removed. A, Anterior view. B, Lateral view. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Attachments to the talus, first metatarsal head, base of the proximal phalanx of the hallux, and extensor retinaculum have been recorded.

Relations Tibialis anterior overlaps the anterior tibial vessels and deep fibular nerve in the upper part of the leg. It lies on the tibia and interosseous membrane. Extensor digitorum longus and extensor hallucis longus lie laterally.

Vascular supply The main body of tibialis anterior is supplied by a series of medial and anterior branches of the anterior tibial artery; the branches may occur in two columns. There is a proximal accessory supply from the anterior tibial recurrent artery. The tendon is supplied by the anterior medial malleolar artery and network, dorsalis pedis artery, medial tarsal arteries, and by the medial malleolar and calcaneal branches of the posterior tibial artery.

Innervation Tibialis anterior is innervated by the deep fibular nerve, L4 and L5.

Actions Tibialis anterior dorsiflexes and inverts the foot. It is most active when both movements are combined, as in walking. Its tendon can be seen through the skin lateral to the anterior border of the tibia and can be traced downwards and medially across the front of the ankle to the medial side of the foot. Tibialis anterior elevates the first metatarsal base and medial cuneiform, and rotates their dorsal aspects laterally.

The muscle is usually quiescent while standing, since the weight of the body acts through vertical lines that pass anterior to the ankle joints. Acting from below, it helps to counteract any tendency to overbalance
backwards by flexing the leg forwards at the ankle. It has a role in supporting the medial part of the longitudinal arch of the foot; although electromyographically detectable activity is minimal during standing, it is manifest during any movement that increases the arch, such as toe-off in walking and running.

Testing Tibialis anterior can be seen to act when the foot is dorsiflexed against resistance. Dorsiflexion is best tested by asking the subject to walk on their heels.

## Extensor hallucis longus

Attachments Extensor hallucis longus lies between, and is partly overlapped by, tibialis anterior and extensor digitorum longus (see Figs $83.6 \mathrm{~A}, \mathrm{~B}$ ). It arises from the middle half of the medial surface of the fibula, medial to extensor digitorum longus, and from the adjacent anterior surface of the interosseous membrane. Its fibres run distally and end in a tendon that forms on the anterior border of the muscle. The tendon passes deep to the superior extensor retinaculum and through the inferior extensor retinaculum, crosses anterior to the anterior tibial vessels to lie on their medial side near the ankle, and is inserted on to the dorsal aspect of the base of the distal phalanx of the hallux. At the metatarsophalangeal joint, a thin prolongation from each side of the tendon covers the dorsal surface of the joint. An expansion from the medial side of the tendon to the base of the proximal phalanx is usually present.

Extensor hallucis longus is sometimes united with extensor digitorum longus and may send a slip to the second toe.

Relations The anterior tibial vessels and deep fibular nerve lie between extensor hallucis longus and tibialis anterior. Extensor hallucis longus lies lateral to the artery proximally, crosses it in the lower third of the leg, and is medial to it on the foot.

Vascular supply Extensor hallucis longus is supplied by the anterior tibial artery via obliquely running branches, with a variable contribution from the perforating branch of the fibular artery (Fig. 83.7). More distally, the tendon is supplied via the anterior medial malleolar artery and network, the dorsalis pedis artery, and the plantar metatarsal artery of the first digit via perforating branches.
Innervation Extensor hallucis longus is innervated by the deep fibular nerve, L5.
Actions Extensor hallucis longus extends the hallux and dorsiflexes the foot. When the hallux is actively extended, relatively little external force is required to overcome the extension of the distal phalanx, whereas considerable force is needed to overcome the extension of the proximal phalanx.

Testing When the hallux is extended against resistance, the tendon of extensor hallucis longus can be seen and felt on the lateral side of the tendon of tibialis anterior.

## Extensor digitorum longus

Attachments Extensor digitorum longus arises from the inferior surface of the lateral condyle of the tibia, the proximal three-quarters of the medial surface of the fibula, the adjacent anterior surface of the interosseous membrane, the deep surface of the deep fascia, the anterior intermuscular septum and the fascial septum between itself and tibialis anterior. These origins form the walls of an osseo-aponeurotic tunnel. Extensor digitorum longus becomes tendinous at about the same level as tibialis anterior, and the tendon passes deep to the superior extensor retinaculum and within a loop of the inferior extensor retinaculum with fibularis tertius (see Figs 83.6, 84.1). It divides into four slips, which run forwards on the dorsum of the foot and are attached in the same way as the tendons of extensor digitorum in the hand. At the metatarsophalangeal joints, the tendons to the second, third and fourth toes are each joined on the lateral side by a tendon of extensor digitorum brevis. The so-called dorsal digital expansions thus formed on the dorsal aspects of the proximal phalanges, as in the fingers, receive contributions from the appropriate lumbrical and interosseous muscles. The expansion narrows as it approaches a proximal interphalangeal joint, and divides into three slips. These are a central (axial) slip, attached to the base of the middle phalanx, and two collateral (coaxial) slips, which reunite on the dorsum of the middle phalanx and are attached to the base of the distal phalanx.

The tendons to the second and fifth toes are sometimes duplicated, and accessory slips may be attached to metatarsals or to the hallux.

Relations Extensor digitorum longus lies on the lateral tibial condyle, fibula, lower end of the tibia, ankle joint and extensor digitorum brevis.

Fig. 83.7 The left anterior tibial and dorsalis pedis arteries. To expose the anterior tibial artery, a large part of tibialis anterior has been excised.

Tibialis anterior and extensor hallucis longus lie medially in the leg, and the fibular muscles lie laterally. In the upper part of the leg, the anterior tibial vessels and deep fibular nerve lie between extensor digitorum longus and tibialis anterior; the nerve runs obliquely and medially beneath its upper part.

Vascular supply The main blood supply to extensor digitorum longus is derived from anteriorly and laterally placed branches of the anterior tibial artery, supplemented distally from the perforating branch of the fibular artery. Proximally, there may also be a supply from the inferior lateral genicular, popliteal or anterior tibial recurrent arteries. At the ankle and in the foot, the tendons are supplied by the anterior lateral malleolar artery and malleolar network, and by lateral tarsal, metatarsal, plantar and digital arteries.

Innervation Extensor digitorum longus is innervated by the deep fibular nerve, L5, S1.

Actions Extensor digitorum longus extends the lateral four toes. Acting synergistically with tibialis anterior, extensor hallucis longus and fibularis tertius, it is a dorsiflexor of the ankle. Acting with extensor hallucis longus, it helps tighten the plantar aponeurosis.

Testing The tendons of extensor digitorum longus can be seen when the toes are extended against resistance.

## Fibularis tertius

Attachments Fibularis tertius (peroneus tertius) often appears to be part of extensor digitorum longus and might be described as its 'fifth tendon'. The muscle fibres of fibularis tertius arise from the distal third or more of the medial surface of the fibula, the adjoining anterior surface of the interosseous membrane, and the anterior intermuscular septum. The tendon passes deep to the superior extensor retinaculum and within the loop of the inferior extensor retinaculum alongside the extensor digitorum longus (see Figs 83.6B, 84.2A). It is inserted on to the medial part of the dorsal surface of the base of the fifth metatarsal; a thin expansion usually extends forwards along the medial border of the shaft of the bone.

Relations Fibularis tertius lies lateral to extensor digitorum longus.
Vascular supply Fibularis tertius is supplied by the same vessels as extensor digitorum longus. In the foot it receives an additional supply from the termination of the arcuate artery and the fourth dorsal metatarsal artery.

Innervation Fibularis tertius is innervated by the deep fibular nerve, L5, S1.

Actions Electromyographic studies show that during the swing phase of gait (see Fig. 84.27), fibularis tertius acts with extensor digitorum longus and tibialis anterior to produce dorsiflexion of the foot, and with fibularis longus and fibularis brevis to effect eversion of the foot (Jungers et al 1993). This levels the foot and helps the toes to clear the ground, an action that improves the efficiency and enhances the economy of bipedal locomotion. Fibularis tertius is not active during the stance phase, a finding that is at variance with the suggestion that the muscle acts primarily to support the lateral longitudinal arch and to transfer the centre of pressure of the foot medially.

Testing Fibularis tertius cannot be tested in isolation, but its tendon can sometimes be seen and felt when the foot is dorsiflexed against resistance.

## LATERAL (FIBULAR OR PERONEAL) COMPARTMENT

The lateral compartment contains fibularis (peroneus) longus and fibularis (peroneus) brevis (see Figs 83.2A, B, 83.6A, B). Both muscles evert the foot and are plantar flexors of the ankle, and both probably play a part in balancing the leg on the foot in standing and walking.

## Fibularis longus

Attachments Fibularis longus is the more superficial of the two muscles of the lateral compartment. It arises from the head and proximal two-thirds of the lateral surface of the fibula, the deep surface of the deep fascia, the anterior and posterior intermuscular septa, and occasionally by a few fibres from the lateral condyle of the tibia. The muscle belly ends in a long tendon that runs distally behind the lateral malleolus in a groove it shares with the tendon of fibularis brevis. The groove is converted into a canal by the superior fibular retinaculum, so that the tendon of fibularis longus and that of fibularis brevis, which lies in front of the longus tendon, are contained in a common synovial sheath. If the fibular retinaculum is ruptured by injury and fails to heal, the tendons can dislocate from the groove. The fibularis longus tendon runs obliquely forwards on the lateral side of the calcaneus, below the fibular trochlea and the tendon of fibularis brevis, and deep to the inferior fibular retinaculum. It crosses the lateral side of the cuboid and then runs under the cuboid in a groove that is converted into a canal by the long plantar ligament (see Fig. 84.20). It crosses the sole of the foot obliquely and is attached by two slips, one to the lateral side of the base of the first metatarsal and one to the lateral aspect of the medial cuneiform; occasionally, a third slip is attached to the base of the second metatarsal. The tendon changes direction below the lateral malleolus
and on the cuboid bone. At both sites it is thickened, and at the second site a sesamoid fibrocartilage (sometimes a bone, the os peroneum) is usually present. A second synovial sheath invests the tendon as it crosses the sole of the foot.

Relations Proximally, fibularis longus lies posterior to extensor digitorum longus and anterior to soleus and flexor hallucis longus. Distally, in the leg, it lies posterior to fibularis brevis. Between its attachments to the head and shaft of the fibula there is a gap through which the common fibular nerve passes.

Vascular supply of lateral compartment Usually, the predominant supply of the lateral compartment muscles is derived from branches of the anterior tibial artery; the superior is commonly the larger. There is also a lesser, variable, contribution from the fibular artery in the distal part of the leg. A fibular branch may replace the inferior branch of the anterior tibial artery; less commonly, the fibular artery provides the main supply to the whole compartment. The upper part of fibularis longus is also supplied by the circumflex fibular branch of the posterior tibial artery, which is usually a branch of the anterior tibial artery. The companion artery to the common fibular nerve, a branch of the popliteal artery, provides a minor contribution proximally. Distally, the tendons are supplied by the fibular perforating, anterior lateral malleolar, lateral calcaneal, lateral tarsal, arcuate, lateral and medial plantar arteries (see Fig. 84.9).

Innervation Fibularis longus is innervated by the superficial fibular nerve, L5, S1.

Actions There is little doubt that fibularis longus can evert the foot and plantar flex the ankle, and possibly act on the leg from its distal attachments. The oblique direction of its tendon across the sole also enables it to support the longitudinal and transverse arches of the foot. With the foot off the ground, eversion is visually and palpably associated with increased prominence of both tendon and muscle. It is not clear to what extent this helps to maintain plantigrade contact of the foot in normal standing, but electromyographic recordings show little or no fibular activity under these conditions. Fibularis longus and brevis come strongly into action to maintain the concavity of the foot during toe-off and tip-toeing. If the subject deliberately sways to one side, fibularis longus and brevis contract on that side, but their involvement in influencing postural interactions between the foot and leg remains uncertain.

Testing Fibularis longus and brevis are tested together by eversion of the foot against resistance; the tendons can be identified laterally at the ankle and in the foot.

## Fibularis brevis

Attachments Fibularis brevis arises from the distal two-thirds of the lateral surface of the fibula, anterior to fibularis longus, and from the anterior and posterior crural intermuscular septa. It passes vertically downwards and ends in a tendon that passes behind the lateral malleolus together with, and anterior to, that of fibularis longus. The two tendons run deep to the superior fibular retinaculum in a common synovial sheath. The tendon of fibularis brevis then runs forwards on the lateral side of the calcaneus above the fibular trochlea and the tendon of fibularis longus, and is inserted into a tuberosity on the lateral side of the base of the fifth metatarsal.

Relations Anteriorly lie extensor digitorum longus and fibularis tertius. Fibularis longus and flexor hallucis longus are posterior. On the lateral surface of the calcaneus, the tendons of fibularis longus and fibularis brevis occupy separate osteofascial canals formed by the calcaneus and the inferior fibular retinaculum; each tendon is enveloped in a separate distal prolongation of the common synovial sheath (see Fig. 84.2A).

## Vascular supply See 'Fibularis longus'.

Innervation Fibularis brevis is innervated by the superficial fibular nerve, L5, S1.

Actions Fibularis brevis may limit inversion of the foot and so relieve strain on the ligaments that are tightened by this movement (the lateral part of interosseous talocalcaneal, lateral talocalcaneal and calcaneofibular ligaments). It participates in eversion of the foot and may help to steady the leg on the foot. See also 'Fibularis longus'.

Testing See 'Fibularis longus'.

## Variants of fibular muscles

Tendinous slips from fibularis longus may extend to the base of the third, fourth or fifth metatarsals, or to adductor hallucis. Fusion of fibularis longus and brevis has been reported but is rare. Fibularis tertius is highly variable in its form and bulk but is seldom completely absent; its distal attachment may be to the fourth metatarsal rather than the fifth. Two other variant fibular muscles, arising from the fibula between fibularis longus and fibularis brevis, have been described. These are fibularis accessorius, whose tendon joins that of fibularis longus in the sole, and fibularis quartus, which arises posteriorly and inserts on to the calcaneus or on to the cuboid.

## POSTERIOR (FLEXOR) COMPARTMENT

The muscles in the posterior compartment of the lower leg form superficial and deep groups, separated by the transverse intermuscular septum.

## Superficial flexor group

The superficial muscles - gastrocnemius, plantaris and soleus (Fig. 83.8; see Figs 83.2A, 82.3) - form the bulk of the calf. Gastrocnemius and soleus, collectively known as the triceps surae, constitute a powerful muscular mass whose main function is plantar flexion of the foot, although soleus in particular has an important postural role (see below). Their large size is a defining human characteristic, and is related to the upright stance and bipedal locomotion of the human. Gastrocnemius and plantaris act on both the knee and the ankle joints, soleus on the latter alone.

## Gastrocnemius

Attachments Gastrocnemius is the most superficial muscle of the group and forms the 'belly' of the calf (see Fig. 82.3). It arises by two heads, connected to the condyles of the femur by strong, flat tendons. The medial, larger head is attached to a depression at the upper and posterior part of the medial condyle behind the adductor tubercle, and to a slightly raised area on the popliteal surface of the femur just above the medial condyle. The lateral head is attached to a recognizable area on the lateral surface of the lateral condyle and to the lower part of the corresponding supracondylar line. Both heads also arise from subjacent areas of the capsule of the knee joint. The tendinous attachments expand to cover the posterior surface of each head with an aponeurosis, from the anterior surface of which the muscle fibres arise. The fleshy part of the muscle extends to about mid-calf. The muscle fibres of the larger medial head extend lower than those of the lateral head. As the muscle descends, the muscle fibres begin to insert into a broad aponeurosis that develops on its anterior surface; up to this point, the muscular masses of the two heads remain separate. The aponeurosis gradually narrows and receives the tendon of soleus on its deep surface to form the calcaneal tendon (for a detailed description of the calcaneal tendon, see page 1440).

On occasion, the lateral head, or the whole muscle, is absent. A third head arising from the popliteal surface of the femur is sometimes present.

Relations Proximally, the two heads of gastrocnemius form the lower boundaries of the popliteal fossa. The lateral head is partially overlaid by the tendon of biceps femoris, the medial head by semimembranosus. Over the rest of its length, the muscle is superficial and the two heads can easily be seen in the living subject. The superficial surface of the muscle is separated by the deep fascia from the short saphenous vein and the fibular communicating and sural nerves. The common fibular nerve crosses behind the lateral head of the muscle, partly under cover of biceps femoris. The deep surface lies posterior to the oblique popliteal ligament, popliteus, soleus, plantaris, popliteal vessels and the tibial nerve. A bursa, which communicates with the knee joint, is located anterior to the tendon of the medial head; if the bursa expands into the popliteal fossa, it does so in the plane between the medial head of gastrocnemius and semimembranosus. The tendon of the lateral head frequently contains a sesamoid bone, the fabella, where it moves over the lateral femoral condyle. A sesamoid bone may occasionally occur in the tendon of the medial head.

Vascular supply Each head of gastrocnemius is supplied by its own sural artery. These arteries are branches of the popliteal artery and arise at variable levels, usually at the level of the tibiofemoral joint line. The medial sural artery almost always arises more proximally than the lateral; the medial may arise proximal to the joint line, the lateral sometimes distal to the line. Each sural artery enters the corresponding

Fig. 83.8 Muscles of the left leg, posterior aspect. Gastrocnemius has been partially removed. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
muscle head with its nerve of supply, the pedicle entering the muscle near its axial border at the level of the middle of the popliteal fossa. Medial or lateral gastrocnemius musculocutaneous flaps may be raised, each based on its neurovascular pedicle. Minor accessory sural arteries arise from the popliteal or from the superior genicular arteries.

The blood supply to the calcaneal tendon is described on page 1440.
Innervation Gastrocnemius is innervated by the tibial nerve, S1 and S2.

Actions The action of gastrocnemius is considered with soleus.
Testing Gastrocnemius is tested by plantar flexion of the foot against resistance, in the supine position and with the knee extended. Plantar flexion (gastrocnemius and soleus) is best tested by asking the subject to perform repetitive unilateral toe rises.

## Plantaris

Attachments Plantaris arises from the lower part of the lateral supracondylar line and the oblique popliteal ligament (see Fig. 83.8). Its small fusiform belly is $7-10 \mathrm{~cm}$ long and ends in a long slender tendon, which crosses obliquely, in an inferomedial direction, between gastrocnemius and soleus, then runs distally along the medial border of the calcaneal tendon and inserts on to the calcaneus just medial to the calcaneal tendon. Occasionally, it ends by fusing with the calcaneal tendon.

The muscle is sometimes double, and occasionally absent. Occasionally, its tendon merges with the flexor retinaculum or with the fascia of the leg.

Vascular supply Plantaris is supplied superficially by the lateral sural and popliteal arteries, and deeply by the superior lateral genicular artery. The distal tendon shares a blood supply with the calcaneal tendon.

Innervation Plantaris is innervated by the tibial nerve, often from the ramus that supplies the lateral head of gastrocnemius, S1 and S2.

Actions In many mammals, plantaris is well developed and inserts directly or indirectly into the plantar aponeurosis. In humans, the muscle is almost vestigial and is normally inserted well short of the plantar aponeurosis, usually into the calcaneus. It is therefore presumed to act with gastrocnemius.

## Soleus

Attachments Soleus is a broad, flat muscle situated immediately deep (anterior) to gastrocnemius (see Fig. 83.8). It arises from the posterior surface of the head and proximal quarter of the shaft of the fibula; the soleal line and the middle third of the medial border of the tibia; and from a fibrous band between the tibia and fibula (tendinous arch of the soleus) that arches over the popliteal vessels and tibial nerve. This origin is aponeurotic; most of the muscular fibres arise from its posterior surface and pass obliquely to the tendon of insertion on the posterior surface of the muscle. Other muscle fibres arise from the anterior surface of the aponeurosis. They are short, oblique and bipennate in arrangement, and converge on a narrow, central intramuscular tendon that merges distally with the principal tendon. The latter gradually becomes thicker and narrower, and joins the tendon of gastrocnemius to form the calcaneal tendon. The muscle is covered proximally by gastrocnemius, but below mid-calf it is broader than the tendon of gastrocnemius and is readily accessible on either side of the tendon.

An accessory part of the muscle is sometimes present distally and medially. It may be inserted into the calcaneal tendon, the calcaneus or the flexor retinaculum.

Relations The superficial surface of soleus is in contact with gastrocnemius and plantaris. Its deep surface is related to flexor digitorum longus, flexor hallucis longus, tibialis posterior and the posterior tibial vessels and tibial nerve, from all of which it is separated by the transverse intermuscular septum of the leg.

Vascular supply Soleus is supplied by two main arteries: the superior arises from the popliteal artery at about the level of the soleal arch, and the inferior from the proximal part of the fibular artery or sometimes from the posterior tibial artery. A secondary supply is derived from the lateral sural, fibular or posterior tibial vessels.

There is a venous plexus within the muscle belly that is important physiologically as part of the muscle pump complex (see below). Pathologically, it is a common site of deep vein thrombosis.

Innervation Soleus is innervated by two branches from the tibial nerve, S1 and S2.

## Actions See 'Triceps surae'.

Testing Soleus is tested by plantar flexion of the foot against resistance in the supine position, with hip and knee flexed; the muscle belly can be palpated separately from those of gastrocnemius.

## Actions of triceps surae

Gastrocnemius and soleus are the chief plantar flexors of the foot; gastrocnemius is also a flexor of the knee. The muscles are usually large and correspondingly powerful. Gastrocnemius provides force for propulsion in walking, running and leaping. Soleus, acting from below, is said to be more concerned with steadying the leg on the foot in standing. This postural role is also suggested by its high content of slow, fatigue-resistant (type 1) muscle fibres. In many adult mammals, the
proportion of this type of fibre in soleus approaches $100 \%$. However, such a rigid separation of functional roles seems unlikely in humans; soleus probably participates in locomotion, and gastrocnemius in posture. Nevertheless, the ankle joint is loose-packed in the erect posture, and since the weight of the body acts through a vertical line that passes anterior to the joint, a strong brace is required behind the joint to maintain stability. Electromyography shows that these forces are supplied mainly by soleus; during symmetrical standing, soleus is continuously active, whereas gastrocnemius is recruited only intermittently. The relative contributions of soleus and gastrocnemius to phasic activity of the triceps surae in walking have yet to be satisfactorily analysed.

## Deep flexor group

The deep flexor group (see Fig. 83.2A, B; Figs 83.9-83.10) lies beneath (anterior to) the transverse intermuscular septum and consists of popliteus, which acts on the knee joint, and flexor digitorum longus, flexor hallucis longus and tibialis posterior, which all produce plantar flexion at the ankle in addition to their specific actions on joints of the foot and digits.

## Popliteus

Popliteus is described on page 1397.

## Flexor digitorum longus

Attachments Flexor digitorum longus is thin and tapered proximally, but widens gradually as it descends (see Figs 83.9A, B). It arises from the posterior surface of the tibia medial to tibialis posterior from just below the soleal line to within 7 or 8 cm of the distal end of the bone; it also arises from the fascia covering tibialis posterior. The muscle ends in a tendon that extends along almost the whole of its posterior surface. The tendon gradually crosses tibialis posterior on its superficial aspect and passes behind the medial malleolus where it shares a groove with tibialis posterior, from which it is separated by a fibrous septum, i.e. each tendon occupies its own compartment lined by a synovial sheath (see Fig. 84.2B). The tendon of flexor digitorum longus then curves obliquely forwards and laterally, in contact with the medial side of the sustentaculum tali, passes deep to the flexor retinaculum, and enters the sole of the foot on the medial side of the tendon of flexor hallucis longus. It crosses superficial to that tendon and receives a strong slip from it (and may also send a slip to it). The tendon of flexor digitorum longus then passes forwards as four separate tendons, one each for the second to fifth toes, deep to the tendons of flexor digitorum brevis. After giving rise to the lumbricals, it passes through the fibrous sheaths of the lateral four toes. The tendons of flexor accessorius insert into the long flexor tendons of the second, third and fourth digits; flexor hallucis longus makes a variable contribution through the connecting slip mentioned above. The long flexor tendons of the lateral four digits are attached to the plantar surfaces of the bases of their distal phalanges; each passes between the slips of the corresponding tendon of flexor digitorum brevis at the base of the proximal phalanx.

A supplementary head of the muscle, flexor accessorius longus, with its own tendon, may arise from the fibula, tibia or deep fascia and insert into the main tendon or into flexor accessorius in the foot. It may send communicating slips to tibialis anterior or to flexor hallucis longus.

Relations Flexor digitorum longus lies medial to flexor hallucis longus. In the leg, its superficial surface is in contact with the transverse intermuscular septum, which separates it from soleus, and distally from the posterior tibial vessels and tibial nerve. Its deep surface is related to the tibia and to tibialis posterior. In the foot, it is covered by abductor hallucis and flexor digitorum brevis, and it crosses superficial to flexor hallucis longus.

Vascular supply A series of transversely running branches of the posterior tibial artery enters the lateral border of flexor digitorum longus. There may be a secondary supply from fibular branches to flexor hallucis longus. The tendons are supplied by the vessels of the ankle and sole of the foot.

Innervation Flexor digitorum longus is innervated by branches of the tibial nerve, L5, S1 and S2.

## Actions See 'Flexor hallucis longus'.

Testing Flexor digitorum longus is tested by flexing the toes against resistance. Aberrant function of flexor digitorum longus is implicated in toe deformities such as hammer toe, claw toe and mallet toe. Its

Fig. 83.9 Muscles of the left leg, posterior aspect. A, The superficial muscles have been extensively removed. B, The superficial muscles have been extensively removed, popliteus has been sectioned and the tendon of flexor digitorum longus removed as it crosses the tendon of tibialis posterior. tendon may be used in transfer procedures for the surgical treatment of tibialis posterior tendon dysfunction.

## Flexor hallucis longus

Attachments Flexor hallucis longus arises from the distal two-thirds of the posterior surface of the fibula (except for the lowest 2.5 cm of this surface); the adjacent interosseous membrane and the posterior crural intermuscular septum; and from the fascia covering tibialis posterior, which it overlaps to a considerable extent (see Fig. 83.9). Its fibres pass obliquely down to a tendon that occupies nearly the whole length of the posterior aspect of the muscle. This tendon grooves the posterior surface of the lower end of the tibia, then, successively, the posterior surface of the talus and the inferior surface of the sustentaculum tali of
the calcaneus (see Fig. 84.2B). Fibrous bands convert the grooves on the talus and calcaneus into a canal lined by a synovial sheath. In dancers, overuse causes thickening of the tendon in this region, and pain and even 'triggering' can occur (hallux saltans). In the sole of the foot, the tendon of flexor hallucis longus passes forwards in the second layer like a bowstring. It crosses the tendon of flexor digitorum longus from lateral to medial, curving obliquely superior to it. At the crossing point (knot of Henry), it gives off two strong slips to the medial two divisions of the tendons of flexor digitorum longus and then crosses the lateral part of flexor hallucis brevis to reach the interval between the sesamoid bones under the head of the first metatarsal. It continues on the plantar aspect of the hallux, and runs in an osseo-aponeurotic tunnel to be attached to the plantar aspect of the base of the distal

Fig. 83.10 A transverse section through the left leg, approximately 6 cm proximal to the medial malleolus.
phalanx. The tendon is retained in position over the lateral part of flexor hallucis brevis by the diverging stems of the distal band of the medial intermuscular septum.

The distal extent of the muscle belly is a distinctive characteristic; in the posteromedial surgical approach to the ankle, flexor hallucis longus is readily identifiable by the fact that muscle fibres are evident almost to calcaneal level. In athletes, the muscle fibres may be present so far inferiorly into the tendon as to be susceptible to impingement when pulled into the tunnel at the talus.

The connecting slip to flexor digitorum longus varies in size; it usually continues into the tendons for the second and third toes but is sometimes restricted to the second toe and occasionally extends to the fourth toe.

Relations Soleus and the calcaneal tendon lie superficial (i.e. posterior) to flexor hallucis longus, separated by the transverse intermuscular septum. Deeply situated are the fibula, tibialis posterior, fibular vessels, distal part of the interosseous membrane and the talocrural joint. Laterally lie fibularis longus and fibularis brevis; medially are tibialis posterior, posterior tibial vessels and the tibial nerve. Flexor hallucis longus is an important surgical landmark at the ankle; staying lateral to it prevents injury to the neurovascular bundle.

Vascular supply Flexor hallucis longus is supplied by numerous branches of the fibular artery. The tendon is supplied by arteries of the ankle and foot.

Innervation Flexor hallucis longus is innervated by branches of the tibial nerve, L5, S1 and S2 (mainly S1).

Testing Flexor hallucis longus is tested by flexion of the hallux against resistance.

## Actions of deep digital flexors

Both flexor hallucis longus and flexor digitorum longus can act as plantar flexors but this action is weak compared with that of gastrocnemius and soleus. When the foot is off the ground, both muscles flex the phalanges, acting primarily on the distal phalanges. When the foot is on the ground and under load, they act synergistically with the small muscles of the foot and, especially in the case of flexor digitorum longus, with the lumbricals and interossei to maintain the pads of the toes in firm contact with the ground, enlarging the weight-bearing area and helping to stabilize the heads of the metatarsals, which form the fulcrum on which the body is propelled forwards. Activity in the long digital flexors is minimal during quiet standing, so they apparently contribute little to the static maintenance of the longitudinal arch, but they become very active during toe-off and tip-toe movements.

## Tibialis posterior

Attachments Tibialis posterior is the most deeply placed muscle of the flexor group (see Fig. 83.9). At its origin it lies between flexor
hallucis longus and flexor digitorum longus, and is overlapped by both, but especially by the former. Its proximal attachment consists of two tapered processes, separated by an angular interval that is traversed by the anterior tibial vessels. The medial process arises from the posterior surface of the interosseous membrane, except at its most distal part, and from a lateral area on the posterior surface of the tibia between the soleal line above and the junction of the middle and lower thirds of the shaft below. The lateral part arises from a medial strip of the posterior fibular surface in its upper two-thirds. The muscle also arises from the transverse intermuscular septum, and from the intermuscular septa that separate it from adjacent muscles. In the distal quarter of the leg, its tendon passes deep to that of flexor digitorum longus, with which it shares a groove behind the medial malleolus, each enclosed in a separate synovial sheath (see Fig. 84.2B). It then passes deep to the flexor retinaculum and superficial to the deltoid ligament to enter the foot. In the foot, it is at first inferior to the plantar calcaneonavicular ligament, where it contains a sesamoid fibrocartilage. The tendon then divides into two. The more superficial and larger division, which is a direct continuation of the tendon, is attached to the tuberosity of the navicular, from which fibres continue to the inferior surface of the medial cuneiform. A tendinous band also passes laterally and a little proximally to the tip and distal margin of the sustentaculum tali. The deeper lateral division gives rise to the tendon of origin of the medial limb of flexor hallucis brevis, and then continues between this muscle and the navicular and medial cuneiform to end on the intermediate cuneiform and the bases of the second, third and fourth metatarsals; the slip to the fourth metatarsal is the strongest.

The slips to the metatarsals vary in number. Slips to the cuboid and lateral cuneiform may also occur. An additional muscle, the tibialis secundus, has been described running from the back of the tibia to the capsule of the ankle joint.

Relations The superficial surface of tibialis posterior is separated from soleus by the transverse intermuscular septum, and is related to flexor digitorum longus, flexor hallucis longus, the posterior tibial vessels, the tibial nerve and the fibular vessels. The deep surface is in contact with the interosseous membrane, tibia, fibula and ankle joint.

Vascular supply Tibialis posterior is supplied by numerous branches of small calibre arising from the posterior tibial and fibular arteries. The tendon is supplied by arteries of the medial malleolar network and by the medial plantar artery.

Innervation Tibialis posterior is innervated by the tibial nerve, L4 and L5.

Actions Tibialis posterior is a powerful muscle that, on contraction, has an excursion of only $1-2 \mathrm{~cm}$. It is the principal invertor of the foot and also initiates elevation of the heel; it is responsible for the hindfoot varus that occurs during a single heel raise. Due to its insertions on to the cuneiforms and the bases of the metatarsals, it has long been thought to assist in elevating the longitudinal arch of the foot, although electromyography shows that it is actually quiescent in standing. It is phasically active in walking, during which it probably acts with the intrinsic foot musculature and the lateral leg muscles to control the degree of pronation of the foot and the distribution of weight through the metatarsal heads. It is said that when the body is supported on one leg, the invertor action of tibialis posterior, exerted from below, helps to maintain balance by resisting any tendency to sway laterally.

