## SECTION EDITORS

Neel Anand MD
Clinical Professor of Surgery Director, Spine Trauma, Minimally Invasive Spine Surgery
Spine Center
Cedars Sinai Medical Center
Los Angeles, CA, USA
Rolfe Birch MChir, FRCPS(Glasg), FRCS(Ed), FRCS(Eng)
Retired Consultant in Charge
War Nerve Injury Clinic, Defence Medical Rehabilitation Centre, Surrey;
Retired Head, Peripheral Nerve Injury Unit, Royal National Orthopaedic Hospital;
Professor in Neurological Orthopaedic Surgery, University College of London London, UK

Patricia Collins BSc, PhD, FHEA
Professor of Anatomy
Anglo-European College of Chiropractic Bournemouth, UK
Editor for Embryology and Development
Alan R Crossman $\mathrm{BSc}, \mathrm{PhD}, \mathrm{DSC}$
Professor Emeritus
University of Manchester
Manchester, UK
Michael Gleeson MD, FRCS,
FRACS, FDS
Professor of Skull Base Surgery
University College London
The National Hospital for Neurology and Neurosurgery
London, UK

Girish Jawaheer MD, FRCS(Eng), FRCS(Paed)
Consultant Paediatric Surgeon
Great North Children's Hospital, Royal
Victoria Infirmary
Newcastle upon Tyne NHS Foundation Trust
Newcastle upon Tyne, UK;
Formerly Specialty Tutor for Paediatric Surgery
Royal College of Surgeons of England
London, UK
Editor for Paediatric Anatomy

## Ariana L Smith MD

Associate Professor of Urology
Director of Pelvic Medicine and Reconstructive Surgery
Penn Medicine, Perelman School of Medicine
University of Pennsylvania Health System Philadelphia, PA, USA

## Jonathan D Spratt

MA(Cantab), FRCS(Eng), FRCR
Clinical Director of Diagnostic Radiology
City Hospitals Sunderland NHS
Foundation Trust
Sunderland, UK;
Former Anatomy Examiner for the Royal College of Surgeons of England and Royal College of Radiologists
Editor for Imaging Anatomy
Mark D Stringer BSc, MS, FRCP,
FRCS, FRCS(Ed), FRACS
Professor of Paediatric Surgery
Christchurch Hospital;
Honorary Professor of Anatomy
University of Otago
Dunedin, New Zealand

R Shane Tubbs MS, PA-C, PhD
Chief Scientific Officer
Seattle Science Foundation, Seattle, WA, USA;
Professor of Human Gross and Developmental Anatomy Department of Anatomical Sciences
St. George's University, Grenada, West Indies;

FORTY-FIRST EDITION

Included in your purchase is a rich variety of BONUS electronic content, to supplement and enhance the printed book.
Look out for this icon , indicating where there is related further electronic text, images, tables, labelled imaging or video material. In addition, you can access 24 'Gray's Commentaries', especially written (electronic only) articles on new and emerging topics related to anatomy. This icon [C] highlights where one relates directly to a topic in the printed book.
Don't miss out on any of this additional electronic content - see the inside front cover for your access instructions.

## COVER IMAGE

Reconstruction of the short and long connections of the hand region in the living human brain using advanced diffusion tractography developed by the NatBrainLab (www.natbrainlab.com). The connections of the hand region resemble a 'poppy flower' with a green stem representing the long projection fibres and four red 'petals' connecting the precentral cortex to postcentral and premotor cortices. This network is important for motor learning and execution of reaching and grasping hand movements (see chapter 25). (Image courtesy of Dr Marco Catani, originally published in Catani M, Dell'Acqua F, Vergani F, et al; Short frontal lobe connections of the human brain. 2012 Cortex 48:273-91.)

## CONTENTS

Preface ..... ix
Preface Commentary
The continuing relevance of anatomy in currentsurgical practice and research$R$ Shane Tubbs
Acknowledgements ..... x

## 'Anatomy is the basis of medical discourse.'

(Hippocrates, De locis in homine 2)
Looking through an almost complete set of the previous editions of Gray's Anatomy, I am struck by the marked difference in size between the first and fortieth editions. That progressive increase in girth has occurred pari passu with ground-breaking advances in basic science and clinical medicine over the past 155 years. Anatomy has become a far wider discipline than Henry Gray, Henry van Dyke Carter or any of their students could have envisaged. Fields such as cell biology, molecular genetics, neuroanatomy, embryology and bioinformatics either had not emerged or were in their infancy in 1858. Techniques that today inform our view of the internal landscape of the body - such as specialized types of light and electron microscopy; imaging modalities, including X-rays, magnetic resonance imaging, computed tomography and ultrasonography; the use of 'soft' perfusion techniques and frozen-thawed, unembalmed cadavers for dissection-based studies; and the advances in information technology that enable endoscopic and robotic surgery and facilitate minimally invasive access to structures previously considered inaccessible - were all unknown. As each development entered mainstream scientific or clinical use, the new perspectives on the body it afforded, whether at submicroscopic or macroscopic level, filtered into the pages of Gray's Anatomy: for example, the introduction of X-ray plates (twenty-seventh edition, 1938) and electron micrographs (thirtysecond edition, 1958).

In the Preface to the first edition, Henry Gray wrote that 'This Work is intended to furnish the Student and Practitioner with an accurate view of the Anatomy of the Human Body, and more especially the application of this science to Practical Surgery.' We remain true to his intention. An appropriate knowledge of clinically relevant, evidence-based anatomy is an essential element in the armamentarium of a practising clinician; indeed, 'If anything, the relevance of anatomy in surgery is more important now than at any other time in the past' (Tubbs, in Preface Commentary, which accompanies this volume).

In my Preface to the fortieth edition, I intimated that the book was quite literally in danger of breaking its binding if any more pages were added. In order to avoid this unfortunate occurrence, the forty-first edition contains a significant amount of material that is exclusively electronic, in the form of 77,000 words of additional text, 300 artworks and tables, 28 videos and 24 specially invited commentaries on topics as diverse as electron microscopy and fluorescence microscopy; the neurovascular bundles of the prostate; stem cells in regenerative medicine; the anatomy of facial ageing; and technical aspects and applications of diagnostic radiology. In keeping with the expectation that anatomy should be evidence-based, the forty-first edition contains many more references in the e-book than could be included in the thirty-ninth and fortieth printed editions.

Neel Anand, Rolfe Birch, Pat Collins, Alan Crossman, Michael Gleeson, Ariana Smith, Jonathan Spratt, Mark Stringer, Shane Tubbs, Alan Wein and Caroline Wigley brought a wealth of scholarship and experience as anatomists, cell biologists and clinicians to their roles as Section Editors. I thank them for their dedication and enthusiastic support, in selecting and interacting with the authors in their Sections and for meeting deadlines, despite the ever-increasing demands on their time from university and/or hospital managers. Pat Collins, Girish Jawaheer, Richard Tunstall and Caroline Wigley worked closely with many authors to update the text and artworks for organogenesis, paediatric anatomy, evidence-based surface anatomy and microstructure, respectively, across Sections 3 to 9. Jonathan Spratt acted as both a Section Editor (thorax) and an indefatigable 'go to' for sourcing images throughout the book; in the latter capacity, he has produced a superb collection of additional labelled images, available in the e-book (see Bonus imaging collection). Over a hundred highly experienced anatomists and clinicians contributed text, often extensively revised from the previous edition, and/or artworks, original micrographs or other images to individual chapters.

As a general rule, the orientation of diagrams and photographs throughout the book has been standardized to show the left side of the body, irrespective of whether a lateral or medial view is presented, and transverse sections are viewed from below to facilitate comparison with clinical images. Clinicopathological examples have been selected where the pathology is either a direct result, or a consequence, of the anatomy, or where the anatomical features are instrumental in the diagnosis/ treatment/management of the condition. Wherever possible, the photomicrographs illustrate human histology and embryology; non-human sources are acknowledged in the captions.

In an ideal world, anatomical terminology would satisfy both anatomists and clinicians. For the avoidance of doubt, the same word should be agreed and used for each structure that is described, whether in the anatomy laboratory or the clinic. In the real world, this goal is achieved with varying degrees of success; alternative terms (co)exist and may (and frequently do) confuse or frustrate. Currently, Terminologia Anatomica (TA) ${ }^{1}$ is the reference source for the terminology for macroscopic anatomy; the text of the forty-first edition of Gray's Anatomy is almost entirely TA-compliant. However, where terminology is at variance with, or, more likely, is not included in, the TA, the alternative term that is chosen either is cited in the relevant consensus document or position paper - e.g. 'European Position Paper on the Anatomical Terminology of the Internal Nose and Paranasal Sinuses ${ }^{\prime 2}$ and the International Interdisciplinary Consensus Statement on the 'Nomenclature of the Veins of the Lower Limbs ${ }^{\prime 3}$ - or enjoys widespread clinical usage: for example, the use of attitudinally appropriate terms in cardiology (see Chapter 57). The continued use of eponyms is contentious. ${ }^{4}$ Proponents of their retention argue that some eponyms are entrenched in medical language and are (therefore) indispensable, that they facilitate communication because their use is so pervasive and that they serve to remind us of the humanism of medicine. Detractors argue that eponyms are inherently inaccurate, non-scientific and often undeserved. In this edition of Gray's Anatomy, synonyms and eponyms are given in parentheses on first usage of a preferred term and not shown thereafter in the text; an updated list of eponyms remains available in the e-book for reference purposes.

I offer my sincere thanks to the editorial team at Elsevier, initially under the leadership of Madelene Hyde and latterly of Jeremy Bowes, for their guidance, professionalism, good humour and unfailing support. In particular, I thank Poppy Garraway, Humayra Rahman Khan, Wendy Lee, Joanna Souch, Julie Taylor, Jan Ross and Louise Cook, for being at the end of a phone or available by e-mail whenever I needed advice or support.

I dedicate my work on the forty-first edition of Gray's Anatomy to the memory of my late husband, Guy Standring.

# The continuing relevance of anatomy in current surgical practice and research 

R Shane Tubbs

When our anatomy forebears embarked on the uncharted study of the human body, they did so without reference. Their focus was to chart and map the body simply to learn and describe intricacies never chronicled before. The anatomical 'map' we use today came about thanks to figures such as da Vinci, Vesalius, Cheselden and, more recently, Henry Gray. On the shoulders of these giants, we see farther than our predecessors. In The Metalogicon, published in 1159, John Salisbury recognized the profound observation of French philosopher Bernard of Chartres, who declared that '...we are like dwarfs on the shoulders of giants, so that we can see more than they, and things at a greater distance, not by virtue of any sharpness of sight on our part, or any physical distinction, but because we are carried high and raised up by their giant size'. So, with the gross anatomy of man presumed, by many scholars, to have been described and understood long ago, how does the modern anatomist bring relevance to the continued study of morphology? Is there any uncharted territory for the modern anatomist to plot in order to sustain our field of study and for it to continue to be perceived as relevant to an educational world, and to medical and dental curricula in which the time allotted to anatomical study has significantly waned? Simply put, yes. Henry Gray, based on the title of his original text, Anatomy, Descriptive and Surgical, knew very well that there was a need to refocus the lenses of teaching and research in the anatomical sciences, and to expand and explore their surgical relevance. Our gross anatomical map of the human body must continue to be updated and legends must continue to be placed on that map to incorporate modern advances in technology. New methods of surgery, such as laparoscopy and endoscopy, as well as the use of the surgical microscope, offer the opportunity to view the human form in a different light and in greater surgical detail than ever before. If anything, the relevance of anatomy in surgery is more important now than at any other time in the past. The modern surgeon must take what is learned macroscopically, in the dissection room, and apply this knowledge to structures seen under magnification and through instruments that provide a surgical field that is, at times, just millimetres in diameter. Therefore, attention to anatomical detail is of vital importance as references and anatomical landmarks are minimized in the surgical theatre of the new millennium.

As mentioned before, early anatomists dissected with curiosity about the unknown and gained knowledge that would become a prerequisite for proper surgical manœuvres. Today, as anatomists, our anatomical knowledge should create in us a curiosity about what we can do with the knowledge that we have gained. The ability to apply that knowledge offers an opportunity to be an integral part of the ever-progressing field of surgery. For example, today, surgical problems are often the impetus for dissection studies, which can influence the way in which surgery is performed and, moreover, can sway the way in which anatomy is taught (e.g. redefining a focus in condensed curricula and with decreased work hours for house officers). Surgically, dissection studies have allowed us to manipulate known human anatomy and to solve, for example, complex neurological problems. As an illustration of the surgical relevance of modern-day anatomical studies for neurological pathologies, we have conducted, in my laboratory, cadaveric feasibility studies that suggested that the phrenic nerve could be reinnervated in high quadriplegic patients who are ventilator-dependent (a morbid condition with an associated high mortality rate) by using the intact, adjacent accessory nerve (i.e. neurotization) (Tubbs et al 2008a) (Fig. 1.6.1). The theory behind this investigation was that the functioning accessory nerve would be used to form a new circuit between it and the dysfunctional phrenic nerve, and that this would allow recovery of diaphragm function. For this technique, a longitudinal incision was made along the lower half of the posterior border of sternocleidomastoid. Dissection was then performed in order to identify both the accessory nerve at this level, at its entrance into trapezius, and the phrenic nerve crossing anterior to scalenus anterior. The medial half of the accessory nerve was then split away from its lateral half and transected at its entrance into
muscle. This distally disconnected medial half of the nerve was then swung medially to the phrenic nerve, which had been transected proximally. The two nerves were then sutured together without tension. This 'rearranging' of human anatomy has now been employed clinically with success. Yang et al (2011) used our study results to treat a 44 -year-old man with complete spinal cord injury at the C2 level. Clinically, left diaphragm activity was decreased and the right diaphragm was completely paralysed. Four weeks after surgery, training of the synchronous activities of trapezius and inspiration was conducted. Six months after surgery, motion was observed in the previously paralysed right diaphragm. Evaluation of lung function indicated improvements in vital capacity and tidal volume. The patient was able to sit in a wheelchair and conduct activities without assisted ventilation 12 months after surgery. For the surgeon, such manipulation of anatomy requires a comprehensive understanding not only of normal anatomy but also of what might occur functionally by rewiring such nerves. For example, patients undergoing this surgery will initially need to think of moving their trapezius to activate their diaphragm. With time, this will not be the case. Similar illustrations of the plasticity of the brain have been seen in patients undergoing hypoglossal to facial nerve neurotization procedures; these patients at first need to think of moving their tongue in order for their facial muscles to contract.

Rewiring of nerves has been addressed in other studies. Thus, we have shown, first in a cadaveric study (Hansasuta et al 2001) and then clinically (Wellons et al 2009), that the medial pectoral nerve can be sectioned near its entrance into the deep surface of pectoralis major and swung round and sewn into the musculocutaneous nerve (Fig. 1.6.2). If this procedure is successful, axonal regrowth from the medial pectoral nerve into the musculocutaneous nerve (about $1 \mathrm{~mm} /$ day) will re-establish function in the anterior arm muscles; the loss of clinically significant function of the dually innervated pectoralis major is minimal and the functional gain of having the anterior arm muscles work is significant (Wellons et al 2009). Being able to bring the hand to the mouth and feed oneself is a task that most take for granted. In children with birth-related injuries to the upper brachial plexus (i.e. Erb's palsy), this movement is often the difference between waiting to be fed or feeding oneself. This method has been used at our institution for over 15 years with an $80 \%$ success rate, where success is measured as the patient regaining function of arm flexion.

Another example of what we have termed 'reverse translational research in anatomy' (i.e. from the bed to the bench and back) is the location of new anatomical diversionary sites (in this case, the medullary cavity of the ilium) that could be used in patients with cerebrospinal fluid absorption problems (i.e. hydrocephalus) and in whom the traditionally used receptacles for absorbing this diverted cerebrospinal fluid (e.g. peritoneal and pleural cavities, heart) are not options, as a consequence of e.g. malabsorption or local infection (Tubbs et al 2015) (Fig. 1.6.3). This alternative site has, for the first time, just been used and with success (unpublished data). Although not proven clinically, an earlier study in primates showed that the manubrium of the sternum could also be used as a distal receptacle for cerebrospinal fluid collection (Tubbs et al 2011). After tubing was tunnelled from the cannulated ventricle, the distal tubing was inserted subcutaneously into the superior aspect of the midline manubrium, where a small hole had been drilled. Up to 50 ml of saline per hour could be infused into the primate sternum without vital sign changes. This study, and the study using the ilium as a depository, both demonstrate the anatomical continuity between the bony medullary cavities and the vascular system. Such positive effects on patient outcomes not only make the study of human anatomy from a slanted perspective extremely gratifying, but are also practical since the results have direct application in the surgical theatre.

In addition to surgical anatomy playing a role in new uses of the normal anatomy, this field can also explore and direct new surgical approaches where the goals are to make surgery more effective and

Fig. 1.6.1 A schematic representation of the anatomically defined technique of using the accessory nerve for neurotization of the phrenic nerve with application to patients with high cervical quadriplegia who are ventilatordependent. With nerve regrowth, axons from the intact and functioning accessory nerve travel into the phrenic nerve to reinnervate this nerve and restore diaphragmatic function. In this example, only one-half of the accessory nerve is used in order to maintain some function of trapezius. (Drawn by Mr David Fisher.)

Fig. 1.6.2 The neurotization of the musculocutaneous nerve with the medial pectoral nerve (inset). Similar to the example illustrated in Figure 1.6.1, such a method of nerve repair is employed in the hope that a patient with an upper brachial plexus injury and anterior arm muscles that are dysfunctional can regain function by regrowth of axons from the intact medial pectoral nerve into and along the musculocutaneous nerve. (Drawn by Mr David Fisher.)
minimally invasive, and involve fewer complications. For example, we have performed feasibility studies looking at a wide range of novel approaches that might be used by the surgeon. These include a dorsal approach to the carpal tunnel for an entrapped median nerve (Tubbs et al 2005a); an anterior approach to the sciatic nerve potentially compressed by piriformis via the obturator foramen (Tubbs, unpublished data); an anterior approach to the upper thoracic vertebrae for spine fusion procedures (Tubbs et al 2010a); an intra-abdominal laparoscopic approach to decompress the pudendal nerve (Loukas et al 2008); and midline endoscopic approaches to the fourth ventricle with application to decompressing a 'trapped' fourth ventricle, as is seen in some cases of hydrocephalus (Tubbs et al 2004). We have also explored the feasibility in cadavers of using endoscopy for exploration of pathologies of the thecal sac (Chern et al 2011). In a series of children with intraspinal pathology (arachnoid cyst, spinal cord tumour, holocord syrinx and split cord malformation), intradural spinal endoscopy was a useful
treatment, resulted in a more limited laminectomy and myelotomy, and, in one case, assisted in identifying a residual spinal cord tumour. It was also useful in the fenestration of a multilevel spinal arachnoid cyst and in confirming communication of fluid spaces in the setting of a complex holocord syrinx. Endoscopy aided the visualization of the spinal cord to ensure the absence of tethering in the case of split spinal cord malformation. These endoscopic approaches were only possible by knowing the normal anatomy and how it appears in a confined field of view, as first seen in the anatomy laboratory.

Lastly, the anatomist can add to the relevance of anatomy for the surgeon with studies that have an impact on the identification or avoidance of important structures during operative manœuvres (i.e. anatomical landmark studies). My group has defined surgical landmarks for anatomical structures such as the superior and inferior gluteal nerves (Apaydin et al 2013, Apaydin et al 2009); vein of Labbé (Tubbs et al 2012); sigmoid sinus (Tubbs et al 2009a); amygdala (Tubbs et al

Fig. 1.6.3 The technique used in a patient with hydrocephalus to divert cerebrospinal fluid from the cerebral ventricles to the ilium. The enlarged ventricles are cannulated with a catheter connected to a subcutaneous valve that drains into tubing tunnelled under the skin and then implanted into the medullary cavity of the ilium; here, the cerebrospinal fluid is absorbed into the vascular system. The techniques described in Figures 1.6.2 and 1.6.3, based on surgical problems and manipulation of known anatomy for surgical benefit, were evaluated and studied in the anatomy laboratory, and have now been used clinically. (Drawn by Mr David Fisher.)

2010b); buccal branch of the trigeminal nerve (Tubbs et al 2010c); radial nerve and posterior interosseous branch (Cox et al 2010, Tubbs et al 2006a); perineal branch of the posterior femoral cutaneous nerve (Tubbs et al 2009b); lateral lacunae (Tubbs et al 2008b) (Fig. 1.6.4); basal vein of Rosenthal (Tubbs et al 2007); greater occipital nerve

Fig. 1.6.4 A superior view of the cranium, with the underlying superior sagittal sinus, cortical veins and lateral lacunae illustrated. This study explored the relationship between the underlying lateral lacunae and the overlying coronal and sagittal sutures, and made measurements between these structures. Neurosurgically, the initial placement of burr-holes avoids the midline in order to prevent damage to the superior sagittal sinus. However, the intracranial entrance of the drill often injures more laterally placed lacunae. Using surface anatomy based on anatomical landmarks, a neurosurgeon can be more aware of the locations of these underlying structures while performing craniotomies. Such landmarks have now been used by neurosurgeons at our institution. (Drawn by Mr David Fisher.)
(Loukas et al 2006); long thoracic nerve (Tubbs et al 2006b); anterior interosseous nerve (Tubbs et al 2006c); accessory nerve (Tubbs et al 2005b); lumbar plexus and its branches (Tubbs et al 2005c); trochlear nerve (Tubbs and Oakes 1998); and frontal sinus (Tubbs et al 2002). Such studies might assist in decreasing the morbidity and increasing the efficiency of surgical approaches and certainly illustrate the surgical relevance of anatomy. Moreover, this list exemplifies the multitude of anatomical structures that may be given greater surgical relevance by addressing how they may be more accurately located in the operating theatre.

In this day and age, if anatomists are not to lose their footing and simply be considered teachers of an old and outdated discipline, the onus is on us to renew interest in our field with timely and salient studies that gird the loins of a profession that is in danger of becoming extinct. It is my opinion, and that of others, that one effective way to achieve this is to remind the world by demonstrations such as those listed here that the study of anatomy is as clinically relevant today as it was at its humble beginnings. Considering the adage that anatomy is the oldest child of Mother Medicine, the fact that surgical problems and anatomical studies go hand in hand is obvious - anatomical research is not a 'dead' science! The modern relevance of anatomy to surgical practice and research must not be underestimated.

## ACKNOWLEDGEMENTS

Within individual figure captions, we have acknowledged all figures kindly loaned from other sources. However, we would particularly like to thank the following authors who have generously loaned so many figures from other books published by Elsevier:

Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010

Drake RL, Vogl AW, Mitchell A, Tibbitts R, Richardson P (eds), Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.
Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed. Elsevier, Urban \& Fischer. Copyright 2013.
Acknowledgements for paediatric anatomy content in chapter 45 to Ritchie Marcus, MD and Guirish A. Solanki, MD, Birmingham Children's Hospital, UK, and for chapter 81 to Christopher Edward Bache, MBChB, FRCS (Tr \& Orth), Birmingham, UK. The editors would like to thank all contributors and illustrators to the previous editions of Gray's Anatomy, including the fortieth and thirty-ninth editions. Much of the illustration in Gray's Anatomy has as its basis the work of illustrators and photographers who contributed towards earlier editions, their figures sometimes being retained almost unchanged, and sometimes being used as the foundation for figures that are new to this edition.

## CONTRIBUTORS TO THE FORTY-FIRST EDITION

The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

Michael A Adams BSc, PhD
Professor of Biomechanics
Centre for Comparative and Clinical Anatomy University of Bristol, UK

L Max Almond MB, ChB, MRCS, MD

## HISTORICAL INTRODUCTION

Gray's Anatomy is now on its way to being 160 years old. The book is a rarity in textbook publishing in having been in continuous publication on both sides of the Atlantic Ocean, since 1858. One and a half centuries is an exceptionally long era for a textbook. Of course, the volume now is very different from the one Mr Henry Gray first created with his colleague Dr Henry Vandyke Carter, in mid-Victorian London. In this introductory essay, I shall explain the long history of Gray's, from those Victorian days right up to today.

The shortcomings of existing anatomical textbooks probably impressed themselves on Henry Gray when he was still a student at St George's Hospital Medical School, near London's Hyde Park Corner, in the early 1840s. He began thinking about creating a new anatomy textbook a decade later, while war was being fought in the Crimea. New legislation was being planned that would establish the General Medical Council (1858) to regulate professional education and standards.

Gray was twenty-eight years old, and a teacher himself at St George's. He was very able, hard-working and highly ambitious, already a Fellow of the Royal Society, and of the Royal College of Surgeons. Although little is known about his personal life, his was a glittering career so far, achieved while he served and taught on the hospital wards and in the dissecting room (Fig. 1) (Anon 1908).

Gray shared the idea for the new book with a talented colleague on the teaching staff at St George's, Henry Vandyke Carter, in November 1855. Carter was from a family of Scarborough artists, and was himself a clever artist and microscopist. He had produced fine illustrations for Gray's scientific publications before, but could see that this idea was a much more complex project. Carter recorded in his diary:

Little to record. Gray made proposal to assist by drawings in bringing out a Manual for students: a good idea but did not come to any plan too exacting, for would not be a simple artist (Carter 1855).

Neither of these young men was interested in producing a pretty book, or an expensive one. Their purpose was to supply an affordable, accurate teaching aid for people like their own students, who might soon be

Fig. 1 Henry Gray (1827-1861) is shown here in the foreground, seated by the feet of the cadaver. The photograph was taken by a medical student, Joseph Langhorn. The room is the dissecting room of St George's Hospital Medical School in Kinnerton Street, London. Gray is shown surrounded by staff and students. When the photo was taken, on 27 March 1860, Carter had left St George's, to become Professor of Anatomy and Physiology at Grant Medical College, in Bombay (nowadays Mumbai). The second edition of Gray's Anatomy was in its proof stages, to appear in December 1860. Gray died just over a year later, in June 1861, at the height of his powers.
required to operate on real patients, or on soldiers injured at Sebastopol or some other battlefield. The book they planned together was a practical one, designed to encourage youngsters to study anatomy, help them pass exams, and assist them as budding surgeons. It was not simply an anatomy textbook, but a guide to dissecting procedure, and to the major operations.

Gray and Carter belonged to a generation of anatomists ready to infuse the study of human anatomy with a new, and respectable, scientificity. Disreputable aspects of the profession's history, acquired during the days of body-snatching, were assiduously being forgotten. The Anatomy Act of 1832 had legalized the requisition of unclaimed bodies from workhouse and hospital mortuaries, and the study of anatomy (now with its own Inspectorate) was rising in respectability in Britain. The private anatomy schools that had flourished in the Regency period were closing their doors, and the major teaching hospitals were erecting new, purpose-built dissection rooms (Richardson 2000).

The best-known student works when Gray and Carter had qualified were probably Erasmus Wilson's Anatomist's Vade Mecum, and Elements of Anatomy by Jones Quain. Both works were small - pocket-sized - but Quain came in two thick volumes. Both Quain's and Wilson's works were good books in their way, but their small pages of dense type, and even smaller illustrations, were somewhat daunting, seeming to demand much nose-to-the-grindstone effort from the reader.

The planned new textbook's dimensions and character were serious matters. Pocket manuals were commercially successful because they appealed to students by offering much knowledge in a small compass.

But pocket-sized books had button-sized illustrations. Knox's Manual of Human Anatomy, for example, was a good book, but was only 6 inches by $4(15 \times 10 \mathrm{~cm})$ and few of its illustrations occupied more than onethird of a page. Gray and Carter must have discussed this matter between themselves, and with Gray's publisher, JW Parker \& Son, before decisions were taken about the size and girth of the new book, and especially the size of its illustrations. While Gray and Carter were working on the book, a new edition of Quain's was published; this time it was a 'triple-decker' - in three volumes - of 1740 pages in all.

The two men were earnestly engaged for the following 18 months in work for the new book. Gray wrote the text, and Carter created the illustrations; all the dissections were undertaken jointly. Their working days were long - all the hours of daylight, eight or nine hours at a stretch - right through 1856, and well into 1857 . We can infer from the warmth of Gray's appreciation of Carter in his published acknowledgements that their collaboration was a happy one.
The Author gratefully acknowledges the great services he has derived in the execution of this work, from the assistance of his friend, Dr. H. V. Carter, late Demonstrator of Anatomy at St George's Hospital. All the drawings from which the engravings were made, were executed by him. (Gray 1858)
With all the dissections done, and Carter's inscribed wood-blocks at the engravers, Gray took six months' leave from his teaching at St George's to work as a personal doctor for a wealthy family. It was probably as good a way as any to get a well-earned break from the dissecting room and the dead-house (Nicol 2002).

Carter sat the examination for medical officers in the East India Company, and sailed for India in the spring of 1858, when the book was still in its proof stages. Gray had left a trusted colleague, Timothy Holmes, to see it through the press. Holmes's association with the first edition would later prove vital to its survival. Gray looked over the final galley proofs, just before the book finally went to press.

## THE FIRST EDITION

The book Gray and Carter had created together, Anatomy, Descriptive and Surgical, appeared at the very end of August 1858, to immediate
acclaim. Reviews in The Lancet and the British Medical Journal were highly complimentary, and students flocked to buy.

It is not difficult to understand why it was a runaway success. Gray's Anatomy knocked its competitors into a cocked hat. It was considerably smaller and more slender than the doorstopper with which modern readers are familiar. The book held well in the hand, it felt substantial, and it contained everything required. To contemporaries, it was small enough to be portable, but large enough for decent illustrations: 'royal octavo' - $91 / 2 \times 6$ inches $(24 \times 15 \mathrm{~cm})$ - about two-thirds of modern A4 size. Its medium-size, single-volume format was far removed from Quain, yet double the size of Knox's Manual.

Simply organized and well designed, the book explains itself confidently and well; the clarity and authority of the prose are manifest. But what made it unique for its day was the outstanding size and quality of the illustrations. Gray thanked the wood engravers Butterworth and Heath for the 'great care and fidelity' they had displayed in the engravings, but it was really to Carter that the book owed its extraordinary success.

The beauty of Carter's illustrations resides in their diagrammatic clarity, quite atypical for their time. The images in contemporary anatomy books were usually 'proxy-labelled': dotted with tiny numbers or letters (often hard to find or read) or bristling with a sheaf of numbered arrows, referring to a key situated elsewhere, usually in a footnote, which was sometimes so lengthy it wrapped round on to the following page. Proxy labels require the reader's eye to move to and fro: from the structure to the proxy label to the legend and back again. There was plenty of scope for slippage, annoyance and distraction. Carter's illustrations, by contrast, unify name and structure, enabling the eye to assimilate both at a glance. We are so familiar with Carter's images that it is hard to appreciate how incredibly modern they must have seemed in 1858. The volume made human anatomy look new, exciting, accessible and do-able

The first edition was covered in a brown bookbinder's cloth embossed all over in a dotted pattern, and with a double picture-frame border. Its spine was lettered in gold blocking:

## GRAY'S <br> ANATOMY

with 'DESCRIPTIVE AND SURGICAL' in small capitals underneath. Gray's Anatomy is how it has been referred to ever since. Carter was given credit with Gray on the book's title page for undertaking all the dissections on which the book was based, and sole credit for all the illustrations, though his name appeared in a significantly smaller type, and he was described as the 'Late Demonstrator in Anatomy at St George's Hospital' rather than being given his full current title, which was Professor of Anatomy and Physiology at Grant Medical College, Bombay. Gray was still only a Lecturer at St George's and he may have been aware that his words had been upstaged by the quality of Carter's anatomical images. He need not have worried: Gray is the famous name on the spine of the book.

Gray was paid $£ 150$ for every thousand copies sold. Carter never received a royalty payment, just a one-off fee at publication, which may have allowed him to purchase the long-wished-for microscope he took with him to India (Fig. 2).

The first edition print-run of 2000 copies sold out swiftly. A parallel edition was published in the United States in 1859, and Gray must have been deeply gratified to have to revise an enlarged new English edition in 1859-60, though he was surely saddened and worried by the death of his publisher, John Parker junior, at the young age of 40, while the book was going through the press. The second edition came out in the December of 1860 and it too sold like hot cakes, as indeed has every subsequent edition.

The following summer, in June 1861, at the height of his powers and full of promise, Henry Gray died unexpectedly at the age of only 34 Gray had contracted smallpox while nursing his nephew. A new strain of the disease was more virulent than the one with which Gray had been vaccinated as a child; the disease became confluent, and Gray died in a matter of days.

Within months, the whole country would be pitched into mourning for the death of Prince Albert. The creative era over which he had presided - especially the decade that had flowered since the Great Exhibition of 1851 - would be history.

## THE BOOK SURVIVES

Anatomy Descriptive and Surgical could have died too. With Carter in India, the death of Gray, so swiftly after that of the younger Parker, might have spelled catastrophe. Certainly, at St George's there was a

Fig. 2 Henry Vandyke Carter (1831-1897). Carter was appointed Honorary Surgeon to Queen Victoria in 1890.
sense of calamity. The grand old medical man Sir Benjamin Brodie, Sergeant-Surgeon to the Queen, and the great supporter of Gray to whom Anatomy had been dedicated, cried forlornly: 'Who is there to take his place?' (Anon 1908)

But old JW Parker ensured the survival of Gray's by inviting Timothy Holmes, the doctor who had helped proof-read the first edition, and who had filled Gray's shoes at the medical school, to serve as Editor for the next edition. Other long-running anatomy works, such as Quain, remained in print in a similar way, co-edited by other hands (Quain 1856).

Holmes (1825-1907) was another gifted St George's man, a scholarship boy who had won an exhibition to Cambridge, where his brilliance was recognized. Holmes was a Fellow of the Royal College of Surgeons at 28. John Parker junior had commissioned him to edit A System of Surgery (1860-64), an important essay series by distinguished surgeons on subjects of their own choosing. Many of Holmes's authors remain important figures, even today: John Simon, James Paget, Henry Gray, Ernest Hart, Jonathan Hutchinson, Brown-Séquard and Joseph Lister. Holmes had lost an eye in an operative accident, and he had a gruff manner that terrified students, yet he published a lament for young Parker that reveals him capable of deep feeling (Holmes 1860).

John Parker senior's heart, however, was no longer in publishing. His son's death had closed down the future for him. The business, with all its stocks and copyrights, was sold to Messrs Longman. Parker retired to the village of Farnham, where he later died.

With Holmes as editor, and Longman as publisher, the immediate future of Gray's Anatomy was assured. The third edition appeared in 1864 with relatively few changes, Gray's estate receiving the balance of his royalty after Holmes was paid $£ 100$ for his work.

## THE MISSING OBITUARY

Why no obituary appeared for Henry Gray in Gray's Anatomy is curious. Gray had referred to Holmes as his 'friend' in the preface to the first edition, yet it would also be true to say that they were rivals. Both had just applied for a vacant post at St George's, as Assistant Surgeon. Had Gray lived, it is thought that Holmes may not have been appointed, despite his seniority in age (Anon 1908).

Later commentators have suggested, as though from inside knowledge, that Holmes's 'proof-reading' included improving Gray's writing
style. This could be a reflection of Holmes's own self-regard, but there may be some truth in it. There can be no doubt that, as Editor of seven subsequent editions of Gray's Anatomy (third to ninth editions, 18641880), Holmes added new material, and had to correct and compress passages, but it is also possible that, back in 1857, Gray's original manuscript had been left in a poor state for Holmes to sort out. In other works, Gray's writing style was lucid, but he always seems to have paid a copyist to transcribe his work prior to submission. The original manuscript of Gray's Anatomy, sadly, has not survived, so it is impossible to be sure how much of the finished version had actually been written by Holmes.

It may be that Gray's glittering career, or perhaps the patronage that unquestionably advanced it, created jealousies among his colleagues, or that there was something in Gray's manner that precluded affection, or that created resentments among clever social inferiors like Carter and Holmes, especially if they felt their contributions to his brilliant career were not given adequate credit. Whatever the explanation, no reference to Gray's life or death appeared in Gray's Anatomy itself until the twentieth century (Howden et al 1918).

## A SUCCESSION OF EDITORS

Holmes expanded areas of the book that Gray himself had developed in the second edition (1860), notably in 'general' anatomy (histology) and 'development' (embryology). In Holmes's time as Editor, the volume grew from 788 pages in 1864 to 960 in 1880 (ninth edition), with the histological section paginated separately in roman numerals at the front of the book. Extra illustrations were added, mainly from other published sources.

The connections with Gray and Carter, and with St George's, were maintained with the appointment of the next editor, T. Pickering Pick, who had been a student at St George's in Gray's time. From 1883 (tenth edition) onwards, Pick kept up with current research, rewrote and integrated the histology and embryology into the volume, dropped Holmes from the title page, removed Gray's preface to the first edition, and added bold subheadings, which certainly improved the appearance and accessibility of the text. Pick said he had 'tried to keep before himself the fact that the work is intended for students of anatomy rather than for the Scientific Anatomist' (thirteenth edition, 1893).

Pick also introduced colour printing (in 1887, eleventh edition) and experimented with the addition of illustrations using the new printing method of half-tone dots: for colour (which worked) and for new black-and-white illustrations (which did not). Half-tone shades of grey compared poorly with Carter's wood engravings, still sharp and clear by comparison.

What Henry Vandyke Carter made of these changes is a rich topic for speculation. He returned to England in 1888, having retired from the Indian Medical Service, full of honours - Deputy Surgeon General, and in 1890, he was made Honorary Surgeon to Queen Victoria. Carter had continued researching throughout his clinical medical career in India, and became one of India's foremost bacteriologists/tropical disease specialists before there was really a name for either discipline. Carter made some important discoveries, including the fungal cause of mycetoma, which he described and named. He was also a key figure in confirming scientifically in India some major international discoveries, such as Hansen's discovery of the cause of leprosy, Koch's discovery of the organism causing tuberculosis, and Laveran's discovery of the organism that causes malaria. Carter married late in life, and his wife was left with two young children when he died in Scarborough in 1897, aged 65. Like Gray, he received no obituary in the book.

When Pick was joined on the title page by Robert Howden (a professional anatomist from the University of Durham) in 1901 (fifteenth edition), the volume was still easily recognizable as the book Gray and Carter had created. Although many of Carter's illustrations had been revised or replaced, many others still remained. Sadly, though, an entire section (embryology) was again separately paginated, as its revision had taken longer than anticipated. Gray's had grown, seemingly inexorably, and was now quite thick and heavy: 1244 pages, weighing 5 lb $8 \mathrm{oz} / 2.5 \mathrm{~kg}$. Both co-editors, and perhaps also its publisher, were dissatisfied with it.

## KEY EDITION: 1905

Serious decisions were taken well in advance of the next edition, which turned out to be Pick's last with Howden. Published 50 years after Gray had first suggested the idea to Carter, the 1905 (sixteenth) edition was a landmark one.

The period 1880-1930 was a difficult time for anatomical illustration, because the new techniques of photo-lithography and half-tone
were not as yet perfected, and in any case could not provide the bold simplicity of line required for a book like Gray's, which depended so heavily on clear illustration and clear lettering. Recognizing the inferiority of half-tone illustrations by comparison with Carter's wood-engraved originals, Pick and Howden courageously decided to jettison the second-rate half-tones altogether. Most of the next edition's illustrations were either Carter's, or old supplementary illustrations inspired by his work, or newly commissioned wood engravings or line drawings, intended 'to harmonize with Carter's original figures'. They successfully emulated Carter's verve. Having fewer pages and lighter paper, the 1905 (sixteenth edition) weighed less than its predecessor, at $4 \mathrm{lb} 11 \mathrm{oz} / 2.1 \mathrm{~kg}$. Typographically, the new edition was superb.

Howden took over as sole editor in 1909 (seventeenth edition) and immediately stamped his personality on Gray's. He excised 'Surgical' from the title, changing it to Anatomy Descriptive and Applied, and removed Carter's name altogether. He also instigated the beginnings of an editorial board of experts for Gray's, by adding to the title page 'Notes on Applied Anatomy' by AJ Jex-Blake and W Fedde Fedden, both St George's men. For the first time, the number of illustrations exceeded one thousand. Howden was responsible for the significant innovation of a short historical note on Henry Gray himself, nearly 60 years after his death, which included a portrait photograph (1918, twentieth edition).

## THE NOMENCLATURE CONTROVERSY

Howden's era, and that of his successor TB Johnston (of Guy's), was overshadowed by a cloud of international controversy concerning anatomical terminology. European anatomists were endeavouring to standardize anatomical terms, often using Latinate constructions, a move resisted in Britain and the United States. Gray's became mired in these debates for over 20 years. The attempt to be fair to all sides by using multiple terms doubtless generated much confusion amongst students, until a working compromise was at last arrived at in 1955 (thirty-second edition, 1958).

Johnston oversaw the second retitling of the book (in 1938, twentyseventh edition): it was now, officially, Gray's Anatomy, finally ending the fiction that it had ever been known as anything else. Gray's suffered from paper shortages and printing difficulties in World War II, but successive editions nevertheless continued to grow in size and weight, while illustrations were replaced and added as the text was revised.

Between Howden's first sole effort (1909, seventeenth edition) and Johnston's last edition (1958, thirty-second edition), Gray's expanded by over 300 pages - from 1296 to 1604 pages, and almost 300 additional illustrations brought the total to over 1300. Johnston also introduced X-ray plates (1938) and, in 1958 (thirty-second edition), electron micrographs by AS Fitton-Jackson, one of the first occasions on which a woman was credited with a contribution to Gray's. Johnston felt compelled to mention that she was 'a blood relative of Henry Gray himself', perhaps by way of mitigation.

## AFTER WORLD WAR II

The editions of Gray's issued in the decades immediately following the Second World War give the impression of intellectual stagnation. Steady expansion continued in an almost formulaic fashion, with the insertion of additional detail. The central historical importance of innovation in the success of Gray's seems to have been lost sight of by its publishers and editors - Johnston (1930-1958, twenty-fourth to thirty-second editions), J Whillis (co-editor with Johnston, 1938-1954), DV Davies (1958-1967, thirty-second to thirty-fourth editions) and F Davies (co-editor with DV Davies 1958-1962, thirty-second to thirty-third editions). Gray's had become so pre-eminent that perhaps complacency crept in, or editors were too daunted or too busy to confront the 'massive undertaking' of a root and branch revision (Tansey 1995). The unexpected deaths of three major figures associated with Gray's in this era, James Whillis, Francis Davies and David Vaughan Davies - each of whom had been ready to take the editorial reins - may have contributed to retarding the process. The work became somewhat dull.

## KEY EDITION: 1973

DV Davies had recognized the need for modernization, but his unexpected death left the work to other hands. Two Professors of Anatomy at Guy's, Roger Warwick and Peter Williams, the latter of whom had been involved as an indexer for Gray's for several years, regarded it as an honour to fulfill Davies's intentions.

Their thirty-fifth edition of 1973 was a significant departure from tradition. Over 780 pages (of 1471) were newly written, almost a third
of the illustrations were newly commissioned, and the illustration captions were freshly written throughout. With a complete re-typesetting of the text in larger double-column pages, a new index and the innovation of a bibliography, this edition of Gray's looked and felt quite unlike its 1967 (thirty-fourth edition) predecessor, and much more like its modern incarnation.

This 1973 edition departed from earlier volumes in other significant ways. The editors made explicit their intention to try to counter the impetus towards specialization and compartmentalization in twentiethcentury medicine, by embracing and attempting to reintegrate the complexity of the available knowledge. Warwick and Williams openly renounced the pose of omniscience adopted by many textbooks, believing it important to accept and mention areas of ignorance or uncertainty. They shared with the reader the difficulty of keeping abreast in the sea of research, and accepted with a refreshing humility the impossibility of fulfilling their own ambitious programme.

Warwick and Williams's 1973 edition had much in common with Gray and Carter's first edition. It was bold and innovative - respectful of its heritage, while also striking out into new territory. It was visually attractive and visually informative. It embodied a sense of a treasury of information laid out for the reader (Williams and Warwick 1973). It was published simultaneously in the United States (the American Gray's
had developed a distinct character of its own in the interval), and sold extremely well there (Williams and Warwick 1973).

The influence of the Warwick and Williams edition was forceful and long-lasting, and set a new pattern for the following quarter-century. As has transpired several times before, wittingly or unwittingly, a new editor was being prepared for the future: Dr Susan Standring (of Guy's), who created the new bibliography for the 1973 edition of Gray's, went on to serve on the editorial board, and has served as Editor-in-Chief for the last two editions before this one (2005-2008, thirty-ninth and fortieth editions). Both editions are important for different reasons.

For the thirty-ninth edition, the entire content of Gray's was reorganized, from systematic to regional anatomy. This great sea-change was not just organizational but historic, because, since its outset, Gray's had prioritized bodily systems, with subsidiary emphasis on how the systems interweave in the regions of the body. Professor Standring explained that this regional change of emphasis had long been asked for by readers and users of Gray's, and that new imaging techniques in our era have raised the clinical importance of local anatomy (Standring 2005). The change was facilitated by an enormous collective effort on the part of the editorial team and the illustrators. The subsequent and current editions consolidate that momentous change. (See Table 1.)

Table 1 Gray's Anatomy Editions

| Edition | Date | Author/Editor(s) | Publisher | Title |

## THE DOCTORS' BIBLE

Neither Gray nor Carter, the young men who - by their committed hard work between 1856 and 1858 - created the original Gray's Anatomy, would have conceived that so many years after their deaths their book would not only be a household name, but also be regarded as a work of such pre-eminent importance that a novelist half a world away would rank it as cardinal - alongside the Bible and Shakespeare - to a doctor's education (Sinclair Lewis 1925, Richardson 2008). From this forty-first edition of Gray's Anatomy, we can look back to appraise the long-term value of their efforts. We can discern how the book they created triumphed over its competitors, and has survived pre-eminent. Gray's is a remarkable publishing phenomenon. Although the volume now looks quite different to the original, and contains so much more, its kinship with the Gray's Anatomy of 1858 is easily demonstrable by direct descent, every edition updated by Henry Gray's successor. Works are rare indeed that have had such a long history of continuous publication on both sides of the Atlantic, and such a useful one.

Ruth Richardson, MA, DPhil, FRHistS Senior Visiting Research Fellow, Centre for Life-Writing Research, King's College London;
Affiliated Scholar in the History and Philosophy of Science, University of Cambridge, UK

## ACKNOWLEDGEMENTS

For their assistance while I was undertaking the research for this essay, I should like to thank the Librarians and Archivists and Staff at the British Library, Society of Apothecaries, London School of Hygiene and Tropical Medicine, Royal College of Surgeons, Royal Society of Medicine, St Bride Printing Library, St George's Hospital Tooting, Scarborough City Museum and Art Gallery, University of Reading, Wellcome Institute Library, Westminster City Archives and Windsor Castle; and the following individuals: Anne Bayliss, Gordon Bell, David Buchanan, Dee Cook, Arthur Credland, Chris Hamlin, Victoria Killick, Louise King, Keith Nicol, Sarah Potts, Mark Smalley, and Nallini Thevakarrunai. Above all, my thanks to Brian Hurwitz, who has read and advised on the evolving text.

## ANATOMICAL NOMENCLATURE

Anatomy is the study of the structure of the body. Conventionally, it is divided into topographical (macroscopic or gross) anatomy (which may be further divided into regional anatomy, surface anatomy, neuroanatomy, endoscopic and imaging anatomy); developmental anatomy (embryogenesis and subsequent organogenesis); and the anatomy of microscopic and submicroscopic structure (histology).

Anatomical language is one of the fundamental languages of medicine. The unambiguous description of thousands of structures is impossible without an extensive and often highly specialized vocabulary. Ideally, these terms, which are often derived from Latin or Greek, should be used to the exclusion of any other, and eponyms should be avoided. In reality, this does not always happen. Many terms are vernacularized and, around the world, synonyms and eponyms still abound in the literature, in medical undergraduate classrooms and in clinics. The Terminologia Anatomica, ${ }^{1}$ drawn up by the Federative Committee on Anatomical Terminology (FCAT) in 1998, continues to serve as our reference source for the terminology for macroscopic anatomy, and the text of the forty-first edition of Gray's Anatomy is almost entirely TA-compliant. However, where terminology is at variance with, or, more likely, is not included in, the TA, the alternative term used either is cited in the relevant consensus document or position paper, or enjoys widespread clinical usage. Synonyms and eponyms are given in parentheses on first usage of a preferred term and not shown thereafter in the text; an updated list of eponyms and short biographical details of the clinicians and anatomists whose names are used in this way is available in the e-book for reference purposes (see Preface, p. ix, for further discussion of the use of eponyms).

## PLANES, DIRECTIONS AND RELATIONSHIPS

To avoid ambiguity, all anatomical descriptions assume that the body is in the conventional 'anatomical position', i.e. standing erect and facing forwards, upper limbs by the side with the palms facing forwards, and lower limbs together with the toes facing forwards (Fig. 1). Descriptions are based on four imaginary planes - median, sagittal, coronal and horizontal - applied to a body in the anatomical position. The median plane passes longitudinally through the body and divides it into right and left halves. The sagittal plane is any vertical plane parallel
${ }^{1}$ Terminologia Anatomica (1998) is the joint creation of the Federative Committee on Anatomical Terminology (FCAT) and the Member Associations of the International Federation of Associations of Anatomists (IFAA).
with the median plane; although often employed, 'parasagittal' is therefore redundant and should not be used. The coronal (frontal) plane is orthogonal to the median plane and divides the body into anterior (front) and posterior (back). The horizontal (transverse) plane is orthogonal to both median and sagittal planes. Radiologists refer to transverse planes as (trans)axial; convention dictates that axial anatomy is viewed as though looking from the feet towards the head.

Structures nearer the head are superior, cranial or (sometimes) cephalic (cephalad), whereas structures closer to the feet are inferior; caudal is most often used in embryology to refer to the hind end of the embryo. Medial and lateral indicate closeness to the median plane, medial being closer than lateral; in the anatomical position, the little finger is medial to the thumb, and the great toe is medial to the little toe. Specialized terms may also be used to indicate medial and lateral. Thus, in the upper limb, ulnar and radial are used to mean medial and lateral, respectively; in the lower limb, tibial and fibular (peroneal) are used to mean medial and lateral, respectively. Terms may be based on embryological relationships; the border of the upper limb that includes the thumb, and the border of the lower limb that includes the great toe are the pre-axial borders, whilst the opposite borders are the post-axial borders. Various degrees of obliquity are acknowledged using compound terms, e.g. posterolateral.

When referring to structures in the trunk and upper limb, we have freely used the synonyms anterior, ventral, flexor, palmar and volar, and posterior, dorsal and extensor. We recognize that these synonyms are not always satisfactory, e.g. the extensor aspect of the leg is anterior with respect to the knee and ankle joints, and superior in the foot and digits; the plantar (flexor) aspect of the foot is inferior. Dorsal (dorsum) and ventral are terms used particularly by embryologists and neuroanatomists; they therefore feature most often in Sections 2 and 3

Distal and proximal are used particularly to describe structures in the limbs, taking the datum point as the attachment of the limb to the trunk (sometimes referred to as the root), such that a proximal structure is closer to the attachment of the limb than a distal structure. However, proximal and distal are also used in describing branching structures, e.g. bronchi, vessels and nerves. External (outer) and internal (inner) refer to the distance from the centre of an organ or cavity, e.g. the layers of the body wall, or the cortex and medulla of the kidney. Superficial and deep are used to describe the relationships between adjacent structures. Ipsilateral refers to the same side (of the body, organ or structure), bilateral to both sides, and contralateral to the opposite side.

Teeth are described using specific terms that indicate their relationship to their neighbours and to their position within the dental arch; these terms are described on page 517.

Fig. 1 The terminology widely used in descriptive anatomy. Abbreviations shown on arrows: $A D$, adduction; $A B$, abduction; FLEX, flexion (of the thigh at the hip joint); EXT, extension (of the leg at the knee joint).

## BIBLIOGRAPHY OF SELECTED TITLES

The following references contain information relevant to numerous chapters in this edition. They are therefore cited here rather than at the end of individual chapters. For an extended historical bibliography, all references from the thirty-eighth edition (which includes all references cited in earlier editions, up to and including the thirty-eighth edition) are available in the e-book that accompanies Gray's Anatomy.

## CHAPTER

## Basic structure and function of cells

## CELL STRUCTURE

## GENERAL CHARACTERISTICS OF CELLS

The shapes of mammalian cells vary widely depending on their interactions with each other, their extracellular environment and internal structures. Their surfaces are often highly folded when absorptive or transport functions take place across their boundaries. Cell size is limited by rates of diffusion, either that of material entering or leaving cells, or that of diffusion within them. Movement of macromolecules can be much accelerated and also directed by processes of active transport across the plasma membrane and by transport mechanisms within the cell. According to the location of absorptive or transport functions, apical microvilli (Fig. 1.1) or basolateral infoldings create a large surface area for transport or diffusion.

Motility is a characteristic of most cells, in the form of movements of cytoplasm or specific organelles from one part of the cell to another It also includes: the extension of parts of the cell surface such as pseudopodia, lamellipodia, filopodia and microvilli; locomotion of entire cells, as in the amoeboid migration of tissue macrophages; the beating of flagella or cilia to move the cell (e.g. in spermatozoa) or fluids overlying it (e.g. in respiratory epithelium); cell division; and muscle contraction. Cell movements are also involved in the uptake of materials from their environment (endocytosis, phagocytosis) and the passage of large molecular complexes out of cells (exocytosis, secretion).

Epithelial cells rarely operate independently of each other and commonly form aggregates by adhesion, often assisted by specialized intercellular junctions. They may also communicate with each other either by generating and detecting molecular signals that diffuse across intercellular spaces, or more rapidly by generating interactions between membrane-bound signalling molecules. Cohesive groups of cells constitute tissues, and more complex assemblies of tissues form functional systems or organs.

Most cells are between 5 and $50 \mu \mathrm{~m}$ in diameter: e.g. resting lymphocytes are $6 \mu \mathrm{~m}$ across, red blood cells $7.5 \mu \mathrm{~m}$ and columnar epithelial cells $20 \mu \mathrm{~m}$ tall and $10 \mu \mathrm{~m}$ wide (all measurements are approximate). Some cells are much larger than this: e.g. megakaryocytes of the bone marrow and osteoclasts of the remodelling bone are more than $200 \mu \mathrm{~m}$ in diameter. Neurones and skeletal muscle cells have relatively extended shapes, some of the former being over 1 m in length.

## CELLULAR ORGANIZATION

Each cell is contained within its limiting plasma membrane, which encloses the cytoplasm. All cells, except mature red blood cells, also contain a nucleus that is surrounded by a nuclear membrane or envelope (see Fig. 1.1; Fig. 1.2). The nucleus includes: the genome of the cell contained within the chromosomes; the nucleolus; and other subnuclear structures. The cytoplasm contains cytomembranes and several membrane-bound structures, called organelles, which form separate

Fig. 1.1 The main structural components and internal organization of a generalized cell.

Fig. 1.2 The structural organization and some principal organelles of a typical cell. This example is a ciliated columnar epithelial cell from human nasal mucosa. The central cell, which occupies most of the field of view, is closely apposed to its neighbours along their lateral plasma membranes. Within the apical junctional complex, these membranes form a tightly sealed zone (tight junction) that isolates underlying tissues from, in this instance, the nasal cavity. Abbreviations: AJC, apical junctional complex; APM, apical plasma membrane; C, cilia; Cy, cytoplasm; EN, euchromatic nucleus; LPM, lateral plasma membrane; M, mitochondria; MV, microvilli; N, nucleolus. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
and distinct compartments within the cytoplasm. Cytomembranes include the rough and smooth endoplasmic reticulum and Golgi apparatus, as well as vesicles derived from them. Organelles include lysosomes, peroxisomes and mitochondria. The nucleus and mitochondria are enclosed by a double-membrane system; lysosomes and peroxisomes have a single bounding membrane. There are also nonmembranous structures, called inclusions, which lie free in the cytosolic compartment. They include lipid droplets, glycogen aggregates and pigments (e.g. lipofuscin). In addition, ribosomes and several filamentous protein networks, known collectively as the cytoskeleton, are found in the cytosol. The cytoskeleton determines general cell shape and supports specialized extensions of the cell surface (microvilli, cilia, flagella). It is involved in the assembly of specific structures (e.g. centrioles) and controls cargo transport in the cytoplasm. The cytosol contains many soluble proteins, ions and metabolites.

## Plasma membrane

Cells are enclosed by a distinct plasma membrane, which shares features with the cytomembrane system that compartmentalizes the cytoplasm and surrounds the nucleus. All membranes are composed of lipids (mainly phospholipids, cholesterol and glycolipids) and proteins, in approximately equal ratios. Plasma membrane lipids form a lipid bilayer, a layer two molecules thick. The hydrophobic ends of each lipid molecule face the interior of the membrane and the hydrophilic ends face outwards. Most proteins are embedded within, or float in, the lipid bilayer as a fluid mosaic. Some proteins, because of extensive hydrophobic regions of their polypeptide chains, span the entire width of the membrane (transmembrane proteins), whereas others are only superficially attached to the bilayer by lipid groups. Both are integral (intrinsic) membrane proteins, as distinct from peripheral (extrinsic) membrane proteins, which are membrane-bound only through their association with other proteins. Carbohydrates in the form of oligosac-

Fig. 1.3 The molecular organization of the plasma membrane, according to the fluid mosaic model of membrane structure. Intrinsic or integral membrane proteins include diffusion or transport channel complexes, receptor proteins and adhesion molecules. These may span the thickness of the membrane (transmembrane proteins) and can have both extracellular and cytoplasmic domains. Transmembrane proteins have hydrophobic zones, which cross the phospholipid bilayer and allow the protein to 'float' in the plane of the membrane. Some proteins are restricted in their freedom of movement where their cytoplasmic domains are tethered to the cytoskeleton.
charides and polysaccharides are bound either to proteins (glycoproteins) or to lipids (glycolipids), and project mainly into the extracellular domain (Fig. 1.3).

In the electron microscope, membranes fixed and contrasted by heavy metals such as osmium tetroxide appear in section as two densely stained layers separated by an electron-translucent zone - the classic unit membrane. The total thickness of each layer is about 7.5 nm . The overall thickness of the plasma membrane is typically 15 nm . Freezefracture cleavage planes usually pass along the hydrophobic portion of the bilayer, where the hydrophobic tails of phospholipids meet, and split the bilayer into two leaflets. Each cleaved leaflet has a surface and a face. The surface of each leaflet faces either the extracellular surface (ES) or the intracellular or protoplasmic (cytoplasmic) surface (PS). The extracellular face (EF) and protoplasmic face (PF) of each leaflet are artificially produced during membrane splitting. This technique has also demonstrated intramembranous particles embedded in the lipid bilayer; in most cases, these represent large transmembrane protein molecules or complexes of proteins. Intramembranous particles are distributed asymmetrically between the two half-layers, usually adhering more to one half of the bilayer than to the other. In plasma membranes, the intracellular leaflet carries most particles, seen on its face (the PF). Where they have been identified, clusters of particles usually represent channels for the transmembrane passage of ions or molecules between adjacent cells (gap junctions).

Biophysical measurements show the lipid bilayer to be highly fluid, allowing diffusion in the plane of the membrane. Thus proteins are able to move freely in such planes unless anchored from within the cell. Membranes in general, and the plasma membrane in particular, form boundaries selectively limiting diffusion and creating physiologically distinct compartments. Lipid bilayers are impermeable to hydrophilic solutes and ions, and so membranes actively control the passage of ions and small organic molecules such as nutrients, through the activity of membrane transport proteins. However, lipid-soluble substances can pass directly through the membrane so that, for example, steroid hormones enter the cytoplasm freely. Their receptor proteins are either cytosolic or nuclear, rather than being located on the cell surface.

Plasma membranes are able to generate electrochemical gradients and potential differences by selective ion transport, and actively take up or export small molecules by energy-dependent processes. They also provide surfaces for the attachment of enzymes, sites for the receptors

Combinations of biochemical, biophysical and biological techniques have revealed that lipids are not homogenously distributed in membranes, but that some are organized into microdomains in the bilayer, called 'detergent-resistant membranes' or lipid 'rafts', rich in sphingomyelin and cholesterol. The ability of select subsets of proteins to partition into different lipid microdomains has profound effects on their function, e.g. in T-cell receptor and cell-cell signalling. The highly organized environment of the domains provides a signalling, trafficking and membrane fusion environment.
of external signals, including hormones and other ligands, and sites for the recognition and attachment of other cells. Internally, plasma membranes can act as points of attachment for intracellular structures, in particular those concerned with cell motility and other cytoskeletal functions. Cell membranes are synthesized by the rough endoplasmic reticulum in conjunction with the Golgi apparatus.

## Cell coat (glycocalyx)

The external surface of a plasma membrane differs structurally from internal membranes in that it possesses an external, fuzzy, carbohydraterich coat, the glycocalyx. The cell coat forms an integral part of the plasma membrane, projecting as a diffusely filamentous layer 2-20 nm or more from the lipoprotein surface. The cell coat is composed of the carbohydrate portions of glycoproteins and glycolipids embedded in the plasma membrane (see Fig. 1.3).

The precise composition of the glycocalyx varies with cell type; many tissue- and cell type-specific antigens are located in the coat, including the major histocompatibility complex of the immune system and, in the case of erythrocytes, blood group antigens. Therefore, the glycocalyx plays a significant role in organ transplant compatibility. The glycocalyx found on apical microvilli of enterocytes, the cells forming the lining epithelium of the intestine, consists of enzymes involved in the digestive process. Intestinal microvilli are cylindrical projections ( $1-2 \mu \mathrm{~m}$ long and about $0.1 \mu \mathrm{~m}$ in diameter) forming a closely packed layer called the brush border that increases the absorptive function of enterocytes.

## Cytoplasm

## Compartments and functional organization

The cytoplasm consists of the cytosol, a gel-like material enclosed by the cell or plasma membrane. The cytosol is made up of colloidal proteins such as enzymes, carbohydrates and small protein molecules, together with ribosomes and ribonucleic acids. The cytoplasm contains two cytomembrane systems, the endoplasmic reticulum and Golgi apparatus, as well as membrane-bound organelles (lysosomes, peroxisomes and mitochondria), membrane-free inclusions (lipid droplets, glycogen and pigments) and the cytoskeleton. The nuclear contents, the nucleoplasm, are separated from the cytoplasm by the nuclear envelope.

## Endoplasmic reticulum

The endoplasmic reticulum is a system of interconnecting membranelined channels within the cytoplasm (Fig. 1.4). These channels take various forms, including cisternae (flattened sacs), tubules and vesicles. The membranes divide the cytoplasm into two major compartments. The intramembranous compartment, or cisternal space, is where secretory products are stored or transported to the Golgi complex and cell exterior. The cisternal space is continuous with the perinuclear space.

Structurally, the channel system can be divided into rough or granular endoplasmic reticulum (RER), which has ribosomes attached to its outer, cytosolic surface, and smooth or agranular endoplasmic reticulum (SER), which lacks ribosomes. The functions of the endoplasmic reticulum vary greatly and include: the synthesis, folding and transport of proteins; synthesis and transport of phospholipids and steroids; and storage of calcium within the cisternal space and regulated release into the cytoplasm. In general, RER is well developed in cells that produce

Fig. 1.4 Smooth endoplasmic reticulum with associated vesicles. The dense particles are glycogen granules. (Courtesy of Rose Watson, Cancer Research UK.)
abundant proteins; SER is abundant in steroid-producing cells and muscle cells. A variant of the endoplasmic reticulum in muscle cells is the sarcoplasmic reticulum, involved in calcium storage and release for muscle contraction. For further reading on the endoplasmic reticulum, see Bravo et al (2013).

## Smooth endoplasmic reticulum

The smooth endoplasmic reticulum (see Fig. 1.4) is associated with carbohydrate metabolism and many other metabolic processes, including detoxification and synthesis of lipids, cholesterol and steroids. The membranes of the smooth endoplasmic reticulum serve as surfaces for the attachment of many enzyme systems, e.g. the enzyme cytochrome P450, which is involved in important detoxification mechanisms and is thus accessible to its substrates, which are generally lipophilic. The membranes also cooperate with the rough endoplasmic reticulum and the Golgi apparatus to synthesize new membranes; the protein, carbohydrate and lipid components are added in different structural compartments. The smooth endoplasmic reticulum in hepatocytes contains the enzyme glucose-6-phosphatase, which converts glucose-6phosphate to glucose, a step in gluconeogenesis.

## Rough endoplasmic reticulum

The rough endoplasmic reticulum is a site of protein synthesis; its cytosolic surface is studded with ribosomes (Fig. 1.5E). Ribosomes only bind to the endoplasmic reticulum when proteins targeted for secretion begin to be synthesized. Most proteins pass through its membranes and accumulate within its cisternae, although some integral membrane proteins, e.g. plasma membrane receptors, are inserted into the rough endoplasmic reticulum membrane, where they remain. After passage from the rough endoplasmic reticulum, proteins remain in membranebound cytoplasmic organelles such as lysosomes, become incorporated into new plasma membrane, or are secreted by the cell. Some carbohydrates are also synthesized by enzymes within the cavities of the rough endoplasmic reticulum and may be attached to newly formed protein (glycosylation). Vesicles are budded off from the rough endoplasmic reticulum for transport to the Golgi as part of the protein-targeting mechanism of the cell.

## Ribosomes, polyribosomes and protein synthesis

Ribosomes are macromolecular machines that catalyse the synthesis of proteins from amino acids; synthesis and assembly into subunits takes place in the nucleolus and includes the association of ribosomal RNA (rRNA) with ribosomal proteins translocated from their site of synthesis in the cytoplasm. The individual subunits are then transported into the cytoplasm, where they remain separate from each other when not actively synthesizing proteins. Ribosomes are granules approximately 25 nm in diameter, composed of rRNA molecules and proteins assembled into two unequal subunits. The subunits can be separated by their sedimentation coefficients (S) in an ultracentrifuge into larger 60S and smaller 40 S components. These are associated with 73 different proteins ( 40 in the large subunit and 33 in the small), which have structural and enzymatic functions. Three small, highly convoluted rRNA strands (28S, 5.8S and 5S) make up the large subunit, and one strand (18S) is in the small subunit.

A typical cell contains millions of ribosomes. They may form groups (polyribosomes or polysomes) attached to messenger RNA (mRNA), which they translate during protein synthesis for use outside the system of membrane compartments, e.g. enzymes of the cytosol and cytoskeletal proteins. Some of the cytosolic products include proteins that can be inserted directly into (or through) membranes of selected organelles, such as mitochondria and peroxisomes. Ribosomes may be attached to the membranes of the rough endoplasmic reticulum (see Fig. 1.5E).

In a mature polyribosome, all the attachment sites of the mRNA are occupied as ribosomes move along it, synthesizing protein according to its nucleotide sequence. Consequently, the number and spacing of ribosomes in a polyribosome indicate the length of the mRNA molecule and hence the size of the protein being made. The two subunits have separate roles in protein synthesis. The 40S subunit is the site of attachment and translation of mRNA. The 605 subunit is responsible for the release of the new protein and, where appropriate, attachment to the endoplasmic reticulum via an intermediate docking protein that directs the newly synthesized protein through the membrane into the cisternal space.

## Golgi apparatus (Golgi complex)

The Golgi apparatus is a distinct cytomembrane system located near the nucleus and the centrosome. It is particularly prominent in secretory cells and can be visualized when stained with silver or other metallic

The glycocalyx plays a significant role in maintenance of the integrity of tissues and in a wide range of dynamic cellular processes, e.g. serving as a vascular permeability barrier and transducing fluid shear stress to the endothelial cell cytoskeleton (Weinbaum et al 2007). Disruption of the glycocalyx on the endothelial surface of large blood vessels precedes inflammation, a conditioning factor of atheromatosis (e.g. deposits of cholesterol in the vascular wall leading to partial or complete obstruction of the vascular lumen).

Protein synthesis on ribosomes may be suppressed by a class of RNA molecules known as small interfering RNA (siRNA) or silencing RNA. These molecules are typically 20-25 nucleotides in length and bind (as a complex with proteins) to specific mRNA molecules via their complementary sequence. This triggers the enzymatic destruction of the mRNA or prevents the movement of ribosomes along it. Synthesis of the encoded protein is thus prevented. Their normal function may have antiviral or other protective effects; there is also potential for developing artificial siRNAs as a therapeutic tool for silencing disease-related genes.

Fig. 1.5 The Golgi apparatus and functionally related organelles. A, Golgi apparatus $(G)$ adjacent to the nucleus ( $N$ ) ( $V$, vesicle). salts．Traffic between the endoplasmic reticulum and the Golgi appara－ tus is bidirectional and takes place via carrier vesicles derived from the donor site that bud，tether and fuse with the target site．

Golgins are long coiled－coil proteins attached to the cytoplasmic surface of cisternal membranes，forming a fibrillar matrix surrounding the Golgi apparatus to stabilize it；they have a role in vesicle trafficking （for further reading on golgins，see Munro 2011）．The Golgi apparatus has several functions：it links anterograde and retrograde protein and lipid flow in the secretory pathway；it is the site where protein and lipid glycosylation occurs；and it provides membrane platforms to which signalling and sorting proteins bind．

Ultrastructurally，the Golgi apparatus（Fig．1．5A）displays a contin－ uous ribbon－like structure consisting of a stack of several flattened membranous cisternae，together with clusters of vesicles surrounding its surfaces．Cisternae differ in enzymatic content and activity．Small transport vesicles from the rough endoplasmic reticulum are received at one face of the Golgi stack，the convex cis－face（entry or forming surface）．Here，they deliver their contents to the first cisterna in the series by membrane fusion．From the edges of this cisterna，the protein is transported to the next cisterna by vesicular budding and then fusion，and this process is repeated across medial cisternae until the final cisterna at the concave trans－face（exit or condensing surface）is reached．Here，larger vesicles are formed for delivery to other parts of the cell．

The cis－Golgi and trans－Golgi membranous networks form an inte－ gral part of the Golgi apparatus．The cis－Golgi network is a region of complex membranous channels interposed between the rough endo－ plasmic reticulum and the Golgi cis－face，which receives and transmits vesicles in both directions．Its function is to select appropriate proteins synthesized on the rough endoplasmic reticulum for delivery by vesicles to the Golgi stack，while inappropriate proteins are shuttled back to the rough endoplasmic reticulum．

The trans－Golgi network，at the other side of the Golgi stack，is also a region of interconnected membrane channels engaged in protein sorting．Here，modified proteins processed in the Golgi cisternae are packaged selectively into vesicles and dispatched to different parts of the cell．The packaging depends on the detection，by the trans－Golgi network，of particular amino－acid signal sequences，leading to their enclosure in membranes of appropriate composition that will further modify their contents，e．g．by extracting water to concentrate them （vesicles entering the exocytosis pathway）or by pumping in protons to acidify their contents（lysosomes destined for the intracellular sorting pathway）．

Within the Golgi stack proper，proteins undergo a series of sequen－ tial chemical modifications by Golgi resident enzymes synthesized in the rough endoplasmic reticulum．These include：glycosylation （changes in glycosyl groups，e．g．removal of mannose，addition of N －acetylglucosamine and sialic acid）；sulphation（addition of sulphate groups to glycosaminoglycans）；and phosphorylation（addition of phosphate groups）．Some modifications serve as signals to direct pro－ teins and lipids to their final destination within cells，including lyso－ somes and plasma membrane．Lipids formed in the endoplasmic reticulum are also routed for incorporation into vesicles．

## Exocytic（secretory）pathway

Secreted proteins，lipids，glycoproteins，small molecules such as amines and other cellular products destined for export from the cell are trans－ ported to the plasma membrane in small vesicles released from the trans－face of the Golgi apparatus．This pathway either is constitutive，in which transport and secretion occur more or less continuously，as with immunoglobulins produced by plasma cells，or it is regulated by exter－ nal signals，as in the control of salivary secretion by autonomic neural stimulation．In regulated secretion，the secretory product is stored tem－ porarily in membrane－bound secretory granules or vesicles．Exocytosis is achieved by fusion of the secretory vesicular membrane with the plasma membrane and release of the vesicle contents into the extracel－ lular domain．In polarized cells，e．g．most epithelia，exocytosis occurs at the apical plasma membrane．Glandular epithelial cells secrete into a duct lumen，as in the pancreas，or on to a free surface，such as the lining of the stomach．In hepatocytes，bile is secreted across a very small area of plasma membrane forming the wall of the bile canaliculus．This region is defined as the apical plasma membrane and is the site of exocrine secretion，whereas secretion of hepatocyte plasma proteins into the blood stream is targeted to the basolateral surfaces facing the sinusoids．Packaging of different secretory products into appropriate vesicles takes place in the trans－Golgi network．Delivery of secretory vesicles to their correct plasma membrane domains is achieved by sorting sequences in the cytoplasmic tails of vesicular membrane proteins．

## Endocytic（internalization）pathway

The endocytic pathway begins at the plasma membrane and ends in lysosomes involved in the degradation of the endocytic cargo through the enzymatic activity of lysosomal hydrolases．Endocytic cargo is internalized from the plasma membrane to early endosomes and then to late endosomes．Late endosomes transport their cargo to lyso－ somes，where the cargo material is degraded following fusion and mixing of contents of endosomes and lysosomes．Early endosomes derive from endocytic vesicles（clathrin－coated vesicles and caveolae）． Once internalized，endocytic vesicles shed their coat of adaptin and clathrin，and fuse to form an early endosome，where the receptor molecules release their bound ligands．Membrane and receptors from the early endosomes can be recycled to the cell surface as exocytic vesicles．

Clathrin－dependent endocytosis occurs at specialized patches of plasma membrane called coated pits；this mechanism is also used to internalize ligands bound to surface receptor molecules and is also termed receptor－mediated endocytosis．Caveolae（little caves）are struc－ turally distinct pinocytotic vesicles most widely used by endothelial and smooth muscle cells，when they are involved in transcytosis，signal transduction and possibly other functions．In addition to late endo－ somes，lysosomes can also fuse with phagosomes，autophagosomes and plasma membrane patches for membrane repair．Lysosomal hydro－ lases process or degrade exogenous materials（phagocytosis or hetero－ phagy）as well as endogenous material（autophagy）．Phagocytosis consists of the cellular uptake of invading pathogens，apoptotic cells and other foreign material by specialized cells．Lysosomes are numerous in actively phagocytic cells，e．g．macrophages and neutrophil granulo－ cytes，in which lysosomes are responsible for destroying phagocytosed particles，e．g．bacteria．In these cells，the phagosome，a vesicle poten－ tially containing a pathogenic microorganism，may fuse with several lysosomes．

Autophagy involves the degradation and recycling within an autophagosome of cytoplasmic components that are no longer needed， including organelles．The assembly of the autophagosome involves several proteins，including autophagy－related（Atg）proteins，as well as Hsc70 chaperone，that translocate the substrate into the lysosome（Boya et al 2013）．Autophagosomes sequester cytoplasmic components and then fuse with lysosomes without the participation of a late endosome． The 26 S proteasome（see below）is also involved in cellular degradation but autophagy refers specifically to a lysosomal degradation－recycling pathway．Autophagosomes are seen in response to starvation and cell growth．

Late endosomes receive lysosomal enzymes from primary lysosomes derived from the Golgi apparatus after late endosome－lysosome mem－ brane tethering and fusion followed by diffusion of lysosomal contents into the endosomal lumen．The pH inside the fused hybrid organelle， now a secondary lysosome，is low（about 5．0）and this activates lyso－ somal acid hydrolases to degrade the endosomal contents．The products of hydrolysis either are passed through the membrane into the cytosol， or may be retained in the secondary lysosome．Secondary lysosomes may grow considerably in size by vesicle fusion to form multivesicular bodies，and the enzyme concentration may increase greatly to form large lysosomes（Fig．1．5B）．

## Lysosomes

Lysosomes are membrane－bound organelles $80-800 \mathrm{~nm}$ in diameter， often with complex inclusions of material undergoing hydrolysis（sec－ ondary lysosomes）．Two classes of proteins participate in lysosomal function：soluble acid hydrolases and integral lysosomal membrane proteins．Each of the 50 known acid hydrolases（including proteases， lipases，carbohydrases，esterases and nucleases）degrades a specific sub－ strate．There are about 25 lysosomal membrane proteins participating in the acidification of the lysosomal lumen，protein import from the cytosol，membrane fusion and transport of degradation products to the cytoplasm．Material that has been hydrolysed within secondary lyso－ somes may be completely degraded to soluble products，e．g．amino acids，which are recycled through metabolic pathways．However，degra－ dation is usually incomplete and some debris remains．A debris－laden vesicle is called a residual body or tertiary lysosome（see Fig．1．5B），and may be passed to the cell surface，where it is ejected by exocytosis； alternatively，it may persist inside the cell as an inert residual body． Considerable numbers of residual bodies can accumulate in long－lived cells，often fusing to form larger dense vacuoles with complex lamellar inclusions．As their contents are often darkly pigmented，this may change the colour of the tissue；e．g．in neurones，the end－product of lysosomal digestion，lipofuscin（neuromelanin or senility pigment）， gives ageing brains a brownish－yellow colouration．Lysosomal enzymes

Carrier vesicles in transit from the endoplasmic reticulum to the Golgi apparatus (anterograde transport) are coated by coat protein complex II (COPII), whereas COPI-containing vesicles function in the retrograde transport route from the Golgi apparatus (reviewed in Spang (2013)).

The membranes contain specific signal proteins that may allocate them to microtubule-based transport pathways and allow them to dock with appropriate targets elsewhere in the cell, e.g. the plasma membrane in the case of secretory vesicles. Vesicle formation and budding at the trans-Golgi network involves the addition of clathrin on their external surface, to form coated pits.

Specialized cells of the immune system, called antigen-presenting cells, degrade protein molecules, called antigens, transported by the endocytic pathway for lysosomal breakdown, and expose their fragments to the cell exterior to elicit an immune response mediated initially by helper T cells.
may also be secreted - often as part of a process to alter the extracellular matrix, as in osteoclast-mediated erosion during bone resorption. For further reading on lysosome biogenesis, see Saftig and Klumperman (2009).

## Lysosomal dysfunction

Lysosomal storage diseases (LSDs) are a consequence of lysosomal dysfunction. Approximately 60 different types of LSD have been identified on the basis of the type of material accumulated in cells (such as mucopolysaccharides, sphingolipids, glycoproteins, glycogen and lipofuscins). LSDs are characterized by severe neurodegeneration, mental decline, and cognitive and behavioural abnormalities. Autophagy impairment caused by defective lysosome-autophagosome coupling triggers a pathogenic cascade by the accumulation of substrates that contribute to neurodegenerative disorders including Parkinson's disease, Alzheimer's disease, Huntington's disease and several tau-opathies.

Many lysosomal storage diseases are known, e.g. Tay-Sachs disease (GM2 gangliosidosis), in which a faulty $\beta$-hexosaminidase A leads to the accumulation of the glycosphingolipid GM2 ganglioside in neurones, causing death during childhood. In Danon disease, a vacuolar skeletal myopathy and cardiomyopathy with neurodegeneration in hemizygous males, lysosomes fail to fuse with autophagosomes because of a mutation of the lysosomal membrane protein LAMP-2 (lysosomal associated membrane protein-2).

## 26S proteasome

A protein can be degraded by different mechanisms, depending on the cell type and different pathological conditions. Furthermore, the same substrate can engage different proteolytic pathways (Park and Cuervo 2013). Three major protein degradation mechanisms operate in eukaryotic cells to dispose of non-functional cellular proteins: the autophagosome-lysosomal pathway (see above); the apoptotic procaspase-caspase pathway (see below); and the ubiquitinated protein-26S proteasome pathway. The 26 S proteasome is a multicatalytic protease found in the cytosol and the nucleus that degrades intracellular proteins conjugated to a polyubiquitin chain by an enzymatic cascade. The 26 S proteasome consists of several subunits arranged into two 19S polar caps, where protein recognition and adenosine $5^{\prime}$ triphosphate (ATP)-dependent target processing occur, flanking a 20 S central barrel-shaped structure with an inner proteolytic chamber (Tomko and Hochstrasser 2013). The 26S proteasome participates in the removal of misfolded or abnormally assembled proteins, the degradation of cyclins involved in the control of the cell cycle, the processing and degradation of transcription regulators, cellular-mediated immune responses, and cell cycle arrest and apoptosis.

## Peroxisomes

Peroxisomes are small ( $0.2-1 \mu \mathrm{~m}$ in diameter) membrane-bound organelles present in most mammalian cells. They contain more than 50 enzymes responsible for multiple catabolic and synthetic biochemical pathways, in particular the $\beta$-oxidation of very-long-chain fatty acids ( $>$ C22) and the metabolism of hydrogen peroxide (hence the name peroxisome). Peroxisomes derive from the endoplasmic reticulum through the transfer of proteins from the endoplasmic reticulum to peroxisomes by vesicles that bud from specialized sites of the endoplasmic reticulum and by a lipid non-vesicular pathway. All matrix proteins and some peroxisomal membrane proteins are synthesized by cytosolic ribosomes and contain a peroxisome targeting signal that enables them to be imported by proteins called peroxins (Braverman et al 2013, Theodoulou et al 2013). Mature peroxisomes divide by small daughter peroxisomes pinching off from a large parental peroxisome.

Peroxisomes often contain crystalline inclusions composed mainly of high concentrations of the enzyme urate oxidase. Oxidases use molecular oxygen to oxidize specific organic substrates (such as L-amino acids, D -amino acids, urate, xanthine and very-long-chain fatty acids) and produce hydrogen peroxide that is detoxified (degraded) by peroxisomal catalase. Peroxisomes are particularly numerous in hepatocytes. Peroxisomes are important in the oxidative detoxification of various substances taken into or produced within cells, including ethanol. Peroxin mutation is a characteristic feature of Zellweger syndrome (craniofacial dysmorphism and malformations of brain, liver, eye and kidney; cerebrohepatorenal syndrome). Neonatal leukodystrophy is an X-linked peroxisomal disease affecting mostly males, caused by deficiency in $\beta$-oxidation of very-long-chain fatty acids. The build-up of very-long-chain fatty acids in the nervous system and suprarenal glands determines progressive deterioration of brain function and suprarenal insufficiency (Addison's disease). For further reading, see Braverman et al (2013).

B, The location of the elementary particles that couple oxidation and phosphorylation reactions. (A, Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

## Mitochondria

In the electron microscope, mitochondria usually appear as round or elliptical bodies $0.5-2.0 \mu \mathrm{~m}$ long (Fig. 1.6), consisting of an outer mitochondrial membrane; an inner mitochrondrial membrane, separated from the outer membrane by an intermembrane space; cristae, infoldings of the inner membrane that harbour ATP synthase to generate ATP; and the mitochondrial matrix, a space enclosed by the inner membrane and numerous cristae. The permeability of the two mitochondrial membranes differs considerably: the outer membrane is freely permeable to many substances because of the presence of large non-specific channels formed by proteins (porins), whereas the inner membrane is permeable to only a narrow range of molecules. The presence of cardiolipin, a phospholipid, in the inner membrane may contribute to this relative impermeability.

Mitochondria are the principal source of chemical energy in most cells. Mitochondria are the site of the citric acid (Krebs') cycle and the electron transport (cytochrome) pathway by which complex organic molecules are finally oxidized to carbon dioxide and water. This process provides the energy to drive the production of ATP from adenosine diphosphate (ADP) and inorganic phosphate (oxidative phosphorylation). The various enzymes of the citric acid cycle are located in the mitochondrial matrix, whereas those of the cytochrome system and oxidative phosphorylation are localized chiefly in the inner mitochondrial membrane.

The intermembrane space houses cytochrome $c$, a molecule involved in activation of apoptosis.

The number of mitochondria in a particular cell reflects its general energy requirements; e.g. in hepatocytes there may be as many as 2000, whereas in resting lymphocytes there are usually very few. Mature

The transcription factor EB (TFEB) is responsible for regulating lysosomal biogenesis and function, lysosome-to-nucleus signalling and lipid catabolism (for further reading, see Settembre et al (2013)). If any of the actions of lysosomal hydrolases, of the lysosome acidification mechanism or of lysosomal membrane proteins fails, the degradation and recycling of extracellular substrates delivered to lysosomes by the late endosome and the degradation and recycling of intracellular substrates by autophagy lead to progressive lysosomal dysfunction in several tissues and organs.

Experimentally, TFEB activation can reduce the accumulation of the pathogenic protein in a cellular model of Huntington's disease (a neurodegenerative genetic disorder that affects muscle coordination) and improves the Parkinson's disease phenotype in a murine model.

Cristae are abundant in mitochondria seen in cardiac muscle cells and in steroid-producing cells (in the suprarenal cortex, corpus luteum and Leydig cells). The protein steroidogenic acute regulatory protein (StAR) regulates the synthesis of steroids by transporting cholesterol across the outer mitochondrial membrane. A mutation in the gene encoding StAR causes defective suprarenal and gonadal steroidogenesis.
erythrocytes lack mitochondria altogether. Cells with few mitochondria generally rely largely on glycolysis for their energy supplies. These include some very active cells, e.g. fast twitch skeletal muscle fibres, which are able to work rapidly but for only a limited duration. Mitochondria appear in the light microscope as long, thin structures in the cytoplasm of most cells, particularly those with a high metabolic rate, e.g. secretory cells in exocrine glands. In living cells, mitochondria constantly change shape and intracellular position; they multiply by growth and fission, and may undergo fusion.

The mitochondrial matrix is an aqueous environment. It contains a variety of enzymes, and strands of mitochondrial DNA with the capacity for transcription and translation of a unique set of mitochondrial genes (mitochondrial mRNAs and transfer RNAs, mitochondrial ribosomes with rRNAs). The DNA forms a closed loop, about $5 \mu \mathrm{~m}$ across; several identical copies are present in each mitochondrion. The ratio between its bases differs from that of nuclear DNA, and the RNA sequences also differ in the precise genetic code used in protein synthesis. At least 13 respiratory chain enzymes of the matrix and inner membrane are encoded by the small number of genes along the mitochondrial DNA The great majority of mitochondrial proteins are encoded by nuclear genes and made in the cytosol, then inserted through special channels in the mitochondrial membranes to reach their destinations. Their membrane lipids are synthesized in the endoplasmic reticulum.

It has been shown that mitochondria are of maternal origin because the mitochondria of spermatozoa are not generally incorporated into the ovum at fertilization. Thus mitochondria (and mitochondrial genetic variations and mutations) are passed only through the female line.

Mitochondria are distributed within a cell according to regional energy requirements, e.g. near the bases of cilia in ciliated epithelia, in the basal domain of the cells of proximal convoluted tubules in the renal cortex (where considerable active transport occurs) and around the proximal segment, called middle piece, of the flagellum in spermatozoa. They may be involved with tissue-specific metabolic reactions, e.g. various urea-forming enzymes are found in liver cell mitochondria. Moreover, a number of genetic diseases of mitochondria affect particular tissues exclusively, e.g. mitochondrial myopathies (skeletal muscle) and mitochondrial neuropathies (nervous tissue). For further information on mitochondrial genetics and disorders, see Chinnery and Hudson (2013).

## Cytosolic inclusions

The aqueous cytosol surrounds the membranous organelles described above. It also contains various non-membranous inclusions, including free ribosomes, components of the cytoskeleton, and other inclusions, such as storage granules (e.g. glycogen), pigments (such as lipofuscin granules, remnants of the lipid oxidative mechanism seen in the suprarenal cortex) and lipid droplets.

## Lipid droplets

Lipid droplets are spherical bodies of various sizes found within many cells, but are especially prominent in the adipocytes (fat cells) of adipose connective tissue. They do not belong to the Golgi-related vacuolar system of the cell. They are not membrane-bound, but are droplets of lipid suspended in the cytosol and surrounded by perilipin proteins, which regulate lipid storage and lipolysis. See Smith and Ordovás (2012) for further reading on obesity and perilipins. In cells specialized for lipid storage, the vacuoles reach $80 \mu \mathrm{~m}$ or more in diameter. They function as stores of chemical energy, thermal insulators and mechanical shock absorbers in adipocytes. In many cells, they may represent end-products of other metabolic pathways, e.g. in steroid-synthesizing cells, where they are a prominent feature of the cytoplasm. They may also be secreted, as in the alveolar epithelium of the lactating breast.

## Transport across cell membranes

Lipid bilayers are increasingly impermeable to molecules as they increase in size or hydrophobicity. Transport mechanisms are therefore required to carry essential polar molecules, including ions, nutrients, nucleotides and metabolites of various kinds, across the plasma membrane and into or out of membrane-bound intracellular compartments. Transport is facilitated by a variety of membrane transport proteins, each with specificity for a particular class of molecule, e.g. sugars. Transport proteins fall mainly into two major classes: channel proteins and carrier proteins.

Channel proteins form aqueous pores in the membrane, which open and close under the regulation of intracellular signals, e.g. G-proteins, to allow the flux of solutes (usually inorganic ions) of specific size and charge. Transport through ion channels is always passive, and ion flow through an open channel depends only on the ion concentration gradi-
ent and its electronic charge, and the potential difference across the membrane. These factors combine to produce an electrochemical gradient, which governs ion flux. Channel proteins are utilized most effectively by the excitable plasma membranes of nerve cells, where the resting membrane potential can change transiently from about -80 mV (negative inside the cell) to +40 mV (positive inside the cell) when stimulated by a neurotransmitter (as a result of the opening and subsequent closure of channels selectively permeable to sodium and potassium).

Carrier proteins bind their specific solutes, such as amino acids, and transport them across the membrane through a series of conformational changes. This latter process is slower than ion transport through membrane channels. Transport by carrier proteins can occur either passively by simple diffusion, or actively against the electrochemical gradient of the solute. Active transport must therefore be coupled to a source of energy, such as ATP generation, or energy released by the coordinate movement of an ion down its electrochemical gradient. Linked transport can be in the same direction as the solute, in which case the carrier protein is described as a symporter, or in the opposite direction, when the carrier acts as an antiporter.

## Translocation of proteins across intracellular membranes

Proteins are generally synthesized on ribosomes in the cytosol or on the rough endoplasmic reticulum. A few are made on mitochondrial ribosomes. Once synthesized, many proteins remain in the cytosol, where they carry out their functions. Others, such as integral membrane proteins or proteins for secretion, are translocated across intracellular membranes for post-translational modification and targeting to their destinations. This is achieved by the signal sequence, an addressing system contained within the protein sequence of amino acids, which is recognized by receptors or translocators in the appropriate membrane. Proteins are thus sorted by their signal sequence (or set of sequences that become spatially grouped as a signal patch when the protein folds into its tertiary configuration), so that they are recognized by and enter the correct intracellular membrane compartment.

## Cell signalling

Cellular systems in the body communicate with each other to coordinate and integrate their functions. This occurs through a variety of processes known collectively as cell signalling, in which a signalling molecule produced by one cell is detected by another, almost always by means of a specific receptor protein molecule. The recipient cell transduces the signal, which it most often detects at the plasma membrane, into intracellular chemical messages that change cell behaviour.

The signal may act over a long distance, e.g. endocrine signalling through the release of hormones into the blood stream, or neuronal synaptic signalling via electrical impulse transmission along axons and subsequent release of chemical transmitters of the signal at synapses or neuromuscular junctions. A specialized variation of endocrine signalling (neurocrine or neuroendocrine signalling) occurs when neurones or paraneurones (e.g. chromaffin cells of the suprarenal medulla) secrete a hormone into interstitial fluid and the blood stream.

Alternatively, signalling may occur at short range through a paracrine mechanism, in which cells of one type release molecules into the interstitial fluid of the local environment, to be detected by nearby cells of a different type that express the specific receptor protein. Neurocrine cell signalling uses chemical messengers found also in the central nervous system, which may act in a paracrine manner via interstitial fluid or reach more distant target tissues via the blood stream. Cells may generate and respond to the same signal. This is autocrine signalling, a phenomenon that reinforces the coordinated activities of a group of like cells, which respond together to a high concentration of a local signalling molecule. The most extreme form of short-distance signalling is contact-dependent (juxtacrine) signalling, where one cell responds to transmembrane proteins of an adjacent cell that bind to surface receptors in the responding cell membrane. Contact-dependent signalling also includes cellular responses to integrins on the cell surface binding to elements of the extracellular matrix. Juxtacrine signalling is important during development and in immune responses. These different types of intercellular signalling mechanism are illustrated in Figure 1.7. For further reading on cell signalling pathways, see Kierszenbaum and Tres (2012).

## Signalling molecules and their receptors

The majority of signalling molecules (ligands) are hydrophilic and so cannot cross the plasma membrane of a recipient cell to effect changes

Mitochondrial ribosomes are smaller and quite distinct from those of the rest of the cell in that they (and mitochondrial nucleic acids) resemble those of bacteria. This similarity underpins the theory that mitochondrial ancestors were oxygen-utilizing bacteria that existed in a symbiotic relationship with eukaryotic cells unable to metabolize the oxygen produced by early plants. As mitochondria are formed only from previously existing ones, it follows that all mitochondria in the body are descended from those in the cytoplasm of the fertilized ovum.

Fig. 1.7 The different modes of cell-cell signalling.
inside the cell unless they first bind to a plasma membrane receptor protein. Ligands are mainly proteins (usually glycoproteins), polypeptides or highly charged biogenic amines. They include: classic peptide hormones of the endocrine system; cytokines, which are mainly of haemopoietic cell origin and involved in inflammatory responses and tissue remodelling (e.g. the interferons, interleukins, tumour necrosis factor, leukaemia inhibitory factor); and polypeptide growth factors (e.g. the epidermal growth factor superfamily, nerve growth factor, platelet-derived growth factor, the fibroblast growth factor family, transforming growth factor beta and the insulin-like growth factors). Polypeptide growth factors are multifunctional molecules with more widespread actions and cellular sources than their names suggest. They and their receptors are commonly mutated or aberrantly expressed in certain cancers. The cancer-causing gene variant is termed a transforming oncogene and the normal (wild-type) version of the gene is a cellular oncogene or proto-oncogene. The activated receptor acts as a transducer to generate intracellular signals, which are either small diffusible second messengers (e.g. calcium, cyclic adenosine monophosphate or the plasma membrane lipid-soluble diacylglycerol), or larger protein complexes that amplify and relay the signal to target control systems.

Some signals are hydrophobic and able to cross the plasma membrane freely. Classic examples are the steroid hormones, thyroid hormones, retinoids and vitamin D. Steroids, for instance, enter cells non-selectively, but elicit a specific response only in those target cells that express specific cytoplasmic or nuclear receptors. Light stimuli also cross the plasma membranes of photoreceptor cells and interact intracellularly, at least in rod cells, with membrane-bound photosensitive receptor proteins. Hydrophobic ligands are transported in the blood stream or interstitial fluids, generally bound to carrier proteins, and they often have a longer half-life and longer-lasting effects on their targets than do water-soluble ligands.

A separate group of signalling molecules able to cross the plasma membrane freely is typified by the gas, nitric oxide. The principal target of short-range nitric oxide signalling is smooth muscle, which relaxes in response. Nitric oxide is released from vascular endothelium as a result of the action of autonomic nerves that supply the vessel wall causing local relaxation of smooth muscle and dilation of vessels. This mechanism is responsible for penile erection. Nitric oxide is unusual

among signalling molecules in having no specific receptor protein; it acts directly on intracellular enzymes of the response pathway.

## Receptor proteins

There are some 20 different families of receptor proteins, each with several isoforms responding to different ligands. The great majority of these receptors are transmembrane proteins. Members of each family share structural features that indicate either shared ligand-binding characteristics in the extracellular domain or shared signal transduction properties in the cytoplasmic domain, or both. There is little relationship either between the nature of a ligand and the family of receptor proteins to which it binds and activates, or the signal transduction strategies by which an intracellular response is achieved. The same ligand may activate fundamentally different types of receptor in different cell types.

Cell surface receptor proteins are generally grouped according to their linkage to one of three intracellular systems: ion channel-linked receptors; G-protein coupled receptors; and receptors that link to enzyme systems. Other receptors do not fit neatly into any of these categories. All the known G-protein coupled receptors belong to a structural group of proteins that pass through the membrane seven times in a series of serpentine loops. These receptors are thus known as seven-pass transmembrane receptors or, because the transmembrane regions are formed from $\alpha$-helical domains, as seven-helix receptors. The best known of this large group of phylogenetically ancient receptors are the odorant-binding proteins of the olfactory system; the lightsensitive receptor protein, rhodopsin; and many of the receptors for clinically useful drugs. A comprehensive list of receptor proteins, their activating ligands and examples of the resultant biological function is given in Pollard and Earnshaw (2008).

## Intracellular signalling

A wide variety of small molecules carry signals within cells, conveying the signal from its source (e.g. activated plasma membrane receptor) to its target (e.g. the nucleus). These second messengers convey signals as fluctuations in local concentration, according to rates of synthesis and degradation by specific enzymes (e.g. cyclases involved in cyclic nucleotide (cAMP, cGMP) synthesis), or, in the case of calcium, according to the activities of calcium channels and pumps. Other, lipidic, second
messengers such as phosphatidylinositol, derive from membranes and may act within the membrane to generate downstream effects. For further consideration of the complexity of intracellular signalling pathways, see Pollard and Earnshaw (2008).

## Cytoskeleton

The cytoskeleton is a three-dimensional network of filamentous intracellular proteins of different shapes, sizes and composition distributed throughout the cytoplasm. It provides mechanical support, maintains cell shape and rigidity, and enables cells to adopt highly asymmetric or irregular profiles. It plays an important part in establishing structural polarity and different functional domains within a cell. It also provides mechanical support for permanent projections from the cell surface (see below), including persistent microvilli and cilia, and transient processes, such as the thin finger-like protrusions called filopodia (0.1$0.3 \mu \mathrm{~m}$ ) and lamellipodia ( $0.1-0.2 \mu \mathrm{~m}$ ). Filopodia consist of parallel bundles of actin filaments and have a role in cell migration, wound healing and neurite growth. The protrusive thin and broad lamellipodia, found at the leading edge of a motile cell, contain a branched network of actin filaments.

The cytoskeleton restricts specific structures to particular cellular locations. For example, the Golgi apparatus is near the nucleus and endoplasmic reticulum, and mitochondria are near sites of energy requirement. In addition, the cytoskeleton provides tracks for intracellular transport (e.g. shuttling vesicles and macromolecules, called cargoes, among cytoplasmic sites), the movement of chromosomes during cell division (mitosis and meiosis) or movement of the entire cell during embryonic morphogenesis or the chemotactic extravascular migration of leukocytes during homing. Examples of highly developed and specialized functions of the cytoskeleton include the contraction of the sarcomere in striated muscle cells and the bending of the axoneme of cilia and flagella.

The catalogue of cytoskeletal structural proteins is extensive and still increasing. The major filamentous structures found in non-muscle cells
are microfilaments ( 7 nm thick), microtubules ( 25 nm thick) and intermediate filaments ( 10 nm thick). Other important components are proteins that bind to the principal filamentous types to assemble or disassemble them, regulate their stability or generate movement. These include actin-binding proteins such as myosin, which in some cells can assemble into thick filaments, and microtubule-associated proteins. Pathologies involving cytoskeletal abnormalities include ciliopathies (resulting from the abnormal assembly and function of centrioles, basal bodies and cilia); neurodegenerative diseases (a consequence of defective anterograde transport of neurotransmitters along microtubules in axons); and sterility (determined by defective or absent microtubuleassociated dynein in axonemes, e.g. Kartagener's syndrome).

## Actin filaments (microfilaments)

Actin filaments are flexible filaments, 7 nm thick (Fig. 1.8). Within most cell types, actin constitutes the most abundant protein and in some motile cells its concentration may exceed $200 \mu \mathrm{M}(10 \mathrm{mg}$ protein per ml cytoplasm). The filaments are formed by the ATP-dependent polymerization of actin monomer (with a molecular mass of 43 kDa ) into a characteristic string of beads in which the subunits are arranged in a linear tight helix with a distance of 13 subunits between turns (Dominguez 2010). The polymerized filamentous form is termed F-actin (fibrillar actin) and the unpolymerized monomeric form is known as G-actin (globular actin). Each monomer has an asymmetric structure. When monomers polymerize, they confer a defined polarity on the filament: the plus or barbed end favours monomer addition, and the minus or pointed end favours monomer dissociation.

Treadmilling designates the simultaneous polymerization of an actin filament at one end and depolymerization at the other end to maintain its constant length.

See Bray (2001) for further reading.

## Actin-binding proteins

A wide variety of actin-binding proteins are capable of modulating the form of actin within the cell. These interactions are fundamental to the

Septins are emerging as a novel cytoskeletal member because of their filamentous organization and association with actin filaments and microtubules. They are guanosine triphosphate (GTP)-binding proteins that form hetero-oligomeric complexes (see Mostowy and Cossart (2012) for additional information).

This polarity can be visualized in negatively stained images by allowing F-actin to react with fragments containing the active head region of myosin. Myosins bind to filamentous actin at an angle to give the appearance of a series of arrowheads pointing towards the minus end of the filament, with the barbs pointing towards the plus end.

It involves the addition of ATP-bound G-actin monomers at the barbed end (fast-growing plus end) and removal of ADP-bound G-actin at the pointed end (slow-growing minus end). Actin filaments grow or shrink by addition or loss of G-actin monomer at both ends. Essentially, actin polymerization in vitro proceeds in three steps: nucleation (aggregation of G -actin monomers into a 3-4-monomer aggregate), elongation (addition of G -actin monomers to the aggregate) and a dynamic steady state (treadmilling). Specific toxins (e.g. cytochalasins, phalloidins and lantrunculins) bind to actin and affect its polymerization. Cytochalasin D blocks the addition of new G-actin monomers to the barbed end of F-actin; phalloidin binds to the interface between G-actin monomers in F-actin, thus preventing depolymerization; and lantrunculin binds to G -actin monomers, blocking their addition to an actin filament.

Fig. 1.9 The
cytoskeleton. A, An immunofluorescence micrograph of $\alpha$-actin microfilaments (green) in human airway smooth muscle cells in culture. The actin-binding protein, vinculin (red), is localized at the ends of actin filament bundles; nuclei are blue. B, An immunofluorescence micrograph of keratin intermediate filaments (green) in human keratinocytes in culture. Desmosome junctions are labelled with antibody against desmoplakin (red). Nuclei are stained blue (Hoechst). C, An electron micrograph of human nerve showing microtubules (small, hollow structures in cross-section, long arrow) in a transverse section of an unmyelinated axon (A), engulfed by a Schwann cell (S). Neuronal intermediate filaments (neurofilaments) are the solid, electron-dense profiles, also in transverse section (short arrow). C, Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
organization of cytoplasm and to cell shape. The actin cytoskeleton is organized as closely packed parallel arrays of actin filaments forming bundles or cables, or loosely packed criss-crossed actin filaments forming networks (Fig. 1.9A). Actin-binding proteins hold together bundles and networks of actin filaments. Actin-binding proteins can be grouped into G-actin (monomer) binding proteins and F-actin (polymer) capping, cross-linking and severing proteins. Actin-binding proteins may have more than one function.

Capping proteins bind to the ends of the actin filament either to stabilize an actin filament or to promote its disassembly (see Fig. 1.8).

Cross-linking or bundling proteins tie actin filaments together in longitudinal arrays to form bundles, cables or core structures. The bundles may be closely packed in microvilli and filopodia, where parallel filaments are tied tightly together to form stiff bundles orientated in the same direction. Cross-linking proteins of the microvillus actin bundle core include fimbrin and villin.

Other actin-bundling proteins form rather looser bundles of filaments that run antiparallel to each other with respect to their plus and minus ends. They include myosin II, which can form cross-links with ATP-dependent motor activity, and cause adjacent actin filaments to slide on each other in the striated muscle sarcomere, and either change the shape of cells or (if the actin bundles are anchored into the cell
membrane at both ends), maintain a degree of active rigidity. Filamin interconnects adjacent actin filaments to produce loose filamentous gel-like networks composed of randomly orientated F-actin.

F-actin can branch. The assembly of branched filamentous actin networks involves a complex of seven actin-related proteins $2 / 3$ (Arp2/3) that is structurally similar to the barbed end of actin.

See Rotty et al (2013) for further reading.
Branched actin generated by the Arp2/3 protein complex localizes at the leading edge of migrating cells, lamellipodia and phagosomes (required for the capture by endocytosis and phagocytosis of particles and foreign pathogens by immune cells). Formin can elongate preexisting actin filaments by removing capping proteins at the barbed end.

Other classes of actin-binding protein link the actin cytoskeleton to the plasma membrane either directly or indirectly through a variety of membrane-associated proteins. The latter may also create links via transmembrane proteins to the extracellular matrix. Best known of these is the family of spectrin-like molecules, which can bind to actin and also to each other and to various membrane-associated proteins to create supportive networks beneath the plasma membrane. Tetrameres of spectrin $\alpha$ and $\beta$ chains line the intracellular side of the plasma membrane of erythrocytes and maintain their integrity by their association with short actin filaments at either end of the tetramer.

Class V myosins are unconventional motor proteins transporting cargoes (such as vesicles and organelles) along actin filaments. Class I myosins are involved in membrane dynamics and actin organization at the cell cortex, thus affecting cell migration, endocytosis, pinocytosis and phagocytosis. Tropomyosin, an important regulatory protein of muscle fibres, is also present in non-muscle cells, where its function may be primarily to stabilize actin filaments against depolymerization.

## Myosins, the motor proteins

The myosin family of microfilaments is often classified within a distinct category of motor proteins. Myosin proteins have a globular head region consisting of a heavy and a light chain. The heavy chain bears an $\alpha$-helical tail of varying length. The head has an ATPase activity and can bind to and move along actin filaments - the basis for myosin function as a motor protein. The best-known class is myosin II, which occurs in muscle and in many non-muscle cells. Its molecules have two heads and two tails, intertwined to form a long rod. The rods can bind to each other to form long, thick filaments, as seen in striated and smooth muscle fibres and myoepithelial cells. Myosin II molecules can also assemble into smaller groups, especially dimers, which can crosslink individual actin microfilaments in stress fibres and other F-actin arrays. The ATP-dependent sliding of myosin on actin forms the basis for muscle contraction and the extension of microfilament bundles, as seen in cellular motility or in the contraction of the ring of actin and myosin around the cleavage furrow of dividing cells. There are a number of known subtypes of myosin II; they assemble in different ways and have different dynamic properties. In skeletal muscle the myosin molecules form bipolar filaments 15 nm thick. Because these filaments have a symmetric antiparallel arrangement of subunits, the midpoint is bare of head regions. In smooth muscle the molecules form thicker, flattened bundles and are orientated in random directions on either face of the bundle. These arrangements have important consequences for the contractile force characteristics of the different types of muscle cell.

Related molecules include the myosin I subfamily of single-headed molecules with tails of varying length. Functions of myosin I include the movements of membranes in endocytosis, filopodial formation in neuronal growth cones, actin-actin sliding and attachment of actin to membranes as seen in microvilli. As indicated above, molecular motors of the myosin V family are implicated in the movements of cargoes on actin filaments. So, for example, myosin Va transports vesicles along F-actin tracks in a similar manner to kinesin and cytoplasmic dyneinrelated cargo transport along microtubules. Each class of motor protein has different properties, but during cargo trafficking they often function together in a coordinated fashion. (See Hammer 3rd and Sellers (2012) for further reading on class $V$ myosins.)

## Other thin filaments

A heterogeneous group of filamentous structures with diameters of $2-4 \mathrm{~nm}$ occurs in various cells. The two most widely studied forms, titin and nebulin, constitute around $13 \%$ of the total protein of skeletal muscle. They are amongst the largest known molecules and have subunit weights of around $10^{6}$; native molecules are about $1 \mu \mathrm{~m}$ in length. Their repetitive bead-like structure gives them elastic properties that are important for the effective functioning of muscle, and possibly for other cells.

Profilin and thymosin $\beta 4$ are G-actin binding proteins. Profilin binds to G-actin bound to ATP; it inhibits addition of G-actin to the slowgrowing (pointed) end of F-actin but enables the fast-growing (barbed) end to grow faster and then dissociates from the actin filament. In addition, profilin participates in the conversion of ADP back to the ATP-Gactin bound form. Thymosin $\beta 4$ binds to the ATP-G-actin bound form, preventing polymerization by sequestering ATP-G-actin into a reserve pool.

Members of the F-actin capping protein family are heterodimers consisting of an $\alpha$ subunit ( $\mathrm{CP} \alpha$ ) and a $\beta$ subunit ( $\mathrm{CP} \beta$ ) that cap the barbed end of actin filaments within all eukaryotic cells. Gelsolin has a dual role: it severs F-actin and caps the newly formed barbed end, blocking further filament elongation.

Fascin is an additional cross-linking protein. Villin is also a severing protein, causing the disassembly of actin filaments and the collapse of the microvillus.

In the presence of activated nucleation promotion factors, such as Wiskott-Aldrich syndrome protein (WASP) and WASP family verprolinhomologous protein (WAVE, also known as SCAR), the Arp2/3 protein complex binds to the side of an existing actin filament (mother filament) and initiates the formation of a branching actin daughter filament at a $70^{\circ}$ angle relative to the mother filament utilizing G-actin delivered to the Arp2/3 complex site.

Spectrin-related molecules are present in many other cells. For instance, fodrin is found in neurones and dystrophin occurs in muscle cells, linking the contractile apparatus with the extracellular matrix via integral membrane proteins. Proteins such as ankyrin (which also binds actin directly), vinculin, talin, zyxin and paxillin connect actin-binding proteins to integral plasma membrane proteins such as integrins (directly or indirectly), and thence to focal adhesions (consisting of a bundle of actin filaments attached to a portion of a plasma membrane linked to the extracellular matrix).

## Microtubules

Microtubules are polymers of tubulin with the form of hollow, relatively rigid cylinders, approximately 25 nm in diameter and of varying length (up to $70 \mu \mathrm{~m}$ in spermatozoan flagella). They are present in most cell types, being particularly abundant in neurones, leukocytes and blood platelets. Microtubules are the predominant constituents of the mitotic spindles of dividing cells and also form part of the axoneme of cilia, flagella and centrioles.

Microtubules consist of tubulin dimers and microtubule-associated proteins. There are two major classes of tubulin: $\alpha$ - and $\beta$-tubulins. Before microtubule assembly, tubulins are associated as dimers with a combined molecular mass of 100 kDa ( 50 kDa each). Each protein subunit is approximately 5 nm across and is arranged along the long axis in straight rows of alternating $\alpha$ - and $\beta$-tubulins, forming protofilaments (see Fig. 1.8). Typically, 13 protofilaments (the number can vary between 11 and 16) associate in a ring to form the wall of a hollow cylindrical microtubule. Each longitudinal row is slightly out of alignment with its neighbour, so that a spiral pattern of alternating $\alpha$ and $\beta$ subunits appears when the microtubule is viewed from the side. There is a dynamic equilibrium between the dimers and assembled microtubules: dimeric asymmetry creates polarity ( $\alpha$-tubulins are all orientated towards the minus end, $\beta$-tubulins towards the plus end). Tubulin is added preferentially to the plus end; the minus end is relatively slowgrowing. Microtubules frequently grow and shrink at a rapid and constant rate, a phenomenon known as dynamic instability, in which growing tubules can undergo a 'catastrophe', abruptly shifting from net growth to rapid shrinkage. The primary determinant of whether microtubules grow or shrink is the rate of GTP hydrolysis. Tubulins are GTPbinding proteins; microtubule growth is accompanied by hydrolysis of GTP, which may regulate the dynamic behaviour of the tubules. Microtubule growth is initiated at specific sites, the microtubule-organizing centres, of which the best known are centrosomes (from which most cellular microtubules polymerize) and the centriole-derived basal bodies (from which cilia grow). Microtubule-organizing centres include a specialized tubulin isoform known as $\gamma$-tubulin that is essential for the nucleation of microtubule growth.

Various drugs (e.g. colcemid, vinblastine, griseofulvin, nocodazole) cause microtubule depolymerization by binding the soluble tubulin dimers and so shifting the equilibrium towards the unpolymerized state. Microtubule disassembly causes a wide variety of effects, including the inhibition of cell division by disruption of the mitotic spindle. Conversely, the drug paclitaxel (taxol) is a microtubule depolymerization inhibitor because it stabilizes microtubules and promotes abnormal microtubule assembly. Although this can cause a peripheral neuropathy, paclitaxel is widely used as an effective chemotherapeutic agent in the treatment of breast and ovarian cancer.

## Microtubule-associated proteins

Various proteins that can bind to assembled tubulins may be concerned with structural properties or associated with motility. One important class of microtubule-associated proteins (MAPs) consists of proteins that associate with the plus ends of microtubules. They regulate the dynamic instability of microtubules as well as interactions with other cellular substructures. Structural MAPs form cross-bridges between adjacent microtubules or between microtubules and other structures such as intermediate filaments, mitochondria and the plasma membrane. Microtubule-associated proteins found in neurones include: MAPs 1A and 1 B , which are present in neuronal dendrites and axons; MAPs 2 A and 2B, found chiefly in dendrites; and tau, found only in axons. MAP 4 is the major microtubule-associated protein in many other cell types. Structural microtubule-associated proteins are implicated in microtubule formation, maintenance and disassembly, and are therefore of considerable significance in cell morphogenesis, mitotic division, and the maintenance and modulation of cell shape. Transport-associated microtubule-associated proteins are found in situations in which movement occurs over the surfaces of microtubules, e.g. cargo transport, bending of cilia and flagella, and some movements of mitotic spindles They include a large family of motor proteins, the best known of which are the dyneins and kinesins. Another protein, dynamin, is involved in endocytosis. The kinetochore proteins assemble at the chromosomal centromere during mitosis and meiosis. They attach (and thus fasten chromosomes) to spindle microtubules; some of the kinetochore proteins are responsible for chromosomal movements in mitotic and meiotic anaphase.

All of these microtubule-associated proteins bind to microtubules and either actively slide along their surfaces or promote microtubule assembly or disassembly. Kinesins and dyneins can simultaneously attach to membranes such as transport vesicles and convey them along

Fig. 1.10 A duplicated pair of centrioles in a human carcinoma specimen. Each centriole pair consists of a mother and daughter, orientated approximately at right angles to each other so that one is sectioned transversely ( T ) and the other longitudinally (L). The transversely sectioned centrioles are seen as rings of microtubule triplets (arrow). (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
microtubules for considerable distances, thus enabling selective targeting of materials within the cell. Such movements occur in both directions along microtubules. Kinesin-dependent motion is usually towards the plus ends of microtubules, e.g. from the cell body towards the axon terminals in neurones, and away from the centrosome in other cells. Conversely, dynein-related movements are in the opposite direction, i.e. to the minus ends of microtubules. Dyneins also form the arms of peripheral microtubules in cilia and flagella, where they make dynamic cross-bridges to adjacent microtubule pairs. When these tethered dyneins try to move, the resulting shearing forces cause the axonemal array of microtubules to bend, generating ciliary and flagellar beating movements. Kinesins form a large and diverse family of related microtubule-stimulated ATPases. Some kinesins are motors that move cargo and others cause microtubule disassembly, whilst still others cross-link mitotic spindle microtubules to push the two centriolar poles apart during mitotic prophase. See Bray (2001) for further reading.

## Centrioles, centrosomes and basal bodies

Centrioles are microtubular cylinders $0.2 \mu \mathrm{~m}$ in diameter and $0.4 \mu \mathrm{~m}$ long (Fig. 1.10). They are formed by a ring of nine microtubule triplets linked by a number of other proteins. At least two centrioles occur in all animal cells that are capable of mitotic division (eggs, which undergo meiosis instead of mitosis, lack centrioles). See Gönczy (2012) for further reading on the structure and assembly of the centriole. They usually lie close together, at right angles or, most usually, at an oblique angle to each other (an arrangement often termed a diplosome), within the centrosome, a densely filamentous region of cytoplasm at the centre of the cell. The centrosome is the major microtubule-organizing centre of most cells; it is the site at which new microtubules are formed and the mitotic spindle is generated during cell division. Centriole biogenesis is a complex process. At the beginning of the S phase (DNA replication phase) of the cell cycle (see below), a new daughter centriole forms at right angles to each separated maternal centriole. Each motherdaughter pair forms one pole of the next mitotic spindle, and the daughter centriole becomes fully mature only as the progeny cells are about to enter the next mitosis. Because centrosomes are microtubuleorganizing centres, they lie at the centre of a network of microtubules, all of which have their minus ends proximal to the centrosome.

The microtubule-organizing centre contains complexes of $\gamma$-tubulin that nucleate microtubule polymerization at the minus ends of microtubules. Basal bodies are microtubule-organizing centres that are closely related to centrioles, and are believed to be derived from them. They are located at the bases of cilia and flagella, which they anchor to the cell surface. The outer microtubule doublets of the axoneme of cilia and flagella originate from two of the microtubules in each triplet of the basal body.

## Microtubule-based transport of cargoes

The transport of cargoes along microtubules via the motor proteins kinesin and cytoplasmic dynein respectively is the means by which neurotransmitters are delivered along axons to neuronal synapses

The association of membrane vesicles with dynein motors means that certain cytomembranes (including the Golgi apparatus) concentrate near the centrosome. This is convenient because the microtubules provide a means of targeting Golgi vesicular products to different parts of the cell.
(anterograde axonal transport) and membrane-bound vesicles are returned for recycling to the neuronal soma (retrograde axonal transport) (p. 45). In addition to anterograde and retrograde motor proteins, the assembly and maintenance of all cilia and flagella involve the participation of non-membrane-bound macromolecular protein complexes called intraflagellar transport (IFT) particles. IFT particles localize along the polarized microtubules of the axoneme, beneath the ciliary and flagellar membrane. IFT particles consist of two protein subcomplexes: IFT-A (with a role in returning cargoes from the tip of the axoneme to the cell body) and IFT-B (with a role in delivering cargoes from the cell body to the tip of the axoneme). For further reading, see Scholey (2008) and Hao and Scholey (2009).

During ciliogenesis, IFT requires the anterograde kinesin-2 motor and the retrograde IFT-dynein motor to transport IFT particles-cargo complexes in opposite directions along the microtubules, from the basal body to the tip of the ciliary axoneme and back again (intraciliary transport). IFT is not just restricted to microtubules of cilia and flagella. During spermatid development, IFT particles-motor protein-cargo complexes appear to utilize microtubules of the manchette, a transient microtubule-containing structure, to deliver tubulin dimers and other proteins by intramanchette transport during the development of the spermatid tail (Kierszenbaum et al 2011). IFT also occurs along the modified cilium of photoreceptor cells of the retina. Mutations in IFT proteins lead to the absence of cilia and are lethal during embryogenesis. Ciliopathies, many related to the defective sensory and/or mechanical function of cilia, include retinal degeneration, polycystic kidney disease, Bardet-Biedl syndrome, Jeune asphyxiating thoracic dystrophy, respiratory disease and defective determination of the left-right axis. The seven-protein complex designated BBSome (for Bardet-Biedl syndrome, an obesity/retinopathy ciliopathy) is a component of the basal body and participates in the formation of the primary cilium by regulating the export and/or import of ciliary proteins. The transport of the BBSome up and down and round about in cilia occurs in association with anterograde IFT-B and retrograde IFT-A particles. For further reading on the BBSome, see Jin and Nachury (2009). For further reading on ciliogenesis, see Baldari and Rosenbaum (2010).

## Intermediate filaments

Intermediate filaments are about 10 nm thick and are formed by a heterogeneous group of filamentous proteins. In contrast to actin filaments and microtubules, which are assembled from globular proteins with nucleotide-binding and hydrolysing activity, intermediate filaments consist of filamentous monomers lacking enzymatic activity. Intermediate filament proteins assemble to form linear filaments in a three-step process. First, a pair of intermediate filament protein subunits, each consisting of a central $\alpha$-helical rod domain of about 310 amino acids flanked by head and tail non- $\alpha$-helical domains of variable size, form a parallel dimer through their central $\alpha$-helical rod domains coiled around each other. The variability of intermediate filament protein subunits resides in the length and amino-acid sequence of the head and tail domains, thought to be involved in regulating the interaction of intermediate filaments with other proteins. Second, a tetrameric unit is formed by two antiparallel half-staggered coiled dimers. Third, eight tetramers associate laterally to form a 16 nm thick unit length filament (ULF). Individual ULFs join end to end to form short filaments that continue growing longitudinally by annealing to other ULFs and existing filaments. Filament elongation is followed by internal compaction leading to the 30 nm thick intermediate filament (see Fig. 1.8). The tight association of dimers, tetramers and ULFs provides intermediate filaments with high tensile strength and resistance to stretching, compression, twisting and bending forces. In contrast to actin filaments and microtubules, intermediate filaments are nonpolar (because of the antiparallel alignment of the initial tetramers) and do not bind nucleotides (as in G-actin and tubulin dimers), and ULFs anneal end to end to each other (in contrast to the polarized F-actin and microtubules, with one end, the plus end, growing faster than the other end, the minus end). See Herrmann et al (2007) for further reading.

Intermediate filaments are found in different cell types and are often present in large numbers, either to provide structural strength where it is needed (see Fig. 1.9B,C) or to provide scaffolding for the attachment of other structures. Intermediate filaments form extensive cytoplasmic networks extending from cage-like perinuclear arrangements to the cell surface. Intermediate filaments of different molecular classes are characteristic of particular tissues or states of maturity and are therefore important indicators of the origins of cells or degrees of differentiation, as well as being of considerable value in histopathology.

Intermediate filament proteins have been classified into five distinct types on the basis of their primary structure and tissue-specific expres-
sion. Of the different classes of intermediate filaments, keratin (cytokeratin) proteins are found in epithelia, where keratin filaments are always composed of equal ratios of type I (acidic) and type II (basic to neutral) keratins to form heteropolymers. About 20 types of each of the acidic and basic/neutral keratin proteins are known. For further reading on keratins in normal and diseased epithelia, see Pan et al (2012). Within the epidermis, expression of keratin heteropolymers changes as keratinocytes mature during their transition from basal to superficial layers. Genetic abnormalities of keratins are known to affect the mechanical stability of epithelia. For example, the disease epidermolysis bullosa simplex is caused by lysis of epidermal basal cells and blistering of the skin after mechanical trauma. Defects in genes encoding keratins 5 and 14 produce cytoskeletal instability leading to cellular fragility in the basal cells of the epidermis. When keratins 1 and 10 are affected, cells in the spinous (prickle) cell layer of the epidermis lyse, and this produces the intraepidermal blistering of epidermolytic hyperkeratosis. See Porter and Lane (2003) for further reading.

Type III intermediate filament proteins, including vimentin, desmin, glial fibrillary acidic protein and peripherin, form homopolymer intermediate filaments. Vimentin is expressed in mesenchyme-derived cells of connective tissue and some ectodermal cells during early development; desmins in muscle cells; glial fibrillary acidic protein in glial cells; and peripherin in peripheral axons. Type IV intermediate filaments include neurofilaments, nestin, syncoilin and $\alpha$-internexin. Neurofilaments are a major cytoskeletal element in neurones, particularly in axons (see Fig. 1.9C), where they are the dominant protein. Neurofilaments (NF) are heteropolymers of low (NF-L), medium (NF-M) and high (NF-H) molecular weight (the NF-L form is always present in combination with either NF-M or NF-H forms). Abnormal accumulations of neurofilaments (neurofibrillary tangles) are characteristic features of a number of neuropathological conditions. Nestin resembles a neurofilament protein, which forms intermediate filaments in neurectodermal stem cells in particular. The type V intermediate filament group includes the nuclear lamins A, lamin B1 and lamin B2 lining the inner surface of the nuclear envelope of all nucleated cells. Lamin C is a splice variant of lamin A. Lamins provide a mechanical framework for the nucleus and act as attachment sites for a number of proteins that organize chromatin at the periphery of the nucleus. They are unusual in that they form an irregular anastomosing network of filaments rather than linear bundles. See Burke and Stewart (2013) for further reading.

## Nucleus

The nucleus (see Figs 1.1-1.2) is generally the largest intracellular structure and is usually spherical or ellipsoid in shape, with a diameter of $3-10 \mu \mathrm{~m}$. Conventional histological stains, such as haematoxylin or toluidine blue, detect the acidic components (phosphate groups) of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) in cells and tissue sections. DNA and RNA molecules are said to be basophilic because of the binding affinity of their negatively charged phosphate groups to basic dyes such as haematoxylin. A specific stain for DNA is the Feulgen reaction.

## Nuclear envelope

The nucleus is surrounded by the nuclear envelope, which consists of an inner nuclear membrane (INM) and an outer nuclear membrane (ONM), separated by a $40-50 \mathrm{~nm}$ perinuclear space that is spanned by nuclear pore complexes (NPCs). The perinuclear space is continuous with the lumen of the endoplasmic reticulum. The ONM has multiple connections with the endoplasmic reticulum, with which it shares its membrane protein components. The INM contains its own specific integral membrane proteins (lamin B receptor and emerin, both providing binding sites for chromatin bridging proteins). A mutation in the gene encoding emerin causes X-linked Emery-Dreifuss muscular dystrophy (EDMD), characterized by skeletal muscle wasting and cardiomyopathy.

The nuclear lamina, a 15-20 nm thick, protein-dense meshwork, is associated with the inner face of the INM. The major components of the nuclear lamina are lamins, the type V intermediate filament proteins consisting of A-type and B-type classes.

The nuclear lamina reinforces the nuclear membrane mechanically, determines the shape of the nucleus and provides a binding site for a range of proteins that anchor chromatin to the cytoskeleton. Nuclear lamin A, with over 350 mutations, is the most mutated protein linked to human disease. These are referred to as laminopathies, characterized by nuclear structural abnormalities that cause structurally weakened nuclei, leading to mechanical damage. Lamin A mutations cause a

A-type lamins include lamin A (interacting with emerin), lamin C, lamin C2 and lamin A $\Delta 10$ encoded by a single gene (LMNA). Lamin A and lamin C are the major A-type lamins expressed in somatic cells, whereas lamin C 2 is expressed in testis. B-type lamins include lamin B1 and lamin B2 (expressed in somatic cells), and testis-specific lamin B3. Lamin B1 is encoded by the LMNB1 gene; lamin B2 is encoded by the LMNB2 gene.
surprisingly wide range of diseases, from progeria to various dystrophies, including an autosomal dominant form of EDMD. A truncated farnesylated form of lamin A, referred to as progerin, leads to defects in cell proliferation and DNA damage of mesenchymal stem cells and vascular smooth muscle cells. Affected patients display cardiovascular disease and die at an early age. Mice lacking lamin B1 and lamin B2 survive until birth; however, neuronal development is compromised when lamin B1 or lamin B2 is absent. Overexpression of lamin B1 is associated with autosomal dominant leukodystrophy characterized by gradual demyelination in the central nervous system. See Worman (2012) and Burke and Stewart (2013) for additional reading on lamins and laminopathies.

Condensed chromatin (heterochromatin) tends to aggregate near the nuclear envelope during interphase. At the end of mitotic and meiotic prophase (see below), the lamin filaments disassemble by phosphorylation, causing the nuclear membranes to vesiculate and disperse into the endoplasmic reticulum. During the final stages of mitosis (telophase), proteins of the nuclear periphery, including lamins, associate with the surface of the chromosomes, providing docking sites for membrane vesicles. Fusion of these vesicles reconstitutes the nuclear envelope, including the nuclear lamina, following lamin dephosphorylation. See Simon and Wilson (2011) for further reading on the nucleoskeleton.

The transport of molecules between the nucleus and the cytoplasm occurs via specialized nuclear pore structures that perforate the nuclear membrane (Fig. 1.11A). They act as highly selective directional molecular filters, permitting proteins such as histones and gene regulatory proteins (which are synthesized in the cytoplasm but function in the nucleus) to enter the nucleus, and molecules that are synthesized in the nucleus but destined for the cytoplasm (e.g. ribosomal subunits, transfer RNAs and messenger RNAs) to leave the nucleus.

Ultrastructurally, nuclear pores appear as disc-like structures with an outer diameter of 130 nm and an inner pore with an effective diameter for free diffusion of 9 nm (Fig. 1.11B). The nuclear envelope of an active cell contains up to 4000 such pores. The nuclear pore complex has an octagonal symmetry and is formed by an assembly of more than 50 proteins, the nucleoporins. The inner and outer nuclear membranes fuse around the pore complex (see Fig. 1.11A). Nuclear pores are freely

Fig. 1.11 A, The nuclear envelope with nuclear pores (arrows) in transverse section, showing the continuity between the inner and outer phospholipid layers of the envelope on either side of the pore. The fine 'membrane' appearing to span the pore is formed by proteins of the pore complex. Note that the chromatin is less condensed in the region of nuclear pores. Abbreviations: N, nucleus; C, cytoplasm. B, Nuclear pores seen 'en face' as spherical structures (arrows) in a tangential section through the nuclear envelope. The appearance of the envelope varies in electron density as the plane of section passes through different regions of the curved double membrane, which is interrupted at intervals by pores through the envelope (see also Fig. 1.1). The surrounding cytoplasm with ribosomes is less electron-dense. Human tissues. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
permeable to small molecules, ions and proteins up to about 17 kDa . See Raices and D'Angelo (2012) for further reading on nuclear pore complex composition. Most proteins that enter the nucleus do so as complexes with specific transport receptor proteins known as importins. Importins shuttle back and forth between the nucleus and cytoplasm. Binding of the cargo to the importin requires a short sequence of amino acids known as a nuclear localization sequence (NLS), and can either be direct or take place via an adapter protein. Interactions of the importin with components of the nuclear pore move it, together with its cargo, through the pore by an energy-independent process. A complementary cycle functions in export of proteins and RNA molecules from the nucleus to the cytoplasm using transport receptors known as exportins.

A small GTPase called Ras-related nuclear protein (Ran) regulates the import and export of proteins across the nuclear envelope.

For further reading on the Ran pathway and exportins/importins, see Clarke and Zhang (2008) and Raices and D'Angelo (2012).

## Chromatin

DNA is organized within the nucleus in a DNA-protein complex known as chromatin. The protein constituents of chromatin are the histones and the non-histone proteins. Non-histone proteins are an extremely heterogeneous group that includes structural proteins, DNA and RNA polymerases, and gene regulatory proteins. Histones are the most abundant group of proteins in chromatin, primarily responsible for the packaging of chromosomal DNA into its primary level of organization, the nucleosome. There are four core histone proteins - H2A, H2B, H3 and H 4 - which combine in equal ratios to form a compact octameric nucleosome core. A fifth histone, H1, is involved in further compaction of the chromatin. The DNA molecule (one per chromosome) winds twice around each nucleosome core, taking up 165 nucleotide pairs. This packaging organizes the DNA into a chromatin fibre 11 nm in diameter, and imparts to this form of chromatin the electron microscopic appearance of beads on a string, in which each bead is separated by a variable length of DNA, typically about 35 nucleotide pairs long. The nucleosome core region and one of the linker regions constitute the nucleosome proper, which is typically about 200 nucleotide pairs in length. However, chromatin rarely exists in this simple form and is usually packaged further into a 30 nm thick fibre, involving a single H1 histone per nucleosome, which interacts with both DNA and protein to impose a higher order of nucleosome packing. Usually, 30 nm thick fibres are further coiled or folded into larger domains. Individual domains are believed to decondense and extend during active transcription. In a typical interphase nucleus, euchromatin (nuclear regions that appear pale in appropriately stained tissue sections, or relatively electron-lucent in electron micrographs; see Fig. 1.2) is likely to consist mainly of 30 nm fibres and loops, and contains the transcriptionally active genes. Transcriptionally active cells, such as most neurones, have nuclei that are predominantly euchromatic. See Luger et al (2012) for further reading on the nucleosome and chromatin structure.

Heterochromatin (nuclear regions that appear dark in appropriately stained tissue sections or electron-dense in electron micrographs) is characteristically located mainly around the periphery of the nucleus, except over the nuclear pores (see Fig. 1.11A), and adjacent to the nucleolus (see Fig. 1.2). It is a relatively compacted form of chromatin in which the histone proteins carry a specific set of post-translational modifications, including methylation at characteristic residues. This facilitates the binding of specific heterochromatin-associated proteins. Heterochromatin includes non-coding regions of DNA, such as centromeric regions, which are known as constitutive heterochromatin. DNA becomes transcriptionally inactive in some cells as they differentiate during development or cell maturation, and contributes to heterochromatin; it is known as facultative heterochromatin. The inactive X chromosome in females is an example of facultative heterochromatin and can be identified in the light microscope as the deeply staining Barr body often located near the nuclear periphery or a drumstick extension of a nuclear lobe of a mature multilobed neutrophil leukocyte.

In transcriptionally inactive cells, chromatin is predominantly in the condensed, heterochromatic state, and may comprise as much as $90 \%$ of the total. Examples of such cells are mature neutrophil leukocytes (in which the condensed chromatin is present in a multilobular, densely staining nucleus) and the highly condensed nuclei of orthochromatic erythroblasts (late-stage erythrocyte precursors). In most mature cells, a mixture of the two occurs, indicating that only a proportion of the DNA is being transcribed. A particular instance of this is seen in the B lymphocyte-derived plasma cell, in which much of the chromatin is in the condensed condition and is arranged in regular masses around the perimeter of the nucleus, producing the so-called 'clock-face' nucleus (see Figs 4.6, 4.12). Although this cell is actively transcribing, much of
its protein synthesis is of a single immunoglobulin type, and consequently much of its genome is in an inactive state.

During mitosis, the chromatin is further reorganized and condensed to form the much-shortened chromosomes characteristic of metaphase. This shortening is achieved through further levels of close packing of the chromatin. The condensed chromosomes are stabilized by protein complexes known as condensins. Progressive folding of the chromosomal DNA by interactions with specific proteins can reduce 5 cm of chromosomal DNA by 10,000 -fold, to a length of $5 \mu \mathrm{~m}$ in the mitotic chromosome.

## Chromosomes and telomeres

The nuclear DNA of eukaryotic cells is organized into linear units called chromosomes. The DNA in a normal human diploid cell contains $6 \times 10^{9}$ nucleotide pairs organized in the form of 46 chromosomes (44 autosomes and 2 sex chromosomes). The largest human chromosome (number 1) contains $2.5 \times 10^{8}$ nucleotide pairs, and the smallest (the $Y$ chromosome) $5 \times 10^{7}$ nucleotide pairs.

Each chromosomal DNA molecule contains a number of specialized nucleotide sequences that are associated with its maintenance. One is the centromeric DNA region. During mitosis, a disc-shaped structure composed of a complex array of proteins, the kinetochore, forms as a substructure at the centromeric region of DNA to which kinetochore microtubules of the spindle attach. Another region, the telomere, defines the end of each chromosomal DNA molecule. Telomeres consist of hundreds of repeats of the nucleotide sequence (TTAGGG) ${ }_{n}$. The very ends of the chromosomes cannot be replicated by the same DNA polymerase as the rest of the chromosome, and are maintained by a specific enzyme called telomerase, which contains an RNA subunit acting as the template for lengthening the TTAGGG repeats. See Nandakumar and Cech (2013) for further reading on the recruitment of telomerase to telomeres. Thus telomerase is a specialized type of polymerase known as a reverse transcriptase that turns sequences in RNA back into DNA. The number of tandem repeats of the telomeric DNA sequence varies. The telomere appears to shorten with successive cell divisions because telomerase activity reduces or is absent in differentiated cells with a finite lifespan. In mammals, telomerase is active in the germ-cell lineage and in stem cells, but its expression in somatic cells may lead to or prompt cancer. A lack of telomere maintenance determines the shrinking of telomeres in proliferating cells to the point when cells stop dividing, a condition known as replicative senescence. See Sahin and DePinho (2012) for further reading on telomeres and progressive DNA damage.

The role of the telomere in ageing and cell senescence is further discussed at the end of this chapter.
Karyotypes: classification of human chromosomes
A number of genetic abnormalities can be directly related to the chromosomal pattern. The characterization or karyotyping of chromosome number and structure is therefore of considerable diagnostic importance. The identifying features of individual chromosomes are most
easily seen during metaphase, although prophase chromosomes can be used for more detailed analyses.

Lymphocytes separated from blood samples, or cells taken from other tissues, are used as a source of chromosomes. Diagnosis of fetal chromosome patterns is generally carried out on samples of amniotic fluid containing fetal cells aspirated from the uterus by amniocentesis, or on a small piece of chorionic villus tissue removed from the placenta. Whatever their origin, the cells are cultured in vitro and stimulated to divide by treatment with agents that stimulate cell division. Mitosis is interrupted at metaphase with spindle inhibitors. The chromosomes are dispersed by first causing the cells to swell in a hypotonic solution, then the cells are gently fixed and mechanically ruptured on a slide to spread the chromosomes. They are subsequently stained in various ways to allow the identification of individual chromosomes by size, shape and distribution of stain (Fig. 1.12). General techniques show the obvious landmarks, e.g. lengths of arms and positions of constrictions. Banding techniques demonstrate differential staining patterns, characteristic for each chromosome type. Fluorescence staining with quinacrine mustard and related compounds produces Q bands, and Giemsa staining (after treatment that partially denatures the chromatin) gives G bands (Fig. 1.12 A ). Other less widely used methods include: reverse Giemsa staining, in which the light and dark areas are reversed ( R bands); the staining of constitutive heterochromatin with silver salts (C-banding); and T-banding to stain the ends (telomeres) of chromosomes. Collectively, these methods permit the classification of chromosomes into numbered autosomal pairs in order of decreasing size, from 1 to 22, plus the sex chromosomes.

A summary of the major classes of chromosome is given in Table 1.1.

Methodological advances in banding techniques improved the recognition of abnormal chromosome patterns. The use of in situ hybridization with fluorescent DNA probes specific for each chromosome (Fig. 1.12B) permits the identification of even very small abnormalities.