Tibialis posterior is also important in the maintenance of the medial part of the longitudinal arch of the foot. In overweight individuals with pes planus (flat foot deformity), unaccustomed activity can result in inflammation and degeneration of the terminal portion of the tendon, which leads to elongation of the tendon, attenuation of the spring ligament and progressive collapse of the medial longitudinal arch. As the excursion is so short, the muscle cannot compensate for the lengthening of its tendon, a failure that results in tibialis posterior tendon dysfunction.

Testing Tibialis posterior is tested by asking the subject to move the foot into a position of maximal plantar flexion and inversion against the resistance of the examiner's hand; the tendon can be seen and felt just proximal to the medial malleolus. Testing tibialis posterior function is important in establishing a diagnosis of a common fibular nerve neuropathy and differentiating it from an L5 radiculopathy, which are two common clinical conditions. In a common fibular nerve neuropathy, tibialis posterior has normal function, whereas in an L5 radiculopathy, tibialis posterior is weak.

## VASCULAR SUPPLY

## ARTERIES

## Anterior tibial artery

The anterior tibial artery arises at the distal border of popliteus (Fig. 83.11; see Figs 78.4A, B, 83.7, 83.10, 82.1, 82.4, 84.9). At first in the flexor compartment, it passes between the heads of tibialis posterior and through the oval aperture in the proximal part of the interosseous membrane to reach the extensor (anterior) compartment, passing medial to the fibular neck; it is vulnerable here during tibial osteotomy. Descending on the anterior aspect of the membrane, it approaches the tibia and, distally, lies anterior to it. At the ankle, the anterior tibial artery is located approximately midway between the malleoli, and it continues on the dorsum of the foot, lateral to extensor hallucis longus, as the dorsalis pedis artery.

The anterior tibial artery may, on occasion, be small but it is rarely absent. Its function may be replaced by perforating branches from the posterior tibial artery or by the perforating branch of the fibular artery. It occasionally deviates laterally, regaining its usual position at the ankle. It may also be larger than normal, in which case its territory of supply in the foot may be increased to include the plantar surface.

## Relations

In its proximal two-thirds the anterior tibial artery lies on the interosseous membrane, and in its distal third it is anterior to the tibia and

Fig. 83.11 Three-dimensional CT imaging illustrating the arterial supply of the lower limb. Note the relationships of the arteries to the surrounding bones. (Courtesy of Dr Yoginder Vaid and Mr Jon C Betts, Jr.)
ankle joint. Proximally, it lies between tibialis anterior and extensor digitorum longus, then between tibialis anterior and extensor hallucis longus. At the ankle it is crossed superficially from the lateral side by the tendon of extensor hallucis longus and then lies between this tendon and the first tendon of extensor digitorum longus. Its proximal two-thirds are covered by adjoining muscles and deep fascia, its distal third by the skin, fasciae and extensor retinacula. It is accompanied by venae comitantes. The deep fibular nerve, curling laterally round the fibular neck, reaches the lateral side of the artery where it enters the extensor region, is then anterior to the artery in the middle third of the leg, and becomes lateral again distally.

## Branches

The named branches of the anterior tibial artery are the posterior and anterior tibial recurrent, muscular, perforating, and anterior medial and lateral malleolar arteries.

Posterior tibial recurrent artery The posterior tibial recurrent artery is an inconstant branch that arises before the anterior tibial artery reaches the extensor compartment of the leg. It ascends anterior to popliteus, anastomosing with the inferior genicular branches of the popliteal artery. It supplies the superior tibiofibular joint.

Anterior tibial recurrent artery The anterior tibial recurrent artery arises near the posterior tibial recurrent artery. It ascends in tibialis anterior, ramifies on the front and sides of the knee joint, and joins the patellar anastomosis, which interconnects with the genicular branches of the popliteal and circumflex fibular arteries.

Muscular branches Numerous branches supply the adjacent muscles. Some then pierce the deep fascia to supply the skin, while others traverse the interosseous membrane to anastomose with branches of the posterior tibial and fibular arteries.

Perforating branches Most of the fasciocutaneous perforators pass along the anterior fibular fascial septum behind extensor digitorum longus before penetrating the deep fascia to supply the skin.

Anterior medial malleolar artery The anterior medial malleolar artery arises approximately 5 cm proximal to the ankle. It passes posterior to the tendons of extensor hallucis longus and tibialis anterior medial to the joint, where it joins branches of the posterior tibial and medial plantar arteries.

Anterior lateral malleolar artery The anterior lateral malleolar artery runs posterior to the tendons of extensor digitorum longus and fibularis tertius to the lateral side of the ankle and anastomoses with the perforating branch of the fibular artery and ascending branches of the lateral tarsal artery.

## Posterior tibial artery

The posterior tibial artery begins at the distal border of popliteus, between the tibia and fibula (see Figs 78.4B, 82.4, 83.11). It descends medially in the flexor compartment and divides under abductor hallucis, midway between the medial malleolus and the calcaneal tubercle, into the medial and lateral plantar arteries. The artery may be much reduced in length or in calibre; the fibular artery then takes over its distal territory of supply and may consequently be increased in size.

## Relations

The posterior tibial artery is successively posterior to tibialis posterior, flexor digitorum longus, the tibia and the ankle joint. Proximally, gastrocnemius, soleus and the transverse intermuscular septum of the leg are superficial to the artery, and distally, it is covered only by skin and fascia. It is parallel with and approximately 2.5 cm anterior to the medial border of the calcaneal tendon; terminally, it is deep to the flexor retinaculum. The artery is accompanied by two veins and the tibial nerve. The nerve is at first medial to the artery but soon crosses behind it and subsequently becomes largely posterolateral in position.

## Branches

The named branches of the posterior tibial artery are the circumflex fibular, nutrient, muscular, perforating, communicating, medial malleolar, calcaneal, lateral and medial plantar, and fibular arteries.

Circumflex fibular artery The circumflex fibular artery, which sometimes arises from the anterior tibial artery, passes laterally round the neck of the fibula through the soleus to anastomose with the
inferior medial and lateral genicular and anterior tibial recurrent arteries. It supplies bone and related articular structures.

Nutrient artery of the tibia The nutrient artery of the tibia arises from the posterior tibia near its origin. After giving off a few muscular branches, it descends into the bone immediately distal to the soleal line. It is one of the largest of the nutrient arteries.

Muscular lbranches Muscular branches are distributed to the soleus and deep flexors of the leg.

Perforating branches Approximately five fasciocutaneous perforators emerge between flexor digitorum longus and soleus, and pass through the deep fascia, often accompanying the perforating veins that connect the deep and superficial venous systems. The arterial perforators then divide into anterior and posterior branches to supply the regional periosteum and skin. These vessels are utilized in raising medial fasciocutaneous perforator flaps in the leg.

Communicating branch The communicating branch runs posteriorly across the tibia approximately 5 cm above its distal end, deep to flexor hallucis longus, to join a communicating branch of the fibular artery.

Medial malleolar branches The medial malleolar branches pass round the medial malleolus to the medial malleolar network, which supplies the skin.
Calcaneal branches Calcaneal branches arise just proximal to the terminal division of the posterior tibial artery. They pierce the flexor retinaculum to supply fat and skin behind the calcaneal tendon and in the heel, and muscles on the tibial side of the sole; the branches anastomose with medial malleolar arteries and calcaneal branches of the fibular artery.

## Medial plantar artery

The medial plantar artery is the smaller terminal branch of the posterior tibial artery and passes distally along the medial side of the foot, medial to the medial plantar nerve (see Figs 78.4B, 84.25). At first deep to abductor hallucis, it runs distally between this muscle and flexor digitorum brevis, and supplies both. Near the first metatarsal base, its size, already diminished by muscular branches, is further reduced to a superficial stem that divides to form three superficial digital branches. These accompany the digital branches of the medial plantar nerve and join the first to third plantar metatarsal arteries. The main trunk of the medial plantar artery then runs on to reach the medial border of the hallux, where it anastomoses with a branch of the first plantar metatarsal artery.

## Lateral plantar artery

The lateral plantar artery is the larger terminal branch of the posterior tibial artery (see Figs 78.4B, 84.25). It passes distally and laterally to the fifth metatarsal base, lateral to the lateral plantar nerve. (The medial and lateral plantar nerves lie between the corresponding plantar arteries.) Turning medially with the deep branch of the lateral plantar nerve, it reaches the interval between the first and second metatarsal bases, and unites with the deep plantar artery to complete the plantar arch. As it passes laterally, it is first between the calcaneus and abductor hallucis, then between flexor digitorum brevis and flexor accessorius. Running distally to the fifth metatarsal base, it passes between flexor digitorum brevis and abductor digiti minimi, and is covered by the plantar aponeurosis, superficial fascia and skin.

## Branches

Muscular branches supply the adjoining muscles. Superficial branches supply the skin and subcutaneous tissue along the lateral sole. Anastomotic branches run to the lateral border of the foot, joining branches of the lateral tarsal and arcuate arteries. A calcaneal branch sometimes pierces abductor hallucis to supply the skin of the heel.

## Fibular artery

The fibular artery arises from the posterior tibial artery approximately 2.5 cm distal to popliteus and passes obliquely to the fibula, descending along its medial crest either in a fibrous canal between tibialis posterior and flexor hallucis longus or within flexor hallucis longus (see

Figs 78.4B, 82.4, 83.2, 83.10). Reaching the inferior tibiofibular syndesmosis, it divides into calcaneal branches that ramify on the lateral and posterior surfaces of the calcaneus. Proximally, it is covered by soleus and the transverse intermuscular septum between soleus and the deep muscles of the leg, and distally it is overlapped by flexor hallucis longus.

The fibular artery may branch high from the posterior tibial artery or may even branch from the popliteal artery separately, resulting in a true 'trifurcation'. It may also branch more distally from the posterior tibial artery, sometimes 7 or 8 cm distal to popliteus. Its size tends to be inversely related to the size of the other arteries of the leg. It may be reduced in size but is more often enlarged, when it may join, reinforce or even replace the posterior tibial artery in the distal leg and foot.

## Branches

The fibular artery has muscular, nutrient, perforating, communicating and calcaneal branches.

Muscular branches Multiple short branches supply soleus, tibialis posterior, flexor hallucis longus and the fibular muscles.

Nutrient artery The nutrient artery branches from the main trunk approximately 7 cm from its origin and enters the fibula $14-19 \mathrm{~cm}$ from the apex of the head of the fibula.

Perforating branches The main perforating branch traverses the interosseous membrane approximately 5 cm proximal to the lateral malleolus to enter the extensor compartment, where it anastomoses with the anterior lateral malleolar artery. Descending anterior to the inferior tibiofibular syndesmosis, it supplies the tarsus and anastomoses with the lateral tarsal artery. This branch is sometimes enlarged and may replace the dorsalis pedis artery.

Fasciocutaneous perforators from the lateral muscular branches pass along the posterior fibular fascial septum to penetrate the deep fascia and reach the skin. These vessels are utilized in raising fasciocutaneous posterolateral leg flaps (see below).

Communicating branch The communicating branch connects to a communicating branch of the posterior tibial artery approximately 5 cm proximal to the ankle.

Calcaneall branches Calcaneal (terminal) branches anastomose with the anterior lateral malleolar and calcaneal branches of the posterior tibial artery.

## Perforator flaps in the knee and leg

The perforators, which arise from the rich vascular anastomosis around the patella, generally traverse the tendon of quadriceps femoris to supply the skin over the patella and the peripatellar region (see Fig. 78.7). The skin flaps based on these perforators may be used as distally based or proximally based flaps to cover defects over the knee and popliteal region. The direct cutaneous branch of the popliteal artery and a superficial sural artery, which accompanies the sural nerve, provide additional perforators to the skin over the back of the knee. The posterior tibial artery gives off an average of ten perforators to the skin covering the anteromedial and posterior parts of the leg. In the upper third of the leg, the perforating vessels are predominantly muscular and periosteocutaneous, while in the lower third, the perforating vessels are mainly direct subcutaneous types. They anastomose with the perforating branches of the anterior tibial artery anteriorly and fibular artery posteriorly. Inferiorly, the posterior tibial artery forms a rich anastomotic ring around the ankle joint with the fibular and anterior tibial arteries. Perforators from these vessels supply the calcaneal tendon and the overlying skin. The posterior tibial artery gives off three direct cutaneous perforators in the lower part of the leg; a distally based skin or adipofascial flap based on one of these perforators may be used to reconstruct a defect over the anterior or the posterior aspect of the lower leg. The anterior tibial artery gives off an average of six perforators, which supply the anterolateral part of the leg. They emerge in two longitudinal rows; one perforator is fairly large and accompanies the superficial fibular nerve. A small skin flap based on any one of these perforators may be used to cover small defects over the tibia, and a neurocutaneous flap that includes the superficial fibular nerve may be used.

The fibular artery has an average of five perforators. A constant perforator pierces the deep fascia approximately 5 cm above the lateral malleolus and divides into an ascending and a descending branch. A vascularized fibula graft based on the fibular artery is now the standard graft used in reconstruction of the mandible, while small
fasciocutaneous and adipofascial flaps based on the perforators of the fibular artery are useful in covering soft tissue defects over the heel and proximal part of the foot.

## DEEP AND SUPERFICIAL VENOUS SYSTEM

## Posterior tibial veins

The posterior tibial veins accompany the posterior tibial artery (see Fig. 78.8). They receive tributaries from the calf muscles (especially from the venous plexus in the soleus) and connections from superficial veins and the fibular veins.

## Fibular veins

The fibular veins, running with their artery, receive tributaries from soleus and from superficial veins.

## Anterior tibial veins

The anterior tibial veins, continuations of the venae comitantes of the dorsalis pedis artery, leave the anterior compartment between the tibia and fibula, and pass through the proximal end of the interosseous membrane. They unite with the posterior tibial veins to form the popliteal vein at the distal border of popliteus.

## Long and short saphenous veins

The long and short saphenous veins are described on pages 1370-1371 and 1399, respectively.

## Venous disease

Chronic venous disease is common. Sustained overdistension of the superficial veins of the lower limb may result in the development of short, dilated venous segments or varicosities. Varicose veins can occur as a consequence of venous valve failure at the proximal end of the long saphenous vein at the saphenofemoral junction, or in the perforating veins that pass from the superficial system to the high-pressure deep veins. Varicose veins have thin walls and 'leak' red blood cells into adjacent soft tissues. As these cells are broken down, haemosiderin is deposited in the soft tissues, resulting in a brown pigmentation. This phenomenon, together with the fact that venous stasis produces oedema, renders the soft tissues of the leg unhealthy and prone to ulceration, particularly after minor trauma.

Acute venous disease occurs most commonly in the posterior compartment of the leg. This is attributed to the sluggish blood flow that occurs, at times, in the deep veins of the calf. This relative stasis predisposes to the formation of venous thrombi. Fragments of these thrombi may become dislodged and carried in the venous return to the heart to cause a life-threatening pulmonary embolism. Blockage of the normal venous system may contribute to increased local venous pressure and oedema.

## INNERVATION

## Tibial nerve

The tibial nerve, the larger component of the sciatic nerve, is derived from the ventral branches (anterior divisions) of the fourth and fifth lumbar and first to third sacral ventral rami. It descends along the back of the thigh and popliteal fossa to the distal border of popliteus. It then passes anterior to the arch of soleus with the popliteal artery and continues into the leg. In the thigh, it is overlapped proximally by the hamstring muscles but it becomes more superficial in the popliteal fossa, where it is lateral to the popliteal vessels. At the level of the knee, the tibial nerve becomes superficial to the popliteal vessels and crosses to the medial side of the artery. In the distal popliteal fossa, it is overlapped by the junction of the two heads of gastrocnemius.

In the leg, the tibial nerve descends with the posterior tibial vessels to lie between the heel and the medial malleolus (see Fig. 82.4). Proximally, it is deep to soleus and gastrocnemius, but in its distal third is covered only by skin and fasciae, and overlapped sometimes by flexor hallucis longus. At first medial to the posterior tibial vessels, it crosses behind them and descends lateral to them until it bifurcates. It lies on
tibialis posterior for most of its course except distally, where it adjoins the posterior surface of the tibia. The tibial nerve ends under the flexor retinaculum by dividing into the medial and lateral plantar nerves.

## Branches

The branches of the tibial nerve are articular, muscular, sural, medial calcaneal and medial and lateral plantar nerves. The medial and lateral plantar nerves and the medial calcaneal nerve are described on page 1447

Articular branches Articular branches to the knee joint accompany the superior and inferior medial genicular arteries and the middle genicular artery; they form a plexus with a branch from the obturator nerve and also supply the oblique popliteal ligament. The branches accompanying the superior and inferior medial genicular arteries supply the medial part of the capsule. A branch of the nerve to popliteus (tibial nerve) supplies the posterior portion of the superior tibiofibular joint. Just before the tibial nerve bifurcates, it gives off branches that supply the ankle joint.

Muscular branches Proximal muscular branches arise between the heads of gastrocnemius and supply gastrocnemius, plantaris, soleus and popliteus. The nerve to soleus enters its superficial aspect. The branch to popliteus descends obliquely across the popliteal vessels, curling round the distal border of the muscle to its anterior surface. It also supplies tibialis posterior, the superior tibiofibular joint and the tibia, and gives off an interosseous branch that descends near the fibula to reach the distal tibiofibular joint.

Muscular branches in the leg, either independently or by a common trunk, supply soleus (on its deep surface), tibialis posterior, flexor digitorum longus and flexor hallucis longus. The branch to flexor hallucis longus accompanies the fibular vessels.

Surall nerve The sural nerve descends between the heads of gastrocnemius, pierces the deep fascia proximally in the leg, and is joined at a variable level by the sural communicating branch of the common fibular nerve. Some authors term this branch the lateral sural cutaneous nerve, and call the main trunk (from the tibial nerve) the medial sural cutaneous nerve. The sural nerve descends lateral to the calcaneal tendon, near the short saphenous vein, to the region between the lateral malleolus and the calcaneus, and supplies the posterior and lateral skin of the distal third of the leg. It then passes distal to the lateral malleolus along the lateral side of the foot and fifth toe, supplying the overlying skin. It connects with the posterior femoral cutaneous nerve in the leg and with the superficial fibular nerve on the dorsum of the foot.

The sural nerve is often used as an autologous peripheral nerve graft on the grounds that it is easily harvested, readily identified and exclusively cutaneous.

## Lesions of the tibial nerve

The tibial nerve is vulnerable to direct injury in the popliteal fossa, where it lies superficial to the popliteal vessels at the level of the knee, or to compression at the tendinous arch of the soleus. It may be damaged in compartment syndrome that affects the deep flexor compartment of the calf. The tibial nerve or the medial and lateral plantar nerves may become entrapped beneath the flexor retinaculum or the so-called plantar tunnels (beneath the fascia of the abductor hallucis) at the ankle, resulting in tarsal tunnel syndrome.

## Common fibular nerve

The common fibular nerve (common peroneal nerve) is approximately half the size of the tibial nerve and is derived from the dorsal branches of the fourth and fifth lumbar and first and second sacral ventral rami. It descends obliquely along the lateral side of the popliteal fossa to the fibular head, medial to biceps femoris. It lies between the tendon of biceps femoris, to which it is bound by fascia, and the lateral head of gastrocnemius (Fig. 83.12). The nerve then passes into the anterolateral compartment of the leg through a tight opening in the thick fascia overlying tibialis anterior. It curves lateral to the fibular neck, deep to fibularis longus, and divides into superficial and deep fibular nerves; an articular trunk, derived from the deep fibular nerve, provides an articular branch that travels with the anterior tibial recurrent artery and a proximal branch to tibialis anterior.

## Branches

The common fibular nerve has articular and cutaneous branches, and terminates as the superficial and deep fibular nerves.

Fig. 83.12 The course, relations and branches of the right common fibular nerve. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. SpringerVerlag, London.)

Articular branches There are three articular branches. Two accompany the superior and inferior lateral genicular arteries; they may arise in common. The third, the recurrent articular branch, arises near the termination of the common fibular nerve. It ascends with the anterior recurrent tibial artery through tibialis anterior and supplies the anterolateral part of the knee joint capsule and the proximal tibiofibular joint.

Cutaneous branches The two cutaneous branches, often from a common trunk, are the lateral sural and sural communicating nerves. The lateral sural cutaneous nerve (lateral cutaneous nerve of the calf) supplies the skin on the anterior, posterior and lateral surfaces of the proximal leg. The sural communicating nerve arises near the head of the fibula and crosses the lateral head of gastrocnemius to join the sural nerve. It may descend separately as far as the heel.

## Lesions of the common fibular nerve

The common fibular nerve is relatively unprotected as it traverses the lateral aspect of the neck of the fibula and is easily compressed at this site, e.g. by plaster casts or ganglia. The nerve may also become entrapped by a fascial band beneath fibularis longus within the so-called fibular tunnel, between the attachments of fibularis longus to the head and shaft of the fibula. Traction lesions can accompany dislocations of the lateral compartment of the knee, and are most likely to occur if the distal attachments of biceps femoris and the ligaments that insert on to the fibular head are avulsed, possibly with a small part of the fibular head; the nerve is tethered to the tendon of biceps femoris by dense fascia and so is pulled proximally. Severe traction lesions may produce longitudinal injuries affecting a long segment of the common fibular nerve. Torsional injury following ankle injury (sprain or fracture) may result in common fibular neuropathy; the injury is transmitted from the ankle along the interosseous membrane to the proximal leg (Lalezari et al 2012). Patients with such injury present with a foot drop. Physical examination reveals weakness or paralysis of ankle dorsiflexion, toe extension and eversion of the foot, but inversion and plantar flexion are normal. Sensation on the dorsum of the foot, including the first dorsal web space, is diminished. The ankle reflex is preserved. Since the common fibular nerve divides at the fibular neck into the superficial and deep fibular nerves, injuries to the nerve at this level may damage either the main trunk or its branches. Electrodiagnostic studies can help localize a common fibular nerve injury to the fibular neck region. At this level, nerve conduction studies may show slowed velocities and electromyography would demonstrate denervation in the muscles innervated by the common fibular nerve (such as tibialis anterior or fibularis longus), whereas more proximally innervated muscles (particularly the short head of biceps femoris) would be normal.

## Superficial fibular nerve

The superficial fibular nerve (superficial peroneal nerve) begins at the bifurcation of the common fibular nerve. It lies deep to fibularis longus at first, then passes anteroinferiorly between fibularis longus and brevis and extensor digitorum longus, and pierces the deep fascia in the distal third of the leg (see Fig. 83.12). It divides into a large medial dorsal cutaneous nerve and a smaller, more laterally placed, intermediate dorsal cutaneous nerve, usually after piercing the deep fascia, but sometimes while it is still deep to the fascia. As the nerve lies between the muscles it supplies fibularis longus, fibularis brevis and the skin of the lower leg. The deep course, i.e. the compartmental localization, and the peripheral digital distribution of the superficial fibular nerve are subject to considerable variation (see Kosinksi's classification; Kosinski 1926, Solomon et al 2001).

## Branches

The medial dorsal cutaneous nerve passes in front of the ankle joint and divides into two dorsal digital branches; one of these supplies the medial side of the hallux and the other supplies the adjacent side of the second and third toes. It communicates with the saphenous and deep fibular nerves. The smaller intermediate branch crosses the dorsum of the foot laterally. It divides into dorsal digital branches that supply the contiguous sides of the third to fifth toes and the skin of the lateral aspect of the ankle, where it connects with the sural nerve. Both branches, especially the intermediate, are at risk during the placement of portal skin incisions for arthroscopy and during surgical approaches
to the lateral malleolus. Branches of the superficial fibular nerve supply the skin of the dorsum of all the toes except that of the lateral side of the fifth toe (supplied by the sural nerve) and the adjoining sides of the great and second toes (supplied by the medial terminal branch of the deep fibular nerve). Some of the lateral branches of the superficial fibular nerve are frequently absent and are replaced by sural nerve branches.

Accessory fibular nerves An accessory superficial fibular nerve and an accessory deep fibular nerve have been described as variant branches of the superficial fibular nerve; both are probably the product of atypical branching of the parent nerve deep to the deep fascia (see above).

## Lesions of the superficial fibular nerve

A lesion of the superficial fibular nerve causes weakness of foot eversion and sensory loss on the lateral aspect of the leg that extends on to the dorsum of the foot. The nerve can be subject to entrapment as it penetrates the deep fascia of the leg and it may also be involved in compartment syndrome that affects the lateral compartment of the leg.

## Deep fibular nerve

The deep fibular nerve (deep peroneal nerve) begins at the bifurcation of the common fibular nerve, between the fibula and the proximal part of fibularis longus. It passes obliquely forwards deep to extensor digitorum longus to the front of the interosseous membrane and reaches the anterior tibial artery in the proximal third of the leg. It descends with the artery to the ankle, where it divides into lateral and medial terminal branches. As it descends, the nerve is first lateral to the artery, then anterior, and finally lateral again at the ankle.

## Branches

The deep fibular nerve supplies muscular branches to tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius, and an articular branch to the ankle joint.

The lateral terminal branch crosses the ankle deep to extensor digitorum brevis, enlarges as a pseudoganglion and supplies extensor digitorum brevis. From the enlargement, three minute interosseous branches supply the tarsal and metatarsophalangeal joints of the middle three toes.

The medial terminal branch runs distally on the dorsum of the foot lateral to the dorsalis pedis artery, and connects with the medial branch of the superficial fibular nerve in the first interosseous space. It divides into two dorsal digital nerves, which supply adjacent sides of the great and second toes. Before dividing, it gives off an interosseous branch, which supplies the first metatarsophalangeal joint. The deep fibular nerve may end as three terminal branches.

## Lesions of the deep fibular nerve

Isolated injury to the deep fibular nerve may result from compartment syndrome that affects the anterior compartment of the leg or from an intraneural ganglion cyst (mucinous cyst within the nerve derived from the superior tibiofibular joint via the articular branch that travels with the anterior tibial recurrent artery (Spinner et al 2003)). Individuals with lesions of the deep fibular nerve have weakness of ankle dorsiflexion and extension of all toes but normal foot eversion. Sensory impairment is confined to the first interdigital web space.

## Saphenous nerve

The saphenous nerve is described on page 1399.

The ankle joint (talocrural joint) is a diarthrodial articulation involving the distal tibia and fibula and the body of the talus; it is the only example in the human body of a true mortise joint. The human foot is a complex structure adapted to allow orthograde bipedal stance and locomotion and is the only part of the body that is in regular contact with the ground (Jones 1949). There are 28 separate bones in the human foot, including the sesamoid bones of the first metatarsophalangeal joint, and 31 joints, including the ankle joint. The hindfoot comprises the calcaneus and talus; the midfoot comprises the navicular, cuboid and three cuneiforms; the forefoot comprises five metatarsals, fourteen phalanges and two sesamoid bones. With regard to the nomenclature of the surfaces of the foot, the terms 'plantar' and 'dorsal' are used to denote inferior and superior surfaces, respectively.

## SKIN AND SOFT TISSUES

## SKIN

## Vascular supply and lymphatic drainage

The skin around the ankle is supplied by anterior lateral and anterior medial malleolar arteries from the anterior tibial artery, posterior medial malleolar branches from the posterior tibial artery, posterior lateral malleolar branches from the fibular artery, and fasciocutaneous perforators from the anterior and posterior tibial and fibular arteries. The main blood supply to the medial side of the heel is from the medial calcaneal branches of the posterior tibial artery or, sometimes, the lateral plantar artery passing through the flexor retinaculum. The skin of the lateral side of the heel is supplied by lateral calcaneal branches of the fibular artery and the lateral tarsal artery. The arterial supply to the skin of the foot is rich and is derived from branches of the dorsalis pedis (the direct continuation of the anterior tibial artery), posterior tibial and fibular arteries. The skin covering the dorsum of the foot is supplied by the dorsalis pedis artery and by its continuation, the first dorsal metatarsal artery, with smaller contributions from the anterior perforating branch of the fibular artery and the marginal anastomotic arteries on the medial and lateral borders of the foot. The skin covering the plantar surface of the foot is supplied by perforating branches of the medial and lateral plantar arteries (the terminal branches of the posterior tibial artery). The skin of the forefoot is supplied by cutaneous branches of the common digital arteries.

Cutaneous venous drainage is via dorsal and plantar venous arches, which drain into medial and lateral marginal veins. The medial and lateral marginal veins form the long and small saphenous veins, respectively. On the plantar aspect of the foot, a superficial venous network forms an intradermal and subdermal mesh that drains to the medial and lateral marginal veins. Branches that accompany the medial and lateral plantar arteries arise from a deep venous network. Uniquely within the lower limb, venous flow in the foot is bidirectional. However, when valves are present, flow is from the plantar to the superficial dorsal system. From here, blood leaves the foot in the superficial and deep veins of the lower limb.

Superficial lymphatic drainage of all areas of the leg and foot (except the superficial posterolateral area) is via lymphatic vessels that accompany the long saphenous vein and its tributaries. The superficial posterolateral foot and leg drain into the popliteal lymph nodes via lymphatic vessels that accompany the small saphenous vein. Deep lymphatic vessels that accompany the dorsalis pedis, posterior tibial and fibular arteries drain into the popliteal lymph nodes.

## Innervation

The skin covering the ankle and foot is supplied by nerves derived from the fourth and fifth lumbar and first sacral spinal nerves (see Figs 78.12,
78.14). Innervation of the dorsum of the foot is provided medially by the saphenous nerve, centrally by the superficial fibular nerve, and laterally by the sural nerve; the deep fibular nerve supplies the dorsum of the first web space. Dorsal branches of the medial and lateral plantar nerves supply the nail beds. The plantar aspect of the foot is supplied by the medial and lateral plantar nerves, which arise as terminal branches of the tibial nerve. The medial plantar nerve supplies sensation to the plantar aspect of the great toe and the second, the third and the medial half of the fourth toes. The lateral plantar nerve supplies the remaining lateral aspect of the fourth and the entire fifth toe. The heel is innervated by calcaneal branches of the tibial and sural nerves. Injury to any of these nerves can lead to painful neuromas and loss of protective sensation. The sural nerve and its branches are especially prone to neuroma formation.

## SOFT TISSUES

## Retinacula at the ankle

In the vicinity of the ankle joint, the tendons of the muscles of the leg are bound down by localized, band-shaped thickenings of the deep fascia termed retinacula, which collectively serve to prevent bowstringing of the underlying tendons during muscle contraction. There are superior and inferior extensor retinacula, superior and inferior fibular retinacula, and a flexor retinaculum.

## Extensor retinacula

## Superior extensor retinaculum

The superior extensor retinaculum binds down the tendons of tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius immediately proximal to the anterior aspect of the ankle joint (see Fig. 83.6; Fig. 84.1). The anterior tibial vessels and deep fibular nerve pass deep to the retinaculum, and the superficial fibular nerve passes superficially. The retinaculum is attached laterally to the distal end of the anterior border of the fibula and medially to the anterior border of the tibia. Its proximal border is continuous with the deep fascia of the leg, and dense connective tissue connects its distal border to the inferior extensor retinaculum. Laterally, it blends with the superior fibular retinaculum and medially with the upper border of the extensor retinaculum. The tendon of tibialis anterior is the only extensor tendon that possesses a synovial sheath at the level of the superior extensor retinaculum.

## Inferior extensor retinaculum

The inferior extensor retinaculum is a Y-shaped band lying anterior to the ankle joint (see Fig. 83.6; Fig. 84.2). The stem of the Y is at the lateral end, where it is attached to the upper surface of the calcaneus, anterior to the calcaneal sulcus. The band passes medially, forming a strong loop around the tendons of fibularis tertius and extensor digitorum longus (see Fig. 84.2A). From the deep surface of the loop, a band passes laterally behind the interosseous talocalcaneal ligament and the cervical ligament, and is attached to the calcaneal sulcus. At the medial end of the loop, two diverging limbs extend medially to complete the ' Y ' shape of the retinaculum. The proximal limb consists of two layers. The deep layer passes deep to the tendons of extensor hallucis longus and tibialis anterior, but superficial to the anterior tibial vessels and deep fibular nerve, to reach the medial malleolus. The superficial layer crosses superficial to the tendon of extensor hallucis longus and then adheres firmly to the deep one; in some cases, it continues superficial to the tendon of tibialis anterior, before blending with the deep layer. The distal limb extends downwards and medially, and blends with the plantar aponeurosis. It is superficial to the tendons of extensor hallucis longus and tibialis anterior, the dorsalis pedis artery and the terminal branches of the deep fibular nerve.

Fig. 84.1 The synovial sheaths of the tendons of the ankle, anterior aspect. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

## Flexor retinaculum

The flexor retinaculum is attached anteriorly to the medial malleolus, distal to which it is continuous with the deep fascia on the dorsum of the foot (see Fig. 84.2B). From its malleolar attachment, it extends posteroinferiorly to the medial process of the calcaneus and the plantar aponeurosis. Proximally, there is no clear demarcation between its border and the deep fascia of the leg, especially the deep transverse layer of the deep fascia. Distally, its border is continuous with the plantar aponeurosis, and many fibres of abductor hallucis are attached to it. The flexor retinaculum converts grooves on the tibia and calcaneus into canals for the tendons, and bridges over the posterior tibial vessels and tibial nerve. As these structures enter the sole, they are, from medial to lateral, the tendons of tibialis posterior and flexor digitorum longus, the posterior tibial vessels, the tibial nerve and the tendon of flexor hallucis longus (see Fig. 84.14).

## Fibular retinacula

The fibular retinacula are fibrous bands that retain the tendons of fibularis longus and brevis in position as these tendons cross the lateral aspect of the ankle region (see Fig. 84.2A).

## Superior fibular retinaculum

The superior fibular retinaculum is a short band that extends from the back of the lateral malleolus to the deep transverse fascia of the leg and the lateral surface of the calcaneus. Damage to the retinaculum can lead to instability of the tendons of fibularis longus and brevis.

## Inferior fibular retinaculum

The inferior fibular retinaculum is continuous in front with the inferior extensor retinaculum, and is attached posteriorly to the lateral surface of the calcaneus. Some of its fibres are fused with the periosteum on the fibular trochlea (peroneal trochlea or tubercle) of the calcaneus, forming a septum between the tendons of fibularis longus and brevis.

## Synovial sheaths at the ankle

Anterior to the ankle, the synovial sheath for tibialis anterior extends from the proximal margin of the superior extensor retinaculum to the interval between the diverging limbs of the inferior retinaculum (see Figs 84.1-84.2B). A common sheath encloses the tendons of extensor digitorum longus and fibularis tertius, starting just above the level of the malleoli, and reaching to the level of the base of the fifth metatarsal (see Figs 84.1, 84.2A). Although variable, the sheath for extensor hallucis longus begins near that for extensor digitorum longus and extends as far as the base of the first metatarsal (see Figs 84.1-84.2).

Posteromedial to the ankle, the sheath for tibialis posterior starts approximately 4 cm above the medial malleolus and ends just proximal to the attachment of the tendon to the tuberosity of the navicular (see Fig. 84.2B). The sheath for flexor hallucis longus begins at the level of the medial malleolus, and extends distally as far as the base of the first metatarsal (see Fig. 84.2B). Occasionally, as a result of overuse, particularly in ballet dancers where balance on the tips of the toes en pointe involves sustained extreme plantar flexion of the ankle and great toe in the weight-bearing position, a fibrous nodule may develop in the tendon, just proximal to the tendon sheath. This may result in the thickened tendon being caught intermittently in the sheath, causing pain and 'triggering' of the great toe, a condition referred to as hallux saltans. Surgical opening of the sheath may be required. In athletes, the muscle belly of flexor hallucis longus may be abnormally large and may extend more distally than usual; it can also catch at the opening of the sheath. The sheath for flexor digitorum longus begins slightly superior to the level of the medial malleolus and ends at the level of the navicular.

Posterolateral to the ankle, the tendons of fibularis longus and brevis are enclosed in a single sheath deep to the superior fibular retinaculum. This sheath splits into two separate sheaths enclosing their respective tendons deep to the inferior fibular retinaculum (see Fig. 84.2A). From the lateral malleolus, it extends for about 4 cm both proximally and distally.

## Plantar aponeurosis

The plantar aponeurosis is composed of densely compacted collagen fibres orientated mainly longitudinally, but also transversely (Fig. 84.3). Its medial and lateral borders overlie the intrinsic muscles of the great and fifth toes, respectively, while its dense central part overlies the extrinsic and intrinsic flexors of the digits.

The central part is the strongest and thickest. The fascia is narrow posteriorly, where it is attached to the medial process of the calcaneal tuberosity proximal to flexor digitorum brevis, and traced distally it becomes broader and somewhat thinner. Just proximal to the level of the metatarsal heads, it divides into five bands, one for each toe. As these five digital bands diverge below the metatarsal shafts, they are united by transverse fibres. Proximal, plantar and a little distal to the metatarsal heads and the metatarsophalangeal joints, the superficial stratum of each of the five bands is connected to the dermis by skin ligaments (retinacula cutis). These ligaments reach the skin of the first metatarsophalangeal joint proximal to, and in the floors of, the furrows that separate the toes from the sole; Ledderhose's disease (plantar fibromatosis) may involve these ligaments, resulting in contractures of the affected digits. The deep stratum of each digital band of the aponeurosis yields two septa that flank the digital flexor tendons and separate them from the lumbricals and the digital vessels and nerves. These septa pass deeply to fuse with the interosseous fascia, the deep transverse metatarsal ligaments (which run between the heads of adjacent metatarsals), the plantar ligaments of the metatarsophalangeal joints, and the periosteum and fibrous flexor sheaths at the base of each proximal phalanx. Pads of fat develop in the web spaces between the metatarsal heads and the bases of the proximal phalanges; they cushion the digital nerves and vessels from adjoining tendinous structures and extraneous plantar pressures. Just distal to the metatarsal heads, a plantar interdigital ligament (superficial transverse metatarsal ligament) blends progressively with the deep aspect of the superficial stratum of the plantar aponeurosis where it enters the toes (see Fig. 84.3). The central part of

Fig. 84.2 The synovial sheaths of the tendons of the ankle. A, Lateral aspect. B, Medial aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
the plantar aponeurosis thus provides an intermediary structure between the skin and the osteoligamentous framework of the foot via numerous cutaneous retinacula and deep septa that extend to the metatarsals and phalanges. The central part is also continuous with the medial and lateral parts; at the junctions, two intermuscular septa, medial and lateral, extend in oblique vertical planes between the medial, intermediate and lateral groups of plantar muscles to reach bone. Thinner, horizontal intermuscular septa, derived from the vertical intermuscular septa, pass between the muscle layers.

The lateral part of the plantar aponeurosis, which covers abductor digiti minimi, is thin distally and thick proximally, where it forms a strong band, sometimes containing muscle fibres, between the lateral process of the calcaneal tuberosity and the base of the fifth metatarsal. It is continuous medially with the central part of the aponeurosis, and with the fascia on the dorsum of the foot around its lateral border. The medial part of the plantar aponeurosis, which covers abductor hallucis, is thin. It is continuous proximally with the flexor retinaculum, medially with the dorsal fascia of the foot, and laterally with the central part of the plantar aponeurosis.

## Plantar fasciitis

Plantar fasciitis is a common cause of plantar heel pain.

## Fascial compartments of the foot

There are four main compartments of the plantar aspect of the foot (Fig. 84.4). The medial compartment contains abductor hallucis and flexor hallucis brevis, as well as the tendon of flexor hallucis longus. The medial compartment is bounded inferiorly and medially by the medial part of the plantar aponeurosis and its medial extension, laterally by
an intermuscular septum, and dorsally by the first metatarsal. The central compartment contains flexor digitorum brevis, the lumbricals, flexor accessorius (quadratus plantae), adductor hallucis, and the tendons of flexor digitorum longus. The central compartment is bounded by the plantar aponeurosis inferiorly, the osseofascial tarsometatarsal structures dorsally and intermuscular septa medially and laterally. The lateral compartment contains abductor digiti minimi and flexor digiti minimi brevis, and its boundaries are the fifth metatarsal dorsally, the plantar aponeurosis inferiorly and laterally, and an intermuscular septum medially. The interosseous compartment contains the seven interossei and its boundaries are the interosseous fascia and the metatarsals.

The dorsal aspect of the foot effectively contains a single compartment, which is occupied by the extrinsic extensor tendons and extensor digitorum brevis, and is roofed by the deep dorsal fascia (see below)

## Lateral intermuscular septum

The lateral intermuscular septum is incomplete, especially at its proximal end where the lateral plantar artery and nerve enter the lateral compartment. Distally, its deep attachments are to the fibrous sheath of fibularis longus and to the fifth metatarsal.

## Medial intermuscular septum

The medial intermuscular septum is incomplete where the tendon of flexor digitorum longus enters the central compartment and where adductor hallucis and the lateral head of flexor hallucis brevis enter the medial compartment. The septum divides into three bands - proximal, intermediate and distal, each of which displays lateral and medial divisions as it approaches its deep attachments. The proximal band is

Many contributing aetiological factors have been reported, such as obesity, abnormal posture, advanced age, and extrinsic factors such as poor footwear and excessive biomechanical stressors (League 2008). These factors may lead to inflammation and degeneration of the plantar aponeurosis. However, recent histological studies have called into question the role of inflammation in the aetiology of the disease and have led to the recommendation that the term 'fasciitis' be replaced with 'fasciosis' (Lemont et al 2003). The stress and strain applied to the plantar aponeurosis may lead to the formation of a bony spur at its proximal attachment to the calcaneus. Clinically, palpation of the plantar aponeurosis at the medial tubercle of the calcaneus may result in localized tenderness and exacerbated heel pain in patients. Multiple treatments, from conservative therapies to surgical interventions, have been used to provide pain relief. Non-operative treatments include stretching exercises, orthoses, extracorporeal shockwave therapy, multiple steroid injections, padding and strapping (Landorf and Menz 2008). Recently, the use of cryosurgery has been investigated for this condition (Cavazos et al 2009). Surgical treatments include partial or complete release of the plantar aponeurosis with concomitant heel spur resection and nerve decompression, when necessary (League 2008).
attached laterally to the cuboid and blends medially with the tendon of tibialis posterior. The middle band is attached laterally to the cuboid and the long plantar ligament, and medially to the medial cuneiform. The distal band divides to enclose the tendon of flexor hallucis longus and is attached to the fascia over flexor hallucis brevis.

## Deep dorsal fascia

The deep fascia on the dorsum of the foot (fascia dorsalis pedis) is a thin layer, continuous above with the inferior extensor retinaculum; it covers the dorsal extensor tendons and extensor digitorum brevis.

## Compartment syndrome in the foot

A compartment syndrome results from an increase in intracompartmental pressure sufficient to impair venous outflow from that compartment. As blood enters at arterial pressure, the compartment pressure increases further until it exceeds arterial pressure, at which point inflow of arterial blood ceases, leading to muscle and nerve ischaemia. Failure

Fig. 84.3 The plantar aponeurosis. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
to relieve the increased pressure in the compartment surgically results in necrosis of the soft tissues within the compartment. The most common cause of compartment syndrome in the foot is trauma, usually of high-energy (high-impact) type; crush injuries, calcaneal fractures and disruption of the tarsometatarsal joints are the usual antecedents associated with compartment syndrome in the foot.

## Specialized adipose tissue (heel and metatarsal pads)

The heel is subject to repeated high impacts and is anatomically adapted to withstand these pressures. The adult heel pad has an average thickness of 18 mm and a mean epidermal thickness of 0.64 mm (dorsal epidermal thickness averages 0.069 mm ). The heel pad contains elastic adipose tissue organized as spiral fibrous septa anchored to each other, to the calcaneus and to the skin. The septa are U-shaped, fat-filled columns designed to resist compressive loads and are reinforced internally with elastic diagonal and transverse fibres, which separate the fat into compartments.

In the forefoot, the subcutaneous tissue consists of fibrous lamellae arranged in a complex whorl containing adipose tissue attached via vertical fibres to the dermis superficially and the plantar aponeurosis deeply. The fat is particularly thick in the region of the metatarsophalangeal joints, which cushions the foot during the toe-off phase of gait (see below). Like the heel pad, the metatarsal fat pad is designed to withstand compressive and shearing forces. Atrophy of either may be a cause of persistent pain in the distal plantar region.

## BONES

Functionally, the skeleton of the foot may be divided into the tarsus, metatarsus and phalanges. Anatomically, it may be divided into the hindfoot (calcaneus and talus), midfoot (navicular, cuboid and cuneiforms), and forefoot (metatarsals, phalanges, and sesamoid bones of the great toe).

## DISTAL TIBIA

The distal end of the tibia has anterior, medial, posterior, lateral and distal surfaces, and projects inferomedially as the medial malleolus (see Figs 83.3-83.4). The distal surface, also called the tibial plafond, articulates with the talus and is wider anteriorly than posteriorly. It is concave sagittally and slightly convex transversely, and continues medially into the malleolar articular surface. The medial malleolus is short and thick, and has a smooth lateral surface with a crescentic or comma-shaped facet that articulates with the medial surface of the talar body. The distal end of the tibia, including its ossification, is described in detail on page 1404 .

Ligamentous attachments No muscles are attached to the distal tibia. The interosseous membrane, the deltoid ligament, and the anterior and posterior tibiofibular ligaments are attached to the distal tibia.

Vascular supply The distal tibia is supplied by an arterial network formed by branches of the dorsalis pedis, posterior tibial and fibular arteries.

Fig. 84.4 A coronal section through the midfoot showing the main fascial compartments.

Innervation The distal tibia is innervated by branches from the deep fibular, tibial, saphenous and sural nerves.

## DISTAL FIBULA

The distal end of the fibula or lateral malleolus projects distally and posteriorly relative to the medial malleolus (see Figs 83.3-83.4). Its lateral aspect is subcutaneous, the posterior surface has a broad groove with a prominent lateral border, and the anterior surface is rough and somewhat rounded and articulates with the anteroinferior aspect of the tibia. The medial surface has a triangular articular facet and is vertically convex with its apex directed distally. It articulates with the lateral talar surface. Behind the facet is a rough malleolar fossa for ligamentous attachment. The distal end of the fibula, including its ossification, is described in detail on page 1406.

Ligamentous attachments No muscles are attached to the distal fibula below the level of the interosseous ligament. The ligamentous attachments are those of the lateral ligament complex, i.e. the anterior talofibular, the calcaneofibular and the posterior talofibular ligaments. The interosseous membrane is attached on its medial aspect.

Vascular supply The distal fibula is supplied by an arterial network made up of branches of the dorsalis pedis, posterior tibial and fibular arteries.

Innervation The distal fibula is innervated by the deep fibular, tibial, saphenous and sural nerves.

## TARSUS

The seven tarsal bones occupy the proximal half of the foot (Figs 84.5-84.6). The tarsus and carpus are homologous, but the tarsal elements are larger, reflecting their role in supporting and distributing body weight. As in the carpus, tarsal bones are arranged in proximal and distal rows, but medially, there is an additional single intermediate tarsal element, the navicular. The proximal row is made up of the talus and calcaneus; the long axis of the talus is inclined anteromedially and inferiorly, and its distally directed head is medial to the calcaneus and at a superior level. The distal row contains, from medial to lateral, the medial, intermediate and lateral cuneiforms and the cuboid. Collectively, these bones display an arched transverse alignment that is dorsally convex. Medially, the navicular is interposed between the head of

B, A dorsoplantar radiograph of adult foot in full plantigrade contact with the ground, during symmetrical standing, in a man aged 24 years. Key: 1, interphalangeal joint; 2, middle phalanx; 3, head of fifth metatarsal; 4 , shaft of fifth metatarsal; 5 , base of fifth metatarsal; 6 , lateral cuneiform; 7, cuboid; 8, calcaneus; 9, head of distal phalanx; 10, shaft of distal phalanx; 11, base of distal phalanx; 12, head of proximal phalanx; 13 , shaft of proximal phalanx; 14, base of proximal phalanx; 15, first metatarsophalangeal joint; 16, lateral (fibular) sesamoid; 17, medial (tibial) sesamoid; 18, shaft of first metatarsal; 19, first metatarsocuneiform joint; 20, medial cuneiform; 21, intermediate cuneiform; 22, tuberosity of navicular; 23, talar head. (Courtesy of New York College of Podiatric Medicine, New York, NY.)
the talus and the cuneiforms. Laterally, the calcaneus articulates with the cuboid.

The tarsus and metatarsus are arranged to form intersecting longitudinal and transverse arches. Hence, thrust and weight are not transmitted from the tibia to the ground (or vice versa) directly through the tarsus, but are distributed through the tarsals and metatarsals to the

Fig. 84.7 Ossification of the bones of the foot.
ends of the longitudinal arches. For the purposes of description, each tarsal bone is arbitrarily considered to be cuboidal in form, with six surfaces. The ossification sites and timing of ossification are summarized in Figure 84.7.

## Talus

The talus is an intercalated bone with no tendinous attachments. It is the osseous link between the foot and leg through the ankle joint (see Figs 84.16 and 84.18).

Head Directed distally and somewhat inferomedially, the head has a distal surface, which is ovoid and convex; its long axis is also inclined inferomedially to articulate with the proximal navicular surface (see Fig. 84.5A). The plantar surface of the head has three articular areas, separated by smooth ridges (Fig. 84.8C). The most posterior and largest is oval and slightly convex, and rests on a shelf-like medial calcaneal projection, the sustentaculum tali. Anterolateral to this and usually continuous with it, a flat articular facet rests on the anteromedial part of the dorsal (proximal) calcaneal surface; distally, it continues into the navicular surface. Between the two calcaneal facets, a part of the talar head, covered with articular cartilage, is in contact with the plantar calcaneonavicular (spring) ligament, which is covered here, superiorly, by fibrocartilage (see Fig. 84.13B). When the foot is inverted passively, the dorsolateral aspect of the head is visible and palpable approximately 3 cm distal to the tibia; it is hidden by extensor tendons when the toes are dorsiflexed.

Neck The neck is the narrow, medially inclined region between the head and body. Its rough surfaces are for ligaments. The medial plantar surface has a deep sulcus tali that, when the talus and calcaneus are articulated, forms a roof to the tarsal sinus, which is occupied by interosseous talocalcaneal and cervical ligaments.

The long axis of the neck, inclined downwards, distally and medially, makes an angle of approximately $150^{\circ}$ with that of the body; it is smaller (130-140 $)$ at birth, accounting in part for the inverted foot in young children. The dorsal talonavicular ligament and ankle articular capsule are attached distally to the dorsal surface of the talus. Thus, the proximal part of this surface lies within the capsule of the ankle joint.

In a hypermobile flat foot undergoing pronation, the talar head is unsupported medially by the sustentaculum tali. The resulting lack of support results in a visible medial protrusion of the talar head as the foot adducts and plantar flexes towards the ground (Michaud 2011).

The medial articular facet of the talar body and part of the trochlear surface may extend on to the neck. The anterior talofibular ligament is attached on the lateral aspect of the neck, spreading along the adjacent anterior border of the lateral surface. The interosseous talocalcaneal and cervical ligaments are attached to the inferior surface of the neck. A dorsolateral, so-called 'squatting facet' is commonly present on the talar neck in those individuals who habitually adopt the squatting position; it articulates with the anterior tibial margin in extreme dorsiflexion and may be doubled.

Body The body is cuboidal, covered dorsally by a trochlear surface articulating with the distal end of the tibia. It is anteroposteriorly convex, gently concave transversely, widest anteriorly and, therefore, sellar in shape. The triangular lateral surface is smooth and vertically concave for articulation with the lateral malleolus. Superiorly, it is continuous with the trochlear surface; inferiorly, its apex is a lateral process. Proximally, the medial surface is (posterosuperiorly) covered by a comma-shaped facet, which is deeper in front and articulates with the medial malleolus. Distally, this surface is rough and contains numerous vascular foramina. The small posterior surface features a rough projection termed the posterior process. The process is marked by an oblique groove between two tubercles. The lateral tubercle is usually larger; the medial is less prominent and lies immediately behind the sustentaculum tali. The plantar surface articulates with the middle third of the dorsal calcaneal surface by an oval concave facet, its long axis directed distolaterally at an angle of approximately $45^{\circ}$ with the median plane. The medial edge of the trochlear surface is straight, but its lateral edge inclines medially in its posterior part and is often broadened into a small, elongated triangular area, which is in contact with the posterior tibiofibular ligament in dorsiflexion

The posterior talofibular ligament is attached to the lateral tubercle of the posterior process (posterolateral tubercle). Its attachment extends up to the groove, or depression, between the process and posterior trochlear border. The posterior talocalcaneal ligament is attached to the plantar border of the posterior process. The groove between the tubercles of the process contains the tendon of flexor hallucis longus and continues distally into the groove on the plantar aspect of the sustentaculum tali. The medial talocalcaneal ligament is attached below to the medial tubercle, whereas the most posterior superficial fibres of the deltoid ligament are attached above the tubercle. The deep fibres of the deltoid ligament are attached more superiorly to the rough area immediately below the comma-shaped articular facet on the medial surface.

Ligamentous attachments No muscles are attached to the talus. However, many ligaments are attached to the bone, and these confer stability to the talocrural, subtalar and talocalcaneonavicular joints.

Vascular supply The talar blood supply is rather tenuous because of the lack of muscle attachments. The first comprehensive account of talar blood supply was provided by Wildenauer in 1950. The extraosseous blood supply is via the posterior tibial, dorsalis pedis and fibular arteries (Fig. 84.9). The 'artery of the tarsal canal' arises from the posterior tibial artery approximately 1 cm proximal to the origin of the medial and lateral plantar arteries (Fig. 84.10) and passes anteriorly between the sheaths of flexor digitorum longus and flexor hallucis longus to enter the tarsal canal, in which it lies anteriorly, close to the talus. (The 'tarsal canal' is the term that is commonly used to describe the tunnel-shaped medial end of the tarsal sinus.) Branches from the arterial network in the tarsal canal enter the talus. The artery continues through the tarsal canal into the lateral part of the tarsal sinus, where it anastomoses with the artery of the tarsal sinus, forming a vascular sling under the talar neck. A branch of the artery of the tarsal canal known as the deltoid branch passes deep to the deltoid ligament and supplies part of the medial aspect of the talar body. Sometimes, it arises from the posterior tibial artery; rarely, it arises from the medial plantar artery; it may be the only remaining arterial supply to the talus when this bone is fractured. The dorsalis pedis artery supplies branches to the superior aspect of the talar neck and also gives off the artery of the tarsal sinus. This large vessel is always present and anastomoses with the artery of the tarsal canal. The artery of the tarsal sinus receives a contribution from the anterior perforating branch of the fibular artery and supplies direct branches to the talus. The fibular artery provides small branches, which form a plexus of vessels posteriorly with branches of the posterior tibial artery; however, the contribution that the fibular artery makes to the talar blood supply is thought to be insignificant.

The intraosseous blood supply of the talar head arises medially from branches of the dorsalis pedis and laterally via vessels that arise from the anastomosis between the arteries of the tarsal canal and tarsal sinus.

The middle third of the talar body, other than its most superior aspect, and the lateral third, other than its posterior aspect, are supplied mainly by the anastomotic arcade in the tarsal canal. The medial third of the body of the talus is supplied by the branch of the artery of the tarsal canal to the deltoid ligament.

Innervation The talus is innervated by branches from the deep fibular, tibial, saphenous and sural nerves.

Ossification A single ossification centre appears prenatally at 6 months (see Fig. 84.7). The posterolateral process sometimes fuses with an accessory bone called the os trigonum.

Talar fractures Since $70 \%$ of the surface of the talus is covered by articular cartilage, displaced talar neck fractures, where the blood supply to the talar body is interrupted, may result in avascular necrosis and non-union. Transchondral fractures of the superior aspect of the talus are frequently overlooked on initial radiographs of patients with ankle complaints (Trepal et al 1986). A systematic review by Halvorson et al (2012) reported that approximately $33 \%$ of talar neck fractures progress to avascular necrosis, $20 \%$ progress to malunions and $5 \%$ progress to non-unions. In general, these complications do not occur in nondisplaced fractures. If a subchondral lucency is seen in the talus on radiographs at 8 weeks after fracture of the talar neck (Hawkins sign), it may be assumed that vascularity to the talar body is intact and that the fracture is likely to heal satisfactorily.

## Calcaneus

The calcaneus is the largest of the tarsal bones and projects posterior to the tibia and fibula as a short lever for muscles of the calf attached to its posterior surface. It is irregularly cuboidal, its long axis being inclined distally upwards and laterally (see Fig. 84.8A,B). It has a relatively thin cortex (Daftary et al 2005). The superior or proximal surface is divisible into three areas. The posterior third is rough and concavoconvex; the convexity is transverse and supports fibroadipose tissue (Kager's fat pad) between the calcaneal tendon and ankle joint. The middle third carries the posterior talar facet, which is oval and convex anteroposteriorly. The anterior third is partly articular; distal (anterior) to the posterior articular facet, a rough depression, the calcaneal sulcus, narrows into a groove on the medial side and completes the tarsal sinus with the talus (see Fig. 84.8B). (The tarsal sinus is a conical hollow bounded by the talus medially, superiorly and laterally, with the superior surface of the calcaneus below. Its medial end is narrow and tunnelshaped, and is often referred to as the tarsal canal.) Distal and medial to this groove, an elongated articular area covers the sustentaculum tali (talar shelf) and extends distolaterally on the body of the bone. This facet is often divided into middle and anterior talar facets by a nonarticular interval at the anterior limit of the sustentaculum tali (the incidence of this subdivision varies with sex, race and occupation). Rarely, all three facets on the upper surface of the calcaneus are fused into one irregular area.

The anterior surface is the smallest, and is an obliquely set concavoconvex articular facet for the cuboid. The posterior surface is divided into three regions: a smooth proximal (superior) area separated from the calcaneal tendon by a bursa and adipose tissue; a middle area, which is the largest, limited above by a groove and below by a rough ridge for the calcaneal tendon; and a distal (inferior) area, vertically striated and inclined downwards and forwards, which is the subcutaneous weight-bearing surface.

The plantar surface is rough, especially proximally as the calcaneal tuberosity, the lateral and medial processes of which extend distally, separated by a notch. The medial process is longer and broader (see Fig. 84.8B). Further distally, an anterior tubercle marks the distal limit of the attachment of the long plantar ligament.

The lateral surface is almost flat. It is proximally deeper and palpable on the lateral aspect of the heel distal to the lateral malleolus. Distally, it presents the fibular trochlea (see Fig. $84.8 \mathrm{~A}, \mathrm{~B}$ ), which is exceedingly variable in size and palpable 2 cm distal to the lateral malleolus when well developed. It bears an oblique groove for the tendon of fibularis longus and a shallower proximal groove for the tendon of fibularis brevis. About 1 cm or more behind and above the fibular trochlea, a second elevation may exist for attachment of the calcaneofibular part of the lateral ligament.

The medial surface is vertically concave, and its concavity is accentuated by the sustentaculum tali, which projects medially from the distal part of its upper border (see Fig. 84.8B). Superiorly, the process bears the middle talar facets and inferiorly a groove, which is continuous with that on the talar posterior surface for the tendon of flexor hallucis longus (see Fig. 84.8A,B). The medial aspect of the sustentaculum tali

This accessory bone is occasionally found and arises from a separate ossification centre that appears between 8 and 11 years of age. When the os trigonum fuses to the posterolateral process of the talus it is called the trigonal process (Stieda's process). Another accessory bone (although rare) of the foot is the os supratalare, which lies on the dorsal aspect of the talus; it rarely measures more than 4 mm in length.

A detailed analysis of patterns of anterior talar articular facets in a series of 401 Indian calcanei revealed four types. Type I ( $67 \%$ ) showed one continuous facet on the sustentaculum extending to the distomedial calcaneal corner; type II (26\%) presented two facets, one sustentacular and one distal calcaneal; type III (5\%) possessed only a single sustentacular facet; and type IV (2\%) showed confluent anterior and posterior facets (Gupta et al 1977).

Fig. 84.10 Branches of the posterior tibial artery, posteromedial view of the ankle.
can be felt immediately distal to the tip of the medial malleolus; occasionally, it is also grooved by the tendon of flexor digitorum longus.

Muscle and ligamentous attachments The interosseous talocalcaneal and cervical ligaments and the medial root of the inferior extensor retinaculum are attached in the calcaneal sulcus. The nonarticular area distal to the posterior talar facet is the site of attachment of extensor digitorum brevis (in part), the principal band of the inferior extensor retinaculum and the stem of the bifurcate ligament.

Abductor hallucis and the superficial part of the flexor retinaculum and, distally, the plantar aponeurosis and flexor digitorum brevis are all attached to the medial process (medial condyle) of the calcaneal tuberosity at its prominent medial margin. The medial process of the calcaneal tuberosity is the primary weight-bearing portion of the calcaneus. Clinically, pain over the medial tuberosity is often associated with plantar fasciitis (Yi et al 2011). Abductor digiti minimi is attached to the lateral process, extending medially to the medial process. The long plantar ligament is attached to the rough region between the processes proximally, and extends to the anterior tubercle distally. The plantar calcaneocuboid ligament (short plantar ligament) is attached
to the tubercle and the area distal to it. The lateral tendinous head of flexor accessorius is attached distal to the lateral process near the lateral margin of the long plantar ligament. Plantaris is attached to the posterior surface near the medial side of the calcaneal tendon. The anterior part of the lateral surface is crossed by the fibular tendons but is largely subcutaneous. The calcaneofibular ligament is attached $1-2 \mathrm{~cm}$ proximal to the fibular trochlea, usually to a low, rounded elevation.

The dorsal surface of the sustentaculum tali is part of the talocalcaneonavicular joint; its plantar surface is grooved by the tendon of flexor hallucis longus, and margins of the groove give attachment to the deep part of the flexor retinaculum. The plantar calcaneonavicular ligament is attached distally to the medial margin of the sustentaculum, which is narrow, rough and convex. A slip from the tendon of tibialis posterior, and superficial fibres of the deltoid ligament and medial talocalcaneal ligaments are attached proximally. Distal to the attachment of the deltoid ligament, the tendon of flexor digitorum longus is related to the margin of the sustentaculum tali and may groove it. The large medial head of flexor accessorius is attached distal to the groove for flexor hallucis longus.

Vascular supply The calcaneus receives its arterial supply from the medial and lateral calcaneal arteries (arising from the posterior tibial and fibular arteries, respectively), fibular artery, posterior calcaneal anastomosis (formed from the posterior tibial and fibular arteries), medial and lateral plantar arteries, artery of the tarsal sinus and tarsal canal, branches of the lateral tarsal artery and perforating fibular arteries.

Innervation The calcaneus is innervated by branches of the tibial, sural and deep fibular nerves.

Ossification The calcaneus is the only tarsal bone that always has two ossification centres (see Fig. 84.7). In addition to the main ossification centre, there is a scale-like posterior apophysis that covers most of the posterior, and part of the plantar, surfaces. The main centre appears prenatally in the third month, whereas the posterior apophysis appears in the sixth year in females and the eighth year in males, fusing in the fourteenth and sixteenth years, respectively.

An os calcaneus secundarius, an accessory bone rather than a secondary ossification centre, occasionally occurs. When present, it is located on the so-called anterior process of the calcaneus, from which the bifurcate ligament arises, in an interval between the anteromedial aspect of the calcaneus, the proximal ends of the cuboid and navicular, and the head of the talus. Other rare accessory bones of the calcaneus include the calcaneus accessorius in the region of the fibular trochlea; the os sustentaculi on the posterior aspect of the sustentaculum tali; the os subcalcis on the plantar aspect of the calcaneus slightly posterior to the origin of the plantar aponeurosis; and the os aponeurosis plantaris, which lies within the plantar aponeurosis in close proximity to the medial process of the calcaneal tuberosity.

## Navicular

The navicular articulates with the talar head proximally and with the cuneiform bones distally (see Fig. 84.8A; Fig. 84.11). In convex pes planovalgus (vertical talus), the navicular is subluxed dorsally and articulates instead with the talar neck. The downward displacement of the talar head creates a characteristic convex 'rocker-bottom foot'. The distal surface of the navicular is transversely convex and divided into three facets (the medial being the largest) for articulation with the cuneiforms. The proximal surface is oval and concave, and articulates with the talar head. The dorsal surface is rough and convex. The medial surface is also rough and projects proximally as a prominent tuberosity, palpable approximately 2.5 cm distal and plantar to the medial malleolus. The plantar surface, rough and concave, is separated from the tuberosity medially by a groove for the tendon of tibialis posterior. The lateral surface is rough and irregular, and often bears a facet for articulation with the cuboid.

The facet for articulation with the medial cuneiform is roughly triangular, its rounded apex is medial and its 'base', facing laterally, is often markedly curved; the articular facets for the intermediate and lateral cuneiforms are also triangular, with plantar-facing apices. The facet for the lateral cuneiform may appear as a wide crescent or a semicircle rather than a triangle. Dorsal talonavicular, cuneonavicular and cubonavicular ligaments are attached to the dorsal navicular surface.