## Nucleolus

Nucleoli are a prominent feature of an interphase nucleus (see Fig. 1.2). They are the site of most of the synthesis of ribosomal RNA (rRNA) and assembly of ribosome subunits. Nucleoli organize at the end of mitosis

Table 1.1 Summary of the major classes of chromosome

| Group | Features |
| :--- | :--- |
| $1-3$ (A) | Large metacentric chromosomes |
| $4-5$ (B) | Large submetacentric chromosomes |
| $6-12+X$ (C) | Metacentrics of medium size |
| $13-15$ (D) | Medium-sized acrocentrics with satellites |
| $16-18$ (E) | Shorter metacentrics (16) or submetacentrics $(17,18)$ |
| $19-20$ (F) | Shortest metacentrics |
| $21-22+Y(G)$ | Short acrocentrics; 21,22 with satellites, $Y$ without |

Fig. 1.12 Chromosomes from normal males, arranged as karyotypes. A, G-banded preparation. B, Preparation stained by multiplex fluorescence in situ hybridization to identify each chromosome. (Courtesy of Dr Denise Sheer, Cancer Research UK.)

Telomerase has been associated with ageing and cell senescence because a gradual loss of telomeres may lead to tissue atrophy, stem cell depletion and deficient tissue repair or regeneration. Mutations causing loss of function of telomerase or the RNA-containing template have been associated with dyskeratosis congenita (characterized by abnormal skin pigmentation, nail dystrophy and mucosal leukoplasia), aplastic anaemia and pulmonary fibrosis.
and consist of repeated clusters of ribosomal DNA (rDNA) genes and processing molecules responsible for producing ribosome subunits. The initial step of the assembly of a ribosome subunit starts with the transcription of rDNA genes by RNA polymerase I. The rDNA genes, arranged in tandem repeats called nucleolar organizing regions (NORs), are located on acrocentric chromosomes. There are five pairs of acrocentric chromosomes in humans. The initial 47S rRNA precursor transcript is cleaved to form the mature $28 \mathrm{~S}, 18 \mathrm{~S}$ and 5.8 S rRNAs, assembled with the 5 S rRNA (synthesized by RNA polymerase III outside the nucleolus) and coupled to small nucleolar ribonucleoproteins and other non-ribosomal proteins to form 60 S (containing 28 S rRNA, 5.8 S rRNA and 5 S rRNA) and 40 S (containing 18 S rRNA) preribosome subunits. These are then exported to the cytoplasm across nuclear pores as mature ribosome subunits. About 726 human nucleolar proteins have been identified by protein purification and mass spectrometry. For further reading on nucleolar functions, see Boisvert et al (2007).

Ribosomal biogenesis occurs in distinct subregions of the nucleolus, visualized by electron microscopy. The three nucleolar subregions are fibrillar centres (FCs), dense fibrillar components (DFCs) and granular components (GCs). Transcription of the rDNA repeats takes place at the FC-DFC boundary; pools of RNA polymerase I reside in the FC region; processing of transcripts and coupling to small nucleolar ribonucleoproteins take place in DFC; and the assembly of ribosome subunits is completed in the GC region.

The nucleolus is disassembled when cells enter mitosis and transcription becomes inactive. It reforms after nuclear envelope reorganization in telophase, in a process associated with the onset of transcription in nucleolar organizing centres on each specific chromosome, and becomes functional during the $\mathrm{G}_{1}$ phase of the cell cycle. An adequate pool of ribosome subunits during cell growth and cell division requires steady nucleolar activity to support protein synthesis. Several DNA helicases, a conserved group of enzymes that unwind DNA, accumulate in the nucleolus under specific conditions such as Bloom's syndrome (an autosomal recessive disorder characterized by growth deficiency, immunodeficiency and a predisposition to cancer) and Werner's syndrome (an autosomal recessive condition characterized by the early appearance of various age-related diseases).

## CELL DIVISION AND THE CELL CYCLE

During prenatal development, most cells undergo repeated division (see Video 1.1) as the body grows in size and complexity. As cells mature, they differentiate structurally and functionally. Some cells, such as neurones, lose the ability to divide. Others may persist throughout the lifetime of the individual as replication-competent stem cells, e.g. cells in the haemopoietic tissue of bone marrow. Many stem cells divide infrequently, but give rise to daughter cells that undergo repeated cycles of mitotic division as transit (or transient) amplifying cells. Their divisions may occur in rapid succession, as in cell lineages with a short lifespan and similarly fast turnover and replacement time. Transit amplifying cells are all destined to differentiate and ultimately to die and be replaced, unlike the population of parental stem cells, which self-renews.

Patterns and rates of cell division within tissues vary considerably. In many epithelia, such as the crypts between intestinal villi, the replacement of damaged or ageing cells by division of stem cells can be rapid. Rates of cell division may also vary according to demand, as occurs in the healing of wounded skin, in which cell proliferation increases to a peak and then returns to the normal replacement level. The rate of cell division is tightly coupled to the demand for growth and replacement. Where this coupling is faulty, tissues either fail to grow or replace their cells, or they can overgrow, producing neoplasms.

The cell cycle is an ordered sequence of events, culminating in cell growth and division to produce two daughter cells. It generally lasts a minimum of 12 hours, but in most adult tissues can be considerably longer, and is divided into four distinct phases, which are known as $\mathrm{G}_{1}$ (for gap 1), S (for DNA synthesis), $G_{2}$ (for gap 2) and $M$ (for mitosis). The combination of $G_{1}, S$ and $G_{2}$ phases is known as interphase. $M$ is the mitotic phase, which is further divided into four phases (see below). $G_{1}$ is the period when cells respond to growth factors directing the cell to initiate another cycle; once made, this decision is irreversible. It is also the phase in which most of the molecular machinery required to complete another cell cycle is generated. Centrosomes duplicate during S phase in preparation for mitosis. Cells that retain the capacity for proliferation, but which are no longer dividing, have entered a phase called $\mathrm{G}_{0}$ and are described as quiescent even though they may be quite active physiologically. Growth factors can stimulate quiescent cells to leave $\mathrm{G}_{0}$ and re-enter the cell cycle, whereas the proteins encoded by

Fig. 1.13 The cell cycle consists of an interphase ( $G_{1}$ phase, $S$ phase and $\mathrm{G}_{2}$ phase) followed by mitosis. The cyclin D/Cdk4 complex assembles at the beginning of $\mathrm{G}_{1}$; the cyclin $\mathrm{E} / \mathrm{Cdk} 2$ complex assembles near the end of $G_{1}$ as the cell is preparing to cross checkpoint 1 to start DNA synthesis (during S phase). The cyclin A/Cdk2 complex assembles as DNA synthesis starts. Completion of $G_{2}$ is indicated by the assembled cyclin $A /$ Cdk1 complex. A cell crosses checkpoint 2 to initiate mitosis when the cyclin B/Cdk1 complex assembles. The cyclin B/Cdk1 complex is degraded by the 26 S proteasome and an assembled cyclin D/Cdk4 marks the start of the $\mathrm{G}_{1}$ phase of a new cell cycle. For details, see text.
(Modified with permission from Kierszenbaum AL, Tres LL. Histology and Cell Biology: An Introduction to Pathology. 3rd ed, Philadelphia: Elsevier, Saunders; 2011.)
certain tumour suppressor genes (e.g. the gene mutated in retinoblastoma, $R b$ ) block the cycle in $\mathrm{G}_{1}$. DNA synthesis (replication of the genome) occurs during S phase, at the end of which the DNA content of the cell has doubled. During $\mathrm{G}_{2}$, the cell prepares for division; this period ends with the onset of chromosome condensation and breakdown of the nuclear envelope. The times taken for $S, G_{2}$ and $M$ are similar for most cell types, and occupy 6-8, 2-4 and 1-2 hours respectively. In contrast, the duration of $\mathrm{G}_{1}$ shows considerable variation, sometimes ranging from less than 2 hours in rapidly dividing cells to more than 100 hours, within the same tissue.

The passage of a cell through the cell cycle is controlled by proteins in the cytoplasm: cyclins and cyclin-dependent kinases (Cdks; Fig 1.13). Cyclins include $\mathrm{G}_{1}$ cyclins (D cyclins), S-phase cyclins (cyclins E and A) and mitotic cyclins (B cyclins). Cdks, protein kinases, which are activated by binding of a cyclin subunit, include $\mathrm{G}_{1} \mathrm{Cdk}(\mathrm{Cdk} 4)$, an S-phase Cdk (Cdk2) and an M-phase Cdk (Cdk1). Cell cycle progression is driven in part by changes in the activity of Cdks. Each cell cycle stage is characterized by the activity of one or more Cdk-cyclin pairs. Transitions between cell cycle stages are triggered by highly specific proteolysis by the 26 S proteasome of the cyclins and other key components.

To give one example, the transition from $G_{2}$ to mitosis is driven by activation of Cdk1 by its partners, the A- and B-type cyclins; the characteristic changes in cellular structure that occur as cells enter mitosis are largely driven by phosphorylation of proteins by active Cdk1-cyclin A and Cdk1-cyclin B. Cells exit from mitosis when an E3 ubiquitin ligase, the anaphase promoting complex, also called cyclosome (APC/C), marks the cyclins for destruction. In addition, APC/C prompts the degradation of the mitotic cyclin $B$ and the destruction of cohesins, thus allowing sister chromatids to separate.

There are important checkpoints in the cell cycle (see Fig. 1.13). Checkpoint 1 requires $G_{1}$ cyclins to bind to their corresponding Cdks to signal the cell to prepare for DNA synthesis. S-phase promoting factor (SPF; cyclin A bound to Cdk2) enters the nucleus to stimulate DNA synthesis. Checkpoint 2 requires M-phase promoting factor (mitotic cyclin B bound to M-phase Cdk1) to trigger the assembly of the mitotic spindle, breakdown of the nuclear envelope, arrest of gene transcription and condensation of chromosomes. During metaphase of mitosis, M-phase promoting factor activates APC/C, which determines the breakdown of cohesins, the protein complex holding sister chromatids together. Then, at anaphase, separated chromatids move to the opposite poles of the spindle. Finally, B cyclins are destroyed following

The targets for proteolysis are marked for destruction by E3 ubiquitin ligases, which decorate them with polymers of the small protein ubiquitin, a sign for recognition by the 26 S proteasome.
their attachment to ubiquitin, targeting them for destruction by the 26 S proteasome. As $\mathrm{G}_{1}$ starts, cyclins D, bound to Cdk4, start preparation for a new cell cycle.

Quality control checkpoint 2 operates to delay cell-cycle progression when DNA has been damaged by radiation or chemical mutagens. Cells with checkpoint defects, such as loss of the protein p53, which is a major negative control element in the division cycle of all cells, are commonly associated with the development of malignancy. An example is Li Fraumeni syndrome, where a defective p53 gene leads to a high frequency of cancer in affected individuals. In cells, p53 protein binds DNA and stimulates another gene to produce p21 protein, which interacts with Cdk2 to prevent S-phase promoting activity. When mutant p53 can no longer bind DNA to stimulate production of p21 to stop DNA synthesis, cells acquire oncogenic properties. The p53 gene is an example of a tumour suppressor gene. For further reading on p53 mutations and cancer, see Muller and Vousden (2013).

## Mitosis and meiosis

Mitosis is the process that results in the distribution of identical copies of the parent cell genome to the two daughter somatic cells. In meiosis, the divisions immediately before the final production of gametes halve the number of chromosomes to the haploid number, so that at fertilization the diploid number is restored. Moreover, meiosis includes a phase in which exchange of genetic material occurs between homologous chromosomes. This allows a rearrangement of genes to take place, which means that the daughter cells differ from the parental cell in both their precise genetic sequence and their haploid state. Mitosis and meiosis are alike in many respects, and differ principally in chromosomal behaviour during the early stages of cell division. In meiosis, two divisions occur in succession, without an intervening S phase. Meiosis I is distinct from mitosis, whereas meiosis II is more like mitosis.

## Mitosis

New DNA is synthesized during the S phase of the cell cycle interphase. This means that the amount of DNA in diploid cells has doubled to the tetraploid value by the onset of mitosis, although the chromosome number is still diploid. During mitosis, this amount is halved between the two daughter cells, so that DNA quantity and chromosome number are diploid in both cells. The cellular changes that achieve this distribution are conventionally divided into four phases called prophase, metaphase, anaphase and telophase (Figs 1.14-1.15, Video 1.1).

## Prophase

During prophase, the strands of chromatin, which are highly extended during interphase, shorten, thicken and resolve themselves into recognizable chromosomes. Each chromosome is made up of duplicate chromatids (the products of DNA replication) joined at their centromeres. Outside the nucleus, the two centriole pairs begin to separate, and move towards opposite poles of the cell. Parallel microtubules are assembled between them to create the mitotic spindle, and others radiate to form the microtubule asters, which come to form the spindle poles or mitotic centre. As prophase proceeds, the nucleoli disappear, and the nuclear envelope suddenly disintegrates to release the chromosomes, an event that marks the end of prophase.

## Prometaphase-metaphase

As the nuclear envelope disappears, the spindle microtubules extend into the central region of the cell, attaching to the chromosomes, which subsequently move towards the equator of the spindle (prometaphase). The spindle consists of kinetochore microtubules attached to the kinetochore, a multiprotein structure assembled at the centromeric DNA region, and polar microtubules, which are not attached to chromosomes but instead overlap with each other at the centre of the cell. The grouping of chromosomes at the spindle equator is called the metaphase or equatorial plate. The chromosomes, attached at their centromeres, appear to be arranged in a ring when viewed from either pole of the cell, or to lie linearly across this plane when viewed from above. Cytoplasmic movements during late metaphase effect the approximately equal distribution of mitochondria and other cell structures around the cell periphery.

## Anaphase

By the end of metaphase every chromosome consists of a pair of sister chromatids attached to opposing spindle poles by bundles of microtubules associated with the kinetochore. The onset of anaphase begins with the proteolytic cleavage by the enzyme separase of a key subunit of protein complexes known as cohesins. The latter hold the replicated sister chromatids together to resist separation even when exposed to

Fig. 1.14 The stages in mitosis, including the appearance and distribution of the chromosomes.
microtubule-dependent pulling forces. Proteolytic cleavage releases the cohesion between sister chromatids, which then move towards opposite spindle poles while the microtubule bundles attached to the kinetochores shorten and move polewards. At the end of anaphase the sister chromatids are grouped at either end of the cell, and both clusters are

Fig. 1.15

(Courtesy of Dr Herman Silljé, Max-PlanckInstitut für Biochemie, Martinsried, Germany.)
diploid in number. An infolding of the cell equator begins, deepening during telophase as the cleavage furrow.

## Telophase

During telophase the nuclear envelopes reform, beginning with the association of membranous vesicles with the surface of the chromosomes. Later, after the vesicles have fused and the nuclear envelope is complete, the chromosomes decondense and the nucleoli reform. At the same time, cytoplasmic division, which usually begins in early anaphase, continues until the new cells separate, each with its derived nucleus. The spindle remnant now disintegrates. While the cleavage furrow is active, a peripheral band or belt of actin and myosin appears in the constricting zone; contraction of this band is responsible for furrow formation.

Failure of disjunction of chromatids, so that sister chromatids pass to the same pole, may sometimes occur. Of the two new cells, one will have more, and the other fewer, chromosomes than the diploid number. Exposure to ionizing radiation promotes non-disjunction and may, by chromosomal damage, inhibit mitosis altogether. A typical symptom of radiation exposure is the failure of rapidly dividing epithelia to replace lost cells, with consequent ulceration of the skin and mucous membranes. Mitosis can also be disrupted by chemical agents, particularly vinblastine, paclitaxel (taxol) and their derivatives. These compounds either disassemble spindle microtubules or interfere with their dynamics, so that mitosis is arrested in metaphase.

## Meiosis

There are two consecutive cell divisions during meiosis: meiosis I and meiosis II (Fig. 1.16). Details of this process differ at a cellular level for male and female lineages.

## A Events preceding meiosis

## B Meiotic prophase

Fig. 1.16 The stages in meiosis, depicted by two pairs of maternal and paternal homologues (dark and pale colours). DNA and chromosome complement changes and exchange of genetic information between homologues are indicated.

## Meiosis I

## Prophase I

Meiotic prophase I is a long and complex phase that differs considerably from mitotic prophase and is customarily divided into five substages, called leptotene, zygotene, pachytene, diplotene and diakinesis. There are three distinctive features of male meiotic prophase that are not seen during mitotic prophase: the pairing, or synapse, of homologous chromosomes of paternal and maternal origin to form bivalent structures; the organization of nucleoli by autosomal bivalents; and significant non-ribosomal RNA synthesis by autosomal bivalents (in contrast to the transcriptional inactivity of the XY chromosomal pair) (see Tres 2005). In the female, meiotic prophase I starts during fetal gonadogenesis, is arrested at the diplotene stage and resumes at puberty. In the male, meiosis starts at puberty.

Leptotene stage During leptotene, homologous chromosomes (maternal and paternal copies of the same chromosome), replicated in a preceding $S$ phase and each consisting of sister chromatids joined at the centromere (see above), locate one another within the nucleus, and the process of genetic recombination is initiated. Cytologically, chromosomes begin to condense, appearing as individual threads that are attached via their telomeres to the nuclear envelope. They often show characteristic beading throughout their length.

Zygotene stage During zygotene, the homologous chromosomes initiate pairing or synapsis, during which they become intimately associated with one another. Synapsis may begin near the telomeres at the inner surface of the nuclear membrane, and during this stage the telomeres often cluster to one side of the nucleus (a stage known as the bouquet because the chromosomes resemble a bouquet of flowers). The pairs of synapsed homologues, also known as bivalents, are linked together by a tripartite ribbon, the synaptonemal complex, which consists of two lateral dense elements and a central, less dense, linear element.

The sex chromosomes also start to synapse during zygotene. In males, with distinct X and Y chromosomes, synapsis involves a region of shared DNA sequence known as the pseudoautosomal region. The XY bivalent adopts a special condensed structure, known as the sex vesicle, which becomes associated later at pachytene with migratory nucleolar masses originating in the autosomal bivalents.

Chromosome behaviour in meiosis is intimately linked with the process of genetic recombination. This begins during leptotene, as homologous chromosomes first locate one another at a distance. Synapsis, stabilized by the synaptonemal complex, facilitates recombination, as sites of genetic exchange are turned into specialized structures known as chiasmata, which are topological crossing-over points that hold homologous chromosomes together.

Pachytene stage When synapsis is complete for all chromosomes, the cell is said to be in pachytene. Each bivalent looks like a single thick structure, but is actually two pairs of sister chromatids held together by the synaptonemal complex. Genetic recombination between non-sister chromatids is completed at this point, with sites where it has occurred (usually one per chromosome arm) appearing as recombination nodules in the centre of the synaptonemal complex.

Diplotene stage During diplotene, the synaptonemal complex disassembles and pairs of homologous chromosomes, now much shortened, separate, except where crossing over has occurred (chiasmata). This process is called disjunction. At least one chiasma forms between each homologous pair, exchanging maternal and paternal sequences; up to five have been observed. In the ovaries, primary oocytes become diplotene by the fifth month in utero and each remains at this stage until the period before ovulation (up to 50 years).

Diakinesis Diakinesis is the prometaphase of the first meiotic division. The chromosomes, still as bivalents, become even shorter and thicker. They gradually attach to the spindle and become aligned at a metaphase plate. In eggs, the spindle forms without centrosomes. Microtubules first nucleate and are stabilized near the chromosomes; the action of various motor molecules eventually sorts them into a bipolar spindle. Perhaps surprisingly, this spindle is as efficient a machine for chromosome segregation as the spindle of mitotic cells with centrosomes at the poles.

## Metaphase I

Metaphase I resembles mitotic metaphase, except that the bodies attaching to the spindle microtubules are bivalents, not single chromosomes. These become arranged so that the homologous pairs occupy the
equatorial plane of the spindle. The centromeres of each pair of sister chromatids function as a single unit, facing a single spindle pole. Homologous chromosomes are pulled towards opposite spindle poles, but are held paired at the spindle midzone by chiasmata. Errors in chromosome segregation (known as non-disjunction) lead to the production of aneuploid progeny. Most human aneuploid embryos are non-viable and this is the major cause of fetal loss (spontaneous abortion), particularly during the first trimester of pregnancy in humans. The most common form of viable aneuploid progeny in humans is Down's syndrome (trisomy for chromosome 21), which exhibits a dramatic increase with maternal age.

## Anaphase and telophase I

Anaphase I of meiosis begins with the release of cohesion between the arms of sister chromatids, much as it does during mitosis. As positioning of bivalent pairs is random, assortment of maternal and paternal chromosomes in each telophase nucleus is also random. Critically, sister centromeres, and thus chromatids, do not separate during anaphase I.

During meiosis I, cytoplasmic division occurs by specialized mechanisms. In females, the division is highly asymmetric, producing one egg and one tiny cell known as a polar body. In males, the process results in production of spermatocytes that remain joined by small cytoplasmic bridges.

## Meiosis II

Meiosis II commences after only a short interval during which no DNA synthesis occurs. The centromeres of sister chromatids remain paired, but rotate so that each one can face an opposite spindle pole. Onset of anaphase II is triggered by loss of cohesion between the centromeres, as it is in mitosis. This second division is more like mitosis, in that chromatids separate during anaphase, but, unlike mitosis, the separating chromatids are genetically different (the result of genetic recombination). Cytoplasmic division also occurs and thus, in the male, four haploid cells, interconnected by cytoplasmic bridges, result from meiosis I and II.

## CELL POLARITY AND DOMAINS

Epithelia are organized into sheets or glandular structures with very different environments on either side. These cells actively transfer macromolecules and ions between the two surfaces and are thus polarized in structure and function. In polarized cells, particularly in epithelia, the cell is generally subdivided into domains that reflect the polarization of activities within it. The free surface, e.g. that facing the intestinal lumen or airway, is the apical surface, and its adjacent cytoplasm is the apical cell domain. This is where the cell interfaces with a specific body compartment (or, in the case of the epidermis, with the outside world). The apical surface is specialized to act as a barrier, restricting access of substances from this compartment to the rest of the body. Specific components are selectively absorbed from, or added to, the external compartment by the active processes, respectively, of active transport and endocytosis inwardly or exocytosis and secretion outwardly. The apical surface is often covered with small protrusions of the cell surface, microvilli, which increase the surface area, particularly for absorption.

The surface of the cell opposite to the apical surface is the basal surface, with its associated basolateral cell domain. In a single-layered epithelium, this surface faces the basal lamina. The remaining surfaces are known as the lateral cell surfaces. In many instances, the lateral and basal surfaces perform similar functions and the cellular domain is termed the basolateral domain. Cells actively transport substances, such as digested nutrients from the intestinal lumen or endocrine secretions, across their basal (or basolateral) surfaces into the subjacent connective tissue matrix and the blood capillaries within it. Dissolved non-polar gases (oxygen and carbon dioxide) diffuse freely between the cell and the blood stream across the basolateral surface. Apical and basolateral surfaces are separated by a tight intercellular seal, the tight junction (occluding junction, zonula adherens), which prevents the passage of even small ions through the space between adjacent cells and thus maintains the difference between environments on either side of the epithelium.

## Cell surface apical differentiations

The surfaces of many different types of cell are specialized to form
structures that project from the surface. These projections may permit
movement of the cell itself (flagella), or of fluids across the apical cell surface (cilia), or increase the surface area available for absorption (microvilli). Infoldings of the basolateral plasma membrane also increase the area for transport across this surface of the cell. In most non-dividing epithelial cells, the centriole-derived basal body gives rise to a non-motile primary cilium, which has an important mechanosensory role.

## Cilia and flagella

Cilia and flagella are motile, hair-like projections of the cell surface, which create currents in the surrounding fluid or movements of the cell to which they are attached, or both. There are two categories of cilia: single non-motile primary cilia and multiple motile cilia. Primary cilia are immotile but can detect physical and biochemical signals. Motile cilia are present in large numbers on the apical epithelial domain of the upper respiratory tract and oviducts, and beat in a wave-like motion to generate fluid movement. Cilia also occur, in modified form, at the dendritic endings of olfactory receptor cells, vestibular hair cells (kinocilium), and the photoreceptor rods and cones of the retina. Flagella, with a primary function in cell locomotion, are found on single-cell eukaryotes and in spermatozoa, which each possess a single flagellum $70 \mu \mathrm{~m}$ long.

A cilium or flagellum consists of a shaft ( $0.25 \mu \mathrm{~m}$ diameter) constituting most of its length, a tapering tip and a basal body at its base, which lies within the surface cytoplasm of the cell (Fig. 1.17). Other than at its base, the entire structure of the cilium is covered by plasma membrane. The core of the cilium is the axoneme, a cylinder of nine microtubule doublets that surrounds a central pair of single microtubules (see Fig. 1.17). Ciliogenesis of primary cilia and motile cilia involves distinct steps. A centriole-derived basal body migrates to the apical cell domain and axonemal microtubule doublets emerge from
its distal region, called the transition zone. The continued elongation of the cilium requires the import and intraciliary transport of tubulin dimers to the distal tip by bidirectional motor-driven proteins of the intraflagellar transport complex.

The constant length of cilia is maintained by a steady-state balance between tubulin turnover and addition of new tubulin dimers at the ciliary tip.

Several filamentous structures are associated with the $9+2$ doublet microtubule of the axoneme in the cilium or flagellum shaft, e.g. radial spokes extend inwards from the outer doublet microtubules towards the central pair, surrounded by an inner sheath (see Fig. 1.17). The outer doublet microtubules bear two rows of tangential dynein arms attached to the complete A subfibre of the doublet (consisting of 13 protofilaments), which point towards the incomplete B subfibre of the adjacent doublet (consisting of 10-11 protofilaments). Adjacent doublets are also linked by thin nexin filaments. Tektins are scaffolding filamentous proteins extending along the axonemal microtubules.

In motile cilia, arrays of dynein arms with ATPase activity cause outer microtubule doublets to move past one another, resulting in a largescale bending motion. Microtubules do not change in length. Movements of cilia and flagella are broadly similar. In addition to the axoneme, spermatozoan flagella have outer dense fibres and a fibrous sheath surrounding the axoneme. Flagella move by rapid undulation, which passes from the attached to the free end. In human spermatozoa, there is an additional helical component to this motion. In cilia, the beating is planar but asymmetric. In the effective stroke, the cilium remains stiff except at the base, where it bends to produce an oar-like stroke. The recovery stroke follows, during which the bend passes from base to tip, returning the cilium to its initial position for the next cycle. The activity of groups of cilia is usually coordinated so that the bending of one is rapidly followed by the bending of the next and so on,

Fig. 1.17 A, The structure of a cilium shown in longitudinal (left) and transverse (right) section. A and B are subfibres of the peripheral microtubule doublets (see text); the basal body is structurally similar to a centriole, but with microtubule triplets. B, The apical region of respiratory epithelial cells, showing the proximal parts of three cilia sectioned longitudinally, anchored into the cytoplasm by basal bodies (BB). Other cilia project out of the plane of section and are cut transversely, showing the ' $9+2$ ' arrangement of microtubules. (B, With permission from Young B, Heath JW. Wheater's Functional Histology. 4th ed. Edinburgh: Elsevier, Churchill Livingstone; 2000.)

As indicated on page 15, the IFT-B protein complex participates in intraciliary/intraflagellar anterograde transport of cargoes, a step essential for the assembly and maintenance of cilia and flagella; the IFT-A protein complex is required for retrograde transport of cargoes to the cell body for turnover. The movement of IFT proteins along microtubules is catalysed by kinesin-2 (towards the ciliary tip; anterograde direction) and cytoplasmic dynein-2 motor proteins (towards the cell body; retrograde direction). A cargo includes axonemal components, ciliary/flagellar membrane proteins (including the BBSome) and ciliary signal transduction proteins.
resulting in long travelling waves of metachronal synchrony. These pass over the tissue surface in the same direction as the effective stroke. Ciliary motion is important in clearing mucus from airways, moving eggs along oviducts, and circulating cerebrospinal fluid in brain ventricles. In the node of the developing embryo, cilium-driven flow is essential for determining left-right visceral asymmetry (developing patterning). Cilia also have a sensory function, determined by the presence of receptor and channel proteins on the ciliary membrane. Primary cilia in the collecting ducts of the uriniferous tubule sense the flow of urine and also modulate duct morphogenesis. Cilia are essential for signalling through the hedgehog pathway, a mechanism involved in organizing the body plan, organogenesis and tumorigenesis in vertebrates. For additional reading on hedgehog signalling and primary cilia, see Briscoe and Thérond (2013).

There is a group of genetic diseases in which cilia beat either ineffectively or not at all, e.g. Kartagener's immotile cilia syndrome. Affected cilia exhibit deficient function or a lack of dynein arms. Males are typically sterile because of the loss of spermatozoan motility, and half have an alimentary tract that is a mirror image of the usual pattern (situs inversus), i.e. it rotates in the opposite direction during early development. Defects in ciliary motility disrupt airway mucus clearance, leading to chronic sinusitis and bronchiectasis. Defects in sensory cilia determine polycystic kidney disease, anosmia and retinal degeneration.

## Microvilli

Microvilli are finger-like cell surface extensions usually $0.1 \mu \mathrm{~m}$ in diameter and up to $2 \mu \mathrm{~m}$ long (Fig. 1.18).

Microvilli are covered by plasma membrane and supported internally by closely packed bundles of actin filaments linked by crossbridges of the actin-bundling proteins, fascin and fimbrin. Other bridges composed of myosin I and calmodulin connect the filament bundles to the plasma membrane. At the tip of each microvillus, the free ends of microfilaments are inserted into a dense mass that includes the protein, villin. The actin filament bundles of microvilli are embedded in the apical cytoplasm amongst a meshwork of transversely running actin filaments stabilized by spectrin to form the terminal web, which is underlain by keratin intermediate filaments. The web is anchored laterally to the tight junctions and zonula adherens of the apical epithelial junctional complex. Myosin II and tropomyosin are also found in the terminal web, which may explain its contractile activity.

Microvilli greatly increase the area of cell surface (up to 40 times), particularly at sites of active absorption. In the small intestine, they have

Fig. 1.18 Microvilli sectioned longitudinally in the striated border of an intestinal absorptive cell in a human duodenal biopsy specimen. Actin filaments fill the cores of the microvilli and insert into the apical cytoplasm. A prominent glycocalyx (formed by the extracellular domains of plasma membrane glycoproteins) is seen as a fuzzy coat at the tips of and between microvilli; it includes enzymes concerned with the final stages of digestion. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
 (
a very thick cell coat or glycocalyx, which reflects the presence of integral membrane glycoproteins, including enzymes concerned with digestion and absorption. Irregular microvilli, filopodia, are also found on the surfaces of many types of cell, particularly free macrophages and fibroblasts, where they may be associated with phagocytosis and cell motility. For further reading on the cytoskeleton of microvilli, see Brown and McKnight (2010).

Long and branching microvilli are called stereocilia, an early misnomer, as they are not motile and lack microtubules. An appropriate name is stereovilli. They are found on cochlear and vestibular receptor cells, where they act as sensory transducers, and also in the absorptive epithelium of the epididymis.

## Intercellular junctions

The basolateral region of the plasma membrane of epithelial cells establishes junctions with adjacent cells and with structural components of the extracellular matrix. Intercellular junctions are resilient and dynamic, and prevent epithelial tissues from dissociating into their component cells. In adults, the epidermis withstands imposed deformations because of the interplay of two components of intercellular junctions, the junctional cytoskeleton and cell adhesion molecules (Fig. 1.19). The establishment and maintenance of cell polarity in an epithelial layer depends on two circumferential apical belts, the tight junctions and the zonulae adherentes, running in parallel to each other and associated with F-actin. These two belts control epithelial permeability and determine epithelial cell polarity. The apical cell domain resides above the belts; the basolateral cell domain resides below the belts. Desmosomes (maculae adherentes) are a third class of spot-like intercellular adhesion. In contrast to tight junctions and the zonulae adherentes, desmosomes do not form belts and link instead to intermediate filaments. The hemidesmosome, anchoring epithelial cells to the basal lamina, also links to intermediate filaments. Gap junctions are unique: they provide direct connection between adjacent cells and are not linked to the cytoskeleton. Molecular aspects of cell adhesion molecules will be considered first and then integrated with the junctional cytoskeleton to define specific structural and molecular aspects of different intercellular junctions.

## Cell adhesion molecules

Cell adhesion molecules are transmembrane or membrane-anchored glycoproteins that bridge the intercellular space from the plasma membrane to form adhesive contacts. There are a number of molecular subgroups, which are broadly divisible on the basis of their dependence on calcium for function. Calcium-dependent cell adhesion molecules include cadherins and selectins. Calcium-independent cell adhesion molecules include the immunoglobulin-like superfamily of cell adhesion molecules (Ig-CAMs), including nectins, and integrins, the only cell adhesion molecules consisting of two subunits ( $\alpha$ and $\beta$ subunits).

## Calcium-dependent cell adhesion molecules: cadherins and selectins

Cadherins are single-pass transmembrane glycoproteins, with five heavily glycosylated calcium-binding external domains and an intracellular catenin-binding cytoplasmic tail. Catenins are intracellular proteins linking cadherins to F-actin in the belt-arranged zonula adherens. The extracellular segment of cadherins participates in $\mathrm{Ca}^{2+}$-dependent homophilic trans-interactions in which a cadherin molecule on one cell binds to an identical cadherin molecule on an adjacent cell. After binding, cadherins cluster laterally (cis-interaction) at cell-cell junctions to form a zipper-like structure that stabilizes tight adhesion between cells.

Different cell types possess different members of the cadherin family, e.g. N-cadherins in nervous tissue, E-cadherins in epithelia, and P-cadherins in the placenta. Two further members of the cadherin family are the desmogleins and the desmocollins. Cadherins are present in macula adherens and desmosomes but not in tight junctions or hemidesmosomes (see below). Alterations in the expression of cadherins in the epidermis produce pathological conditions such as blisters and ulcerations. See Brieher and Yap (2013) for further reading on cadherins and their associated cytoskeleton.

As with cadherins, selectins are $\mathrm{Ca}^{2+}$-dependent. In contrast to cadherins, selectins do not establish homophilic trans-interactions. Instead, they bind to carbohydrates and belong to the group of lectins. Each selectin has an extracellular carbohydrate recognition domain (CRD) with binding affinity to a specific oligosaccharide attached to a protein or lipid. The molecular configuration and binding affinity of the CRD to carbohydrate moieties is $\mathrm{Ca}^{2+}$-dependent. Selectins participate in the homing of leukocytes circulating in blood towards tissues by

When arranged in a regular parallel series, as typified by the absorptive surfaces of the epithelial enterocytes of the small intestine and the proximal convoluted tubule of the nephron of the kidneys, microvilli acquire a fuzzy appearance like the bristles of a paintbrush (the designations brush border or striated border are used at the light microscope level).

The cytoplasmic tail recruits proteins of the catenin complex: $\beta$-catenin is the first to be recruited and the cadherin- $\beta$-catenin complex rapidly recruits $\alpha$-catenin; $\alpha$-catenin binds directly to F-actin and coordinates the activity of actin nucleating proteins and actin binding partners (such as vinculin and $\alpha$-actinin) to provide the dynamic forces to modulate cell-cell adhesion; p120-catenin binds to the cytoplasmic tail of cadherin and becomes a positive regulator of cadherin function.

Fig. 1.19 Intercellular junctions: the apical junctional complex and other junctional specializations, illustrating the protein components of each junction and of the basal lamina. An anastomotic network of contacts between adjacent cell membranes forms a tight occluding junction. Basal plasma membrane is attached to a basal lamina at a hemidesmosome. In a gap junction, numerous channels (pores within connexons) are clustered to form a plaque-like junctional region between adjacent plasma membranes. (A and C are transmission electron micrographs; B and D are freeze-fractured preparations.) A, An apical junctional complex. B, A tight junction. C, A hemidesmosome. D, A gap junction. (B, Courtesy of Dr Andrew Kent, King's College London. D, Courtesy of Professor Dieter Hülser, University of Stuttgart. A,C, From human tissue, courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK. Diagram modified from Kierszenbaum AL, Tres LL. 2012. Histology and Cell Biology: An Introduction to Pathology. 3rd ed, Philadelphia: Elsevier, Saunders; 2011.)
extravasation across the endothelium. For additional reading on the significance and mechanism of homing, see Girard et al (2012).

Three major types of selectin include L-selectin (for lymphocytes), E-selectin (for endothelial cells) and P-selectin (for platelets).

## Calcium-independent cell adhesion molecules: $\lg -\mathrm{CAMs}$, nectins and integrins

Ig-CAMs are cell-surface glycoproteins with an extracellular domain characterized by a variable number of immunoglobulin-like loops. Most Ig-CAMs have a transmembrane domain; others are attached to the cell surface by a glycophosphatidyl inositol (GPI) anchor. As in cadherins, Ig-CAMs establish homophilic interactions contributing to cell-cell adhesion, although in a $\mathrm{Ca}^{2+}$-independent manner. The cytoplasmic tail of Ig-CAMs also interacts with cytoskeletal components such as F-actin, ankyrins and spectrin. Ig-CAMs can directly or indirectly bind growth factor receptors and control their internalization.

Different types are expressed in different tissues. Neural cell adhesion molecules ( N -CAMs) are found on a number of cell types but are expressed widely by neural cells. Intercellular adhesion molecules (ICAMs) are expressed on vascular endothelial cells. Cell adhesion molecule binding is predominantly homophilic, although some use a heterophilic mechanism, e.g. vascular intercellular adhesion molecule (VCAM), which can bind to integrins.

Nectins and nectin-like molecules (Necls) are members of the Ig-CAM superfamily (see Takai et al (2008) for further reading on nectins and Necls). They have an extracellular domain with three Ig-like
loops, a transmembrane segment and a cytoplasmic tail. The nectins and Necls consist of four and five members, respectively. These are present in the belt-like tight junctions and zonula adherens.

The nectin-afadin complex initiates the formation of a zonula adherens and after cell-cell contacts are formed between adjacent cells, cadherins are recruited to these contact sites. Afadin and $\alpha$-catenin interact with one another and also with F-actin through adaptor proteins.

Integrins mediate cell-extracellular matrix and cell-cell interactions, and integrate extracellular signals with the cytoskeleton and cellular signalling pathways. Because integrins can be activated by proteins binding to their extracellular or their intracellular domains, they can function in a bidirectional fashion by transmitting information outside-in (cues from the extracellular environment) and inside-out (cues from the intracellular environment) of the cell. The integrin family of proteins consists of $\alpha$ subunits and $\beta$ subunits forming transmembrane heterodimers. The amino-acid sequence arginine-glycineaspartic acid, or RGD motif, on target ligands (such as fibronectin, laminin and other extracellular matrix proteins) has binding affinity to the extracellular binding head of integrins. For further reading on integrins and their ligands properties, see Barczyk et al (2010).

The actin-binding protein talin binds the cytoplasmic domain of integrin $\beta$ subunit and activates integrins. Vinculin interacts with talin and $\alpha$-actinin cross-links two filaments of actin. Kindlins, named after the gene mutated in Kindler's syndrome, a skin blistering disease, interact with talin to activate integrins.

Homing, a process that also enables thymus-derived T cells (see Ch. 4) to home in on lymph nodes, consists of two phases. In the first, selectin phase, carbohydrate ligands on the surface of leukocytes adhere loosely to selectins present on the surface of endothelial cells. During the second, cooperative sequential integrin phase, strong adhesion permits the transendothelial migration of leukocytes into the extravascular space in cooperation with cell adhesion molecules of the Ig-CAM superfamily.

Nectins can interact homophilically or heterophilically with other nectins to mediate, primarily, adhesion. The intracellular domain of nectins binds to the cytoplasmic adaptor protein afadin, which links to actin, whereas Necls interact with scaffolding proteins but not to afadin. Necls are involved in a large variety of cellular functions, including axon-glial interaction, Schwann cell differentiation and myelination.

In humans there are about $18 \alpha$-subunit subtypes and $8 \beta$-subunit subtypes, which produce 24 integrin heterodimers. The subunits are associated by non-covalent interactions and consist of an extracellular ligand-binding head, two multidomain segments, two single-pass transmembrane segments and two cytoplasmic tails. Upon binding of extracellular ligands, integrins undergo a conformational change (integrin activation), which allows the recruitment of several cytoplasmic F-actin activator proteins (such as talin, vinculin, $\alpha$-actinin and kindlins) to their short cytoplasmic domain. This results in the formation of a protein complex that interacts with the actin cytoskeleton.

In addition, the protein complex promotes the recruitment and activation of several protein kinases (such as focal adhesion kinase), leading to the activation of signalling pathways essential for several cellular activities such as cell migration, proliferation, survival and gene expression.

Genetic mutations in integrins or integrin regulators have been associated with Glanzmann's thrombasthenia (caused by mutations in integrin $\beta 3$ subunit), the immunodeficiency disorder leukocyte adhesion deficiency types I and III (determined by mutations in integrin $\beta 2$ subunit and kindlin 3, respectively) and skin diseases (caused by mutations in kindlin 1 and integrin $\alpha 2, \alpha 6$ and $\beta 3$ subunits). Integrins are essential in the homing process, following the selectin phase, and are also involved in tumour progression and metastasis.

## Specialized intercellular junctions

Specialized cell-cell junctions are the hallmark of all epithelial tissues. There are two major categories: symmetric junctions and asymmetric junctions. Symmetric junctions may be subdivided into three types: tight junctions (also known as occluding junctions or zonulae occludentes); anchoring junctions (including zonulae adherentes, or belt desmosomes, and maculae adherentes, or spot desmosomes); and communication junctions, represented by gap junctions. Tight junctions and anchoring junctions are components of the epithelial apical junctional complex. Hemidesmosomes are asymmetric junctions (see Fig. 1.19).

## Tight junctions (occluding junctions, zonulae occludentes)

Tight junctions are the most apical component of the epithelial apical junctional complex. The main functions of tight junctions are the regulation of the paracellular permeability of the epithelial layer and the formation of an apical-basolateral intramembrane diffusion barrier, the hallmark of epithelial cell polarity. Tight junctions form a continuous belt (zonula) around the cell perimeter, near the apical domain of epithelial cells, and are connected to the actin cytoskeleton. At the site of the tight junction, the plasma membranes of adjacent cells come into close contact, so that the space between them is obliterated. Freezefracture electron microscopy shows that the contact between these membranes is represented by branching and anastomosing sealing strands of protein particles on the P (protoplasmic) face of the lipid bilayer (Fig. 1.19A,B). A tight junction contains numerous proteins: occludins and claudins, members of the tetraspanin family of proteins, containing four transmembrane domains, two loops and two cytoplasmic tails - occludins and tetraspanins provide the molecular basis for the formation of the branching and anastomosing strands seen in freeze-fracture preparations; the afadin-nectin complex and junctional adhesion molecules (JAMs), each forming cis-homodimers and interacting with each other through their extracellular domains (forming transhomodimers) - nectins and JAMs are members of the immunoglobulin superfamily, and the afadin component of the afadin-nectin complex interacts with F-actin; and cytosolic zonula occludens proteins 1, 2 and 3 (ZO-1, ZO-2 and ZO-3). ZO-1 protein is associated with afadin and the intracellular domain of JAMs. All three ZO proteins facilitate the reciprocal interaction of occludins, claudins and JAMs with F-actin. Defects in paracellular magnesium permeability and reabsorption in kidneys occur when there is a mutation in claudin 16 and claudin 19 (renal magnesium wasting). For further reading on claudins, see Escudero-Esparza et al (2011). For further reading on JAMs, see Bazzoni (2003).

## Anchoring junctions

In contrast to tight junctions, zonulae adherentes and maculae adherentes are characterized by the presence, along the cytosolic sides of the plasma membranes of adjacent epithelial cells, of symmetric dense plaques connected to each other across the intercellular space by cadherins. They differ in that F-actin is associated with plaques in zonulae adherentes and intermediate filaments are linked to plaques in maculae adherentes.

## Zonula adherens (belt desmosome)

A zonula adherens is a continuous belt-like zone of adhesion parallel and just basal to a tight junction and also encircling the apical perimeter of epithelial cells. $\mathrm{Ca}^{2+}$-dependent cell adhesion molecules (members of the desmoglein and desmocollin families of cadherins) are key components of a zonula adherens. In addition to the cadherin-catenin complex, a zonula adherens also houses the afadin-nectin complex.

A specific component of a zonula adherens is a cytoplasmic dense plaque attached to the cytosolic side of the plasma membrane. It consists of desmoplakin, plakophilin and plakoglobin proteins (the latter is also known as $\gamma$-catenin). A similar plaque is seen in a macula adherens or spot desmosome (see below).

## Fascia adherens

A fascia adherens is similar to a zonula adherens, but is more limited in extent and forms a strip or patch of adhesion, e.g. between
smooth muscle cells, in the intercalated discs of cardiac muscle cells and between glial cells and neurones. The junctions involve cadherins attached indirectly to actin filaments on the inner side of the membrane.

## Desmosomes (maculae adherentes)

Desmosomes are limited, plaque-like areas of particularly strong intercellular contact. In epithelial cells, they may be located subjacent to the tight junction and zonula adherens belts, forming collectively the epithelial apical junctional complex (see Fig. 1.19A). The intercellular gap is approximately 25 nm ; it is filled with electron-dense filamentous material (the intercellular cadherins) running transversely across it and is also marked by a series of densely staining bands (the cytoplasmic dense plaques) running parallel to the cell surfaces. Adhesion is mediated by $\mathrm{Ca}^{2+}$-dependent cadherins, desmogleins and desmocollins. Within the cells on either side, each cytoplasmic dense plaque underlies the plasma membrane and consists of the proteins plakophilin, desmoplakin and plakoglobin ( $\gamma$-catenin), into which the ends of intermediate filaments are inserted. The type of intermediate filament depends on the cell type, e.g. keratins are found in epithelia and desmin filaments are found in cardiac muscle cells. Desmosomes form strong anchorage points, likened to spot-welds, between cells subject to mechanical stress, e.g. in the prickle cell layer of the epidermis, where they are extremely numerous and large.

## Hemidesmosomes

Hemidesmosomes are asymmetric anchoring junctions found between the basal side of epithelial cells and the associated basal lamina. The latter is a component of the basement membrane and contains laminin, an integrin ligand. The other component of the basement membrane is the reticular lamina, a collagen-containing layer produced by fibroblasts that also contains fibronectin, another integrin ligand. Hemidesmosomes resemble a single-sided desmosome, anchored on one side to the plasma membrane, and on the other to the basal lamina and adjacent collagen fibrils (Fig. 1.19C). The plaque has distinct proteins not seen in the plaques of a zonula adherens or a macula adherens: BPAG1 (bullous pemphigoid antigen 1), a member of the plakin family, and BPAG2 (bullous pemphigoid antigen 2), which possesses an extracellular collagenous domain. BPAG1 and BPAG2 were initially detected in patients with bullous pemphigoid, an autoimmune blistering disease. On the cytoplasmic side of the dense plaque there is a less dense plate into which keratin filaments are inserted, where they interact with the protein plectin associated with integrin $\alpha 6 \beta 4$. Hemidesmosomes use integrins and anchoring filaments (laminin 5) as their adhesion molecules anchored to the basal lamina, whereas desmosomes use cadherins.

## Focal adhesion plaques

Less highly structured attachments with a similar arrangement exist between many other cell types and their surrounding matrices, e.g. between smooth muscle cells and their matrix fibrils, and between the ends of skeletal muscle cells and tendon fibres. The smaller, punctate adhesions resemble focal adhesion plaques, which are regions of local attachment between cells and the extracellular matrix. They are typically situated at or near the ends of actin filament bundles (stress fibres), anchored through intermediary proteins to the cytoplasmic domains of integrins. In turn, these are attached at their external ends to collagen or other filamentous structures in the extracellular matrix. They are usually short-lived; their formation and subsequent disruption are part of the motile behaviour of migratory cells. See Geiger et al (2009) for further reading on focal adhesions.

## Gap junctions (communicating junctions)

Gap junctions resemble tight junctions in transverse section, but the two apposed lipid bilayers are separated by an apparent gap of 3 nm , which is bridged by a cluster of transmembrane channels (connexons). Each connexon is formed by a ring of six connexin proteins whose external surfaces meet those of the adjacent cell in the middle. A minute central pore links one cell to the next (Fig. 1.19D). Larger assemblies of many thousands of channels are often packed in hexagonal arrays. Gap junctions occur between numerous cells, including hepatocytes and cardiac myocytes.

## AGEING, CELLULAR SENESCENCE, CANCER AND APOPTOSIS

Ageing is a universal feature of biological organisms, defined by a gradual decline over time in cell and tissue function that often, but not

Essentially, two molecules, cadherins and afadin, link to the actin cytoskeleton. In cultured cells, nectins appear to initiate the formation of a zonula adherens before the involvement of cadherins.
always, decreases the longevity of an individual. The hallmarks of ageing are reviewed in López-Otín et al (2013).

Cellular senescence is defined by an irreversible arrest in cell proliferation when cells experience DNA damage at telomeres and a decrease in mitogenic signalling. In contrast to reversibly arrested quiescent cells in $\mathrm{G}_{0}$ of the cell cycle, senescent growth arrest is irreversible; cells in this state cannot be stimulated to proliferate by known stimuli and cannot be prompted to re-enter the cell cycle by physiological mechanisms. For further reading on senescence and the cell cycle, see Chandler and Peters (2013). Senescent cells can cause or foster degenerative diseases. In old age, cellular senescence in humans determines typical pathologies, including atherosclerosis leading to stroke, osteoporosis, macular degeneration, cardiopulmonary and renal failure, and neurodegenerative diseases such as Alzheimer's and Parkinson's disease.

Senescent cells undergo changes in gene expression, which result in the secretion of proinflammatory cytokines, growth factors and proteases, activities that collectively define a senescence-associated secretory phenotype capable of triggering angiogenesis, inflammatory responses, stem cell renewal and differentiation, and which may also determine resistance to cancer chemotherapy. Senescent cells can be identified histochemically by their expression of either senescenceassociated $\beta$-galactosidase, a lysosomal marker which is overexpressed in these cells, or the tumour suppressor protein p16 ${ }^{\text {INK4a, }}$ which promotes the formation of senescence-associated chromatin. For further reading on ageing, cellular senescence and cancer, see Campisi (2013).

Cellular senescence can be caused by a disruption of metabolic signalling pathways, derived from mitogens and proliferation factors, and the activation of tumour suppressors, combined with telomere shortening and genomic damage. See Sahin and DePinho (2012) for further reading.

Cellular senescence suppresses tumorigenesis because cell proliferation is required for cancer development. However, senescent cells can stimulate the proliferation and malignant progression of adjacent premalignant cells by the release of senescence-inducing oncogenic stimuli. Cancer cells must harbour mutations to prevent telomere-dependent and oncogene-induced senescence, such as in the p53 and p16retinoblastoma protein pathways. See López-Otín et al (2013) for further reading on the pathogenesis of ageing.

## Apoptosis

Cells die as a result of either tissue injury (necrosis) or the internal activation of a 'suicide' programme (apoptosis) in response to extrinsic or intrinsic cues. Apoptosis (programmed cell death) is defined by the controlled demolition of cellular constituents and the ultimate uptake of apoptotic cell fragments by other cells to prevent immune responses. Some senescent cells become resistant to cell-death signalling, i.e. they are apoptosis-resistant. In effect, senescence blocks growth of damaged or stressed cells, whereas apoptosis quickly disposes of them. Apoptosis is a central mechanism controlling multicellular development. During morphogenesis, apoptosis mediates activities such as the separation of the developing digits, and plays an important role in regulating the number of neurones in the nervous system (the majority of neurones die during development). Apoptosis also ensures that inappropriate or inefficient T cells are eliminated in the thymus during clonal selection.

The morphological changes exhibited by necrotic cells are very different from those seen in apoptotic cells. Necrotic cells swell and subsequently rupture, and the resulting debris may induce an inflammatory response. Apoptotic cells shrink, their nuclei and chromosomes fragment, forming apoptotic bodies, and their plasma membranes undergo conformational changes that act as a signal to local phagocytes. The dead cells are removed rapidly, and as their intracellular contents are not released into the extracellular environment, inflammatory reactions are avoided; the apoptotic fragments also stimulate macrophages to release anti-inflammatory cytokines.

Apoptosis and cell proliferation are intimately coupled; several cell cycle regulators can influence both cell division and apoptosis. The signals that trigger apoptosis include withdrawal of survival factors or exposure to inappropriate proliferative stimuli. Three main routes to the induction of apoptosis have been established (Fig. 1.20). Two, the Fas ligand (FasL) pathway and the granzyme B pathway, are extrinsic, whereas the mitochondrial route is intrinsic. The Fas ligand (FasL) pathway involves binding of FasL to death receptors on the plasma membrane and recruitment of adaptor proteins, such as the Fas-associated death domain proteins, followed by the recruitment and activation of caspase 8 . The granzyme B pathway involves creation of a perforin plasma membrane channel enabling the caspase-like granzyme $B$ to

Fig. 1.20 Caspase activation pathways during apoptosis. A, The granzyme $B$ extrinsic pathway activates caspase 8 and caspase 3 following entry of granzyme B across the plasma membrane pore-forming protein, perforin. This pathway is observed in cytotoxic T cells or natural killer cells for delivery of the protease granzyme B to target cells. B, The Fas ligand (FasL) extrinsic pathway is initiated by binding of FasL to clustered transmembrane death receptors that recruit adaptor proteins, such as the Fas-associated death-domain protein (FADD) to their intracellular domain, which in turn recruits and aggregates caspase 8 molecules, which become activated. Activated caspase 8 activates caspase 7 and caspase 3 . C, The cytochrome c intrinsic pathway starts when granzyme B or activated caspase 8 causes the truncation by proteolysis of the protein BIDD (BH3-interacting domain death agonist), which penetrates a mitochondrion through BAX-BAK (BCL-2 associated X protein-BCL-2 antagonist killer) channel proteins on the outer mitochondrial membrane, causing the release of cytochrome $c$. Cytochrome $c$ enables the assembly of the apoptosome (consisting of seven molecules of apoptosis protease-activating factor-1 (APAF1) and seven molecules of caspase 9), which in turn activates caspase 3 and caspase 7. Finally, the proteolytic activation cascade of caspase 6 , caspase 2, caspase 8 and caspase 10 executes cell deconstruction.
enter the cell. The intrinsic mitochondrial route involves the release of cytochrome $c$ from the space between the inner and outer mitochondrial membranes into the cytosol. Extrinsic and intrinsic pathways work cooperatively in the subsequent activation of a family of initiatoreffector proteases, known as caspases (cysteine aspartic acid-specific proteases), which are present in healthy cells as inactive precursor enzymes or zymogens. Activation of caspases 3, 6 and 7 mediates apoptosis by initiating a cascade of degradative processes that target major constituents of the cell cytoskeleton, producing membrane blebbing, a distinctive feature of apoptosis caused by cytosolic and nuclear fragments flowing into the developing apoptotic bodies. Caspase cleavage inactivates many systems that normally promote damage repair and support cell viability, and activates a number of proteins that promote the death and disassembly of the cell. For further reading on apoptosis, see Taylor et al (2008).

## Bonus e-book video

Video 1.1 Mitosis in a cell with fluorescently-labelled chromosomes and microtubules.

The ends of the chromosomes, or telomeres, become shorter and more dysfunctional with each DNA replication round. Telomere shortening has been shown to activate DNA damage responses, leading to mitochondrial dysfunction (a decrease in production of ATP and an increase in reactive oxygen species) and the activation of p53, which induces growth arrest, apoptosis and senescence of stem cells and progenitor cells. p53 interconnects with different longevity metabolic signalling pathways, including the insulin, insulin-like growth factor I (IGFI) and mammalian target of rapamycin (mTOR) pathways, which are known to regulate lifespan by increasing the expression of genes involved in stress resistance and energy balance. Mutations in TERC (the RNA component of telomerase) and TERT (the catalytic component of telomerase) are found in patients with the premature ageing syndrome, dyskeratosis congenita (poor growth of fingernails and toenails, skin pigmentation and oral leukoplakia). Other important contributors to cell senescence are dysregulated autophagy and lack of disposal of misfolded proteins by the ubiquitin-26S proteasome machinery. These responses are collectively designated telomere-initiated cellular senescence.

Cells evolved as single, free-living organisms, but natural selection favoured more complex communities of cells, multicellular organisms, where groups of cells specialize during development to carry out specific functions for the body as a whole. This allowed the emergence of larger organisms with greater control over their internal environment and the evolution of highly specialized organic structures such as the brain. The human body contains more than 200 different cell types, sharing the same genome but with different patterns of gene expression.

Some cells in the body are essentially migratory, but most exist as cellular aggregates in which individual cells carry out similar or closely related functions in a coordinated manner. These aggregates are termed tissues, and can be classified into a fairly small number of broad categories on the basis of their structure, function and molecular properties. On the basis of their structure, most tissues are divided into four major types: epithelia, connective or supporting tissue, muscle and nervous tissue. Epithelia are continuous layers of cells with little intercellular space, which cover or line surfaces, or have been so derived. In connective tissues, the cells are embedded in an extracellular matrix, which, typically, forms a substantial and important component of the tissue. Muscle consists largely of specialized contractile cells. Nervous tissue consists of cells specialized for conducting and transmitting electrical and chemical signals and the cells that support this activity.

There is molecular evidence that this structure-based scheme of classification has validity. Thus the intermediate filament proteins characteristic of all epithelia are keratins (Pan et al 2012); those of connective tissue are vimentins; those of muscle are desmins; and those of nervous tissue are neurofilament and glial fibrillary acidic proteins. However, cells such as myofibroblasts, neuroepithelial sensory receptors and ependymal cells of the central nervous system have features of more than one tissue type. Despite its anomalies, the scheme is useful for descriptive purposes; it is widely used and will be adopted here.

In this chapter, two of the major tissue categories, epithelia and general connective and supporting tissues, will be described. Specialized skeletal connective tissues, i.e. cartilage and bone, together with skeletal muscle, are described in detail in Chapter 5 as part of the musculoskeletal system overview. Smooth muscle and cardiac muscle are described in Chapter 6. Nervous system tissues are described in Chapter 3. Specialized defensive cells, which also form a migrant population within the general connective tissues, are considered in more detail in Chapter 4, with blood, lymphoid tissues and haemopoiesis.

## EPITHELIA

The term epithelium is applied to the layer or layers of cells that cover the body surfaces or line the body cavities that open on to it. The fate of embryonic epithelial populations is illustrated in Figure 12.3. Epithelia function generally as selective barriers that facilitate, or inhibit, the passage of substances across the surfaces they cover. In addition, they may: protect underlying tissues against dehydration, chemical or mechanical damage; synthesize and secrete products into the spaces that they line; and function as sensory surfaces. In this respect, many features of nervous tissue can be regarded as those of a modified epithelium and the two tissue types share an origin in embryonic ectoderm.

Epithelia (Fig. 2.1) are predominantly cellular and the little extracellular material they possess is limited to the basal lamina. Intercellular junctions, which are usually numerous, maintain the mechanical cohesiveness of the epithelial sheet and contribute to its barrier functions. A series of three intercellular junctions forms a typical epithelial junctional complex: in sequence from the apical surface, this consists of a tight junctional zone, an adherent (intermediate) junctional zone and a region of discrete desmosome junctions. Epithelial cell shape is most usually polygonal and partly determined by cytoplasmic features such as secretory granules. The basal surface of an epithelium lies in contact with a thin layer of filamentous protein and proteoglycan termed the
basal lamina, which is synthesized predominantly by the epithelial cells. The basal lamina is described on page 34.

Epithelia can usually regenerate when injured. Indeed, many epithelia continuously replace their cells to offset cell loss caused by mechanical abrasion (reviewed in Blanpain et al (2007)). Blood vessels do not penetrate typical epithelia and so cells receive their nutrition by diffusion from capillaries of neighbouring connective tissues. This arrangement limits the maximum thickness of living epithelial cell layers. Epithelia, together with their supporting connective tissue, can often be removed surgically as one layer, which is collectively known as a membrane. Where the surface of a membrane is moistened by mucous glands it is called a mucous membrane or mucosa, whereas a similar layer of connective tissue covered by mesothelium is called a serous membrane or serosa.

## CLASSIFICATION

Epithelia can be classified as unilaminar (single-layered, simple), in which a single layer of cells rests on a basal lamina; or multilaminar, in which the layer is more than one cell thick. The latter includes: stratified squamous epithelia, in which flattened superficial cells are constantly replaced from the basal layers; urothelium (transitional epithelium), which serves special functions in the urinary tract; and other multilaminar epithelia such as those lining the largest ducts of some exocrine glands, which, like urothelium, are replaced only very slowly under normal conditions. Seminiferous epithelium is a specialized multilaminar tissue found only in the testis.

## Unilaminar (simple) epithelia

Unilaminar epithelia are further classified according to the shape of their cells, into squamous, cuboidal, columnar and pseudostratified types. Cell shape may, in some cases, be related to cell volume. Where little cytoplasm is present, there are generally few organelles and therefore there is low metabolic activity and cells are squamous or low cuboidal. Highly active cells, e.g. secretory epithelia, contain abundant mitochondria and endoplasmic reticulum, and are typically tall cuboidal or columnar. Unilaminar epithelia can also be subdivided into those that have special functions, such as those with cilia, numerous microvilli, secretory vacuoles (in mucous and serous glandular cells) or sensory features. Myoepithelial cells, which are contractile, are found as isolated cells associated with glandular structures, e.g. salivary and mammary glands.

## Squamous epithelium

Simple squamous epithelium is composed of flattened, tightly apposed, polygonal cells (squames). This type of epithelium is described as tessellated when the cells have complex, interlocking borders rather than straight boundaries. The cytoplasm may in places be only $0.1 \mu \mathrm{~m}$ thick and the nucleus usually bulges into the overlying space (Fig. 2.2A). These cells line the alveoli of the lungs, where their surface area is huge and cytoplasmic volume correspondingly large, and they also form the outer capsular wall of renal corpuscles, the thin segments of the renal tubules and various parts of the inner ear. Because it is so thin, simple squamous epithelium allows rapid diffusion of gases and water across its surface; it may also engage in active transport, as indicated by the presence of numerous endocytic vesicles in these cells. Tight junctions (occluding junctions, zonulae adherentes) between adjacent cells ensure that materials pass primarily through cells, rather than between them.

## Cuboidal and columnar epithelia

Cuboidal and columnar epithelia consist of regular rows of cylindrical cells (Figs 2.2B, C). Cuboidal cells are approximately square in vertical section, whereas columnar cells are taller than their diameter, and both

COMPLEX DERIVED STRUCTURES

- Multicellular - exocrine and endocrine glands
- Sensory structures - e.g. taste buds
- Tooth germ
- Nervous tissue - often classified separately, but retains many
characteristics of its epithelial origins
- Seminiferous epithelium

Fig. 2.1 Classification of epithelial tissues and cells.
are polygonal when sectioned horizontally. Commonly, microvilli are found on their free surfaces, which considerably increases the absorptive area, e.g. in the epithelia of the small intestine (columnar cells with a striated border of very regular microvilli), the gallbladder (columnar cells with a brush border of microvilli); proximal convoluted tubules of the kidney (large cuboidal to low columnar cells with brush borders); and the epididymis (columnar cells with extremely long microvilli, erroneously termed stereocilia).

Ciliated columnar epithelium lines most of the respiratory tract, except for the lower pharynx and vocal folds, and it is pseudostratified (Fig. 2.2D) as far as the larger bronchioles; it also lines some of the tympanic cavity and auditory tube; the uterine tube; and the efferent ductules of the testis. Submucosal mucous glands and mucosal goblet cells secrete mucus on to the luminal surface of much of the respiratory tract, and cilia sweep a layer of mucus, trapped dust particles and so on from the lung towards the pharynx in the mucociliary rejection current, which clears the respiratory passages of inhaled particles. Cilia in the uterine tube assist the passage of oocytes and fertilized ova to the uterus.

Some columnar cells are specialized for secretion, and aggregates of such cells may be described as glandular tissue. Their apical domains typically contain mucus- or protein-filled (zymogen) vesicles, e.g. mucin-secreting and chief cells of the gastric epithelium. Where mucous cells lie among non-secretory cells, e.g. in the intestinal epithelium, their apical cytoplasm and its secretory contents often expand to produce a characteristic cell shape, and they are known as goblet cells (see Fig. 2.2D). For further details of glandular tissue, see page 32, and for the characteristics of mucus, see page 40 .

## Pseudostratified epithelium

Pseudostratified epithelium is a single-layered (simple) columnar epithelium in which nuclei lie at different levels in a vertical section (Fig. 2.2 D ). All cells are in contact with the basal lamina throughout their lifespan, but not all cells extend through the entire thickness of the epithelium. Some constitute an immature basal cell layer of smaller cells, which are often mitotic and able to replace damaged mature cells. Migrating lymphocytes and mast cells within columnar epithelia may also give a similar, pseudostratified appearance because their nuclei are found at different depths. Much of the ciliated lining of the respiratory tract is of the pseudostratified type, and so is the sensory epithelium of the olfactory area.

## Sensory epithelia

Sensory epithelia are found in special sense organs of the olfactory, gustatory and vestibulocochlear receptor systems. All of these contain sensory cells surrounded by supportive non-receptor cells. Olfactory receptors are modified neurones and their axons pass directly to the brain, but the other types are specialized epithelial cells that synapse with terminals of afferent (and sometimes efferent) nerve fibres.

## Myoepithelial cells

Myoepithelial cells, which are also sometimes termed basket cells, are fusiform or stellate in shape (Fig. 2.3), contain actin and myosin filaments, and contract when stimulated by nervous or endocrine signals. They surround the secretory portions and ducts of some glands, e.g. mammary, lacrimal, salivary and sweat glands, and lie between the basal lamina and the glandular or ductal epithelium. Their contraction assists the initial flow of secretion into larger conduits. Myoepithelial cells are ultrastructurally similar to smooth muscle cells in the arrangement of their actin and myosin, but differ from them because they originate, like the glandular cells, from embryonic ectoderm or endoderm. They can be identified immunohistochemically on the basis of the co-localization of myofilament proteins (which signify their contractile function (Fig. 2.4)) and keratin intermediate filaments (which accords with their epithelial lineage).

## Multilaminar (stratified) epithelia

Multilaminar epithelia are found at surfaces subjected to mechanical damage or other potentially harmful conditions. They can be divided into those that continue to replace their surface cells from deeper layers, designated stratified squamous epithelia, and others in which replacement is extremely slow except after injury.

## Stratified squamous epithelia

Stratified squamous epithelia are multilayered tissues in which the formation, maturation and loss of cells is continuous, although the rates of these processes can change, e.g. after injury. New cells are formed in the most basal layers by the mitotic division of stem cells and transit (or transient) amplifying cells. The daughter cells move more superficially, changing gradually from a cuboidal shape to a more

Fig. 2.5 A, Keratinized stratified squamous epithelium in thin skin. Pigmented melanocytes are seen in the basal layer and a few keratinocytes of the prickle cell layer also contain melanin granules. The dead, keratinized layer (K) lacks nuclei. B, Non-keratinized stratified squamous epithelium of the uterine ectocervix, stained with periodic-acid Schiff (PAS) reagent. The basement membrane (short arrows) and superficial squames, which retain their nuclei, are PAS-positive; squames sloughing off the surface are indicated (long arrow). C, Stratified low columnar epithelium of an interlobular excretory duct of the sublingual salivary gland. D, Urothelium (transitional epithelium) lining the relaxed urinary bladder. The most superficial cells have a thickened plasma membrane as a result of the presence of intramembranous plaques, which give an eosinophilic appearance to the luminal surface (arrows). All human tissues. (All human tissues, courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
flattened form, and are eventually shed from the surface as a highly flattened squame. Typically, the cells are held together by numerous desmosomes to form strong, contiguous cellular sheets that provide protection to the underlying tissues against mechanical, microbial and chemical damage. Stratified squamous epithelia may be broadly subdivided into keratinized and non-keratinized types.

## Keratinized epithelium

Keratinized epithelium (Fig. 2.5A) is found at surfaces that are subject to drying or mechanical stresses, or are exposed to high levels of abrasion. These include the entire epidermis and the mucocutaneous junctions of the lips, nostrils, distal anal canal, outer surface of the tympanic membrane and parts of the oral lining (gingivae, hard palate and filiform papillae on the anterior part of the dorsal surface of the tongue). Their cells, keratinocytes, are described in more detail on page 141. A distinguishing feature of keratinized epithelia is that cells of the superficial layer, the stratum corneum, are anucleate, dead, flattened squames that eventually flake off from the surface. In addition, the tough keratin intermediate filaments become firmly embedded in a matrix protein. This unusual combination of strongly coherent layers of living cells and more superficial strata made of plates of inert, mechanically robust protein complexes, interleaved with water-resistant lipid, makes this type of epithelium an efficient barrier against different types of injury, microbial invasion and water loss.

## Non-keratinized epithelium

Non-keratinized epithelium is present at surfaces that are subject to abrasion but protected from drying (Fig. 2.5B). These include: the buccal cavity (except for the areas noted above); oropharynx and laryngopharynx; oesophagus; part of the anal canal; vagina; distal uterine cervix; distal urethra; cornea; inner surfaces of the eyelids; and the vestibule of the nasal cavities. Cells go through the same transitions in
general shape as are seen in the keratinized type, but they do not fill completely with keratin or secrete glycolipid, and they retain their nuclei until they desquamate at the surface. In sites where considerable abrasion occurs, e.g. parts of the buccal cavity, the epithelium is thicker and its most superficial cells may partly keratinize, so that it is referred to as parakeratinized, in contrast to the orthokeratinized state of fully keratinized epithelium. Diets deficient in vitamin A may induce keratinization of such epithelia, and excessive doses may lead to its transformation into mucus-secreting epithelium.