Muscle and ligamentous attachments The navicular tuberosity is the main attachment of tibialis posterior, and a groove lateral to it transmits part of the tendon distally to the cuneiforms and middle three metatarsal bases. The plantar calcaneonavicular ligament is attached to

Calcaneal apophysitis (Sever's disease) is a self-limiting inflammatory condition seen in some child athletes, boys more commonly than girls. It is not a true apophysitis and the use of imaging for its initial diagnosis is a subject of controversy (Kose 2010, Rachel et al 2011). Calcaneal apophysitis is often treated with stretching, therapeutic heel lifts, icing and non-steroidal anti-inflammatory drugs (Micheli and Ireland 1987).

a slight projection lateral to the groove and adjacent to the proximal surface. The calcaneonavicular part of the bifurcate ligament is attached to the rough part of the lateral surface (see Fig. 84.5B).

Vascular supply The dorsal aspect of the navicular is supplied either from a branch of, or directly from, the dorsalis pedis artery. The medial plantar artery supplies its plantar aspect, and the tuberosity is supplied by an anastomosis between the dorsalis pedis and medial plantar arteries.

Innervation The navicular is innervated by the deep fibular and medial plantar nerves.

Ossification The navicular ossification centre appears during the third year (see Fig. 84.7). It is sometimes affected by avascular necrosis between the ages of 4 and 7 years (Köhler's disease). An accessory navicular bone, which is considered an anatomical variant, occasionally occurs. It arises from a separate ossification centre in the region of the posteromedial aspect of the navicular tuberosity. There are three distinct types of accessory navicular. Type I is probably a sesamoid bone within the plantar aspect of the tendon of tibialis posterior at the level of the inferior calcaneonavicular ligament. In type II, the accessory bone is separated from the body of the navicular by a synchondrosis. These types are sometimes known as os tibiale externum or naviculare secundarium. Type III is commonly called the cornuate navicular or gorilloid navicular (Barnes 2003), where the accessory bone is united to the navicular by a bony ridge, and may represent the possible end stage of type II. An accessory navicular may be the source of pain in athletes. Type II is the most commonly symptomatic variant; it has been suggested that the pull of the tendon of tibialis posterior, the degree of foot pronation, and the location of the accessory bone in relation to the undersurface of the navicular may produce tension, shear and/or compression forces on the synchondrosis. An accessory navicular is one aetiology of posterior tibial tendon dysfunction (PTTD). The altered mechanics cause abnormal stresses, leading to tendon degeneration, decreased strength and possible tendon rupture.

Rarely, the navicular is bipartite and it arises from two distinct centres of ossification. This can lead to premature degeneration within the talocalcaneonavicular joint (Müller-Weiss disease). Occasionally, a small bone is found within the talocalcaneonavicular joint on its dorsal aspect. Referred to as an os talonaviculare dorsale, it represents either a separate accessory bone or a fractured osteophyte of the proximal dorsal aspect of the navicular. A bipartite navicular is sometimes found with cuneonavicular coalitions.

## Cuboid

The cuboid, the most lateral bone in the distal tarsal row, lies between the calcaneus proximally and the fourth and fifth metatarsals distally (see Figs 84.8A, 84.11). Its dorsolateral surface is rough for the attachment of ligaments. The plantar surface is crossed distally by an oblique groove for the tendon of fibularis longus and bounded proximally by a ridge that ends laterally in the tuberosity of the cuboid, the lateral aspect of which is faceted for a sesamoid bone or cartilage that is frequently found in the tendon of fibularis longus. Proximal to its ridge, the rough plantar surface extends proximally and medially because of the obliquity of the calcaneocuboid joint, making its medial border much longer than the lateral. The lateral surface is rough; the groove for fibularis longus extends from a deep notch on its plantar edge. The medial surface, which is much more extensive and partly non-articular, bears an oval facet for articulation with the lateral cuneiform, and proximal to this another facet (sometimes absent) for articulation with the navicular; the two form a continuous surface separated by a smooth vertical ridge. The distal surface is divided vertically into a medial quadrilateral articular area for the base of the fourth metatarsal and a lateral triangular area, its apex lateral, for the base of the fifth metatarsal. The proximal surface, triangular and concavo-convex, articulates with the distal calcaneal surface; its medial plantar angle projects proximally and inferiorly to the distal end of the calcaneus.

Muscle and ligamentous attachments The dorsal calcaneocuboid, cubonavicular, cuneocuboid and cubometatarsal ligaments are attached to the dorsal surface. Deep fibres of the long plantar ligament are attached to the proximal edge of the plantar ridge. Slips from the tendons of tibialis posterior and flexor hallucis brevis are attached to the projecting proximomedial part of the plantar surface. Interosseous, cuneocuboid and cubonavicular ligaments are attached to the rough part of the medial cuboidal surface. Proximally, the medial calcaneocuboid ligament, which is the lateral limb of the bifurcate ligament, is also attached to this surface. The placement and trapezoidal shape of the cuboid give it the ability to act as the 'keystone' of the lateral longitudinal arch of the foot. During locomotion, the tension of the calcaneocuboid joint helps 'lock' the mid-tarsal joint and acts as a major stabilizer of the foot.

Vascular supply The cuboid is supplied by deep branches of the medial and lateral plantar arteries and by branches from the dorsal arterial network.

Innervation The cuboid is innervated by branches from the lateral plantar, sural and deep fibular nerves.

Ossification The cuboid frequently begins to ossify before birth, the primary ossification centre appearing just before birth (see Fig. 84.7). An os cuboides secundarium is a rare accessory bone situated on the plantar aspect of the cuboid and is sometimes involved in the infrequently reported cubonavicular coalitions.

## Cuneiforms

The wedge-like cuneiform bones articulate with the navicular proximally and with the bases of the first to third metatarsals distally; the medial cuneiform is the largest, the intermediate the smallest. The dorsal surfaces of the intermediate and lateral cuneiforms form the base of the wedge. The wedge is reversed in the medial cuneiform, which is a prime factor in shaping the transverse arch. The proximal surfaces of all three form a concavity for the distal surface of the navicular. The medial and lateral cuneiforms project distally beyond the intermediate cuneiform and so form a recess (mortise) for the second metatarsal base.

## Medial cuneiform

The medial cuneiform (see Figs 84.5, 84.8A, 84.11) articulates with the navicular and base of the first metatarsal. It has a rough, narrow dorsal surface. The distal surface is a kidney-shaped facet for the first metatarsal base, its 'hilum' being lateral. The proximal surface bears a piriform facet for the navicular, which is concave vertically and dorsally narrowed. The medial surface, rough and subcutaneous, is vertically convex; its distal plantar angle carries a large impression, which receives the principal attachment of the tendon of tibialis anterior (see Fig. 84.5B). The lateral surface is partly non-articular; there is a smooth right-angled strip along its proximal and dorsal margins for the intermediate cuneiform. Its distal dorsal area is separated by a vertical ridge from a small, almost square, facet for articulation with the dorsal part of the medial surface of the second metatarsal base. Plantar to this, the medial cuneiform is attached to the medial side of the second metatarsal base by a strong ligament (Lisfranc's ligament). Proximally, an intercuneiform interosseous ligament connects this surface to the intermediate cuneiform. The distal and plantar areas of the surface are roughened by attachment of part of the tendon of fibularis longus.

Muscle attachments The plantar surface receives a slip from the tendon of tibialis posterior, in addition to part of the insertion of the tendon of fibularis longus. The medial surface receives the attachment of most of the tendon of tibialis anterior.

Vascular supply The medial cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation The medial cuneiform is supplied by the deep fibular and medial plantar nerves.

Ossification The medial cuneiform may have two separate ossification centres, which appear during the second year of life (see Fig. 84.7). Very rarely, the medial cuneiform is bipartite and there is a horizontal cleavage plane between the two parts.

The os cuneo- 1 metatarsale-I plantare is a rare accessory bone that occurs on the plantar aspect of the foot at the base of the first metatarsal and articulates with the plantar base of the first metatarsal and the medial cuneiform.

## Intermediate cuneiform

The intermediate (middle) cuneiform articulates proximally with the navicular and distally with the second metatarsal base (see Figs 84.5A, 84.11). It has a narrow plantar surface that receives a slip from the tendon of tibialis posterior. The distal and proximal surfaces are both triangular articular facets. The medial surface is partly articular; it articulates via a smooth, angled region that is occasionally double with the medial cuneiform along its proximal and dorsal margins. The lateral surface is also partly articular; along its proximal margin a vertical segment, usually indented, abuts the lateral cuneiform. Strong interosseous ligaments connect the non-articular parts of both surfaces to the adjacent cuneiforms. An intricate arrangement of dorsal and plantar ligaments spans the tarsometatarsal joint, connecting the most distal row of tarsals to their respective metatarsals. However, the plantar ligament between the intermediate cuneiform and the base of the second metatarsal is uniquely absent (Castro et al 2010, Chaney 2010, de Palma et al 1997, Blouet et al 1983).

Muscle attachments Part of the tendon of tibialis posterior is attached to the intermediate cuneiform.

Vascular supply The intermediate cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation The intermediate cuneiform is innervated by the deep fibular and medial plantar nerves.

Ossification The ossification centre appears during the third year of life (see Fig. 84.7). The os cuneo-2 metatarsale-II dorsale, a rare accessory bone, lies on the dorsal aspect of the joint between the intermediate cuneiform and the second metatarsal. It is wedge-shaped with its base orientated dorsally.

## Lateral cuneiform

The lateral cuneiform lies between the intermediate cuneiform and cuboid, and also articulates with the navicular and, distally, with the third metatarsal base (see Figs $84.5 \mathrm{~A}, 84.11$ ). Like the intermediate cuneiform, its dorsal surface, which is rough and almost rectangular, is the base of a wedge. The plantar surface is narrow and receives a slip from tibialis posterior and sometimes part of flexor hallucis brevis. The distal surface is a triangular articular facet for the third metatarsal base. The proximal surface is rough on its plantar aspect, but its dorsal twothirds articulate with the navicular by a triangular facet. The medial surface is partly non-articular and has a vertical segment, indented by the intermediate cuneiform, on its proximal margin; on its distal margin, a narrower strip (often two small facets) articulates with the lateral side of the second metatarsal base. The lateral surface, also partly non-articular, bears a triangular or oval proximal facet for the cuboid; a semilunar facet on its dorsal and distal margin articulates with the dorsal part of the medial side of the fourth metatarsal base. Nonarticular areas of the medial and lateral surfaces receive intercuneiform and cuneocuboid ligaments, respectively, which are important in the maintenance of the transverse arch of the foot.

Muscle attachments The plantar surface of the lateral cuneiform receives a slip from the tendon of tibialis posterior and, occasionally, part of flexor hallucis brevis.

Vascular supply The lateral cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation The lateral cuneiform is innervated by branches of the deep fibular and lateral plantar nerves.

Ossification The lateral cuneiform ossifies during the first year of life (see Fig. 84.7)

## Tarsal coalition

Tarsal coalition is a hereditary condition in which there is a fibrous, cartilaginous or osseous union of two or more tarsal bones. The aetiology of tarsal coalition is unclear; suggestions include genetic predisposition, failure of segmentation of primitive mesenchyme, trauma, arthritic changes, and/or osteochondroses of the tarsal bones (e.g. Köhler's disease) (Gregersen 1977, Zaw and Calder 2010, Lemley et al 2006, Harris 1965, Varner and Michelson 2000).

## METATARSUS

The five metatarsals lie in the distal half of the foot and connect the tarsus with the phalanges. Like the metacarpals, they are miniature long bones and have a shaft, proximal base and distal head. Except for the first and fifth, the shafts are long and slender, longitudinally convex dorsally, and concave on their plantar aspects. Prismatic in section, they taper distally. Their bases articulate with the distal tarsal row and with adjacent metatarsal bases. The line of each tarsometatarsal joint, except the first, inclines proximally and laterally with the metatarsal bases being oblique relative to their shafts. The heads articulate with the proximal phalanges, each by a convex surface that passes farther on to its plantar aspect, where it ends on the summits of two eminences. The sides of the heads are flat, with a depression surmounted by a dorsal tubercle for a collateral ligament of the metatarsophalangeal joint.

On occasion, an os intermetatarseum is encountered between the medial cuneiform and the bases of the first and second metatarsals and represents a rare accessory bone in this region.

Harris and Beath (1948) were the first to recognize an association between tarsal coalitions and 'peroneal (fibular) spastic flat foot'. The two most common examples are talocalcaneal and calcaneonavicular coalitions, which usually present with symptoms early in the second decade of life. They are often, but not invariably, associated with flat feet (pes planus). A talonavicular coalition is rare (Brennan et al 2012), but when present, it is often associated with a 'ball-and-socket' ankle joint. Surgical resection of tarsal coalitions may eradicate associated pain but seldom improves the range of movement.

## Individual metatarsals

## First metatarsal

The first metatarsal (see Figs 84.5, 84.11) is the shortest and thickest, and has a strong shaft, of marked prismatic form. The base sometimes has a lateral facet or ill-defined smooth area as a result of contact with the second metatarsal. Its large proximal surface, usually indented on the medial and lateral margins, articulates with the medial cuneiform. Its circumference is grooved for tarsometatarsal ligaments and, medially, part of the tendon of tibialis anterior is attached; its plantar angle has a rough, oval, lateral prominence for the tendon of fibularis longus. The medial head of the first dorsal interosseous is attached to the flat lateral surface of the shaft. The large head has a plantar elevation, the crista, which separates two grooved facets (of which the medial is larger), on which sesamoid bones glide. The most common joint deformity related to the first metatarsal is hallux valgus.

Muscle attachments The first metatarsal receives attachments from the tendon of tibialis anterior medially, and the tendon of fibularis longus on its plantar aspect. It gives origin to the medial head of the first dorsal interosseus on the proximal aspect of the lateral surface.

Vascular supply The first metatarsal is supplied by the first dorsal and first plantar metatarsal arteries and a superficial branch of the medial plantar artery, which together form a periosteal arterial network. A nutrient artery enters the lateral surface of the mid-diaphysis. The head receives a medial, lateral and plantar supply from these arteries.

Innervation The first metatarsal is innervated by the deep fibular and medial plantar nerves.

Ossification The first metatarsal has two centres of ossification, one in the shaft and the other in the base (unlike the other metatarsals, in which the secondary ossification centre is distal). They appear during the tenth week of prenatal life and the third year of life, respectively (see Fig. 84.7,) and fuse between the seventeenth and twentieth years. There may be a third centre in the first metatarsal head.

## Second metatarsal

The second metatarsal is the longest (see Figs 84.5, 84.11). Its cuneiform base bears four articular facets. The proximal one, concave and triangular, is for the intermediate cuneiform. The dorsomedial one, for the medial cuneiform, is variable in size and usually continuous with that for the intermediate cuneiform. Two lateral facets, dorsal and plantar, are separated by non-articular bone, each divided by a ridge into distal demifacets, which articulate with the third metatarsal base, and a proximal pair (sometimes continuous) for the lateral cuneiform. The areas of these facets vary, particularly the plantar facet, which may be absent. An oval pressure facet, caused by contact with the first metatarsal, may appear on the medial side of the base, plantar to that for the medial cuneiform. Because of its length, its steep inclination, and the position of its base recessed in the tarsometatarsal joint, it is at risk of stress overload; perhaps this is why it is a common site for stress fractures (particularly in athletes) and an avascular phenomenon in its head (Freiberg's infraction). The second metatarsal head is affected in $68 \%$ of cases, the third metatarsal head in $27 \%$ of cases, and the fourth metatarsal head in 3\% of cases. Freiberg's disease is the only osteochondrosis more common in females and occurs at a ratio of $5: 1$ with peak age of onset between 11 and 17 years (Carmont et al 2009, Cerrato 2011).

Muscle attachments The lateral head of the first dorsal interosseous and the medial head of the second are attached to the medial and lateral surfaces of the shaft, respectively.

Vascular supply The blood supply of the second, third and fourth metatarsals follows the same pattern as that described for the first metatarsal, i.e. the bones are all supplied by branches of the dorsal and plantar metatarsal arteries. The nutrient artery enters the diaphysis on its lateral side near the metatarsal base. A constant plantar vessel supplies the heads of the metatarsals.

Innervation The second metatarsal is innervated by branches of the deep fibular and branches of the medial plantar nerve.

Ossification There are two centres of ossification, one in the shaft and one distally in the metatarsal head (see Fig. 84.7). Ossification of the shaft starts during the ninth prenatal week and ossification of the
metatarsal head starts between the third and fourth years; fusion occurs between the seventeenth and twentieth years.

## Third metatarsal

The third metatarsal (see Figs 84.5, 84.11) has a flat triangular base, articulating proximally with the lateral cuneiform, medially with the second metatarsal, via dorsal and plantar facets, and laterally, via a single facet, with the dorsal angle of the fourth metatarsal. The medial plantar facet is frequently absent. The third tarsometatarsal joint is relatively immobile and predisposes the third metatarsal to stress fracture.

Muscle attachments The lateral heads of the second dorsal interosseous and first plantar interosseous are attached to the medial surface of the shaft. The medial head of the third dorsal interosseous is attached to its lateral surface.

Vascular supply The blood supply of the third metatarsal is the same as that of the second metatarsal, described above.

Innervation The third metatarsal is innervated by the deep fibular and lateral plantar nerves.
Ossification There are two centres of ossification, one in the shaft and one distally in the metatarsal head (see Fig. 84.7). Ossification of the shaft starts during the ninth prenatal week and ossification of the metatarsal head starts between the third and fourth years; fusion occurs between the seventeenth and twentieth years.

## Fourth metatarsal

The fourth metatarsal is smaller than the third (see Figs 84.5, 84.11). Its base has, proximally, an oblique quadrilateral facet for articulation with the cuboid; laterally, a single facet for the fifth metatarsal; and medially, an oval facet for the third metatarsal. The latter is sometimes divided by a ridge, in which case the proximal part articulates with the lateral cuneiform.

Muscle attachments The lateral head of the third dorsal and second plantar interossei are attached to the medial surface. The medial head of the fourth dorsal interosseous is attached to the lateral surface.

Vascular supply The blood supply of the fourth metatarsal is the same as that of the second and third metatarsals, described above.

Innervation The fourth metatarsal is innervated by the deep fibular and lateral plantar nerves.

Ossification There are two centres of ossification, one in the shaft and one distally in the metatarsal head (see Fig. 84.7). Ossification of the shaft starts during the ninth prenatal week and ossification of the metatarsal head commences between the third and fourth years; fusion occurs between the seventeenth and twentieth years.

## Fifth metatarsal

The fifth metatarsal has a tuberosity on the lateral side of its base (see Figs $84.5,84.11$ ). The base articulates proximally with the cuboid by a triangular, oblique surface, and medially with the fourth metatarsal. The tuberosity can be seen and palpated midway along the lateral border of the foot; in acute inversion it may be fractured. The metaphysialdiaphysial junction of the fifth metatarsal base is prone to traumatic or stress fractures. It is believed that fractures at this level damage the nutrient artery and the extraosseous arterial plexus, resulting in compromised vascularity of the fracture site, consequent poor fracture healing and non-union that often requires surgical fixation.

Muscle attachments The tendon of fibularis tertius is attached to the medial part of the dorsal surface and medial border of the shaft, and that of fibularis brevis to the dorsal surface of the tuberosity. A strong band of the plantar aponeurosis, sometimes containing muscle, connects the apex of the tuberosity to the lateral process of the calcaneal tuberosity. It is this attachment, and not that of fibularis brevis, that is responsible for avulsion fractures of the tuberosity. The tendon of abductor digiti minimi grooves the plantar surface of the base and flexor digiti minimi brevis is attached here. The lateral heads of the fourth dorsal and the third plantar interossei are attached to the medial side of the shaft.

Vascular supply The fifth metatarsal is supplied by dorsal and plantar metatarsal arteries and an inconstant fibular marginal artery. The nutrient artery enters the diaphysis proximally and medially.

Innervation The fifth metatarsal is innervated by branches from the sural, superficial fibular and lateral plantar nerves.

Ossification There are three centres of ossification, one at the base in the region of the tuberosity (an apophysis), one in the shaft and one distally in the metatarsal head. Ossification of the shaft starts during the tenth prenatal week and ossification of the metatarsal head starts between the third and fourth years (see Fig. 84.7). Fusion of the distal and shaft centres occurs between the seventeenth and twentieth years; the proximal apophysis fuses earlier. An os vesalianum pedis is a rare variant that should not be confused with the basal apophysis (Fig. 84.12).

## PHALANGES OF THE FOOT

In general, the phalanges of the foot resemble those of the hand; there are two in the great toe, and three in each of the other toes (see Fig.

Fig. 84.12 Sites of sesamoid and accessory bones found in the left foot. A, Medial aspect. B, Lateral aspect. C, Plantar aspect.
84.5). On occasion, there are only two phalanges in the little toe and, rarely, this is the case with the other toes. The phalanges of the toes are much shorter than their counterparts in the hand, and their shafts, especially those of the proximal set, are compressed from side to side. In the proximal phalanges, the compressed shaft is convex dorsally, with a plantar concavity. The base is concave for articulation with a metatarsal head, and the head is a trochlea for the middle phalanx. Middle phalanges are small and short, but broader than their proximal counterparts. Distal phalanges resemble those in the fingers, but are smaller and flatter. Each has a broad base for articulation with a middle phalanx and an expanded distal end. A rough tuberosity on the plantar aspect of the latter supports the pulp of the toe and provides a weightbearing area.

Muscle attachments Tendons of the long digital flexors and extensors are attached to the plantar and dorsal aspects of the bases of the distal phalanges of the lateral four toes. Flexor hallucis longus and extensor hallucis longus are similarly attached to the great toe. The bases of the middle phalanges receive the tendons of flexor digitorum brevis and extensor digitorum brevis. The proximal phalanges of the second, third, fourth and fifth toes each receive a lumbrical on their medial side; those of the second, third and fourth toes also receive an interosseous muscle on both sides. For further details of muscular, capsular and ligamentous arrangements in the toes, refer to Figure 84.5. The terminal phalanx of the great toe normally shows a small degree of abduction, as may the proximal phalanx. This is presumed to be unrelated to footwear because this degree of deviation has also been observed in fetal specimens.

Vascular supply The proximal phalanges receive most of their blood supply from the dorsal digital arteries. The middle phalanges are supplied by plantar and dorsal digital arteries. The distal phalanges receive their supply mainly from plantar digital arteries.

Innervation The phalanges are innervated by the plantar and dorsal digital nerves.

Ossification Phalanges are ossified from a primary centre for the shaft and a basal epiphysis (see Fig. 84.7). Primary centres for the distal phalanges appear between the ninth and twelfth prenatal weeks, and somewhat later in the fifth digit. Primary centres for the proximal phalanges appear between the eleventh and fifteenth weeks, and later for the middle phalanges, but there is wide variation. Basal centres appear between the second and eighth years (usually second or third in the great toe), and union with the shaft occurs by the eighteenth year. There is considerable variation in ossification and fusion dates.

## SESAMOID BONES

Most sesamoid bones are only a few millimetres in diameter and their shape is variable. Some have a predictable location (see below), but many others vary in terms of location and frequency of occurrence (see Fig. 84.12). Some sesamoid bones ossify, whereas others remain cartilaginous. Most sesamoid bones are embedded in tendons in close proximity to joints. Their precise role is not understood; it is believed that they may alter the direction of muscle pull, decrease friction and modify pressure.

## Medial and lateral sesamoid bones of the first metatarsophalangeal joint

The two constant sesamoid bones within the foot are those of the first metatarsophalangeal articulation. The medial (tibial) sesamoid bone is generally larger than the lateral (fibular) sesamoid bone and lies slightly more distally. During dorsiflexion of the great toe, the sesamoid bones lie below the first metatarsal head, offering protection to the otherwise exposed plantar aspect of the first metatarsal head. The medial sesamoid is approximately 10 mm wide and 14 mm long, and the lateral sesamoid is usually smaller (approximately 8 mm wide and 10 mm long); the overall sizes of the sesamoid bones vary considerably.

The sesamoid bones are embedded within the double tendon of flexor hallucis brevis and articulate on their dorsal surfaces with the plantar facets of the first metatarsal head. They are separated by the crista or intersesamoidal ridge, which provides stability to the sesamoid bone complex. (This ridge can be eroded to the point of obliteration in severe cases of hallux valgus.) The sesamoid bones are connected to the plantar base of the proximal phalanx through the plantar plate, which is an extension of the tendon of flexor hallucis brevis. A thin layer of the tendon of flexor hallucis brevis covers the plantar surface
of each sesamoid, whereas the dorsal or superior surface is covered by hyaline cartilage. The sesamoid bones are suspended by a sling-like mechanism made up of the collateral ligaments of the first metatarsophalangeal joint and the sesamoid ligaments on either side of the joint. The plantar aponeurosis also has an attachment to the sesamoid bones.

Approximately $30 \%$ of these sesamoid bones are bipartite. The medial is much more commonly affected and may have two, three or four parts, but the fibular sesamoid rarely has more than two. The condition may be bilateral. The sesamoid bones may be congenitally absent.

Muscle attachments The medial sesamoid bone receives an attachment from abductor hallucis, which medially stabilizes the sesamoid complex. The lateral sesamoid receives some fibres from the tendon of adductor hallucis and this provides lateral stabilization. The medial and lateral sesamoid bones are connected by the intersesamoid ligament, which forms the floor of the tendinous canal for the tendon of flexor hallucis longus.

Vascular supply There are three patterns of blood supply to the sesamoid bones. In $50 \%$ of cases, the arterial supply is derived from the medial plantar artery and the deep plantar arch; in $25 \%$ of cases, it is predominantly from the deep plantar arch; and in $25 \%$ of cases, it is from the medial plantar artery alone. The major arterial blood supply to the sesamoid bones enters from the proximal and plantar aspects, and only a minor contribution enters through their distal poles.
Innervation The medial and lateral sesamoid bones are innervated by the plantar digital nerves.
Ossification The ossification centres of the sesamoid bones can be multiple or single.

## Other sesamoid and accessory bones

Accessory or inconstant sesamoid bones may occur under any weightbearing surface of the foot but are most common under the second to fifth metatarsal heads. They are extremely variable in size and their incidence is difficult to determine.

A true sesamoid bone occasionally occurs in the tendon of tibialis posterior. It lies on the plantar aspect of the navicular tuberosity within the tendon at the level of the inferior border of the calcaneonavicular ligament (see above, accessory naviculars). Very rarely, a sesamoid bone is found within the tendon of tibialis anterior near its insertion at the level of the anteroinferior corner of the medial cuneiform, where there is an articular facet. An os peroneum is a sesamoid bone within the tendon of fibularis longus that articulates with the lateral surface of the calcaneus, the calcaneocuboid joint or, more frequently, the plantar aspect of the cuboid where there is an articular facet. The bone is situated where the tendon of fibularis longus angles around the plantar aspect of the lateral border of the cuboid and is usually cartilaginous. The frequency of the os peroneum has been reported to be as low as $4.7 \%$ and as high as $90 \%$ (Coskun et al 2009, Oyedele et al 2006, Muehleman et al 2009).

## JOINTS

## ANKLE (TALOCRURAL) JOINT

The ankle joint is a hinge joint, approximately uniaxial. The lower end of the tibia and its medial malleolus, together with the lateral malleolus of the fibula and inferior transverse tibiofibular ligament, form a deep recess ('mortise') for the body of the talus. Although it appears to be a simple hinge, its axis of rotation is dynamic, shifting during dorsiflexion and plantar flexion. Starting from the plantigrade position, the normal range of dorsiflexion is $10^{\circ}$ when the knee is straight, and $30^{\circ}$ with the knee flexed (when the calcaneal tendon will be relaxed). The range of normal plantar flexion is $30^{\circ}$. (The values of these ranges are all approximate.) Dorsiflexion results in the joint adopting the 'close-packed' position, with maximal congruence and ligamentous tension; from this position, all major thrusting movements are exerted, in walking, running and jumping. The malleoli grip the talus, and even in relaxation, no appreciable lateral movement can occur without stretch of the inferior tibiofibular syndesmosis. The superior talar surface is broader in front, and in dorsiflexion, the malleolar gap is increased by slight lateral rotation of the fibula, by 'give' at the inferior tibiofibular syndesmosis and gliding at the superior tibiofibular joint. Normal ankles show valgus inclination at birth. The morphology changes in the first few years of life and the ankle reaches the adult position by the age of three years (Nakai et al 2000).

Articulating surfaces Articular surfaces are covered by hyaline cartilage. The talar trochlear surface, which is convex sagittally and gently concave transversely, is wider anteriorly; the distal tibial articular surface is reciprocally curved. The talar articular surface for the medial malleolus is a proximal area on the medial talar surface, and is fairly flat, comma-shaped and deeper anteriorly. The larger lateral talar articular surface is triangular and vertically concave, while the articular surface on the lateral malleolus is reciprocally curved. Posteriorly, the edge between the trochlear and fibular articular surfaces of the talus is bevelled to a narrow, flat triangular area that articulates with the inferior transverse tibiofibular ligament (Fig. 84.13A); all surfaces are contiguous. The bones are held together by a fibrous capsule, and by medial collateral (deltoid), anterior and posterior talofibular and calcaneofibular ligaments.

Fibrous capsule Around the joint, the fibrous capsule is thin in front and behind. It is attached proximally to the borders of the tibial and malleolar articular surfaces, and distally to the talus near the margins of its trochlear surface, except anteriorly where it reaches the dorsum of the talar neck. The capsule is strengthened by strong collateral ligaments. Its posterior part consists mainly of transverse fibres. It blends with the inferior transverse ligament and is thickened laterally where it reaches the fibular malleolar fossa.

Ligaments The ligaments of the ankle joint are the medial and lateral collateral ligaments.

Medial collateral ligament (deltoid ligament) The medial collateral ligament (deltoid ligament) is a strong, triangular band, attached to the apex and the anterior and posterior borders of the medial malleolus (Panchani et al 2014; Fig. 84.13B). Of its superficial fibres, anterior (tibionavicular) fibres pass anteriorly to the navicular tuberosity, behind which they blend with the medial margin of the plantar calcaneonavicular ligament; intermediate (tibiocalcaneal) fibres descend almost vertically to the entire length of the sustentaculum tali; posterior (superficial posterior tibiotalar) fibres pass posterolaterally to the medial side of the talus and its medial tubercle; and additional fibres posterior to the sustentaculum tali have been reported (Panchani et al 2014). Of its deep fibres, anterior (anterior tibiotalar) fibres pass from the medial malleolus to the non-articular part of the medial talar surface; intermediate fibres deep to the tibiocalcaneal ligament descend almost vertically to the entire length of the sustentaculum tali; posterior (deep posterior tibiotalar) fibres pass posterolaterally to the medial side of the talus and its medial tubercle; and additional fibres may pass to the spring ligament (Pankovich and Shivaram 1979, Milner and Soames 1998, Boss and Hintermann 2002). The tendons of tibialis posterior and flexor digitorum longus cross the ligament. The medial collateral ligament of the ankle is rarely injured alone: tears are commonly associated with a fracture of the distal fibula. Chronic instability is rare.

Lateral collateral ligament The lateral collateral ligament has three discrete parts. The anterior talofibular ligament extends anteromedially from the anterior margin of the lateral malleolus to the talus, attached anterior to its lateral articular facet and to the lateral aspect of its neck (Fig. 84.13C). The posterior talofibular ligament runs almost horizontally from the distal part of the lateral malleolar fossa to the lateral tubercle of the posterior talar process (see Fig. 84.13A); a 'tibial slip' of fibres, also known as transverse fibres of the posterior talofibular ligament, connects it to the medial malleolus. The calcaneofibular ligament, a long cord, runs from a depression anterior to the apex of the lateral malleolus to a tubercle on the lateral calcaneal surface and is crossed by the tendons of fibularis longus and brevis (see Fig. 84.13A,C). The lateral ligament complex - more specifically, the anterior talofibular ligament - is injured most commonly with inversion sprains; the posterior talofibular ligament is almost always spared. Although the resulting increased laxity is tolerated in most cases, some require surgical reconstruction.

Synovial membrane The joint is lined by a synovial membrane, which projects into the inferior tibiofibular joint.

Vascular supply and lymphatic drainage The ankle joint is supplied by malleolar branches of the anterior and posterior tibial and fibular arteries. Lymphatic drainage is via vessels accompanying the arteries and via the long and small saphenous veins, superficially.

Innervation The ankle joint is innervated by branches from the deep fibular, saphenous, sural and tibial nerves (or medial and lateral

plantar nerves, depending on the level of division of the tibial nerve). Occasionally, the superficial fibular nerve also supplies the ankle joint.