## Stratified cuboidal and columnar epithelia

Two or more layers of cuboidal or low columnar cells (Fig. 2.5C) are typical of the walls of the larger ducts of some exocrine glands, e.g. the pancreas, salivary glands and the ducts of sweat glands, and they presumably provide more strength than a single layer. Parts of the male urethra are also lined by stratified columnar epithelium. The layers are not continually replaced by basal mitoses and there is no progression of form from base to surface, but they can repair themselves if damaged.

## Urothelium (urinary or transitional epithelium)

Urothelium (Fig. 2.5D) is a specialized epithelium that lines much of the urinary tract and prevents its rather toxic contents from damaging surrounding structures. It extends from the ends of the collecting ducts of the kidneys, through the ureters and bladder, to the proximal portion of the urethra. In males it lines the urethra as far as the ejaculatory ducts, then becomes intermittent and is finally replaced by stratified columnar epithelium in the membranous urethra. In females it extends as far as the urogenital membrane.

The epithelium appears to be 4-6 cells thick and lines organs that undergo considerable distension and contraction. It can therefore stretch greatly without losing its integrity. In stretching, the cells become
flattened without altering their positions relative to each other, because they are firmly connected by numerous desmosomes. However, the urothelium appears to be reduced to only 2-3 cells thick. The epithelium is called transitional because of the apparent transition from a stratified cuboidal epithelium to a stratified squamous epithelium, which occurs as it is stretched to accommodate urine, particularly in the bladder. The basal cells are basophilic and contain many ribosomes; they are uninucleate (diploid), and cuboidal when relaxed. More apically, they form large binucleate or, more often, polyploid uninucleate cells. The surface cells are the largest and may even be octoploid; in the relaxed state they typically bulge into the lumen as dome-shaped cells with a thickened, eosinophilic glycocalyx or cell coat. Their luminal surfaces are covered by a specialized plasma membrane in which plaques of intramembranous glycoprotein particles are embedded to stiffen the membrane. When the epithelium is relaxed, the surface area of the cells is reduced and the plaques are partially internalized by the hinge-like action of the more flexible interplaque membrane regions. The plaques re-emerge on to the surface when it is stretched.

Normally, cell turnover is very slow; cell division is infrequent and is restricted to the basal layer. However, when damaged, the epithelium regenerates quite rapidly.

## Seminiferous epithelium

Seminiferous epithelium is a highly specialized, complex stratified epithelium. It consists of a heterogeneous population of cells that form the lineage of the spermatozoa (spermatogonia, spermatocytes, spermatids), together with supporting cells (Sertoli cells). It is described in detail on page 1275 .

## GLANDS

One of the features of many epithelia is their ability to alter the environment facing their free surfaces by the directed transport of ions, water or macromolecules. This is particularly well demonstrated in glandular tissue, in which the metabolism and structural organization of the cells are specialized for the synthesis and secretion of macromolecules, usually from the apical surface. Such cells may exist in isolation amongst other non-secretory cells of an epithelium, e.g. goblet cells in the absorptive lining of the small intestine, or may form highly coherent sheets of epithelium with a common secretory function, e.g. the mucous lining of the stomach and, in a highly invaginated structure, the complex salivary glands.

Glands may be subdivided into exocrine glands and endocrine glands. Exocrine glands secrete, usually via a duct, on to surfaces that are continuous with the exterior of the body, including the alimentary tract, respiratory system, urinary and genital ducts and their derivatives, and the skin. Endocrine glands are ductless and secrete hormones directly into interstitial fluid and thence the circulatory system, which conveys them throughout the body to affect the activities of other cells. In addition to strictly epithelial glands, some tissues derived from the nervous system, including the suprarenal medulla and neurohypophysis, are neurosecretory.

Paracrine glandular cells are similar to endocrine cells but their secretions diffuse locally to cellular targets in the immediate vicinity; many are classed as neuroendocrine cells because they secrete molecules used elsewhere in the nervous system as neurotransmitters or neuromodulators. Modes of signalling by secretory cells are illustrated in Figure 1.6.

## EXOCRINE GLANDS

## Types of secretory process

The mechanism of secretion varies considerably. If the secretions are initially packaged into membrane-bound vesicles, these are conveyed to the cell surface, where they are discharged. In merocrine secretion, which is by far the most common secretory mechanism, vesicle membranes fuse with the plasma membrane to release their contents to the exterior (Fig. 2.6). Specialized transmembrane molecules in the secretory vesicle wall recognize marker proteins on the cytoplasmic side of the plasma membrane and bind to them. This initiates interactions with other proteins that cause the fusion of the two membranes and the consequent release of the vesicle contents. The stimulus for secretion varies with the type of cell but often appears to involve a rise in intracellular calcium. Glands such as the simple sweat glands of the skin, where ions and water are actively transported from plasma as an exudate, were once classified as eccrine glands. They are now known to synthesize and
secrete small amounts of protein by a merocrine mechanism, and have been reclassified as merocrine glands.

In apocrine glands, some of the apical cytoplasm is pinched off with the contained secretions, which are stored in the cell as membrane-free droplets (see Fig. 2.6). The best-understood example of this is the secretion of milk fat by mammary gland cells, in which a small amount of cytoplasm is incorporated into the plasma membrane-bound lipid globule as it is released from the cell. Larger amounts of cytoplasm are included in secretions by specialized apocrine sweat glands in the axilla (Stoeckelhuber et al 2011) and anogenital regions of the body. In some tissues there is a combination of different types of secretion, e.g. mammary gland cells secrete milk fat by apocrine secretion and milk protein, casein, by merocrine secretion.

In holocrine glands (see Fig. 2.6), e.g. sebaceous glands in the skin, the cells first fill with secretory products (lipid droplets or sebum, in this instance), after which the entire cell disintegrates to liberate the accumulated mass of secretion into the adjacent duct or, more usually, hair follicle.

## Structural and functional classification

Exocrine glands are either unicellular or multicellular. The latter may be in the form of simple sheets of secretory cells, e.g. the lining of the stomach, or may be structurally more complex and invaginated to a variable degree. Such glands (see Fig. 2.6) may be simple units or their connection to the surface may be branched. Simple unbranched tubular glands exist in the walls of many of the hollow viscera, e.g. the small intestine and uterus, whereas some simple glands have expanded, flasklike ends (acini or alveoli). Such glands may consist entirely of secretory cells, or may have a blind-ending secretory portion that leads through a non-secretory duct to the surface, in which case the ducts may modify the secretions as they pass along them.

Glands with ducts may be branched (compound) and sometimes form elaborate ductal trees. Such glands generally have acinar or alveolar secretory lobules, as in the exocrine pancreas, but the secretory units may alternatively be tubular or mixed tubulo-acinar. More than one type of secretory cell may occur within a particular secretory unit, or individual units may be specialized to just one type of secretion (e.g. serous acini of salivary glands).

Exocrine glands are also classified by their secretory products. Secretory cells in mucus-secreting or mucous glands have frothy cytoplasm and basal, flattened nuclei. They stain deeply with metachromatic stains and periodic acid-Schiff (PAS) methods that detect carbohydrate residues. However, in general (i.e. non-specific) histological preparations, they are weakly stained because much of their content of water-rich mucin has been extracted by the processing procedures. Secretory cells in serous glands have centrally placed nuclei and eosinophilic secretory storage granules in their cytoplasm. They secrete mainly glycoproteins (including lysozyme) and digestive enzymes.

Some glands are almost entirely mucous (e.g. the sublingual salivary gland), whereas others are mainly serous (e.g. the parotid salivary gland). The submandibular gland is mixed, in that some lobules are predominantly mucous and others serous. Mucous acini may share a lumen with clusters of serous cells (seen in routine preparations as serous demilunes). Although this simple approach to classification is useful for general descriptive purposes, the diversity of molecules synthesized and secreted by glands is such that complex mixtures often exist within the same cell.

## ENDOCRINE GLANDS

Endocrine glands secrete directly into connective tissue interstitial fluid and thence the circulation. Their cells are grouped around beds of capillaries or sinusoids, which typically are lined by fenestrated endothelia to allow the rapid passage of macromolecules through their walls. Endocrine cells may be arranged in clusters within vascular networks, in cords between parallel vascular channels or as hollow structures (follicles) surrounding their stored secretions. In addition to the cells of specialized ductless endocrine glands (e.g. pituitary, pineal, thyroid and parathyroid), hormone-producing cells also form components of other organ systems. These include: the cells of the pancreatic islets; thymic epithelial cells; renin-secreting cells of the kidney juxtaglomerular apparatus; erythropoietin-secreting cells of the kidney; circumventricular organs; interstitial testicular (Leydig) cells; interstitial follicular and luteal ovarian cells; and placental cells (in pregnancy). Some cardiac myocytes, particularly in the walls of the atria, also have endocrine functions. These cells are all described in detail within the appropriate regional sections.

Structural classification of glands - Ductal branching pattern of complex glands

Fig. 2.6 Classification of the different types of epithelial gland.

Isolated endocrine cells also exist scattered amongst other tissues as part of the dispersed (diffuse) neuroendocrine system, e.g. throughout the alimentary and respiratory tracts. Neuroendocrine cells are generally situated within a mucosal epithelium and their bases often rest on the basal lamina (see below). In response to an external stimulus, they secrete their product basally into interstitial fluid. A typical neuroendocrine cell is shown in Figure 2.7. The secretory granules vary in shape, size and ultrastructure according to cell type. Cells often take the name of the secretion they produce, e.g. gastrin-secreting G cells of the small intestine. Neuroendocrine cells share many of their secretory products with chemical mediators in the nervous system.

## CONTROL OF GLANDULAR SECRETION

The activities of cells in the various tissue and organ systems of the body are tightly regulated by the coordinated activity of the endocrine and autonomic nervous systems. Endocrine (and paracrine) signals reach target cells in interstitial fluid, often via blood plasma, and together with autonomic nervous signals they ensure that the body responds to normal physiological stimuli and adjusts to changes in the external environment. Hormone secretion is itself controlled in a number of ways, e.g. by neural control, regulatory feedback loops or according to various cyclical, rhythmical or pulsatile patterns of release. Endocrine
glands have a rich vascular supply and their blood flow is controlled by autonomic vasomotor nerves, which can thus modify glandular activity.

Glandular activity may also be controlled directly by autonomic secretomotor fibres, which may either form synapses on the bases of gland cells (e.g. in the suprarenal medulla) or release neuromediators in the vicinity of the glands and reach them by diffusion. Alternatively, the autonomic nervous system may act indirectly on gland cells, e.g. on neuroendocrine $G$ cells via histamine, released neurogenically from another neuroendocrine cell in the gastric lining. Such paracrine activities of neuroendocrine cells are also important in the respiratory system.

Circulating hormones from the adenohypophysis stimulate synthesis and secretion by target cells in many endocrine glands. Such signals, mostly detected by receptors at the cell surface and mediated by second messenger systems, may increase the synthetic activity of gland cells, and may cause them to discharge their secretions by exocytosis. Secretions from certain exocrine glandular cells are expressed rapidly from those glands by the contraction of associated myoepithelial cells (see Figs 2.3, 2.4) that enclose the secretory units and smaller ducts. Myoepithelial cells may be under direct neural control, as in the salivary glands, or they may respond to circulating hormones, as in the mammary gland, where they respond to the concentration of circulating oxytocin.

Fig. 2.7 An electron micrograph of a neuroendocrine cell between two absorptive cells in the colon (rat tissue). Dense neurosecretory granules are seen in the basal cytoplasm, apposed to the basal lamina (arrows). (Courtesy of Michael Crowder MD.)

## Feedback loops and endocrine axes

The pituitary gland, in particular the adenohypophysis, is often termed the master gland because of its central role in endocrine physiological processes. It provides the means by which the central nervous system regulates and integrates, by non-neural mechanisms, the widespread functions of the body, including the activities of other endocrine glands and, often indirectly, exocrine glands such as the breast. Regulatory hormones from the adenohypophysis stimulate synthesis and secretion in target cells of many endocrine glands; these glands therefore respond to, as well as generate, hormonal signals.

The hypothalamus and the adenohypophysis in the brain are central to most regulatory feedback loops within the endocrine system. Loops can be either positive or negative, e.g. the hypothalamus stimulates release of follicle stimulating hormone (FSH) by the adenohypophysis, which in turn stimulates ovarian follicular maturation and secretion of oestradiol, which acts on breast and endometrial target tissues. Oestradiol, in this case, also acts back on the adenohypophysis and hypothalamus to reinforce their function positively in a feedback loop. In contrast, hypothalamic and adenohypophysial stimulation of testicular production of testosterone, which acts on targets such as skeletal muscle, is negatively regulated in a feedback loop generated by circulating testosterone. Such negative feedback regulation is a widely utilized physiological mechanism.

## BASEMENT MEMBRANE AND BASAL LAMINA

There is a narrow layer of extracellular matrix, which stains strongly for carbohydrates, at the interface between connective and other tissues, e.g. between epithelia and their supporting connective tissues. In early histological texts this layer was termed the basement membrane As almost all of its components are synthesized by the epithelium or other tissues, rather than the adjacent connective tissue, it will be discussed here.

Electron microscopy revealed that the basement membrane is composed of two distinct components. A thin, finely fibrillar layer, the basal lamina, is associated closely with the basal cell surface (Fig. 2.8). A variable reticular lamina of larger fibrils and glycosaminoglycans of the extracellular matrix underlies this layer and is continuous with the connective tissue proper, although it is much reduced or largely absent in some tissues, e.g. surrounding muscle fibres, Schwann cells and capillary endothelia. In other tissues, the basal lamina separates two layers of cells and there are no intervening typical connective tissue elements. This occurs in the thick basal lamina of the renal glomerular filter and the basal lamina of the thin portions of the lung interalveolar septa across which gases exchange between blood and air.

The basal lamina is usually about 80 nm thick, varying between 40 and 120 nm , and consists of a sheet-like fibrillar layer, the lamina densa (20-50 nm wide), separated from the plasma membrane of the cell it supports by a narrow electron-lucent zone, the lamina lucida. The lamina lucida is absent from tissues prepared by rapid freezing and so may be an artefact. In many tissues this zone is crossed by integral

Fig. 2.8 The basal lamina as seen in an electron micrograph, underlying the basal epithelial layer of human skin (see Fig. 7.3). The finely fibrillar dense layer (long arrows) corresponds to the lamina densa, and fine collagen fibrils (*) lie in the subjacent connective tissue. These contribute to the appearance of the basement membrane in light microscope preparations stained for carbohydrate-rich structures. The two cells seen in the upper field are basal keratinocytes (K), joined by desmosomes (short arrow), with dense keratin filaments in their cytoplasm. (Courtesy of J McMillan MD, St John's Institute of Dermatology, St Thomas' Hospital, London.)
plasma membrane proteins, e.g. keratinocyte hemidesmosomes are anchored into the lamina densa in the basal lamina of the epidermis. The basal lamina is a delicate felt-like network composed largely of two glycoprotein polymers, laminin and type IV collagen, which selfassemble into two-dimensional sheets interwoven with each other. Early embryonic basal lamina is formed only of the laminin polymer. Two other molecules cross-link and stabilize the network: entactin (nidogen) and perlecan (a large heparan sulphate proteoglycan).

Although all basal laminae have a similar form, their thickness and precise molecular composition vary between tissues and even within a tissue, e.g. between the crypts and villi of the small intestine. The isoforms of laminin and collagen type IV differ in various tissues; thus Schwann cells and muscle cells express laminin-2 (merosin) rather than the prototypical laminin-1. Laminin-5, although not itself a basal lamina component, is found in the hemidesmosomes of the basal epidermis and links the basal lamina with epidermal transmembrane proteins, $\alpha_{6} \beta_{4}$ integrin and collagen type XVII (BPAG2, bullous pemphigoid antigen 2, one of the targets of the autoimmune blistering skin disease, bullous pemphigoid). The particular isoform of collagen type IV in the basal lamina of different tissues is reflected in tissue-specific disease patterns. Mutations in a collagen expressed by muscle and kidney glomeruli cause Alport's syndrome, a form of renal failure. Renal failure also occurs in Goodpasture's syndrome, in which renal basal lamina collagen is targeted by autoantibodies.

In Descemet's membrane in the cornea, collagen type VIII replaces collagen type IV in the much thickened (increasing with age, up to $10 \mu \mathrm{~m}$, ) endothelial basal lamina. The basal lamina of the neuromuscular junction contains agrin, a heparan sulphate proteoglycan, which plays a part in the clustering of muscle acetylcholine receptors in the plasma membrane at these junctions.

## RETICULAR LAMINA

The reticular lamina consists of a dense extracellular matrix that contains collagen. In skin, it contains fibrils of type VII collagen (anchoring fibrils), which bind the lamina densa to the adjacent connective tissue. The high concentration of proteoglycans in the reticular lamina is responsible for the positive reaction of the entire basement membrane to stains for carbohydrates, which is seen in sections prepared for light microscopy.

## FUNCTIONS OF BASAL LAMINA

Basal laminae perform a number of important roles (Iozzo 2005). They form selectively permeable barriers (anionic filters) between adjacent tissues, e.g. in the glomerular filter of the kidney; anchor epithelial and

Fig. 2.9 General loose connective tissue (human), with bundles of collagen fibres (C) within an amorphous ground substance, penetrated by a neurovascular bundle of blood vessels (BV), lymphatics and nerves. A small autonomic ganglion is arrowed. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
connective tissues, and so stabilize and orientate the tissue layers; may exert instructive effects on adjacent tissues, and so determine their polarity, rate of cell division, cell survival, etc.; and regulate angiogenesis. In addition, they may act as pathways for the migration and pathfinding activities of growing cell processes, both in development and in tissue repair, e.g. in guiding the outgrowth of axons and the re-establishment of neuromuscular junctions during regeneration after injury in the peripheral nervous system. Changes in basal lamina thickness are often associated with pathological conditions, e.g. the thickening of the glomerular basal lamina in glomerulonephritis and diabetes.

## CONNECTIVE AND SUPPORTING TISSUES

The connective tissues are defined as those composed predominantly of intercellular material, the extracellular matrix, which is secreted mainly by the connective tissue cells. The cells are therefore usually widely separated by their matrix, which is composed of fibrous proteins and a relatively amorphous ground substance (Fig. 2.9). Many of the special properties of connective tissues are determined by the composition of the matrix, and their classification is also largely based on its characteristics. In some types of connective tissue, the cellular component eventually dominates the tissue, even though the tissue originally has a high matrix:cell ratio, e.g. adipose tissue. Connective tissues are derived from embryonic mesenchyme or, in the head region, largely from neural crest.

Connective tissues have several essential roles in the body. These may be subdivided into structural roles, which largely reflect the special mechanical properties of the extracellular matrix components, and defensive roles, in which the cellular component has the dominant role. Connective tissues often also play important trophic and morphogenetic parts in organizing and influencing the growth and differentiation of surrounding tissues, e.g. in the development of glands from an epithelial surface.

Structural connective tissues are divided into ordinary (or general) types, which are widely distributed, and special skeletal types, i.e. cartilage and bone, which are described in Chapter 5. A third type, haemolymphoid tissues, consists of peripheral blood cells, lymphoid tissues and their precursors; these tissues are described in Chapter 4. They are often grouped with other types of connective tissue because of their similar mesenchymal origins and because the various defensive cells of the blood also form part of a typical connective tissue cell population. They reach connective tissues via the blood circulation and migrate into them through the endothelial walls of vessels.

## CELLS OF GENERAL CONNECTIVE TISSUES

Cells of general connective tissues can be separated into the resident cell population (fibroblasts, adipocytes, mesenchymal stem cells, etc.) and a population of migrant cells with various defensive functions (macrophages, lymphocytes, mast cells, neutrophils and eosinophils), which may change in number and moderate their activities according

Fig. 2.10 An electron micrograph of a fibroblast in human connective tissue, surrounded by bundles of finely banded collagen fibrils (shown at high magnification in the insert), which they secrete. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
to demand. Embryologically, fibroblasts and adipocytes arise from mesenchymal stem cells, some of which may remain in the tissues to provide a source of replacement cells postnatally. As noted above, the cells of haemopoietic origin migrate into the tissue from bone marrow and lymphoid tissue.

## Resident cells

## Fibroblasts

Fibroblasts are usually the most numerous resident cells. They are flattened and irregular in outline, with extended processes, and in profile they appear fusiform or spindle-shaped (Fig. 2.10; see also Fig. 2.12). Fibroblasts synthesize most of the extracellular matrix of connective tissue (see Fig. 2.10); accordingly, they have all the features typical of cells active in the synthesis and secretion of proteins. Their nuclei are relatively large and euchromatic, and possess prominent nucleoli. In young, highly active cells, the cytoplasm is abundant and basophilic (reflecting the high concentration of rough endoplasmic reticulum), mitochondria are abundant and several sets of Golgi apparatus are present. In old and relatively inactive fibroblasts (often termed fibrocytes), the cytoplasmic volume is reduced, the endoplasmic reticulum is sparse and the nucleus is flattened and heterochromatic.

Fibroblasts are usually adherent to the fibres of the matrix (collagen and elastin), which they lay down. In some highly cellular structures, e.g. liver, kidney and spleen, and in most lymphoid tissue, fibroblasts and delicate collagenous fibres (type III collagen; reticular fibres) form fibrocellular networks, which are often called reticular tissue. The fibroblasts may then be termed reticular cells or reticulocytes.

Fibroblasts are particularly active during wound repair following traumatic injury or inflammation, when tissue mass is lost through cell death. They proliferate and lay down a fibrous matrix that becomes invaded by numerous blood vessels (granulation tissue). Contraction of wounds is, at least in part, caused by the shortening of myofibroblasts, specialized contractile fibroblast-like cells (Hinz et al 2012) with properties similar to smooth muscle cells. It was thought that myofibroblasts differentiated from fibroblasts (reviewed in McAnulty (2007)) or their progenitor mesenchymal stem cells (see below) in granulation tissue. However, recent evidence suggests that in wound healing and in many fibrotic disease processes, including hepatic cirrhosis, the myofibroblast precursor is the vascular pericyte or a closely related cell (reviewed in Duffield (2012)). In cases where the specialized cells of the damaged region cannot divide and regenerate functional tissue, e.g. cardiac muscle cells after infarction, connective tissue fibroblasts and their extracellular matrix fill the void to form a scar. An exception is the central nervous system, where glial scars are formed after injury. Fibroblast activity is influenced by various factors such as steroid hormone concentration, dietary content and prevalent mechanical stresses. Collagen formation is impaired in vitamin C deficiency.

## Adipocytes (lipocytes, fat cells)

Adipocytes occur singly or in groups in many, but not all, connective tissues. They are numerous in adipose tissue (Fig. 2.11). Individually,

Fig．2．11 Adipose tissue（human，from a lymph node specimen）． Adipocytes（A）are distended polygonal cells filled with lipid，which has been extracted by the tissue processing．This leaves only the plasma membranes with scant cytoplasm and nuclei（arrows），occasionally visible compressed against the cell periphery．Small blood vessels（BV）penetrate the adipose tissue；larger vessels are seen on the right．（Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew，Department of Histopathology，Royal Cornwall Hospitals Trust，UK．）
the cells are oval or spherical in shape，but when packed together they are polygonal．They vary in diameter，averaging $50 \mu \mathrm{~m}$ ．Each cell con－ sists of a peripheral rim of cytoplasm，in which the nucleus is embed－ ded，surrounding a single large central globule of fat，which consists of glycerol esters of oleic，palmitic and stearic acids．There is a small accu－ mulation of cytoplasm around the oval nucleus，which is typically compressed against the cell membrane by the lipid droplet，together with the Golgi complex．Many cytoskeletal filaments，some endoplas－ mic reticulum and a few mitochondria lie around the lipid droplet， which is in direct contact with the surrounding cytoplasm and not enclosed within a membrane．In sections of tissue not specially treated to preserve lipids，the lipid droplet is usually dissolved out by the sol－ vents used in routine preparations，so that only the nucleus and the peripheral rim of cytoplasm surrounding a central empty space remain．

Another form of adipose tissue，brown fat，occurs in the interscapu－ lar region of neonates，a location it shares with the classic brown fat of rodents．Brown fat is characterized by the presence of large cells，each of which contains several separate droplets of fat（multilocular adipose tissue）rather than a single globule（typical of unilocular adipose tissue； see above），and by mitochondria in which the cristae are unusually large and numerous．White fat cells are specialized to store chemical energy，whereas the physiological role of brown adipose tissue（BAT） cells is to metabolize fatty acids and generate heat；BAT cells uncouple cellular respiration via the mitochondrial uncoupling protein UCP1．It had been thought that brown fat disappears during postnatal growth， but significant deposits of UCP1－positive brown fat have been detected by positron emission tomography（PET）scanning methods in adults， mainly in the supraclavicular region，in the neck and along the spine． Recent evidence suggests that these human UCP1－positive cells may not be classic brown fat cells but a distinct type of thermogenic fat cell called a beige fat cell，thought to be derived from precursor cells in white fat （Wu et al 2012）．Such cells may represent an evolutionarily conserved cellular mechanism to provide flexibility in adaptive thermogenesis．

It has long been recognized that adipose tissue is central to the control of energy balance and lipid homeostasis．There is a growing view that it may play a similarly important role as an endocrine organ， secreting a class of peptides called adipokines（Trayhurn and Wood 2004），which may enter the blood via capillaries or lymph．Different types of adipose tissue display functional and regional heterogeneity and differ in their involvement with disease processes（reviewed in Hassan et al（2012））．The mobilization of fat is under nervous or hor－ monal control；noradrenaline（norepinephrine）released at sympathetic

Fig．2．12 Macrophages（ M ）in chronically inflamed human connective tissue，showing prominent pigmented，haemosiderin－containing cytoplasmic granules derived from ingested erythrocytes．Many are multinucleate．Also seen are plasma cells（ P ），small lymphocytes（ L ）and other haemopoietic cells．（Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew，Department of Histopathology，Royal Cornwall Hospitals Trust，UK．）
nerve endings in adipose tissue is particularly important in this respect． No new adipose tissue is thought to form after the immediate postnatal period，and accumulation of body fat，as in obesity，is due to excessive accumulation of lipid in existing adipocytes，which become very large． Conversely，weight loss results from the mobilization and metabolism of lipid from adipocyte stores，with the consequent shrinkage of the cells．

## Mesenchymal stem cells

Mesenchymal stem cells are normally inconspicuous cells in connective tissues．They are derived from embryonic mesenchyme and are able to differentiate into the mature cells of connective tissue during normal growth and development，in the turnover of cells throughout life and， most conspicuously，in the repair of damaged tissues in wound healing． There is emerging evidence that，even in mature tissues，mesenchymal stem cells remain pluripotent and able to give rise to all the resident cells of connective tissues in response to local signals and cues．The potential therapeutic use of mesenchymal stem cell－based therapy for a wide range of autoimmune disorders and degenerative diseases is reflected in a burgeoning literature in the field of translational medi－ cine．（See，for example，Ankrum and Karp（2010），Jackson et al（2012） and Ren et al（2012））

## Migrant cells

## Macrophages

Macrophages are numerous in connective tissues，where they are either attached to matrix fibres or are motile and migratory（Fig．2．12）．They are relatively large cells， $15-20 \mu \mathrm{~m}$ in diameter，with indented and rela－ tively heterochromatic nuclei and a prominent nucleolus．Their cyto－ plasm is slightly basophilic，contains many lysosomes and typically has a foamy appearance under the light microscope．Macrophages are important phagocytes and form part of the mononuclear phagocyte system．They can engulf and digest particulate organic materials，such as bacteria，and are able to clear dead or damaged cells from a tissue too．They are also the source of a number of secreted cytokines that have profound effects on many other cell types．Macrophages are able to proliferate in connective tissues to a limited extent，but are derived and replaced primarily from haemopoietic stem cells in the bone marrow，which circulate in the blood as monocytes before migrating through vessel walls into connective tissues，where they differentiate．

Many properties of macrophages in general connective tissue are similar to those of related cells in other sites．These include：circulating monocytes，from which they are derived；alveolar macrophages in the
lungs, which take up inhaled particles not cleared by the mucociliary rejection current; phagocytic cells in the lymph nodes, spleen and bone marrow; Kupffer cells of the liver sinusoids; and microglial cells of the central nervous system.

## Lymphocytes

Lymphocytes are normally present in small numbers; they are numerous in general connective tissue only in pathological states, when they migrate in from adjacent lymphoid tissue or from the circulation. The majority are small cells ( $6-8 \mu \mathrm{~m}$ ) with highly heterochromatic nuclei but they enlarge when stimulated. Two major functional classes exist, termed B and T lymphocytes. B lymphocytes originate in the bone marrow, then migrate to various lymphoid tissues, where they proliferate. When antigenically stimulated, they undergo further mitotic divisions, then enlarge as they mature, commonly in general connective tissues, to form plasma cells that synthesize and secrete antibodies (immunoglobulins). Mature plasma cells are rounded or ovoid, up to $15 \mu \mathrm{~m}$ across, and have an extensive rough endoplasmic reticulum. Their nuclei are spherical, often eccentrically situated, and have a characteristic 'clock-face' configuration of heterochromatin (see Fig. 4.12) that is regularly distributed in peripheral clumps. The prominent Golgi complex is visible with a light microscope as a pale region to one side of the nucleus and the remaining cytoplasm is deeply basophilic because of the abundant rough endoplasmic reticulum. Mature plasma cells do not divide.

T lymphocytes originate from precursors in bone marrow haemopoietic tissue but later migrate to the thymus, where they develop T-cell identity, before passing into the peripheral lymphoid system, where they continue to multiply. When antigenically stimulated, T cells enlarge and their cytoplasm becomes filled with free polysome clusters. The functions of T lymphocytes are numerous: different subsets recognize and destroy virus-infected cells, tissue and organ grafts, or interact with B lymphocytes and several other defensive cell types.

## Mast cells

Mast cells are important defensive cells. They occur particularly in loose connective tissues and in the fibrous capsules of certain organs such as the liver, and are numerous around blood vessels. Mast cells are round or oval, approximately $20 \mu \mathrm{~m}$ in diameter, with many filopodia extending from the cell surface. The nucleus is centrally placed and relatively small. The cytoplasm contains large numbers of prominent vesicles and a well-developed Golgi apparatus, but scant endoplasmic reticulum. The vesicles have a high content of glycosaminoglycans and show a strongly positive reaction with the PAS stain for carbohydrates. They are membrane-bound, vary in size and shape (mean diameter $0.5 \mu \mathrm{~m}$ ) and also have a rather heterogeneous content of dense, lipid-containing material, which may be finely granular, lamellar or in the form of membranous whorls.

The major granule components, many of them associated with inflammation (Frenzel and Hermine 2013), are the proteoglycan heparin, histamine, tryptase, superoxide dismutase, aryl sulphatase, $\beta$-hexosaminidase and various other enzymes, including chymase in connective tissue but not mucosal mast cells, together with chemotactic factors for neutrophil and eosinophil granulocytes. There are functional differences between mast cells found in different tissues.

Mast cells may be stimulated to release some or all of their contents, either by direct mechanical or chemical trauma, or after contact with particular antigens to which the body has previously been exposed. The consequences of granule release include alteration of capillary permeability, smooth muscle contraction, and activation and attraction to the locality of various other defensive cells. Responses to mast cell degranulation may be localized, e.g. urticaria, or there may occasionally be a generalized response to the release of large amounts of histamine into the circulation (anaphylactic shock). Mast cells closely resemble basophil granulocytes of the general circulation but are thought to develop as distinct descendants of an earlier myeloid lineage precursor. It is believed that they are generated in the bone marrow and circulate to the tissues as immature basophil-like cells, migrating through the capillary and venule walls to their final destination. For further reading, see Bischoff (2007) and Collington et al (2011).

## Granulocytes (polymorphonuclear leukocytes)

Neutrophil and eosinophil granulocytes are immigrant cells from the circulation. Relatively infrequent in normal connective tissues, their numbers may increase dramatically in infected tissues, where they are important components of cellular defence. Neutrophils are highly phagocytic, especially towards bacteria. The functions of eosinophils are less well understood. These cells are described further in Chapter 4.

## CELLS OF SPECIALIZED CONNECTIVE TISSUES

Skeletal tissues - namely, cartilage and bone - are generally classified with the connective tissues, but their structure and functions are highly specialized and they are described in Chapter 5. As with the general connective tissues, these specialized types are characterized by their extracellular matrix, which forms the major component of the tissues and is responsible for their properties. The resident cells are different from those in general connective tissues. Cartilage is populated by chondroblasts, which synthesize the matrix, and by mature chondrocytes. Bone matrix is elaborated by osteoblasts. Their mature progeny, osteocytes, are embedded within the matrix, which they help to mineralize, turn over and maintain. A third cell type, the osteoclast, has a different lineage origin and is derived from haemopoietic tissue; osteoclasts are responsible for bone degradation and remodelling in collaboration with osteoblasts.

## EXTRACELLULAR MATRIX

The term extracellular matrix is applied collectively to the extracellular components of connective and supporting tissues. Essentially, it consists of a system of insoluble protein fibres, adhesive glycoproteins and soluble complexes composed of carbohydrate polymers linked to protein molecules (proteoglycans and glycosaminoglycans), which bind water. The extracellular matrix distributes the mechanical stresses on tissues and also provides the structural environment of the cells embedded in it, forming a framework to which they adhere and on which they can move (reviewed in Even-Ram and Yamada (2005) and Wolf and Friedl (2011)). With the exception of bone matrix, it provides a highly hydrated medium, through which metabolites, gases and nutrients can diffuse freely between cells and the blood vessels traversing it or, in the case of cartilage, passing nearby.

There are many complex interactions between connective tissue cells and the extracellular matrix. The cells continually synthesize, secrete, modify and degrade extracellular matrix components, and respond to contact with the matrix in the regulation of cell metabolism, proliferation and motility. Degradation of the matrix is an important feature of embryonic development, morphogenesis, angiogenesis, tissue repair and remodelling (Mott and Werb 2004). Various types of proteinase are involved, principally metalloproteinases such as matrix metalloproteinases (MMPs), and those with a disintegrin and metalloproteinase domain (ADAMs) that include ADAMs with a thrombospondin domain (ADAMTS). Tissue remodelling depends on the controlled degradation of the extracellular matrix by secreted MMPs, regulated by their specific inhibitors, as occurs, for instance, during involution of the postpartum uterus or during menstrual lysis and shedding of the endometrium (Gaide Chevronnay et al 2012). In the process of matrix degradation, bioactive peptides are liberated that act as growth factors, cytokines and other signalling molecules to change the behaviour of cells in the vicinity. While precisely regulated under physiological conditions, pathologically dysregulated extracellular matrix degradation is a cause of many diseases, such as atherosclerosis, emphysema, osteoarthritis and diabetic vascular complications.

The insoluble fibres are mainly of two types of structural protein: members of the collagen family, and elastin (Fig. 2.13). The

Fig. 2.13 Elastic fibres, seen as fine, dark, relatively straight fibres in a whole-mount preparation of mesentery, stained for elastin. The wavy pink bands are collagen bundles and oval grey nuclei are mainly of fibroblasts.
interfibrillar matrix (ground substance) includes a number of adhesive glycoproteins that perform a variety of functions in connective tissues, including cell-matrix adhesion and matrix-cell signalling. These glycoproteins include fibronectin, laminin, tenascin and vitronectin, in addition to a number of other less well characterized proteins. The glycosaminoglycans of the interfibrillar matrix are, with one notable exception, post-translationally modified proteoglycan molecules in which long polysaccharide side chains are added to short core proteins during transit through the secretory pathway between the rough endoplasmic reticulum and the trans-Golgi network. The exception, the polymeric disaccharide, hyaluronan, has no protein core and is synthesized entirely by cell surface enzymes. For further reading on extracellular matrix molecules, see Pollard et al (2008). Functional attributes of connective tissues vary and depend on the abundance of its different components. Collagen fibres resist tension, whereas elastin provides a measure of resilience to deformation by stretching. The highly hydrated, soluble polymers of the interfibrillar material (proteoglycans and glycosaminoglycans, mainly hyaluronan) generally form a stiff gel resisting compressive forces. Thus tissues that are specialized to resist tensile forces (e.g. tendons) are rich in collagen fibrils; tissues that accommodate changes in shape and volume (e.g. mesenteries) are rich in elastic fibres; and those that absorb compressive forces (e.g. cartilages) are rich in glycosaminoglycans and proteoglycans. In bone, mineral crystals take the place of most of the soluble polymers and endow the tissue with incompressible rigidity.

## Fibrillar matrix

## Collagens

Collagens make up a very large proportion (approximately 30\%) of all the proteins of the body. They consist of a wide range of related molecules that have various roles in the organization and properties of connective (and some other) tissues. The first collagen to be characterized was type I, the most abundant of all the collagens and a constituent of the dermis, fasciae, bone, tendon, ligaments, blood vessels and the sclera of the eyeball. The characteristic collagen of cartilage and the vitreous body of the eye, with a slightly different chemical composition, is type II, whereas type III is present in several tissues, including the dermis and blood vessels, and type IV is in basal lamina. The other types are widely distributed in various tissues. Five of the collagens, types I, II, III, V and XI, form fibrils; types IV, VIII and X form sheets or meshworks; types VI, VII, IX, XII, XIV and XVIII have an anchoring or linking role; and types XIII and XVII are transmembrane proteins.

Biochemically, all collagens have a number of features in common. Unlike most other proteins, they contain high levels of hydroxyproline and all are composed of three polypeptides that form triple helices and are substantially modified post-translationally. After secretion, individual molecules are further cross-linked to form stable polymers. Functionally, collagens are structural proteins with considerable mechanical strength. Just a few of their distinguishing structural features are described below. For further reading on the molecular structure and functions of the collagens, see Pollard et al (2008).

## Type I collagen

Type I collagen is very widely distributed. It forms inextensible fibrils in which collagen molecules (triple helices) are aligned side by side in a staggered fashion, with three-quarters of the length of each molecule in contact with neighbouring molecules. The fibril has well-marked bands of charged and uncharged amino acids arranged across it; these stain with heavy metals in a banding pattern that repeats every 65 nm in longitudinal sections viewed in the electron microscope (see Fig. 2.10 insert).

Fibril diameters vary between tissues and with age. Developing tissues often have thinner fibrils than mature tissues. Corneal stroma fibrils are of uniform and thin diameter, whereas tendon fibrils may be up to 20 times thicker and quite variable. Tissues in which the fibrils are subject to high tensile loading tend to have thicker fibrils. Thick fibrils are composites of uniform thin fibrils with a diameter of 8-12 nm. The fibrils themselves are relatively flexible, but when mineralized (as in bone) or surrounded by high concentrations of proteoglycan (as in cartilage), the resulting fibre-reinforced composite materials are rigid.

Fresh type I collagen fibres are tightly packed assemblies of parallel fibrils and are white and glistening. They form variably wavy (crimped) bundles of various sizes that are generally visible at the light microscope level. The component fibres may leave one bundle and interweave with others. In some situations, collagen fibrils are laid down in precise geometrical patterns, in which successive layers alternate in direction, e.g. corneal stroma, where the high degree of order is essential for transpar-

Fig. 2.14 Reticular fibres (type III collagen; reticulin demonstrated by silver-staining) in human liver, forming a delicate meshwork within the space of Disse between hepatocytes (H), plasma membranes and the sinusoidal endothelia (S). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
ency. Tendons, aponeuroses and ligaments are also highly ordered tissues (Ch. 5).

## Types II, III, V and XI collagens

Types II, III, V and XI collagens can also aggregate to form linear fibrils. Type II collagen occurs in extremely thin $(10 \mathrm{~nm})$, short fibrils in the vitreous humour and in very thick fibrils in ageing human cartilage. The amino-acid sequence and banding pattern are very similar to those of type I collagen, as are the post-translational modifications of the triple helical protein molecule. The fine fibrils in the vitreous may fuse into thicker aggregates in older tissue.

Type III collagen is very widely distributed, particularly in young and repairing tissues. It usually co-localizes with type I collagen, and covalent links between type I and type III collagen have been demonstrated. In skin, many fibrils are probably composites of type I and type III collagens.

## Reticular fibres

Fine branching and anastomosing reticular fibres form the supporting mesh framework of many glands, including the liver (Fig. 2.14), the kidney and lymphoreticular tissue (lymph nodes, spleen, etc.). Classically, these fibres stained intensely with silver salts, although they are poorly stained using conventional histological techniques. They associate with basal laminae and are often found in the neighbourhood of collagen fibre bundles. Reticular fibres are formed principally of type III collagen.

## Elastin

Elastin is a 70 kDa protein, rich in the hydrophobic amino acids valine and alanine. Elastic fibrils, which also contain fibrillin, are highly crosslinked via two elastin-specific amino acids, desmosine and isodesmosine, which are formed extracellularly from lysine residues. They are less widely distributed than collagen, yellowish in colour, typically cross-linked and usually thinner ( $10-20 \mathrm{~nm}$ ) than collagen fibrils. They can be thick, e.g. in the ligamenta flava and ligamentum nuchae. Unlike collagen type I, they show no banding pattern in the electron microscope. They stain poorly with routine histological stains but are stained with orcein-containing preparations (see Fig. 2.13). They sometimes appear as sheets, as in the fenestrated elastic lamellae of the aortic wall. Elastin-rich structures stretch easily with almost perfect recoil, although they tend to calcify with age and lose elasticity. Elastin is highly resistant to attack by acid and alkali, even at high temperatures.

## Interfibrillar matrix

## Glycosaminoglycans

The structural soluble polymers characteristic of the extracellular matrix are the acidic glycosaminoglycans, which are unbranched chains of repeating disaccharide units, each unit carrying one or more negatively charged groups (carboxylate or sulphate esters, or both). The anionic charge is balanced by cations ( $\mathrm{Na}^{+}, \mathrm{K}^{+}$, etc.) in the interstitial fluid. Their polyanionic character endows the glycosaminoglycans with high osmotic activity, which helps to keep the fibrils apart, confers stiffness
on the porous gel that they collectively create, and gives the tissue a varying degree of basophilia. Glycosaminoglycans are named according to the tissues in which they were first found, e.g. hyaluronan (vitreous body), chondroitins (cartilage), dermatan (skin), keratan (cornea), heparan (liver). This terminology is no longer relevant, as most glycosaminoglycans are very widely distributed, whereas, conversely, some corneas contain little or no keratan sulphate. Of the glycosaminoglycans, all except hyaluronan have short protein cores and are highly variable in their carbohydrate side-chain structure.

## Hyaluronan

Hyaluronan was formerly called hyaluronic acid (or hyaluronate, as only the salt exists at physiological pH ). It is a very large, highly hydrated molecule ( $25,000 \mathrm{kDa}$ ). Hyaluronan is found in all extracellular matrices and in most tissues, and is a prominent component of embryonic and developing tissues.

Hyaluronan is important in the aggregation of proteoglycans and link proteins that possess specific hyaluronan binding sites (e.g. laminin). Indeed, the very large aggregates that are formed may be the essential compression-resisting units in cartilage. Hyaluronan also forms very viscous solutions, which are probably the major lubricants in synovial joints. Because of its ability to bind water, it is often present in semi-rigid structures (e.g. vitreous humour in the eye), where it cooperates with sparse but regular meshworks of thin collagen fibrils.

## Proteoglycans

Proteoglycans have been classified according to the size of their protein core; their nomenclature is under review. The same core protein can bear different glycosaminoglycan side chains in different tissues. The functions of many proteoglycans are poorly understood. Some of the better-known proteoglycans are: aggrecan in cartilage, perlecan in basal laminae, decorin associated with fibroblasts in collagen fibril assembly, and syndecan in embryonic tissues.

## Adhesive glycoproteins

These proteins include molecules that mediate adhesion between cells and the extracellular matrix, often in association with collagens, proteoglycans or other matrix components. All of them are glycosylated and they are, therefore, glycoproteins. General connective tissue contains the well-known families of fibronectins (and osteonectin in bone), laminins and tenascins; there is a rapidly growing list of other glycoproteins associated with extracellular adhesion (Pollard et al 2008). They possess binding sites for other extracellular matrix molecules and for cell adhesion molecules, especially the integrins; in this way they enable cells selectively to adhere to and migrate through, appropriate matrix structures (reviewed in Jacquemet et al (2013)). They also function as signalling molecules, which are detected by cell surface receptors and initiate changes within the cytoplasm (e.g. to promote the formation of hemidesmosomes or other areas of strong adhesion; reorganize the cytoskeleton; and promote or inhibit locomotion and cell division).

## Fibronectin

Fibronectin is a large glycoprotein consisting of a dimer joined by disulphide links. Each subunit is composed of a string of large repetitive domains linked by flexible regions. Fibronectin subunits have binding sites for collagen, heparin and cell surface receptors, especially integrins, and so can promote adhesion between all these elements. In connective tissues, the molecules are able to bind to cell surfaces in an orderly fashion, to form short fibronectin filaments. The liver secretes a related protein, plasma fibronectin, into the circulation. The selective adhesion of different cell types to the matrix during development and in postnatal life is mediated by numerous isoforms of fibronectin generated by alternative splicing. Isoforms found in embryonic tissues are also expressed during wound repair, when they facilitate tissue proliferation and cell movements; the adult form is re-expressed once repair is complete.

## Laminin

Laminin is a large ( 850 kDa ) flexible molecule composed of three polypeptide chains (designated $\alpha, \beta$ and $\gamma$ ). There are many isoforms of the different chains, and at least 18 types of laminin. The prototypical molecule has a cruciform shape, in which the terminal two-thirds are wound round each other to form the stem of a cross, and the shorter free ends form the upright and transverse members. Laminin bears binding sites for other extracellular matrix molecules such as heparan sulphate, type IV collagen and entactin, and also for laminin receptor molecules (integrins) situated in cell plasma membranes. Laminin molecules can assemble themselves into flat regular meshworks, e.g. in the basal lamina.

## Tenascin

Tenascin is large glycoprotein composed of six subunits that are joined at one end to form a structure that resembles the spokes of a wheel. There is a family of tenascin molecules, generated by alternative splicing of the tenascin gene transcript. Tenascin is abundant in embryonic tissues but its distribution is restricted in the adult. It appears to be important in guiding cell migration and axonal growth in early development: it may either promote or inhibit these activities, depending on the cell type and tenascin isoform.

## CLASSIFICATION OF CONNECTIVE TISSUES

Connective and supporting tissues differ considerably in appearance, consistency and composition in different regions. These differences reflect local functional requirements and are related to the predominance of the cell types; the concentration, arrangement and types of fibre; and the characteristics of the interfibrillar matrix. On these bases, general connective tissues can be classified into irregular and regular types, according to the degree of orientation of their fibrous components.

## Irregular connective tissues

Irregular connective tissues can be further subdivided into loose, dense and adipose connective tissue.

## Loose (areolar) connective tissue

Loose connective tissue is the most generalized form and is extensively distributed. Its chief function is to bind structures together, while still allowing a considerable amount of movement to take place. It constitutes the submucosa in the digestive tract and other viscera lined by mucosae, and the subcutaneous tissue in regions where this is devoid of fat (e.g. eyelids, penis, scrotum and labia), and it connects muscles, vessels and nerves with surrounding structures. It is present in the interior of organs, where it binds together the lobes and lobules of glands, forms the supporting layer (lamina propria) of mucosal epithelia and vascular endothelia, and lies within and between fascicles of muscle and nerve fibres.

Loose connective tissue consists of a meshwork of thin collagen and elastin fibres interlacing in all directions (see Fig. 2.13) to give a measure of both elasticity and tensile strength. The large meshes contain the soft, semi-fluid interfibrillar matrix or ground substance, and different connective tissue cells, which are scattered along the fibres or in the meshes. It also contains adipocytes, usually in small groups, and particularly around blood vessels.

A variant of loose connective tissue occurs in the choroid and the sclera of the eye, where large numbers of pigment cells (melanocytes) are also present.

## Dense irregular connective tissue

Dense irregular connective tissue is found in regions that are under considerable mechanical stress and where protection is given to ensheathed organs. The matrix is relatively acellular and contains a high proportion of collagen fibres organized into thick bundles interweaving in three dimensions and imparting considerable strength. There are few active fibroblasts, which are usually flattened with heterochromatic nuclei. Dense irregular connective tissue occurs in: the reticular layer of the dermis; the superficial connective tissue sheaths of muscle and nerves, and the adventitia of large blood vessels; and the capsules of various glands and organs (e.g. testis, sclera of the eye, periostea and perichondria).

## Adipose tissue

A few adipocytes occur in loose connective tissue in most parts of the body. However, they constitute the principal component of adipose tissue (see Fig. 2.11), where they are embedded in a vascular loose connective tissue, usually divided into lobules by stronger fibrous septa carrying the larger blood vessels. Adipose tissue only occurs in certain regions. In particular it is found: in subcutaneous tissue; in the mesenteries and omenta; in the female breast; in bone marrow; as retro-orbital fat behind the eyeball; around the kidneys; deep to the plantar skin of the foot; and as localized pads in the synovial membrane of many joints. Its distribution in subcutaneous tissue shows characteristic age and sex differences. Fat deposits serve as energy stores, sources of metabolic lipids, thermal insulation (subcutaneous fat) and mechanical shock-absorbers (e.g. soles of the feet, palms of the hands, gluteal region and synovial membranes).

Fig. 2.15 Dense regular connective tissue in a tendon. Thick parallel bundles of type I collagen (here stained pink) give tendon its white colour in life. The elongated nuclei of inactive fibroblasts (tendon cells) are visible between collagen bundles.

## Regular connective tissues

Regular connective tissues include highly fibrous tissues in which fibres are regularly orientated, either to form sheets such as fasciae and aponeuroses, or as thicker bundles such as ligaments or tendons (Fig. 2.15). The direction of the fibres within these structures is related to the stresses that they undergo: fibrous bundles display considerable interweaving, even within tendons, which increases their structural stability and resilience.

The fibroblasts that secrete the fibres may eventually become trapped within the fibrous structure, where they become compressed, relatively inactive cells with stellate profiles and small heterochromatic nuclei; these cells are called tendon cells. Fibroblasts on the external surface may be active in continued fibre formation and they constitute a pool of cells available for repair of injured tissue.

Although regular connective tissue is predominantly collagenous, some ligaments contain significant amounts of elastin, e.g. the ligamenta flava of the vertebral laminae and the vocal folds. The collagen fibres may form precise geometrical patterns, as in the cornea.

## Mucoid tissue

Mucoid tissue is found chiefly as a stage in the development of connective tissue from mesenchyme. It exists in Wharton's jelly, which forms the bulk of the umbilical cord, and consists substantially of extracellular matrix, largely made up of hydrated mucoid material and a fine meshwork of collagen fibres, in which nucleated, fibroblast-like cells with branching processes are found. Fibres are usually rare in typical mucoid tissue, although the full-term umbilical cord contains perivascular collagen fibres. Postnatally, mucoid tissue is seen in the pulp of a developing tooth, the vitreous body of the eye (a persistent form of mucoid tissue that contains few fibres or cells) and the nucleus pulposus of the intervertebral disc.

## TRANSDIFFERENTIATION AND METAPLASIA

Transitions occur between populations of cells forming an epithelium (sheets of polarized cells) and mesenchymal types (where the cells lack polarity) during normal development (see Thiery et al (2009)). In postnatal life, most well-described transitions between morphologically different cell types do not cross an epithelial-mesenchymal boundary but are transitions between types of epithelial cell or, less frequently, between mesenchymal (connective tissue) cell types. Most instances of such transdifferentiation (metaplasia, see Commentary 1.4) are adaptive, to changing environmental conditions or trauma, and almost all are pathological; the altered cells are termed metaplastic. A very common and physiologically normal example is the squamous metaplasia of columnar secretory epithelium of the distal endocervical canal, when exposed to the hormonally stimulated vaginal environment. Gastric metaplasia of the lower oesophagus may occur when chronic reflux of gastric juices exposes its stratified squamous epithelial lining to acid, and the original epithelium is replaced by a mucus-secreting columnar epithelium typical of the stomach (Barrett's oesophagus); this is pathological and susceptible to malignant change. Similarly, the respiratory epithelium (see Fig. 2.2D) of the upper airway often develops

Fig. 2.16 A generalized mucosa and supporting tissues. For details and variations, see text.
foci of stratified squamous metaplasia in response to irritants in cigarette smoke. Mesenchymal (osseous) metaplasia can occur, for example, in the fibrous connective tissue of muscles subjected to repeated damage, where trabeculi of bone develop. It is thought that stem cells (rather than the differentiated cells) in the affected tissue respond to changes in their environment by altering their differentiation pathway, a process that may be reversible if the stimulus is removed.

## MUCOSA (MUCOUS MEMBRANE)

A mucosa or mucous membrane (Fig 2.16) lines many internal hollow organs in which the inner surfaces are moistened by mucus, such as the intestines, conducting portions of the airway, and the genital and urinary tracts. A mucosa proper consists of an epithelial lining, which may have the ducts of mucosal, submucosal or extrinsic glands opening on to its surface, an underlying loose connective tissue, the lamina propria, and a thin layer of smooth muscle, the muscularis mucosae. This last layer either may be absent from some mucosae, or may be replaced by a layer of elastic fibres. The term mucous membrane reflects the fact that these tissues can all be peeled away as a sheet or membrane from underlying structures; the plane of separation occurs along the muscularis mucosae.

Submucosa is a layer of supporting connective tissue that usually lies below the muscularis mucosae. It may contain mucous or seromucous submucosal glands. Inflammation of the viscera involves, primarily, the connective tissues of the submucosa and lamina propria, and is characterised by dilated vessels, oedema, and accumulations of extravasated immune defence cells. Most mucosae are also supported by one or more layers of smooth muscle, the muscularis externa. Contraction of this muscle may constrict the mucosal lumen (e.g. in the airway) or, where there are two or more muscle layers orientated in opposing directions (e.g. in the intestines), cause peristaltic movement of the viscus and the contents of its lumen. The outer surface of the muscle may be covered by a serosa or, where the structure is retroperitoneal or passes through the pelvic floor, by a connective tissue adventitia.

## MUCUS

Mucus is a viscous suspension of complex glycoproteins (mucins) of various kinds, and is secreted by scattered individual epithelial (goblet) cells, a secretory surface epithelium (e.g. the stomach lining) or mucous and seromucous glands. The precise composition of the mucus varies with the tissue and secretory cells that produce it. All mucins consist of filamentous core proteins to which are attached carbohydrate chains, usually branched; salivary mucus contains nearly 600 chains. Carbohydrate residues include glucose, fucose, galactose and N -acetylglucosamine (sialic acid). The terminals of some carbohydrate chains are identical to the blood group antigens of the ABO group in the majority of the population (secretors, bearing the secretor gene $S^{e}$ ), and can be detected in salivary mucus by means of appropriate clinical tests. The long polymeric carbohydrate chains bind water and protect surfaces against
drying；they also provide good lubricating properties．In concentrated form，mucins form viscous layers that protect the underlying tissues against damage．

Synthesis of mucus starts in the rough endoplasmic reticulum．It is then passed to the Golgi complex，where it is conjugated with sulphated carbohydrates to form the glycoprotein，mucinogen，and this is exported in small，dense，membrane－bound vesicles that swell as they approach the cell surface，with which they fuse before releasing their contents．

## SEROSA（SEROUS MEMBRANE）

Serosa consists of a single layer of squamous mesothelial cells，express－ ing keratin intermediate filaments，supported by an underlying layer of loose connective tissue that contains numerous blood and lymphatic vessels．Serosa lines the pleural，pericardial and peritoneal cavities，and covers the external surfaces of organs lying within those cavities and，in the abdomen，the mesenteries that envelop them．A potential space， filled with a small amount of protein－containing serous fluid－largely an exudate of interstitial fluid－exists between the outer parietal and the inner visceral layers of the serosa．

## FASCIA

Fascia is a generic term applied to sheaths，sheets or other dissectible masses of connective tissue that are large enough to be visible to the unaided eye．The terms superficial fascia and deep fascia，widely used to describe the connective tissue between the skin and underlying muscle，and the connective tissue surrounding muscles，viscera and related structures，respectively，are no longer included in the Terminolo－ gia Anatomica，although they remain in common usage in the English language．Tela subcutanea，hypodermis and subcutaneous tissue are the recommended synonymous terms that replace superficial fascia． Deeper－lying condensations of connective tissue have been defined according to their location，e．g．investing muscles（fascia musculorum） or viscera（fascia visceralis）．Loosely packed connective tissue surrounds peripheral nerves，blood and lymph vessels as they pass between other structures，often linking them together as neurovascular bundles． Some large vessels，e．g．the common carotid and femoral arteries，are invested by a dense connective tissue sheath that may be functionally significant，aiding venous return by approximating large veins to pulsat－ ing arteries．

The nervous system has two major divisions, the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain, spinal cord, optic nerve and retina, and contains the majority of neuronal cell bodies. The PNS includes all nervous tissue outside the CNS and consists of the cranial and spinal nerves, the peripheral autonomic nervous system (ANS) and the special senses (taste, olfaction, vision, hearing and balance). It is composed mainly of the axons of sensory and motor neurones that pass between the CNS and the body. The ANS is subdivided into sympathetic and parasympathetic components. It consists of neurones that innervate secretory glands and cardiac and smooth muscle, and is concerned primarily with control of the internal environment. Neurones in the wall of the gastrointestinal tract form the enteric nervous system (ENS) and are capable of sustaining local reflex activity that is independent of the CNS. The ENS contains as many intrinsic neurones in its ganglia as the entire spinal cord and is often considered as a third division of the nervous system (Gershon 1998).

In the CNS, the cell bodies of neurones are often grouped together in discrete areas termed nuclei, or they may form more extensive layers or masses of cells; collectively they constitute the grey matter. Neuronal dendrites and synaptic contacts are mostly confined to areas of grey matter and form part of its meshwork of neuronal and glial processes, termed the neuropil. Their axons join bundles of nerve fibres that tend to be grouped separately to form tracts. In the spinal cord, cerebellum, cerebral cortices and some other areas, concentrations of tracts constitute the white matter, so called because the axons are often ensheathed in lipid-rich sheaths of myelin, which is white when fresh (Fig. 3.1; see Fig. 16.9).

The PNS is composed of the efferent axons (fibres) of motor neurones situated inside the CNS, and the cell bodies of sensory neurones (grouped together as ganglia) and their afferent processes. Sensory cells in dorsal root ganglia give off both centrally and peripherally directed processes; there are no synapses on their cell bodies. Also included are ganglionic neurones of the ANS, which receive synaptic contacts from the peripheral fibres of preganglionic autonomic neurones whose cell bodies lie within the CNS. For further details of the organization of the nervous system, see Chapter 16.

When the neural tube is formed during prenatal development (Sanes et al 2011), its walls thicken greatly but do not completely obliterate the cavity within. The latter remains in the spinal cord as the narrow central canal and becomes greatly expanded in the brain to form a series of interconnected cavities called the ventricular system. In the fore- and hindbrains, parts of the neural tube roof do not generate neurones but become thin, folded sheets of secretory tissue, which are invaded by blood vessels and are called the choroid plexuses. The latter secrete cerebrospinal fluid (CSF), which fills the ventricles and subarachnoid spaces, and penetrates the intercellular spaces of the brain and spinal cord to create their interstitial fluid. The CNS has a rich blood supply, which is essential to sustain its high metabolic rate. The blood-brain barrier places considerable restrictions on the substances that are able to diffuse from the blood stream into the neuropil.

Neurones encode information, conduct it over considerable distances, and then transmit it to other neurones or to various non-neural targets such as muscle cells. The propagation of this information within the nervous system depends on rapid electrical signals, the action potentials. Transmission to other cells is mediated by secretion of neurotransmitters at special junctions, either with other neurones (synapses), or with cells outside the nervous system, e.g. muscle cells at neuromuscular junctions, gland cells or adipose tissue, and causes changes in the behaviour of the target cells.

The nervous system contains large populations of non-neuronal cells, termed neuroglia or glia. These cells do not generate action potentials, but convey information encoded as transient changes in intracellular calcium concentration, termed calcium signalling. Glia interact
with neurones in many different ways; their two-way communication is essential for normal brain activity.

It was thought for many years that glia outnumbered neurones by 10 times in the CNS, but recent studies using the isotropic fractionator method have challenged that popular view, suggesting instead that the two cell populations are rather similar in size (Azevedo et al 2009). That said, the glia: neurone ratio has been reported to be as high as $17: 1$ in the thalamus (Pakkenberg and Gundersen 1988).

The glial population in the CNS consists of microglia and macroglia; the latter are subdivided into oligodendrocytes and astrocytes. The principal glial cell in the PNS is the Schwann cell. Satellite cells surround each neuronal soma in ganglia.

For further reading on the nervous system, see Finger (2001), Kandel et al (2012), Kettenmann and Ransom (2012), Levitan and Kaczmarek (2001), Nicholls et al (2011) and Squire et al (2012).

## NEURONES

Most of the neurones in the CNS are either clustered into nuclei, columns or layers, or dispersed within grey matter. Neurones in the PNS are confined to ganglia. Irrespective of location, neurones share many general features, which are discussed here in the context of central neurones. Special characteristics of ganglionic neurones and their adjacent tissues are discussed on page 57.

Neurones exhibit great variability in their size (cell bodies range from 5 to $100 \mu \mathrm{~m}$ diameter) and shape (Spruston 2008). Their surface areas are extensive because most neurones display numerous branched cell processes. They usually have a rounded or polygonal cell body (perikaryon or soma). This is a central mass of cytoplasm that encloses a nucleus and gives off long, branched extensions with which most intercellular contacts are made. Typically, one of these processes, the axon, is much longer than the others, the dendrites (Fig. 3.2). Generally, dendrites conduct electrical signals towards a soma whereas axons conduct impulses away from it.

Neurones can be classified according to the number and arrangement of their processes (Bota and Swanson 2007). Multipolar neurones (Fig. 3.3) are common; they have an extensive dendritic tree that arises either from a single primary dendrite or directly from the soma, and a single axon. Bipolar neurones, which typify neurones of the special sensory systems, have only a single dendrite that emerges from the soma opposite the axonal pole. Unipolar neurones, which transmit general sensation, e.g. dorsal root ganglion neurones, have a single short process that bifurcates into a peripheral and a central process. This arrangement arises by the fusion of the proximal axonal and dendritic processes of a bipolar neurone during development, and so such neurones may also be termed pseudounipolar. Neurones may also be classified according to whether their axons terminate locally on other neurones (interneurones), or transmit impulses over long distances, often to distinct territories via defined tracts (projection neurones).

Neurones are postmitotic cells and, with few exceptions, they are not replaced when lost.

## SOMA

The plasma membrane of the soma is generally unmyelinated and is contacted by both inhibitory and excitatory axosomatic synapses; very occasionally, somasomatic and dendrosomatic contacts may be made. The non-synaptic surface may contain gap junctions and is partly covered by either astrocytic or satellite oligodendrocyte processes.

The cytoplasm of a typical soma (see Fig. 3.2) is rich in rough and smooth endoplasmic reticulum and free polyribosomes, indicating a high level of protein synthetic activity. Free polyribosomes often

Fig. 3.1 A section through the human cerebellum stained to show the arrangement in the brain of the central white matter (WM, deep pink) and the highly folded outer grey matter (GM). In the cerebellum, GM consists of an inner granular layer of tightly packed small neurones (blue) and an outermost molecular layer (pale pink), where neuronal processes make synaptic contacts. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 3.2 A schematic view of typical neurones featuring one with the soma cut away to show the nucleus and cytoplasmic organelles, dendritic trees with synaptic contacts, other types of synapse, the axon hillock and a myelinated axon.
congregate in large groups associated with the rough endoplasmic reticulum. These aggregates of RNA-rich structures are visible by light microscopy as basophilic Nissl bodies or granules. They are distributed throughout the cell body and large dendrites; the axon hillock is conspicuously ribosome-free. Nissl bodies are more obvious in large, highly active cells, such as spinal motor neurones (Fig. 3.4), which contain large stacks of rough endoplasmic reticulum and polyribosome aggregates. Maintenance and turnover of cytoplasmic and membranous components are necessary activities in all cells; the huge total volume of cytoplasm within the soma and processes of many neurones requires a considerable commitment of protein synthetic machinery. Neurones also synthesize other proteins (enzyme systems, G-protein coupled receptors, scaffold proteins) involved in the production of neurotransmitters and in the reception and transduction of incoming stimuli. Various transmembrane channel proteins and enzymes are located at the surfaces of neurones, where they are associated with movements of ions.

The nucleus is characteristically large and euchromatic, and contains at least one prominent nucleolus; these are features typical of all cells engaged in substantial levels of protein synthesis. The cytoplasm contains many mitochondria and moderate numbers of lysosomes. Golgi complexes are usually close to the nucleus, near the bases of the main dendrites and opposite the axon hillock.

The neuronal cytoskeleton is a prominent feature of its cytoplasm and gives shape, strength and support to the dendrites and axons. A number of neurodegenerative diseases are characterized by abnormal aggregates of cytoskeletal proteins (reviewed in Cairns et al (2004)). Neurofilaments (the intermediate filaments of neurones) and microtubules are abundant in the soma and along dendrites and axons; the proportions vary with the type of neurone and cell process. Bundles of neurofilaments constitute neurofibrils, which can be seen by light microscopy in silver-stained or immunolabelled sections. Neurofilaments are heteropolymers of proteins assembled from three polypep-
tide subunits, NF-L ( 68 kDa ), NF-M ( 160 kDa ) and NF-H (200 kDa). NF-M and NF-H have long C-terminal domains that project as side arms from the assembled neurofilament and bind to neighbouring filaments. They can be heavily phosphorylated, particularly in the highly stable neurofilaments of mature axons, and are thought to give axons their tensile strength. Some axons are almost filled by neurofilaments.

Microtubules are important in axonal transport, although dendrites usually have more microtubules than axons. Centrioles persist in mature postmitotic neurones, where they are concerned with the generation of microtubules rather than cell division. Centrioles are associated with cilia on the surfaces of developing neuroblasts. Their significance, other than at some sensory endings (e.g. the olfactory mucosa), is not known.

Pigment granules (Fig. 3.5) appear in certain regions, e.g. neurones of the substantia nigra contain neuromelanin, which is probably a waste product of catecholamine synthesis. A similar pigment gives a bluish colour to the neurones in the locus coeruleus. Some neurones are unusually rich in metals, which may form components of enzyme systems, e.g. zinc in the hippocampus and iron in the red nucleus. Ageing neurones, especially in spinal ganglia, accumulate granules of lipofuscin (senility pigment) in residual bodies, which are lysosomes packed with partially degraded lipoprotein material.

## DENDRITES

Dendrites are highly branched, usually short processes that project from the soma (see Fig. 3.2; Shah et al 2010). The branching patterns of many dendritic arrays are probably established by random adhesive interactions between dendritic growth cones and afferent axons that occur during development. There is an overproduction of dendrites in early development, and this is pruned in response to functional demand as the nervous system matures and information is processed through the dendritic tree. There is evidence that dendritic trees may be plastic structures throughout adult life, expanding and contracting as the traffic of synaptic activity varies through afferent axodendritic contacts (for a review, see Wong and Ghosh (2002)). Groups of neurones with similar functions have a similar stereotypic tree structure (Fig. 3.6), suggesting that the branching patterns of dendrites are important determinants of the integration of the afferent inputs that converge on the tree. For a review of current research on dendritic trees in the normal and pathological brain, see Kulkarni and Firestein (2012).

Dendrites differ from axons in many respects. They represent the afferent rather than the efferent system of the neurone, and receive both excitatory and inhibitory axodendritic contacts. They may also make dendrodendritic and dendrosomatic connections (see Fig. 3.9), some of which are reciprocal. Synapses occur either on small projections called dendritic spines or on the smooth dendritic surface. Dendrites contain ribosomes, smooth endoplasmic reticulum, microtubules, neurofilaments, actin filaments and Golgi complexes. Their neurofilament proteins are poorly phosphorylated and their microtubules express the microtubule-associated protein (MAP)-2 almost exclusively in comparison with axons.

The shapes of dendritic spines range from simple protrusions to structures with a slender stalk and expanded distal end. Most spines are not more than $2 \mu \mathrm{~m}$ long, and have one or more terminal expansions; they can also be short and stubby, branched or bulbous. Large mushroom spines are assumed to have differentiated in response to afferent activity ('memory spines'; Matsuzaki et al 2004). These large spines often contain a spine apparatus, an organelle consisting of small sacs of endoplasmic reticulum interleaved by electron-dense bars (Gray 1959, Segal et al 2010). Mouse mutants deficient in these organelles show memory deficits (Deller et al 2003). Free ribosomes and polyribosomes are concentrated at the base of the spine. Ribosomal accumulations near synaptic sites provide a mechanism for activity-dependent synaptic plasticity through the local regulation of protein synthesis.