For a comprehensive account of the innervation of the ankle joint (and other foot joints), see Gardner and Gray (1968) and Sarrafian (2011).

Relations Anteriorly, from medial to lateral, are tibialis anterior, extensor hallucis longus, the anterior tibial vessels, deep fibular nerve, extensor digitorum longus and fibularis tertius; posteromedially, from medial to lateral, are tibialis posterior, flexor digitorum longus, the posterior tibial vessels, tibial nerve and flexor hallucis longus; in the groove behind the lateral malleolus are the tendons of fibularis longus and brevis. The tendon of fibularis brevis lies anterior to the tendon of fibularis longus at this level (Fig. 84.14). The long saphenous vein and saphenous nerve cross the ankle joint medial to the tendon of tibialis anterior and anterior to the medial malleolus, the nerve lying posterior to the vein.

All of the above structures are at risk during surgery on the ankle; the main structures at risk are the neurovascular structures located anteriorly and posteromedially. Branches of the superficial fibular nerve are at risk of injury on the anterolateral aspect of the ankle, particularly during ankle arthroscopy.

Factors maintaining stability Passive stability is conferred upon the ankle mainly by the medial and lateral ligament complexes, the distal tibiofibular ligaments, the tendons crossing the joint, the bony contours and the capsular attachments. Gravity, muscle action and ground reaction forces provide dynamic stability. Stability requires the continuous action of soleus assisted by gastrocnemius; it increases when leaning forwards, and decreases when leaning backwards. If backward sway takes the projection of the centre of gravity ('weight line') posterior to the transverse axes of the ankle joints, the muscles that plantar flex and dorsiflex relax and contract, respectively.

Failure of the fibular muscles can lead progressively to varus instability of the ankle, whereas long-standing failure of the tendon of tibialis posterior, posterior tibial tendon dysfunction, can result in valgus instability of the ankle and particularly a planovalgus foot deformity commonly referred to as adult acquired flat-foot deformity.

## Posterior tibial tendon dysfunction

Available with the Gray's Anatomy e-book
Muscles producing movement Dorsiflexion is produced by tibialis anterior, assisted by extensors digitorum longus and hallucis longus, and fibularis tertius. Plantar flexion is produced by gastrocnemius and

The aetiology of posterior tibial tendon dysfunction is complex. The incidence is greater in obese, middle-aged women. There are multiple contributory factors such as diabetes mellitus and hypertension, which are further complicated by steroid exposure or previous trauma or surgery in the region of the tendon of tibialis posterior. There is often a progressive disruption not only of this tendon, but also of multiple ligamentous complexes such as the spring ligament and those supporting the naviculocuneiform and tarsometatarsal ligaments. This leads to a marked collapse of the medial longitudinal arch, which can be staged using the original Johnson and Strom (1989) classification system and that of Myerson (1997). Along with the varying methods used to diagnose posterior tibial tendon dysfunction, a clinically important test is the single heel-rise test used in the initial stages of adult acquired flatfoot deformity (Deland 2008, Gluck et al 2010, Durrant et al 2011).

Fig. 84.14 A transverse section through the lower part of the left ankle joint, superior aspect.
soleus, assisted by plantaris, tibialis posterior, flexor hallucis longus and flexor digitorum longus.

Ankle fractures Ankle fractures are common and of importance because failure to achieve accurate anatomical alignment in the treatment of ankle fractures often results in significant long-term morbidity. Except for very simple and non-displaced fractures, most ankle fractures are associated with a ligamentous injury. The direction and nature of forces applied to the ankle correlate with the fracture pattern and concomitant ligament injury.

## INFERIOR TIBIOFIBULAR JOINT

The inferior tibiofibular joint is usually considered a syndesmosis. It consists of the anterior and posterior tibiofibular and interosseous ligaments.

Articulating surfaces The distal tibiofibular joint is between the rough, medial convex surface on the distal end of the fibula and the rough concave surface of the fibular notch of the tibia. These surfaces are separated distally for approximately 4 mm by a synovial prolongation from the ankle joint, and may be covered by articular cartilage in their lowest parts.

Fibrous capsule The inferior tibiofibular joint does not have a capsule.

Ligaments The ligaments of the inferior tibiofibular joint are the anterior, interosseous and posterior ligaments.

Anterior tibiofibular ligament The anterior tibiofibular ligament is a flat band, which descends laterally between the adjacent margins of the tibia and fibula, anterior to the syndesmosis (see Fig. 84.13C). Bassett's ligament is a variant that presents as a low-lying slip of the ligament, which is inserted so far distally on the fibula that it may cause irritation of the lateral aspect of the talus; it is amenable to arthroscopic removal (Subhas et al 2008).
Interosseous tibiofibular ligament The interosseous tibiofibular ligament is continuous with the interosseous membrane and contains many short bands between the rough adjacent tibial and fibular surfaces; it is the strongest union between the bones.
Posterior tibiofibular ligament The posterior tibiofibular ligament is stronger than the anterior, and is placed similarly on the posterior aspect of the syndesmosis (see Fig. 84.13A). Its distal, deep part is the
inferior transverse ligament, a thick band of yellow fibres, which crosses from the proximal end of the lateral malleolar fossa to the posterior border of the tibial articular surface almost to the medial malleolus. The ligament projects distal to the bones, in contact with the talus. Its colour reflects its content of yellow elastic fibres.

Synovial membrane The synovial membrane of the ankle joint projects into the distal 4 mm or so of the inferior tibiofibular joint.

Vascular supply and lymphatic drainage The inferior tibiofibular joint is supplied by the perforating branch of the fibular artery and lateral malleolar branches of the anterior and posterior tibial arteries. Lymphatic drainage is via vessels corresponding to the arteries, and via vessels that accompany the great and small saphenous veins.

Innervation The inferior tibiofibular joint is innervated by branches from the deep fibular and sural nerves.

Relations No significant structures pass anterior to the anterior aspect of the inferior tibiofibular joint but the superficial fibular nerve is at risk during surgery to this area. Posteriorly, the fibular artery passes over the posterior tibiofibular ligament and is at risk in the posterolateral approach to the fibula.

Factors maintaining stability Stability is maintained in part by the bone contours, but mainly by the dense anterior and posterior tibiofibular and the interosseous ligaments.

Muscles producing movement No muscles act on the inferior tibiofibular joint, which moves only slightly. Because of the varying slope of the lateral surface of the body of the talus, the fibula undergoes a small degree of lateral rotation during dorsiflexion at the ankle, and this results in slight widening of the interval between the bones. Testing for a significant disruption of this joint is usually carried out with the patient under anaesthesia and involves applying a lateral rotation and abduction force, looking for abnormal widening of the syndesmosis. Another helpful clinical test for evaluating a syndesmotic injury is the Hopkinson squeeze test. This test is carried out by compressing the fibula to the tibia at the midpoint of the leg. An injured syndesmosis will result in pain in the area of the inferior tibiofibular joint (Scheyerer et al 2011, Hopkinson et al 1990). Excessive anterior/posterior glide of the fibula relative to the tibia also indicates a disruption of the joint.

## TARSAL JOINTS

## Talocalcaneal joint

Anterior and posterior articulations between the calcaneus and talus form a functional unit termed the talocalcaneal or subtalar joint (see Fig. 84.16). The posterior articulation is referred to as the talocalcaneal joint and the anterior articulation is regarded as part of the talocalcaneonavicular joint. The talocalcaneal joint is a modified multiaxial joint and its permitted movements are considered together with those at other tarsal joints. The bones are connected by a fibrous capsule, and by lateral, medial, interosseous talocalcaneal and cervical ligaments.

Articulating surfaces The subtalar joint proper involves the concave posterior calcaneal facet on the posterior part of the inferior surface of the talus and the convex posterior facet on the superior surface of the calcaneus (Fig. 84.15).

Fibrous capsule The fibrous capsule envelops the joint; its fibres are short and attached to its articular margins.

Ligaments The ligaments of the talocalcaneal joint are the lateral, medial and interosseous talocalcaneal ligaments and the cervical ligament.

Lateral talocalcaneal ligament The lateral talocalcaneal ligament is a short flat fasciculus that descends obliquely and runs inferoposteriorly from the lateral process of the talus to the lateral calcaneal surface and is attached anterosuperior to the calcaneofibular ligament.

Medial talocalcaneal ligament The medial talocalcaneal ligament connects the medial tubercle of the talus to the posterior aspect of the sustentaculum tali and adjacent medial surface of the calcaneus. Its fibres blend with the medial (deltoid) ligament of the ankle joint; the most posterior fibres line the groove for flexor hallucis longus between the talus and calcaneus.

Fig. 84.15 A, Disarticulated talocalcaneal and talocalcaneonavicular joints, seen from above. B, A disarticulated talus (seen from below). (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Fig. 84.16 A coronal section through the left ankle and talocalcaneal joint (seen from behind). (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Interosseous talocalcaneal ligament The interosseous talocalcaneal ligament is a broad, flat, bilaminar transverse band in the tarsal sinus (see Fig. 84.15A; Fig. 84.16). It descends obliquely and laterally from the sulcus tali to the calcaneal sulcus. The posterior lamina of the ligament is associated with the talocalcaneal joint, and the anterior lamina with the talocalcaneonavicular joint. Its medial fibres are taut in eversion of the foot.

Posterior talocalcaneal ligament The posterior talocalcaneal ligament is attached to the plantar border of the posterior process (posterolateral tubercle) of the body of the talus.

Cervical ligament The cervical ligament is just lateral to the tarsal sinus and attached to the superior calcaneal surface (see Fig. 84.13C). It is
medial to the attachment of extensor digitorum brevis, from where it ascends medially to an inferolateral tubercle on the talar neck (BarclaySmith 1896). It is considered to be taut in inversion of the foot.

Synovial membrane The synovial cavity of the talocalcaneal joint is usually quite separate and does not communicate with those of other tarsal joints. However, direct communication with the ankle joint has been observed in rare instances.

Innervation The talocalcaneal joint is innervated by branches of the tibial, medial plantar and sural nerves.

Relations Posteromedially, in the region of the posterior aspect of the talocalcaneal joint, and viewed from anterior to posterior, veins on
either side of the posterior tibial artery, the tibial nerve and the tendon of flexor hallucis longus are seen. These neurovascular structures are at risk in posteromedial approaches to the ankle and talocalcaneal joints. On the lateral side, the tendon of fibularis brevis lies anterior to the tendon of fibularis longus, both passing behind the lateral malleolus in proximity to the talocalcaneal joint. The sural nerve lies just posterior to the tendons of the fibularis longus and brevis.

Factors maintaining stability Stability is conferred by the bony contours of the hindfoot plus the above-mentioned ligaments; it is not known which ligaments provide the most stability. An additional ligamentous restraint is provided by the calcaneofibular component of the lateral ligament complex. The tendons crossing the articulation also add stability.

Muscles producing movement Heel inversion is controlled by tibialis anterior, tibialis posterior and the gastrocnemius-soleus complex via the calcaneal tendon; the extrinsic flexors of the toes also contribute. Eversion of the foot results from the pull of fibularis longus, brevis and tertius in addition to the extrinsic muscles that extend the toes.

## Talocalcaneonavicular joint

Barclay-Smith provided an eloquent account of the talocalcaneonavicular joint in 1896; for more recent studies, see Bonnel et al (2011) and Bonnel et al (2013). In terms of function, and in clinical practice, it is helpful to regard this complex joint as comprising two articulations, i.e. the anterior part of the 'subtalar' joint and the talonavicular joint. It is a compound, multiaxial articulation.

Articulating surfaces The ovoid talar head is continuous with the triple-faceted anterior area of its inferior surface. This part fits the concavity formed collectively by the posterior surface of the navicular, the middle and anterior talar facets of the calcaneus, and the superior fibrocartilaginous surface of the plantar calcaneonavicular ligament (spring ligament). The bones are connected by a fibrous capsule and by the talonavicular and plantar calcaneonavicular ligaments, and the calcaneonavicular part of the bifurcate ligament.

Fibrous capsule The fibrous capsule is poorly developed, except posteriorly, where it is thick and blends with the anterior part of the interosseous ligament filling the tarsal sinus.

Ligaments The ligaments of the talocalcaneonavicular joint are the talonavicular and plantar calcaneonavicular (spring) ligaments.

Talonavicular ligament The talonavicular ligament is a broad, thin band (see Fig. 84.13B,C). It connects the dorsal surfaces of the neck of the talus and the navicular, and is covered by extensor tendons. The plantar calcaneonavicular ligament and the calcaneonavicular part of the bifurcate ligament (see Fig. 84.13C) are the plantar and lateral ligaments of the joint, respectively. Although the calcaneus and navicular do not articulate directly, they are connected by the calcaneonavicular part of the bifurcate ligament and the plantar calcaneonavicular ligament.

Plantar calcaneonavicular (spring) ligament The plantar calcaneonavicular (spring) ligament is a broad, thick band connecting the anterior margin of the sustentaculum tali to the plantar surface of the navicular (see Figs 84.13B, 84.15A; Fig. 84.17). It ties the calcaneus to the navicular below the head of the talus as part of its articular cavity and it maintains the medial longitudinal arch of the foot. According to Davis et al (1996), the spring ligament is made up of two distinct structures: the superomedial calcaneonavicular portion and the inferior calcaneonavicular portion.

The dorsal surface of the superomedial calcaneonavicular portion has a triangular fibrocartilaginous facet on which part of the talar head rests (see Fig. 84.15A). Its plantar surface is supported medially by the tendon of tibialis posterior and laterally by the tendons of flexors hallucis longus and digitorum longus; its medial border is blended with the anterior superficial fibres of the medial (deltoid) ligament. Jennings and Christensen (2008) showed that transection of the spring ligament leads to instability of the hindfoot, including talar head plantar flexion and adduction, consistent with pes planovalgus (adult acquired flatfoot) deformity. The inferior calcaneonavicular portion can become attenuated in adult acquired flat-foot deformity, and may require surgical correction.

Fig. 84.17 Ligaments on the plantar aspect of the left foot. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Synovial membrane The talocalcaneonavicular joint is a synovial joint whose cavity sometimes communicates with that of the talocalcaneal joint.

Innervation The talocalcaneonavicular joint is innervated by the deep fibular and medial plantar nerves.

Relations On the medial side, from dorsal to plantar, lie the tendon of tibialis posterior and the tendon of flexor digitorum longus above the sustentaculum tali, and the flexor hallucis longus tendon below. At this point, flexor hallucis longus lies deep to the medial and lateral plantar branches of the posterior tibial artery and tibial nerve. The latter structures are at risk during medial approaches to the joint, e.g. resection of talocalcaneal coalition. Dorsally from medial to lateral, lie the tendons of tibialis anterior and extensor hallucis longus, the deep fibular nerve and the dorsalis pedis artery, the muscle belly of extensor hallucis brevis passing medially and deep to the tendons of extensor digitorum longus and fibularis tertius. Structures at risk during the dorsal approach to the talonavicular joint include the branches of the superficial fibular nerve superficially and the dorsalis pedis artery and deep fibular nerve deep to the inferior extensor retinaculum.

Factors maintaining stability Stability of the joint is due to a combination of factors: bony contours, the strong plantar calcaneonavicular (spring) ligament, and the calcaneonavicular component of the bifurcate ligament.

Muscles producing movement The muscles producing movement are as described above for the talocalcaneal joint.

## Calcaneocuboid joint

The calcaneocuboid joint is at the same level as the talonavicular joint and together they represent the transverse tarsal joint. It is a saddle (sellar) or biaxial joint with concavo-convex surfaces.

The superomedial portion is the larger of the two, and originates from the superomedial aspect of the sustentaculum tali and the anterior edge of the anterior facet of the calcaneus. The inferior calcaneonavicular portion originates from between the middle and anterior calcaneal facets at the anterior portion of the sustentaculum tali. Both portions insert on the inferior surface of the midnavicular, with the superomedial portion inserting medial to the inferior portion.

Articulating surfaces The articular surfaces of the calcaneocuboid joint, which is 2 cm proximal to the tubercle on the fifth metatarsal base, are between the anterior (distal) surface of the calcaneus and the posterior (proximal) surface of the cuboid.

Fibrous capsule The fibrous capsule is thickened dorsally as the dorsal calcaneocuboid ligament. The synovial cavity of this joint is separate, and does not communicate with those of other tarsal articulations.

Ligaments The ligaments of the calcaneocuboid joint are the bifurcate, long plantar and plantar calcaneocuboid ligaments.

Bifurcate ligament The bifurcate ligament (Chopart's ligament) is a strong Y-shaped band (see Fig. 84.13C). It is attached by its stem proximally to the anterior part of the upper calcaneal surface, and distally it divides into calcaneocuboid and calcaneonavicular parts. A separate ligament, the lateral calcaneocuboid ligament, extends to the dorsomedial aspect of the cuboid, forming a main bond between the two rows of tarsal bones; the (medial) calcaneonavicular ligament is attached to the dorsolateral aspect of the navicular.

Long plantar ligament The long plantar ligament is the longest ligament associated with the tarsus (see Figs 84.13C, 84.17; Fig. 84.18). It extends from the plantar surface of the calcaneus (anterior to the processes of its tuberosity) and from its anterior tubercle, to the ridge and tuberosity on the plantar surface of the cuboid. Deep fibres are attached to the cuboid and more superficial fibres continue to the bases of the second to fourth, and sometimes fifth, metatarsals. This ligament, together with the groove on the plantar surface of the cuboid, makes a tunnel for the tendon of fibularis longus. It is a most powerful factor limiting depression of the lateral longitudinal arch.

Plantar calcaneocuboid ligament This short ligament (see Fig. 84.17) is deeper than the long plantar ligament, from which it is separated by areolar tissue. It is a short, wide and strong band stretching from the anterior calcaneal tubercle and the depression anterior to it, to the adjoining part of the plantar surface of the cuboid; it also supports the lateral longitudinal arch.

Synovial membrane A synovial membrane lines the calcaneocuboid joint.

Innervation The calcaneocuboid joint is innervated on its plantar aspect by the lateral plantar nerve, and dorsally by the sural and deep fibular nerves.

Relations Fibularis longus and abductor digiti minimi pass in proximity to the joint, and the lateral plantar nerve passes medially. Extensor digitorum brevis overlies the lateral aspect of the joint. The sural nerve and the tendon of fibularis longus are at risk during approaches to an os peroneum.

Factors maintaining stability The calcaneocuboid joint only permits a small amount of movement; its stability reflects the bony contours and strong ligaments described above.

Muscles producing movement Gliding occurs between the calcaneus and cuboid, with conjunct rotation on each other during inversion and eversion of the entire foot. The same muscles that act on the talocalcaneal and talocalcaneonavicular joints bring about these movements.

## Naviculocuneiform joint

The naviculocuneiform joint is a compound joint, often described as a plane joint.

Articulating surfaces The navicular articulates distally with the cuneiform bones where the distal navicular surface is transversely convex and divided into three facets by low ridges that are adapted to the proximal, slightly curved surfaces of the cuneiforms.

Fibrous capsule The fibrous capsule is continuous with those of the intercuneiform and cuneocuboid joints, and it is also connected to the second and third cuneometatarsal joints and intermetatarsal joints between the second to fourth metatarsals.

Ligaments The ligaments of the naviculocuneiform joint are the dorsal and plantar ligaments.

Dorsal and plantar ligaments The dorsal and plantar ligaments connect the navicular to each cuneiform; of the three dorsal ligaments, one is attached to each cuneiform. The fasciculus from the navicular to the medial cuneiform is continued as the capsule of the joint around its medial aspect, and then blends medially with the plantar ligament. Plantar ligaments have similar attachments and receive slips from the tendon of tibialis posterior.

Synovial membrane The synovial membrane lines the fibrous capsule in the manner outlined above.

Fig. 84.18 A sagittal section of the foot showing ankle and tarsal joints. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Innervation The naviculocuneiform joint is innervated dorsally by branches from the deep fibular nerve. The medial plantar nerve innervates the medial and intermediate naviculocuneiform joints, and the lateral plantar nerve innervates the lateral naviculocuneiform joint.

Relations The tendon of tibialis posterior sends fibres to the medial cuneiform and crosses the joint on its medial side; it is vulnerable to injury when a medial surgical approach is used, as are the dorsal venous arch and the saphenous nerve. The tendon of tibialis anterior passes over the dorsomedial aspect of the joint and the tendon of extensor hallucis longus is lateral. Running over the intermediate cuneiform, from medial to lateral, are the deep fibular nerve, the dorsalis pedis artery and extensor hallucis brevis, all of which are vulnerable during dorsal exposure of the joint. On the lateral aspect of the joint, the superficial structures at risk are the superficial fibular nerve and the dorsal venous arch of the foot.

Muscles producing movement Movements at the naviculocuneiform, cuboideonavicular, intercuneiform and cuneocuboid joints are slight and subtle gliding and rotational movements that occur during pronation or supination of the foot; when alterations occur in a loaded foot in contact with the ground, they increase suppleness when the forefoot is stressed, e.g. in the initial thrust of running and jumping. The muscles responsible for these slight movements are tibialis anterior, tibialis posterior, fibularis longus and brevis, and the long flexors and extensors of the toes.

## Cuboideonavicular joint

The cuboideonavicular joint is usually a fibrous joint, the bones being connected by dorsal, plantar and interosseous ligaments. This syndesmosis is often a synovial joint that is almost plane; its articular capsule and synovial lining are continuous with that of the naviculocuneiform joint. The dorsal ligament extends distolaterally, and the plantar nearly transversely from the cuboid to the navicular. The interosseous ligament is made of strong transverse fibres and connects nonarticular parts of adjacent surfaces to the two bones.

## Intercuneiform and cuneocuboid joints

The intercuneiform and cuneocuboid joints are all synovial and approximately plane or slightly curved. Their articular capsules and synovial linings are continuous with those of the naviculocuneiform joints. The bones are connected by dorsal, plantar and interosseous ligaments (see Figs 84.13B,C, 84.15A).

Ligaments The ligaments of the intercuneiform and cuneocuboid joints are the dorsal, plantar and interosseous ligaments.

Dorsal and plantar ligaments The dorsal and plantar ligaments each have three transverse bands that pass between the medial and intermediate cuneiforms, the intermediate and lateral cuneiforms, and the lateral cuneiform and cuboid. The plantar ligaments receive slips from the tendon of tibialis posterior.

Interosseous ligaments The interosseous ligaments connect nonarticular areas of adjacent surfaces and are strong agents in maintaining the transverse arch.

Innervation The intercuneiform and cuneocuboid joints are innervated dorsally via the deep fibular nerve. The plantar aspect of the medial two joints is innervated from the medial plantar nerve, and the plantar aspect of the lateral joints is innervated from the lateral plantar nerve.

Muscles producing movement The muscles producing movement are as described above for the naviculocuneiform joint.

## TARSOMETATARSAL JOINTS

Tarsometatarsal articulations are approximately plane synovial joints.
Articulating surfaces The first metatarsal articulates with the medial cuneiform; the second is recessed between the medial and lateral cuneiforms and articulates with the intermediate cuneiform; the third articulates with the lateral cuneiform; the fourth articulates with the lateral cuneiform and the cuboid; and the fifth articulates with the cuboid. The joints are approximately on an imaginary line traced from
the tubercle of the fifth metatarsal to the tarsometatarsal joint of the great toe, except for that between the second metatarsal and intermediate cuneiform, which is $2-3 \mathrm{~mm}$ proximal to this line (see Figs 84.5 A , 84.11). Ryan et al (2012) reported that the average joint depths for the first, second and third metatarsal-cuneiform joints were 32.3, 26.9, and 23.6 mm , respectively.

Fibrous capsule The tarsometatarsal joint of the great toe has its own capsule. The articular capsules and cavities of the second and third toes are continuous with those of the intercuneiform and naviculocuneiform joints, but are separated from the fourth and fifth joints by an interosseous ligament between the lateral cuneiform and fourth metatarsal base.

Ligaments The bones are connected by dorsal and plantar tarsometatarsal and cuneometatarsal interosseous ligaments.

Dorsal ligaments The dorsal ligaments are strong and flat. The first metatarsal is joined to the medial cuneiform by an articular capsule, and the other tarsometatarsal capsules blend with the dorsal and plantar ligaments. The second metatarsal receives a band from each cuneiform, the third from the lateral cuneiform, the fourth from the lateral cuneiform and the cuboid, and the fifth from the cuboid alone.

Plantar ligaments The plantar ligaments are longitudinal and oblique bands, and are less regular than the dorsal ligaments. Those for the first and second metatarsals are strongest. The second and third metatarsals are joined by oblique bands to the medial cuneiform, and the fourth and fifth metatarsals by a few fibres to the cuboid.

Cuneometatarsal interosseous ligaments There are three cuneometatarsal interosseous ligaments. One (the strongest) passes from the lateral surface of the medial cuneiform to the adjacent angle of the second metatarsal (see Fig. 84.17). Known as Lisfranc's ligament, it is crucial to the stability of the tarsometatarsal joint complex. Disruption of this ligament can lead to instability and deformity, and subsequent degenerative changes. A second ligament connects the lateral cuneiform to the adjacent angle of the second metatarsal; it does not divide the joint between the second metatarsal and lateral cuneiform, and is inconstant. A third ligament connects the lateral angle of the lateral cuneiform to the adjacent fourth metatarsal base.

Synovial membrane The first tarsometatarsal joint has its own capsule, with a synovial lining. The other joints are similarly arranged, but there is a communication between the second and third and between the fourth and fifth tarsometatarsal joints.

Innervation The interosseous cuneometatarsal ligaments are innervated dorsally via the deep fibular nerve. The plantar aspects of the medial two joints are innervated from the medial plantar nerve, and the plantar aspects of the lateral joints are innervated by the lateral plantar nerve.

Relations From medial to lateral, the following structures cross the dorsal aspect of the tarsometatarsal joints: the saphenous nerve, the dorsal venous arch, the tendon of extensor hallucis longus, the dorsalis pedis artery, the deep fibular nerve, extensor hallucis brevis, the tendons of extensor digitorum longus, extensor digitorum brevis, fibularis tertius and fibularis brevis. Branches of the superficial fibular nerve are variable in location on the dorsum. The sural nerve lies just inferior to the tendon of fibularis brevis in the subcutaneous tissues. Surgery involving the tarsometatarsal joints is performed through a dorsal approach, and therefore all of these structures are potentially at risk of injury.

Factors maintaining stability The major stabilizers of the tarsometatarsal joints are the associated ligaments. However, despite the strength of the ligaments, this joint complex is vulnerable to injury because of the lack of ligamentous connection between the first and second metatarsal bases. The medial interosseous ligament or Lisfranc's ligament is responsible for the tell-tale avulsion fracture of the second metatarsal base, which may be the only radiographic indication of abnormality after injury to this part of the foot. It is a highly significant injury that is often missed; failure to recognize and treat this injury by surgical reduction and fixation can lead to long-term disability.

Muscles producing movement Movements between the tarsals and metatarsals are limited to flexion and extension, except in the first tarsometatarsal joint, where some abduction and rotation occur. The muscles that produce this motion are tibialis anterior and fibularis
longus. Flexion and extension are brought about by the long and short flexors and extensors of the toes. Movement between the medial cuneiform and first metatarsal, and between the fourth and fifth metatarsal bases and the cuboid, is moderate and allows the foot to adapt to uneven surfaces, whereas movement between the second and third metatarsal bases and their corresponding cuneiforms is very limited.

## INTERMETATARSAL JOINTS

The intermetatarsal ligaments are very strong and are present between all the lateral four metatarsals; they are absent between the first and second metatarsals. The base of the second metatarsal is joined to the first tarsometatarsal joint by the cuneometatarsal interosseous ligament.

Ligaments The ligaments of the intermetatarsal joints include the dorsal and plantar intermetatarsal ligaments.

Dorsal and plantar intermetatarsal ligaments As with their dorsal counterparts, the plantar intermetatarsal ligaments are longitudinal, oblique or transverse and they vary considerably in both number and organization. The plantar ligaments are significantly stronger than the corresponding dorsal ligaments. The strongest is the second oblique plantar ligament, which connects the medial cuneiform to the bases of the second and third metatarsals.

Other ligaments All the metatarsal heads are connected indirectly by deep transverse metatarsal ligaments. Dorsal and plantar ligaments pass transversely between adjacent bases; interosseous ligaments are strong transverse bands that connect non-articular parts of the adjacent surfaces (see Fig. 84.17)

## METATARSOPHALANGEAL JOINTS

Metatarsophalangeal articulations are ovoid or ellipsoid joints between the rounded metatarsal heads and shallow cavities on the proximal phalangeal bases. They are usually 2.5 cm proximal to the web spaces of the toes.

Articulating surfaces Articular surfaces cover the distal and plantar, but not the dorsal, aspects of the metatarsal heads. The plantar aspect of the first metatarsal head has two longitudinal grooves separated by a ridge (the crista). Each articulates with a sesamoid bone embedded in the capsule of the joint, formed here by the two tendons of flexor hallucis brevis. The sesamoid bones are connected to each other by the intersesamoid ligament, which forms the floor of the tendinous canal for the tendon of flexor hallucis longus. The medial sesamoid bone receives an attachment from abductor hallucis and the lateral sesamoid bone receives an attachment from adductor hallucis, forming the conjoint tendon.

Articular areas on the proximal phalangeal bases are concave. The ligaments are capsular, plantar, deep transverse metatarsal and collateral.

Fibrous capsules Fibrous capsules are attached to their articular margins. They are thin dorsally, and may be separated from the extrinsic extensor tendons by small bursae, or they may be replaced by the tendons, but they are inseparable from the plantar and collateral ligaments. The plantar aponeurosis blends with the plantar capsule to form the so-called 'plantar plate', which inserts distally into the base of the proximal phalanx via medial and lateral bundles. Proximally, the plate is attached to the metatarsal head via a thin synovial fold. It also receives an attachment from the accessory collateral ligament.

Ligaments The ligaments of the metatarsophalangeal joints are the plantar, deep transverse metatarsal and collateral ligaments.

Plantar ligaments The plantar ligaments are thick and dense. They lie between and blend with the collateral ligaments, being loosely attached to the metatarsals and firmly attached to the phalangeal bases. Their margins blend with the deep transverse metatarsal ligaments. Their plantar surfaces are grooved for the flexor tendons, the fibrous sheaths of which connect with the edges of the grooves, and their deep surfaces extend the articular areas for metatarsal heads.

Deep transverse metatarsal ligaments The deep transverse metatarsal ligaments are four short, wide, flat bands that unite the plantar liga-
ments of adjoining metatarsophalangeal joints. The interossei are dorsal to, and the lumbricals, digital vessels and nerves are plantar to, these ligaments. They resemble the deep transverse metacarpal ligaments except that, in the foot, there is a deep transverse metatarsal ligament between the plantar ligament of the second metatarsophalangeal joint and that of the first metatarsophalangeal joint (see Fig. 84.17).

Collateral ligaments The collateral ligaments are strong cords flanking each joint. They are attached to the dorsal tubercles on the metatarsal heads and the corresponding side of the phalangeal bases, and they slope inferodistally. The first metatarsophalangeal joint also contains metatarsosesamoid ligaments. On either side, the ligaments arise from the metatarsal head with a narrow origin and then fan out to insert on the border of the proximal phalanx and the plantar plate. Each collateral ligament consists of the phalangeal collateral ligament, which inserts into the base of the proximal phalanx, and the accessory collateral ligament, which inserts into the plantar plate.

Synovial membrane Each metatarsophalangeal joint is a separate synovial joint.

Innervation The main nerve supply of the metatarsophalangeal joints is from the plantar digital nerves, which supply the first, second, third and medial half of the fourth metatarsophalangeal joint on their plantar aspects. Digital branches of the lateral plantar nerve supply the lateral half of the fourth joint, and both medial and lateral aspects of the fifth joint, on their plantar sides. The medial dorsal cutaneous branch of the superficial fibular nerve supplies the dorsomedial side of the hallucal metatarsophalangeal joint. The deep fibular nerve supplies the dorsolateral side of the hallucal metatarsophalangeal joint and the medial side of the metatarsophalangeal joint of the second toe.

Relations Dorsally, the tendon of extensor hallucis longus lies medial to the tendon of extensor hallucis brevis. The same arrangement occurs in the lateral four toes with the tendons of extensor digitorum longus and brevis. The interossei are plantarmedial and plantarlateral, dorsal to the transverse intermetatarsal ligament, whereas the lumbrical tendons and the digital artery and nerve are plantar to the transverse intermetatarsal ligament. The extrinsic and intrinsic flexors lie on the plantar aspect of the joint in the midline. If approaching the metatarsophalangeal joint surgically from the plantar surface, it is important not to stray from the midline.

Factors maintaining stability The first metatarsophalangeal joint owes its stability to its capsuloligamentous structures, and to flexor and extensor hallucis brevis, with a small contribution from flexor and extensor hallucis longus or the bony contours. The collateral ligaments and plantar plates stabilize the metatarsophalangeal joints of the lateral four toes. Rupture of the plantar plate can lead to dislocation of the metatarsophalangeal joint and, possibly, hammer toe deformity.

Muscles producing movement The types of movements that occur at these joints are like those that occur at the corresponding joints in the hand, but the range of movement is quite different. In contrast to the metacarpophalangeal joints, the range of active extension that can occur at the metatarsophalangeal joints $\left(50-60^{\circ}\right)$ is greater than that of flexion $\left(30-40^{\circ}\right)$; this is an adaptation to the needs of walking, and is most marked in the joint of the great toe, where flexion is a few degrees while extension may reach $90^{\circ}$. When the foot is on the ground, metatarsophalangeal joints are already extended to at least $25^{\circ}$ because the metatarsals incline proximally in the longitudinal arches of the foot (see Fig. 84.8A). The range of passive movements in these joints is $90^{\circ}$ (extension) and $45^{\circ}$ (flexion), according to Kapandji (2011). The following muscles produce movements at the metatarsophalangeal joints:

Flexion Flexor digitorum brevis, lumbricals and interossei, assisted by flexor digitorum longus and flexor accessorius. In the fifth toe, flexor digiti minimi brevis assists. For the great toe, flexors hallucis longus and brevis and the oblique head of the adductor hallucis are the only flexors.

Extension Extensors digitorum longus and extensor digitorum brevis, extensor hallucis longus.

Adduction Adductor hallucis; in the third to fifth toes, the first, second and third plantar interossei, respectively.

Abduction Abductor hallucis; in the second toe, the first and second dorsal interossei; in the third and fourth toes, the corresponding dorsal interossei; in the fifth toe, abductor digiti minimi.

Note that the line of reference for adduction and abduction is along the second digit, which has the least mobile metatarsal. The second toe may therefore be 'abducted' medially and laterally by the first and second dorsal interossei, respectively.

Hallux valgus Hallux valgus is a common condition, occurring mainly in individuals who have a genetic predisposition. Footwear is implicated in the condition, which presumably accounts for the greater incidence in females. Metatarsus primus varus, an adduction deformity of the first metatarsal, is commonly associated with hallux valgus.

The more spheroidal the shape of the first metatarsal head, the more likely it is to be unstable. Conversely, a flat metatarsal head is less likely to be associated with hallux valgus. No muscle inserts into the first metatarsal head, and therefore its position is determined by the position of the proximal phalanx. As the proximal phalanx moves laterally on the metatarsal head, it pushes the head medially. This leads to attenuation of the medial soft tissue structures and contracture of the lateral ones. The sesamoid sling (i.e. plantar plate and flexor hallucis brevis), which is anchored laterally by adductor hallucis, remains in place as the head moves medially, displacing the sesamoid bones from beneath the metatarsal head. As this happens, the weakest point of the medial capsule fails, so that abductor hallucis slips under the metatarsal head. This leads to failure of the intrinsic muscles to stabilize the joint, and the pull of abductor hallucis leads to spinning of the proximal phalanx, which results in a varus deformity. Failure to intervene surgically inevitably results in a progressive deformity.

## INTERPHALANGEAL JOINTS

Interphalangeal articulations are almost pure hinge joints, in which the trochlear surfaces on the phalangeal heads articulate with reciprocally curved surfaces on adjacent phalangeal bases. Each has an articular capsule and two collateral ligaments, as occurs in the metatarsophalangeal joints. The plantar surface of the capsule is a thickened fibrous plate, like the plantar metatarsophalangeal ligaments, and is often termed the plantar ligament.

Innervation The interphalangeal articulations are innervated by branches from the plantar digital nerves. The medial dorsal cutaneous branch of the superficial fibular nerve also supplies the interphalangeal joint of the great toe. Branches of the deep fibular, intermediate dorsal cutaneous and sural nerves sometimes supply the joints of the lateral four toes.

Muscles producing movement Movements are flexion and extension, which are greater in amplitude between the proximal and middle phalanges than between the middle and distal. Flexion is marked, but extension is limited by tension of the flexor muscles and plantar ligaments. Abduction, adduction and rotation occur to a minor extent. The following muscles produce movements at the interphalangeal joints:

Flexion Flexor digitorum longus, flexor digitorum brevis, and flexor hallucis longus. Flexor accessorius assists flexor digitorum longus to maintain an extended toe and neutralize the medial pull of flexor digitorum longus.

Extension Extensor digitorum longus, extensor digitorum brevis, extensor hallucis longus and extensor hallucis brevis.

## ARCHES OF THE FOOT

Three main arches are recognized in the foot. They are the medial longitudinal, the lateral longitudinal and the transverse arches. The roles of the arches of the foot in standing, walking and running are discussed later in this chapter.

## Medial longitudinal arch

The medial margin of the foot arches up between the heel proximally and the medial three metatarsophalangeal joints to form a visible arch (see Fig. 84.8A). It is made up of the calcaneus, talar head, navicular, the three cuneiforms and the medial three metatarsals. The posterior and anterior pillars are the posterior part of the inferior calcaneal surface and the three metatarsal heads, respectively. The bones themselves contribute little to the stability of the arch, whereas the ligaments contribute significantly. The most important ligamentous structure is the plantar aponeurosis, which acts as a tie beam between the supporting pillars
(Hicks 1954). Dorsiflexion, especially of the great toe, draws the two pillars together, thus heightening the arch: the so-called 'windlass' mechanism. Next in importance is the spring ligament, which supports the head of the talus. If this ligament fails, the navicular and calcaneus separate, allowing the talar head, which is the highest point of the arch, to descend, leading to a flat-foot deformity. The talocalcaneal ligaments and the anterior fibres of the deltoid ligament, from the tibia to the navicular, also contribute to the stability of the arch.

Muscles play a role in the maintenance of the medial longitudinal arch. Flexor hallucis longus acts as a bowstring. Flexor digitorum longus, abductor hallucis and the medial half of flexor digitorum brevis also contribute but to a lesser extent. Tibialis posterior and anterior invert and adduct the foot, and so help to raise its medial border. The importance of tibialis posterior is manifest by the collapse of the medial longitudinal arch that accompanies failure of its tendon (see below).

## Lateral longitudinal arch

The lateral longitudinal arch is a much less pronounced arch than the medial one. The bones making up the lateral longitudinal arch are the calcaneus, the cuboid and the fourth and fifth metatarsals; they contribute little to the arch in terms of stability (see Fig. 84.8A). The pillars are the calcaneus posteriorly and the lateral two metatarsal heads anteriorly. Ligaments play a more important role in stabilizing the arch, especially the lateral part of the plantar aponeurosis and the long and short plantar ligaments. However, the tendon of fibularis longus makes the most important contribution to the maintenance of the lateral arch. The lateral two tendons of flexor digitorum longus (and flexor accessorius), the muscles of the first layer (lateral half of flexor digitorum brevis and abductor digiti minimi), and fibularis brevis and tertius also contribute to the maintenance of the lateral longitudinal arch.

## Transverse arch

The bones involved in the transverse arch are the bases of the five metatarsals, the cuboid and the cuneiforms (see Fig. 84.8A). The intermediate and lateral cuneiforms are wedge-shaped and thus adapted to maintenance of the transverse arch. The ligaments, which bind the cuneiforms and the metatarsal bases, mainly provide the stability of the arch, as does the tendon of fibularis longus, which tends to approximate the medial and lateral borders of the foot. A shallow arch is maintained at the metatarsal heads by the deep transverse ligaments, transverse fibres that tie together the digital slips of the plantar aponeurosis, and, to a lesser extent, by the transverse head of adductor hallucis.

## Pes planus and pes cavus

The term pes planus denotes an excessively flat foot. There is no precise degree of flatness that defines pes planus but it may be either physiological or pathological. In physiological pes planus, the feet are flexible and rarely problematic. There is a high prevalence in children of preschool age. In the age group 2-6 years, normal arch volumes in the sitting and standing positions correlate with the height of the navicular (lowest palpable medial projection of the navicular to the floor (Chang et al 2012)). In marked contrast, pathological pes planus is often associated with stiffness and pain. The windlass (or 'Jack's great toe') test involves passively dorsiflexing the great toe at the metatarsophalangeal joint. This tightens the plantar aponeurosis and, in flexible pes planus, results in accentuation of the medial longitudinal arch. In pathological pes planus, no accentuation of the arch is seen. This test can also be carried out by asking the individual to stand with both feet plantar flexed while viewing the hindfoot from behind. In flexible flat feet, the calcaneus swings into a varus position; in pathological pes planus it does not. Causes of pathological pes planus include tarsal coalition, disruption of the tendon of tibialis posterior, rupture of the spring ligament, tarsometatarsal arthritis (and subsequent collapse), and hindfoot (talocalcaneal or subtalar joint) degenerative or inflammatory arthritis.

Pes cavus denotes an excessively high-arched foot. The majority of cases arise as a result of a neurological disorder (e.g. Charcot-MarieTooth disease, tethered spinal cord, poliomyelitis). According to the anatomical location of the deformity, pes cavus may be classified into hindfoot, midfoot or forefoot cavus. When pes cavus involves all three parts of the foot, it is called 'global' cavus.

In Charcot-Marie-Tooth disease, an overactive fibularis longus leads to plantar hyperflexion of the first metatarsal. To keep the forefoot in contact with the ground, the patient develops a progressive compensatory hindfoot varus. If ignored, the hindfoot varus, which is initially flexible, becomes fixed.

## MUSCLES

The muscles acting on the foot may be divided into extrinsic and intrinsic groups.

## EXTRINSIC MUSCLES

The extrinsic muscles are described in Chapter 83. Their tendons cross the ankle, and move and stabilize this joint. Distally, the tendons also act on the joints of the foot and help to stabilize them. The muscles can be grouped according to their arrangement in the leg. The extensors arise in the anterior compartment of the leg and their tendons pass anterior to the ankle, where they are bound down by the extensor retinacula. The lateral group arises in the relatively narrow lateral compartment of the leg and their tendons pass posterior to the lateral malleolus, bound down by the fibular retinacula. The flexors arise in the posterior compartment of the leg and their tendons pass posterior to the ankle, where the tendons of the superficial group of flexors are inserted into the calcaneus (see below), and the tendons of the deep group of flexors are bound down by the flexor retinaculum.

## Anterior group

Tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius are described on pages 1406-1408.

## Lateral group

Fibularis longus and fibularis brevis are described on page 1408.

## Posterior group

## Superficial group

Gastrocnemius, soleus and plantaris are described on pages 1409-1410; the calcaneal tendon is described below.

## Calcaneal (Achilles) tendon

The calcaneal tendon is the common tendon of gastrocnemius and soleus. It is the thickest and strongest tendon in the human body (see Fig. 82.3). Approximately 15 cm long, it begins near the middle of the calf; its anterior surface receives muscle fibres from soleus almost to its inferior end. It gradually becomes more rounded until approximately 4 cm above the calcaneus; below this level, it expands and becomes attached to the midpoint of the posterior surface of the calcaneus. Agedependent variability in the terminal insertion site of the calcaneal tendon (Snow et al 1995, Kim et al 2010, Kim et al 2011) may explain why calcaneal tendinopathy is infrequently found in children and adolescents. It also has implications for the appropriate siting of surgical entry portals about the calcaneal tendon insertion in order to reduce the risk of iatrogenic injury to the tendon (Lohrer et al 2008). The fibres of the calcaneal tendon are not aligned strictly vertically and they display a variable degree of spiralization (Cummins and Anson 1946). The tendon fibres spiral laterally through $90^{\circ}$ as they descend, so that the fibres associated with gastrocnemius come to insert on the calcaneus more laterally, and those associated with soleus more medially. The fibres in the tendon of plantaris (described in Ch. 83) exhibit varying degrees of blending with the fibres of the calcaneal tendon, sometimes blending entirely at its insertion or inserting into the plantar aponeurosis.

Tensile properties The estimated tensile breaking load of a fetal calcaneal tendon increases from 2 kg at 6 months post fertilization to 18 kg at full term (Yamada 1970). In adults, the average estimated tensile breaking load of the calcaneal tendon is 192 kg , decreasing to 160 kg in the eighth decade (Takigawa 1953), which may explain why calcaneal tendon ruptures are infrequently encountered in youth (Yamada 1970).

Vascular supply The blood supply to the calcaneal tendon is poor; the predominant artery is a recurrent branch of the posterior tibial artery, which mainly supplies peritendinous tissues (Salmon et al 1994). There is an additional supply from the paratenon (Carr and Norris 1989, Chen et al 2009), as well as a supply proximally from intramuscular arterial branches and distally from the calcaneus. Microdissection and angiographic studies have identified three main vascular territories: a proximal section, a hypovascular midsection and a distal
section (Ahmed et al 1998, Zantop et al 2003, Chen et al 2009). The posterior tibial artery primarily supplies the proximal and distal sections, and the midsection receives a relatively poor blood supply from the fibular artery (Chen et al 2009). These findings support previous work showing that the hypovascular midsection of the calcaneal tendon is the area most prone to rupture and also underscore the importance of avoiding disruption of the vascular supply to the tendon during percutaneous surgery. The vascularity of the skin overlying the calcaneal tendon varies according to location: the skin on the medial side of the tendon is supplied by the posterior tibial artery and on the lateral side by the fibular artery (Yepes et al 2010). The skin covering the posterior aspect of the tendon is the most poorly vascularized; medial or lateral incisions of the skin surrounding the tendon should reduce post-surgical healing complications relative to a direct posterior approach.

The calcaneal tendon is not the only plantar flexor of the ankle, which is one of the reasons that ruptures of the calcaneal tendon may not always be clinically apparent. However, it is a frequent site of pathology because of its susceptibility to rupture, degenerative change (tendinosis) and inflammation (paratendinitis); the area of relative avascularity in the mid-substance of the tendon is where the majority of problems occur.

Relations The calcaneal tendon is subcutaneous. The sural nerve crosses its lateral border about 10 cm above its insertion; the nerve is especially vulnerable here to iatrogenic injury during surgery. Distally, there are bursae superficial and deep to the tendon. The muscle belly of flexor hallucis longus lies deep to the deep fascia on the anterior surface of the tendon.

Actions The calcaneal tendon produces plantar flexion of the ankle joint. The tendon fibres spiral laterally through $90^{\circ}$ as they descend, so that the fibres associated with gastrocnemius come to insert on the bone more laterally, and those associated with soleus more medially.

Heel bursae There are three locations about the heel where bursae occur. The most common is the retrocalcaneal bursa, which lies between the calcaneal tendon and the posterior surface of the calcaneus. An almost constant finding, it has an anterior bursal wall composed of fibrocartilage and a thin posterior wall, which blends with the thin epitenon (epitendineum) of the calcaneal tendon. Dorsiflexion of the ankle results in compression of the bursa. Less common are an adventitious bursa superficial to the calcaneal tendon, and a subcalcaneal bursa between the inferior surface of the calcaneus and the origin of the plantar aponeurosis. A prominent superolateral calcaneal tuberosity may impinge on the deep aspect of the calcaneal tendon where it inserts on to the calcaneus (Haglund's disease). It is often associated with a retrocalcaneal bursa, and symptoms are exacerbated by dorsiflexion of the ankle because this movement increases the pressure within the bursa and causes impingement of calcaneus against the tendon insertion.

## Plantaris

Plantaris is described on page 1410.

## Deep group

The deep muscles of the calf include popliteus, which acts on the knee joint, and flexor hallucis longus, flexor digitorum longus and tibialis posterior, which all act on the ankle joint and joints of the foot.

## Flexor hallucis longus

Flexor hallucis longus is described on page 1411. The tendon of flexor hallucis longus is described below.

## Flexor digitorum longus

Flexor digitorum longus is described on page 1410.

## Tibialis posterior

Tibialis posterior is described on page 1412.

## INTRINSIC MUSCLES

The intrinsic muscles, i.e. those contained entirely within the foot, follow the primitive limb pattern of plantar flexors and dorsal extensors.

The plantar muscles may be divided into medial, lateral and intermediate groups. The medial and lateral groups consist of the intrinsic muscles of the great and fifth toes, respectively, and the central or

Fig. 84.20 Muscles of the sole of the foot. A, First layer. B, Second layer. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
intermediate group includes the lumbricals, interossei and intrinsic digital flexors. It is customary to group the muscles in four layers because this is the order in which they are encountered during dissection. In clinical practice and in terms of function, however, the former grouping is often more useful. The vascular supply and innervation of the intrinsic muscles of the foot are given at the end of this section.

## Plantar muscles of the foot: first layer

This superficial layer includes abductor hallucis, abductor digiti minimi and flexor digitorum brevis (Fig. 84.20). All three extend from the calcaneal tuberosity to the toes, and all assist in maintaining the concavity of the foot.

## Abductor hallucis

Attachments Abductor hallucis arises principally from the flexor retinaculum, but also from the medial process of the calcaneal tuberosity, the plantar aponeurosis, and the intermuscular septum between this muscle and flexor digitorum brevis. The muscle fibres end in a tendon that is attached, together with the medial tendon of flexor hallucis brevis, to the medial side of the base of the proximal phalanx of the great toe. Frequently, some fibres are attached more proximally to the medial sesamoid bone of this toe. The muscle may also send some fibres to the dermis along the medial border of the foot.

Relations Abductor hallucis lies along the medial border of the foot and covers the origins of the plantar vessels and nerves (Fig. 84.21). The space created for the plantar nerves and vessels by abductor hallucis and its relationship to the calcaneus is called the porta pedis.

Actions Abductor hallucis produces abduction of the great toe relative to the longitudinal axis of the foot at the shaft of the second metatarsal.

Testing Abductor hallucis is tested clinically by instructing the subject to resist a forcibly applied lateral deviation of the proximal phalanx.

Clinical anatomy Abductor hallucis fascia is strong and can be used in soft tissue augmentation following correction of hallux valgus deformity. Rarely, persistent, exaggerated tonus in the muscle may be a cause of varus deformity of the foot, necessitating surgical intervention. An abductor hallucis flap is sometimes used for provision of soft tissue coverage.

## Flexor digitorum brevis

Attachments Flexor digitorum brevis arises by a narrow tendon from the medial process of the calcaneal tuberosity, from the central part of the plantar aponeurosis, and from the intermuscular septa between it and adjacent muscles (see Fig. 84.20A). It divides into four tendons, which pass to the lateral four toes; the tendons enter digital tendinous sheaths accompanied by the tendons of flexor digitorum longus, which lie deep to them. At the bases of the proximal phalanges, each tendon divides around the corresponding tendon of flexor digitorum longus; the two slips then reunite and partially decussate, forming a tunnel through which the tendon of flexor digitorum longus passes to the distal phalanx. The tendon of flexor digitorum brevis divides again and attaches to both sides of the shaft of the middle phalanx. The way in which the tendon of flexor digitorum brevis divides and attaches to the phalanges is identical to that of the tendons of flexor digitorum superficialis in the hand. The slip to a given toe may be absent, or it may be replaced by a small muscular slip from the extrinsic flexor tendons or from flexor accessorius. Conversely, the slip may be joined by a second, supernumerary slip.

Relations Flexor digitorum brevis lies immediately deep to the central part of the plantar aponeurosis (see Fig. 84.20A). Its deep surface is separated from the lateral plantar vessels and nerves by a thin layer of fascia.

Actions Flexor digitorum brevis flexes the lateral four toes at the proximal interphalangeal joint, with equal effect in any position of the ankle joint.

Fig. 84.21 Plantar nerves and vessels in relation to muscle layers. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Testing To test the action of flexor digitorum brevis, the examiner passively extends the distal interphalangeal joint and asks the subject to flex the toes at the proximal interphalangeal joint. Contracture of the tendons of flexor digitorum brevis can lead to toe deformities, and release or lengthening procedures may be required. The muscle belly is sometimes excised as a flap to cover a soft tissue defect.

## Abductor digiti minimi

Attachments Abductor digiti minimi arises from both processes of the calcaneal tuberosity, from the plantar surface of the bone between them, from the plantar aponeurosis and from the intermuscular septum between the muscle and flexor digitorum brevis. Its tendon glides in a smooth groove on the plantar surface of the base of the fifth metatarsal and is attached, with flexor digiti minimi brevis, to the lateral side of the base of the proximal phalanx of the fifth toe; hence it is more a flexor than an abductor. Some of the fibres arising from the lateral calcaneal process usually reach the tip of the tuberosity of the fifth metatarsal (see Fig. 84.5B) and may form a separate muscle: abductor ossis metatarsi digiti quinti. An accessory slip from the base of the fifth metatarsal is not infrequent.

Relations Abductor digiti minimi lies along the lateral border of the foot, and its medial margin is related to the lateral plantar vessels and nerve (see Fig. 84.21).

Actions Despite its name, abductor digiti minimi is more a flexor than an abductor of the metatarsophalangeal joint of the fifth toe.

## Plantar muscles of the foot: second layer

The second layer consists of flexor accessorius and the four lumbrical muscles. The tendons of flexor hallucis longus and flexor digitorum longus run in the same plane as the muscles of the second layer (see Fig. 84.20B); flexor hallucis longus and flexor digitorum longus are described on pages 1410-1412.

## Flexor tendinous sheaths

The terminations of the tendons of the extrinsic and intrinsic flexor muscles are contained in osseo-aponeurotic canals similar to those that occur in the fingers. These canals are bounded above by the phalanges and below by fibrous bands, the digital fibrous sheaths, which arch across the tendons and attach on either side to the margins of the phalanges (see Fig. 84.20A). Along the proximal and middle phalanges, the fibrous bands are strong and the fibres are transverse (anular part); opposite the joints they are much thinner and the fibres decussate (cruciform part). Each osseo-aponeurotic canal has a synovial lining, which is reflected around its tendon; within this sheath, vincula tendinum are arranged as they are in the fingers.

## Flexor accessorius (quadratus plantae)

Attachments Flexor accessorius (quadratus plantae) arises by two heads, with the long plantar ligament situated deeply in the interval between the two heads (see Figs 84.20B, 84.19C). The medial head is larger and is attached to the medial concave surface of the calcaneus, below the groove for the tendon of flexor hallucis longus. The lateral head is flat and tendinous, and is attached to the calcaneus distal to the lateral process of the tuberosity, and to the long plantar ligament. The muscle belly inserts into the tendon of flexor digitorum longus at the point where it is bound by a fibrous slip to the tendon of flexor hallucis longus and where it divides into its four tendons.

The muscle is sometimes absent altogether. Its distal attachment to the tendons of flexor digitorum longus may vary, which means that the fourth and fifth long flexor tendons may, at times, fail to receive slips from the flexor accessorius.

Relations The medial plantar nerve passes medial to and the lateral plantar nerve passes superficial to flexor accessorius.

Actions By pulling on the tendons of flexor digitorum longus, flexor accessorius provides a means of flexing the lateral four toes in any position of the ankle joint.

## Lumbrical muscles

Attachments The lumbrical muscles are four small muscles (numbered from the medial side of the foot) that are accessory to the tendons of flexor digitorum longus (see Fig. 84.20). They arise from these tendons as far back as their angles of separation, each springing from the sides of two adjacent tendons, except for the first lumbrical, which arises only from the medial border of the first tendon. The muscles end in tendons that pass distally on the medial sides of the four lateral toes and are attached to the dorsal digital expansions on their proximal phalanges.

Relations The lumbricals are intimately related to the tendons of flexor digitorum longus before the latter enter their corresponding fibrous flexor sheaths. The lumbricals remain outside the fibrous flexor sheaths and cross the plantar aspects of the deep transverse metatarsal ligaments before reaching the dorsal digital expansions.

Actions The lumbricals help to maintain extension of the interphalangeal joints of the toes. In injuries of the tibial nerve, and in conditions such as the hereditary motor-sensory neuropathies (e.g. Charcot-Marie-Tooth disease), lumbrical dysfunction contributes to clawing of the toes.

## Plantar muscles of the foot: third layer

The third layer of the foot contains the shorter intrinsic muscles of the toes, i.e. flexor hallucis brevis, adductor hallucis and flexor digiti minimi brevis (Fig. 84.22).

## Flexor hallucis brevis

Attachments Flexor hallucis brevis has a bifurcate tendon of origin (see Figs 84.20, 84.22). The lateral limb arises from the medial part of the plantar surface of the cuboid, posterior to the groove for the tendon of fibularis longus, and from the adjacent part of the lateral cuneiform. The medial limb has a deep attachment directly continuous with the lateral division of the tendon of tibialis posterior, and a more superficial attachment to the middle band of the medial intermuscular septum. The belly of the muscle divides into medial and lateral parts, the twin tendons of which are attached to the sides of the base of the proximal phalanx of the great toe. The medial part blends with the tendon of abductor hallucis, and the lateral with that of adductor hallucis, as they reach their terminations.

Fig. 84.22 Muscles of the sole of the foot, third layer. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

A sesamoid bone usually occurs in each tendon near its attachment. Clinical problems with flexor hallucis brevis are usually related to the associated sesamoid bones. However, excision of both sesamoid bones leads to disruption of both tendons and a subsequent extension deformity at the first metatarsophalangeal joint; such surgery is, therefore, not recommended.

Accessory slips may arise proximally from the calcaneus or long plantar ligament. A tendinous slip may extend to the proximal phalanx of the second toe.

Relations Flexor hallucis brevis lies on the underside of the first metatarsal shaft; abductor hallucis lies medially. The medial digital nerve to the great toe and the tendon of flexor hallucis longus pass to the great toe on its plantar surface. The medial plantar nerve lies more superficially on its lateral side.

Actions Flexor hallucis brevis flexes the proximal phalanx of the great toe.

Testing The individual is asked to flex the first metatarsophalangeal joint with the interphalangeal joint extended, thereby eliminating the action of flexor hallucis longus.

## Adductor hallucis

Attachments Adductor hallucis arises by oblique and transverse heads (see Figs 84.20B, 84.22 and 84.19A). The oblique head arises from the bases of the second, third and fourth metatarsals, and from the fibrous sheath of the tendon of fibularis longus. The transverse head - a narrow, flat fasciculus - arises from the plantar metatarsophalangeal ligaments of the third, fourth and fifth toes (sometimes only from the third and fourth), and from the deep transverse metatarsal ligaments between them. The oblique head has medial and lateral parts. The medial part blends with the lateral part of flexor hallucis brevis and is attached to the lateral sesamoid bone of the great toe. The lateral part joins the transverse head and is also attached to the lateral sesamoid bone and directly to the base of the first phalanx of the great toe. There
is no phalangeal attachment for the transverse part of the muscle; fibres that fail to reach the lateral sesamoid bone are attached with the oblique part.

The transverse part of adductor hallucis is sometimes absent; part of the muscle may be attached to the first metatarsal, constituting an opponens hallucis; a slip may also extend to the proximal phalanx of the second toe.

Relations Adductor hallucis lies plantar to the metatarsal shafts and interossei and the long and short toe flexors. The medial and lateral plantar arteries and nerves are superficial, and flexor hallucis brevis is proximal and medial.

Actions Adductor hallucis partly flexes the proximal phalanx of the great toe, but also stabilizes the metatarsal heads.

Clinical anatomy Adductor hallucis is one of the deforming forces in hallux valgus and needs to be released during a distal soft tissue release when there is a fixed deformity.

## Flexor digiti minimi brevis

Attachments Flexor digiti minimi brevis arises from the medial part of the plantar surface of the base of the fifth metatarsal, and from the sheath of fibularis longus (see Figs $84.20 B, 84.22$ and 84.19A). It has a distal tendon that inserts into the lateral side of the base of the proximal phalanx of the fifth toe; this tendon usually blends laterally with that of abductor digiti minimi. Occasionally, some of its deeper fibres extend to the lateral part of the distal half of the fifth metatarsal, constituting what may be described as a distinct muscle: opponens digiti minimi.

Relations The fifth metatarsal shaft lies on the deep surface of flexor digiti minimi brevis, the interossei lie medially and abductor digiti minimi is lateral. The most lateral branch of the lateral plantar nerve lies superficially and just medial to flexor digiti minimi brevis.

Actions Flexor digiti minimi brevis flexes the metatarsophalangeal joint of the fifth toe.

## Plantar muscles of the foot: fourth layer

The fourth layer of muscles of the foot consists of the plantar and dorsal interossei and the tendons of tibialis posterior and fibularis longus (tibialis posterior and fibularis longus are described in Ch. 83). The interossei resemble their counterparts in the hand except that, when describing adduction and abduction of the toes, the axis of reference is a longitudinal axis corresponding to the shaft of the second metatarsal (unlike in the hand, where reference is made to the long axis of the third metacarpal).

## Dorsal interossei

Attachments The dorsal interossei (Fig. 84.23A; see Fig. 84.19A) are situated between the metatarsals. They consist of four bipennate muscles, each arising by two heads from the sides of the adjacent metatarsals. Their tendons are attached to the bases of the proximal phalanges and to the dorsal digital expansions. The first inserts into the medial side of the second toe; the other three pass to the lateral sides of the second, third and fourth toes.

Relations Between the heads of each of the three lateral muscles, there is an angular space through which a perforating artery passes to the dorsum of the foot. Between the heads of the first muscle, the corresponding space transmits the terminal part of the dorsalis pedis artery to the sole (see Fig. 84.1).

Actions Dorsal interossei abduct the toes relative to the longitudinal axis of the second metatarsal. They also flex the metatarsophalangeal joints and extend the interphalangeal joints of the lateral four toes. The great and fifth toes have their own abductors.

Clinical anatomy Denervation of the interossei leads to claw-toe deformities. Development of clawed toes should alert the clinician to the possibility of a neuropathic process (e.g. Charcot-Marie-Tooth disease, tethered spinal cord).

## Plantar interossei

There are three plantar interossei (see Fig. 84.23B). They lie below, rather than between, the metatarsals, and each is connected to only one metatarsal. They are unipennate, unlike the dorsal interossei; they arise

Fig. 84.23 The interossei of the left foot. A, The dorsal interossei viewed from the dorsal aspect. B, The plantar interossei viewed from the plantar aspect. The axis to which the movements of abduction and adduction are referred is indicated.
from the bases and medial sides of the third, fourth and fifth metatarsals, and insert into the medial sides of the bases of the proximal phalanges of the numerically corresponding toes, and into their dorsal digital expansions.

Relations The plantar interossei lie plantar to the dorsal interossei and deep to the muscles of the third layer.

Actions Plantar interossei adduct the third, fourth and fifth toes, flex the metatarsophalangeal joints and extend the interphalangeal joints.

Clinical anatomy The clinical anatomy of the plantar interossei is similar to that of the dorsal interossei.

## Extensor muscles of the foot

## Extensor digitorum brevis and extensor hallucis brevis

Attachments Extensor digitorum brevis (see Fig. 84.2A) is a thin muscle that arises from the distal part of the superolateral surface of the calcaneus in front of the shallow lateral groove for fibularis brevis, from the interosseous talocalcaneal ligament, and from the deep surface of the stem of the inferior extensor retinaculum. It slants distally and medially across the dorsum of the foot and ends in four tendons. The medial part of the muscle is usually a more or less distinct slip, ending in a tendon that crosses the dorsalis pedis artery superficially to insert into the dorsal aspect of the base of the proximal phalanx of the great toe; this slip is termed extensor hallucis brevis. The other three tendons attach to the lateral sides of the tendons of extensor digitorum longus for the second, third and fourth toes.

The muscle is subject to much variation, e.g. accessory slips from the talus and navicular, an extra tendon to the fifth digit, or an absence of one or more tendons. It may be connected to the adjacent dorsal interossei.

Relations The most medial tendon, that of extensor hallucis brevis, courses dorsomedially and passes superficial to the dorsalis pedis artery and the deep fibular nerve. The remaining three tendons pass obliquely deep to the corresponding tendons of extensor digitorum longus.

Actions The muscle assists in extending the phalanges of the middle three toes via the tendons of extensor digitorum longus; for the great toe, it assists in extension of the metatarsophalangeal joint.

Clinical anatomy Laceration of extensor digitorum brevis leads to little in the way of functional impairment because the long extensors can compensate for the loss of the muscle. The proximal part of the muscle can be used as interposition material to prevent bone fusion after resection of a calcaneonavicular bar (a common tarsal coalition)

The muscle belly and tendon of extensor hallucis brevis serve as guides to the location of the dorsalis pedis artery and deep fibular nerve. The tendon of extensor hallucis brevis can be used as a local graft.