## AXONS

The axon originates either from the soma or from the proximal segment of a dendrite at a specialized region free of Nissl granules, the axon hillock (see Fig. 3.2). Action potentials are initiated here, at the junction with the proximal axon (axon initial segment). The axonal plasma membrane (axolemma) is undercoated at the hillock by a concentration of cytoskeletal molecules, including spectrin and actin fibrils, which are important in anchoring numerous voltage-sensitive channels to the membrane. For details, see Bender and Trussell (2012), and for neural electrophysiological techniques, see Sakmann and Neher (2009). The

Fig. 3.3 The variety of shapes of neurones and their processes. The inset shows a human multipolar retinal ganglion cell, filled with fluorescent dye by microinjection. (Inset, Courtesy of Drs Richard Wingate, James Morgan and Ian Thompson, King's College, London.)

Fig. 3.4 Spinal motor neurones (toluidine blue stained resin section, rat tissue) showing a group of cell bodies (somata, S), some with the proximal parts of axonal and dendritic processes $(P)$ visible. Their nuclei $(\mathrm{N})$ typically have prominent, deeply staining nucleoli, indicative of metabolically highly active cells; two are visible in the plane of section Nissl granules (G) are seen in the cytoplasm. Surrounding the neuronal somata is the neuropil, consisting of the interwoven processes of these and other neurones and of glial cells.

Fig. 3.5 Neurones in the substantia nigra of the human midbrain, showing cytoplasmic granules of neuromelanin pigment (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 3.6 A Purkinje neurone from the cerebellum of a rat stained by the Golgi-Cox method, showing the extensive two-dimensional array of dendrites. (Courtesy of $\operatorname{Dr}$ Martin Sadler and Professor M Berry, Division of Anatomy and Cell Biology, GKT School of Medicine, London.)
axon hillock is unmyelinated and often participates in inhibitory axoaxonal synapses. It is unique because it contains ribosomal aggregates immediately below the postsynaptic membrane (Kole and Stuart 2012).

In the CNS, small, unmyelinated axons lie free in the neuropil, whereas in the PNS they are embedded in Schwann cell cytoplasm. Myelin, which is formed around almost all axons of $>2 \mu \mathrm{~m}$ diameter by oligodendrocytes in the CNS and by Schwann cells in the PNS, begins at the distal end of the axon hillock. Nodes of Ranvier are specialized regions of myelin-free axon where action potentials are generated and where an axon may branch. In both CNS and PNS, the territory of a myelinated axon between adjacent nodes is called an internode; the region close to a node, where the myelin sheath terminates, is called the paranode; and the region just beyond that is the juxtaparanode. Myelin thickness and internodal lengths are, in general, positively correlated with axon diameter. The density of sodium channels in the axolemma is highest at nodes of Ranvier, and very low along internodal membranes; sodium channels are spread more evenly within the axolemma of unmyelinated axons. Fast potassium channels are present in the paranodal regions of myelinated axons. Fine processes of glial cytoplasm (astrocytic in the CNS, Schwann cell in the PNS) surround the nodal axolemma.

The terminals of an axon are unmyelinated. Most expand into presynaptic boutons, which may form connections with axons, dendrites, neuronal somata or, in the periphery, muscle fibres, glands and lymphoid tissue. Exceptions include the free afferent sensory endings in, for example, the epidermis, which are unspecialized structurally, and the peripheral terminals of afferent sensory fibres with encapsulated endings (see Fig. 3.27). Axon terminals contain abundant small clear synaptic vesicles and large dense-core vesicles. The former contain a neurotransmitter (e.g. glutamate, $\gamma$-aminobutyric acid (GABA), acetylcholine) that is released into the synaptic cleft on the arrival of an action potential at the terminal and which then binds to cognate receptors on the postsynaptic membrane. Depending on the nature of the transmitter and its receptors, the postsynaptic neurone will become excited or inhibited. The dense-core vesicles contain neuropeptides, including brain-derived neurotrophic factor (BDNF; Dieni et al 2012). Axon terminals may themselves be contacted by other axons, forming axoaxonal presynaptic inhibitory circuits. Further details of neuronal microcircuitry are given in Kandel et al (2012) and Haines (2006).

Axons contain microtubules, neurofilaments, mitochondria, membrane vesicles, cisternae and lysosomes. They do not usually contain ribosomes or Golgi complexes, other than at the axon hillock; exceptionally, the neurosecretory fibres of hypothalamo-hypophysial neurones contain the mRNA of neuropeptides. Organelles are differentially distributed along axons, e.g. there is a greater density of mitochondria and membrane vesicles in the axon hillock, at nodes and in presynaptic endings. Axonal microtubules are interconnected by cross-linking MAPs, of which tau is the most abundant. Microtubules have an intrinsic polarity, and in axons all microtubules are uniformly orientated with their rapidly growing ends directed away from the soma towards the axon terminal. The microtubule binding protein tau plays an important
role in Alzheimer's disease (Cairns et al 2004): formation of tau oligomers and the subsequent pathological filament arrays are critical steps in the aetiopathogenesis of this condition. Neurofilament proteins ranging from high to low molecular weights are highly phosphorylated in mature axons, whereas growing and regenerating axons express a calmodulin-binding membrane-associated phosphoprotein, growthassociated protein-43 (GAP-43), as well as poorly phosphorylated neurofilaments.

Neurones respond differently to injury, depending on whether the damage occurs in the CNS or the PNS. The glial microenvironment of a damaged central axon does not facilitate axonal regrowth; consequently, reconnection with original synaptic targets does not normally occur. In marked contrast, the glial microenvironment in the PNS is capable of facilitating axonal regrowth. However, functional outcome of clinical repair of a large mixed peripheral nerve, especially if the injury occurs some distance from the target organ, or produces a long defect in the damaged nerve, is frequently unsatisfactory (Birch 2011; see also Commentary 1.6).

## Axoplasmic flow

Neuronal organelles and cytoplasm are in continual motion. Bidirectional streaming of vesicles along axons results in a net transport of materials from the soma to the terminals, with more limited movement in the opposite direction. Two major types of transport occur, one slow and one relatively fast. Slow axonal transport is a bulk flow of axoplasm only in the anterograde direction, carrying cytoskeletal proteins and soluble, non-membrane-bound proteins from the soma to the terminals at a rate of approximately $0.1-3 \mathrm{~mm}$ a day. In contrast, fast axonal transport carries membrane-bound vesicular material (endosomes and lysosomal autophagic vacuoles) and mitochondria at approximately 200 mm a day in the retrograde direction (towards the soma) and approximately 40 mm per day anterogradely (in particular, synaptic vesicles containing neurotransmitters).

Rapid flow depends on microtubules. Vesicles with side projections line up along microtubules and are transported along them by their side arms. Two microtubule-based motor proteins with adenosine $5^{\prime}$ triphosphatase (ATPase) activity are involved in fast transport: kinesin family proteins are responsible for the fast component of anterograde transport, and cytoplasmic dynein is responsible for retrograde transport. Retrograde transport mediates the movement of neurotrophic viruses, e.g. herpes zoster, rabies and polio, from peripheral terminals, and their subsequent concentration in the neuronal soma. It has been suggested that specific pools of endocytic organelles, signalling endosomes, mediate the long-distance axonal transport of growth factors, such as neurotrophins and their signalling receptors. Defects in axonal and dendritic transport have been linked to various neurodegenerative processes. See Guzik and Goldstein (2004), Hinckelmann et al (2013) and Schmieg et al (2014) for reviews of axonal transport in health and disease.

## SYNAPSES

Transmission of impulses across specialized junctions (synapses) between two neurones is largely chemical and depends on the release of neurotransmitters from the presynaptic terminal. These neurotransmitters bind to cognate receptors in the postsynaptic neuronal membrane, resulting in a change of membrane conductance and leading to either a depolarization or a hyperpolarization (Ryan and Grant 2009).

The patterns of axonal termination vary considerably. A single axon may synapse with one neurone (e.g. climbing fibres ending on cerebellar Purkinje neurones), or more often with many neurones (e.g. cerebellar parallel fibres, which provide an extreme example of this phenomenon). In synaptic glomeruli (e.g. in the olfactory bulb), groups of synapses between two or many neurones form interactive units encapsulated by neuroglia (Fig. 3.7; Perea et al 2009).

Electrical synapses (direct communication via gap junctions) are rare in the human CNS and are confined largely to groups of neurones with tightly coupled activity, e.g. the inspiratory centre in the medulla. They will not be discussed further here.

## Classification of chemical synapses

Chemical synapses have an asymmetric structural organization (Figs 3.8-3.9) in keeping with the unidirectional nature of their transmission. Typical chemical synapses share a number of important features. They all display an area containing a presynaptic density apposed to a

Fig. 3.7 The arrangement of a complex synaptic unit. A cerebellar synaptic glomerulus with excitatory (' + ') and inhibitory ('-') synapses grouped around a central axonal bouton. The directions of transmission are shown by the arrows.
corresponding postsynaptic density; the two are separated by a narrow (20-30 nm) gap, the synaptic cleft. Synaptic vesicles containing the appropriate neurotransmitter are found on the presynaptic side, clustered near the presynaptic density at the presynaptic membrane. Together these define the active zone, the area of the synapse where neurotransmission takes place (Eggermann et al 2012, Gray 1959).

Chemical synapses can be classified according to a number of different parameters, including the neuronal regions forming the synapse, their ultrastructural characteristics, the chemical nature of their neurotransmitter(s) and their effects on the electrical state of the postsynaptic neurone. The following classification is limited to associations between neurones. Neuromuscular junctions share many (though not all) of these parameters, and are often referred to as peripheral synapses. They are described separately on page 63.

Synapses can occur between almost any surface regions of the participating neurones. The most common type occurs between an axon and either a dendrite or a soma, when the axon is expanded as a small bulb or bouton (see Figs 3.8-3.9). This may be a terminal of an axonal branch (terminal bouton) or one of a row of bead-like endings, when the axon makes contact at several points, often with more than one neurone (bouton de passage). Boutons may synapse with dendrites, including thorny protrusions named dendritic spines or the flat surface of a dendritic shaft; a soma (usually on its flat surface, but occasionally on spines); the axon hillock; and the terminal boutons of other axons.

The connection is classified according to the direction of transmission, and the incoming terminal region is named first. Most common are axodendritic synapses, although axosomatic connections are frequent. All other possible combinations are found but are less common, i.e. axo-axonal, dendro-axonal, dendrodendritic, somatodendritic or somatosomatic. Axodendritic and axosomatic synapses occur in all regions of the CNS and in autonomic ganglia, including those of the ENS. The other types appear restricted to regions of complex interaction between larger sensory neurones and microneurones, e.g. in the thalamus.

Ultrastructurally, synaptic vesicles may be internally clear or dense, and of different size (loosely categorized as small or large) and shape (round, flat or pleomorphic, i.e. irregularly shaped). The submembranous densities may be thicker on the postsynaptic than on the presynaptic side (asymmetric synapses), or equivalent in thickness (symmetrical synapses), and can be perforated or non-perforated. Synaptic ribbons

Fig. 3.8 Electron micrographs demonstrating various types of synapse. A, A cross-section of a dendrite (D) on which two synaptic boutons (B) end. The upper bouton contains round vesicles, and the lower bouton contains flattened vesicles of the small type. A number of pre- and postsynaptic ( P ) thickenings mark the specialized zones of contact. B, A type I synapse (S, postsynaptic site) containing both small, round, clear vesicles and also large, dense-cored vesicles of the neurosecretory type. C, A large terminal bouton (B) of an optic nerve afferent fibre, which is making contact with a number of postsynaptic processes, in the dorsal lateral geniculate nucleus of the rat. One of the postsynaptic processes (*) also receives a synaptic contact from a bouton (Bf) containing flattened vesicles. D, Reciprocal synapses (S) between two neuronal processes in the olfactory bulb. (Courtesy of Professor AR Lieberman, Department of Anatomy, University College, London.)

Fig. 3.9 The structural arrangements of different types of synaptic contact.
are found at sites of neurotransmission in the retina and inner ear. They have a distinctive morphology, in that the synaptic vesicles are grouped around a ribbon- or rod-like density orientated perpendicular to the cell membrane (see Fig. 3.9).

Synaptic boutons make obvious close contacts with postsynaptic structures but many other terminals lack specialized contact zones. Areas of transmitter release occur in the varicosities of unmyelinated axons, where effects are sometimes diffuse, e.g. the aminergic pathways of the basal ganglia, and in autonomic fibres in the periphery. In some instances, such axons may ramify widely throughout extensive areas of the brain and affect the behaviour of very large populations of neurones, e.g. the diffuse cholinergic innervation of the cerebral cortices. Pathological degeneration of these pathways can therefore cause widespread disturbances in neural function.

Neurones express a variety of neurotransmitters, either as one class of neurotransmitter per cell or more often as several. Good correlations exist between some types of transmitter and specialized structural features of synapses. In general, asymmetric synapses with relatively small spherical vesicles are associated with acetylcholine (ACh), glutamate, serotonin (5-hydroxytryptamine, $5-\mathrm{HT}$ ) and some amines; those with dense-core vesicles include many peptidergic synapses and other amines (e.g. noradrenaline (norepinephrine), adrenaline (epinephrine), dopamine). Symmetrical synapses with flattened or pleomorphic vesicles have been shown to contain either GABA or glycine.

Neurosecretory endings found in various parts of the brain and in neuroendocrine glands and cells of the dispersed neuroendocrine system share many features with presynaptic boutons. They all contain peptides or glycoproteins within dense-core vesicles. The latter are of characteristic size and appearance: they are often ellipsoidal or irregular in shape, and relatively large, e.g. oxytocin and vasopressin vesicles in the neurohypophysis may be up to 200 nm in diameter.

Synapses may cause depolarization or hyperpolarization of the postsynaptic membrane, depending on the neurotransmitter released and the classes of receptor molecule in the postsynaptic membrane. Depolarization of the postsynaptic membrane results in excitation of the postsynaptic neurone, whereas hyperpolarization has the effect of transiently inhibiting electrical activity. Subtle variations in these responses may also occur at synapses where mixtures of neuromediators are present and their effects are integrated. For details of the synaptic organization of the brain, see Shepherd (2003).

## Type I and II synapses

There are two broad categories of synapse, type I and type II. In active zones of type I synapses the cytoplasmic density is thicker on the postsynaptic side. In type II synapses the pre- and postsynaptic densities are thinner and more symmetrical. Type I boutons contain a predominance of small spherical vesicles approximately 50 nm in diameter, and type II boutons contain oval or flattened vesicles. Throughout the CNS, type I synapses are generally excitatory and type II are inhibitory. In a few
instances, types I and II synapses are found in close proximity, orientated in opposite directions across the synaptic cleft (a reciprocal synapse).

## Mechanisms of synaptic activity

Synaptic activation begins with arrival of one or more action potentials at the presynaptic bouton, which causes the opening of voltage-sensitive calcium channels in the presynaptic membrane. The response time in typical fast-acting synapses is then very rapid; classic neurotransmitter (e.g. ACh, glutamate or GABA) is released in less than a millisecond. Release-ready synaptic vesicles are docked to the presynaptic membrane and primed through processes not yet fully understood. On $\mathrm{Ca}^{2+}$ influx through voltage-sensitive channels, their membranes fuse to open a pore through which neurotransmitter diffuses into the synaptic cleft (Eggermann et al 2012; Gray 1959).

Once the vesicle has discharged its contents, its membrane is incorporated into the presynaptic plasma membrane and is then recycled back into the bouton by endocytosis near the edges of the active zone. The recycling time for a synaptic vesicle may be in the range of a few seconds to minutes; newly recycled vesicles may be used instantly for the next cycle of neurotransmitter release (cycling pool of vesicles). The fusion of vesicles with the presynaptic membrane is responsible for the observed quantal behaviour of neurotransmitter release, both during neural activation and spontaneously, in the slightly leaky resting condition (Neher and Sakaba 2008; Suedhof 2012).

Postsynaptic events vary greatly, depending on the receptor molecules and their related molecular complexes (Murakoshi and Yasuda 2012). Receptors are generally classed as either ionotropic or metabotropic. Ionotropic receptors are multimeric protein complexes that harbour intrinsic ion channels that can be operated by conformational changes induced when neurotransmitter molecules bind the receptor complex, causing a voltage change within the postsynaptic cell. Examples are the nicotinic $A C h$ receptor and the related $G A B A_{A}$ receptor, which are formed from five subunits, and the tetrameric ionotropic glutamate receptors, such as the $N$-methyl-D-aspartate (NMDA) receptor or the $\alpha$-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor. Alternatively, the receptor and ion channel may be separate molecules, coupled by G-proteins, some via a complex cascade of chemical interactions (a second messenger system), e.g. the adenylate cyclase pathway. Postsynaptic effects are generally rapid and short-lived, because the transmitter is quickly inactivated either by an extracellular enzyme (e.g. acetylcholinesterase, AChE), or by uptake into neurones or glial cells. Examples of such metabotropic receptors are the muscarinic ACh receptor and the dopamine receptor.

## Neurohormones

Neurohormones are included in the class of molecules with neurotransmitter-like activity. They are synthesized in neurones and released into the blood circulation by exocytosis at synaptic bouton-like
structures. As with classic endocrine gland hormones, they may act at great distances from their site of secretion. Neurones secrete into the CSF or local interstitial fluid to affect other cells, either diffusely or at a distance. To encompass this wide range of phenomena the general term neuromediation has been used, and the chemicals involved are called neuromediators.

## Neuromodulators

Some neuromediators do not appear to affect the postsynaptic membrane directly but they can affect its responses to other neuromediators, either enhancing their activity (by increasing or prolonging the immediate response), or perhaps limiting or inhibiting their action. These substances are called neuromodulators. A single synaptic terminal may contain one or more neuromodulators in addition to a neurotransmitter, usually (though not always) in separate vesicles. Neuropeptides (see below) are nearly all neuromodulators, at least in some of their actions. They are stored within dense granular synaptic vesicles of various sizes and appearances.

## Development and plasticity of synapses

Embryonic synapses first appear as inconspicuous dense zones flanking synaptic clefts. Immature synapses often appear after birth, suggesting that they may be labile, and are reinforced if transmission is functionally effective, or withdrawn if redundant. This is implicit in some theories of memory (Squire and Kandel 2008), which postulate that synapses are modifiable by frequency of use, to establish preferential conduction pathways. Evidence from hippocampal neurones suggests that even brief synaptic activity can increase the strength and sensitivity of the synapse for some hours or longer (long-term potentiation, LTP). During early postnatal life, the normal developmental increase in numbers and sizes of synapses and dendritic spines depends on the degree of neural activity and is impaired in areas of damage or functional deprivation.

## Neurotransmitter molecules

Until recently, the molecules known to be involved in chemical synapses were limited to a fairly small group of classic neurotransmitters, e.g. ACh, noradrenaline (norepinephrine), adrenaline (epinephrine), dopamine and histamine, all of which had well-defined rapid effects on other neurones, muscle cells or glands. However, many synaptic interactions cannot be explained on the basis of classic neurotransmitters, and it is now known that other substances, particularly some amino acids such as glutamate, glycine, aspartate, GABA and the monoamine, serotonin, also function as transmitters. Substances first identified as hypophysial hormones or as part of the dispersed neuroendocrine system (see below) of the alimentary tract, can be detected widely throughout the CNS and PNS, often associated with functionally integrated systems. Many of these are peptides; more than one hundred (together with other candidates) function mainly as neuromodulators and influence the activities of classic transmitters.

## Acetylcholine

Acetylcholine (ACh) is perhaps the most extensively studied neurotransmitter of the classic type. Its precursor, choline, is synthesized in the neuronal soma and transported to the axon terminals, where it is acetylated by the enzyme choline acetyl transferase (ChAT), and stored in clear spherical vesicles $40-50 \mathrm{~nm}$ in diameter. ACh is synthesized by motor neurones and released at all their motor terminals on skeletal muscle. It is released by preganglionic fibres at synapses in parasympathetic and sympathetic ganglia, and many parasympathetic, and some sympathetic, ganglionic neurones are cholinergic. ACh is also associated with the degradative extracellular enzyme AChE, which inactivates the transmitter by converting it to choline.

The effects of ACh on nicotinic receptors (i.e. those in which nicotine is an agonist) are rapid and excitatory. In the CNS, the nicotinic ACh receptor mediates the effect of tobacco (for review, see Albuquerque et al (2009)). In the peripheral autonomic nervous system, the slower, more sustained excitatory effects of cholinergic autonomic endings are mediated by muscarinic receptors via a second messenger system.

## Monoamines

Monoamines include the catecholamines (noradrenaline (norepinephrine), adrenaline (epinephrine) and dopamine), the indoleamine serotonin (5-hydroxytryptamine, 5 -HT) and histamine (Haas et al 2008). They are synthesized by neurones in sympathetic ganglia and by their homologues, the chromaffin cells of the suprarenal medulla and paraganglia. Within the CNS, the somata of monoaminergic neurones
lie mainly in the brainstem, although their axons ramify widely into all parts of the nervous system. Monoaminergic cells are also present in the retina.

Noradrenaline is the chief transmitter present in sympathetic ganglionic neurones with endings in various tissues, notably smooth muscle and glands, and in other sites including adipose and haemopoietic tissues and the corneal epithelium. It is also found at widely distributed synaptic endings within the CNS, many of them the terminals of neuronal somata situated in the locus coeruleus in the medullary floor. The actions of noradrenaline depend on its site of action and vary with the type of postsynaptic receptor, e.g. it strongly inhibits neurones of the submucosal plexus of the intestine and of the locus coeruleus via $\alpha_{2}$-adrenergic receptors, whereas it mediates depolarization, producing vasoconstriction, via $\beta$-receptors in vascular smooth muscle. Adrenaline is present in central and peripheral nervous pathways and occurs with noradrenaline in the suprarenal medulla. Both adrenaline and noradrenaline are found in dense-cored synaptic vesicles approximately 50 nm in diameter.

Dopamine is a neuromediator of considerable clinical importance, found mainly in neurones with cell bodies in the telencephalon, diencephalon and mesencephalon. A major dopaminergic neuronal population in the midbrain constitutes the substantia nigra, so called because its cells contain neuromelanin, a black granular by-product of dopamine synthesis. Dopaminergic endings are particularly numerous in the corpus striatum, limbic system and cerebral cortex. Structurally, dopaminergic synapses contain numerous dense-cored vesicles that resemble those containing noradrenaline. Pathological reduction in dopaminergic activity has widespread effects on motor control, affective behaviour and other neural activities, as seen in Parkinson's syndrome.

Serotonin and histamine are found in neurones mainly within the CNS. Serotonin is typically synthesized in small midline neuronal clusters in the brainstem, mainly in the raphe nuclei; the axons from these neurones ramify extensively throughout the entire brain and spinal cord. Synaptic terminals contain rounded, clear vesicles approximately 50 nm in diameter and are of the asymmetrical type. Histaminergic neurones appear to be relatively sparse and are restricted largely to the hypothalamus.

## Amino acids

There are three major amino acids: GABA, glutamate and glycine, which bind to specific receptors (Barrera and Edwardson 2008). GABA is a major inhibitory transmitter released at the terminals of local circuit neurones within the brainstem and spinal cord (e.g. the recurrent inhibitory Renshaw loop), cerebellum (where it is the main transmitter of Purkinje cells), basal ganglia, cerebral cortex, thalamus and subthalamus. It is stored in flattened or pleomorphic vesicles within symmetrical synapses. GABA may be inhibitory to postsynaptic neurones, or may mediate either presynaptic inhibition or facilitation, depending on the synaptic arrangement (Gassmann and Bettler 2012).

Glutamate is the major excitatory transmitter present widely within the CNS, including the major projection pathways from the cortex to the thalamus, tectum, substantia nigra and pontine nuclei. It is found in the central terminals of the auditory and trigeminal nerves, and in the terminals of parallel fibres ending on Purkinje cells in the cerebellum. Structurally, glutamate is associated with asymmetrical synapses containing small (approximately 30 nm ), round, clear synaptic vesicles (Contractor et al 2011). For further reading, see Willard and Koochekpour (2013).

Glycine is a well-established inhibitory transmitter of the CNS, particularly the lower brainstem and spinal cord, where it is mainly found in local circuit neurones. Recent evidence suggests that glycine may also be released from glutamatergic axon terminals to participate in activation of NMDA receptors, and from astrocytes into the synaptic cleft via activation of non-NMDA-type glutamatergic ionotropic receptors in the glial cell membrane (see Harsing and Matyus (2013) for further references).

## ATP and adenosine

ATP serves not only as a universal energy substrate, but also as an extracellular signalling molecule. Specific ionotropic (P2X) and metabotropic (P2Y) receptors are expressed in neurones and even more prominently on all types of glial cell. Adenosine is a degradation product of ATP and has specific metabotropic receptors that may be located presynaptically (Burnstock et al 2011).

## Nitric oxide

Nitric oxide (NO) is of considerable importance at autonomic and enteric synapses, where it mediates smooth muscle relaxation. It
functions in several types of synaptic plasticity, including hippocampal long-term potentiation (LTP), when it may act as a retrograde messenger after postsynaptic NMDA receptor activation. NO is able to diffuse freely through cell membranes, and so is not under such tight quantal control as vesicle-mediated neurotransmission.

## Neuropeptides

Many neuropeptides coexist with other neuromediators in the same synaptic terminals. As many as three peptides often share a particular ending with a well-established neurotransmitter, in some cases within the same synaptic vesicles. Some peptides occur in both the CNS and the PNS, particularly in the ganglion cells and peripheral terminals of the ANS, whilst others are entirely restricted to the CNS. Only a few examples are given here.

Most of the neuropeptides are classified according to the site where they were first discovered. For example, the gastrointestinal peptides were initially found in the gut wall, and a group that includes releasing hormones, adenohypophysial and neurohypophysial hormones was first associated with the pituitary gland. Some of these peptides are closely related to each other in their chemistry because they are derived from the same gene products (e.g. the pro-opiomelanocortin group), which are cleaved to produce smaller peptides.

Substance P (SP) was the first of the peptides to be characterized as a gastrointestinal neuromediator and is considered to be the prototypic neuropeptide. It is an 11-amino-acid polypeptide that belongs to the tachykinin neuropeptide family, and is a major neuromediator in the brain and spinal cord. Contained within large granular synaptic vesicles, SP is found in approximately $20 \%$ of dorsal root and trigeminal ganglion cells, in particular in small nociceptive neurones, and in some fibres of the facial, glossopharyngeal and vagal nerves. Within the CNS, SP is present in several apparently unrelated major pathways, and has been described in the limbic system, basal ganglia, amygdala and hypothalamus. Its known action is prolonged postsynaptic excitation, particularly from nociceptive afferent terminals, which sustains the effects of noxious stimuli. SP is one of the main neuropeptides that trigger an inflammatory response in the skin and has also been implicated in the vomiting reflex, changes in cardiovascular tone, stimulation of salivary secretion, smooth muscle contraction, and vasodilation.

Vasoactive intestinal polypeptide (VIP), another gastrointestinal peptide, is widely present in the CNS, where it is probably an excitatory neurotransmitter or neuromodulator. It is found in distinctive bipolar neurones of the cerebral cortex; small dorsal root ganglion cells, particularly of the sacral region; the median eminence of the hypothalamus, where it may be involved in endocrine regulation; intramural ganglion cells of the gut wall; and sympathetic ganglia.

Somatostatin (ST, somatotropin release inhibiting factor) has a broad distribution within the CNS, and may be a central neurotransmitter or neuromodulator. It also occurs in small dorsal root ganglion cells. Beta-endorphin, leu- and metenkephalins, and the dynorphins belong to a group of peptides called the naturally occurring opiates that possess analgesic properties. They bind to opiate receptors in the brain where, in general, their action seems to be inhibitory. Enkephalins have been localized in many areas of the brain. Their particular localization in the septal nuclei, amygdaloid complex, basal ganglia and hypothalamus suggests that they are important mediators in the limbic system and in the control of endocrine function. They have also been implicated strongly in the central control of pain pathways, because they are found in the peri-aqueductal grey matter of the midbrain, a number of reticular raphe nuclei, the spinal nucleus of the trigeminal nerve and the substantia gelatinosa of the spinal cord. The enkephalinergic pathways exert an important presynaptic inhibitory action on nociceptive afferents in the spinal cord and brainstem. Like many other neuromediators, enkephalins also occur widely in other parts of the brain in lower concentrations.

## CENTRAL GLIA

Glial (neuroglial) cells (Fig 3.10) vary considerably in type and number in different regions of the CNS. There are two major groups, macroglia (astrocytes and oligodendrocytes) and microglia, classified according to origin. Macroglia arise within the neural plate, in parallel with neurones, and constitute the great majority of glial cells. Their functions are diverse and are now known to extend beyond a passive supporting role (reviewed in Kettenmann and Ransom (2012)). Microglia have a small soma (see Fig. 3.19) and are derived from a distinct lineage of monocytic cells originating from the yolk sac.

Fig. 3.10 The different types of non-neuronal cell in the CNS and their structural organization and interrelationships with each other and with neurones.

## ASTROCYTES

Astrocytes are the most abundant and diverse glial cell type but their identity is not well defined (Matyash and Kettenmann 2010). There is no common marker that labels all astrocytes, in the way that myelin basic protein is a marker for oligodendrocytes or the calcium-binding protein Iba1 is a marker for microglia. A commonly used marker is the expression of glial fibrillary acidic protein (GFAP), which forms intermediate filaments, but GFAP is not expressed in all astrocytes.

The morphology of astrocytes is extremely diverse. Classically, two forms were distinguished: protoplasmic and fibrous astrocytes. Protoplasmic astrocytes (star-shaped cells) are found in grey matter, possess several stem processes that branch further into a very complex network, and contact synapses, both at the pre- and postsynaptic membranes. Fibrous astrocytes are predominantly found in white matter and their processes are often orientated in parallel with the axons. Radial glial cells are found early in development and serve as stem cells for neurones and glial cells. They may be categorized as astrocytes because they transform later in development into typical astrocytes. There are a number of other types of astrocyte with specialized morphologies. Bergmann glial cells in the cerebellum have somata in the Purkinje cell layer, processes that intermingle with the dendritic trees of the Purkinje neurones and terminal end-feet at the pial surface. Müller cells in the retina have a radial morphology and span the entire retina. Other astrocytic cells are tanycytes, velate astrocytes (cerebellum) and pituicytes (infundibulum and neurohypophysis of the pituitary gland). Pituicyte processes end mostly on endothelial cells in the neurohypophysis and tuber cinereum.

Astrocyte complexity and morphological diversity has reached the highest evolutionary level in humans (Fig. 3.11). A single astrocyte may enwrap several neuronal somata and make contacts with tens of thousands of individual synapses; bipolar astrocytes located in layer 5 and 6 of the cortex may extend processes up to 1 mm long.

Astrocytes in grey matter form a syncytium in which cells are interconnected by gap junctions, permitting the exchange of ions (e.g. calcium, propagated in waves) and small molecules such as ATP or glucose. They are the only cells in the brain capable of converting glucose into glycogen, which serves as an energy store. Before re-releasing glucose, astrocytes convert it to lactate, which is taken up by neurones; failure in glucose flow through the astrocytic network results in impairment of neuronal function.

Astrocytes not only respond to neuronal activity but also modulate that activity. They enwrap all penetrating and intracerebral arterioles and capillaries, control the ionic and metabolic environment of the neuropil and mediate neurovascular coupling. They form specialized structures that contact either the pial surface (as the glia limitans) or blood vessels; their end-feet entirely enwrap blood vessels and are instrumental in the induction of the blood-brain barrier.

Traumatic injury to the CNS induces astrogliosis, seen as a local increase in the number and size of GFAP-positive cells and a characteristic extensive meshwork of processes. The microenvironment of this glial scar, which may also include cells of oligodendrocyte lineage and myelin debris, plays an important role in inhibiting regrowth of damaged CNS axons (Robel et al 2011, Seifert et al 2006).

Astrocytes control the diameter of the vessels they contact and can trigger either their dilation or their contraction, depending on the substances they release and the levels of associated neuronal activity. They express water channels (aquaporins) at the end-feet covering the capillaries; it has been suggested that this may represent the means by which astrocytes control brain volume (Tait et al 2008), and it may be relevant to understanding mechanisms of brain tissue swelling, a major clinical complication. Astrocytes express different glutamate transporters that efficiently maintain low levels of extracellular glutamate, which is excitotoxic. Internalized glutamate is converted into glutamine and released from astrocytes to be taken up by local neurones and reconverted to glutamate via the glutamate-glutamine cycle. They play a similar role in controlling extracellular GABA levels via expression of GABA transporters. Astrocytes possess both passive and active mechanisms to control extracellular potassium levels at a resting level of about 3 mmol . They also express transporters that regulate pH and are thought to play an important role in controlling extracellular pH in the brain. For further reading on the concept of the 'tripartite synapse', where astrocytic processes interact with pre- and postsynaptic neuronal elements, see Haydon and Carmignoto (2006).

It has become evident that astrocytes are involved in the modulation of long-term potentiation (considered as a cellular mechanism of memory formation) and heterosynaptic depression. They modulate neuronal activity by releasing neuroactive substances such as D-serine, ATP or glutamate; it is unclear whether they express all the elements required for neurotransmitter release by a vesicular mechanism (Parpura and Zorec 2010).

Fig. 3.12 The relationship between the glia limitans, perivascular cells and blood vessels within the brain, in longitudinal (A) and transverse (B) sections. A sheath of astrocytic end-feet wraps around the vessel and, in vessels larger than capillaries, its investment of pial meninges. Vascular endothelial cells are joined by tight junctions and supported by pericytes; perivascular macrophages lie outside the endothelial basal lamina (light blue).

## Blood-brain barrier

Proteins circulating in the blood enter most tissues of the body except those of the brain, spinal cord and peripheral nerves. This concept of a blood-brain or a blood-nerve barrier applies to many substances some are actively transported across the blood-brain barrier, others are actively excluded. The blood-brain barrier is located at the capillary endothelium within the brain and is dependent on the presence of tight junctions (occluding junctions, zonulae adherentes) between endothelial cells coupled with a relative lack of transcytotic vesicular transport. The tightness of the barrier is substantially supported by the close apposition of astrocytes, which direct the formation of endothelial tight junctions, to blood capillaries (reviewed in Abbott et al (2006), Cardoso et al (2010); Fig. 3.12).

The blood-brain barrier develops during embryonic life but may not be fully completed by birth. There are certain areas of the adult brain where the endothelial cells are not linked by tight junctions,
which means that a free exchange of molecules occurs between blood and adjacent brain. Most of these areas are situated close to the ventricles and are known as circumventricular organs; these areas make up less than $1 \%$ of the total area of the brain. Elsewhere, unrestricted diffusion through the blood-brain barrier is only possible for substances that can cross biological membranes because of their lipophilic character. Lipophilic molecules may be actively re-exported by the brain endothelium.

Breakdown of the blood-brain barrier occurs when the brain is damaged by ischaemia or infection, and is also associated with primary and metastatic cerebral tumours. Reduced blood flow to a region of the brain alters the permeability and regulatory transport functions of the barrier locally; the increased stress on compromised endothelial cells results in leakage of fluid, ions, serum proteins and intracellular substances into the extracellular space of the brain. The integrity of the barrier can be evaluated clinically using computed tomography and functional magnetic resonance imaging. Breakdown of the blood-brain barrier may be seen at postmortem in jaundiced patients who have had an infarction. Normally, the brain, spinal cord and peripheral nerves remain unstained by the bile post mortem, although the choroid plexus is often stained a deep yellow. However, areas of recent infarction (1-3 days) will also be stained by bile pigment because of the localized breakdown of the blood-brain barrier.

## OLIGODENDROCYTES

Oligodendrocytes myelinate CNS axons and are most commonly seen as intrafascicular cells in myelinated tracts (Figs 3.13-3.14). They usually have round nuclei and their cytoplasm contains numerous mitochondria, microtubules and glycogen. They display a spectrum of morphological variation, from cells with large euchromatic nuclei and pale cytoplasm, to cells with heterochromatic nuclei and dense cytoplasm. In contrast to Schwann cells, which myelinate only one axonal segment, individual oligodendrocytes myelinate up to 50 axonal segments. Some oligodendrocytes are not associated with axons, and are either precursor cells or perineuronal (satellite) oligodendrocytes with processes that ramify around neuronal somata.

Within tracts, interfascicular oligodendrocytes are arranged in long rows interspersed at regular intervals with single astrocytes. Since oligodendrocyte processes are radially aligned to the axis of each row, myelinated tracts typically consist of cables of axons myelinated by a row of oligodendrocytes running down the axis of each cable.

Oligodendrocytes originate from the ventricular neurectoderm and the subependymal layer in the fetus, and continue to be generated from the subependymal plate postnatally. Stem cells migrate and seed into white and grey matter to form a pool of adult progenitor cells, which can later differentiate to replenish defunct oligodendrocytes, and possibly remyelinate axons in pathologically demyelinated regions. These cells display a highly branching morphology and express a specific chondroitin sulphate proteoglycan (Neuron Glia 2 (NG2) in rats and its homologue, melanoma cell surface chondroitin sulphate proteoglycan (MSCP), in humans). The name NG2 cell is used to describe the cells in both species: several different names have also been used since it was first recognized, including polydendrocyte (Nishiyama et al 2009) and syantocyte (Butt et al 2005). NG2 cells express a complex set of voltage-gated channels and ionotropic receptors for glutamate

and GABA; they form direct synapses with axons, enabling transient activation of these receptors (Hill and Nishiyama 2014). There is considerable support for the view that the NG2 cell is a distinct glial type.

## Nodes of Ranvier and incisures of Schmidt-Lanterman

The territory ensheathed by an oligodendrocyte (or Schwann cell) process defines an internode, the interval between internodes is called a node of Ranvier (Fig. 3.15) and the territory immediately adjacent to the nodal gap is a paranode, where loops of oligodendrocyte cytoplasm abut the axolemma. Nodal axolemma is contacted by fine filopodia of perinodal cells, which have been shown in animal studies to have a presumptive adult oligodendrocyte progenitor phenotype; their function is unknown. Schmidt-Lanterman incisures are helical decompactions of internodal myelin where the major dense line of the myelin sheath splits to enclose a spiral of oligodendrocyte cytoplasm. Their structure suggests that they may play a role in the transport of molecules across the myelin sheath, but their function is not known.

## MYELIN AND MYELINATION

Myelin is formed by oligodendrocytes (CNS) and Schwann cells (PNS). A single oligodendrocyte may ensheathe up to 50 separate axon segments, depending on calibre, whereas myelinating Schwann cells ensheathe axons on a $1: 1$ basis.

In general, myelin is laid down around axons above $2 \mu \mathrm{~m}$ in diameter. However, the critical minimal axon diameter for myelination is smaller and more variable in the CNS than in the PNS (approximately $0.2 \mu \mathrm{~m}$ in the CNS compared with $1-2 \mu \mathrm{~m}$ in the PNS). There is considerable overlap between the size of the smallest myelinated and the largest unmyelinated axons, and so axonal calibre is unlikely to be the only factor in determining myelination. Moreover, the first axons to become ensheathed ultimately attain larger diameters than those that are ensheathed at a later date. There is a reasonable linear relationship between axon diameter and internodal length and myelin sheath thickness: as the sheath thickens from a few lamellae to up to 200, the axon may also grow from 1 to $15 \mu \mathrm{~m}$ in diameter. Internodal lengths increase about 10 -fold during the same time (Nave 2010).

It is not known precisely how myelin is formed in either PNS or CNS. Akt/mTOR (mammalian (or mechanistic) target of rapamycin) signalling has emerged as one of the major pathways involved in myelination; it has been implicated in the regulation of several steps during the development of myelinating Schwann cells and oligodendrocytes (Norrmén and Suter 2013). In the CNS, myelination also depends in part on expression of a protein (Wiskott-Aldrich syndrome protein family verprolin homologous; WAVE), which influences the actin cytoskeleton, oligodendrocyte lamellipodia formation and myelination (Kim et al 2006). The ultrastructural appearance of myelin is usually explained in terms of the spiral wrapping of an extensive, flat glial process (lamellipodium) around an axon, and the subsequent extrusion of cytoplasm from the sheath at all points other than incisures and paranodes. In this way, the compacted external surfaces of the plasma membrane of the ensheathing glial cell are thought to produce the minor dense lines, and the compacted inner cytoplasmic surfaces, the major dense lines, of the mature myelin sheath (Fig. 3.16). These lines, first described in early electron microscope studies of the myelin sheath, correspond to the intraperiod and period lines respectively, defined in X-ray studies of myelin. The inner and outer zones of occlusion of the spiral process are continuous with the minor dense line and are called

Fig. 3.16 Suggested stages in myelination of a peripheral axon by an ensheathing Schwann cell.

the inner and outer mesaxons. For further reading on aspects of myelination, see Bakhti et al (2013).

There are significant differences between central and peripheral myelin, reflecting the fact that oligodendrocytes and Schwann cells express different proteins during myelinogenesis. The basic dimensions of the myelin membrane are different. CNS myelin has a period repeat thickness of 15.7 nm whereas PNS myelin has a period to period line thickness of 18.5 nm , and the major dense line space is approximately 1.7 nm in CNS myelin, compared with 2.5 nm in PNS myelin. Myelin membrane contains protein, lipid and water, which forms at least 20\% of the wet weight. It is a relatively lipid-rich membrane and contains $70-80 \%$ lipid. All classes of lipid have been found; perhaps not surprisingly, the precise lipid composition of PNS and CNS myelin is different. The major lipid species are cholesterol (the most common single molecule), phospholipids and glycosphingolipids. Minor lipid species include galactosylglycerides, phosphoinositides and gangliosides. The major glycolipids are galactocerebroside and its sulphate ester, sulphatide; these lipids are not unique to myelin but they are present in characteristically high concentrations. CNS and PNS myelin also contain low concentrations of acidic glycolipids, which constitute important antigens in some inflammatory demyelinating states. Gangliosides, which are glycosphingolipids characterized by the presence of sialic acid ( $N$-acetylneuraminic acid), account for less than $1 \%$ of the lipid in myelin.

A relatively small number of protein species account for the majority of myelin protein. Some of these proteins are common to both PNS and CNS myelin, but others are different. Proteolipid protein (PLP) and its splice variant DM20 are found only in CNS myelin, whereas myelin basic protein (MBP) and myelin associated glycoprotein (MAG) occur in both. MAG is a member of the immunoglobulin supergene family, and is localized specifically at those regions of the myelin segment where compaction starts: namely, the mesaxons and inner periaxonal membranes, paranodal loops and incisures, in both CNS and PNS sheaths. It is thought to have a functional role in membrane adhesion.

In the developing CNS, axonal outgrowth precedes the migration of oligodendrocyte precursors, and oligodendrocytes associate with and myelinate axons after their phase of elongation; oligodendrocyte myelin gene expression is not dependent on axon association. In marked contrast, Schwann cells in the developing PNS are associated with axons during the entire phase of axonal growth. Myelination does not occur simultaneously in all parts of the body in late fetal and early postnatal development. White matter tracts and nerves in the periphery have their own specific temporal patterns that relate to their degree of functional maturity.

Mutations of the major myelin structural proteins have now been recognized in a number of inherited human neurological diseases. As would be expected, these mutations produce defects in myelination and in the stability of nodal and paranodal architecture that are consistent with the suggested functional roles of the relevant proteins in maintaining the integrity of the myelin sheath.

## EPENDYMA

Ependymal cells line the ventricles (Fig. 3.17; see Fig. 3.10) and central canal of the spinal cord. They form a single-layered epithelium that varies from squamous to columnar in form. At the ventricular surface, cells are joined by gap junctions and occasional desmosomes. Their apical surfaces have numerous microvilli and/or cilia, the latter contributing to the flow of CSF. There is considerable regional variation in the

Fig. 3.17 Ciliated columnar epithelial lining of the lateral ventricle ( V ), overlying the subventricular zone (SVZ). C, cilia; E, ependymal cells. Mouse tissue, toluidine blue stained resin section.
ependymal lining of the ventricles but four major types have been described. These are: general ependymal, which overlies grey matter; general ependymal, which overlies white matter; specialized areas of ependyma in the third and fourth ventricles; and choroidal epithelium.

The ependymal cells overlying areas of grey matter are cuboidal. Each cell bears approximately 20 central apical cilia, surrounded by short microvilli. The cells are joined by gap junctions and desmosomes. Beneath them there may be a subependymal (or subventricular) zone, from two to three cells deep, consisting of cells that generally resemble ependymal cells. In rodents, the subventricular zone contains neural progenitor cells, which can give rise to new neurones, but the existence of these stem cells in the adult human brain is controversial (Sanai et al 2011, Kempermann 2011). The capillaries beneath the ependymal cells have no fenestrations and few transcytotic vesicles, which is typical of the CNS. Where the ependyma overlies myelinated tracts of white matter, the cells are much flatter and few are ciliated. There are gap junctions and desmosomes between these cells, but their lateral margins interdigitate, unlike their counterparts overlying grey matter. No subependymal zone is present.

Specialized areas of ependymal cells called the circumventricular organs are found in four areas around the margins of the third ventricle: namely, the lining of the median eminence of the hypothalamus; the subcommissural organ; the subfornical organ; and the vascular organ of the lamina terminalis. The area postrema, at the inferoposterior limit of the fourth ventricle, has a similar structure. In all of these sites the ependymal cells are only rarely ciliated and their ventricular surfaces bear many microvilli and apical blebs. They have numerous mitochondria, well-formed Golgi complexes and rather flattened basal nuclei. They are joined laterally by tight junctions, which form a barrier to the passage of materials across the ependyma, and by desmosomes. Many of the cells are tanycytes (ependymal astrocytes) and have basal processes that project into the perivascular space surrounding the underlying capillaries. Significantly, these capillaries are fenestrated and therefore do not form a blood-brain barrier. It is believed that neuropeptides can pass from nervous tissue into the CSF by active transport through the ependymal cells in these specialized areas, and so access a wide population of neurones via the permeable ependymal lining of the rest of the ventricle.

The ependyma is highly modified where it lies adjacent to the vascular layer of the choroid plexuses.

## Choroid plexus

The choroid plexus forms the CSF and actively regulates the concentration of molecules in the CSF. It consists of highly vascularized masses of pia mater enclosed by pockets of ependymal cells. The ependymal cells resemble those of the circumventricular organs, except that they do not have basal processes, but form a cuboidal epithelium that rests on a basal lamina adjacent to the enclosed fold of meningeal pia mater and its capillaries (Fig. 3.18). The cells have numerous long microvilli with only a few cilia interspersed between them. They also have many mitochondria, large Golgi complexes and basal nuclei, features consistent with their secretory activity; they produce most components of the CSF. They are linked by tight junctions forming a transepithelial barrier (a component of the blood-CSF barrier), and by desmosomes. Their lateral margins are highly folded.

The choroid plexus has a villous structure where the stroma is composed of pial meningeal cells, and contains fine bundles of collagen and blood vessels. Choroidal capillaries are lined by a fenestrated endothelium. During fetal life, erythropoiesis occurs in the stroma, which is occupied by bone marrow-like cells. In adult life, the stroma contains phagocytic cells, which, together with the cells of the choroid plexus epithelium, phagocytose particles and proteins from the ventricular lumen.

Age-related changes occur in the choroid plexus, which can be detected by neuroimaging. Calcification of the choroid plexus can be detected by X-ray or CT scan very rarely in individuals in the first decade of life and in the majority in the eighth decade. The incidence of calcification rises sharply, from 35\% of CT scans in the fifth decade to $75 \%$ in the sixth decade. Visible calcification is usually restricted to the glomus region of the choroid plexus, i.e. the vascular bulge in the choroid plexus as it curves to follow the anterior wall of the lateral ventricle into the temporal horn.

## MICROGLIA

Microglia are the endogenous immune cells of the brain (Kettenmann et al 2011, Eggen et al 2013). They originate from an embryonic monocyte precursor and invade the brain early during development. While the invading cells have an ameboid morphology, microglial cells in a mature brain are highly ramified cells. They have elongated nuclei, scant cytoplasm and several highly branched processes. They occupy a defined territory in the brain parenchyma and are found in all areas of the CNS including optic nerve, retina and spinal cord. Their density shows little variation.

Resting microglia, a term used to refer to microglia in the normal brain, should more accurately be described as surveying microglia. Microglial processes are fast-moving structures that rapidly scan their territory while the soma remains fixed in position. Microglial cells express receptors for neurotransmitters and thus can sense neuronal activity. It is likely that they interact with synapses, from which it has been inferred that they may influence synaptic transmission.

All pathological changes in the brain result in the activation of microglial cells (Fig. 3.19), e.g. activated microglia are found in the brain tissue of multiple sclerosis, Alzheimer's disease and stroke patients. The most common indication of their activation is a change from a ramified to an ameboid morphology, which may occur within a few hours of the onset of injury or disease process.

In general, microglia respond to two types of signal: 'on' signals, which either appear de novo or are strongly upregulated, e.g. cell wall components of invading bacteria; and 'off' signals, which are normally present but disappear or decrease in pathological states, e.g. defined cytokines or neurotransmitters. Both types of event are interpreted as signals for activation. The functional repertoire of activated microglia includes proliferation; migration to the site of injury; expression of major histocompatibility complex (MHC) II molecules to interact with infiltrating lymphocytes; and the release of a variety of different substances including chemokines, cytokines and growth factors. These cells are therefore capable of significantly influencing ongoing pathological processes.

Microglial cells are the professional phagocytes of the nervous system and actively migrate through tissue. A number of factors such as ATP and complement factors act as chemoattractants. This behaviour is relevant not only in pathology but also during development where microglial cells remove apoptotic cells. After a pathological insult, microglial cells revert to their surveying phenotype, re-acquiring a ramified morphology.

## Entry of inflammatory cells into the brain

Although the CNS has long been considered to be an immunologically privileged site, lymphocyte and macrophage surveillance of the brain may be a normal, but very low-grade, activity that is enhanced in disease. Lymphocytes can enter the brain in response to virus infections and as part of the autoimmune response in multiple sclerosis. Activated, but not resting, lymphocytes pass through the endothelium of small venules, a process that requires the expression of recognition and adhesion molecules (induced following cytokine activation), and subsequently migrate into the brain parenchyma. Within the CNS, microglia can be induced by T-cell cytokines to act as efficient antigen-presenting cells. After leaving the CNS, lymphocytes probably drain along lymphatic pathways to regional cervical lymph nodes.

Fig. 3.19 Activated microglial cells in the human central nervous system, in a biopsy from a patient with Rasmussen's encephalitis, visualized using MHC class II antigen immunohistochemistry. (Courtesy of Dr Norman Gregson, Division of Neurology, GKT School of Medicine, London.)

Monocytes enter the CNS in the early stages of infarction and autoimmune disease and, in particular, in pyogenic infections, probably by passing through the endothelium of local vessels. Once in the brain, monocytes are difficult to distinguish from intrinsic microglia because both cell types express a similar marker profile. During the inflammatory phase of meningitis, polymorphonuclear leukocytes and lymphocytes pass into the CSF through the endothelium of large veins in the subarachnoid space. Recent developments in research on brain inflammatory disorders are reviewed in Anthony and Pitossi (2013).

## PERIPHERAL NERVES

Afferent nerve fibres connect peripheral receptors to the CNS; they are derived from neuronal somata located either in special sense organs (e.g. the olfactory epithelium) or in the sensory ganglia of the craniospinal nerves. Efferent nerve fibres connect the CNS to the effector cells and tissues and are the peripheral axons of neurones with somata in the central grey matter.

Peripheral nerve fibres are grouped in widely variable numbers into bundles (fasciculi). The size, number and pattern of fasciculi vary in different nerves and at different levels along their paths (Fig. 3.20). Their number increases and their size decreases some distance proximal to a point of branching. Where nerves are subjected to pressure, e.g. deep to a retinaculum, fasciculi are increased in number but reduced in size, and the amount of associated connective tissue and degree of vascularity also increase. At these points, nerves may occasionally show a pink, fusiform dilation, sometimes termed a pseudoganglion or gangliform enlargement.

## CLASSIFICATION OF PERIPHERAL NERVE FIBRES

Classification of peripheral nerve fibres is based on various parameters such as conduction velocity, function and fibre diameter. Of two classifications in common use, the first divides fibres into three major classes, designated A, B and C, corresponding to peaks in the distribution of their conduction velocities. In humans, this classification is used mainly for afferent fibres from the skin. Group A fibres are subdivided into $\alpha, \beta, \gamma$ and $\delta$ subgroups; fibre diameter and conduction velocity are proportional in most fibres. Group $A \alpha$ fibres are the largest and conduct most rapidly, and C fibres are the smallest and slowest.

The largest afferent axons (A $\alpha$ fibres) innervate encapsulated cutaneous mechanoreceptors, Golgi tendon organs and muscle spindles, and some large alimentary enteroceptors. A $\beta$ fibres form secondary endings on some muscle spindle (intrafusal) fibres and also innervate cutaneous and joint capsule mechanoreceptors. A $\delta$ fibres innervate thermoreceptors, stretch-sensitive free endings, hair receptors and nociceptors, including those in dental pulp, skin and connective tissue. A $\gamma$ fibres are exclusively fusimotor to plate and trail endings on intrafusal muscle

Fig. 3.20 A transverse section of a biopsied human sural nerve, showing the arrangement of the connective tissue sheaths. Individual axons, myelinated and unmyelinated, are arranged in a small fascicle bounded by a perineurium. Abbreviations: P, perineurium; Ep, epineurium; E, endoneurium. (Courtesy of Professor Susan Standring, GKT School of Medicine, London.)
fibres. B fibres are myelinated autonomic preganglionic efferent fibres. C fibres are unmyelinated and have thermoreceptive, nociceptive and interoceptive functions, including the perception of slow, burning pain and visceral pain. This scheme can be applied to fibres of both spinal and cranial nerves except perhaps those of the olfactory nerve, where the fibres form a uniquely small and slow group. The largest somatic efferent fibres ( $\mathrm{A} \alpha$ ) innervate extrafusal muscle fibres (at motor endplates) exclusively and conduct at a maximum of $120 \mathrm{~m} / \mathrm{s}$. Fibres to fast twitch muscles are larger than those to slow twitch muscle. Smaller (A $\gamma$ ) fibres of gamma motor neurones, and autonomic preganglionic (B) and postganglionic (C) efferent fibres conduct, in order, progressively more slowly ( $40 \mathrm{~m} / \mathrm{s}$ to less than $10 \mathrm{~m} / \mathrm{s}$ ).

A different classification, used for afferent fibres from muscles, divides fibres into groups I-IV on the basis of their calibre; groups I-III are myelinated and group IV is unmyelinated. Group I fibres are large (12-22 $\mu \mathrm{m}$ ), and include primary sensory fibres of muscle spindles (group Ia) and smaller fibres of Golgi tendon organs (group Ib). Group II fibres are the secondary sensory terminals of muscle spindles, with diameters of $6-12 \mu \mathrm{~m}$. Group III fibres, $1-6 \mu \mathrm{~m}$ in diameter, have free sensory endings in the connective tissue sheaths around and within muscles and are nociceptive and, in skin, also thermosensitive. Group IV fibres are unmyelinated, with diameters below $1.5 \mu \mathrm{~m}$; they include free endings in skin and muscle, and are primarily nociceptive.

## CONNECTIVE TISSUE SHEATHS

Nerve trunks, whether uni- or multifascicular, are limited externally by an epineurium, which is connected to surrounding tissues by mesoneurium. Mesoneurium is a loose connective tissue sheath (see Ch. 2) containing the extrinsic, segmental blood supply of the nerve, and so is of clinical importance in nerve injury. Individual fasciculi of the nerve trunk are enclosed by a multilayered perineurium, which in turn surrounds the endoneurium or intrafascicular connective tissue (see Fig. 3.20).

## Epineurium

Epineurium is a condensation of loose (areolar) connective tissue derived from mesoderm. As a general rule, the more fasciculi present in a peripheral nerve, the thicker the epineurium. Epineurium contains fibroblasts, collagen (types I and III) and variable amounts of fat, and it cushions the nerve it surrounds. Loss of this protective layer may be associated with pressure palsies seen in wasted, bedridden patients. The epineurium also contains lymphatics (which probably pass to regional lymph nodes) and blood vessels, vasa nervorum, that pass across the perineurium to communicate with a network of fine vessels within the endoneurium, forming the intrinsic system of vascular plexuses.

## Perineurium

Perineurium extends from the CNS-PNS transition zone to the periphery, where it is continuous with the capsules of muscle spindles and encapsulated sensory endings, but ends openly at unencapsulated endings and neuromuscular junctions. It consists of alternating layers of flattened polygonal cells (thought to be derived from fibroblasts) and collagen. It can often contain 15-20 layers of such cells, each layer enclosed by a basal lamina up to $0.5 \mu \mathrm{~m}$ thick. Within each layer the cells interdigitate along extensive tight junctions; their cytoplasm typically contains vesicles and bundles of microfilaments and their plasma membrane often shows evidence of pinocytosis. These features are consistent with the function of the perineurium as a metabolically active diffusion barrier; together with the blood-nerve barrier, the perineurium is thought to play an essential role in maintaining the osmotic milieu and fluid pressure within the endoneurium. Lymphatic vessels have not been detected in the perineurium.

## Endoneurium

Strictly speaking, the term endoneurium is restricted to intrafascicular connective tissue and excludes the perineurial partitions within fascicles. Endoneurium consists of a fibrous matrix composed predominantly of type III collagen (reticulin) fibres, characteristically organized in fine bundles lying parallel to the long axis of the nerve, and condensed around individual Schwann cell-axon units and endoneurial vessels. The fibrous and cellular components of the endoneurium are bathed in endoneurial fluid at a slightly higher pressure than that outside in the surrounding epineurium. The major cellular constituents
of the endoneurium are Schwann cells and endothelial cells; minor components are fibroblasts (constituting approximately 4\% of the total endoneurial cell population), resident macrophages and mast cells. Schwann cell-axon units and blood vessels are enclosed within individual basal laminae and therefore isolated from the other cellular and extracellular components of the endoneurium.

Endoneurial arterioles have a poorly developed smooth muscle layer and do not autoregulate well. In sharp contrast, epineurial and perineurial vessels have a dense perivascular plexus of peptidergic, serotoninergic and adrenergic nerves. There are free nerve endings in all layers of neural connective tissue sheaths and there are some encapsulated (Pacinian) corpuscles in the endoneurium. These probably contribute to the acute sensitivity of nerves trapped in fibrosis after injury or surgery.

## SCHWANN CELLS

Schwann cells are the major glial type in the PNS. In vitro they are fusiform in appearance. Both in vitro and in vivo, Schwann cells ensheathe peripheral axons, and myelinate those greater than $2 \mu \mathrm{~m}$ in diameter. In a mature peripheral nerve, they are distributed along the axons in longitudinal chains; the geometry of their association depends on whether the axon is myelinated or unmyelinated. In myelinated axons the territory of a Schwann cell defines an internode.

The molecular phenotype of mature myelin-forming Schwann cells is different from that of mature non-myelin-forming Schwann cells. Adult myelin-forming Schwann cells are characterized by the presence of several myelin proteins, some, but not all, of which are shared with oligodendrocytes and central myelin. In contrast, expression of the low-affinity neurotrophin receptor ( $\mathrm{p} 75^{\mathrm{NTR}}$ ) and GFAP intermediate filament protein (which differs from the CNS form in its posttranslational modification) characterizes adult non-myelin-forming Schwann cells.

Schwann cells arise from Schwann cell precursors that, in turn, are generated from multipotent cells of the neural crest. Neuronal signals regulate many aspects of Schwann cell behaviour in developing and postnatal nerves. Axon-associated signals appear to control the proliferation of developing Schwann cells and their precursors; the developmentally programmed death of those precursors in order to match numbers of axons and glia within each peripheral nerve bundle; the production of basal laminae by Schwann cells; and the induction and maintenance of myelination. Axonal neuregulin 1 signalling via ErbB2/ B3 receptors on Schwann cells is essential for Schwann cell myelination and also determines myelin thickness. An extensive literature supports the view that Schwann cells are key players in the acute injury response in the PNS (see Commentary 1.6), helping to provide a microenvironment that facilitates axonal regrowth (Birch 2011). Few Schwann cells persist in chronically denervated nerves. For further reading about Schwann cells, see Kidd et al (2013).

## Unmyelinated axons

Unmyelinated axons are commonly $1.0 \mu \mathrm{~m}$ in diameter, although some may be $1.5 \mu \mathrm{~m}$ or even $2 \mu \mathrm{~m}$ in diameter. Groups of up to 10 or more small axons ( $0.15-2.0 \mu \mathrm{~m}$ in diameter) are enclosed within a chain of overlapping Schwann cells that is surrounded by a basal lamina. Within each Schwann cell, individual axons are usually sequestered from their neighbours by delicate processes of cytoplasm. It seems likely, on the basis of quantitative studies in subhuman primates, that axons from adjacent cord segments may share Schwann cell columns; this phenomenon may play a role in the evolution of neuropathic pain after nerve injury. In the absence of a myelin sheath and nodes of Ranvier, action potential propagation along unmyelinated axons is not saltatory but continuous, and relatively slow ( $0.5-4.0 \mathrm{~m} / \mathrm{s}$ ).

## Myelinated axons

Myelinated axons (Fig. 3.21) have a $1: 1$ relationship with their ensheathing Schwann cells. The territorial extent of individual Schwann cells varies directly with the diameter of the axon they surround, from 150 to $1500 \mu \mathrm{~m}$. Specialized domains of axo-glial interaction define nodes of Ranvier and their neighbouring compartments, paranodes and juxtaparanodes (Pereira et al 2012; Fig. 3.22). These domains contain multiprotein complexes characterized by unique sets of transmembrane and cytoskeletal proteins and clusters of ion channels; the mechanisms regulating channel clustering and node formation remain a subject of intense scrutiny (Peles and Salzer 2000, Poliak and Peles 2003, Horresh

Fig. 3.21 An electron micrograph of a transverse section of biopsied human sural nerve, showing a myelinated axon and several unmyelinated axons (A), ensheathed by Schwann cells (S). (Courtesy of Professor Susan Standring, GKT School of Medicine, London.)
et al 2008). The region under the compact myelin sheath that extends between two juxtaparanodes is the internode. The molecular domains of myelinated axons, including that of the axon initial segment are reviewed in Buttermore et al (2013)).

Schwann cell cytoplasm forms a continuous layer only in the perinuclear (mid-internodal) and paranodal regions, where it forms a collar from which microvilli project into the nodal gap substance. Elsewhere it is dispersed as a lace-like network over the inner (adaxonal) and outer (abaxonal) surfaces of the myelin sheath.

## Nodes of Ranvier

The nodal compartment consists of a short length of exposed axolemma, typically $0.8-1.1 \mu \mathrm{~m}$ long, surrounded by a nodal gap substance composed of various extracellular components, some of which may possess nerve growth-repulsive characteristics. Multiple processes (microvilli) protrude into the gap substance from the outer collar of Schwann cytoplasm and contact the nodal axolemma. Voltage-gated $\mathrm{Na}^{+}$channels, the cell adhesion molecules NrCAM and neurofascin-186, the cytoskeletal adaptor ankyrin G25,26 and the actin-binding protein spectrin $\beta$ IV are clustered at nodes. The calibre of the nodal axon is usually significantly less than that of the internodal axon, particularly in large-calibre fibres.

## Paranodes

The axolemma on either side of a node is contacted by paranodal loops of Schwann cell cytoplasm via specialized septate junctions that spiral around the axon. The junctions are thought to form a partial diffusion barrier into the peri-axonal space; restrict the movement of $\mathrm{K}^{+}$channels from under the compact myelin; and limit lateral diffusion of membrane components. Caspr, contactin and their putative ligand NF155 (an isoform of neurofascin) are concentrated in paranodes.

## Juxtaparanodes

The region of the axon lying just beyond the innermost paranodal junction is now recognized as a distinct domain defined by the localization of voltage-gated $\mathrm{K}^{+}$channels (delayed-rectifier $\mathrm{K}^{+}$channels Kv1.1, Kv1.2 and their Kvb2 subunit). Clustering of Kv1 channels at the juxtaparanodal region depends on their association with the Caspr2/TAG-1 adhesion complex.

## Schmidt-Lanterman incisures

Schmidt-Lanterman incisures are helical decompactions of internodal myelin that appear as funnel-like profiles in teased fibre preparations labelled for markers of non-compacted myelin (e.g. MAG, Cx32). At an incisure the major dense line of the myelin sheath splits to enclose a continuous spiral band of cytoplasm passing between abaxonal and adaxonal layers of Schwann cell cytoplasm. The minor dense line of incisural myelin is also split, creating a channel connecting the periaxonal space with the endoneurial extracellular fluid. The function of

Fig. 3.22 The general plan of a peripheral myelinated nerve fibre in longitudinal section, including one complete internodal segment and two adjacent paranodal bulbs, used as a key for the more detailed microarchitecture of specific subregions. A, A transverse electron microscope section through the centre of a node of Ranvier, with numerous finger-like processes of adjacent Schwann cells converging towards the nodal axolemma. Many microtubules and neurofilaments are visible within the axoplasm. B, The arrangement of the axon, myelin sheath and Schwann cell cytoplasm at the node of Ranvier, in the paranodal bulbs and in the juxtaparanodal region. The axon is myelinated by a Schwann cell surrounded by a basal lamina (BL). Only a portion of the internode, which is located beneath the compact myelin (CM) sheath, is shown. A spiral of paranodal (green) and juxtaparanodal (blue) proteins extends into the internode; this spiral is apposed to the inner mesaxon of the myelin sheath (not shown). $\mathrm{K}^{+}$channels and Caspr2 are concentrated in the juxtaparanodal region. In the paranodal region, the compact myelin sheath opens up into a series of paranodal cytoplasmic loops (PNL) that invaginate and closely appose the axon, forming a series of septum-like junctions that spiral around the axon. Caspr, contactin and an isoform of neurofascin (NF155) are concentrated in this region. At the node, numerous microvilli (MV) project from the outer collar of the Schwann cell to contact the axolemma. The axon is enormously enriched in intramembranous particles at the node that correspond to $\mathrm{Na}^{+}$channels ( $\mathrm{Na}^{+}$ch). Ankyrin G (ank G ) isoforms and the cell adhesion molecules NrCAM and NF186 are also concentrated in this region. (A, Courtesy of Professor Susan Standring, GKT School of Medicine, London. B, Redrawn from Peles and Salzer 2000.)
incisures is not known; their structure suggests that they may participate in transport of molecules across the myelin sheath.

## SATELLITE CELLS

Many non-neuronal cells of the nervous system have been called satellite cells, including small, round extracapsular cells in peripheral ganglia, ganglionic capsular cells, Schwann cells, any cell that is closely associated with neuronal somata, and precursor cells associated with striated muscle fibres (Hanani 2010). Within the nervous system, the term is most commonly reserved for flat, epithelioid cells (ganglionic glial cells, capsular cells) that surround the neuronal somata of peripheral ganglia (see Fig. 3.23). Their cytoplasm resembles that of Schwann cells, and their deep surfaces interdigitate with reciprocal infoldings in the membranes of the enclosed neurones.

## Enteric glia

Enteric nerves lack an endoneurium and so do not have the collagenous coats of other peripheral nerves. The enteric ganglionic neurones are supported by glia that closely resemble astrocytes; they contain more GFAP than non-myelinating Schwann cells and do not produce a basal lamina. Evidence for their roles in gut function is reviewed in Gulbransen and Sharkey (2012).

## Olfactory ensheathing glia

The olfactory system is unusual because it supports neurogenesis throughout life. Olfactory receptor neurones are continuously renewed
from horizontal basal stem cells in the olfactory epithelium (Leung et al 2007, Forni and Wray 2012). They extend new axons through the lamina propria and cribriform plate into the CNS environment of the olfactory bulb, where they synapse with second-order neurones. Olfactory ensheathing cells (OECs, also known as olfactory ensheathing glia) accompany olfactory axons from the lamina propria of the olfactory epithelium to their synaptic contacts in the glomeruli of the olfactory bulbs and are thought to play a role in directing them to their correct position in the olfactory bulb (Higginson and Barnett 2011). This unusual arrangement is unique; elsewhere in the nervous system the territories of peripheral and central glia are clearly demarcated at CNSPNS transition zones. OECs and the end-feet of astrocytes lying between the bundles of olfactory axons both contribute to the glia limitans at the pial surface of the olfactory bulbs.

OECs share many properties with Schwann cells and express similar antigenic and morphological properties. They ensheathe olfactory sensory axons in a manner comparable to the relationship that exists transitorily between Schwann cells and axons in very immature peripheral nerves, i.e. they surround, but do not segregate, bundles of up to 50 fine unmyelinated axons to form approximately 20 fila olfactoria. Both OECs and Schwann cells can myelinate axons, even though normally none of the axons in the olfactory nerve is myelinated. It was thought that OECs shared a common origin with olfactory receptor neurones in the olfactory placode, but recent fate-mapping experiments in chicken embryos and genetic linkage-tracing studies in mice have shown that OECs are derived from neural crest cells (Forni and Wray 2012).

OECs have a malleable phenotype. There may be several subtypes: some OECs express GFAP as either fine filaments or more diffusely in their cytoplasm, and some express $\mathrm{p} 75^{\mathrm{NTR}}$ and the O 4 antigen.

## BLOOD SUPPLY OF PERIPHERAL NERVES

The blood vessels supplying a nerve, end in a capillary plexus that pierces the perineurium. The branches of the plexus run parallel with the fibres, connected by short transverse vessels, forming narrow, rectangular meshes similar to those found in muscle. The blood supply of peripheral nerves is unusual. Endoneurial capillaries have atypically large diameters and intercapillary distances are greater than in many other tissues. Peripheral nerves have two separate, functionally independent vascular systems: an extrinsic system (regional nutritive vessels and epineurial vessels) and an intrinsic system (longitudinally running microvessels in the endoneurium). Anastomoses between the two systems produce considerable overlap between the territories of the segmental arteries. This unique pattern of vessels, together with a high basal nerve blood flow relative to metabolic requirements, means that peripheral nerves possess a high degree of resistance to ischaemia.

## Blood-nerve barrier

Just as the neuropil within the CNS is protected by a blood-brain barrier, the endoneurial contents of peripheral nerve fibres are protected by a blood-nerve barrier and by the cells of the perineurium. The blood-nerve barrier operates at the level of the endoneurial capillary walls, where the endothelial cells are joined by tight junctions, and are non-fenestrated and surrounded by continuous basal laminae. The barrier is much less efficient in dorsal root ganglia and autonomic ganglia and in the distal parts of peripheral nerves.

## GANGLIA

Ganglia are aggregations of neuronal somata and are of varying form and size. They occur in the dorsal roots of spinal nerves; in the sensory roots of the trigeminal, facial, vestibulocochlear, glossopharyngeal and vagal cranial nerves; and in the peripheral autonomic nervous system (ANS). Each ganglion is enclosed within a capsule of fibrous connective tissue and contains neuronal somata and neuronal processes. Enteric ganglia are an exception to this rule; they resemble the CNS in both structure and function, and are not covered by a connective tissue capsule. Some ganglia, particularly in the ANS, contain axons that originate from neuronal somata that lie elsewhere in the nervous system and which pass through the ganglia without synapsing.

## Sensory ganglia

The sensory ganglia of dorsal spinal roots (Fig. 3.23) and the ganglia of the trigeminal, facial, glossopharyngeal and vagal cranial nerves are enclosed in a periganglionic connective tissue capsule that resembles the perineurium surrounding peripheral nerves. Ganglionic neurones are unipolar (sometimes called pseudounipolar, see above). They have spherical or oval somata of varying size, aggregated in groups between fasciculi of myelinated and unmyelinated nerve fibres. For each neurone, a single axodendritic process bifurcates into central and peripheral

Fig. 3.23 Sensory neurones in a dorsal root ganglion (rat). Neurones (N) are typically variable in size but all are encapsulated by satellite cells (S). Myelinated axons are seen above and below the neuronal somata. Toluidine blue stained resin section. (Courtesy of Dr Clare Farmer, King's College, London.)

processes; in myelinated fibres the junction occurs at a node of Ranvier. The peripheral process terminates in a sensory ending and, because it conducts impulses towards the soma, it functions as an elongated dendrite, strictly speaking. However, it has the typical structural and functional properties of a peripheral axon, and is conventionally described as an axon.

Each neuronal soma is surrounded by a sheath of satellite glial cells (SGCs). (A notable exception is the spiral, or cochlear, ganglion, where most neuronal somata are myelinated, presumably contributing to fast electrical transmission.) The axodendritic process and its peripheral and central divisions, ensheathed by Schwann cells, lie outside the SGC sheath. All the cells in the ganglion lie within a highly vascularized connective tissue that is continuous with the endoneurium of the nerve root. In dorsal root ganglia there is no clear regional mapping of the innervated body regions. In contrast, each of the three nerve branches (ophthalmic, maxillary and mandibular) of the trigeminal nerve is mapped to a different part of the trigeminal ganglion. Although sensory neurones receive no synapses, they are endowed with receptors for numerous neurotransmitters and hormones, and can thus communicate chemically amongst themselves and with SGCs.

SGCs are the main type of glial cell in sensory ganglia. They share several properties with astrocytes, including expression of glutamine synthetase and various neurotransmitter transporters. In addition, like astrocytes, the SGCs that surround a neurone are coupled by gap junctions and express receptors for ATP. Unlike astrocytes, SGCs completely surround individual sensory neurones (and more rarely two or three neurons) in a glial sheath. They undergo major changes as a result of injury to peripheral nerves, and appear to contribute to chronic pain in a number of animal pain models.

Herpes zoster Primary infection with the varicella zoster virus causes chickenpox. Following recovery, the virus remains dormant within dorsal root ganglia or trigeminal ganglia, mostly in the neurones, and less commonly in the SGCs. Reactivation of the virus leads to herpes zoster (shingles), which involves the dermatome(s) supplied by the affected sensory nerve(s). Diagnostic signs are severe pain, erythema and blistering as occurs in chickenpox, often confined to one of the divisions of the trigeminal nerve or to a spinal nerve dermatome. Herpes zoster involving the geniculate ganglion compresses the facial nerve and results in a lower motor neurone facial paralysis, known as Ramsay Hunt syndrome. Occasionally, if the vestibulocochlear nerve becomes involved, there is vertigo, tinnitus and some deafness. The most important complication of herpes zoster is post-herpetic neuralgia, a severe and persistent pain that is highly refractory to treatment.

## Autonomic ganglia

The main types of cell in autonomic ganglia are the ganglionic neurones, small intensely fluorescent (SIF) cells and satellite glial cells (SGCs). Most of the neurones have somata ranging from 25 to $50 \mu \mathrm{~m}$ and complex dendritic fields; dendritic glomeruli have been observed in ganglia in experimental animals. Ganglionic neurones receive many axodendritic synapses from preganglionic axons; axosomatic synapses are less numerous. Postganglionic fibres commonly arise from the initial stem of a large dendrite and produce few or no collateral processes. Given their close relationship to the ganglionic neurones, autonomic SGCs may have the potential to influence synaptic transmission. SIF cells are characterized by being smaller than the neurones and by having numerous granules that contain noradrenaline (norepinephrine), dopamine and serotonin. They are almost completely invested by a sheath of SGCs and receive and make synapses; their physiological role is currently obscure, but they lend credence to the idea that autonomic ganglia are far more than simple relay stations.

Sympathetic neurones are multipolar and their dendritic trees, on which preganglionic motor axons synapse, are more elaborate than those of parasympathetic neurones (Fig. 3.24). The neurones are surrounded by a mixed neuropil of afferent and efferent fibres, dendrites, synapses and non-neural cells. There is considerable variation in the ratio of pre- and postganglionic fibres in different types of ganglion. Preganglionic sympathetic axons may synapse with many postganglionic neurones for the wide dissemination and perhaps amplification of sympathetic activity, a feature not found to the same degree in parasympathetic ganglia. Dissemination may also be achieved by connections with ganglionic interneurones or by the diffusion within the ganglion of transmitter substances produced either locally (paracrine effect) or elsewhere (endocrine effect). Some axons within a ganglion may be efferent fibres en route to another ganglion, or afferents from viscera and glands. These fibres may synapse with neurones in the

Fig. 3.24 A parasympathetic autonomic ganglion from a human stomach. Large neuronal somata, some with nuclei and prominent nucleoli in the plane of section, are encapsulated by satellite cells and surrounded by nerve fibres and non-neuronal cells. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 3.25 An enteric ganglion (outlined) of the myenteric (Auerbach's) plexus between the inner circular and outer longitudinal layers of smooth muscle ( M ) in the wall of the human intestine. An enteric ganglionic neurone is arrowed. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
ganglion, e.g. substance P-containing axons of dorsal root neurones synapse on neurones in prevertebral ganglia, thereby enabling interactions between the sensory system and the ANS.

## Enteric ganglia

The enteric nervous system (ENS) lies within the walls of the gastrointestinal tract (see Fig. 2.15 for the layers of a typical viscus) and includes the myenteric and submucosal plexuses and associated ganglia (Furness 2012, Neunlist et al 2013). The ganglionic neurones (Fig. 3.25) serve different functions, including the regulation of gut motility (in conjunction with interstitial cells of Cajal (Huizinga et al 2009)), mucosal transport and mucosal blood flow. Unlike the other two divisions of the ANS, the ENS is largely independent of the CNS, and the extrinsic autonomic fibres that supply the gut wall exert only modulatory effects on it. Submucosal neurones, together with sympathetic axons, regulate the local blood flow.

Hirschsprung's disease is a congenital disease in which dysfunctional neural crest migration means that the ganglia of both the myenteric and submucosal plexuses in the distal bowel fail to develop. The resulting lack of propulsive activity in the aganglionic bowel leads to functional obstruction and megacolon, which can be life-threatening. Around 1 in 5,000 infants is born with the condition and is typically diagnosed in
the neonatal period. Treatment usually consists of removing the diseased intestinal segment.

The enteric plexuses consist of sensory neurones, interneurones and a variety of motor neurones. These neurones are endowed with receptors for a large number of neurotransmitters and also release a variety of neurotransmitters. All classes of enteric neurone are equally distributed along the entire ganglionic network; consequently the ENS consists of numerous repeating modules.

The myenteric plexus contains the motor neurones that control the movements of gastrointestinal smooth muscle. The main excitatory neurotransmitter is acetylcholine, which may be co-localized with an excitatory peptide (usually a tachykinin, such as substance P ). The main inhibitory neurotransmitter is nitric oxide (NO), released from neurones that may also release the inhibitory peptide vasoactive intestinal peptide (VIP).

An important function of myenteric neurones is to mediate the peristaltic reflex, which is induced by intestinal wall distension or by mechanical stimulation of the mucosa. These stimuli initiate contraction oral to the site of the stimulus, and relaxation anal to the site, creating a pressure gradient that propels the intestinal contents. Interstitial cells of Cajal (ICC) are pacemaker cells believed to integrate neuronal signals with rhythmic oscillations of muscle contraction; disturbance of ICC function may be a factor in a number of gastrointestinal disorders (Huizinga et al 2009).

Enteric glia are the main type of glial cell in the ENS. In some respects they resemble astrocytes, e.g. they form end-feet with blood vessels, respond to numerous chemical mediators, and are extensively coupled among themselves by gap junctions. They appear to play an important role in neuroprotection and in maintaining the integrity of the intestinal mucosal barrier.

## DISPERSED NEUROENDOCRINE SYSTEM

Although the nervous, neuroendocrine and endocrine systems all operate by intercellular communication, they differ in the mode, speed and degree or localization of the effects produced (Day and Salzet 2002). The autonomic nervous system uses impulse conduction and neurotransmitter release to transmit information, and the responses induced are rapid and localized. The dispersed neuroendocrine system uses only secretion. It is slower and the induced responses are less localized, because the secretions, e.g. neuromediators, can act either on contiguous cells, or on groups of nearby cells reached by diffusion, or on distant cells via the blood stream. Many of its effector molecules operate in both the nervous system and the neuroendocrine system. The endocrine system proper, which consists of clusters of cells and discrete, ductless, hormone-producing glands, is even slower and less localized, although its effects are specific and often prolonged. These regulatory systems overlap in function, and can be considered as a single neuroendocrine regulator of the metabolic activities and internal environment of the organism, acting to provide conditions in which it can function successfully. Neural and neuroendocrine axes appear to cooperate to modulate some forms of immunological reaction; the extensive system of vessels, circulating hormones and nerve fibres that link the brain with all viscera are thought to constitute a neuroimmune network (Fig. 3.26).

Some cells can take up and decarboxylate amine precursor compounds (amine precursor uptake and decarboxylation, or APUD, cells). They are characterized by dense-core cytoplasmic granules (see Fig. 2.6), similar to the neurotransmitter vesicles seen in some types of neuronal terminal. The group includes cells described as chromaffin cells (phaeochromocytes), derived from neuroectoderm and innervated by preganglionic sympathetic nerve fibres. Chromaffin cells synthesize and secrete catecholamines (dopamine, noradrenaline (norepinephrine) or adrenaline (epinephrine)). Their name refers to the finding that their cytoplasmic store of catecholamines is sufficiently concentrated to give an intense yellow-brown colouration, the positive chromaffin reaction, when they are treated with aqueous solutions of chromium salts, particularly potassium dichromate. Classic chromaffin cells include clusters of cells in the suprarenal medulla; the para-aortic bodies, which secrete noradrenaline; paraganglia; certain cells in the carotid bodies; and small groups of cells irregularly dispersed among the paravertebral sympathetic ganglia, splanchnic nerves and prevertebral autonomic plexuses.

The alimentary tract contains a large population of cells of a similar type (previously called neuroendocrine or enterochromaffin cells) in its wall. These cells act as sensory transducers, activating intrinsic and extrinsic primary afferent neurones via their release of 5hydroxytryptamine (5-HT, serotonin). The neonatal respiratory tract

Fig. 3.26 The ways in which the nervous system, neuroendocrine system and immune system are integrated, demonstrated in the intestine. Neurocrine signals from enteric neuroendocrine cells and signals from immune defence cells (e.g. lymphocytes, macrophages and mast cells) act on other cells of those systems and on neurones with sensory endings in the intestinal wall, either locally or at a distance. Some neuronal soma lie within enteric ganglia in the gut wall; others have their bodies in peripheral ganglia. Neuronal signals may act locally, be transmitted to the CNS or enter a reflex pathway via sympathetic ganglia.
contains a prominent system of neuroendocrine cells, both dispersed and aggregated (neuroepithelial bodies); the numbers of both types decline during childhood. Merkel cells (see Commentary 1.3) in the basal epidermis of the skin store neuropeptides, which they release to associated nerve endings or other cells in a neuroendocrine role, in response to pressure and possibly other stimuli (Lucarz and Brand 2007). Experimental animal studies have revealed 5-HT-containing intraepithelial paraneurones in the urothelial lining of the urethra; these cells are thought to relay information from the luminal surface of the urethra to underlying sensory nerves.

A number of descriptions and terms have been applied to cells of this system in the older literature (see online text for details).

For further reading, see Day and Salzet (2002).

## SENSORY ENDINGS

## GENERAL FEATURES OF SENSORY RECEPTORS

There are three major forms of sensory receptor: neuroepithelial, epithelial and neuronal (Fig. 3.27).

A neuroepithelial receptor is a neurone with a soma lying near a sensory surface and an axon that conveys sensory signals into the CNS to synapse on second-order neurones. This is an evolutionarily primitive arrangement, and the only examples remaining in humans are the sensory neurones of the olfactory epithelium.

An epithelial receptor is a cell that is modified from a non-nervous sensory epithelium and innervated by a primary sensory neurone with a soma lying near the CNS, e.g. auditory receptors and taste buds. When activated, this type of receptor excites its neurone by neurotransmission across a synaptic gap.

A neuronal receptor is a primary sensory neurone that has a soma in a craniospinal ganglion and a peripheral axon ending in a sensory terminal. All cutaneous sensors and proprioceptors are of this type; their sensory terminals may be encapsulated or linked to special mesodermal or ectodermal structures to form a part of the sensory apparatus. The extraneural cells are not necessarily excitable, but create an appropriate environment for the excitation of the neuronal process.

The receptor stimulus is transduced into a graded change of electrical potential at the receptor surface (receptor potential), and this initiates an all-or-none action potential that is transmitted to the CNS. This may occur either in the receptor, when this is a neurone, or partly in the
receptor and partly in the neurone that innervates it, in the case of epithelial receptors. Transduction varies with the modality of the stimulus, and usually causes depolarization of the receptor membrane (or hyperpolarization, in the retina). In mechanoreceptors, transduction may involve the deformation of membrane structure, which causes either strain or stretch-sensitive ion channels to open. In chemoreceptors, receptor action may resemble that for ACh at neuromuscular junctions. Visual receptors share similarities with chemoreceptors: light causes changes in receptor proteins, which activate G proteins, resulting in the release of second messengers and altered membrane permeability.

The quantitative responses of sensory endings to stimuli vary greatly and increase the flexibility of the functional design of sensory systems. Although increased excitation with increasing stimulus level is a common pattern ('on' response), some receptors respond to decreased stimulation ('off' response). Even unstimulated receptors show varying degrees of spontaneous background activity against which an increase or decrease in activity occurs with changing levels of stimulus. In all receptors studied, when stimulation is maintained at a steady level, there is an initial burst (the dynamic phase) followed by a gradual adaptation to steady level (the static phase). Though all receptors show these two phases, one or other may predominate, providing a distinction between rapidly adapting endings that accurately record the rate of stimulus onset, and slowly adapting endings that signal the constant amplitude of a stimulus, e.g. position sense. Dynamic and static phases are reflected in the amplitude and duration of the receptor potential and also in the frequency of action potentials in the sensory fibres. The stimulus strength necessary to elicit a response in a receptor, i.e. its threshold level, varies greatly between receptors, and provides an extra level of information about stimulus strength.

For further information on sensory receptors, see Nolte (2008).

## FUNCTIONAL CLASSIFICATION OF RECEPTORS

Receptors have been classified in several ways. They may be classified by the modalities to which they are sensitive, such as mechanoreceptors (which are responsive to deformation, e.g. touch, pressure, sound waves, etc.), chemoreceptors, photoreceptors and thermoreceptors. Some receptors are polymodal, i.e. they respond selectively to more than one modality; they usually have high thresholds and respond to damaging stimuli associated with irritation or pain (nociceptors).

Another widely used classification divides receptors on the basis of their distribution in the body into exteroceptors, proprioceptors and interoceptors. Exteroceptors and proprioceptors are receptors of the somatic afferent components of the nervous system, while interoceptors are receptors of the visceral afferent pathways.

Exteroceptors respond to external stimuli and are found at, or close to, body surfaces. They can be subdivided into the general or cutaneous sense organs and special sensory organs. General sensory receptors include free and encapsulated terminals in skin and near hairs; none of these has absolute specificity for a particular sensory modality. Special sensory organs are the olfactory, visual, acoustic, vestibular and taste receptors.

Proprioceptors respond to stimuli to deeper tissues, especially of the locomotor system, and are concerned with detecting movement, mechanical stresses and position. They include Golgi tendon organs, muscle spindles, Pacinian corpuscles, other endings in joints, and vestibular receptors. Proprioceptors are stimulated by the contraction of muscles, movements of joints and changes in the position of the body. They are essential for the coordination of muscles, the grading of muscular contraction, and the maintenance of equilibrium.

Interoceptors are found in the walls of the viscera, glands and vessels, where their terminations include free nerve endings, encapsulated terminals and endings associated with specialized epithelial cells. Nerve terminals are found in the layers of visceral walls and the adventitia of blood vessels, but the detailed structure and function of many of these endings are not well established. Encapsulated (lamellated) endings occur in the heart, adventitia and mesenteries. Free terminal arborizations occur in the endocardium, the endomysium of all muscles, and connective tissue generally. Tension produced by excessive muscular contraction or by visceral distension often causes pain, particularly in pathological states, which is frequently poorly localized and of a deepseated nature. Visceral pain is often referred to the corresponding dermatome (see Fig. 16.10). Polymodal nociceptors (irritant receptors) respond to a variety of stimuli such as noxious chemicals or damaging mechanical stimuli. They are mainly the free endings of fine, unmyelinated fibres that are widely distributed in the epithelia of the alimentary and respiratory tracts; they may initiate protective reflexes.

They include: clear cells (so named because of their poor staining properties in routine preparations); argentaffin cells (reduce silver salts); argyrophil cells (absorb silver); small intensely fluorescent cells; peptide-producing cells (particularly of the hypothalamus, hypophysis, pineal and parathyroid glands, and placenta); Kulchitsky cells in the lungs; and paraneurones. Many cells of the dispersed (or diffuse) neuroendocrine system are derived embryologically from the neural crest. Some - in particular, cells from the gastrointestinal system - are now known to be endodermal in origin.

Fig. 3.27 Some major types of sensory ending of general afferent fibres (omitting neuromuscular, neurotendinous and hair-related types). The traces below each type of ending indicate (top) their response (firing rate (vertical lines) and adaption with time) to an appropriate stimulus (below) of the duration indicated. The Pacinian corpuscle's response to vibration (rapid sequence of on-off stimuli) is also shown.

Interoceptors include vascular chemoreceptors, e.g. the carotid body, and baroceptors, which are concerned with the regulation of blood flow and pressure and the control of respiration.

## FREE NERVE ENDINGS

Sensory endings that branch to form plexuses occur in many sites (see Fig. 3.27). They occur in all connective tissues, including those of the dermis, fasciae, capsules of organs, ligaments, tendons, adventitia of blood vessels, meninges, articular capsules, periosteum, perichondrium, Haversian systems in bone, parietal peritoneum, walls of viscera and the endomysium of all types of muscle. They also innervate the epithelium of the skin, cornea, buccal cavity, and the alimentary and respiratory tracts and their associated glands. Within epithelia, free sensory endings lack Schwann cell ensheathment and are enveloped instead by epithelial cells. Afferent fibres from free terminals may be myelinated or unmyelinated but are always of small diameter and low conduction velocity. When afferent axons are myelinated, their terminal arborizations lack a myelin sheath. These terminals serve several sensory modalities. In the dermis, they may be responsive to moderate cold or heat (thermoreceptors); light mechanical touch (mechanoreceptors); damaging heat, cold or deformation (unimodal nociceptors); and damaging stimuli of several kinds (polymodal nociceptors). Similar fibres in deeper tissues may also signal extreme conditions, which are experienced, as with all nociceptors, as ache or pain. Free endings in the cornea, dentine and periosteum may be exclusively nociceptive.

Special types of free ending are associated with epidermal structures in the skin. They include terminals associated with hair follicles (peritrichial receptors), which branch from myelinated fibres in the deep dermal cutaneous plexus; the number, size and form of the endings are related to the size and type of hair follicle innervated. These endings respond mainly to movement when hair is deformed and belong to the rapidly adapting mechanoreceptor group.

Merkel tactile endings (see Commentary 1.3) lie either at the base of the epidermis or around the apical ends of some hair follicles, and most are innervated by large myelinated axons. Each axon expands into a disc that is applied closely to the base of a Merkel cell in the basal layer of the epidermis. The cells are believed to be derived from the epidermis, although a neural crest origin remains possible. They contain many large (50-100 nm) dense-core vesicles, presumably containing transmitters. Merkel endings are thought to be slow-adapting mechanoreceptors, responsive to sustained pressure and sensitive to the edges of applied objects. Their functions are controversial, however, and likely to be more varied.

## ENCAPSULATED ENDINGS

Encapsulated endings are a major group of special endings that includes lamellated corpuscles of various kinds (e.g. Meissner's, Pacinian), Golgi tendon organs, neuromuscular spindles and Ruffini endings (see Fig. 3.27). They exhibit considerable variety in their size, shape and distribution but share a common feature: namely, that each axon terminal is encapsulated by non-excitable cells (Proske and Gandevia 2012).

## Meissner's corpuscles

Meissner's corpuscles are found in the dermal papillae of all parts of the hand and foot, the anterior aspect of the forearm, the lips, palpebral conjunctiva and mucous membrane of the apical part of the tongue. They are most concentrated in thick hairless skin, especially of the finger pads, where there may be up to 24 corpuscles per $\mathrm{cm}^{2}$ in young adults. Mature corpuscles are cylindrical in shape, approximately $80 \mu \mathrm{~m}$ long and $30 \mu \mathrm{~m}$ across, with their long axes perpendicular to the skin surface. Each corpuscle has a connective tissue capsule and central core composed of a stack of flat modified Schwann cells (Fig. 3.28). Meissner's corpuscles are rapidly adapting mechanoreceptors, sensitive to shape and textural changes in exploratory and discriminatory touch; their acute sensitivity provides the neural basis for reading Braille text.

## Pacinian corpuscles

Pacinian corpuscles are situated subcutaneously in the palmar and plantar aspects of the hand and foot and their digits, the external genitalia, arm, neck, nipple, periosteal and interosseous membranes, and near joints and within the mesenteries (Fig. 3.29). They are oval, spherical or irregularly coiled and measure up to 2 mm in length and $100-500 \mu \mathrm{~m}$ or more across; the larger ones are visible to the naked eye. Each corpuscle has a capsule, an intermediate growth zone and a central core that contains an axon terminal. The capsule is formed by approximately 30 concentrically arranged lamellae of flat cells approximately $0.2 \mu \mathrm{~m}$ thick (see Fig. 3.28). Adjacent cells overlap and successive lamellae are separated by an amorphous proteoglycan matrix that contains circularly orientated collagen fibres, closely applied to the surfaces of the lamellar cells. The amount of collagen increases with age. The intermediate zone is cellular and its cells become incorporated

Fig. 3.28 A tactile Meissner's corpuscle in a dermal papilla in the skin, demonstrated using the modified Bielschowsky silver stain technique. (Courtesy of Professor N Cauna, University of Pittsburgh.)

Fig. 3.29 A Pacinian corpuscle in human dermis. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
into the capsule or core, so that it is not clearly defined in mature corpuscles. The core consists of approximately 60 bilateral, compacted lamellae lying on both sides of a central nerve terminal.

Each corpuscle is supplied by a myelinated axon, which initially loses its myelin sheath and subsequently loses its ensheathing Schwann cell at its junction with the core. The naked axon runs through the central axis of the core and ends in a slightly expanded bulb. It is in contact with the innermost core lamellae, is transversely oval and sends short projections of unknown function into clefts in the lamellae. The axon contains numerous large mitochondria, and minute vesicles, approximately 5 nm in diameter, which aggregate opposite the clefts. The cells of the capsule and core lamellae are thought to be specialized fibroblasts but some may be Schwann cells. Elastic fibrous tissue forms an overall external capsule to the corpuscle. Pacinian corpuscles are supplied by capillaries that accompany the axon as it enters the capsule.

Pacinian corpuscles act as very rapidly adapting mechanoreceptors. They respond only to sudden disturbances and are especially sensitive to very-high-frequency vibration. The rapidity may be partly due to the lamellated capsule acting as a high pass frequency filter, damping slow distortions by fluid movement between lamellar cells. Groups of corpuscles respond to pressure changes, e.g. on grasping or releasing an object.

## Ruffini endings

Ruffini endings are slowly adapting mechanoreceptors. They are found in the dermis of thin, hairy skin, where they function as dermal stretch receptors and are responsive to maintained stresses in dermal collagen. They consist of the highly branched, unmyelinated endings of myelinated afferents. They ramify between bundles of collagen fibres within a spindle-shaped structure, which is enclosed partly by a fibrocellular sheath derived from the perineurium of the nerve. Ruffini endings appear electrophysiologically similar to Golgi tendon organs, which they resemble, although they are less organized structurally. Similar structures appear in joint capsules (see below).

## Golgi tendon organs

Golgi tendon organs are found mainly near musculotendinous junctions (Fig. 3.30), where more than 50 may occur at any one site. Each terminal is closely related to a group of muscle fibres (up to 20) as they insert into the tendon. Golgi tendon organs are approximately $500 \mu \mathrm{~m}$ long and $100 \mu \mathrm{~m}$ in diameter, and consist of small bundles of tendon

Fig. 3.30 The structure and innervation of a Golgi tendon organ. For clarity, the perineurium and endoneurium have been omitted to show the distribution of nerve fibres ramifying between the collagen fibre bundles of the
tendon.

fibres enclosed in a delicate capsule．The collagen bundles（intrafusal fasciculi）are less compact than elsewhere in the tendon，the collagen fibres are smaller and the fibroblasts larger and more numerous．A single，thickly myelinated 1 b afferent nerve fibre enters the capsule and divides．Its branches，which may lose their ensheathing Schwann cells， terminate in leaf－like enlargements containing vesicles and mitochon－ dria，which wrap around the tendon．A basal lamina or process of Schwann cell cytoplasm separates the nerve terminals from the collagen bundles that constitute the tendon．Golgi tendon organs are activated by passive stretch of the tendon but are much more sensitive to active contraction of the muscle．They are important in providing propriocep－ tive information that complements the information coming from neu－ romuscular spindles．Their responses are slowly adapting and they signal maintained tension．

## Neuromuscular spindles

Neuromuscular spindles are mechanosensors essential for propriocep－ tion（Boyd 1985）．Each spindle contains a few small，specialized intrafusal muscle fibres，innervated by both sensory and motor nerve fibres（Figs 3．31－3．32）．The whole is surrounded equatorially by a fusiform spindle capsule of connective tissue，consisting of an outer perineurium－like sheath of flattened fibroblasts and collagen，and an inner sheath that forms delicate tubes around individual intrafusal fibres（Fig．3．33）．A gelatinous fluid rich in glycosaminoglycans fills the space between the two sheaths．

There are usually 5－14 intrafusal fibres（the number varies between muscles）and two major types of fibre，nuclear bag and nuclear chain fibres，which are distinguished by the arrangement of nuclei in their sarcoplasm．In nuclear bag fibres，an equatorial cluster of nuclei makes the fibre bulge slightly，whereas the nuclei in nuclear chain fibres form a single axial row．Nuclear bag fibres are subdivided into bag1 and bag2 fibres，are greater in diameter than chain fibres and extend beyond the surrounding capsule to the endomysium of nearby extrafusal muscle fibres．Nuclear chain fibres are attached at their poles to the capsule or to the sheaths of nuclear bag fibres．

The intrafusal fibres resemble typical skeletal muscle fibres，except that the zone of myofibrils is thin around the nuclei．Dynamic bag1 fibres generally lack M lines，possess little sarcoplasmic reticulum，and have an abundance of mitochondria and oxidative enzymes，but little glycogen．Static bag2 fibres have distinct $M$ lines and abundant glyco－ gen．Nuclear chain fibres have marked $M$ lines，sarcoplasmic reticulum and T－tubules，and abundant glycogen，but few mitochondria．Each fibre type carries distinct myosin heavy chain isoforms．These variations reflect the contractile properties of different intrafusal fibres．

Muscle spindles receive two types of sensory innervation via the unmyelinated terminations of large myelinated axons．Primary（anulo－ spiral）endings are equatorially placed and form spirals around the nucleated parts of intrafusal fibres．They are the endings of large sensory fibres（group Ia afferents），each of which sends branches to a number of intrafusal muscle fibres．Each terminal lies in a deep sarcolemmal groove in the spindle plasma membrane beneath its basal lamina Secondary（flower spray）endings，which may be spray－shaped or anular， are largely confined to bag2 and nuclear chain fibres，and are the branched terminals of somewhat thinner myelinated（group II）affer－ ents．They are varicose and spread in a narrow band on both sides of the primary endings．They lie close to the sarcolemma，though not in grooves．In essence，primary endings are rapidly adapting，while second－ ary endings have a regular，slowly adapting response to static stretch．

There are three types of motor endings in muscle spindles．Two are from fine，myelinated，fusimotor $(\gamma)$ efferents and one is from myeli－ nated $(\beta)$ efferent collaterals of axons that supply extrafusal slow twitch muscle fibres．The fusimotor efferents terminate nearer the equatorial region，where their terminals either resemble the motor end－plates of extrafusal fibres（plate endings）or are more diffuse（trail endings） Stimulation of the fusimotor and $\beta$－efferents causes contraction of the intrafusal fibres and，consequently，activation of their sensory endings．

Muscle spindles signal the length of extrafusal muscle both at rest and throughout contraction and relaxation，the velocity of their con－ traction and changes in velocity．These modalities may be related to the different behaviours of the three major types of intrafusal fibre and their sensory terminals．The sensory fusimotor endings of one type of nuclear bag fibre（dynamic bag1）are particularly concerned with signalling rapid changes in length that occur during movement，whilst those of the second bag fibre type（static bag2）and of chain fibres are less responsive to movement．These elements can therefore detect complex changes in the state of the extrafusal muscle surrounding spindles and can signal fluctuations in length，tension，velocity of length change and

Fig．3．31 A neuromuscular spindle，showing nuclear bag and nuclear chain fibres within the spindle capsule（green）；these are innervated by the sensory anulospiral and＇flower spray＇afferent fibre endings（blue）and by the $\gamma$ and $\beta$ fusimotor（efferent fibre）endings（red）．The $\beta$ efferent fibres are collaterals of fibres innervating extrafusal slow twitch muscle cells（M）．
acceleration．Moreover，they are under complex central control；efferent （fusimotor）nerve fibres，by regulating the strength of contraction，can adjust the length of the intrafusal fibres and thereby the responsiveness of spindle sensory endings．In summary，the organization of spindles allows them to monitor muscle conditions actively in order to compare intended and actual movements，and to provide a detailed input to spinal，cerebellar，extrapyramidal and cortical centres about the state of the locomotor apparatus．

## JOINT RECEPTORS

The arrays of receptors situated in and near articular capsules provide information on the position，movements and stresses acting on joints．

Fig. 3.32 Nuclear bag and nuclear chain fibres in a neuromuscular spindle. Dynamic $\beta$ - and $\gamma$-efferents innervate dynamic bag1 intrafusal fibres, whereas static $\beta$ - and $\gamma$-efferents innervate static bag2 and nuclear chain intrafusal fibres.

Fig. 3.33 A neuromuscular spindle in transverse section in a human extraocular muscle. The spindle capsule (C) encloses intrafusal fibres (IF) of varying diameters. Typical muscle fibres (M) in transverse section are shown above the spindle. Toluidine blue stained resin section.

Structural and functional studies have demonstrated at least four types of joint receptor; their proportions and distribution vary with site. Three are encapsulated endings, the fourth a free terminal arborization.

Type I endings are encapsulated corpuscles of the slowly adapting mechanoreceptor type and resemble Ruffini endings. They lie in the superficial layers of the fibrous capsules of joints in small clusters and are innervated by myelinated afferent axons. Being slowly adapting, they provide awareness of joint position and movement, and respond to patterns of stress in articular capsules. They are particularly common in joints where static positional sense is necessary for the control of posture (e.g. hip, knee).

Type II endings are lamellated receptors and resemble small versions of the large Pacinian corpuscles found in general connective tissue. They occur in small groups throughout joint capsules, particularly in the
deeper layers and other articular structures (e.g. the fat pad of the temporomandibular joint). They are rapidly adapting, low-threshold mechanoreceptors, sensitive to movement and pressure changes, and they respond to joint movement and transient stresses in the joint capsule. They are supplied by myelinated afferent axons but are probably not involved in the conscious awareness of joint sensation.

Type III endings are identical to Golgi tendon organs in structure and function; they occur in articular ligaments but not in joint capsules. They are high-threshold, slowly adapting receptors and may serve, at least in part, to prevent excessive stresses at joints by reflex inhibition of the adjacent muscles. They are innervated by large myelinated afferent axons.

Type IV endings are free terminals of myelinated and unmyelinated axons that ramify in articular capsules and the adjacent fat pads, and around the blood vessels of the synovial layer. They are high-threshold, slowly adapting receptors and are thought to respond to excessive movements, providing a basis for articular pain.

## NEUROMUSCULAR JUNCTIONS

## SKELETAL MUSCLE

The most intensively studied effector endings are those that innervate muscle, particularly skeletal muscle. All neuromuscular (myoneural) junctions are axon terminals of motor neurones. They are specialized for the release of neurotransmitter on to the sarcolemma of skeletal muscle fibres, causing a change in their electrical state that leads to contraction. Each axon branches near its terminal to innervate from several to hundreds of muscle fibres, the number depending on the precision of motor control required (Shi et al 2012).

The detailed structure of a motor terminal varies with the type of muscle innervated. Two major types of ending are recognized, innervating either extrafusal muscle fibres or the intrafusal fibres of neuromuscular spindles. In the former type, each axonal terminal usually ends midway along a muscle fibre in a discoidal motor end-plate (Fig. 3.34 A ), and usually initiates action potentials that are rapidly conducted to all parts of the muscle fibre. In the latter type, the axon gives off numerous branches that form a cluster of small expansions extending along the muscle fibre; in the absence of propagated muscle excitation, these excite the fibre at several points. Both types of ending are associated with a specialized receptive region of the muscle fibre, the sole plate, where a number of muscle cell nuclei are grouped within the granular sarcoplasm.

The sole plate contains numerous mitochondria, endoplasmic reticulum and Golgi complexes. The terminal branches of the axon are plugged into shallow grooves in the surface of the sole plate (primary clefts), from where numerous pleats extend for a short distance into the underlying sarcoplasm (secondary clefts) (Fig. 3.34B,C). The axon terminal contains mitochondria and many clear, 60 nm spherical vesicles similar to those in presynaptic boutons, which are clustered over the zone of membrane apposition. It is ensheathed by Schwann cells whose cytoplasmic projections extend into the synaptic cleft. The plasma membranes of the axon terminal and the muscle cell are separated by a $30-50 \mathrm{~nm}$ gap and an interposed basal lamina, which follows the surface folding of the sole-plate membrane into the secondary clefts. Endings of fast and slow twitch muscle fibres differ in detail: the sarcolemmal grooves are deeper, and the presynaptic vesicles more numerous, in the fast fibres.

Junctions with skeletal muscle are cholinergic: the release of ACh changes the ionic permeability of the muscle fibre (Sine 2012). Clustering of ACh receptors at the neuromuscular junction depends in part on the presence in the muscle basal lamina of agrin, which is secreted by the motor neurone, and is important in establishing the postjunctional molecular machinery. When the depolarization of the sarcolemma reaches a particular threshold, it initiates an action potential in the sarcolemma, which is then propagated rapidly over the whole cell surface and also deep within the fibre via the invaginations (T-tubules) of the sarcolemma, causing contraction. The amount of ACh released by the arrival of a single nerve impulse is sufficient to trigger an action potential. However, because ACh is very rapidly hydrolysed by the enzyme AChE, present at the sarcolemmal surface of the sole plate, a single nerve impulse only gives rise to one muscle action potential, i.e. there is a one-to-one relationship between neuronal and muscle action potentials. Thus the contraction of a muscle fibre is controlled by the firing frequency of its motor neurone.

Neuromuscular junctions are partially blocked by high concentrations of lactic acid, as in some types of muscle fatigue.

Fig. 3.34 The neuromuscular junction. A, Whole-mount preparation of teased skeletal muscle fibres (pale, faintly striated, diagonally orientated structures). The terminal part of the axon (silver-stained, brown) branches to form motor end-plates on adjacent muscle fibres. The sole plate recesses in the sarcolemma, into which the motor end-plates fit, are demonstrated by the presence of acetylcholinesterase (shown by enzyme histochemistry, blue). B, The axonal motor end-plate and the deeply infolded sarcolemma. C, Electron micrograph showing the expanded motor end-plate of an axon filled with vesicles containing synaptic transmitter (ACh) (above); the deep infoldings of the sarcolemmal sole plate (below) form subsynaptic gutters. ## AUTONOMIC MOTOR TERMINATIONS

Autonomic neuromuscular junctions differ in several important ways from the skeletal neuromuscular junction and from synapses in the CNS and PNS. There is no fixed junction with well-defined pre- and postjunctional specializations. Unmyelinated, highly branched, postganglionic autonomic axons become beaded or varicose as they reach the effector smooth muscle. These varicosities are not static but move along axons. They are packed with mitochondria and vesicles containing neurotransmitters, which are released from the varicosities during conduction of an impulse along the axon. The distance (cleft) between the varicosity and smooth muscle membrane varies considerably depending on the tissue, from 20 nm in densely innervated structures such as the vas deferens to $1-2 \mu \mathrm{~m}$ in large elastic arteries. Unlike skeletal muscle, the effector tissue is a muscle bundle rather than a single cell. Gap junctions between individual smooth muscle cells are lowresistance pathways that allow electronic coupling and the spread of activity within the effector bundle; they vary in size from punctate junctions to junctional areas of more than $1 \mu \mathrm{~m}$ in diameter.

Adrenergic sympathetic postganglionic terminals contain densecored vesicles. Cholinergic terminals, which are typical of all parasympathetic and some sympathetic endings, contain clear spherical vesicles like those in the motor end-plates of skeletal muscle. A third category of autonomic neurones has non-adrenergic, non-cholinergic endings that contain a wide variety of chemicals with transmitter properties. ATP is a neurotransmitter at these terminals, which express purinergic receptors (Burnstock et al 2011). The axons typically contain large, $80-200 \mathrm{~nm}$, dense opaque vesicles, congregated in varicosities at intervals along their length. These terminals are formed in many sites, including the lungs, blood vessel walls, the urogenital tract and the external muscle layers and sphincters of the gastrointestinal tract. In the intestinal wall, neuronal somata lie in the myenteric plexus, and their axons spread caudally for a few millimetres, mainly to innervate circular muscle. Purinergic neurones are under cholinergic control from preganglionic sympathetic neurones. Their endings mainly hyperpolarize smooth muscle cells, causing relaxation, e.g. preceding peristaltic waves, opening sphincters and, probably, causing reflex distension in gastric filling. Autonomic efferents innervate exocrine glands, myoepithelial cells, adipose tissue (noradrenaline (norepinephrine) released from postganglionic sympathetic axons binds to $\beta_{3}$-receptors on adipocytes to stimulate lipolysis) and the vasculature and parenchymal fields of lymphocytes and associated cells in several lymphoid organs, including the thymus, spleen and lymph nodes.

## CNS-PNS TRANSITION ZONE

The transition between CNS and PNS usually occurs some distance from the point at which nerve roots emerge from the brain or the spinal cord. The segment of root that contains components of both CNS and PNS tissue is called the CNS-PNS transition zone (TZ). All axons in the PNS, other than postganglionic autonomic neurones, cross such a TZ. Macroscopically, as a nerve root is traced towards the spinal cord or the brain, it splits into several thinner rootlets that may, in turn, subdivide into minirootlets. The TZ is located within either rootlet or minirootlet (Fig. 3.35). The arrangement of roots and rootlets varies according to whether the root trunk is ventral, dorsal or cranial. Thus, in dorsal roots, the main root trunk separates into a fan of rootlets and minirootlets that enter the spinal cord in sequence along the dorsolateral sulcus. In certain cranial nerves, the minirootlets come together central to the TZ and enter the brain as a stump of white matter.

Fig. 3.35 The nerve root-spinal cord junction. A-G, Different CNS-PNS borderline arrangements. A, A pointed borderline. The extent of the transitional zone (TZ) is indicated. B-G, Glial fringe omitted. B, A concave borderline (white line) and inverted TZ. C, A flat borderline situated at the level of the root (R)-spinal cord junction. D and E, A convex, dome-shaped borderline; the CNS expansion into the rootlet is moderate in D and extensive in E. F, The root (R) splits into rootlets (r), each with its own TZ and attaching separately to the spinal cord (SC). G, The arrangement found in several cranial nerve roots (e.g. vestibulocochlear nerve). The PNS component of the root separates into a bundle of closely packed minirootlets, each equipped with a TZ The minirootlets reunite centrally. BS, brainstem. (Adapted with permission from Dyck PJ, Thomas PK, Griffin JW, et al (eds) Peripheral Neuropathy, 3rd ed. Philadelphia: Saunders, 1993.)

Fig. 3.36 The types of change in electrical potential that can be recorded across the cell membrane of a motor neurone at the points indicated. Excitatory and inhibitory synapses on the surfaces of the dendrites and soma cause local graded changes of potential that summate at the axon hillock and may initiate a series of all-or-none action potentials, which in turn are conducted along the axon to the effector terminals.

Microscopically, the TZ is characterized by an axial CNS compartment surrounded by a PNS compartment. The zone lies more peripherally in sensory nerves than in motor nerves, but in both, the apex of the TZ is described as a glial dome, whose convex surface is usually directed distally. The centre of the dome consists of fibres with a typical CNS organization, surrounded by an outer mantle of astrocytes (corresponding to the glia limitans). From this mantle, numerous glial processes project into the endoneurial compartment of the peripheral nerve, where they interdigitate with its Schwann cells. The astrocytes form a loose reticulum through which axons pass. Peripheral myelinated axons usually cross the zone at a node of Ranvier, which is here termed a PNS-CNS compound node.

Boundary cap (BC) cells are neural crest derivatives that form transient, discrete clusters localized at the presumptive dorsal root entry zones and motor exit points of the embryonic spinal cord. They are
thought to prevent cell mixing at these interfaces not only by helping dorsal root ganglion afferents navigate their path to targets in the spinal cord but also by inhibiting motoneurone cell bodies exiting to the periphery. For further reading, see Zujovic et al (2011).

## CONDUCTION OF THE NERVOUS IMPULSE

All cells generate a steady electrical potential across their plasma membrane (the membrane potential). This potential is generated by an uneven distribution of potassium ions across the membrane (higher in the intracellular compartment than in the extracellular compartment), and by a selective permeability of the membrane for potassium (Fig. 3.36). The distribution of sodium ions is opposite to that for potassium ions, but at rest the sodium conductance of the membrane is low. In
neurones this membrane potential is known as the resting potential, and amounts to approximately -60 mV (potential inside the cell measured relative to the outside of the cell). Non-excitable cells have an even higher membrane potential. Neurones receive, conduct and transmit information by changes in membrane conductance for sodium, potassium, calcium or chloride ions. Increase in the sodium or calcium conductance causes an influx of these ions and results in a depolarization of the cell, while chloride influx or potassium efflux results in hyperpolarization. Plasma membrane permeability to these ions is altered by the opening or closing of ion-specific transmembrane channels, triggered by voltage changes or chemical signals such as transmitters (Catterall 2010).

Chemically triggered ionic fluxes may be either direct, where the chemical agent (neurotransmitter) binds to the channel itself to cause it to open, or indirect, where the neurotransmitter is bound by a transmembrane receptor molecule that activates a complex second messenger system within the cell to open separate transmembrane channels. Electrically induced changes in membrane potential depend on the presence of voltage-sensitive ion channels, which, when the transmembrane potential reaches a critical level, open to allow the influx or efflux of specific ions. In all cases, the channels remain open only transiently, and the numbers that open and close determine the total flux of ions across the membrane (Bezanilla 2008).

The types and concentrations of transmembrane channels and related proteins, and therefore the electrical activity of the membranes, vary in different parts of the cell. Dendrites and neuronal somata depend mainly on neurotransmitter action and show graded potentials, whereas axons have voltage-gated channels that give rise to action potentials.

In graded potentials, a flow of current occurs when a synapse is activated; the influence of an individual synapse on the membrane potential of neighbouring regions decreases with distance. Thus synapses on the distal tips of dendrites may, on their own, have relatively little effect on the membrane potential of the cell body. The electrical state of a neurone therefore depends on many factors, including the numbers and positions of thousands of excitatory and inhibitory synapses, their degree of activation, and the branching pattern of the dendritic tree and geometry of the cell body. The integrated activity directed towards the neuronal cell body is converted to an output directed away from the soma at the site where the axon leaves the cell body, at its junction with the axon hillock. Voltage-sensitive channels are concentrated at this trigger zone, the axon initial segment, and when this region is sufficiently depolarized, an action potential is generated and is subsequently conducted along the axon.

## ACTION POTENTIAL

The action potential is a brief, self-propagating reversal of membrane polarity. It depends on an initial influx of sodium ions, which causes a reversal of polarity to about +20 mV , followed by a rapid return towards the resting potential as potassium ions flow out. The rapid reversal process is completed in approximately 0.5 msec , followed by a slower recovery phase of up to 5 msec , when the resting potential is even hyperpolarized. Once the axon hillock reaches threshold, propagation of the action potential is independent of the initiating stimulus; thus the size and duration of action potentials are always the same (described as all-or-none) for a particular neurone, no matter how much a stimulus may exceed the threshold value.

Once initiated, an action potential spreads spontaneously and at a relatively constant velocity, within the range of $4-120 \mathrm{~m} / \mathrm{s}$. Conduction velocity depends on a number of factors related to the way in which the current spreads, e.g. axonal cross-sectional area, the numbers and positioning of ion channels, and membrane capacitance (influenced particularly by the presence of myelin). In axons lacking myelin, action potential conduction is analogous to a flame moving along a fuse. Just as each segment of fuse is ignited by its upstream neighbour, each segment of axon membrane is driven to threshold by the depolariza-
tion of neighbouring membrane. Sodium channels within the newly depolarized segment open and positively charged sodium ions enter, driving the local potential inside the axon towards positive values. This inward current in turn depolarizes the neighbouring, downstream, nondepolarized membrane, and the cyclic propagation of the action potential is completed. Several milliseconds after the action potential, the sodium channels are inactivated, a period known as the refractory period. The length of the refractory period determines the maximum frequency at which action potentials can be conducted along a nerve fibre; it varies in different neurones and affects the amount of information that can be carried by an individual fibre.

Myelinated fibres are electrically insulated by their myelin sheaths along most of their lengths, except at nodes of Ranvier. The distance between nodes, referred to as the internodal distance, is directly related to axon diameter and varies between 0.2 and 2.0 mm . Voltage-gated sodium channels are clustered at nodes, and the nodal membrane is the only place where high densities of inward sodium current can be generated across the axon membrane. Conduction in myelinated axons is self-propagating, but instead of physically adjacent regions of membrane acting to excite one another (as occurs along unmyelinated axons), it is the depolarization occurring in the neighbouring upstream node that excites a node to threshold. Reaching threshold causes the sodium channels at the node to open and generate inward sodium current, but instead of this acting on the adjacent membrane, the high resistance and low capacitance of the myelin sheath directs the current towards the next downstream node, exciting it to threshold and completing the cycle. The action potential thus jumps from node to node, a process known as saltatory conduction, which greatly increases the conduction velocity.

A number of disorders of the CNS and PNS include demyelination as a characteristic feature. Perhaps most common amongst these is multiple sclerosis, which is characterized by primary demyelination at scattered sites within the CNS (it is now recognized that axonal loss also contributes to the progression of multiple sclerosis). Primary demyelination is the loss of the myelin sheath with axonal preservation, and is usually segmental, i.e. it rarely extends along the entire length of an affected axon. The phenomenon is associated with conduction block because the newly exposed, previously internodal, axolemma contains relatively few voltage-sensitive $\mathrm{Na}^{+}$channels. There is experimental evidence that conduction can be restored in some demyelinated axons, and experimental and clinical evidence that remyelinated axons can conduct at near-normal speeds, because even though their sheaths are thinner than the original myelin sheaths, the safety factor (i.e. the factor by which the outward current at a quiescent node next to an excited node exceeds the minimum current required to evoke a response) is greater than 1 . The myelin loss that occurs in the early stages of Wallerian degeneration in both CNS and PNS, usually distal to a site of trauma but also in response to a prolonged period of ischaemia or exposure to a neuronotoxic substance, is accompanied by axonal degeneration (the term secondary demyelination is sometimes used to describe this form of myelin loss).

Axonal conduction is naturally unidirectional, from dendrites and soma to axon terminals. When an action potential reaches the axonal terminals, it causes depolarization of the presynaptic membrane, and as a result, quanta of neurotransmitter (which correspond to the content of individual vesicles) are released to change the degree of excitation of the next neurone, muscle fibre or glandular cell.

# Blood, lymphoid tissues and haemopoiesis 

Blood is an opaque fluid with a viscosity greater than that of water (mean relative viscosity 4.75 at $18^{\circ} \mathrm{C}$ ), and a specific gravity of 1.06 at $15^{\circ} \mathrm{C}$. It is bright red when oxygenated, in the systemic arteries, and dark red to purple when deoxygenated, in systemic veins. Blood is a mixture of a clear liquid, plasma and cellular elements, and consequently the hydrodynamic flow of blood in vessels behaves in a complex manner that is not entirely predictable by simple Newtonian equations.

Plasma is a clear, yellowish fluid that contains many substances in solution or suspension: low-molecular-weight solutes give a mean freezing-point depression of $0.54^{\circ} \mathrm{C}$. Plasma contains high concentrations of sodium and chloride ions, potassium, calcium, magnesium, phosphate, bicarbonate, traces of many other ions, glucose, amino acids and vitamins. It also includes high-molecular-weight plasma proteins, e.g. clotting factors, particularly prothrombin; immunoglobulins and complement proteins involved in immunological defence; glycoproteins, lipoproteins, polypeptide and steroid hormones, and globulins for the transport of hormones and iron. The plasma is involved in the transport of most molecules that are released or secreted by cells in response to pathological or physiological stimuli and so the routine chemical analysis of plasma is of great diagnostic importance. There is increasing interest in using metabolomics approaches for the highthroughput analysis of small molecules or metabolites in the serum, as a potential aid to diagnosis and understanding of disease (Psychogios et al 2011).

The precipitation of the protein fibrin from plasma to form a clot (Fig. 4.1) is initiated by the release of specific materials from damaged cells and blood platelets in the presence of calcium ions. If blood or plasma samples are allowed to stand, they will separate into a clot and a clear yellowish fluid, the serum. Clot formation is prevented by removal of calcium ions, e.g. by addition of citrate, oxalate or various organic calcium chelators (EDTA, EGTA) to the sample. Heparin is also widely used as an anticlotting agent because it interferes with fibrin clot formation.

In postnatal life, blood cells are formed in the bone marrow. Haemopoiesis produces red cells (erythrocytes) and a wide variety of

defensive cells (white blood cells, or leukocytes). The latter include neutrophil, eosinophil and basophil granulocytes, B lymphocytes and monocytes. T lymphocytes develop in the thymus from bone marrowderived progenitors. These cells all contribute to the immune system of the human (for an overview of the immune system, see Murphy (2011)). Platelets are produced in the bone marrow as cellular fragments of megakaryocytes. Only erythrocytes and platelets are generally confined to the blood vascular system, whereas all leukocytes can leave the circulation and enter extravascular tissues. The numbers of cells doing so increases greatly during inflammation caused by local infections or tissue damage.

The lymphoid tissues are the thymus, lymph nodes, spleen and the lymphoid follicles associated mainly with the alimentary and respiratory tracts. Lymphocytes populate lymphoid tissues and are concerned with immune defence. Lymphoid tissue also contains supportive stromal cells, which are non-haemopoietic in origin (e.g. thymic epithelium); non-haemopoietic follicular dendritic cells of lymph nodes and splenic follicles; haemopoietically derived dendritic cells; and macrophages of the mononuclear phagocyte system. Dendritic cells and blood monocyte-derived macrophages are found additionally in most tissues and organs, where they function as antigen-presenting cells (APCs).

## CELLS OF PERIPHERAL BLOOD

## ERYTHROCYTES

Erythrocytes (red blood cells, RBCs) account for the largest proportion of blood cells ( $99 \%$ of the total number), with normal values of $4.1-6.0 \times 10^{6} / \mu \mathrm{l}$ in adult males and 3.9-5.5 $\times 10^{6} / \mu \mathrm{l}$ in adult females. Polycythaemia (increased red cell mass) can occur in individuals living at high altitude, or pathologically in conditions resulting in arterial hypoxia. Reduction in red cell mass (anaemia) has many underlying causes but in rare instances can be due to structural defects in erythrocytes (see below).

Each erythrocyte is a biconcave disc (see Fig. 4.1; Fig. 4.2) with a mean diameter in dried smear preparations of $7.1 \mu \mathrm{~m}$; in fresh preparations the mean diameter is $7.8 \mu \mathrm{~m}$, decreasing slightly with age. Mature erythrocytes lack nuclei. They are pale red by transmitted light, with

Fig. 4.2 A human heart muscle biopsy specimen, showing an erythrocyte within a capillary. The erythrocyte biconcave disc is typically electrondense and almost fills the capillary lumen. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
paler centres because of their biconcave shape. The properties of their cell coat cause them to adhere to one another by their rims to form loose piles of cells (rouleaux). In normal blood, a few cells assume a shrunken, star-like, crenated form; this shape can be reproduced by placing normal biconcave erythrocytes in a hypertonic solution, which causes osmotic shrinkage. In hypotonic solutions erythrocytes take up water and become spherical; they may eventually lyse to release their haemoglobin (haemolysis), leaving red-cell ghosts.

Erythrocytes have a plasma membrane that encloses mainly a single protein, haemoglobin, as a $33 \%$ solution. The plasma membrane of erythrocytes is $60 \%$ lipid and glycolipid, and $40 \%$ protein and glycoprotein.

More than 15 classes of protein are present, including two major types. Glycophorins A and B (each with a molecular mass of approximately 50 kDa ) span the membrane, and their negatively charged carbohydrate chains project from the outer surface of the cell. Their sialic acid groups confer most of the fixed charge on the cell surface. A second transmembrane macromolecule, band 3 protein, forms an important anion channel, exchanging bicarbonate for chloride ions across the membrane and allowing the release of $\mathrm{CO}_{2}$ in the lungs.

The filamentous protein, spectrin, is responsible for maintaining the shape of the erythrocyte. A dimer is formed of $\alpha 1$ and $\beta 1$ spectrin monomers, and two dimers then come together to form a tetramer (Machnicka et al 2013). These are joined by junctional complexes that contain (among other proteins) ankyrin, short actin filaments, tropomyosin and protein 4.1, forming a hexagonal lattice that supports the plasma membrane (Mankelow et al 2012). The junctional complex also interacts with transmembrane proteins. This structure gives the membrane great flexibility; red cells are deformable but regain their biconcave shape and dimensions after passing through the smallest capillaries, which are $4 \mu \mathrm{~m}$ in diameter (Mohandas and Gallagher 2008). Erythrocyte membrane flexibility also contributes to the normally low viscosity of blood. Molecular defects in the cytoskeleton result in abnormalities of red cell shape, membrane fragility, premature destruction of erythrocytes in the spleen and haemolytic anaemia (Iolascon et al 1998).

Fetal erythrocytes up to the fourth month of gestation differ markedly from those of adults, in that they are larger, are nucleated and contain a different type of haemoglobin (HbF). After this time they are progressively replaced by the adult type of cell.

## Haemoglobin

Haemoglobin (Hb) is a globular protein with a molecular mass of 67 kDa . It consists of globulin molecules bound to haem, an ironcontaining porphyrin group. The oxygen-binding power of haemoglobin is provided by the iron atoms of the haem groups, and these are maintained in the ferrous ( $\mathrm{Fe}^{++}$) state by the presence of glutathione within the erythrocyte. The haemoglobin molecule is a tetramer, made up of four subunits, each a coiled polypeptide chain holding a single haem group.

Mutations in the haemoglobin chains can result in a range of pathologies (Forget and Bunn 2013).

## Lifespan

Erythrocytes last between 100 and 120 days before being destroyed. As erythrocytes age, they become increasingly fragile, and their surface charges decrease as their content of negatively charged membrane glycoproteins diminishes. The lipid content of their membranes also reduces. Aged erythrocytes are taken up by the macrophages of the spleen (Mebius and Kraal 2005) and liver sinusoids, usually without prior lysis, and are hydrolysed in phagocytic vacuoles where the haemoglobin is split into its globulin and porphyrin moieties. Globulin is further degraded to amino acids, which pass into the general amino-acid pool. Iron is removed from the porphyrin ring and either transported in the circulation bound to transferrin and used in the synthesis of new haemoglobin in the bone marrow, or stored in the liver as ferritin or haemosiderin. The remainder of the haem group is converted in the liver to bilirubin and excreted in the bile. Haemoglobin that is released by destruction of erythrocytes in the body binds to haptoglobin, and is taken up via CD163 receptors expressed on the surface of macrophages (Kristiansen et al 2001).

The recognition of effete erythrocytes by macrophages appears to take place by a number of mechanisms (Bratosin et al 1998). These include the exposure of phospholipids (such as phosphatidyl serine) that are normally found on the inner leaflet of the membrane bilayer, alterations in the carbohydrates expressed by the cells (most notably the loss of sialic acid) and the binding of autoantibodies to antigens
exposed on the aged erythrocyte. These lead to the cells being recognised and taken up by macrophages. Red cells are destroyed at the rate of $5 \times 10^{11}$ cells a day (or nearly 6 million a second) and are normally replaced from the bone marrow (see Fig. 4.12) at the same rate.

## Blood groups

Over 300 red cell antigens are recognizable with specific antisera. They can interact with naturally occurring or induced antibodies in the plasma of recipients of an unmatched transfusion, causing agglutination and lysis of the erythrocytes. Erythrocytes of a single individual carry several different types of antigen, each type belonging to an antigenic system in which a number of alternative antigens are possible in different persons. So far, 19 major groups have been identified. They vary in their distribution frequencies between different populations, and include the ABO, Rhesus, MNS, Lutheran, Kell, Lewis, Duffy, Kidd, Diego, Cartwright, Colton, Sid, Scianna, Yt, Auberger, Ii, Xg, Indian and Dombrock systems. Clinically, the ABO and Rhesus groups are of most importance.

Leukocytes also bear highly polymorphic antigens encoded by allelic gene variants. These belong to the group of major histocompatibility complex (MHC) antigens, also termed human leukocyte antigens (HLA) in humans. HLA class I antigens are expressed by all nucleated cells. Class II antigens are expressed on antigen-presenting cells (APCs) of the immune system, but can also be induced on many parenchymal cell types, e.g. after exposure to interferon. HLA class I and II antigens play important roles in cell-cell interactions in the immune system, particularly in the presentation of antigens to T lymphocytes by APCs.

## LEUKOCYTES

Leukocytes (white blood cells) belong to at least five different categories (see Fig. 4.12) and are distinguishable by their size, nuclear shape and cytoplasmic inclusions. In practice, leukocytes are often divided into two main groups: namely, those with prominent stainable cytoplasmic granules, the granulocytes, and those without.

## Granulocytes

This group consists of eosinophil granulocytes, with granules that bind acidic dyes such as eosin; basophil granulocytes, with granules that bind basic dyes strongly; and neutrophil granulocytes, with granules that stain only weakly with either type of dye. Granulocytes (Fig. 4.3) all possess irregular or multilobed nuclei and belong to the myeloid series of blood cells (see Fig. 4.12).

## Neutrophil granulocytes

Neutrophil granulocytes (neutrophils) are also referred to as polymorphonuclear leukocytes (polymorphs) because of their irregularly

Fig. 4.3 Neutrophil ( N ) and basophil ( B ) granulocytes within a renal glomerular capillary in a human kidney biopsy. The neutrophil nucleus is more segmented (four lobes are visible) and the granules are smaller and more electron-dense than in the basophil. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

In normal blood, five types of polypeptide chain can occur: namely, $\alpha, \beta$ and two $\beta$-like polypeptides, $\gamma$ and $\delta$. A third, $\beta$-like $\eta$ chain is restricted to early fetal development. Each haemoglobin molecule contains two $\alpha$-chains and two others, so that several combinations, and hence a number of different types of haemoglobin molecule, are possible. For example, haemoglobin $\mathrm{A}(\mathrm{HbA})$, which is the major adult class, contains $2 \alpha$ - and $2 \beta$-chains; a variant, $\mathrm{HbA}_{2}$ with $2 \alpha$ - and 2 $\delta$-chains, accounts for only $2 \%$ of adult haemoglobin. Haemoglobin F ( HbF ), found in fetal and early postnatal life, consists of $2 \alpha$ - and 2 $\gamma$-chains. Adult red cells normally contain less than $1 \%$ of HbF .

In the genetic condition thalassaemia, only one type of chain is expressed normally, the mutant chain being absent or present at much reduced levels. Thus, a molecule may contain $4 \alpha$-chains ( $\beta$-thalassaemia) or $4 \beta$-chains ( $\alpha$-thalassaemia). In haemoglobin S (HbS) of sickle-cell disease, a point mutation in the $\beta$-chain gene (valine substituted for glutamine) causes the haemoglobin to polymerize under conditions of low oxygen concentration, thus deforming the red blood cell.

In the ABO system, two allelic genes are inherited in simple Mendelian fashion. Thus the genome may be homozygous and carry the AA complement, the blood group being A , or the BB complement, which gives blood group B, or it may carry neither (OO), producing blood group O. In the heterozygous condition the following combinations can occur: AB (blood group AB ), AO (blood group A ) and BO (blood group B). The ABO blood group antigens are all membrane glycolipids.

Individuals with group $A B$ blood lack antibodies to both A and B antigens, and so can be transfused with blood of any group; they are termed universal recipients. Conversely, those with group O, universal donors, can give blood to any recipient, since anti-A and anti-B
antibodies in the donated blood are diluted to insignificant levels. Normally, however, blood is only transfused between persons with corresponding groups because anomalous antibodies of the ABO system are occasionally found in blood and may cause agglutination or lysis. The anti-ABO agglutinins, unlike those of the Rhesus system, belong to the immunoglobulin M (IgM) class and do not cross the placenta during pregnancy.

The Rhesus antigen system is determined by three sets of alleles: namely, Cc, Dd and Ee. The most important clinically is Dd. Inheritance of the Rh factor also obeys simple Mendelian laws; it is therefore possible for a Rhesus-negative mother to bear a Rhesus-positive child. Under these circumstances, fetal Rh antigens can stimulate the production of anti-Rh antibodies by the mother; as these belong to the IgG class of antibody they are able to cross the placenta. For most of the pregnancy the stroma stops the blood group antibodies from crossing into the fetal circulation. However, immediately prior to birth, the antibodies can cross this barrier and cause destruction of fetal erythrocytes. In the first such pregnancy little damage usually occurs because anti-Rh antibodies have not been induced, but in subsequent Rh-positive pregnancies massive destruction of fetal red cells may result, causing fetal or neonatal death (haemolytic disease of the newborn). Sensitization of the maternal immune system can also result from abortion or miscarriage, or occasionally even from amniocentesis, which may introduce fetal antigens into the maternal circulation. Treatment is by exchange transfusion of the neonate or, prophylactically, by giving Rh-immune (anti-D) serum to the mother after the first Rh-positive pregnancy, which destroys the fetal Rh antigen in her circulation before sensitization can occur.
segmented (multilobed) nuclei. They form the largest proportion of the white blood cells (40-75\% in adults, with a normal count of 2500$7500 / \mu \mathrm{l}$ ) and have a diameter of $12-14 \mu \mathrm{~m}$. The cells may be spherical in the circulation, but they can flatten and become actively motile within the extracellular matrix of connective tissues.

The numerous cytoplasmic granules are heterogeneous in size, shape and content, but all are membrane-bound and contain hydrolytic and other enzymes. Two major types can be distinguished according to their developmental origin and contents. Non-specific or primary (azurophilic) granules are formed early in neutrophil maturation. They are relatively large $(0.5 \mu \mathrm{~m})$ spheroidal lysosomes containing myeloperoxidase, acid phosphatase, elastase and several other enzymes. Specific or secondary granules are formed later, and occur in a wide range of shapes including spheres, ellipsoids and rods. These contain strong bacteriocidal components including alkaline phosphatase, lactoferrin and collagenase, none of which is found in primary granules. Conversely, secondary granules lack peroxidase and acid phosphatase. Some enzymes, e.g. lysozyme, are present in both types of granule

In mature neutrophils the nucleus is characteristically multilobed with up to six (usually three or four) segments joined by narrow nuclear strands; this is known as the segmented stage. Less mature cells have fewer lobes. The earliest to be released under normal conditions are juveniles (band or stab cells), in which the nucleus is an unsegmented crescent or band. In certain clinical conditions, even earlier stages in neutrophil formation, when cells display indented or rounded nuclei (metamyelocytes or myelocytes) may be released from the bone marrow. In mature cells the edges of the nuclear lobes are often irregular. In females $3 \%$ of the nuclei of neutrophils show a conspicuous 'drumstick' formation, which represents the sex chromatin of the inactive X chromosome (Barr body). Neutrophil cytoplasm contains few mitochondria but abundant cytoskeletal elements, including actin filaments, microtubules and their associated proteins, all characteristic of highly motile cells.

Neutrophils are important in the defence of the body against microorganisms. They can phagocytose microbes and small particles in the circulation and, after extravasation, they carry out similar activities in other tissues. They function effectively in relatively anaerobic conditions, relying largely on glycolytic metabolism, and they fulfil an important role in the acute inflammatory phase of tissue injury, responding to chemotaxins released by damaged tissue. Phagocytosis of cellular debris or invading microorganisms is followed by fusion of the phagocytic vacuole with granules, which results in bacterial killing and digestion. Actively phagocytic neutrophils are able to reduce oxygen enzymatically to form reactive oxygen species including superoxide radicals and hydrogen peroxide, which enhance bacterial destruction probably by activation of some of the granule contents (Segal 2005, Nathan 2006). Neutrophils can also produce neutrophil extracellular traps (NETs), which are web-like structures composed of DNA and proteolytic enzymes that can trap bacteria and kill them (Kaplan and Radic 2012).

Phagocytosis is greatly facilitated by circulating antibodies to molecules such as bacterial antigens, which the body has previously encountered. Antibodies coat the antigenic target and bind the plasma complement protein, C1, to their non-variable Fc regions. This activates the complement cascade, which involves some 20 plasma proteins synthesized mainly in the liver, and completes the process of opsonization. The complement cascade involves the sequential cleavage of the complement proteins into a large fragment, which generally binds to the antigenic surface, and a small bioactive fragment, which is released The final step is the recognition of complement by receptors on the surfaces of neutrophils (and macrophages), which promotes phagocytosis of the organism.

Neutrophils are short-lived; they spend some 6-7 hours circulating in the blood and a few days in connective tissues. The number of circulating neutrophils varies, and often rises during episodes of acute bacterial infection. They die after carrying out their phagocytic role; dead neutrophils, bacteria, tissue debris (including tissue damaged by neutrophil enzymes and toxins) and interstitial fluid form the characteristic, greenish-yellow pus of infected tissue. The colour is derived from the natural colour of neutrophil myeloperoxidase.