## Vascular supply to the intrinsic muscles of the foot

Abductor hallucis is supplied by the medial malleolar network, medial calcaneal branches of the lateral plantar artery (see Fig. 84.9), the medial plantar artery (directly and via superficial and deep branches), the first plantar metatarsal artery and perforators from the plantar arterial arch. Flexor digitorum brevis is supplied by the lateral and medial plantar arteries, the plantar metatarsal arteries and the plantar digital arteries to the lateral four toes. Abductor digiti minimi is supplied by the medial and lateral plantar arteries (see Figs 84.21, 84.25A), the plantar digital artery to the lateral side of this muscle, branches from the deep plantar arch, the fourth plantar metatarsal artery, and end twigs from the arcuate and lateral tarsal arteries (see Fig. 84.9). Flexor accessorius is supplied by the stem of the medial plantar artery (to the medial head), the lateral plantar artery and the deep plantar arch. The lumbricals are supplied by the lateral plantar artery and deep plantar arch and by four plantar metatarsal arteries (four distal perforating arteries joined by three proximal perforating arteries). Their tendons are supplied by twigs from the dorsal digital arteries (and their parent dorsal metatarsal arteries) to the lateral four toes. Flexor hallucis brevis is supplied by branches of the medial plantar artery, the first plantar metatarsal artery, the lateral plantar artery and the deep plantar arch. Adductor hallucis is supplied by branches of the medial and lateral plantar arteries, the deep plantar arch and the first to fourth plantar metatarsal arteries. Flexor digiti minimi brevis is supplied by end twigs of the arcuate and lateral tarsal arteries, and the lateral plantar artery and its digital (plantar) branch to the lateral side of the fifth toe. Dorsal interossei are supplied by the arcuate artery, lateral and medial tarsal arteries, the first to fourth plantar arteries and the first to fourth dorsal metatarsal arteries (receiving proximal and distal perforating arteries), and by the dorsal digital arteries of the lateral four toes. Plantar interossei are supplied by the lateral plantar artery, the deep plantar arch, the second to fourth plantar metatarsal arteries and the dorsal digital arteries of the lateral three toes. Extensor digitorum brevis is supplied by the anterior perforating branch of the fibular artery, the anterior lateral malleolar artery, lateral tarsal arteries, dorsalis pedis artery, arcuate artery, the first, second and third dorsal metatarsal arteries, proximal and distal perforating arteries, and the dorsal digital arteries to the medial four toes (including the great toe).

Innervation of the intrinsic muscles of the foot Abductor hallucis is innervated by the medial plantar nerve, S1 and S2. Contraction of the muscle confirms an intact medial plantar nerve when the integrity of this nerve is in question.

Flexor digitorum brevis is innervated by the medial plantar nerve, S1 and S2. Abductor digiti minimi and flexor accessorius are innervated by the lateral plantar nerve, $\mathrm{S} 1, \mathrm{~S} 2$ and S 3 . The first lumbrical is supplied by the medial plantar nerve; the other lumbricals are supplied by the deep branch of the lateral plantar nerve, S2 and S3. Flexor hallucis brevis is supplied by the medial plantar nerve, S1 and S2. Adductor hallucis is innervated by the deep branch of the lateral plantar nerve, S2 and S3. Flexor digiti minimi brevis is innervated by the superficial branch of the lateral plantar nerve, S2 and S3. Dorsal interossei are supplied by the deep branch of the lateral plantar nerve (S2 and S3), except that of the fourth intermetatarsal space, which is supplied by the superficial branch of the lateral plantar nerve. Plantar interossei are supplied by the deep branch of the lateral plantar nerve (S2 and S3), except that of the fourth intermetatarsal space, which is supplied by the superficial branch of the lateral plantar nerve. Extensor digitorum brevis is supplied by the lateral terminal branch of the deep fibular nerve, L5 and S 1 .

## VASCULAR SUPPLY

## ARTERIES

## Dorsalis pedis artery

The dorsalis pedis artery (see Fig. 84.1; Fig. 84.24) is usually the continuation of the anterior tibial artery distal to the ankle. It passes to the proximal end of the first intermetatarsal space, where it turns into the sole between the heads of the first dorsal interosseous to complete the deep plantar arch, and provides the first plantar metatarsal artery.

The artery may be larger than normal, to compensate for a small lateral plantar artery. It may be absent, in which event it is replaced by

Fig. 84.24 The dorsal arteries of the foot.
a large perforating branch of the fibular artery. It often diverges laterally from its usual route.

## Relations

The dorsalis pedis artery crosses, successively, the talocrural articular capsule, talus, navicular and intermediate cuneiform and their ligaments; superficial to it are the skin, fasciae, inferior extensor retinaculum and, near its termination, extensor hallucis brevis. Medial to it is the tendon of extensor hallucis longus and lateral to it are the medial tendon of extensor digitorum longus and medial terminal branch of the deep fibular nerve. The tendons are useful landmarks in the planning of safe anatomical approaches in surgery of the ankle and foot.

## Branches

The dorsalis pedis artery gives rise to the tarsal, arcuate and first dorsal metatarsal arteries (see Figs 84.1, 84.9, 84.24).

Tarsal arteries There are two tarsal arteries, lateral and medial (see Fig. 84.24). They arise as the dorsalis pedis artery crosses the navicular. The lateral runs laterally under extensor digitorum brevis; it supplies this muscle and the tarsal articulations, and anastomoses with branches of the arcuate, anterior lateral malleolar and lateral plantar arteries, and the perforating branch of the fibular artery. Two or three medial tarsal arteries ramify on the medial border of the foot and join the medial malleolar arterial network.

Arcuate artery The arcuate artery (see Fig. 84.24) arises near the medial cuneiform, passes laterally over the metatarsal bases, deep to the tendons of the digital extensors, and anastomoses with the lateral tarsal and plantar arteries. It supplies the second to fourth dorsal metatarsal arteries, running distally superficial to the corresponding dorsal interossei, and divides into two dorsal digital branches for the adjoining toes in the interdigital clefts. Proximally, these branches receive proximal perforating branches from the deep plantar arch. Distally, they are joined by distal perforating branches from the plantar metatarsal arteries. The fourth dorsal metatarsal artery sends a branch to the lateral side of the fifth toe.

The frequency of the arcuate artery has been reported to range from $10 \%$ to $67 \%$, depending on the precise definition of the artery (DiLandro et al 2001).

First dorsal metatarsal artery The first dorsal metatarsal artery (see Fig. 84.24) arises just before the dorsalis pedis artery enters the sole. It runs distally on the first dorsal interosseous and divides at the cleft between the first and second toes. One branch passes under the tendon of extensor hallucis longus and supplies the medial side of the great toe; the other bifurcates to supply the adjoining sides of the great and second toes.
Cutaneous vessels from the dorsalis pedis artery The dorsalis pedis artery and its first dorsal metatarsal branch give rise to small direct cutaneous branches that supply the dorsal foot skin between the extensor retinaculum and the first web space. This vessel provides the basis for a fasciocutaneous flap raised from this region, and which may be used to cover superficial defects elsewhere.

## Deep plantar arch

The deep plantar arch (Fig. 84.25B) is deeply situated, extending from the fifth metatarsal base to the proximal end of the first intermetatarsal space. Convex distally, it is plantar to the bases of the second to fourth metatarsals and corresponding interossei, but dorsal to the oblique part of adductor hallucis.

## Branches

The deep plantar arch gives rise to three perforating and four plantar metatarsal branches, and numerous branches that supply the skin, fasciae and muscles in the sole. Three perforating branches ascend through the proximal ends of the second to fourth intermetatarsal spaces, between the heads of dorsal interossei, and anastomose with the dorsal metatarsal arteries. Four plantar metatarsal arteries extend distally between the metatarsals in contact with the interossei (Fig. 84.25). Each divides into two plantar digital arteries, supplying the adjacent digital aspects. Near its division, each plantar metatarsal artery sends a distal perforating branch dorsally to join a dorsal metatarsal artery. The first plantar metatarsal artery springs from the junction between the lateral plantar and dorsalis pedis arteries, and sends a digital branch to the medial side of the great toe. The lateral digital branch for the fifth toe arises directly from the lateral plantar artery near the fifth metatarsal base. Haemorrhage from the deep plantar arch is difficult to control because of the depth of the vessel and its important close relations.

## Surface anatomy

The lateral plantar artery begins between the heel and medial malleolus, and crosses obliquely to a point 2.5 cm medial to the tuberosity of the fifth metatarsal. With a slight distal convexity, it reaches the proximal end of the first intermetatarsal space.

## Posterior tibial artery

Before the posterior tibial artery divides into its two main terminal branches, it gives off a communicating branch that runs posteriorly across the tibia approximately 5 cm above its distal end, deep to flexor hallucis longus, and joins a communicating branch of the fibular artery; calcaneal branches, which arise just proximal to the termination of the posterior tibial artery, pierce the flexor retinaculum and supply the skin and fat behind the calcaneal tendon; and the artery of the tarsal canal. The terminal branches of the posterior tibial artery are the medial and lateral plantar arteries.

## Branches

Medial plantar artery The medial plantar artery is the smaller terminal branch of the posterior tibial artery (see Fig. 84.25). It arises midway between the medial malleolus and the medial calcaneal tubercle, and passes distally along the medial side of the foot, with the medial plantar nerve lateral to it. At first deep to abductor hallucis, it runs distally between abductor hallucis and flexor digitorum brevis, supplying both. Near the first metatarsal base, when its calibre is already diminished as a result of supplying numerous muscular branches, it is further diminished by a superficial stem. It passes to the medial border of the great toe, where it anastomoses with a branch of the first plantar metatarsal artery. Its superficial stem then trifurcates and supplies three superficial digital branches that accompany the digital branches of the medial plantar nerve and join the first to third plantar metatarsal arteries.
Lateral plantar artery The lateral plantar artery is the larger terminal branch of the posterior tibial artery (see Fig. 84.25). It passes distally and laterally to the fifth metatarsal base; the lateral plantar nerve is medial. The plantar nerves lie between the plantar arteries. Turning medially, with the deep branch of the nerve, it gains the interval between the first and second metatarsal bases, and unites with the dorsalis pedis

Fig. 84.25 The plantar arteries of the left foot. A, Superficial dissection. B, Deep dissection.
artery to complete the deep plantar arch. As it passes laterally, it is first between the calcaneus and abductor hallucis, then between flexor digitorum brevis and flexor accessorius. Running distally to the fifth metatarsal base, it passes between flexor digitorum brevis and abductor digiti minimi, and is covered by the plantar aponeurosis, superficial fascia and skin.

Muscular branches supply the adjoining muscles. Superficial branches emerge along the intermuscular septum to supply the skin and subcutaneous tissue over the lateral part of the sole. Anastomotic branches run to the lateral border and join branches of the lateral tarsal and arcuate arteries. Sometimes, a calcaneal branch pierces abductor hallucis to supply the skin of the heel. Anastomosis between the medial and lateral plantar arteries superficial to the flexor digitorum brevis is sometimes present and is termed the superficial plantar arch.

## Perforator flaps in the ankle and foot region

The arteries around the ankle and in the foot are the medial and lateral calcaneal arteries, medial and lateral plantar arteries and the dorsalis pedis artery (see Fig. 78.7). In the foot, the two plantar arteries with communicating arteries from the dorsalis pedis artery give rise to multiple small perforators. In the sole of the foot, the perforators emerge on either side of the plantar aponeurosis, and also pass through it, to supply the skin. 'Island flaps' from these perforators may be advanced to reconstruct small defects in the weight-bearing area. The skin of the sole of the foot is highly specialized and therefore, ideally, defects in this region should be reconstructed using local skin.

## DEEP AND SUPERFICIAL VENOUS SYSTEMS IN THE FOOT

Plantar digital veins arise from plexuses in the plantar regions of the toes. They connect with dorsal digital veins to form four plantar metatarsal veins, which run proximally in the intermetatarsal spaces and connect via perforating veins with dorsal veins, then continue to form the deep plantar venous arch, which is situated alongside the deep plantar arterial arch. From this venous arch, medial and lateral plantar veins run near the corresponding arteries and, after communicating with the long and short saphenous veins, form the posterior tibial veins behind the medial malleolus.

The principal named superficial veins are the long and short saphenous. Their numerous tributaries are mostly (but not wholly) unnamed; named vessels will be noted (see Fig. 78.9). As in the upper limb, the vessels will be described centripetally from peripheral to major drainage channels.

Dorsal digital veins receive rami from the plantar digital veins in the clefts between the toes and then join to form dorsal metatarsal veins, which are united across the proximal parts of the metatarsals in a dorsal venous arch. Proximal to this arch, an irregular dorsal venous network receives tributaries from deep veins and is continuous proximally with a venous network in the leg. At each side of the foot, this network connects with medial and lateral marginal veins, which are both formed mainly by veins from more superficial parts of the sole. In the sole, superficial veins form a plantar cutaneous arch across the roots of the toes and also drain into the medial and lateral marginal veins. Proximal to the deep plantar arch there is a plantar cutaneous venous plexus, especially dense in the fat of the heel. It connects with the plantar cutaneous venous arch and other deep veins, but drains mainly into the marginal veins. The veins of the sole are an important part of the lower limb 'venous pump' system aiding propulsion of blood up the limb (Broderick et al 2008). Intermittent foot compression devices are available to enhance this flow and so reduce the risk of deep vein thrombosis during periods of increased risk, e.g. after surgery.

## INNERVATION

## Superficial fibular nerve

The superficial fibular nerve is described on page 1416.

## Deep fibular nerve

The deep fibular nerve is described on page 1416.

## Tibial nerve

The branches of the tibial nerve that innervate structures in the ankle and foot are articular, muscular, sural, medial calcaneal and medial and lateral plantar nerves. The course and distribution of the tibial nerve in the calf are described on page 1415.

## Medial calcaneal nerve

The medial calcaneal nerve arises from the tibial nerve and perforates the flexor retinaculum to supply the skin of the heel and medial side of the sole.

## Medial plantar nerve

The medial plantar nerve is the larger terminal division of the tibial nerve, and lies lateral to the medial plantar artery. From its origin under the flexor retinaculum, it passes deep to abductor hallucis, then appears between it and flexor digitorum brevis, gives off a medial proper digital nerve to the great toe, and divides near the metatarsal bases into three common plantar digital nerves (Fig. 84.26; see Fig. 84.21).

Cutaneous branches pierce the plantar aponeurosis between abductor hallucis and flexor digitorum brevis to supply the skin of the sole of the foot. Muscular branches supply abductor hallucis, flexor digitorum brevis, flexor hallucis brevis and the first lumbrical. The first two arise near the origin of the nerve and enter the deep surfaces of the muscles. The branch to flexor hallucis brevis is from the hallucal medial digital nerve, and that to the first lumbrical from the first common plantar digital nerve. Articular branches supply the joints of the tarsus and metatarsus.

Three common plantar digital nerves pass between the slips of the plantar aponeurosis, each dividing into two proper digital branches. The first supplies adjacent sides of the great and second toes; the second supplies adjacent sides of the second and third toes; and the third supplies adjacent sides of the third and fourth toes, and also connects with the lateral plantar nerve. The first gives a branch to the first lumbrical. Each proper digital nerve has cutaneous and articular branches: near the distal phalanges, a dorsal branch supplies structures around the nail. Abductor hallucis, flexor hallucis brevis and the first lumbrical are all supplied by the medial plantar nerve.

## Lateral plantar nerve

The lateral plantar nerve supplies the skin of the fifth toe, the lateral half of the fourth toe, and most of the deep muscles of the foot (see Fig. 84.21). It is located medial to the lateral plantar artery and courses anteriorly towards the tubercle of the fifth metatarsal. Next, it passes between flexor digitorum brevis and flexor accessorius, and ends between flexor digiti minimi brevis and abductor digiti minimi by dividing into superficial and deep branches. Before division, it supplies flexor accessorius and abductor digiti minimi, and gives rise to small branches that pierce the plantar aponeurosis to supply the skin of the lateral part of the sole (see Fig. 84.26). The superficial branch splits into two common plantar digital nerves: the lateral supplies the lateral side of the fifth toe, flexor digiti minimi brevis and the two interossei in the fourth intermetatarsal space; the medial connects with the third common plantar digital branch of the medial plantar nerve and divides into two to supply the adjoining sides of the fourth and fifth toes. The deep branch accompanies the lateral plantar artery deep to the flexor tendons and adductor hallucis, and supplies the second to fourth lumbricals, adductor hallucis and all the interossei (except those of the fourth intermetatarsal space). Branches to the second and third lumbricals pass distally deep to the transverse head of adductor hallucis, and travel around its distal border to reach them. See Video 84.1.

## Nerve entrapment syndromes in the foot

All nerves of the foot can be affected by entrapment, leading classically to a burning sensation in the distribution of that nerve. Tarsal tunnel syndrome is much less common than carpal tunnel syndrome. The flexor retinaculum may compress the tibial nerve or either of its branches (medial and lateral plantar nerves); entrapment at this level is most commonly due to a space-occupying lesion, e.g. a ganglion, or to compression by either a leash of vessels or the deep fascia associated with abductor hallucis. Compression of the first branch of the lateral plantar nerve (Baxter's nerve) by the deep fascia that covers abductor hallucis has been implicated as a possible cause of chronic heel pain and of plantar fasciitis. (Plantar fasciitis, often caused by repetitive highimpact injury to the foot, may be associated with pain, especially over the medial calcaneal process, which may be exacerbated by passive ankle or great toe flexion.) The medial plantar nerve can be compressed at the 'knot of Henry', which is the point where the tendon of flexor hallucis longus crosses deep to the tendon of flexor digitorum longus, to reach its medial side in the sole of the foot. The superficial fibular

Fig. 84.26 The plantar digital nerves. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
nerve can be damaged in severe inversion injuries of the ankle, and the deep fibular nerve is sometimes compressed by osteophytes in the region of the second tarsometatarsal joint. Sural nerve entrapment is usually not due to compression by fascial elements. Entrapment of the third common digital nerve as it passes deep to the intermetatarsal ligament of the third (or less commonly the second) web space can result in a Morton's neuroma, which is probably the most common form of nerve entrapment in the foot.

## ANATOMY OF THE TOENAILS

## NAIL STRUCTURE

A toenail consists of a nail plate and unit (Dykyj 1989; pages 151-152). The toenail is commonly a site of several pathologies, including onychomycosis and onychocryptosis (Jules 1989, Eekhof et al 2012).

## BIOMECHANICS OF STANDING, WALKING AND RUNNING

## PLANES OF MOTION

Much confusion surrounds the descriptive terms for movement in the foot and ankle. Plantar flexion and dorsiflexion refer to movement in the sagittal plane and occur principally, but not exclusively, at the ankle, metatarsophalangeal and interphalangeal joints. Inversion is tilting of the plantar surface of the foot towards the midline, and eversion is tilting away from the midline. This is motion in the coronal plane and takes place principally in the talocalcaneal and transverse tarsal joints. Adduction is movement of the foot towards the midline in the transverse plane; abduction is movement away from the midline. This

Patients with Morton's neuroma usually present with a main complaint of metatarsalgia. While there is no pathognomonic clinical test, diagnostic imaging coupled with clinical tests can provide convergent validity to help with diagnosis (Owens et al 2011). Two commonly used clinical tests are web-space tenderness and forefoot squeeze tests. The web-space tenderness test is performed by placing the side of the thumb into the third web space and pressing down. The forefoot squeeze test is performed by squeezing the forefoot from side to side while concurrently performing the web-space test.
movement occurs at the transverse tarsal joints and, to a limited degree, the first tarsometatarsal and metatarsophalangeal joints.

Supination describes a three-dimensional movement and is a combination of adduction, inversion and plantar flexion. Pronation is the opposite motion, i.e. a combination of abduction, eversion and dorsiflexion. Pronation and supination are usually better terms than eversion and inversion, as the latter rarely occur in isolation and the former describe the 'compound' motion that usually occurs.

Active movements occur at the ankle, talocalcaneonavicular and subtalar joints. Movements at the ankle joint are almost entirely restricted to dorsiflexion and plantar flexion, but slight rotation may occur in plantar flexion. The ranges of movement at the talocalcaneonavicular and subtalar joints are greater; inversion and eversion mainly occur here.

## STANDING

Humans are bipedal: we stand and walk with an erect trunk and knees that are almost straight. Moreover, we are plantigrade, i.e. we set the whole length of the foot down on the ground, whereas most medium to large mammals are digitigrade, i.e. they stand and walk on their toes, and ungulates stand on hooves on the tips of their toes. In the sagittal plane, body weight acts along a line that passes a few centimetres anterior to the tibiotalar joint, exerting a moment that must be balanced by the plantar flexor muscles.

## PROPULSION

The contraction of tibialis posterior, gastrocnemius and soleus is the chief factor responsible for propulsion in walking, running and jumping. The propulsive action of these calf muscles is enhanced by arching of the foot and flexion of the toes. In walking, the weight on the foot is taken successively on the heel, lateral border and the first metatarsophalangeal joint. The last part of the foot to leave the ground is the anterior pillar of the medial longitudinal arch and the medial three toes. In the act of sprinting, the heel does not touch the ground, but the point of take-off is still the anterior pillar of the medial longitudinal arch. As the heel leaves the ground, the toes gradually extend. Extension, of the great toe particularly, tightens the plantar aponeurosis and thus heightens the arch. At the same time, flexor hallucis longus and flexor digitorum longus elongate, which increases their subsequent contraction. The extrinsic and intrinsic toe flexors increase the force of take-off by exerting force on the ground. The most important muscle in this respect is flexor hallucis longus, which is strongly assisted by the intrinsic toe flexors. The lumbricals provide a balancing action to the extrinsic flexors and prevent buckling of the toes during the toe-off phase of gait.

## Walking

In walking, each foot is on the ground (stance phase) for approximately $60 \%$ of the stride, and off the ground (swing phase) for approximately $40 \%$ (Fig. 84.27). Thus, single-support phases (one foot on the ground) alternate with double-support phases (two feet on the ground). The knee is straight at heel strike and remains nearly straight ( $10-30^{\circ}$ ) for most of the stance phase of that leg, bending more only immediately before toe-off. During the swing phase, the knee flexes to a maximum of $60^{\circ}$ at mid-swing.

Stance phase starts with 'heel strike'. With the foot still planted in front of the body, 'foot flat' is reached, and becomes 'mid-stance' when the body comes to be directly above the planted foot. The heel then rises as the contralateral foot makes contact with the ground (the 'double stance' phase). The last event of stance is 'toe-off' when the 'swing phase' starts. Early in the stance phase, while it is 'foot flat' in front of the trunk, the foot pushes downwards and forwards on the ground, decelerating the body as well as supporting it. Later, when the foot is behind the trunk, it pushes downwards and backwards, re-accelerating the body (see Fig. 84.27).

The height of the centre of gravity, and therefore the potential energy of the body, also fluctuates. This is inevitable if the knee is kept nearly fully extended, making the hip move in a near-circular arc about the ankle of the supporting foot. The vertical component of the total force exerted by both feet on the ground in the double-support phase is greater than body weight, giving the body an upward acceleration. The vertical component of the ground force during the single-support phase is less than body weight, giving the body a downward acceleration. The
force fluctuations have to be larger at higher speeds, to give the same vertical movement in less time.

## Development of walking

The average child sits at 6 months, crawls at 9 months, walks with support at 12 months, and walks without support at 18 months. The characteristic early gait matures rapidly and is similar to that of the adult by 3 years. Some minor changes occur up to 7 years, which are largely a reflection of neurological development but are also related to stature (Thomson \& Volpe 2001). Early gait is jerky, unsteady and widebased. Initial ground contact varies, and heel-toe, whole foot and toeheel are all possible. Generally, a plantar flexed posture is adopted, which contrasts with the adult pattern. In adults, heel strike is accompanied by a straight knee, which then flexes. A child strikes the ground with a flexed knee, which is then extended in response to weightbearing, and a short time is spent in single-leg stance (Fig. 84.28). Maturation is associated with diminution of base width and increase in step length and velocity. The earliest changes are development of heel-strike, knee flexion during stance, and reciprocal upper limb swing.

## Running

Walking involves dual-support phases, but in running each foot is on the ground for $40 \%$ (jogging) to $27 \%$ (sprinting) of the stride, so there is an aerial phase - the 'double-float' phase - when neither foot is on the ground. The faster the subject runs, the shorter the stance phase; world-class sprinters spend approximately $22 \%$ of the gait cycle in stance. During each aerial phase, the body rises and then falls under gravity, which means that its height and potential energy are maximal in the middle of this phase and minimal at mid-stance, when, in marked contrast to walking, the knee of the supporting leg bends. The changes in muscle belly lengths are relatively slight during running. The muscles are acting as tensioners of the tendons; indeed, most of the change of length is produced by the stretch and recoil of the tendons. It has been estimated that, of the kinetic and potential energy lost and regained in each stance phase, $35 \%$ is stored temporarily as elastic strain energy in the calcaneal tendon, and $17 \%$ in the ligaments of the arch of the foot. Together, these springs approximately halve the work required from the muscles.

The calcaneal tendon is the most important 'spring' in the leg. Most runners strike the ground first with the heel, and the centre of pressure moves rapidly forwards to the distal heads of the metatarsals, where it remains for most of the stance phase.

As in walking, the ground force acts more or less in line with the leg, so the body is decelerated and re-accelerated during each stance phase. The stance phase starts with deceleration and absorption of energy. Power is generated after stance phase reversal as the limb pushes up with the knee extending and foot plantar flexed, and this continues in the swing phase as the limb is accelerated forwards. Once the limb is ahead of the trunk, the final phase of swing-phase absorption is initiated, during which the limb is decelerated.

The ground force acts upwards on the metatarsal heads, and the calcaneal tendon pulls upwards on the calcaneus. The necessary balancing reaction occurs at the ankle, where the tibia presses downwards on the talus. Together, these three forces flatten the longitudinal arch of the foot, forcing the ankle 10 mm nearer to the ground than it would be if the foot were rigid. Mechanical tests on amputated feet have shown that the foot is a reasonably good spring, giving an energy return of nearly $80 \%$. The plantar aponeurosis, long and short plantar ligaments and the plantar calcaneonavicular ligament are all involved in the spring action; they are predominantly collagenous but presumably have elastic properties similar to those of tendon.

## MOVEMENTS OF THE FOOT

With the foot on the ground, body weight causes some supination (used here to imply uneven distribution of weight to the lateral side of the foot) and flattening of the longitudinal arches; about one-third of the weight borne by the forefoot is taken by the head of the first metatarsal (McDonald and Tavener 1999). When a resting position becomes active, as occurs on starting to walk, the foot is pronated (used here to imply uneven distribution of weight to the medial side of the foot) by muscular effort, and the first metatarsal is depressed (the second less so), which accentuates the longitudinal arch to its maximum height (Hicks 1954). Similar changes can be imposed on a weight-bearing foot by active lateral rotation, which is transmitted through the tibia to the talus and entails passive supination of the foot. Medial rotation has an opposite effect. When the foot is grounded and immobile, muscles that

Fig. 84.27 The events that occur during the different phases of a normal gait cycle. Depicted are: distribution of pressure on the plantar surface of the foot; changes in the angles of hip, knee and ankle joints, together with activity in the corresponding muscle groups; and vertical and horizontal (sagittal plane) components of the ground reaction force during stance phase. (Chart collated from various sources by Michael Gunther, Department of Human Anatomy and Cell Biology, University of Liverpool.)

Fig. 84.28 Development of a mature gait. A, A 1-year-old. Note the flexed elbows and lack of arm swing. The foot is plantar flexed at contact. B, A 3 -year-old. Arm swing is now present, as is heel strike. C, A 6-year-old. There is now an adult-type gait. (With permission from Benson MKD, Fixsen JA, MacNicol MF (eds) 2001 Development of a mature gait. In: Children's Orthopaedics and Fractures, 2nd edn. Edinburgh: Churchill Livingstone.)
move it when it is freely suspended may exert effects on the leg, e.g. the dorsiflexors can then pull the leg forwards at the ankle joint.

The foot has two major functions: to support the body in standing and progression, and to lever it forwards and absorb shock in walking, running and jumping (Alexander 1992). To fulfil the first function, the pedal platform must be able to spread the stresses of standing and moving, and be pliable enough to accommodate walking or running over uneven and sloping surfaces. To fulfil the second function, the foot must be transformable into a strong, adjustable lever in order to resist inertia and powerful thrust; a segmented lever can best meet such stresses if it is arched.

In infants and young children, fatty connective tissue on the plantar aspect may give the foot a flat appearance and soft tissues modify its appearance to varying degrees at all ages. The thickness of the medial mid-foot plantar fat pad ranges from 3.1 to 4.9 mm (Riddiford-Harland et al 2007). However, the skeleton of the human foot is normally arched, and the sole of the foot is usually visibly concave. These arches vary individually in height, especially the longitudinal in its medial part. Since they are dynamic, their heights also differ in different phases of activity.

The medial longitudinal arch contains the calcaneus, talus, navicular, cuneiform and medial three metatarsals. Its summit, at the superior talar articular surface, takes the full thrust from the tibia and passes it backwards to the calcaneus, and forwards through the navicular and cuneiforms to the metatarsals. When the foot is grounded, these forces are transmitted through the three metatarsal heads and calcaneus (especially its tuberosity). The medial arch is higher, and more mobile and resilient than the lateral arch; its flattening progressively tightens the plantar calcaneonavicular ligament and plantar aponeurosis. The lateral arch is adapted to transmit weight and thrust rather than to absorb such forces; the long plantar and plantar calcaneocuboid ligaments tighten as it flattens.

The lateral arch makes contact with the ground more extensively than the medial arch. As the foot flattens, an increasing fraction of load traverses soft tissues, which are inferior to the entire arch. The whole lateral border usually touches the ground, whereas the medial border does not. However, the medial border is visibly concave, usually even in standing, which explains the familiar outline of human footprints

Fig. 84.29 The concept of the foot skeleton as a twisted plate that may be untwisted (supination) or further twisted (pronation) during the maintenance of a plantigrade stance in various positions of the foot.
A, The foot skeleton in supination, as in standing with the feet widely separated. Note the marked medial tilting of the talus and, to a lesser degree, of the calcaneus and the depression of the medial longitudinal arch. B, Relative pronation of the foot, as in standing with the feet close together. C, Supination of the foot when standing on an inclined surface; if the position of the wedge had been reversed, the foot skeleton would, of course, approach maximal pronation. (Based on MacConaill MA 1945 The postural mechanism of the human foot. Proc Roy Irish Acad 50:265-278.)
(though this varies with the position of the feet (Fig. 84.29), the development of associated soft tissues, and the nature of the surface). In any activity, as soon as the heel rises, the toes are extended and muscular structures (including the plantar aponeurosis) tighten up in the sole, accentuating the longitudinal arches. It has been suggested that tension diminishes in the deeper plantar ligaments in this phase.

The sole is transversely concave, both in skeletal form and usually in external appearance, and serial transverse arches are most developed inferior to the metatarsus and adjoining tarsus. Transmission of force occurs at the metatarsal heads, to some degree along the lateral border of the foot, and through subjacent soft tissues.

In standing, with only body weight to support, both the intrinsic and extrinsic muscles appear to relax (Perry 2010). If the longitudinal arches are allowed to sink as a result of muscular relaxation, the plantar ligaments tie the bones into an arched form. The medial arch is more elevated when the feet are together than when they are apart, i.e. inversion with supination increases as the feet are separated. This medial sag can be countered by voluntary contraction of muscles such as tibialis anterior. Pronation and supination ensure that in standing, whatever the position of the feet, a maximal weight-bearing area is grounded, from the metatarsal heads along the lateral border of the foot to the calcaneus. The twist of the ligamentous skeleton of the foot imparted by pronation (which is partly undone in supination) prompts the likening of the foot to a twisted but resilient plate (see Fig. 84.29), where adequate ground contact was ensured whatever the angle between the foot and leg, and adaptable resilience was imparted in standing and progression.

# Nerve biomechanics 

## Kimberly S Topp

Although assumed postures and movements place physical forces on peripheral nerves, the biomechanical properties of these nerves permit continued electrical signalling in the face of reasonable physical demands. Consider the sciatic nerve in an individual moving from a standing to a seated posture. Where it crosses the lateral rotators of the femur, the nerve undergoes lengthening, its cross-sectional shape becomes elliptical and narrowed, and endoneurial fluid is forced proximally and distally away from the site of shape change. The segment of the sciatic nerve in the thigh glides proximally, converging towards the flexing hip joint and diverging away from the flexing knee joint (Topp and Boyd 2006).