Granules may also be released inappropriately from neutrophils. Their enzymes are implicated in various pathological conditions, e.g. rheumatoid arthritis, where tissue destruction and chronic inflammation occur.

## Eosinophil granulocytes

Eosinophil granulocytes (eosinophils; for a review, see Rothenberg and Hogan (2006)) are similar in size (12-15 $\mu \mathrm{m}$ ), shape and motile
capacity to neutrophils, but are present only in small numbers in normal blood ( $100-400 / \mu \mathrm{l}$ ). The nucleus has two prominent lobes connected by a thin strand of chromatin. Their cytoplasmic specific granules are uniformly large ( $0.5 \mu \mathrm{~m}$ ) and give the living cell a slightly yellowish colour. The cytoplasm is packed with granules, which are spherical or ellipsoid and membrane-bound. The core of each granule is composed of a lattice of major basic protein, which is responsible for its strong eosinophilic staining properties. The surrounding matrix contains several lysosomal enzymes including acid phosphatase, ribonuclease, phospholipase and a myeloperoxidase unique to eosinophils.

Like other leukocytes, eosinophils are motile. When suitably stimulated, they are able to pass into the extravascular tissues from the circulation. They are typical minor constituents of the dermis, and of the connective tissue components of the bronchial tree, alimentary tract, uterus and vagina. The total lifespan of these cells is a few days, of which some 10 hours is spent in the circulation, and the remainder in the extravascular tissues.

Eosinophil numbers rise (eosinophilia) in worm infestations and also in certain allergic disorders, and it is thought that they evolved as a primary defence against parasitic attack. They have surface receptors for IgE that bind to IgE-antigen complexes, triggering phagocytosis and release of granule contents. However, they are only weakly phagocytic and their most important function is the destruction of parasites too large to phagocytose. This antiparasitic effect is mediated via toxic molecules released from their granules (e.g. eosinophil cationic protein and major basic protein). They also release histaminase, which limits the inflammatory consequences of mast cell degranulation. High local concentrations of eosinophils, e.g. in bronchial asthma and in cutaneous contact sensitivity and allergic eczema, can cause tissue destruction as a consequence of the release of molecules such as collagenase from their granules.

## Basophil granulocytes

Slightly smaller than other granulocytes, basophil granulocytes are $10-14 \mu \mathrm{~m}$ in diameter, and form only $0.5-1 \%$ of the total leukocyte population of normal blood, with a count of $25-200 / \mu \mathrm{l}$. Their distinguishing feature is the presence of large, conspicuous basophilic granules. The nucleus is somewhat irregular or bilobed, and is usually obscured in stained blood smears by the similar colour of the basophilic granules. The granules are membrane-bound vesicles, which display a variety of crystalline, lamellar and granular inclusions: they contain heparin, histamine and several other inflammatory agents, and closely resemble those of tissue mast cells. Both basophils and mast cells have high-affinity membrane receptors for IgE and are therefore coated with IgE antibody. If this binds to its antigen it triggers degranulation of the cells, producing vasodilation, increased vascular permeability, chemotactic stimuli for other granulocytes, and the symptoms of immediate hypersensitivity, e.g. in allergic rhinitis (hay fever). Despite these similarities, basophils and mast cells develop as separate lineages in the myeloid series, from haemopoietic stem cells in the bone marrow. Evidence from experimental animal models suggests that they are closely related (see Fig. 4.12) but studies on mast cell disorders in humans indicate that their lineages diverge from a more distant ancestral progenitor (Kocabas et al 2005). The role of mast cells in the regulation of responses to pain is of interest clinically as a therapeutic target (Chatterjea and Martinov 2015).

## Mononuclear leukocytes

## Monocytes

Monocytes are the largest of the leukocytes (15-20 $\mu \mathrm{m}$ in diameter) but they form only a small proportion of the total population ( $2-8 \%$ with a count of $100-700 / \mu$ l of blood). The nucleus, which is euchromatic, is relatively large and irregular, often with a characteristic indentation on one side. The cytoplasm is pale-staining, particulate and typically vacuolated. Near the nuclear indentation it contains a prominent Golgi complex and vesicles. Monocytes are actively phagocytic cells and contain numerous lysosomes. Phagocytosis is triggered by recognition of opsonized material, as described for neutrophils. Monocytes are highly motile and possess a well-developed cytoskeleton.

Monocytes express class II MHC antigens and share other similarities to tissue macrophages and dendritic cells. Most monocytes are thought to be in transit via the blood stream from the bone marrow to the peripheral tissues, where they give rise to macrophages and dendritic cells; different monocyte subsets may target inflamed tissues. Like other leukocytes, they pass into extravascular sites through the walls of capillaries and venules.

Fig. 4.4 A small, resting lymphocyte in human peripheral blood. The nuclear:cytoplasmic ratio is high and the cytoplasm contains few organelles, indicative of its quiescent state. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

## Lymphocytes

Lymphocytes (Fig. 4.4; see Figs 4.6, 4.12) are the second most numerous type of leukocyte in adulthood, forming 20-30\% of the total population (1500-2700/ $\mu$ l of blood). In young children they are the most numerous blood leukocyte. Most circulating lymphocytes are small, $6-8 \mu \mathrm{~m}$ in diameter; a few are medium-sized and have an increased cytoplasmic volume, often in response to antigenic stimulation. Occasionally, cells up to $16 \mu \mathrm{~m}$ are seen in peripheral blood. Lymphocytes, like other leukocytes, are found in extravascular tissues (including lymphoid tissue); however, they are the only white blood cells that return to the circulation. The lifespan of lymphocytes ranges from a few days (short-lived) to many years (long-lived). Long-lived lymphocytes are necessary for the maintenance of immunological memory.

Blood lymphocytes are a heterogeneous collection mainly of B and T cells, and consist of different subsets and different stages of activity and maturity. About $85 \%$ of all circulating lymphocytes in normal blood are T cells. Primary immunodeficiency diseases can result from molecular defects in T and B lymphocytes (reviewed in CunninghamRundles and Ponda (2005)). Included with the lymphocytes, but probably constituting a separate lineage subset, are the natural killer (NK) cells. NK cells most closely resemble large T cells morphologically.

Small lymphocytes (both B and T cells) contain a rounded, densely staining nucleus that is surrounded by a very narrow rim of cytoplasm, barely visible in the light microscope. In the electron microscope (see Fig. 4.4), few cytoplasmic organelles can be seen apart from a small number of mitochondria, single ribosomes, sparse profiles of endoplasmic reticulum and occasional lysosomes; these features indicate a low metabolic rate and a quiescent phenotype. However, these cells become motile when they contact solid surfaces, and can pass between endothelial cells to exit from, or re-enter, the vascular system. They migrate extensively within various tissues, including epithelia (Fig. 4.5).

Larger lymphocytes include T and B cells that are functionally activated or proliferating after stimulation by antigen, and NK cells. They contain a nucleus, which is, at least in part, euchromatic; a basophilic cytoplasm, which may appear granular; and numerous polyribosome clusters, consistent with active protein synthesis. The ultrastructural appearance of these cells varies according to their class and is described below.

## B cells

B cells and the plasma cells that develop from them synthesize and secrete antibodies that can specifically recognize and neutralize foreign (non-self) macromolecules (antigens), and can direct various nonlymphocytic cells (e.g. neutrophils, macrophages and dendritic cells) to phagocytose pathogens. B cells differentiate from haemopoietic stem cells in the bone marrow. After deletion of autoreactive cells, the selected B lymphocytes then leave the bone marrow and migrate to peripheral lymphoid sites (e.g. lymph nodes). Here, following stimulation by antigen, they undergo further proliferation and selection, forming

Fig. 4.5 Tubular glands in the appendix, showing intraepithelial lymphocytes (short arrows). A lymphocyte in anaphase is indicated (long arrow).

Fig. 4.6 A mature B cell (plasma cell) in human connective tissue. The abundant rough endoplasmic reticulum is typical of a cell actively synthesizing secretory protein, in this case immunoglobulin. The cell to the left is a fibroblast. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
germinal centres in the lymphoid tissues. Following this, some B cells differentiate into large basophilic (RNA-rich) plasma cells, either within or outside the lymphoid tissues. Plasma cells produce antibodies in their extensive rough endoplasmic reticulum (Fig. 4.6) and secrete them into the adjacent tissues. They have a prominent pale-staining Golgi complex adjacent to an eccentrically placed nucleus, typically with peripheral blocks of condensed heterochromatin resembling the numerals of a clock (clock-faced nucleus) (see Fig. 4.12). Other germinal centre B cells develop into long-lived memory cells capable of responding to their specific antigens not only with a more rapid and higher antibody output, but also with an increased antibody affinity compared with the primary response.

Antibodies are immunoglobulins, grouped into five classes according to their heavy polypeptide chain. Immunoglobulin G (IgG) forms the bulk of circulating antibodies. Immunoglobulin $M$ (IgM) is normally synthesized early in immune responses. Immunoglobulin A (IgA) is present in breast milk, tears, saliva and other secretions of the alimentary tract, coupled to a secretory piece (a 70 kDa protein) that is synthesized by the epithelial cells. This protects the immunoglobulin from proteolytic degradation and is part of the process by which the molecule is transported across the epithelium; IgA thus contributes to mucosal immunity. IgA deficiency is relatively common, particularly in
some ethnic groups (reviewed in Woof and Kerr (2006)). Immunoglobulin E (IgE) is an antibody which binds to receptors on the surfaces of mast cells, eosinophils and blood basophils; it is found only at low concentrations in the circulation. Immunoglobulin $D(\operatorname{IgD})$ is found together with $\operatorname{IgM}$ as a major membrane-bound immunoglobulin on mature, immunocompetent but naïve (prior to antigen exposure) B cells, acting as the cellular receptor for antigen.

When circulating antibodies bind to antigens they form immune complexes. If present in abnormal quantities, these may cause pathological damage to the vascular system and other tissues, either by interfering mechanically with the permeability of the basal lamina (e.g. some types of glomerulonephritis), or by causing local activation of the complement system that generates inflammatory mediators (e.g. C5a), attacks cell membranes and causes vascular disease. In pregnancy, maternal IgG crosses the placenta and confers passive immunity on the fetus. Maternal milk contains secretory immunoglobulins (IgA) that help to combat bacterial and viral organisms in the alimentary tract of the baby during the first few weeks of postnatal life.

## T cells

There are a number of subsets of T (thymus-derived) lymphocytes, all progeny of haemopoietic stem cells in the bone marrow. They develop and mature in the thymus, and subsequently populate peripheral secondary lymphoid organs, which they constantly leave and re-enter via the circulation. As recirculating cells, their major function is immune surveillance. Their activation and subsequent proliferation and functional maturation are under the control of antigen-presenting cells. T cells undertake a wide variety of cell-mediated defensive functions that are not directly dependent on antibody activity, and which constitute the basis of cellular immunity. T-cell responses focus on the destruction of cellular targets such as virus-infected cells, certain bacterial infections, fungi, some protozoal infections, neoplastic cells and the cells of grafts from other individuals (allografts, when the tissue antigens of the donor and recipient are not sufficiently similar). Targets may be killed directly by cytotoxic T cells, or indirectly by accessory cells (e.g. macrophages) that have been recruited and activated by cytokine-secreting helper T cells. A third group, regulatory T cells, acts to regulate or limit immune responses.

Functional groups of T cells are classified according to the molecules they express on their surfaces. The majority of cytokine-secreting helper T cells express CD4, while cytotoxic T cells are characterized by CD8. Regulatory T cells co-express CD4 and CD25. The CD (cluster of differentiation) prefix provides a standard nomenclature for all cell-surface molecules. At present, more than 330 different CD antigens have been designated; each one represents a cell surface molecule that can be identified by specific antibodies. Further details of the classification are beyond the scope of this publication and are given in Male et al (2012).

Structurally, T lymphocytes present different appearances depending on their type and state of activity. When resting, they are typically small lymphocytes and are morphologically indistinguishable from B lymphocytes. When stimulated, they become large (up to $15 \mu \mathrm{~m}$ ), moderately basophilic cells, with a partially euchromatic nucleus and numerous free ribosomes, rough and smooth endoplasmic reticulum, a Golgi complex and a few mitochondria, in their cytoplasm. Cytotoxic T cells contain dense lysosome-like vacuoles that function in cytotoxic killing.

## Cytotoxic $T$ cells

Cytotoxic T lymphocytes (which express CD8) are responsible for the direct cytotoxic killing of target cells (e.g. virus-infected cells); the requirement for direct cell-cell contact ensures the specificity of the response. Recognition of antigen, presented as a peptide fragment on MHC class I molecules, triggers the calcium-dependent release of lytic granules by the T cell. These lysosome-like granules contain perforin (cytolysin), which forms a pore in the target cell membrane. They also contain several different serine protease enzymes (granzymes), which enter the target cell via the perforin pore and induce the programmed cell death (apoptosis; p. 26) of the target.

## Helper $T$ cells

Helper T cells (which express CD4) are characterized by the secretion of cytokines. Two major populations have been identified according to the range of cytokines produced. Th1 helper T cells typically secrete interleukin (IL)-2, tumour necrosis factor alpha (TNF- $\alpha$ ) and interferon gamma (IFN- $\gamma$ ), while Th2 cells produce cytokines such as IL-4, IL-5 and IL-13. These two CD4-expressing populations are termed 'helper' T cells because one aspect of their function is to stimulate the proliferation and maturation of B lymphocytes and cytotoxic T lymphocytes
and enhancing the immune responses mediated by those cells. In addition to Th1 and Th2 cells, other subsets of helper T cells have been described. These include Th 17 cells (which secrete the cytokine IL-17), implicated in autoimmune diseases (Stockinger and Veldhoen 2007). Other subsets (Th9, Th22) have been described and it is likely that many more subsets will be characterized in the future (Jiang and Dong 2013).

Helper T cells are also important in directing the destruction of pathogens by recruiting accessory cells (e.g. macrophages, neutrophils, eosinophils) to the site of infection and by activating their effector functions. This process is tightly coordinated. For example, Th1 helper T cells secrete cytokines that not only attract and activate macrophages but also provide help for B cells and guide their immunoglobulin production to the subclasses that fix complement. Thus these antibodies opsonize the pathogen target, which can then be recognized, ingested and destroyed by the macrophage accessory cells that bear receptors for complement and the Fc region of IgG. These Th1 cells are sometimes referred to as delayed-type hypersensitivity T cells. In contrast, Th2 cells secrete cytokines that induce the development and activation of eosinophils, and also induce B cells to switch their immunoglobulins to non-complement-fixing classes (e.g. IgE). Pathogens such as parasitic worms can then be coated with IgE antibody and hence recognized and destroyed by the effector functions of the eosinophil accessory cells, which bear receptors for the Fc region of IgE.

If helper T-cell activities are non-functional, a state of immunodeficiency results. This means that potentially pathogenic organisms, which are normally kept in check by the immune system, may proliferate and cause overt pathology, e.g. in acquired immune deficiency syndrome (AIDS), where a virus (human immunodeficiency virus, HIV) specifically infects and kills (predominantly) helper T cells, though some antigen-presenting cells are also killed.

## Regulatory T cells

A third population of T cells, 'regulatory' T or 'Treg' cells, are important in controlling the immune response. These $\mathrm{CD} 4^{+}, \mathrm{CD} 25^{+}$cells have an immunomodulatory function and can dampen the effector functions of both cytotoxic and helper T cells. Regulatory T cells (natural Tregs) are produced in the thymus and are an important additional mechanism for maintaining self-tolerance (Safinia et al 2013). Treg function is antigen-specific and depends on direct cell-cell contact. Molecules secreted or induced by Treg cells, such as IL-10 or transforming growth factor beta (TGF- $\beta$ ), also play an important role in mediating Treg suppressive effects on the immune system. Similar induced regulatory T cells can be induced in the periphery and may be important in the induction of oral tolerance to ingested antigens, as well as tolerance to tissue-specific molecules that are not expressed in the thymus (Schmitt and Williams 2013).

## Natural killer (NK) cells

Natural killer (NK) cells have functional similarities to cytotoxic T cells but they lack other typical lymphocyte features and do not express antigen-specific receptors. They normally form only a small percentage of all lymphocyte-like cells and are usually included in the large granular lymphocyte category. When mature, NK cells have a mildly basophilic cytoplasm. Ultrastructurally, their cytoplasm contains ribosomes, rough endoplasmic reticulum and dense, membrane-bound vesicles 200-500 nm in diameter with crystalline cores. These contain the protein perforin, which is capable of inserting holes in the plasma membranes of target cells, and granzymes, which trigger subsequent target cell death by apoptosis. NK cells are activated to kill target cells by a number of factors. They can recognize and kill antibody-coated target cells via a mechanism termed antibody-dependent cell-mediated cytotoxicity (ADCC). They also have receptors that inhibit NK destructive activity when they recognize MHC class I on normal cells. When NK cells detect the loss or downregulation of MHC class I antigens on certain virus-infected cells and some tumour cells, they activate apoptosis-inducing mechanisms that enable them to attack these abnormal cells, albeit relatively non-specifically. For further reading, see Vivier et al (2008) and Chan et al (2014).

## PLATELETS

Blood platelets, also known as thrombocytes, are relatively small ( $2-4 \mu \mathrm{~m}$ across) irregular or oval discs present in large numbers (200,000-400,000/ $\mu \mathrm{l}$ ) in blood. In freshly harvested blood samples they readily adhere to each other and to all available surfaces, unless the blood is treated with citrate or other substances that reduce the availability of calcium ions. Platelets are anucleate cell fragments, derived from megakaryocytes in the bone marrow. They are surrounded
by a plasma membrane with a thick glycoprotein coat, which is responsible for their adhesive properties. A band of 10 microtubules lies around the perimeter of the platelet beneath the plasma membrane; the microtubules are associated with actin filaments, myosin and other proteins related to cell contraction. The cytoplasm also contains mitochondria, glycogen, scant smooth endoplasmic reticulum, tubular invaginations of the plasma membrane, and three major types of membrane-bound vesicle, designated $\alpha, \delta$ and $\lambda$ granules.

Alpha granules are the largest, and have diameters of up to 500 nm . They contain platelet-derived growth factor (PDGF), fibrinogen and other substances. Delta granules are smaller (up to 300 nm ) and contain 5-hydroxytryptamine (5-HT, serotonin) that has been endocytosed from the blood plasma. Lambda granules are the smallest (up to 250 nm ) and contain lysosomal enzymes.

Platelets play an important role in haemostasis. When a blood vessel is damaged, platelets become activated, evert their membrane invaginations to form lamellipodia and filopodia, and aggregate at the site of injury, plugging the wound. They adhere to each other (agglutination) and to other tissues. Adhesion is a function of the thick platelet coat and is promoted by the release of adenosine diphosphate (ADP) and calcium ions from the platelets in response to vessel injury. The contents of released $\alpha$ granules, together with factors released from the damaged tissues, initiate a complex sequence of chemical reactions in the blood plasma, which leads to the precipitation of insoluble fibrin filaments in a three-dimensional meshwork, the fibrin clot (see Fig. 4.1). More platelets attach to the clot, inserting extensions of their surfaces, filopodia, deep into the spaces between the fibrin filaments, to which they adhere strongly. The platelets then contract (clot retraction) by actinmyosin interactions within their cytoplasm, and this concentrates the fibrin clot and pulls the walls of the blood vessel together, which limits any further leakage of blood. After repair of the vessel wall, which may be promoted by the mitogenic activity of PDGF, the clot is dissolved by enzymes such as plasmin. Plasmin is formed by plasminogen activators in the plasma, probably assisted by lysosomal enzymes derived from the $\lambda$ granules of platelets. Platelets typically circulate for 10 days before they are removed, mainly by splenic macrophages.

## LYMPHOID TISSUES

Lymphocytes are located in many sites in the body, most obviously at strategic sites that are liable to infection, e.g. the oropharynx. The main areas of lymphocyte concentration are classified as primary or secondary lymphoid organs, according to whether they are involved in de novo lymphocyte generation (primary lymphoid organs, e.g. bone marrow, thymus) or are the site of mature lymphocyte activation and initiation of an immune response (secondary lymphoid organs, e.g. lymph nodes, spleen).

The secondary or peripheral lymphoid organs are the specialized sites where B and T lymphocytes and antigen-presenting cells come
together to initiate immune responses to foreign antigens (Malhotra et al 2013). These secondary tissues include lymph nodes, spleen, and lymphoid tissue associated with epithelial surfaces (mucosa-associated lymphoid tissue, MALT), e.g. the palatine and nasopharyngeal tonsils, Peyer's patches in the small intestine, lymphoid nodules in the respiratory and urogenital systems, the skin. The microstructure of lymph nodes and of MALT in general is described below. Details of all other lymphoid tissues and organs are included in the descriptions of the appropriate regional anatomy.

Lymphocytes enter secondary lymphoid tissues from the blood, usually by migration through the walls of capillaries or venules (high endothelial venules, HEVs (see Ch. 6)) and leave by the lymphatic system. In the spleen, lymphocyte entry and exit take place via the marginal zone and venous drainage respectively. Antigen-presenting cells (dendritic cells) enter via the lymphatics, bringing with them antigen from peripheral infected sites. In all the secondary tissues there are specific areas where either B or T cells are concentrated. After activation, functionally competent lymphocytes migrate to other sites in the body, where they combat the original infection. Organized lymphoid structures, termed tertiary lymphoid organs, can also develop at sites of chronic inflammation (Stranford and Ruddle 2012).

## LYMPH NODES

Lymph nodes are encapsulated centres of antigen presentation and lymphocyte activation, differentiation and proliferation, which are facilitated by complex trafficking of cells and lymphatic flow through the structure (Girard et al 2012). They generate mature, antigen-primed $B$ and $T$ cells, and filter particles, including microbes, from the lymph by the action of numerous phagocytic macrophages. A normal young adult body contains up to 450 lymph nodes, of which 60-70 are found in the head and neck, 100 in the thorax and as many as 250 in the abdomen and pelvis. Lymph nodes are particularly numerous in the neck, mediastinum, posterior abdominal wall, abdominal mesenteries, pelvis and proximal regions of the limbs (axillary and inguinal lymph nodes). By far the greatest number lie close to the viscera, especially in the mesenteries.

## Microstructure

Lymph nodes (Fig. 4.7) are small, oval or kidney-shaped bodies, $0.1-2.5 \mathrm{~cm}$ long, lying along the course of the lymphatic vessels. Each usually has a slight indentation on one side: the hilum, through which blood vessels enter and leave, and the efferent lymphatic vessel leaves. Several afferent lymphatic vessels enter the capsule around the periphery. Lymph nodes have a highly cellular cortex and a medulla (Fig. 4.8), which contains a network of minute lymphatic channels (sinuses) through which lymph from the afferent lymphatics is filtered, to be

Fig. 4.7 The structure of a lymph node.

All lymphocytes arise from pluripotent haemopoietic stem cells in me bone marrow. The B lymphocyte lineage develops through a series of differentiation stages within the bone marrow. The newly formed B cells then leave through the circulation and migrate to peripheral sites. In contrast, T-lymphocyte development requires the thymus; the bone marrow-derived stem cells must therefore migrate via the blood circulation to the thymus. After their differentiation and maturation into immunocompetent $T$ cells that have survived thymic selection processes ( $1-3 \%$ ), they re-enter the circulation and are transported to peripheral sites where they join the pool of naïve lymphocytes that recirculate through the secondary lymphoid organs via blood and lymphatic circulation systems.

Fig. 4.8 A lymph node (human) showing cortex (C) and medulla (M), and lymphoid follicles (F), some with germinal centres (G). Also shown are the subcapsular sinus (arrow) and medullary blood vessels ( V ). The dark line (top, centre) is a small crease in the tissue section and is an artefact. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
collected at the hilum by the efferent lymphatic. The cortex is absent at the hilum, where the medulla reaches the surface.

The capsule is composed mainly of collagen fibres, elastin fibres (especially in the deeper layers) and a few fibroblasts. Trabeculae of dense connective tissue extend radially into the interior of the node from the capsule. They are continuous with a network of fine type III collagen (reticulin) fibrils, which branch and interconnect to form a very dense network in the cortex, providing attachment for various cells, mostly dendritic cells, macrophages and lymphocytes. There are fewer fibres in the germinal centres of follicles (see below). Reticulin and the associated proteoglycan matrix are produced by fibroblasts associated with the fibrous network.

## Lymphatic and vascular supply

Lymph nodes are permeated by channels through which lymph percolates after its entry from the afferent vessels. The conduit system consists of collagen fibres and associated fibrils surrounded by fibroblast reticular cells, forming a sponge-like reticulum that provides not only spaces for the lymphocytes but also a system for the transport of antigen and signalling molecules (such as chemokines) that control the highly dynamic movement and interaction of the immune cells. Dendritic cells can reach inside the conduits to sample antigen, and then present it to immune cells (Roozendaal et al 2008).

Afferent lymphatic vessels enter at many points on the periphery, branch to form a dense intracapsular plexus, and then open into the subcapsular sinus, a cavity that is peripheral to the whole cortex except at the hilum (see Fig. 4.7). Numerous radial cortical sinuses lead from the subcapsular sinus to the medulla, where they coalesce as larger medullary sinuses. The latter become confluent at the hilum with the efferent vessel that drains the node. All of these spaces are lined by a continuous endothelium and traversed by fine reticular fibres.

Arteries and veins serving lymph nodes pass through the hilum, giving off straight branches that traverse the medulla and send out minor branches as they do so. In the cortex, arteries form dense arcades of arterioles and capillaries in numerous anastomosing loops, eventually returning to highly branched venules and veins. Capillaries are especially profuse around the follicles, which contain fewer vessels. Postcapillary HEVs are abundant in the paracortical zones. They form an important site of blood-borne lymphocyte extravasation into lymphoid tissue, apparently by migration through labile endothelial tight junctions (occluding junctions, zonulae adherentes). The density of the capillary beds increases greatly when lymphocytes multiply in response to antigenic stimulation. Veins leave a node through its principal trabeculae and capsule, and drain them and the surrounding connective tissue.

## Cells and cellular zones of lymph nodes

Although most of the cells in a lymph node are B and T lymphocytes,
their distribution is not homogeneous. In the cortex, cells are densely

Fig. 4.9 A germinal centre in a lymphoid follicle of the human palatine tonsil, immunolabelled to show CD38-positive $B$ cells in the germinal centre (red), IgD-positive naïve B cells (green) in the mantle zone and activated, transferrin receptor (CD71)-positive cells of various lineages (blue). (Courtesy of Dr Cécile Chalouni, Ludwig Institute for Cancer Research, Yale University School of Medicine, USA.)
packed and in the outer cortical area they form lymphoid follicles or nodules (see Fig. 4.8), which are populated mainly by B cells and specialized follicular dendritic cells (FDCs) (see Fig. 4.15). The number, degree of isolation and staining characteristics of follicles vary according to their state of antigenic stimulation. A primary follicle is uniformly populated by small, quiescent lymphocytes, whereas a secondary follicle has a germinal centre (Fig. 4.9), composed mainly of antigenstimulated B cells, which are larger, less deeply staining and more rapidly dividing than those at its periphery.

The role of the germinal centre is to provide a microenvironment that allows the affinity maturation of the B-cell response, so that as the immune response progresses, the affinity or strength with which antibodies bind their antigen increases (Shlomchik and Weisel 2012, Victora and Nussenzweig 2012). There are several zones in the germinal centre where this is allowed to happen. In the 'dark zone', the B cells (centroblasts) undergo rapid proliferation, which is associated with hypermutation of their antibody molecules. They then move into the 'light zone' (as centrocytes), where they can interact with the FDCs, which carry intact unprocessed antigen on their surface in the form of immune complexes (Rezk et al 2013). The centrocytes compete for binding to the antigen; those whose antibody has the highest affinity survive and the rest die. T cells are also present, helping the survival of the B cells and inducing class switching. Macrophages in the germinal centre phagocytose apoptotic lymphocytes (e.g. those B cells that die as part of the process of affinity maturation), and consequently macrophage cytoplasm becomes filled with engulfed lipid and nuclear debris forming sparkling intracellular inclusions (leading to the term tingible body macrophage).

The mantle zone (see Fig. 4.9) is produced as surrounding cells are marginalized by the rapidly growing germinal centre. It is populated by cells similar to those found in primary follicles: mainly quiescent B cells with condensed heterochromatic nuclei and little cytoplasm (hence the deeply basophilic staining of this region in routine preparations; Fig. 4.10), a few helper T cells, FDCs and macrophages. After numerous mitotic divisions the selected B cells give rise to small lymphocytes, some of which become memory B cells and leave the lymph node to join the recirculating pool, while others leave to mature as antibodysecreting plasma cells either in the lymph node medulla or in peripheral tissues.

The deep cortex or paracortex lies between the cortical follicles and the medulla, and is populated mainly by T cells, which are not organized into follicles. Both CD4 and CD8 T-cell subsets are present. The paracortex also contains interdigitating dendritic cells. These dendritic cells include Langerhans cells from the skin and other squamous epithelia, which have migrated as veiled cells via the afferent lymphatics into the draining lymph nodes (see Fig. 4.14). Their role is to present processed antigen to T cells. The region expands greatly in T celldominated immune responses, when its cells are stimulated to proliferate and disperse to peripheral sites.

In the medulla, lymphocytes are much less densely packed in irregular, branching medullary cords between which the reticulin network is easily seen. Other cells include macrophages, which are more numer-

Fig. 4.10 A germinal centre in a follicle of mucosa-associated lymphoid tissue (MALT) in the mucosa and submucosa of the appendix. The bases of tubular glands of the mucosal epithelium are seen in the upper field.
ous in the medulla than in the cortex, plasma cells and a few granulocytes.

## MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT)

Large amounts of unencapsulated lymphoid tissue exist in the walls of the gastrointestinal, respiratory, reproductive and urinary tracts, and in the skin; they are collectively termed mucosa-associated lymphoid tissue (MALT), most of which is found in the gut as gut-associated lymphoid tissue (GALT) (Koboziev et al 2010).

Throughout the body, MALT includes an extremely large population of lymphocytes, reflecting the size of the gastrointestinal tract. Lymphoid cells are located in the lamina propria and in the submucosa as discrete follicles or nodules. More scattered cells, derived from these follicles, are found throughout the lamina propria and in the base of the epithelium (see Figs 4.5, 4.10). MALT includes macroscopically visible lymphoid masses, notably the peripharyngeal lymphoid ring of tonsillar tissue (palatine, nasopharyngeal, tubal and lingual), and the Peyer's patches of the small intestine, all of which are described elsewhere. Most MALT consists of microscopic aggregates of lymphoid tissue, which lack a fibrous capsule. Lymphocyte populations are supported mechanically by a network of fine type III collagen (reticulin) fibres and associated fibroblasts, as they are in lymph nodes.

In common with lymph nodes, MALT provides centres for the activation and proliferation of $B$ and $T$ lymphocytes in its follicles and parafollicular zones, respectively. The function of cells in these zones, including antigen-presenting cells (follicular dendritic cells and interdigitating dendritic cells) and macrophages, as well as T and B cells, is similar to that found in lymph nodes. The close proximity of lymphocytes within MALT to an epithelial surface facilitates their access to pathogens. MALT lacks afferent lymphatic vessels. Lymphocytes migrate into MALT through its HEVs and leave mainly via its efferent lymphatics, which drain interstitial fluid as lymph; the lymphocyte population in MALT is not fixed. Migration from MALT follows a different route from the major peripheral route of recirculation. After antigen activation, lymphocytes travel via the regional lymph nodes to disperse widely along mucosal surfaces to provide protective T- and B-cell immunity.

## Follicle-associated epithelium

The epithelium covering MALT varies in type according to its location. It is unusual in possessing cells that are involved in sampling antigens and transferring them to antigen-presenting cells in the underlying tissues; appropriate clones of T and B cells in local lymphoid tissues are then activated and amplified prior to their exit via the lymphatics. Specialized epithelial cells in the small and large intestine have characteristic short microvilli on their luminal surfaces and are known as microfold (M) cells (Kraehenbuhl and Neutra 2000); in the palatine

Fig. 4.11 Haemopoietic tissue $(H)$ in the marrow cavity of a fetal long bone undergoing endochondral ossification (top). Islands of densely packed nucleated haemopoietic cells of different lineages are separated by large vascular sinusoids (S), which are filled with mature red blood cells in the general circulation.
tonsils they include modified stratified squamous reticulated epithelial cells (see p. 576). The main function of B lymphocytes in MALT is to produce IgA for secretion into the lumen of the tracts that they line (Cerutti et al 2011).

Many of the lymphocytes migrating between cells in the basal regions of epithelia (see Fig. 4.5) are effector cytotoxic and helper T cells that have already been selected in lymphoid nodules and are engaged in immune responses. Similar cells, and activated IgA-producing B cells and plasma cells, are also scattered throughout the entire mucosal lamina propria.

## HAEMOPOIESIS

Postnatally, blood cells are formed primarily in the bone marrow. Other tissues, particularly the spleen and liver, may develop haemopoietic activity once more, if production from the marrow is inadequate.

## BONE MARROW

Bone marrow is a soft pulpy tissue that is found in the marrow cavities of all bones (Fig. 4.11) and even in the larger Haversian canals of lamellar bone. It differs in composition in different bones and at different ages, and occurs in two forms: yellow and red marrow. In old age the marrow of the cranial bones undergoes degeneration and is then termed gelatinous marrow.

## Yellow marrow

Yellow marrow consists of a framework of connective tissue that supports numerous blood vessels and cells, most of which are adipocytes. A small population of typical red marrow cells persists and may be reactivated when the demand for blood cells becomes sufficiently great.

## Red marrow

Red marrow is found throughout the skeleton in the fetus and during the first years of life. After about the fifth year the red marrow, which represents actively haemopoietic tissue, is gradually replaced in the long bones by yellow marrow. The replacement starts earlier, and is generally more advanced, in the more distal bones. By 20-25 years of age, red marrow persists only in the vertebrae, sternum, ribs, clavicles, scapulae, pelvis and cranial bones, and in the proximal ends of the femur and humerus.

Red bone marrow consists of a network of loose connective tissue, the stroma, which supports clusters of haemopoietic cells (haemopoietic cords or islands) and a rich vascular supply in which large, thinwalled sinusoids are the main feature (see Fig. 4.11). The vascular supply is derived from the nutrient artery to the bone, which ramifies in the bone marrow, and terminates in thin-walled arterioles from which the sinusoids arise. These, in turn, drain into disproportionately large veins. Lymphatic vessels are absent from bone marrow. The stroma contains a variable amount of fat, depending on age, site and the haematological status of the body, and small patches of lymphoid tissue are also present. Marrow thus consists of vascular and extravascular compartments, both enclosed within a bony framework from which they are separated by a thin layer of endosteal cells.

## Stroma

Stroma is composed of a delicate network of fine type III collagen (reticulin) fibres secreted by highly branched, specialized fibroblast-like cells (reticular cells) derived from embryonic mesenchyme. When haemopoiesis stops, as occurs in most limb bones in adult life, these cells (or closely related cells) become distended with lipid droplets and fill the marrow with yellow fatty tissue (yellow marrow). If there is a later demand for haemopoiesis, the stellate stromal cells reappear. The stroma also contains numerous macrophages attached to extracellular matrix fibres. These cells actively phagocytose cellular debris created by haemopoietic development, especially the extruded nuclei of erythroblasts, remnants of megakaryocytes and cells that have failed the B-lymphocyte selection process. Stromal cells play a major role in the control of haemopoietic cell differentiation, proliferation and maturation.

Marrow sinusoids are lined by a single layer of endothelial cells, supported by reticulin on their basal surfaces. Although the endothelial cells are interconnected by tight junctions, their cytoplasm is extremely thin in places, and the underlying basal lamina is discontinuous. The passage of newly formed blood cells from the haemopoietic compartment into the blood stream appears to occur through an interactive process with the endothelium, producing temporary apertures (large fenestrae) in their attenuated cytoplasm.

## Haemopoietic tissue

Cords and islands of haematogenous cells consist of clusters of immature blood cells in various stages of development; several different cell lineages are typically represented in each focal group. One or more macrophages lie at the core of each such group of cells. These macrophages engage in phagocytic functions, are important in transferring iron to developing erythroblasts for haemoglobin synthesis, and may play a role, with other stromal cells, in regulating the rate of cell proliferation and maturation of the neighbouring haemopoietic cells.

## CELL LINEAGES

## Haemopoietic stem cells

Within the adult marrow there is a very small number ( $0.05 \%$ of haemopoietic cells) of self-renewing, pluripotent stem cells that are capable of giving rise to all blood cell types, including lymphocytes (Fig. 4.12). Although they cannot be identified morphologically in the marrow, they can be recognized in aspirates by the expression of specific cellsurface marker proteins (e.g. CD34). It is thought that haemopoietic stem cells occupy specific environmental niches in the marrow associated with the endosteum of trabecular bone or with sinusoidal endothelium, and that their microenvironment is important in homeostasis, the balance between self-renewal and differentiation. Stem cells can also be found (at lower concentrations) in the peripheral blood, particularly after treatment with appropriate cytokines.

Progressively more lineage-restricted committed progenitor cells develop from these ancestors (see Laiosa et al (2006) for a review) to produce the various cell types found in peripheral blood. The committed progenitor cells are often termed colony-forming units (CFU) of the lineage(s), e.g. CFU-GM cells give rise, after proliferation, to neutrophil granulocytes, monocytes and certain dendritic cells, whereas CFU-E produce only erythrocytes. Each cell type undergoes a period of maturation in the marrow, often accompanied by several structural changes, before release into the general circulation. In some lineages, e.g. the erythroid series, the final stages of maturation take place in the circulation, whereas in the monocytic lineage, they occur after the cells have left the circulation and entered peripheral tissues where they differentiate into macrophages and some dendritic cells.

To generate a complete set of blood cells from a single pluripotent cell may take some months. The later progenitor cells form mature cells of their particular lineages more quickly. However, because they are not self-renewing, grafts of these later cells eventually fail because the cells they produce all ultimately die. This is of considerable importance in bone marrow replacement therapy. The presence of pluripotent stem cells in the donor marrow is essential for success; only $5 \%$ of the normal number are needed to repopulate the marrow. Following replacement therapy, T lymphocytes reconstitute more slowly than the other haemopoietic lineages, reflecting the progressive reduction in size of the thymus with age (chronic involution).

Within the bone marrow there is also a population of mesenchymal stem cells that can differentiate into a wide variety of nonhaemopoietic cells. These pluripotent stem cells can also be found in the circulation, and are being investigated for their use in repairing damaged organs (see Commentary 1.2).

## Lymphocytes

Lymphocytes are a heterogeneous group of cells that may share a common ancestral lymphoid progenitor cell, distinct from the myeloid progenitor cell (see Fig. 4.12). The first identifiable progenitor cell is the lymphoblast, which divides several times to form prolymphocytes; both cells are characterized by a high nuclear:cytoplasmic ratio. B cells undergo differentiation to their specific lineage subset entirely within the bone marrow and migrate to peripheral or secondary lymphoid tissues as naïve B cells, ready to respond to antigen. However, T cells require the specialized thymic microenvironment for their development. During fetal and early postnatal life, and subsequently at lower levels throughout life, progenitor cells migrate to the thymus where they undergo a process of differentiation and selection as T cells, before leaving to populate secondary lymphoid tissues.

## B-cell development

B cells start their development in the subosteal region of the bone marrow and move centripetally as differentiation progresses. Their development entails the rearrangement of immunoglobulin genes to create a unique receptor for antigen on each $B$ cell, and the progressive expression of cell-surface and intracellular molecules required for mature B-lymphocyte function. Autoreactive cells that meet their selfantigen within the bone marrow are eliminated. Overall, some $25 \%$ of B cells successfully complete these developmental and selection processes; those that fail die by apoptosis and are removed by macrophages. Bone marrow stromal cells (fibroblasts, fat cells and macrophages) express cell-surface molecules and secreted cytokines that control B-lymphocyte development. The mature naïve B lymphocytes leave via the central sinuses. They express antigen receptors (immunoglobulin) of $\operatorname{IgM}$ and IgD classes. Class switching to $\operatorname{IgG}$, $\operatorname{IgA}$ and $\operatorname{IgE}$ occurs in the periphery following antigen activation in response to signals from T helper cells.

## T-cell (thymocyte) development

T cells develop within the thymus from blood-borne, bone marrowderived progenitors that enter the thymus via HEVs at the corticomedullary junction. They first migrate to the outer (subcapsular) region of the thymic cortex and then, as in the bone marrow, move progressively inwards towards the medulla as development continues. T-cell development involves gene rearrangements in the T-cell receptor (TcR) loci to create unique receptors for antigen on each cell, together with the progressive expression of molecules required for mature T-cell function. Selection of the receptor repertoire is more stringent for T cells than for $B$ cells because of the way in which mature $T$ cells recognize peptides derived from protein antigens presented in conjunction with specific molecules of the major histocompatibility complex (MHC) expressed on the surfaces of cells. Thus mature CD8 (cytotoxic) T cells recognize antigen in the form of short peptides complexed with the polymorphic MHC class I molecules, while CD4 (helper/regulatory) T cells recognize the peptides in the context of MHC class II molecules. As the TcR recognizes both the peptide and the MHC molecule, the T cell will only recognize peptides bound to their own (self) type of MHC; it will not 'see' peptides in combination with allelically different MHC molecules (i.e. those from other individuals). This is termed MHC restriction of T-cell recognition. Selection of T cells in the thymus must ensure the survival of those T cells that can respond only to foreign antigens, bound to their own (self) class of MHC molecule. Cells that are incapable of binding to self MHC molecules, or which bind to self-antigens, are eliminated by apoptotic cell death (see p. 26); it is estimated that up to $95 \%$ of T-cell progenitors undergo apoptosis in this way. Cells that express an appropriate TCR and have effective MHC-restricted

Fig. 4.12 The origins and lineage relationships of haemopoietically derived cells of the immune system. Mature cells and selected progenitors (all human) are illustrated (magnifications vary). The dendritic cell was cultured from peripheral blood, immunolabelled to show HLA-DR and photographed using Nomarski optics. The megakaryocyte and erythroblast are from a bone marrow smear, stained with May-Grünwald-Giemsa (MGG); the remaining cells illustrated are from peripheral blood smears (Wright's stain), sections of connective tissue (plasma cell, mast cell), bone (osteoclast) and lung alveolus (macrophage). Platelets (one is arrowed) are subcellular fragments of bone marrow megakaryocytes. Note that circulating small lymphocytes cannot be classified further with routine staining methods. For further explanation of cellular structure and staining properties, along with abbreviations, see the text. (Dendritic cell image courtesy of Dr Cécile Chalouni, Ludwig Institute for Cancer Research, Yale University School of Medicine, USA. All other images courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
binding properties survive to become mature, naïve T cells that leave the thymus and populate the periphery.

Thymic stromal cells play a crucial role in T-cell development and selection. Thymic epithelial cells in the cortex express both MHC class I and II molecules and are unique in their ability to select T cells that recognize self MHC with a moderate affinity (positive selection). Deletion of self-antigen reactive cells (negative selection) is mainly controlled by thymic dendritic cells located at the corticomedullary junction and in the medulla, although the epithelium can also perform this function. Apoptotic thymocytes are removed by thymic macrophages. The role of the thymic epithelium in thymocyte differentiation is complex and involves cell-cell contact as well as the secretion of soluble mediators such as cytokines, chemokines, neuroactive peptides (e.g. somatostatin) and thymic hormones (e.g. thymulin). Thymic fibroblasts and the extracellular matrix also play a role.

## Erythrocytes

Erythrocytes and granulocytes belong to the myeloid lineage. The earliest identifiable erythroid progenitor cells are capable of rapid bursts of cell division to form numerous daughter cells; they have thus been named burst-forming units of the erythroid line (BFU-E; see Fig. 4.12). They give rise to the CFU-E, which, with their immediate progeny, are sensitive to the hormone erythropoietin. This hormone, produced in the kidney, induces further differentiation along the erythroid line.

The first readily identifiable cell of the erythroid series is the proerythroblast, which is a large (about $20 \mu \mathrm{~m}$ ) cell with a large euchromatic nucleus and a moderately basophilic cytoplasm. It also responds to erythropoietin. The proerythroblast contains small amounts of ferritin and bears some of the protein spectrin on its plasma membrane. Proerythroblasts proliferate to produce smaller (12-16 $\mu \mathrm{m}$ ) basophilic erythroblasts, rich in ribosomes, in which haemoglobin-RNA synthesis begins. The cytoplasm becomes partially, and then uniformly, eosinophilic (the polychromatic erythroblast and orthochromatic erythroblast respectively). These cells are only $8-10 \mu \mathrm{~m}$ in diameter and contain very little cytoplasmic RNA. The nucleus becomes pyknotic (dense, deep-staining, shrunken) and is finally extruded from the cell, leaving an anucleate reticulocyte, which enters a sinusoid. Its reticular staining pattern, visible using special stains, results from residual cytoplasmic RNA, which is usually lost within 24 hours of entering the peripheral blood circulation. Reticulocyte numbers in peripheral blood are therefore a good indicator of the rate of red-cell production. The whole process of erythropoiesis takes 5-9 days.

## Granulocytes

Granulocyte formation involves major changes in nuclear morphology and cytoplasmic contents, which are best known for the neutrophil. Initially, myeloid progenitor cells transform into large ( $10-20 \mu \mathrm{~m}$ ) myeloblasts that are similar in general size and appearance to proerythroblasts. These proliferative cells have large euchromatic nuclei and lack cytoplasmic granules. They differentiate into slightly larger promyelocytes, in which the first group of specific proteins is synthesized in the rough endoplasmic reticulum and Golgi apparatus. The proteins are stored in large $(0.3 \mu \mathrm{~m})$ primary (non-specific) granules, which are large lysosomes containing acid phosphatase. Smaller secondary (specific) granules are formed in the smaller myelocyte, which is the last proliferative stage. The nucleus is typically flattened or slightly indented on one side in myelocytes.

In the next, metamyelocyte, stage, the cell size ( $10-15 \mu \mathrm{~m}$ ) decreases, the nucleus becomes heterochromatic and horseshoe-shaped, and protein synthesis almost stops. As the neutrophil is released, the nucleus becomes first heavily indented (the juvenile stab or band form), and subsequently segmented into up to six lobes, characteristic of the mature neutrophil. The whole process usually takes 7 days to complete ( 3 days proliferating and 4 days maturing). Neutrophils may then be stored in the marrow for a further 4 days, depending on demand, before their final release into the circulation.

Eosinophils and basophils pass through a similar sequence but their nuclei do not become as irregular as that of the neutrophil. It is thought that these cells each arise from distinct colony-forming units, which are separate from the CFU-GM.

## Monocytes

Monocytes are formed in the bone marrow. Monocytes and neutrophils appear to be closely related cells; together with some of the antigenpresenting dendritic cells, they arise from a shared progenitor, the
colony-forming unit for granulocytes and macrophages (CFU-GM). Different colony-stimulating factors (CSF) act on the common progenitor to direct its subsequent differentiation pathway. Monocyte progenitors pass through a proliferative monoblast stage $(14 \mu \mathrm{~m})$ and then form differentiating promonocytes, which are slightly smaller cells in which production of small lysosomes begins. After further divisions, monocytes (up to $20 \mu \mathrm{~m}$ ) are released into the general circulation. Most migrate into perivascular and extravascular sites, which they then populate as macrophages, while others may give rise to certain dendritic cells, including Langerhans cells.

## Platelets

Platelets arise in a unique manner by the shedding of thousands of cytoplasmic fragments from the tips of processes of megakaryocytes in the bone marrow. The first detectable cell of this line is the highly basophilic megakaryoblast ( $15-50 \mu \mathrm{~m}$ ), followed by a promegakaryocyte stage ( $20-80 \mu \mathrm{~m}$ ), in which synthesis of granules begins. Finally, the fully differentiated megakaryocyte, a giant cell ( $35-160 \mu \mathrm{~m}$ ) with a large, dense, polyploid, multilobed nucleus, appears. Once differentiation is initiated from the CFU-Meg, DNA replicates without cytoplasmic division (endoreduplication), and the chromosomes are retained within a single polyploid nucleus that may contain up to 256 n chromosomes (where n is the haploid complement present in gametes). Megakaryocyte lineage characteristics and disorders are reviewed in Sun et al (2006).

The cytoplasm contains fine basophilic granules and becomes partitioned into proplatelets by invaginations of the plasma membrane. These are seen ultrastructurally as a network of tubular profiles, which coalesce to form cytoplasmic islands $3-4 \mu \mathrm{~m}$ in diameter. Individual platelets are shed into the circulation from a long, narrow process of megakaryocyte cytoplasm that is protruded through an aperture in the sinusoidal endothelium.

## PHAGOCYTES AND ANTIGEN-PRESENTING CELLS

Macrophages and neutrophils (see above) are specialized phagocytes. Certain dendritic cells (see Fig. 4.12), e.g. Langerhans cells of the skin and other stratified squamous epithelia, are 'professional' antigenpresenting cells (APCs); they take up foreign material by endocytosis and macropinocytosis, and are uniquely capable of efficiently activating naïve as well as mature T lymphocytes. Macrophages are also able to process and present antigen to lymphocytes, but are less effective than dendritic cells. In addition, they play an important role in the effector arm of the immune response, clearing the infectious agent by phagocytosis. The third major cell type involved in antigen presentation and T-cell activation is the B lymphocyte, which is particularly efficient at taking up antigen that binds to its surface immunoglobulin (see above). Follicular dendritic cells of lymph nodes, MALT and the spleen are capable of presenting non-processed antigen to B lymphocytes, but are not classic APCs because they cannot present antigen to helper T cells.

APCs endocytose antigen, digest it intracellularly, mostly to peptide fragments, and present the fragments on their surfaces, generally in conjunction with MHC class II molecules. (Class II molecules are normally found only on APCs, although many other cells can express class II molecules in inflammatory situations.) Recognition of foreign antigen is controlled by a variety of APC cell-surface receptors: Fc and complement receptors mediate uptake of opsonized material, while pattern recognition receptors of the innate immune system, e.g. Toll-like receptors and scavenger receptors, directly recognize pathogen-derived molecules.

## MACROPHAGES

The mononuclear phagocyte system consists of the blood monocytes, from which the other types are derived, and various tissue macrophages, some of which have tissue-specific names. Certain dendritic cells are sometimes included in the mononuclear phagocyte system; although they share a common lineage ancestor, they appear to form a discrete branch of the family tree. Most monocytes and macrophages express class II MHC molecules.

Macrophages are very variable in size (generally $15-25 \mu \mathrm{~m}$ ) and are found in many tissues of the body, where they constitute a heterogeneous family of cells (reviewed in Gordon and Taylor (2005)). They are migrant cells in all general connective tissues, in bone marrow and all lymphoid tissues, and include alveolar macrophages in the lung and Kupffer cells in liver sinusoids. Macrophages often aggregate in
subserous connective tissue of the pleura and peritoneum, where they are visible as milky spots near small lymphatic trunks. They cluster around the terminations of small (penicillar) arterioles in the spleen and are distributed, more diffusely, throughout the splenic cords.

Osteoclasts in bone are closely related to macrophages; they are syncytial cells derived from the fusion of up to 30 progenitor monocytes in bone tissue, where they differentiate further. Microglia of the central nervous system originate from an embryonic monocyte precursor and migrate into the central nervous system during its development. They differ from macrophages in that normally they are quiescent cells in which MHC class II expression is downregulated, and they display little phagocytic activity.

Macrophages vary in structure depending on their location in the body. All have a moderately basophilic cytoplasm containing some rough and smooth endoplasmic reticulum, an active Golgi complex and a large, euchromatic and somewhat irregular nucleus. These features are consistent with an active metabolism: synthesis of lysosomal enzymes continues in mature cells. All macrophages have irregular surfaces with protruding filopodia and they contain varying numbers of endocytic vesicles, larger vacuoles and lysosomes. Some macrophages are highly motile, whereas others tend to remain attached and sedentary, e.g. in hepatic and lymphoid sinuses. Within connective tissues, macrophages may fuse to form large syncytia (giant cells) around particles that are too large to be phagocytosed, or when stimulated by the presence of infectious organisms, e.g. Mycobacterium tuberculosis.

When blood-borne monocytes enter the tissues through the endothelial walls of capillaries and venules, they can undergo a limited number of rounds of mitosis as tissue macrophages before they die and are replaced from the bone marrow, typically after several weeks. There is some evidence that alveolar macrophages of the lung are able to undergo many more mitoses than other macrophages.

## Phagocytosis

The uptake of particulate material and microorganisms is carried out by macrophages in many tissues and organs. When present in general connective tissue, they ingest and kill invading microorganisms and remove debris that has been produced as a consequence of tissue damage. They recognize, engulf and rapidly ingest apoptotic cells in all situations; the mechanism of apoptotic cell uptake does not activate the phagocyte for antigen presentation, and so the process is immunologically silent. In the lung, alveolar macrophages constantly patrol the respiratory surfaces, to which they migrate from pulmonary connective tissue (Fig. 4.13). They engulf inhaled particles, including bacteria, surfactant and debris, and many enter the sputum (hence their alternative names, dust cells or, in cardiac disease, heart failure cells, which are full of extravasated erythrocytes). They perform similar scavenger functions in the pleural and peritoneal cavities. In lymph nodes, macrophages line the walls of sinuses and remove particulate matter from lymph as it percolates through them. In the spleen and liver, macrophages are involved in particle removal and in the detection and destruction of aged or damaged erythrocytes. They begin the degradation of haemoglobin for recycling iron and amino acids.

Macrophages bear surface receptors for the Fc portions of antibodies and for the fragments of the C3 component of complement. Phagocytic

Fig. 4.13 Alveolar macrophages (dust cells, arrows) containing ingested carbon particles, in alveoli and interalveolar septa of the human lung. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
activity is greatly increased when the target has been coated in antibody (opsonized) or complement, or both. Once phagocytosis has occurred, the vacuole bearing the ingested particle fuses with endosomal vesicles, which contain a wide range of lysosomal enzymes, including many hydrolases, and oxidative systems capable of rapid bacteriocidal action. These activities are much enhanced when macrophages are stimulated (activated macrophages) by cytokines, e.g. IFN $-\gamma$, which are secreted by other cells of the immune system, especially T lymphocytes.

Close antibody-mediated binding may initiate the release of lysosomal enzymes on to the surfaces of the cellular targets to which the macrophages bind. This process of cytotoxicity is also used by other cells, including neutrophils and eosinophils, particularly if the targets are too large to be phagocytosed (e.g. nematode worm parasites).

## Secretory activities

Activated macrophages can synthesize and secrete various bioactive substances, e.g. IL-1, which stimulate the proliferation and maturation of other lymphocytes, greatly amplifying the reaction of the immune system to foreign antigens. They also synthesize TNF- $\alpha$, which is able to kill small numbers of neoplastic cells. TNF- $\alpha$ depresses the anabolic activities of many cells in the body, and may be a major factor mediating cachexia (wasting), which typically accompanies more advanced cancers. Other macrophage products include plasminogen activator, which promotes clot removal; various lysosomal enzymes; several complement and clotting factors; and lysozyme (an antibacterial protein). In pathogenesis, these substances may be released inappropriately and damage healthy tissues, e.g. in rheumatoid arthritis and various other inflammatory conditions.

## DENDRITIC CELLS

There are two distinct groups of dendritic cell: myeloid dendritic cells (also known as classic dendritic cells) and plasmacytoid dendritic cells (Liu 2001, Merad et al 2013, Gerlach et al 2013). These cells can arise from both common lymphoid progenitors and common myeloid progenitors. Both groups of cells are involved in antigen presentation, though have somewhat different functional roles in controlling both the adaptive and innate immune systems. The myeloid dendritic cells are professional APCs, which are able to process and present antigen to T lymphocytes, including naïve T cells. They are present as immature dendritic cells in the epidermis of the skin (Fig. 4.14) and other

Fig. 4.14 Dendritic cells in the skin and lymphoid tissues. Their migratory routes are shown: from blood-borne, marrow-derived precursors to immature dendritic cells (Langerhans cells) in skin, and then to migrating veiled cells in afferent lymphatic vessels and interdigitating dendritic cells in lymph nodes. An example of each cell in the sequence (arrowed) is shown in red.
stratified squamous epithelia, e.g. the oral mucosa (Langerhans cells), and in the dermis and most other tissues (interstitial dendritic cells), where they are concerned with immune surveillance. Immature dendritic cells have an antigen-capturing function. They respond to chemotactic signals, e.g. defensins released by epithelial cells in the small intestine, and they express pattern recognition receptors (e.g. Toll-like receptors) on their surface. Binding of pathogen-associated molecular pattern molecules (PAMPs) derived from bacteria (e.g. carbohydrate, lipopolysaccharide or DNA) to these receptors stimulates the dendritic cells to become activated and migrate via the lymphatics to nearby secondary lymphoid tissues, where they can present antigen to T cells. They can also be activated by recognition of damage-associated pattern molecules (DAMPs), such as ATP, DNA, heat-shock proteins and highmobility group box 1 (HMGB1) released from injured or necrotic cells. Mature dendritic cells are known as veiled cells when in the afferent lymphatics and the subcapsular sinuses of lymph nodes, and as interdigitating dendritic cells once they are within the lymphoid tissue proper. Their function within the secondary lymphoid tissue is to present their processed antigen to T lymphocytes, and thus to initiate and stimulate the immune response. For a review of research on dendritic cell function, see Colonna et al (2006).

## Langerhans cells

Langerhans cells (see Fig. 4.14) are one of the best-studied types of immature dendritic cell (reviewed in Berger et al (2006), Chopin and Nutt (2014)). They are present throughout the epidermis of skin, where they were first described, but are most clearly identifiable in the stratum spinosum. They have an irregular nucleus and a clear cytoplasm, and contain characteristic elongated membranous vesicles (Birbeck granules). Langerhans cells endocytose and process antigens, undergoing a process of maturation from antigen-capturing to antigen-presenting cells that express high levels of MHC class I and II molecules, co-stimulatory molecules and adhesion molecules. They migrate to lymph nodes to activate T lymphocytes.

## Interdigitating dendritic cells

Immature dendritic cells are found all over the body, including peripheral blood, and function in antigen-processing and immune surveillance. Mature dendritic cells are present in T-cell-rich areas of secondary lymphoid tissue (paracortical areas of lymph nodes, interfollicular areas of MALT, peri-arteriolar sheaths of splenic white pulp), where they are frequently referred to as interdigitating dendritic cells. Within the secondary lymphoid tissues, they are involved in the presentation to T lymphocytes of antigens associated with either MHC class I (CD8 T cells) or MHC class II (CD4 T cells) molecules. Naïve T cells can only

Fig. 4.15 Follicular dendritic cells (brown) in a germinal centre of the human palatine tonsil (immunoperoxidase-labelled). (Courtesy of Marta Perry MD, UMDS, London.)
respond to antigen presented by dendritic cells. The T cells are stimulated not only by recognition of the antigen-MHC complex by the TcR, but also by interaction with co-stimulatory molecules expressed by the dendritic cells, and by cytokines secreted by the cells. These cytokines not only help activate the T cell but can also direct the nature of the T-cell response (e.g. Th1 or Th2). Appropriate T cells are thus activated to proliferate and are primed for carrying out their immunological functions. Once primed, T cells can then be stimulated by any APC, including macrophages and B cells.

## Follicular dendritic cells

Follicular dendritic cells (FDCs; Fig. 4.15) are a non-migratory population of cells found in the follicles of secondary lymphoid tissues, where they attract and interact with B cells. Unlike other dendritic cells, FDCs are not haemopoietic in origin but are probably derived from the stromal cells of lymphoid tissues. They are unable to endocytose and process antigen, and they lack MHC class II molecules. However, Fc receptors and complement receptors CD21 and CD35 on FDCs allow the cells to bind immune complexes to their surface for subsequent presentation, as unprocessed antigen, to germinal centre B cells. Interactions between B cells, CD4 helper T cells and FDCs in the germinal centres are important in the selection of high-affinity B cells and their maturation to either plasma cells or memory B lymphocytes (Liu 2001).

# Functional anatomy of the musculoskeletal system 

The musculoskeletal system consists of the specialized connective tissues of the articulated bony skeleton and the skeletal muscles that act across the articulations. All the specialized cells of the musculoskeletal system (bone, cartilage, muscle, tendon) are related members of the connective tissue family and are derived from mesenchymal stem cells.

## CARTILAGE

Cartilage is the fetal precursor tissue in the development of many bones. In the adult skeleton it persists at almost all joints between bones and in structures that must be deformable as well as strong, e.g. in the respiratory tract.

## MICROSTRUCTURE OF CARTILAGE

Cartilage is a pliant, load-bearing connective tissue, covered by a fibrous perichondrium except at its junctions with bones and over the articular surfaces of synovial joints. It has a capacity for rapid interstitial and appositional growth in young and growing tissues. Three types of cartilage (hyaline cartilage, white fibrocartilage and yellow elastic cartilage) can be distinguished on the basis of the composition and structure of their extracellular matrices, but many features of the cells and matrix are common to all three types, and these features will be considered first.

## Extracellular matrix

The matrix is mostly comprised of collagen and, in some cases, elastic fibres, embedded in a highly hydrated proteoglycan gel (Fig. 5.1). Large proteoglycan molecules have numerous side chains of glycosaminoglycans (GAGs), carbohydrates with remarkable water-binding properties. A preponderance of fixed negative charges on the surface of GAGs strongly attract polarized water molecules, causing wet cartilage to swell until restricted by tension in the collagen network, or by external loading. In this way, cartilage develops a compressive turgor that enables it to distribute loading evenly on to subchondral bone, rather like a water bed. Effectively, water is held in place by proteoglycans, which are themselves held in place by the collagen network. Other constituents of cartilage include dissolved salts, non-collagenous proteins, and glycoproteins.

Collagens are described on page 38. Most fibrous tissues contain collagen type I, which forms large fibres with a wavy 'crimped' structure; however, this type of collagen is only found in cartilage in the outer layers of the perichondrium and in white fibrocartilage. More typical of cartilage is collagen type II, which forms very thin fibrils dispersed between the proteoglycan molecules so that they do not clump together to form larger fibres. Collagen type II fibrils are often less than 50 nm in diameter and are too small to be seen by light microscopy. Transmission electron microscopy reveals that they have a characteristic cross-banding ( 65 nm periodicity) and are interwoven to create a threedimensional meshwork. The collagen network varies in different types of cartilage and with age. The length of collagen fibrils and fibres in cartilage is unknown, but even relatively short fibrils can reinforce the matrix by interacting physically and chemically with each other, and with other matrix constituents including proteoglycans (Hukins and Aspden 1985), reflecting the fact that the term collagen means 'glue maker'.

Collagen type II is found in the notochord, the nucleus pulposus of an intervertebral disc, the vitreous body of the eye, and the primary corneal stroma.

Cartilage proteoglycans are similar to those found in general, i.e. non-specialized, connective tissue. The most common GAG side chains in cartilage are chondroitin sulphate and keratan sulphate. The most
common proteoglycan molecule, aggrecan, forms huge molecular aggregates with other proteoglycans and with hyaluronan (see Fig. 5.1).

## Cartilage cells

The cells of cartilage are chondroblasts and chondrocytes. Chondroblasts are actively dividing cells, often flattened and irregular in shape, and are abundant in growing tissue where they synthesize the extracellular matrix (Fig. 5.2). Small projections arising from the cell membrane (Fig. 5.3) can form gap junctions with adjacent cells (Bruehlmann et al 2002), but these junctions may be lost when interstitial growth causes greater cell separation. As chondroblasts mature and lose the ability to divide, they develop into the larger but metabolically less active chondrocytes. These oval-shaped cells form sparse populations that maintain the extensive matrix of adult cartilage. The name 'chondrocyte' is commonly employed, as it is here, to denote all of the cartilage

Fig. 5.1 The fine structural organization of hyaline cartilage matrix. Large proteoglycan complexes and type II collagen fibres (cross-banded and of different diameters) are depicted. Proteoglycan complexes bind to the surface of these fibres via their monomeric side chains and link them together. The arrangement of glycosaminoglycans and core protein of the proteoglycan monomer is illustrated in the expansion.

Fig. 5.2 Sections through hyaline cartilage. A, A low-power view of human rib, showing perichondrium (P), young chondroblasts (Cb) embedded in pale-staining interterritorial matrix, and mature chondrocytes (Cc) embedded in the basophilic interterritorial matrix (centre and right). B, Higher magnification of hyaline cartilage in human bronchial wall, showing isogenous groups of chondrocytes (C). Note the more deeply stained basophilic zones (B) (rich in acidic proteoglycans) around the cell clusters, with older, paler-staining matrix (M) between clusters. (B, Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 5.3 An electron micrograph of chondroblasts in rabbit femoral condylar cartilage. The central cell has an active euchromatic nucleus with a prominent nucleolus, and its cytoplasm contains concentric cisternae of rough endoplasmic reticulum, scattered mitochondria, lysosomes and glycogen aggregates. The plasma membrane bears numerous short filopodia which project into the surrounding matrix. The latter shows a delicate feltwork of collagen fibrils within finely granular interfibrillary material. No pericellular lacuna is present; the matrix separates the central chondroblast from the cytoplasm of two adjacent chondroblasts (left, and crescentic profile). (Preparation courtesy of Susan Smith, Department of Anatomy, GKT School of Medicine, London.)
cells embedded in an extensive matrix. Chondrocytes are normally in close contact with their dense matrix (see Fig. 5.3); however, artefacts of tissue processing can sometimes give the illusion of an empty space or 'lacuna' surrounding each cell or group of cells in histological sections. One or more chondrocytes can form a chondron, which consists of the cells and their pericellular matrix (see Fig. 5.2B), surrounded by a protective basket of collagen (Roberts et al 1991, Youn et al 2006).

Chondrocytes synthesize and secrete all of the major components of the cartilage matrix, and their ultrastructure is typical of cells that are active in making and secreting proteins. The nucleus is round or oval, appears euchromatic and possesses one or more nucleoli. The cytoplasm is filled with rough endoplasmic reticulum, transport vesicles and Golgi complexes, and contains many mitochondria and frequent lysosomes, together with numerous glycogen granules, intermediate filaments (vimentin) and pigment granules. When these cells mature to the relatively inactive chondrocyte stage, the nucleus becomes heterochromatic, the nucleolus smaller, and the protein synthetic machinery much reduced; the cells may also accumulate large lipid droplets.

Collagen is synthesized within the rough endoplasmic reticulum in the same way as it is in fibroblasts. Polypeptide chains are assembled into triple helices, and some carbohydrate is added. After transport to the Golgi apparatus, where further glycosylation occurs, the resulting procollagen molecules are secreted into the extracellular space. Terminal registration peptides are cleaved from their ends, forming tropocollagen molecules, and the final assembly into collagen fibrils takes place. Core proteins of the proteoglycan complexes are also synthesized in the rough endoplasmic reticulum and addition of GAG chains begins; the process is completed in the Golgi complex. Hyaluronan, which lacks a protein core, is synthesized by enzymes on the surface of the chondrocyte; it is not modified post-synthetically, and is extruded directly into the matrix without passing through the endoplasmic reticulum.

Matrix turnover is much slower in cartilage than in more metabolically active tissues. Collagen turnover is particularly slow, leaving it vulnerable to the slow process of non-enzymatic glycation, which makes the tissue yellow, stiff and vulnerable to injury (DeGroot et al 2004). Proteoglycans are turned over faster than collagen, with an estimated turnover time of 5 years for adult humans.

Cartilage is often described as avascular. Certainly, the ability of the matrix to deform under load makes it difficult for hollow blood vessels to persist in the tissue beyond early childhood, but a limited vascular supply is often found on the cartilage surface, from where it can revascularize the tissue following injury or degeneration. Metabolite transport to cartilage cells is mostly by the process of diffusion down a concentration gradient from the cartilage surface, although fluid 'pumping' as a result of changing mechanical loading can contribute under certain circumstances. Metabolite transport severely limits cell density and metabolic rate in the adult, and this in turn restricts cartilage thickness to a few millimetres (Junger et al 2009). Cartilage cells situated further than this from a nutrient vessel do not survive, and their surrounding matrix typically becomes calcified. In the larger cartilages, and during the rapid growth of some fetal cartilages, vascular cartilage canals penetrate the tissue at intervals, providing an additional source of nutrients. In some cases these canals are temporary structures but others persist throughout life.

## Hyaline cartilage

Hyaline (glassy) cartilage has a homogeneous, opalescent appearance, sometimes appearing bluish. It is firm and smooth to the touch and shows considerable deformability. The size, shape and arrangement of cells vary at different sites and with age. Chondrocytes are flat near the surface perichondrium, and rounded or angular deeper in the tissue (see Fig. 5.2A). Groups of two or more cells frequently form a cell nest (isogenous cell group) surrounded by a basket of fine collagen fibrils (see Fig. 5.2B). Within such a chondron, daughter cells of a common chondroblast often meet at a straight line. The pericellular matrix closest to the cells is typically lacking in collagen fibrils, but rich in proteoglycans that can exhibit basophilic and metachromatic staining. More distant and older interterritorial matrix appears paler and is mostly collagen type II ( $75 \%$ of dry weight) and proteoglycans ( $22 \%$ ).