When a nerve bed is elongated across a moving joint, the nerve undergoes longitudinal tension. The biomechanical response of that nerve may be documented in a load-elongation curve, in which load is measured in Newtons and length in millimetres (Haftek 1970). To enable comparisons to be made between nerves, it is helpful to measure their cross-sectional areas and starting lengths, and translate the loadelongation curves into stress-strain curves. Stress is defined as the intensity of force per unit cross-sectional area, and may be reported in $\mathrm{N} / \mathrm{m}^{2}$ or MPa (Pascal). Strain is defined as the ratio of change in length to the original length, and is often reported as a percentage of the original length. Three distinct regions are seen in load-elongation or stressstrain curves (Fig. 9.1.1). In the initial 'toe' region of the curve, application of very little load or stress results in significant elongation or strain. In the 'linear behaviour' region, there is a correlation between the applied tensile load or stress and the elongation or strain. In the 'plastic' region of the curve, minimal tensile load or stress results in mechanical failure and discontinuity of nerve structures.

Several structural features of peripheral nerves may be related to segments of the stress-strain curve. Nerve in situ is under tension; the transition between the 'toe' region and the 'linear behaviour' region of the curve corresponds roughly with the in situ strain (Kwan et al 1992). When severed, a peripheral nerve recoils approximately $10 \%$ of its length. The elasticity observed in the stress-strain curve is due to structures that make up visible, periodic light-dark bands that were initially described by, and named after, Felix Fontana (Fontana 1781). These bands vary in their angulation, width, spacing and periodicity; they have long been assumed to be optical artefacts produced by the characteristic zig-zag course of individual nerve fibres (i.e. axons, both myelinated and unmyelinated) lying within the perineurial sheath. A strong linear relationship between increasing nerve strain and decreasing band frequency and axonal undulations has been demonstrated experimentally in rat sciatic nerve using Fourier analysis (Love et al 2013). In vivo microdissection studies coupled with computer modelling suggest that the layers of perineurial cells are probably responsible for the short-wavelength, large-amplitude bands and that wavy spiralling nerve fibres in the endoneurium are responsible for the longwavelength, small-amplitude bands (Merolli et al 2012), the two patterns merging to form the visible bands of Fontana. Interestingly, a recent study of Trembler-J mice, a model of Charcot-Marie-Tooth disease, suggested that the altered bands of Fontana in Trembler-J sciatic nerve appear to be the result of unusually long, sinuous axons moving out of phase (Power et al 2015). The zig-zag, spiralling nerve fibres are thought to provide the elasticity evident in the 'toe' region of the stressstrain curve. Increasing strain in the 'linear behaviour' region of the stress-strain curve causes the bands of Fontana to disappear (Pourmand et al 1994).

Anatomical features have been studied to discern their contribution to the 'linear behaviour' region of the stress-strain curve. The slope of this region is termed Young's modulus of elasticity, or in the case of the load-elongation curve, it indicates the stiffness of a nerve. A steep slope indicates that a nerve is stiff, and significant tensile force results in only modest change in length. The modulus of elasticity or stiffness of an acellular nerve is similar to that of fresh nerve, indicating that connec-
tive tissue fibres contribute to stiffness (Borschel et al 2003). Endoneurial fluid and the perineurial sheath that maintains the fluid compartment also contribute to stiffness. When a nerve is elongated, it undergoes transverse contraction (Walbeehm et al 2004): the reduction in crosssectional area increases endoneurial compartment pressure contributing to nerve stiffness (Millesi et al 1995). As one might predict, nerve roots, which lack a perineurial sheath, demonstrate less stiffness than a peripheral nerve (Beel et al 1986). External features, such as nerve branching and entering/exiting blood vessels, resist elongation of a nerve in its nerve bed, and increase nerve stiffness measured in situ (Millesi et al 1995).

Fig. 9.1.1 Typical load-elongation (A) and stress-strain curves (B) for a peripheral nerve. The transition between the toe region and the linear region in the stress-strain curve (asterisk) has been shown to correspond approximately with the strain in situ. The slope of the stress-strain curve is called the modulus of elasticity and represents the stiffness of the nerve, as seen in the load-elongation curve. If the slope is steep, then the nerve has more stiffness and is less compliant to elongation. If the slope is less steep, then the nerve has less stiffness and is more compliant to elongation. Once the nerve has reached ultimate strain, the structural integrity of the nerve is overcome and the deformation is termed 'plastic' or 'permanent'. (From Topp KS, Boyd BS 2006 Structure and biomechanics of peripheral nerves: nerve responses to physical stresses and implications for physical therapist practice. Phys Ther 86:92-109.)

In the 'plastic' region of the stress-strain curve, increasing longitudinal stress causes non-recoverable elongation and structural integrity is lost. The force per unit cross-sectional area at the point of mechanical failure is termed ultimate stress and occurs at ultimate strain. At this point, a nerve behaves like a viscous material (Haftek 1970). Along the stress-strain curve, structures within the nerve become impaired in a hierarchical fashion. With increasing tensile load, there is first sliding and loss of tenuous connections in the interface between the layer of inner perineurial cells and the sheath of outer perineurial cells and associated epineurial tissues (Tillett et al 2004, Georgeu et al 2005). With continued load, the core of nerve fibres and inner perineurial cell layers is disrupted and function is impaired or lost; ultimately, the sheath of outer perineurial and epineurial tissues ruptures. Given that acellular nerve demonstrates significantly lower tensile strength and ultimate strain than fresh nerve (Borschel et al 2003), the perineurial cell layer should be appreciated for its ability to withstand stress. Although definitive anatomical studies are lacking, it is likely that microscopic disruptions of perineurial cell-cell connections occur with
increasing stress along the 'linear behaviour' region of the stress-strain curve, long before the ultimate strain is reached.

Nerve is best described as a viscoelastic tissue because its biomechanical properties are time-dependent. In response to fixed tension, nerve demonstrates creep or elongation over time (Grewal et al 1996). Slow elongation allows for higher ultimate strain (Haftek 1970, Rydevik et al 1990). When stretched to a fixed length, nerve exhibits stress relaxation or a reduction in tension over time (Wall et al 1991, Driscoll et al 2002).

Returning to the example of the sciatic nerve, during movement from standing to seated, the nerve bed is elongated posterior to the hip as forward trunk motion causes flexion at the hip joint. The sciatic nerve is exposed to tensile load or stress with resultant elongation or strain. Adjusting to these forces, segments of the nerve converge towards the flexing hip joint, with minimal motion in distant segments (Topp and Boyd 2006). Endoneurial pressure resists transverse contraction. When the seated posture is assumed and maintained, the nerve undergoes stress-relaxation - until the next postural adjustment.

# Functional anatomy and biomechanics of the pelvis 

Andry Vleeming, Frank H Willard

This commentary focuses on the anatomy and biomechanics of the pelvic girdle and, specifically, the sacroiliac joints. In bipeds, the pelvis serves as a basic platform with three large levers acting on it (the spine and two lower limbs). Movement of the pelvic platform upon the hip joints relative to the femur, such as flexion and extension (pelvic anteand retroversion), and rotation and abduction/adduction, strongly influences lumbar spinal movement. As well as this substantial external pelvic motion, internal pelvic motion through the sacroiliac joint is essential for effectively transferring loads between the spine and lower limbs. It has been postulated that the sacroiliac joints act as important stress relievers in the 'force-motion' relationships between the trunk and lower limb (Vleeming et al 2007). These joints ensure that the pelvic girdle is a flexible ring of bone that will not easily fracture under the great forces to which it might be subject, either from trauma or from its many bipedal functions (Lovejoy 1988). Analysis of gait mechanics demonstrates that the sacroiliac joints provide sufficient flexibility for the intrapelvic forces to be transferred effectively to and from the lumbar spine and lower extremities (Vleeming et al 2007).

The sacroiliac joint is a highly specialized joint that lends stable (yet flexible) support to the upper body. Both the tightness of the welldeveloped dorsal fibrous apparatus and the specific architecture of the sacroiliac joint result in limited mobility. Numerous researchers have tried to model sacroiliac joint function by studying its principal displacement characteristics. A common assumption of these studies is that increased loading on the sacrum leads to tilting of the sacrum ventrally (nutation), a process by which most dorsal sacroiliac joint ligaments are stretched and the dorsal aspects of the iliac bones are drawn together (Solonen 1957, Vleeming et al 1990a, Vleeming et al 1990b). Counternutation normally takes place in unloaded situations, such as lying. Nutation implies a forward tilting of the sacrum relative to a posterior rotation of the ilia, and vice versa in counternutation.

## Sacroiliac joint movement

Pelvic motion of males and females has been investigated by roentgen stereophotogrammetric motion analysis (RSA). RSA is a technique for measuring small movements and is regarded as the gold standard for determining mobility in orthopaedics (Kibsgård et al 2012). Several studies applied this technique to measure the mean sacroiliac joint mobility, especially around the sagittal axis, in patients with pelvic girdle pain (PGP; Sturesson 2007). The average mobility for men is about $40 \%$ less than for women. However, with age, there was no detectable decrease in total mobility in either gender (in patients up to 50 years old). In fact, there was a significant increase of mobility with age for both moving from a 'supine to sitting position' and from 'standing to lying prone with hyperextension' position, particularly in women. Likewise, gender differences of symphysial motion were analysed in a group of 45 asymptomatic individuals. In men, the average frontal plane movement was 1.4 mm , and in nulliparous women 1.6 mm . However, in multiparous women, motion increased to 3.1 mm (Garras et al 2008).

The increased sacroiliac joint mobility in females compared to males has possible anatomical correlates. The curvature of the sacroiliac joint surfaces is usually less pronounced in women to allow for greater mobility (Vleeming et al 1990a). Also, the pubic angle differs between
men and women (Vleeming et al 2012). The increase in mobility of the pelvic ring seen in the post-pubescent female pelvis is functional in allowing passage for the child during labour. When the data are combined from published studies employing RSA and appropriate placing of markers, the maximum sagittal rotation of the sacroiliac joint never exceeds $3.6^{\circ}$ and translation of the joint never exceeds 2 mm (Kibsgård et al 2012). If these data are amalgamated with the observation that osteophytosis is rare in women, regardless of age ( $1.83 \%$ of females), and is not very common in men (12.27\%; Dar et al 2008), it appears that small sacroiliac joint movements are present, even at an advanced age (Vleeming et al 2012).

## Sacroiliac joint stability

To illustrate the importance of both myofascial and ligamentous stability of the sacroiliac joint, the biomechanical principles of form and force closure were introduced (Vleeming et al 1990a, Vleeming et al 1990b). Form closure refers to a theoretical stable situation in a joint with closely fitting surfaces, where no extra forces are needed to maintain the state of the system. With force closure (leading to joint compression), both a lateral force and friction are needed to withstand vertical load. The structural features that contribute to sacroiliac joint form closure are complementary ridges and grooves of the articular surfaces; dorsocranial 'wedging' of the sacrum into the ilia; a particular high coefficient of friction in the sacroiliac joint (Vleeming et al 1990a, Vleeming et al 1990b); and the integrity of the dorsal binding ligaments in particular, which are among the strongest in the body (Vleeming et al 1990a). Both form and force closure are necessary for balancing friction/ compression in the sacroiliac joint. Force closure is the result of altered joint reaction forces by tensing ligaments, fasciae, muscles and ground reaction forces (Vleeming et al 1990a, Vleeming et al 1990b). Force closure ideally generates a perpendicular compressional reaction force to the sacroiliac joint to overcome the forces of gravity (Vleeming et al 1990b).

## Biomechanical considerations and the active straight leg raise (ASLR) test in pelvic girdle pain (PGP) patients

PGP patients, who test positively on the functional ASLR test, show an inability to raise the leg while lying supine. This test can temporarily be normalized by manual anterior compression of the pelvis or the use of a pelvic belt. This suggests that increased unilateral motion of the sacroiliac joint could lead to impairment and failure to lift the leg (Mens et al 1999).

Likewise, Sturesson (2007), using RSA, studied the effects of surgical application of an anterior external fixation frame for severe PGP patients. This resulted in a mean reduction of movement of the sacroiliac joint around the helical axis of $59 \%$ and around the X-axis of $74 \%$. In addition, the ASLR test and other evidence-based PGP tests were normalized (Vleeming et al 2008). When the frame was tightened, a nutation movement of the sacrum was noticed (Sturesson 2007).

This and other studies mentioned in this commentary imply that 'too much movement' of the sacroiliac joint could be a significant factor in the onset of PGP (Vleeming et al 2008).

# Articularis genus 

Stephanie J Woodley

Articularis genus, sometimes referred to as the 'articular muscle of the knee' (Puig et al 1996), is a small muscle located deep to vastus intermedius on the anterior aspect of the thigh (Fig. 9.3.1). Due to its distal capsular insertions, it is morphologically similar to the subanconeus muscle (articularis cubiti) of the elbow joint, although subanconeus is considered to represent the deep fibres of the medial head of triceps brachii (rather than being a separate entity) and its function is likely to differ from that of articularis genus (Tubbs et al 2006). From an evolutionary perspective, fibres corresponding to articularis genus have been described in early tetrapods (Diogo and Molnar 2014) and it is comparable to the subcrureus muscle of primates including apes, gorillas and lemurs (Murie and Mivart 1872, Hepburn 1892). A distinct, yet small, articularis genus is also found in domestic animals such as the dog, cat and goat (Getty 1975, Kincaid et al 1996, Glenn and Samojla 2002, Evans 2013).

While articularis genus has been of interest to anatomists for over two centuries (refer to DiDio et al (1967) for a historical account), controversy still surrounds many aspects of its architecture. Discrepancies in the literature are most likely to be the result of differences in study methodologies, particularly with respect to the type and scope of data collected and/or in definitions of the muscle and its components. To date, most studies of articularis genus have been dissection-based; there are only three studies in which modern imaging techniques have been used to investigate morphology (Puig et al 1996, Roth et al 2004, Woodley et al 2012) (Table 9.3.1).

Articularis genus consists of staggered layers of bundles (Puig et al 1996, Kimura and Takahashi 1987, Woodley et al 2012) that arise from the distal third of the anterior, medial and lateral surfaces of the femur (Ahmad 1975, DiDio et al 1967, Woodley et al 2012, DiDio et al 1969) (Fig. 9.3.2), with a broad attachment to the proximal and/or posterior margins of the suprapatellar bursa (Puig et al 1996, Ahmad 1975, Kimura and Takahashi 1987, Toscano et al 2004, Woodley et al 2012, Sakuma et al 2014) (Fig. 9.3.3) and specific regions of the articular

Fig. 9.3.1 An anterior view of the thigh showing articularis genus (AG) deep to the reflected vastus intermedius (VI) muscle. Other abbreviations: N , nerve branch to articularis genus from the femoral nerve; P, proximal border of bisected patella; VM, vastus medialis; * midpoint of suprapatellar bursa.
capsule (DiDio et al 1967, Kimura and Takahashi 1987, Woodley et al 2012, Reider et al 1981). The muscle may be triangular, rectangular or trapezoid in shape (DiDio et al 1967, Toscano et al 2004, DiDio et al 1969). There is considerable variation in the reported mean muscle length (between 6.2 and 14 cm in adults; Ahmad 1975, DiDio et al 1967, Toscano et al 2004, Woodley et al 2012), as well as the number of constituent bundles, which typically ranges from 1 to 7 (Puig et al 1996, Ahmad 1975, DiDio et al 1967, Toscano et al 2004, Sakuma et al 2014) but sometimes exceeds 10 (DiDio et al 1969, Reider et al 1981; see Table 9.3.1). The number of bundles may be underestimated when viewed using magnetic resonance imaging (Puig et al 1996, Woodley et al 2012), possibly because of the reasonably compact nature of this muscle. Recent dissection evidence demonstrates that 6 of 11 different muscle bundles, organized in superficial, intermediate and deep layers, are consistently present (Woodley et al 2012; Fig. 9.3.4). The superficial layer usually comprises a large central bundle bordered by lateral and medial bundles; fascicles in some of these bundles may insert into the bursa through an intermediary thin areolar membrane (see Fig. 9.3.4). A central bundle forms the intermediate layer, and two bundles (medial and lateral) make up the deepest part of articularis genus, and may be accompanied by a third, central bundle (Sakuma et al 2014). Bundle

Fig. 9.3.2 A medial view of the bundles of articularis genus arranged into superficial (S), intermediate (I) and deep (D) layers, inserting into the suprapatellar bursa. Note that some superficial fascicles insert into the deep surface of the vastus intermedius (VI) tendon.

Fig. 9.3.3 A sagittal proton density MRI scan of the knee from a 23-year-old female. The distal portion of articularis genus (AG), deep to vastus intermedius (VI), is seen inserting into the suprapatellar bursa (*).

Table 9.3.1 Summary of data relating to the morphology of articularis genus

| Study | Study characteristics (type, specimen number and sex) | General muscle morphology; origin and insertion | Architectural parameters |

${ }^{a}$ Proximal border or apex of patella used as landmark. ${ }^{b}$ Represents number of cadavers/participants, not specimens. ${ }^{c}$ Relative to the distal end of the medial femoral condyle, unclear if data from one specimen or all specimens. ${ }^{d} I n$ this study ' $\pm$ ' refers to SEM. ${ }^{e}$ Angle recorded between anterior surface of femur and posterior surface of muscle bundle. 'Relative to superior edge of trochlea. ${ }^{9} A l l$ data relate to dissection measures unless stated. ${ }^{n} / n$ this study ' $\pm$ ' refers to standard deviation. 'Calculated by multiplying bundle length by width.
Abbreviations: I, insertion; MRI, magnetic resonance imaging; n, number; 0, origin; PCSA, physiological cross-sectional area; VI, vastus intermedius; VL, vastus lateralis; VM, vastus medialis.
orientation is predominantly longitudinal, although the deepest two peripheral bundles may be oriented obliquely (Puig et al 1996, Ahmad 1975, Toscano et al 2004, Woodley et al 2012). Symmetry of bundle arrangement in the right and left limbs of individuals appears variable (40-82\%; DiDio et al 1967, Woodley et al 2012, DiDio et al 1969, Sakuma et al 2014).

Articularis genus is diminutive: its mean physiological cross-sectional area of $1.5 \pm 0.7 \mathrm{~cm}^{2}$ (cadaver specimens; Woodley et al 2012) indicates that it is capable of generating only a small amount of force. Fascicle length (mean $5.9 \pm 1.0 \mathrm{~cm}$; Woodley et al 2012) is likely to be influenced by bundle location (Puig et al 1996, Kimura and Takahashi 1987, Woodley et al 2012). The deepest, most distal layer of articularis genus contains the shortest fascicles, and the superficial, proximal bundles contain the longest (Woodley et al 2012; see Fig. 9.3.4). Functionally,
it is possible that this arrangement enables the longer, superficial fascicles to accommodate changes in muscle length (Woodley et al 2012), particularly during knee flexion, where it is postulated that the length of each bundle of articularis genus elongates two-fold at the end-range of movement (Kimura and Takahashi 1987).

There has been long-standing debate as to whether articularis genus is a deep bundle of quadriceps femoris or an independent muscle (DiDio et al 1967). While it is true that articularis genus and vastus intermedius share an innervation from branches of the femoral nerve (Ahmad 1975, Kimura and Takahashi 1987; see Fig. 9.3.1), other anatomical data tend to favour the view that articularis genus is an independent muscle. First, although a small percentage of superficial fascicles in the superficial bundles of articularis genus may insert into the deep layer of the distal tendon of vastus intermedius (see Fig. 9.3.2),

Fig. 9.3.4 The three layers of articularis genus. A, The superficial (S) layer, where some fascicles insert into the suprapatellar bursa via an areolar membrane (AM). Note the presence of a complete superior plica (arrowheads), positioned between the knee joint cavity and the suprapatellar bursa. B, The intermediate (I) layer beneath the reflected superficial (S) bundles. C, Two deep (D) bundles, positioned laterally and medially. Other abbreviations: P, proximal pole of bisected patella; VI, vastus intermedius tendon; * proximal border of the midpoint of the suprapatellar bursa.

the bulk of articularis genus appears distinct from the overlying quadriceps (Kimura and Takahashi 1987, Woodley et al 2012). Second, the two muscles may be delineated by a distinct fascial layer of variable composition and thickness (Ahmad 1975, DiDio et al 1967, Toscano et al 2004), although this feature is inconsistent (Kimura and Takahashi 1987, Woodley et al 2012, Toscano et al 2004). The fibre type profiles, albeit limited to four cadaver specimens, appear to differ between articularis genus and vastus intermedius (Woodley et al 2012). Perhaps the most reliable method of defining articularis genus is by reference to its discrete distal insertion sites into the suprapatellar bursa and/or joint capsule (Kimura and Takahashi 1987, Woodley et al 2012). Articularis genus may hypertrophy (Puig et al 1996) or atrophy (Toscano et al 2004) in parallel with quadriceps femoris, but the significance of these adaptations is unknown.

When contemplating function, the architectural arrangement of articularis genus is paramount because direct evidence regarding its action is limited to a single study (Ahmad 1975). Ahmad observed elevation of the knee joint capsule and synovial membrane on stimulating a branch of the femoral nerve innervating articularis genus in three patients undergoing surgical amputation. This finding is consistent with previous hypotheses, suggesting that articularis genus is responsible for retracting the suprapatellar bursa or knee joint capsule proximally (Ahmad 1975, DiDio et al 1967, Kimura and Takahashi 1987, Roth et al 2004, Toscano et al 2004), potentially preventing interposition of these structures between the patella and femur during extension of the knee joint (Ahmad 1975, DiDio et al 1967). Functional implications may be elucidated from comparison with the dog stifle (knee) joint, where articularis genus usually consists of two thin bundles (medial and lateral) forming an 'inverted-V' shaped muscle (Kincaid et al 1996), approximately 2 mm wide (Evans 2013). This morphology, together with the distribution of muscle spindles, which are located both in the vicinity of the muscle-capsule interface and isolated within the capsular connective tissue, suggest that in addition to tensioning the suprapatellar bursa (Kincaid et al 1996, Evans 2013), articularis genus may have an important proprioceptive role (Kincaid et al 1996).

A detailed knowledge of the morphology of articularis genus is relevant to understanding normal function of the knee joint as well as its role in possible dysfunction; for example, the possible protective role that articularis genus may have in counteracting impingement of capsular tissues (Ahmad 1975, DiDio et al 1967) might be appropriate to consider in some individuals who present with undifferentiated anterior knee pain (Woodley et al 2012). It is perhaps surprising that this muscle has not been afforded more attention; given its complexity and variability, there is scope for further examination of its detailed anatomy and function, particularly in healthy volunteers. Techniques such as dynamic magnetic resonance imaging and electromyography may be useful adjuncts to morphological investigations, and assist in contributing to a better understanding of the functional and clinical relevance of this interesting muscle.

## SUBJECT INDEX

## Note:

## Index Structure

This index is in a classified form, i.e. arteries, ducts, muscles, nerves, veins, etc. are all listed under these respective main entries, e.g. 'arteries (named)'. This includes subjects/structures such as cells, connections, diseases, syndromes and tracts, e.g. lymphocytes are to be found under 'cells (named)'. Bones are an exception, and specific bones are listed as main entries, e.g. tibia is listed as tibia, not under 'bones'.

Organs and regional structures have their own main entries and subentries (e.g. oesophagus). Cross-references to individual arteries, veins, muscles, etc. are assumed, not explicit.
In most cases, structures are listed under singular nouns, with the plural in brackets.

## Index Entry Order

This index is in a letter-by-letter order, whereby hyphens and spaces between words are excluded from the alphabetization (e.g. 'lymphatic' precedes 'lymph node'). Characters in brackets are also excluded from alphabetization. For example, arc(s) precedes arcade or arch(es).
Terms such as first, second, third (as in arch(es), pharyngeal) are in numerical order ahead of alphabetical sub (or sub-sub) entries.

relations 504, 504f
structures within 504-505
surface anatomy 411-412
vascular supply 505
periurethral 1261, 1280
pineal $274 f, 276,312 f, 357,362-363,394$
arteries 363
calcification 276, 363, 363f
development 258
secretions 363
veins 363
pituitary 274f, 359-361, 360f-361f
adenoma 708
arterial supply 285, 360-361
at birth 245
development 244f, 245, 258, 620
endocrine feedback loops 34
hormones $360 t$
posterior see neurohypophysis
relations 359-360
secretion control $361 f$
tumours 708
venous drainage 360-361
preputial 1281
prostate see prostate
pyloric 1120, 1122f
salivary 527-531, 527f
activity control 530-531
age changes 531
buccal 475, 529
development 615
innervation 530-531, 530f
labial 529
lymph nodes 530
major 507
microstructure 529-530, 530f
minor 507-508, 510, 529
development 615
neonates 531
palatal 529
parotid see gland(s), parotid
retention cyst 529
secretions 527
secretory end-pieces 529, $530 f$
sublingual see gland(s), sublingual
submandibular see gland(s), submandibular
sebaceous 142f, 147f, 149-150, 149f
of breast 946
development 155
ectopic 507
of eyelids 681
in fetus 209
in lips 475
secretion control 33-34
seromucous
nasal 561
pharyngeal tonsil 574
tubuloacinar, in conducting airways 968
serous 32
respiratory tract 968
of von Ebner 513f, 515-516, 529, Eponyms
Skene's see gland(s), para-urethral
of stomach see gland(s), gastric
sublingual 515f, 528-529
arteries 528
development 615
innervation 528
lymphatic drainage 528
microstructure 529, 531f
retention cyst 529, 529f
submandibular 469-470, 515f, 528
arteries 528
deep part 515f, 527f, 528
development 615
innervation 528
lymphatic drainage 528
microstructure 529, 531f
relations 528
superficial part 528
surface anatomy 414
submucosal
in conducting airways 968
duodenal (Brunner's) 1054-1055, 1133f, 1135, Eponyms
suprarenal 1194-1198, 1194f, $1240 f$
accessory 1194
anomalies 1064
arteries 1195-1197, 1195f-1196f
at birth 1194
congenital hyperplasia 1064
cortex 1064, 1194, 1196f-1197f, 1197-1198
development 1064
dimensions 1194
ectopic 1194, 1278
excision 1198
fetal 1064
innervation 1197
left 1194-1195, 1195f, 1240
lymphatics 1092, 1197
medulla 1064, 1194, 1196f-1197f, 1198
microstructure 1197-1198
neonatal 211f, 1064, 1206f
right 1194, 1195f, 1240
tumours 1197
veins 1195-1197, $1195 f$
weight 1194
sweat $32,150-151,150 f$
development 155
eccrine 150, 155-156
tarsal 149, 680-681, Eponyms
development 664
obstruction 681
thymus see thymus
thyroid 470-471
aberrant masses 618
accessory 470
arteries 460f, 464f, 470
development 614f, 618, $618 f$
ectopic 470, 618
fascia 599
follicles 471, 471f
imaging 470, 471f
innervation 470
isthmus 470
lingual 470, 511, 618
lobes 470
lymphatics 470
microstructure 471
neonate 608f, 618
relations 470
sex differences 470
size estimation 470
surface anatomy 413
surfaces 470
veins $459 f-460 f, 470$
tubular 32
unicellular 32
urethral 1263-1264, 1267
development 1218
uterine 1306
vestibular, greater see gland(s), Bartholin's
of Wolfring 683, Eponyms
of Zeis 681, 681f, Eponyms
glans
clitoris 1218-1219, 1289
penis 1218-1219, 1280-1281, 1281f
innervation 1285, 1287f
skin 1281
glaucoma 697, 706, 708
open angle 688
primary closed angle 697
primary open angle 697
glia see cells (named), glia
glial cell (line)-derived neurotrophic factor
(GDNF) 223
glial fibrillary acidic protein (GFAP) 49

## glia limitans

external 245-246
internal 245-246
gliogenesis 246
globulin 69
globus pallidus 364, 369
cells 369
connections 368f-369f, 369
deep-brain stimulation $371,371 f$
dorsal 365
lesions 370
segments 365,369
ventral 365
glomera 131, 131f, 151 f
glomerular filtration 1245f, 1247f, 1249f, 1250
rate (GFR) 1250
at birth 1206
glomerulus (glomeruli)
coelomic (external) 1199, $1200 f$
internal 1199, $1200 f$
'omental' 1104
renal 1246
development 1199-1202
structure 127
synaptic $45,46 f$
glomus jugulare see body (bodies), tympanic
glottis 591, 593
$\square$
glucose, placental transfer 177
glue ear 633, 635, 657
glutamate 48
astrocytes 49
glutamic acid decarboxylase (GAD),

## striatum 366-367

glycine 48
glycocalyx (cell coat) 5f, 6
glycogen
in cardiac muscle 138
skeletal muscle 106
vaginal epithelium 1293-1294
glycolipids 5,52
epidermal 145
of myelin 52
glycolysis, anaerobic 108
glycophorins 69
glycophospholipids, epidermis 144
glycoproteins
adhesive 37-39
myelin associated glycoprotein 52
tectorins 649
glycosaminoglycans (GAGs) 38-39
in cartilage 81
embryonic skin 155
fetal skin 155
国 temporomandibular joint articular disc 543
glycosylation 8
GM2 gangliosidosis (Tay-Sachs disease) 9 goitre 471
[ Golgi apparatus (complex) 6, 7f, Eponyms
Golgi tendon organs 61-62, 61f, 100, 108, 115
gonads
descent 1214-1216
development 1212f, 1213-1214
ambisexual/indifferent stage 1201f, 1208, 1209f, $1212 f$
early 1208, 1209f, 1212f
female see ovary (ovaries)
lymphatic drainage 1092
male see testis (testes)
'streak' 1213
goose bump 150
G-protein coupled receptors 11
grafts/grafting
cranial bone 416
full-thickness 160
hypoglossal nerve 468
internal thoracic artery 1020
knee ligament 1363
radial artery 1020
revascularization 160
saphenous vein 1020
skin 160
see also flap(s) (skin flaps)
(C) spinal nerves - Commentary 6.1
split-thickness 160
temporalis fascia 631
ulnar nerve 784
granulation (of tissue) 35, 158-159
granulations, arachnoid 278, 278f, 435f-436f, 436,
Eponyms
systolic dilation 278
granule(s)
azurophilic 70
basophilic 70
Birbeck 80, 146, Eponyms
cortical, sperm-oocyte fusion 163
eosinophilic 70
glycogen, skeletal muscle 106
granule(s) (Continued)
keratohyalin 144, 154
lamellar 144
lipofuscin 134-135
lytic, T cells 72
neuromelanin 323
neutrophilic 70
Nissl 42-43, 44f, Eponyms
pigment, neurones $43,44 f$
of platelets
alpha 73
delta 73
lambda 73
zymogen 529
granzymes 72
B, apoptosis 26
gravity
centre of, in walking 1448
(C) facial ageing - Commentary 4.3
grey matter see matter, grey
grips 887
chunk 876
pinch 876,887
power 876
groin
pain 1379
strain 1379
see also region(s), inguinal
grommets 635
groove(s) 85
aortic 957
atrioventricular (coronary) 902-903, 919, 996f, 998
bicipital (intertubercular) 787, 806
of bone 85
buccolabial 475
carpal 867
caval, of liver 1161-1162
circumalar 475
coronary see groove(s), atrioventricular
costal 934-935
deltopectoral $819 f$
diaphragmatic see groove(s), interventricular
on femoral condyles 1387
of femoral neck 1348
gingival, free 508
for greater palatine nerve/vessels 486
for greater petrosal nerve 626
on heart surface 998
infraorbital 484,666
interatrial (of Waterston) 998, 1000, Eponyms interscalene 414
intersphincteric 1153-1155
intertubercular (bicipital) 787,806
interventricular (diaphragmatic)
anterior 998
development 916-917
posterior (inferior) 998
labiomarginal 475
laryngotracheal 619, 925
lateral, of femur 1351
linguogingival 614-615, 614f
on lung surface 956-957
for maxillary nerve 487
medial, of femur 1351
mentolabial 475
mid-cheek - Commentary 4.3
for middle meningeal vessels 477
mylohyoid 537-539
nail 155
for nasal septal cartilage 483
nasojugal - Commentary 4.3
nasolabial 475 , Commentary 4.3
nasolacrimal 484-485
for nasopalatine nerve/vessels 483
neural 184, 238
obturator 1343
occipital 624
palatine, greater 486
palpebromalar - Commentary 4.3
paramesonephric 1208-1210
pharyngeal 606
for the pharyngotympanic tube 422
for popliteus 1397, 1402, $1403 f$
primitive 182
radial (spiral) 807
for radial nerve 806
for sigmoid sinus 478