Fig. 5.4 Articular cartilage from the anterior region of the lateral femoral condyle of a young adult human female. Three-dimensional digital volumetric fluorescence imaging of serially sectioned, eosin-Y and acridine orange-stained tissue. Articular surface (top), articular cartilage and subchondral bone (below). Note the changes in size and spatial distribution of articular chondrocytes through the thickness of the cartilage. (Courtesy of Professor Robert L. Sah, Drs Won C. Bae, Kyle D. Jadin, Benjamin L. Wong, Kelvin W. Li and Mrs Barbara L. Schumacher, Department of Bioengineering and Whitaker Institute of Biomedical Engineering, University of California, San Diego.)

After adolescence, hyaline cartilage may become calcified as part of the normal process of bone development, or as an age-related, degenerative change. In costal cartilage, the matrix tends to fibrous striation, especially in old age when cellularity diminishes. The xiphoid process and the cartilages of the nose, larynx and trachea (excepting the elastic cartilaginous epiglottis and corniculate cartilages) resemble costal cartilage in microstructure. Hyaline cartilage is the prototypical form, but it varies more with age and location than either elastic or fibrocartilage. Its regenerative capacity following injury is poor.

Articular cartilage, which covers the articular surfaces of synovial joints, is a specialized hyaline cartilage that lacks a perichondrium (Fig. 5.4). The synovial membrane overlaps and then merges into its structure circumferentially (see Fig. 5.32). The thickness of articular cartilage varies from 1 to 7 mm (typically 2 mm ) in different joints, and decreases from middle to old age. Thickness does not increase in response to increased mechanical loading, at least in adults, although matrix composition and stiffness can adapt somewhat (Gahunia and Pritzker 2012). Central regions tend to be thickest on convex osseous surfaces, and thinnest on concave surfaces.

Articular cartilage provides an extremely smooth, firm yet deformable layer that increases the contact area between bones and thereby reduces contact stress (see Fig. 5.61). Microscopic undulations on the cartilage surface help to trap synovial fluid between the articulating bones (see Fig. 5.60) and enable fluid-film lubrication to reduce friction and wear. Articular cartilage is generally too thin and stiff to be a good shock absorber, although shock absorption may be significant where there are multiple cartilage-covered surfaces, as in the carpus and tarsus.

Adult articular cartilage shows a structural zonation defined by its network of fine collagen type II fibrils (Fig. 5.5). Embedded in the deep calcified zone, fibrils rise vertically through the radial zone towards the cartilage surface, where they appear to reorientate to run parallel to the surface in the tangential zone. These collagen arcades can be visualized using phase-contrast microscopy (Thambyah and Broom 2007) but it is likely that each arcade represents numerous discrete fibrils rather than a single fibre. Their three-dimensional orientation can be appreciated by repeatedly piercing the cartilage surface with a needle; this creates a series of permanent elongated splits in the surface, which can be stained by Indian ink. The resulting split line pattern (Meachim et al 1974) reveals the predominant directions of collagen bundles in the cartilage tangential zone, which may be related to internal lines of tension generated during joint movement.

Each zone of articular cartilage (see Fig. 5.5) has a distinct cell morphology and matrix composition. The tangential (or superficial) zone has relatively small, elongated cells orientated parallel to the surface.

Fig. 5.5 Articular cartilage is not homogenous: the various zones are different in terms of cell size and shape, and the orientation of the collagen fibril network.
(Properties of the articular surface are described below under 'Synovial joints', p. 97.) Deeper within the tangential zone, the collagen fibrils increase in diameter and density, and gradually merge with the transitional (or intermediate) zone. Here, the chondrocytes are large and rounded, and surrounded by collagen fibrils in a range of oblique orientations. Deeper still, in the radial zone, the cells are often disposed in vertical columns, interspersed with vertical collagen fibrils. The matrix in this zone contains collagen types IX and XI, as well as collagen II. An undulating band known as the tidemark indicates the start of the deepest zone, the zone of calcified cartilage, which has mechanical properties intermediate between cartilage and bone. This calcified zone is keyed into the subchondral bone by fine ridges and interdigitations, which serve to prevent shearing (gliding) movements between cartilage and bone. With age, articular cartilage thins by upward advancement of the tidemark, and gradual replacement of calcified cartilage by bone.

Cells of articular cartilage are capable of cell division, but mitosis is rarely observed in adult tissue and cartilage damage is not repaired. Superficial cells are lost progressively from normal young joint surfaces, to be replaced by cells from deeper layers. Age-related reductions in cell number and activity, and biochemical changes in the extracellular matrix, particularly affect the superficial zone of articular cartilage, increasing the risk of mechanical failure and of osteoarthritis (Lotz and Loeser 2012).

Articular cartilage derives nutrients by diffusion from vessels of the synovial membrane, synovial fluid and hypochondral vessels of an adjacent medullary cavity, some capillaries from which penetrate and occasionally traverse the calcified cartilage zone. The contributions from these sources are uncertain and may change with age. Small molecules freely traverse articular cartilage, with diffusion coefficients about half those in aqueous solution. Larger molecules have diffusion coefficients inversely related to their molecular size. The permeability of cartilage to large molecules is greatly affected by variations in its GAG (and hence water) content: a three-fold increase in GAGs increases the diffusion coefficient 100 -fold.

Cartilaginous growth plates (see below under 'Bone') are also composed of hyaline cartilage, and there are similarities between active growth plates and growing articular cartilage on the epiphyses of long bones. In both cases, chondrocytes undergo a sequence of cell divisions and hypertrophy (with cells forming into columns) followed by cell death, and ossification by invading osteoblasts.

## Fibrocartilage

Fibrocartilage is a dense, whitish tissue with a distinct fibrous texture. It forms the intervertebral discs of the spine and menisci of the knee, as well as smaller structures such as the glenoid and acetabular labra, and the lining of bony grooves for tendons. It forms a versatile and tough material that combines considerable tensile strength with the ability to resist high compressive forces and to distribute them evenly

Fig. 5.6 White fibrocartilage in a late human fetal intervertebral disc Chondroblasts lie between coarse collagen type I fibres (blue) derived from the anulus fibrosus. Mallory's triple stain.
on to underlying bone (Adams et al 2013). Histologically, fibrocartilage is intermediate between dense fibrous connective tissues such as tendon and ligaments, and hyaline cartilage. In some structures such as intervertebral discs, matrix composition and cell types vary from one location to another, reflecting varying mechanical properties.

Regions of fibrocartilage that are loaded predominantly in tension consist of large crimped fibres of collagen type I embedded in a hydrated proteoglycan gel. Cells are rounded in young tissue (Fig. 5.6), but become elongated and fibroblast-like with age. They may be linked by gap junctions (Bruehlmann et al 2002). Those regions that are loaded predominantly in compression appear more homogeneous, contain a high proportion of fine collagen type II fibrils in an abundant proteoglycan gel, and contain rounded, chondrocyte-like cells. Fibrocartilage could therefore be regarded as a mingling of two types of tissue rather than a separate type of cartilage. However, no other tissue combines high proportions of proteoglycans with collagen type I, suggesting that fibrocartilage should be regarded as a distinct class of connective tissue.

The articular surfaces of bones that ossify in mesenchymal membranes (e.g. squamous temporal, mandible and clavicle) are covered by white fibrocartilage. The deep layers, adjacent to hypochondral bone, resemble calcified regions of the radial zone of hyaline articular cartilage. The superficial zone contains dense parallel bundles of thick collagen fibres, interspersed with typical dense connective tissue fibroblasts and little ground substance. Fibre bundles in adjacent layers alternate in direction, as they do in the cornea. A transitional zone of irregular bundles of coarse collagen and active fibroblasts separates the superficial and deep layers. The fibroblasts are probably involved in elaboration of proteoglycans and collagen, and may also constitute a germinal zone for deeper cartilage. Fibre diameters and types may differ at different sites according to the functional load.

## Elastic cartilage

Elastic cartilage occurs in the external ear, corniculate cartilages, epiglottis and apices of the arytenoids. Like hyaline cartilage, it contains typical chondrocytes, either singly or in small groups, surrounded by a matrix rich in type II collagen fibrils. However, the more distant interterritorial matrix is pervaded by very fine yellow elastic fibres (Fig. 5.7) containing the protein elastin, which show no periodic banding structure under the electron microscope (as collagen fibrils do). A structure is termed 'elastic' if it returns to its original shape when loaded and then unloaded; elastic fibres (and cartilage) have the special property of being able to do this even after being subjected to deformations greater than $15 \%$, which would damage collagen fibres. This characteristic is termed elastic recoil. Most sites in which elastic cartilage occurs have vibrational functions, such as laryngeal sound-wave production, or the collection and transmission of sound waves in the ear. Elastic cartilage is resistant to degeneration, and its capacity for limited regeneration following traumatic injury can be appreciated from the distorted repair of a cauliflower ear, as seen in participants of some contact sports.

## DEVELOPMENT AND GROWTH OF CARTILAGE

Cartilage is usually formed in embryonic mesenchyme. Mesenchymal cells proliferate and become tightly packed; the shape of their conden-

Fig. 5.7 Elastic cartilage, stained to demonstrate elastin fibres (blueblack). Chondroblasts and larger chondrocytes are embedded in the matrix, which also contains collagen type II fibres.
sation foreshadows that of the future cartilage. They also become rounded, with prominent round or oval nuclei and a low cytoplasm: nucleus ratio. Each cell differentiates into a chondroblast as it secretes a basophilic halo of matrix, composed of a delicate network of fine type II collagen fibrils, type IX collagen and proteoglycan core protein. At some sites, continued secretion of matrix separates the cells, producing typical hyaline cartilage. Elsewhere, many cells become fibroblasts; collagen synthesis predominates and chondroblastic activity appears only in isolated groups or rows of cells that become surrounded by dense bundles of collagen fibres to form white fibrocartilage. In yet other sites, the matrix of early cellular cartilage is permeated first by anastomosing oxytalan fibres, and later by elastin fibres. In all cases, developing cartilage is surrounded by condensed mesenchyme, which differentiates into a bilaminar perichondrium. The cells of the outer layer become fibroblasts and secrete a dense collagenous matrix lined externally by vascular mesenchyme. The cells of the inner layer contain differentiated, but mainly resting, chondroblasts or prechondroblasts.

Cartilage grows by interstitial and appositional mechanisms. Interstitial growth is the result of continued mitosis of early chondroblasts throughout the tissue mass and is obvious only in young cartilage, where plasticity of the matrix permits continued expansion. When a chondroblast divides, its descendants temporarily occupy the same chondron. They are soon separated by a thin septum of secreted matrix, which thickens and further separates the daughter cells. Continuing division produces isogenous groups. Appositional growth is the result of continued proliferation of the cells that form the internal, chondrogenic layer of the perichondrium. Newly formed chondroblasts secrete matrix around themselves, creating superficial lacunae beneath the perichondrium. This continuing process adds additional surface, while the entrapped cells participate in interstitial growth. Apposition is thought to be most prevalent in mature cartilages, but interstitial growth must persist for long periods in growth-plate cartilage. Relatively little is known about the factors that determine the overall shape of cartilage structures.

## BONE

Bone is a strong and rigid connective tissue that has evolved to enable fast terrestrial locomotion. Its strength provides support and protection for the body, while its rigidity enables it to create precisely shaped articular surfaces that do not distort under load, and ensures that forceful muscle contractions result in rapid limb movements rather than bending of bones. Unlike cartilage, bone is a highly vascular tissue with a high cell density; high cellularity enables it to adapt to changing mechanical demands, and to regenerate following injury.

## MACROSCOPIC ANATOMY OF BONE

Macroscopically, living bone is white. Its texture is either dense like ivory (compact bone) or honeycombed by large cavities (trabecular, cancellous or spongy bone), where the bony element is reduced to a latticework of bars and plates known collectively as trabeculae (Figs $5.8-5.9$ ). Compact bone is usually limited to the outer shell or cortex of mature bones, where it is important in determining their strength

Fig. 5.8 A vertical section 2 cm below the anterosuperior border of the iliac crest (female, 42 years). The cancellous bone consists of intersecting curved plates and struts. Osteonal (Haversian) canals can just be seen in the two cortices $(\mathrm{C})$ at this magnification.

Fig. 5.9 Trabecular bone at different sites in the proximal part of the same human femur. All fields are shown at the same scale. A, Subcapital part of the neck. B, Greater trochanter. C, Rim of the articular surface of the head. Note the wide variation in thickness, orientation and spacing of the trabeculae. (Original photographs from Whitehouse WJ, Dyson ED 1974 Scanning electron microscope studies of trabecular bone in the proximal end of the human femur. J Anat 118: 417-414, by permission from Blackwell Publishing.)
and providing rigid articular surfaces. Cortical thickness and architecture vary between and within bones, and generally decrease with age in adults. Trabecular bone provides support to the cortex while minimizing weight. The presence of a large central medullary canal in long bones also helps to reduce their weight. Spaces within bones provide convenient and secure locations for the storage of haemopoietic tissues and fat. Bone forms a reservoir of metabolic calcium (99\% of body calcium is in the bony skeleton) and of phosphate, which is under hormonal and cytokine control.

The proportions of compact to cancellous bone vary between and within bones. Generally, a thick cortex is required to provide strength in bending, e.g. in the mid-diaphysis of a long bone (see Fig. 5.20). Trabecular bone provides strength in compression and so is abundant in the epiphyses of long bones, and in the vertebral bodies of the spine. In flat bones such as the ribs, the interior is uniformly cancellous, and compact bone forms the surface. Internal cavities are usually filled with marrow, either red haemopoietic or yellow adipose, according to age and site. However, in some bones of the skull, notably the mastoid process of the temporal bone and the paranasal sinuses of the frontal, maxilla, sphenoid and ethmoid bones, many of the internal cavities are filled with air, i.e. they are variably pneumatized.

Bones vary not only in their primary shape but also in lesser surface details (secondary markings), which appear mainly in postnatal life. Most bones display features such as elevations and depressions (fossae), smooth areas and rough ridges. Some articular surfaces are called fossae (e.g. the glenoid fossa); lengthy depressions are grooves or sulci (e.g. the humeral bicipital sulcus); a notch is an incisura; and an actual gap is a hiatus. A large projection is termed a process or, if elongated and slender or pointed, a spine. A curved process is a hamulus or cornu (e.g. the pterygoid hamuli of the sphenoid bone and the cornua of the hyoid). A rounded projection is a tuberosity or tubercle, and occasionally a trochanter. Long elevations are crests, or lines if they are less developed; crests are wider and present boundary edges or lips. An epicondyle is a projection close to a condyle and is usually a site where the common tendon of a superficial muscle group or the collateral ligament of the adjacent joint is attached. The terms protuberance, prominence, eminence and torus are less often applied to certain bony projections. The expanded proximal ends of many long bones are often termed the 'head' or caput (e.g. humerus, femur, radius). A hole in a bone is a foramen and becomes a canal when lengthy. Large holes may be called apertures or, if covered largely by connective tissue, fenestrae. Clefts in or between bones are fissures. A lamina is a thin plate; larger laminae may be called squamae (e.g. the temporal squama). Large areas on many bones are featureless and as smooth as articular surfaces, from which they differ by being pierced by visible vascular foramina.

Tendons are usually attached at roughened bone surfaces. Wherever any aggregation of collagen in a muscle reaches bone, surface irregularities correspond in form and extent to the pattern of tendinous fibres. Such markings are almost always elevated above the general surface, as if ossification advanced into the collagen bundles from periosteal bone. How such secondary markings are induced is uncertain but they may result from the continued incorporation of new collagen fibres into the bone, perhaps necessary for minor functional adjustment. There is evidence that their prominence may be related to the power of the muscles involved, and they increase with advancing years as if the pull of muscles and ligaments exercised a cumulative effect over a limited area. Surface markings delineate the shape of attached connective tissue structures, e.g. an obvious tendon, intramuscular tendon or septum, aponeurosis, or tendinous fibres mediating what is otherwise a direct muscular attachment. These markings may be facets, ridges, nodules, rough areas or complex mixtures; they afford accurate indications of the junctions of bone with muscles, tendons, ligaments or articular capsules.

Muscle fibres do not attach directly to periosteum or bone. Force transmission is through the connective tissue that encapsulates (epimysium) and pervades (perimysium and endomysium) all muscles. These two forms of attachment of muscles, which are at the extremes of a range of admixtures, differ in the density of collagen fibres between muscle and bone. Where collagen is visibly concentrated, markings appear on the bone surface. In contrast, the multitude of microscopic connective tissue ties of direct attachment that occur over a larger area do not visibly mark the bone, and so it appears smooth to unaided vision and touch.

Many bones articulate with their neighbours at synovial joints. Small articular surfaces are termed facets or foveae; larger, knuckle-shaped surfaces are condyles; a trochlea is grooved like a pulley. Articular surfaces are smooth and covered by articular cartilage, which means that they lack the vascular foramina typical of the surfaces of most other bones.

Fig. 5.10 A scanning electron micrograph of collagen fibres on the surface of human trabecular bone. Note the branching fibres (female, 2 months, sixth rib).

## MICROSTRUCTURE OF BONE

Bone contains a mineralized collagenous extracellular matrix surrounding a range of specialized cells including osteoblasts, osteocytes and osteoclasts. Periosteum, endosteum and marrow are closely associated tissues. All of these components will be described first individually, and then their overall organization will be considered.

## Bone organic matrix

Approximately $10-20 \%$ of bone mass is water. A significant proportion $(30-40 \%)$ of the remaining dry weight is made up of the organic component of the extracellular matrix. Approximately 30\% of this organic matrix is collagen; the remainder includes various non-collagenous proteins, glycoproteins and carbohydrates. The proportions of these components vary with age, location and metabolic status.

Most of the collagen in bone is an ordered branching network of type I fibres (Fig 5.10). Although type I collagen fibres are found in most connective tissues, their molecular structure in bone is atypical: internal cross-linking between component fibrils is stronger and chemically more inert, and transverse spacings between collagen molecules within each fibril are larger, allowing more space for the deposition of minerals. A small amount of type V collagen is also present, probably to help regulate fibrillogenesis. Collagen fibres contribute greatly to the cohesive mechanical strength of bone, and also to its toughness (which is reflected in the energy required to break a bone).

Collagen is synthesized in bone by osteoblasts. Newly secreted molecules of tropocollagen lose part of their non-helical terminal regions, thus allowing them to polymerize in the extracellular matrix to form fibrils, which then associate to form fibres. These structures are stabilized by various cross-links, which increase in number and strength as the tissue matures. In primary bone, collagen fibres form a complex interwoven meshwork that incorporates other organic molecules; this 'osteoid' material is then mineralized to form woven (non-lamellar) bone. In time, primary bone is almost entirely replaced by regular laminar arrays of nearly parallel collagen fibres, which form the basis of lamellar bone (Currey 2002). Partially mineralized collagen networks can be seen within osteoid on the outer and internal surfaces of bone, and in the endosteal linings of vascular canals. Collagen fibres from the periosteum are incorporated in cortical bone (extrinsic fibres) and anchor this fibrocellular layer at its surface. Terminal collagen fibres of tendons and ligaments are incorporated deep into the matrix of cortical bone. They may be interrupted by new osteons during cortical drift (modelling) and turnover (remodelling), and remain as islands of interstitial lamellae or even trabeculae.

Bone organic matrix includes small amounts of various macromolecules attached to collagen fibres and surrounding bone crystals. They are secreted by osteoblasts and young osteocytes, and include osteonectin, osteocalcin, the bone proteoglycans biglycan and decorin, the bone sialoproteins osteopontin and thrombospondin, many growth factors including transforming growth factor beta (TGF- $\beta$ ), proteases and protease inhibitors, often in a latent form. The functions of some of these molecules are described with osteoblasts (see below).

## Bone minerals

Approximately $60-70 \%$ of bone dry weight is made up of inorganic mineral salts in the form of microcrystalline hydroxyapatite $\left(\mathrm{Ca}_{10}\right.$ $\left.\left(\mathrm{PO}_{4}\right)_{6}(\mathrm{OH})_{2}\right)$. The microcrystals confer hardness and much of the rigidity of bone, and are the main reason why bone is easily seen on radiographs. (Bone must be $50 \%$ mineralized to be visible on radiographs produced with a standard X-ray unit.) Bone mineral also has an important carbonate content, and a lower $\mathrm{Ca} / \mathrm{P}$ ratio than pure hydroxyapatite, together with a small amount of calcium phosphate. Bone crystals are extremely small (which gives them a high surface:volume ratio). They take the form of thin plates or leaf-like structures; the largest are 150 nm long $\times 80 \mathrm{~nm}$ wide $\times 5 \mathrm{~nm}$ thick, although most are half that size. Up to two-thirds of the mineral content of bone is thought to be located within collagen fibrils, where the crystals are packed closely together, with their long axes nearly parallel to the fibrils; crystal formation is probably initiated in the gaps between individual collagen molecules. Narrow spaces between the crystals contain water and organic macromolecules. The mineral substances of bone are mostly acidsoluble. If they are removed, using calcium chelators such as citrates or ethylene diamine tetra-acetic acid (EDTA), the bone retains its shape but becomes highly flexible.

The major ions in bone mineral include calcium, phosphate, hydroxyl and carbonate. Less numerous ions are citrate, magnesium, sodium, potassium, fluoride, chloride, iron, zinc, copper, aluminium, lead, strontium, silicon and boron, many of which are present only in trace quantities. Fluoride ions can substitute for hydroxyl ions, and carbonate can substitute for either hydroxyl or phosphate groups. 'Group IIA cations', such as radium, strontium and lead, all readily substitute for calcium and are therefore known as bone-seeking cations. Since they can be either radioactive or chemically toxic, their presence in bone, where they may be close to haemopoietic bone marrow, may cause illness and characteristic appearances on X-rays.

Mineralization of newly synthesized osteoid is a gradual process that slows over time; it typically reaches $70-80 \%$ in 3 weeks. Immature woven bone mineralizes faster and so may be distinguished from adjacent lamellar bone by its higher degree of mineralization. In cortical bone, lamellae mostly take the form of cylindrical osteons (see Fig. 5.16). These structures mineralize from inside to out, so that the concentration of mineral is highest in the older, more peripheral, lamellae. Although new osteons are less mineralized than old ones, they may show one or more highly mineralized 'arrest lines' within their walls. Mineral distribution is most uniform in established, highly mineralized osteons. Overall, mineralization increases with age, even though bone mass decreases.

## Osteoblasts

Osteoblasts are derived from osteoprogenitor (stem) cells of mesenchymal origin present in bone marrow and other connective tissues. They proliferate and differentiate into osteoblasts prior to bone formation, stimulated by bone morphogenetic proteins (BMPs). A layer of osteoblasts covers the forming surfaces of growing or remodelling bone (Fig. 5.11). In relatively quiescent adult bone, they appear to be present mostly on endosteal rather than periosteal surfaces, but they also occur deep within compact bone wherever osteons are being remodelled. Osteoblasts are responsible for the synthesis, deposition and mineralization of the bone matrix, which they secrete. Once embedded in the matrix, they become osteocytes.

Osteoblasts are basophilic, roughly cuboidal mononuclear cells $15-30 \mu \mathrm{~m}$ across. They contain prominent bundles of actin, myosin and other cytoskeletal proteins associated with the maintenance of cell shape, attachment and motility. Their plasma membranes display many extensions, some of which contact neighbouring osteoblasts and embedded osteocytes at intercellular gap junctions. This arrangement facilitates coordination of the activities of groups of cells, e.g. in the formation of large domains of parallel collagen fibres.

Ultrastructurally, osteoblasts are typical protein-secreting cells. They synthesize and secrete collagens and a number of glycoproteins. Osteocalcin is required for bone mineralization, binds hydroxyapatite and calcium, and is used as a marker of new bone formation. Osteonectin is a phosphorylated glycoprotein that binds strongly to hydroxyapatite and collagen; it may play a role in initiating crystallization and may be a cell adhesion factor. RANKL is the cell surface ligand for RANK (receptor for activation of nuclear factor kappa B), an osteoclast progenitor receptor (see below). Osteoprotegerin is a soluble, high-affinity decoy ligand for RANKL, which restricts osteoclast differentiation. Biglycan and decorin are bone proteoglycans that attract water; decorin also

Fig. 5.11 Bone cells actively remodelling alveolar bone to accommodate a developing tooth. Large multicellular osteoclasts (white arrow) are actively resorbing bone on one surface, while a layer of osteoblasts (black arrow) is depositing osteoid on another. Osteoblasts that have become trapped in the matrix to form osteocytes are shown in the centre (white arrowhead). (Image courtesy of Prof. Tim Arnett, University College London.)
binds the growth factor TGF- $\beta$. The bone sialoproteins, osteopontin and thrombospondin, mediate osteoclast adhesion to bone surfaces by binding to osteoclast integrins. In addition, osteoblasts secrete latent proteases and growth factors including BMPs and TGF- $\beta$ (which is also secreted by osteoclasts and which may be a coupling factor for stimulating new bone formation at resorption sites).

Although extracellular fluid is generally supersaturated with respect to the basic calcium phosphates, mineralization does not occur in most tissues. In bone, osteoblasts secrete osteocalcin (binds calcium at levels sufficient to concentrate the ion locally) and contain membrane-bound vesicles full of alkaline phosphatase (cleaves phosphate ions from various molecules to elevate concentrations locally) and pyrophosphatase (degrades inhibitory pyrophosphate in the extracellular fluid). The vesicles bud off from the osteoblast surface into newly formed osteoid, where they initiate hydroxyapatite crystal formation. Some alkaline phosphatase reaches the blood circulation, where it can be detected in conditions of rapid bone formation or turnover.

Osteoblasts also play a key role in the hormonal regulation of bone resorption. They express receptors for parathyroid hormone (PTH), 1,25-dihydroxy vitamin $\mathrm{D}_{3}$ (calcitriol) and other promoters of bone resorption. When activated, osteoblasts promote osteoclast differentiation via PTH-activated expression of cell surface RANKL, which binds to RANK on immature osteoclasts, establishes cell-cell contact and triggers contact-dependent osteoclast differentiation. In the presence of PTH, osteoblasts also downregulate secretion of osteoprotegerin, a soluble decoy ligand with higher affinity for RANKL. In conditions favouring bone deposition, secreted osteoprotegerin blocks RANKL binding to RANK, restricting the number of mature osteoclasts.

Bone-lining cells are flattened epithelial-like cells that cover the free surfaces of adult bone not undergoing active deposition or resorption. Generally considered to be quiescent osteoblasts or osteoprogenitor cells, they line the periosteal surface and the vascular canals within osteons, and form the outer boundary of the marrow tissue on the endosteal surface of marrow cavities.

## Osteocytes

Osteocytes are the major cell type of mature bone and are distributed throughout its matrix, interconnected by numerous dendritic processes to form a complex cellular network (Fig. 5.12). They are derived from osteoblasts that have become enclosed within their rigid matrix (see Fig. 5.11) and so have lost the ability to divide or to secrete new matrix. (The rigidity of mineralized bone matrix prevents interstitial growth, so that new bone must always be deposited on pre-existing surfaces.) Osteocytes retain contact with each other and with cells at the surfaces of bone (osteoblasts and bone-lining cells) throughout their lifespan.

Mature, relatively inactive osteocytes have an ellipsoid cell body with their longest axis (approximately $25 \mu \mathrm{~m}$ ) parallel to the surrounding lamellae. The rather narrow rim of cytoplasm is faintly basophilic, contains relatively few organelles and surrounds an oval nucleus.

Fig. 5.12 Osteocyte lacunae shown at high magnification in a dry ground section of lamellar bone. The territories of three osteocytes are shown. Their branching dendrites contact those of neighbouring cells via the canaliculi seen here within the bone matrix. Several other osteocyte lacunae are present, out of the focal plane in this section, and tangential to the osteon axis.

Fig. 5.13 Human parietal bone (male neonate) showing primary osteonal bone (grey) and woven bone (white) containing many connecting osteocyte lacunae (black). Internal resorption of the bone has produced large, irregular dark spaces (trabecularization).

Osteocytes in woven bone are larger and more irregular in shape (Fig. 5.13). Numerous fine branching processes containing bundles of microfilaments and some smooth endoplasmic reticulum emerge from each cell body. At their distal tips, these processes form gap junctions with the processes of adjacent cells (osteocytes, osteoblasts and bonelining cells) so that they are in electrical and metabolic continuity.

Extracellular fluid fills the small, variable spaces between osteocyte cell bodies and their rigid lacunae, which may be lined by a variable $(0.2-2 \mu \mathrm{~m})$ layer of unmineralized organic matrix. The same fluid fills the narrow channels or canaliculi that surround the long processes of the osteocytes. Approximately $0.25-0.5 \mu \mathrm{~m}$ wide, the canaliculi provide a route for the diffusion of nutrients, gases and waste products between osteocytes and blood vessels. Canaliculi do not usually extend through and beyond the reversal line surrounding each osteon and so do not communicate with neighbouring systems.

In well-vascularized bone, osteocytes are long-lived cells that actively maintain the bone matrix. The average lifespan of an osteocyte varies with the metabolic activity of the bone and the likelihood that it will be remodelled, but is measured in years. Old osteocytes may retract their processes from the canaliculi; when they die, their lacunae and canaliculi may become plugged with cell debris and minerals, which hinders diffusion through the bone. Dead osteocytes occur commonly in interstitial bone (between osteons) and in central regions of trabecular bone that escape surface remodelling. They are particularly noticeable by the second and third decades. Bones that experience little turnover, e.g. the auditory ossicles, are most likely to contain aged osteocytes and have low osteocyte viability. Osteocyte death leads to matrix resorption by osteoclast activity. Osteocytes themselves are often mineralized.

## Osteoclasts

Osteoclasts are large (diameters of $40 \mu \mathrm{~m}$ or more) polymorphic cells containing up to 20 oval, closely packed nuclei (see Fig. 5.11). They lie

Fig. 5.14 A scanning electron micrograph of a neonatal rabbit osteoclast actively resorbing bone in vitro from the surface of sperm whale dentine. (Courtesy of Professor Alan Boyde, Queen Mary University of London, London, UK.)
in close contact with the bone surface in resorption bays (Howship's lacunae). Their cytoplasm contains numerous mitochondria and vacuoles, many of which are acid phosphatase-positive lysosomes. Rough endoplasmic reticulum is relatively sparse but the Golgi complex is extensive. The cytoplasm also contains numerous coated transport vesicles and microtubule arrays involved in vesicle transport between the Golgi stacks and the cell's ruffled border (the highly infolded region of plasma membrane of an active osteoclast at a site of bone resorption). A well-defined zone of actin filaments and associated proteins occurs beneath the ruffled border around the circumference of a resorption bay, in a region termed the sealing zone.

Functionally, osteoclasts are responsible for the local removal of bone during bone growth and remodelling (Fig. 5.14). They dissolve bone minerals by proton release to create an acidic local environment, and they remove organic matrix by secreting lysosomal (cathepsin K) and non-lysosomal (e.g. collagenase) enzymes. Osteoclasts are stimulated to resorb bone by signals from local cells (including osteoblasts, macrophages and lymphocytes) and by blood-borne factors such as PTH and 1,25-dihydroxy vitamin $\mathrm{D}_{3}$ (calcitriol). Calcitonin, produced by C cells of the thyroid follicle, reduces osteoclast activity.

Osteoclasts differentiate from myeloid stem cells via macrophage-colony-forming units. Differentiation is primarily regulated by two cytokines: macrophage-colony stimulating factor, secreted by osteoblasts, and RANKL, expressed by osteoblasts (see above). The mononuclear precursors fuse to form terminally differentiated multinuclear osteoclasts (Väänänen and Laitala-Leinonen 2008). Osteoclast differentiation inhibitors are potential therapeutic agents for bone lossassociated disorders, e.g. osteoporosis, rheumatoid arthritis, Paget's disease, periodontal disease and osteosarcoma.

## Woven and lamellar bone

The mechanical properties of bone depend not only on matrix composition, as described above, but also on the manner in which the matrix constituents are organized. Woven bone and lamellar bone represent two quite distinct types of organization.

In woven (or bundle) bone, the collagen fibres and bone crystals are irregularly arranged. The diameters of the fibres vary, so that fine and coarse fibres intermingle, producing the appearance of the warp and weft of a woven fabric. Woven bone is typical of young fetal bones, but is also seen in adults during excessively rapid bone remodelling and during fracture repair (Fig. 5.15). It is formed by highly active osteoblasts during development, and is stimulated in the adult by fracture, growth factors or prostaglandin $\mathrm{E}_{2}$.

Lamellar bone, which makes up almost all of an adult skeleton, is more organized and is produced more slowly. The precise arrangement of lamellae (bone layers) varies from site to site. In trabeculae and the outer (periosteal) and inner (endosteal) surfaces of cortical bone, a few lamellae form continuous circumferential layers that are more or less parallel to the bony surfaces. However, in more central regions of cortical bone, the lamellae are arranged in concentric cylinders around neurovascular channels called Haversian canals (Fig. 5.16). This interconnecting, three-dimensional, laminated construction increases the toughness of lamellar bone because the interfaces between lamellae are effective in stopping the growth of cracks; more energy is therefore

Fig. 5.15 An electron micrograph of woven bone from a failed fracture of human distal tibia. Two osteoblasts (O) lie on the free surface (top). Newly synthesized collagenous osteoid matrix $(\mathrm{M})$ is seen in the centre field, with a mineralization front (electron-dense area) below (arrows). (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
required to propagate cracks that are sufficiently extensive to fracture the bone.

Each lamella consists of a sheet of mineralized matrix containing collagen fibres of similar orientation locally, running in branching bundles $2-3 \mu \mathrm{~m}$ thick and often extending the full width of a lamella. The orientation of collagen fibres and crystals differs between $0^{\circ}$ and $90^{\circ}$ in adjacent lamellae, as may be demonstrated by polarized light microscopy (see Fig. 5.18). At the borders of lamellae, packing of collagen fibres into bundles is less perfect and intermediate and random orientations of collagen predominate.

## Cortical bone

The cylindrical structural units that comprise most cortical bone are termed Haversian systems or osteons (Fig. 5.17). Osteons usually lie parallel with each other (Fig. 5.18); in long bones, they lie parallel with the long axis of the bone. Adjacent osteons may encroach on one another because they are usually formed at different times, during successive periods of bone remodelling. Irregular gaps between osteons are filled with interstitial lamellae (see Fig. 5.17A), which are the fragmentary remains of older osteons and circumferential lamellae. Osteons may be spiral or they may branch, and some end blindly. They are round or ellipsoidal in cross-section. The main direction of collagen fibres within osteons varies: in the shaft of long bones, fibres are more longitudinal at sites that are subjected mainly to tension, and more oblique at sites subjected mostly to compression. Peripheral lamellae of osteons contain more transverse fibres.

It has been estimated that there are 21 million osteons in a typical adult skeleton. Their diameter varies from 100 to $400 \mu \mathrm{~m}$, and they usually contain 5-20 lamellae. Each osteon is permeated by the canaliculi of its resident osteocytes, which form pathways for the diffusion of metabolites between osteocytes and blood vessels. The maximum diameter of an osteon ensures that no osteocyte is more than $200 \mu \mathrm{~m}$ from a blood vessel, a distance that may be a limiting factor in their survival.

The central Haversian canals of osteons vary in size, with a mean diameter of $50 \mu \mathrm{~m}$; those near the marrow cavity are somewhat larger. Each canal contains one or two capillaries lined by fenestrated endothelium and surrounded by a basal lamina, which also encloses typical pericytes. They usually contain a few unmyelinated and occasional myelinated axons. The bony surfaces of osteonic canals are perforated by the openings of osteocyte canaliculi and are lined by collagen fibres.

Haversian canals communicate with each other and directly or indirectly with the marrow cavity via vascular (nutrient) channels called

Fig. 5.16 The main features of the microstructure of mature lamellar bone. Areas of compact and trabecular (cancellous) bone are included. Note the general construction of the osteons; distribution of the osteocyte lacunae; Haversian canals and their contents; resorption spaces; and different views of the structural basis of bone lamellation.

Volkmann's canals, which run obliquely or at right angles to the long axes of the osteons (see Fig. 5.18). The majority of these channels appear to branch and anastomose, but some join large vascular connections with vessels in the periosteum and the medullary cavity.

Osteons are distinguished from their neighbours by a cement line that contains little or no collagen, and is strongly basophilic because it has a high content of glycoproteins and proteoglycans. Cement lines are also known as reversal lines because they mark the limit of bone erosion prior to the formation of a new osteon. Canaliculi occasionally pass through cement lines, and so provide a route for exchange between interstitial bone lamellae and vascular channels within osteons. Basophilic resting lines can occur in the absence of erosion; they indicate where bony growth has been interrupted and then resumed.

## Trabecular bone

The organization of trabecular bone (also known as cancellous or spongy bone) is basically lamellar, as shown most clearly under polarized light (Fig. 5.19). Trabeculae take the form of branching bars and curved plates of varying width, length and thickness $(50-400 \mu \mathrm{~m})$ (see Fig. 5.9). They are covered in endosteal tissue because they are adjacent to marrow cavities. Thick trabeculae and regions close to compact bone may contain small osteons, but blood vessels do not otherwise lie within trabeculae; osteocytes therefore rely on canalicular diffusion from adjacent medullary vessels. In young bone, calcified cartilage may occur in the cores of trabeculae, but this is generally replaced by bone during subsequent remodelling.

## Periosteum, endosteum and bone marrow

The outer surface of bone is covered by a condensed collagenous layer, the periosteum. The inner surface is lined by a thinner, more cellular endosteum. Osteoprogenitor cells, osteoblasts, osteoclasts and other cells important in the turnover and homeostasis of bone tissue lie in these layers.

The periosteum is tethered to underlying bone by thick collagen fibres (Sharpey's fibres), which penetrate deep into the outer cortical
bone tissue. It is absent from articular surfaces, and from the points of insertion of tendons and ligaments (entheses) (see Fig. 5.51). The periosteum is highly active during fetal development, when it generates osteoblasts for the appositional growth of bone. These cells form a layer, 2-3 cells deep, between the fibrous periosteum and new woven bone matrix. Osteoprogenitor cells within the mature periosteum are indistinguishable morphologically from fibroblasts. Periosteum is important in the repair of fractures; where it is absent (e.g. within the joint capsule of the femoral neck) fractures are slow to heal.

Quiescent osteoblasts and osteoprogenitor cells act as the principal reservoir of new bone-forming cells for remodelling or repair on the endosteal surfaces of resting adult bone. Bone endosteum is likely to be important in calcium homeostasis because it provides a total surface area of approximately $7.5 \mathrm{~m}^{2}$. It is formed by flattened osteoblast precursor cells and reticular (type III collagen) fibres, and lines all the internal cavities of bone, including the Haversian canals. It overlies the endosteal circumferential lamellae and encloses the medullary cavity.

## NEUROVASCULAR SUPPLY OF BONE

## Vascular supply

The osseous circulation supplies bone tissue, marrow, perichondrium, epiphysial cartilages in young bones, and, in part, articular cartilages. The vascular supply of a long bone depends on several points of inflow that feed complex and regionally variable sinusoidal networks within the bone. The sinusoids drain to venous channels that leave through all surfaces that are not covered by articular cartilage. The flow of blood through cortical bone in the shafts of long bones is mainly centrifugal (Fig. 5.20).

One or two main diaphysial nutrient arteries enter the shaft obliquely through nutrient foramina, which lead into nutrient canals. Their sites of entry and angulation are almost constant and characteristically directed away from the dominant growing epiphysis. Nutrient arteries do not branch in their canals but divide into ascending and descending branches in the medullary cavity; these approach the

Fig. 5.17 A, Osteons in a dry ground transverse section of bone. Concentric lamellae surround the central Haversian canal of each complete osteon; they contain the dark lacunae of osteocytes and the canaliculi, which are occupied in life by their dendrites. These canaliculi interconnect with canaliculi of osteocytes in adjacent lamellae. Incomplete (interstitial) lamellae (e.g. centre field) are the remnants of osteons remodelled by osteoclast erosion. B, A high-power view of osteocytes within lamellae; a Haversian canal is seen on the right. (B, Photograph by Sarah-Jane Smith.)

Fig. 5.18 Osteons in a dry ground longitudinal section of bone. The central Haversian canals ( H ; tubular structures, mainly dark) show transverse nutrient canals (Volkmann's canals, V), which form bridges between adjacent osteons and their blood vessels.
epiphyses, dividing repeatedly into smaller helical branches close to the endosteal surface. The endosteal vessels are vulnerable during surgical operations, such as intramedullary nailing, which involve passing metal implants into the medullary canal. Near the epiphyses, diaphysial vessels are joined by terminal branches of numerous metaphysial and epiphysial arteries (see Fig. 5.20). The former are direct branches of neighbouring systemic vessels; the latter come from peri-articular vascular arcades formed on non-articular bone surfaces. Numerous vascular foramina penetrate bones near their ends, often at fairly specific sites; some are occupied by arteries but most contain thin-walled veins

Fig. 5.19 Trabecular bone in a bone marrow sample taken from the human posterior iliac crest. B, The same field viewed under polarized light, demonstrating lamellar, non-osteonic bone with lamellae orientated in different directions in different regions. Osteocytes are just visible, embedded in the solid matrix. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Within bone, the arteries are unusual in consisting of endothelium with only a thin layer of supportive connective tissue. The epiphysial and metaphysial arterial supply is richer than the diaphysial supply.

Medullary arteries in the shaft give off centripetal branches, which feed a hexagonal mesh of medullary sinusoids that drain into a wide, thin-walled central venous sinus. They also possess cortical branches, which pass through endosteal canals to feed fenestrated capillaries in Haversian systems. The central sinus drains into veins that retrace the paths of nutrient arteries, sometimes piercing the shaft elsewhere as independent emissary veins. Cortical capillaries follow the pattern of Haversian canals, and are mainly longitudinal with oblique connections via Volkmann's canals (see Fig. 5.18). At bone surfaces, cortical capillaries make capillary and venous connections with periosteal plexuses (see Fig. 5.20) formed by arteries from neighbouring muscles that contribute vascular arcades with longitudinal links to the fibrous periosteum. A capillary network permeates the deeper, osteogenic periosteum from this external plexus. At muscular attachments, periosteal and muscular plexuses are confluent and the cortical capillaries then drain into interfascicular venules.

In addition to the centrifugal supply of cortical bone, there is an appreciable centripetal arterial flow to outer cortical zones from periosteal vessels. The large nutrient arteries of epiphyses form many intraosseous anastomoses, their branches passing towards the articular surfaces within the trabecular spaces of the bone. Near the articular cartilages, these form serial anastomotic arcades (e.g. there are three or four in the femoral head), which give off end-arterial loops. The latter often pierce the thin hypochondral compact bone to enter, and sometimes traverse, the calcified zone of articular cartilage, before returning to the epiphysial venous sinusoids.

In immature long bones, the supply is similar but the epiphysis is a discrete vascular zone. Epiphysial and metaphysial arteries enter on both sides of the growth cartilage and rarely, if ever, anastomose.

Fig. 5.20 The main features of the blood supply of a long bone. Note the contrasting supplies of the diaphysis, metaphysis and epiphysis, and their connections with periosteal, endosteal, muscular and peri-articular vessels. The expansion shows part of the diaphysis in more detail. The marrow cavity contains a large central venous sinus, a dense network of medullary sinusoids, and longitudinal medullary arteries and their circumferential rami. Longitudinally oblique transcortical capillaries emerge through minute 'cornet-shaped' foramina to become confluent with the periosteal capillaries and venules. The obliquity of the cortical capillaries is emphasized for clarity. Not to scale.

Growth cartilages are probably supplied from both sources, and from an anastomotic collar in the adjoining periosteum. Occasionally, cartilage canals are incorporated into a growth plate. Metaphysial bone is nourished by terminal branches of metaphysial arteries and by primary nutrient arteries of the shaft, which form terminal blind-ended sprouts or sinusoidal loops in the zone of advancing ossification. Young periosteum is more vascular; its vessels communicate more freely with those of the shaft than their adult counterparts and give off more metaphysial branches.

Large, irregular bones such as the scapula and innominate not only receive a periosteal supply but are also often supplied by large nutrient arteries that penetrate directly into their cancellous bone, the two systems anastomosing freely. Short bones receive numerous fine vessels that supply their compact and cancellous bone and medullary cavities from the periosteum. Arteries enter vertebrae close to the base of their transverse processes (see Fig. 43.20). Each vertebral medullary cavity drains to two large basivertebral veins, which converge to a foramen on the posterior surface of the vertebral body (see Fig. 43.21). Flatter cranial bones are supplied by numerous periosteal or mucoperiosteal vessels. Large, thin-walled veins run tortuously in cancellous bone. Lymphatic vessels accompany periosteal plexuses but have not been convincingly demonstrated in bone.

## Innervation

Nerves are most numerous in the articular extremities of long bones, vertebrae and larger flat bones, and in periosteum. Fine myelinated and
unmyelinated axons accompany nutrient vessels into bone and marrow, and lie in the perivascular spaces of Haversian canals. Osteoblasts possess receptors for several neuropeptides found in these nerves, including neuropeptide Y , calcitonin gene-related peptide, vasoactive intestinal peptide and substance P , indicating that bone has a complex autonomic and sensory innervation.

## DEVELOPMENT AND GROWTH OF BONE

Some of the bones in the skull are laid down within a fibrocellular mesenchymal membrane, by a process known as intramembranous ossification. Most bones are formed by a process of endochondral ossification, in which preformed cartilage templates (models) define their initial shapes and positions, and the cartilage is replaced by bone in an ordered sequence.

## Intramembranous ossification

Intramembranous ossification is the direct formation of bone (membrane bone) within highly vascular sheets or 'membranes' of condensed primitive mesenchyme. At centres of ossification, mesenchymal stem cells differentiate into osteoprogenitor cells, which proliferate around the branches of a capillary network, forming incomplete layers of osteoblasts in contact with the primitive bone matrix. The cells are polarized, and secrete osteoid only from the surface that faces away from the blood vessels. The earliest crystals appear in association with

Fig. 5.21 A, A section of a human fetal hand showing cartilaginous models of the carpal bones and the primary ossification centres, which display varying stages of maturity, in the metacarpals and phalanges. Note that none of the carpal elements shows any evidence of ossification. B, A higherpower view of an early primary ossification centre. The cartilage cells in the shaft have hypertrophied and this region is surrounded by a delicate tube or collar of subperiosteal bone (red). (Photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)
extracellular matrix vesicles produced by the osteoblasts. Crystal formation subsequently extends into collagen fibrils in the surrounding matrix, producing an early labyrinth of woven bone, the primary spongiosa. As layers of calcifying matrix are added to the early trabeculae, osteoblasts become enclosed within primitive lacunae. These new osteocytes retain intercellular contact by means of their fine cytoplasmic processes (dendrites) and, as these elongate, matrix condenses around them to form canaliculi.

As matrix secretion and calcification proceed, trabeculae thicken and vascular spaces become narrower. Where bone remains trabecular, the process slows and the spaces between trabeculae become occupied by haemopoietic tissue. Where compact bone is forming, trabeculae continue to thicken and vascular spaces continue to narrow. Meanwhile, the collagen fibres of the matrix, secreted on the walls of the narrowing spaces between trabeculae, become organized as parallel, longitudinal or spiral bundles, and the cells they enclose occupy concentric sequential rows. These irregular, interconnected masses of compact bone each have a central canal and are called primary osteons (primary Haversian systems). They are later eroded, together with the intervening woven bone, and replaced by generations of mature (secondary) osteons.

While these changes are occurring, mesenchyme condenses on the outer surface to form a fibrovascular periosteum. Bone is laid down increasingly by new osteoblasts, which differentiate from osteoprogenitor cells in the deeper layers of the periosteum. Modelling of the growing bone is achieved by varying rates of resorption and deposition at different sites.

## Endochondral ossification

The hyaline cartilage model that forms during embryogenesis is a miniature template of the bone that will subsequently develop. It becomes surrounded by a condensed, vascular mesenchyme or perichondrium, which resembles the mesenchymal 'membrane' in which intramembranous ossification occurs. Its deeper layers contain osteoprogenitor cells.

The first appearance of a centre of primary ossification (Fig. 5.21) occurs when chondroblasts deep in the centre of the primitive shaft enlarge greatly, and their cytoplasm becomes vacuolated and accumulates glycogen. The intervening matrix is compressed into thin, often perforated, septa. The cells degenerate and may die, leaving enlarged and sometimes confluent lacunae (primary areolae) whose thin walls become calcified during the final stages (Fig. 5.22). Type $X$ collagen is produced in the hypertrophic zone of cartilage. Matrix vesicles originat-

Fig. 5.22 The sequence of cellular events in endochondral ossification. This low-magnification micrograph shows the primary ossification centre in a human fetal bone. See Figure 5.24 for further details. Abbreviations; G , growth zone; H , hypertrophic zone; O, ossification zone; R, remodelling zone.
ing from chondrocytes in the proliferation zone are most evident in the intercolumnar regions, where they appear to initiate crystal formation. At the same time, cells in the deep layer of perichondrium around the centre of the cartilage model differentiate into osteoblasts and form a peripheral layer of bone. Initially, this periosteal collar, formed by intramembranous ossification within the perichondrium, is a thinwalled tube that encloses and supports the central shaft (see Figs 5.215.22). As it increases in diameter, it also extends towards both ends of the shaft.

The periosteal collar, which overlies the calcified cartilaginous walls of degenerate chondrocyte lacunae, is invaded from the deep layers of the periosteum (formerly perichondrium) by osteogenic buds. These are blind-ended capillary sprouts that are accompanied by osteoprogenitor cells and osteoclasts. The latter excavate newly formed bone to reach adjacent calcified cartilage, where they continue to erode the walls of primary chondrocyte lacunae (Figs 5.23-5.24). This process leads to

Fig. 5.23 An Alcian-blue periodic acid-Schiff (PAS)-stained section of human fetal femur showing the hypertrophy and palisading of cartilage cells as the ossifying (mineralizing) front of an early primary centre of ossification is approached (below). Lacunae are enlarged, and matrix partitions are reduced in width and exhibit increased staining density following cartilage calcification. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 5.24 Endochondral ossification in human fetal bone. Spicules of cartilaginous remnants (pale blue) serve as surfaces for the deposition of osteoid (dark blue), shown in the upper half of the field. Mineralized, woven bone is stained red. Three large multinucleate osteoclasts (arrows) are seen centre right, further eroding cartilage and remodelling the developing bone. Blood sinusoids and haemopoietic tissue (below) fill the spaces between areas of ossification. Heidenhain's azan trichrome preparation.

their fusion into larger, irregular communicating spaces, secondary areolae, which fill with embryonic medullary tissue (vascular mesenchyme, osteoblasts and osteoclasts, haemopoietic and marrow stromal cells, etc.). Osteoblasts attach themselves to the delicate residual walls of calcified cartilage and lay down osteoid, which rapidly becomes confluent, forming a continuous lining of bone. Further layers of bone are added, enclosing young osteocytes in lacunae and narrowing the perivascular spaces. Bone deposition on the more central calcified cartilage ceases as the formation of subperiosteal bone continues.

Osteoclastic erosion of the early bone spicules then creates a primitive medullary cavity in which only a few trabeculae, composed of bone with central cores of calcified cartilage (see Fig. 5.23), remain to support the developing marrow tissues. These trabeculae soon become remodelled and replaced by more mature bone or by marrow. Meanwhile, new, adjacent, cartilaginous regions undergo similar changes. Since these are most advanced centrally, and the epiphyses remain cartilaginous, the intermediate zones exhibit a temporospatial sequence of changes when viewed in longitudinal section (Fig. 5.25). This region
of dynamic change from cartilage to bone persists until longitudinal growth of the bone ceases.

Expansion of the cartilaginous extremity (usually an epiphysis; see Fig 5.20) keeps pace with the growth of the rest of the bone by both appositional and interstitial growth. The growth zone expands in all dimensions. Lateral growth of a developing long bone is caused by occasional transverse mitosis in its chondrocytes, and by appositional growth as a result of matrix deposition by cells from the perichondrial collar or ring at this level. The future growth plate therefore expands in concert with the shaft and adjacent future epiphysis. A zone of relatively quiescent chondrocytes (the resting zone) lies on the side of the plate closest to the epiphysis. An actively mitotic zone of cells faces towards the shaft of the bone; the more frequent divisions in the long axis of the bone soon create numerous longitudinal columns (palisades) of disc-shaped chondrocytes, each in a flattened lacuna (see Fig. 5.25). Proliferation and column formation occur in this zone of cartilage growth (the proliferative zone), and its continued longitudinal interstitial expansion provides the basic mode of elongation of a bone.

The columns of cells show increasing maturity towards the centre of the shaft, as their chondrocytes increase in size and accumulate glycogen. In the hypertrophic zone, energy metabolism is depressed at the level of the mineralizing front (see Fig. 5.23). The lacunae are now separated by transverse and longitudinal walls, and the latter are impregnated with apatite crystals in what has become the zone of calcified cartilage (or ossification zone; see Fig. 5.22). The calcified partitions enter the zone of bone formation and are invaded by vascular mesenchyme containing osteoblasts, osteoclasts, etc. The partitions, especially the transverse ones, are then partly eroded while osteoid deposition, bone formation and osteocyte enclosure occur on the surfaces of the longitudinal walls. Lysis of calcified partitions is mediated by osteoclast action, aided by cells associated with the terminal buds of vascular sinusoids that occupy, and come into close contact with, each incomplete columnar trabecular framework.

Continuing cell division in the growth zone adds to the epiphysial ends of cell columns, and the bone grows in length as this sequence of changes proceeds away from the diaphysial centre. The bone also grows in diameter as further subperiosteal bone deposition occurs near the epiphyses, and its medullary cavity enlarges transversely and longitudinally. Internal erosion and remodelling of the newly formed bone tissue continues.

Growth continues in this way for many months or years in different bones, but eventually one or more secondary centres of ossification usually appear in the cartilaginous extremities. Initially, these epiphysial centres (or the ends of bones that lack epiphyses) do not display cell columns. Instead, isogenous cell groups hypertrophy, with matrix calcification, and are then invaded by osteogenic vascular mesenchyme, sometimes from cartilage canals. Bone is formed on calcified cartilage, as described above. As an epiphysis enlarges, its cartilaginous periphery (perichondrium) also forms a zone of proliferation in which cell columns are organized radially; hypertrophy, calcification, erosion and ossification occur at increasing depths from the surface. The early osseous epiphysis is thus surrounded by a superficial growth cartilage, and the growth plate adjacent to the metaphysis soon becomes the most active region.

As a bone reaches maturity, epiphysial and metaphysial ossification processes gradually encroach upon the growth plate from either side; when they meet, bony fusion of the epiphysis occurs and longitudinal growth of the bone ceases. The events that take place during fusion are broadly as follows. As growth ceases, the cartilaginous plate becomes quiescent and gradually thins; proliferation, palisading and hypertrophy of chondrocytes stop, and the cells form short, irregular, conical masses. Patchy calcification is accompanied by resorption of calcified cartilage and some of the adjacent metaphysial bone, forming resorption channels that are invaded by vascular mesenchyme.

Some endothelial sprouts pierce the thin plate of cartilage, and the metaphysial and epiphysial vessels unite. Ossification around these vessels spreads into the intervening zones and results in fusion of epiphysis and metaphysis. This bone is visible in radiographs as a radiodense epiphysial line (a term that is also used to describe the level of the perichondrial collar or ring around the growth cartilage of immature bones, or the surface junction between epiphysis and metaphysis in a mature bone). In smaller epiphyses, which unite earlier, there is usually one initial eccentric area of fusion, and thinning of the residual cartilaginous plate. The original sites of fusion are subsequently resorbed and replaced by new bone. Medullary tissue extends into the whole cartilaginous plate until union is complete and no epiphysial 'scar' persists. In larger epiphyses, which unite later, similar processes also involve multiple perforations in growth plates, and islands of epiphysial bone often persist as epiphysial scars. Calcified cartilage coated by bone forms the epiphysial scar, and is also found below articular cartilage. It has been called metaplastic bone, a term also applied to sites of attachments of tendons, ligaments and other dense connective tissues to bone.

The cartilaginous surfaces of epiphyses that form synovial joints remain unossified, but the typical sequence of cartilaginous zones persists in them throughout life. A similar developmental sequence occurs at synchondroses, except that the proliferative rates of chondrocytes and the replacement of cartilage by bone are similar, although not identical, on either side of the synchondrosis.

## Postnatal growth and maintenance of bone

Modelling, by which is meant changes in general shape, occurs in all growing bones. The process has been studied mainly in cranial and long bones with expanded extremities.

A bone such as the parietal thickens and expands, but decreases in curvature, during growth. Accretion continues at its edges by prolifera-
tion of osteoprogenitor cells at sutures; periosteal bone is mainly added externally and eroded internally, but not at uniform rates or at all times. The rate of formation increases with radial distance from the centre of ossification (in this case, the future parietal eminence). Bone formation may also occur endocranially as well as ectocranially, so changing the curvature of the bone. The relative positions of the original centres of ossification change in three dimensions as the skull bones thicken and grow at the sutures and as the vault of the skull expands to accommodate the growth of the brain. Development of the outer and inner cortical plates is accompanied by internal development of trabeculae and marrow spaces.

Long bones increase in length mainly by endochondral ossification at the epiphysial growth plates. Simultaneous increase in width occurs by subperiosteal deposition and endosteal erosion. Growth at different locations can occur at different rates, or even be replaced by resorption, resulting in a change in the shape of a bone. This explains how, for example, the tibia changes its cross-sectional shape from tubular to triangular. Similarly, the waisted contours of metaphyses are preserved by differential rates of periosteal erosion and endosteal deposition, as metaphysial bone becomes diaphysial in position. The junction between a field of resorption and one of deposition on the surface of a growing bone is called a surface reversal line. The relative position of such a line may remain stable over long periods of growth and shape change.

Lamellar bone forms and is remodelled at variable rates throughout adult life (see below).

Normal development and maintenance of bone requires adequate intake and absorption of calcium, phosphorus and vitamins A, C and D , and a balance between growth hormone (GH, somatotropin), thyroid hormones, oestrogens and androgens. Other biological influences include prostaglandins and glucocorticoids. Vigorous mechanical loading is important for the maintenance of adequate bone mass. Prolonged deficiency in any of these factors can lead to loss of bone tissue (osteopaenia); if bone loss is severe (osteoporosis), it can lead to fracture and deformity.

Vitamin D influences intestinal transport of calcium and phosphate, and therefore affects circulatory calcium levels. In adults, prolonged deficiency (with or without low intake) produces bones that contain regions of deformable, uncalcified osteoid (osteomalacia). During growth, vitamin D deficiency can lead to severe disturbance of growth cartilages and ossification, such as reductions of regular columnar organization in growth plates, and failure of cartilage calcification even though chondrocytes proliferate. Growth plates also become thicker and irregular, as exemplified in classic rickets or juvenile osteomalacia. In rickets, the uncalcified or poorly calcified cartilaginous trabeculae are only partially eroded; osteoblasts secrete layers of osteoid but these fail to ossify in the metaphysial region, and ultimately gravity deforms these softened bones.

Vitamin C is essential for the adequate synthesis of collagen and matrix proteoglycans in connective tissues. When vitamin C is deficient, growth plates become thin, ossification almost stops, and metaphysial trabeculae and cortical bone are reduced in thickness, causing fragility and delayed healing of fractures.

Vitamin A is necessary for normal growth and for a correct balance between deposition and removal of bone. Deficiency retards growth as a result of the failure of internal erosion and remodelling, particularly in the cranial base. Foramina are narrowed, sometimes causing pressure atrophy of the nerves that pass through them. The cranial cavity and spinal canal may fail to expand at the same rate as the developing central nervous system, impairing nervous function. Conversely, excess vitamin A stimulates vascular erosion of growth cartilages, which become thin or totally lost, and longitudinal growth ceases. Retinoic acid, a vitamin A derivative, is involved in pattern formation in limb buds and in the differentiation of osteoblasts.

Balanced endocrine functions are also essential to normal bone maturation, and disturbances in this balance may have profound effects. In addition to its role in calcium metabolism, excess parathyroid hormone (primary hyperparathyroidism) stimulates unchecked osteoclastic erosion of bone, particularly subperiosteally and later endosteally (osteitis fibrosa cystica). Growth hormone is required for normal interstitial proliferation in growth cartilages, ensuring normal increase in stature. Termination of normal growth is imperfectly understood, but may involve a fall in hormone production or in the sensitivity of chondroblasts to insulin-like growth factors regulated by GH. Reduction of GH production in the young leads to quiescence and thinning of growth plates and hence pituitary dwarfism. Conversely, continued hypersecretion in the immature leads to gigantism, and in the adult results in thickening of bones by subperiosteal deposition; the mandible, hands and feet are the most affected, a condition known as acromegaly.

While continued longitudinal growth of bones depends on adequate levels of GH , effective remodelling to achieve a mature shape also requires the action of thyroid hormones. Moreover, growth and skeletal maturity are closely related to endocrine activities of the ovaries, testes and suprarenal cortices. High oestrogen levels increase deposition of endosteal and trabecular bone; conversely, osteoporosis in postmenopausal women reflects reduced ovarian function. In men, fluctuations in the rate of growth, and the timing of skeletal maturation, depend on circulating levels of suprarenal and testicular androgens. In hypogonadism, growth-plate fusion is delayed and the limbs therefore elongate excessively; conversely, in hypergonadism, premature fusion of the epiphyses results in diminished stature.

## Bone remodelling

Stiff materials (including bone) are vulnerable to the accumulation of microdamage during repeated loading. In metals this can result in crack propagation and 'fatigue failure'. Bone reduces the risk of such failure by periodically renewing itself, one small region of tissue at a time. This process is referred to as 'remodelling' because the volume and orientation of newly replaced matrix are not necessarily the same as the old; instead, bone takes this opportunity to adapt its mass and architecture to prevailing mechanical demands. Remodelling affects the local balance between resorption and deposition of bone. Its primary purpose is to renew bone rather than increase its mass, and the process continues throughout life, replacing approximately $10 \%$ of bone each year in adults (Brandi 2009).

Internal remodelling continuously supplies young osteons with labile calcium reserves, and provides a malleable bony architecture that is responsive to changing patterns of stress. A bone-remodelling unit consists of an advancing cutting cone and a closing cone. Activated osteoclasts form a cutting cone that excavates a cylindrical tunnel of bone (resorption canal) and advances ahead of a central growing blood vessel at a rate of $50 \mu \mathrm{~m} /$ day. A cutting cone is typically 2 mm long and takes 1-3 months to form; a similar period is required to create the new (secondary) osteon by completing the closing cone (Fig. 5.26). Osteoblasts follow the osteoclasts, filling in the space created with new osteoid, starting at the peripheral surface or walls of the tunnel.

Fig. 5.26 Bone remodelling. Longitudinal and cross-sections of a time line illustrating the formation of an osteon. Osteoclasts cut a cylindrical channel through bone. Osteoblasts follow, laying down bone on the surface of the channel until matrix surrounds the central blood vessel of the newly formed osteon (closing cone of a new osteon).

Successive layers of bone are deposited on the surface of the previous layer as cohorts of osteoblasts become embedded (as osteocytes) in the matrix they secrete, until the most central lamella is close to the blood vessel at the axis of the cylinder. The 'closing cone' (see Fig. 5.26) may contain 4000 osteoblasts per $\mathrm{mm}^{2}$. In this way, the walls of resorption canals are lined with new lamellar matrix and the vascular channels are progressively narrowed. A hypermineralized basophilic cement (or growth-reversal) line marks the edge of a new osteon, indicating the border between the resorptive activity of the cutting cone and the bony matrix not remodelled by this activity. Remnants of the circumferential lamellae of old osteons form interstitial lamellae between newer osteons (see Fig. 5.17A).

The remodelling unit in cancellous bone, equivalent to the secondary osteon of compact bone, is the basic (or bony) structural unit; it has an average thickness of $40-70 \mu \mathrm{~m}$ and an average length of $100 \mu \mathrm{~m}$, but may be more extensive and irregular in shape. Separate structural units can sometimes be visualized in microradiographs because of differences in their age and extent of mineralization (Farlay et al 2005).

Adult bone shape and mass are partly determined by genetic inheritance (Sigurdsson et al 2008). However, the pattern and extent of remodelling are largely dictated by the mechanical loading applied to the bone. Bone resorption occurs when muscle or gravitational forces are reduced, as occurs in bed rest, or in zero gravity conditions in space (Shackelford et al 2004). Reduced activity in old age is another major cause of bone loss. The rate of remodelling decreases with age, which means that numbers of osteons and osteon fragments can be used to estimate the age of skeletal material at death. Conversely, increased sporting or occupational loading of the skeleton can cause bone hypertrophy, as exemplified by the $35 \%$ increase in cortical thickness in the racket arm of elite tennis players (Jones et al 1977). Bones appear to respond to the maximum deformation they experience (see Fig. 5.68), rather than to cumulative load. Bone subjected to constant pressure can actually resorb, a response that underpins much orthodontic treatment, because teeth can be made to migrate slowly through alveolar bone by the application of steady lateral or medial pressure.

## Growth of individual bones

Ossification centres appear over a long period during bone growth: many in embryonic life, some in prenatal life, and others well into the postnatal growing period. Ossification centres are initially microscopic but soon become macroscopic, which means that their growth can then be followed by radiological and other scanning techniques.

Some bones, including carpal, tarsal, lacrimal, nasal and zygomatic bones, inferior nasal conchae and auditory ossicles, ossify from a single centre, which may appear between the eighth intrauterine week and the tenth year: a wide interval for studying growth or estimating age. Most bones ossify from several centres, one of which appears in the centre of the future bone in late embryonic or early fetal life (seventh week to fourth month). Ossification progresses from the centres towards the ends, which are still cartilaginous at birth (Fig. 5.27). These terminal regions ossify from separate centres, which are sometimes multiple, and which appear between birth and the late teens; they are therefore secondary to the earlier primary centre from which much of the bone ossifies. This is the pattern in long bones, as well as in some shorter bones such as the metacarpals and metatarsals, and in the ribs and clavicles.

At birth, a bone such as the tibia is typically ossified throughout its diaphysis from a primary centre that appears in the seventh intrauterine week, whereas its cartilaginous epiphyses ossify from secondary centres. As the epiphyses enlarge, almost all the cartilage is replaced by bone, except for a specialized layer of articular (hyaline) cartilage that persists at the joint surface, and a thicker zone between the diaphysis and epiphysis. Persistence of this epiphysial growth plate, or growth cartilage, allows increase in bone length until the usual dimensions are reached, by which time the epiphysial plate has ossified. The bone has then reached maturity. Coalescence of the epiphysis and diaphysis is fusion, the amalgamation of separate osseous units into one.

Many long bones have epiphyses at both their proximal and their distal extremities. Metacarpals, metatarsals and phalanges have only one epiphysis. Typical ribs have epiphyses for the head and articular tubercle and one for the non-articular area. The costal cartilages represent the unossified hyaline cartilage of the developing rib and therefore do not display epiphyses. Epiphysial ossification is sometimes complex, e.g. the proximal end of the humerus is wholly cartilaginous at birth and subsequently develops three centres during childhood, which coalesce into a single mass before they fuse with the diaphysis. Only one of these centres forms an articular surface; the others form the greater

(B)

Fig. 5.27 A, A radiograph of a neonatal arm. Ossification from primary centres is well advanced in all of the limb bones except the carpals, which are still wholly cartilaginous. The gaps by which individual elements appear to be separated are filled by radiolucent hyaline cartilage, in which epiphysial or carpal ossification will subsequently occur. Note the flaring contours, narrow midshaft and relatively expanded metaphyses of the long bones, and the proportions of the limb segments - in particular, the relatively large hand - that are characteristic of this age. B, The bones and cartilages of a neonatal left arm. Compare the radiolucent areas in the radiograph ( $\mathbf{A}$ ) with the preserved cartilaginous epiphyses and carpal elements in this specimen. (B, Prepared by Michael C.E. Hutchinson; photographed by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)
and lesser tubercles, which give muscular attachments. Similar composite epiphyses occur at the distal end of the humerus and in the femur, ribs and vertebrae.

Many cranial bones ossify from multiple centres. The sphenoid, temporal and occipital bones are almost certainly composites of multiple elements in their evolutionary history. Some show evidence of fusion between membrane and cartilage bones that unite during growth.

If bone growth rate were uniform, ossification centres would appear in a strict descending order of bone size. However, disparate rates of ossification occur at different sites and do not appear to be related to bone size. The appearance of primary centres for bones of such different sizes as the phalanges and femora are separated by, at most, a week of embryonic life. Those for carpal and tarsal bones show some correlation between size and order of ossification, from largest (calcaneus in the fifth fetal month) to smallest (pisiform in the ninth to twelfth postnatal year). In individual bones, succession of centres is related to the volume of bone that each centre produces. The largest epiphyses, e.g. the adjacent ends of the femur and tibia, are the earliest to begin to ossify (immediately before or after birth) and are of forensic interest. At epiphysial plates, the rate of growth is initially equal at both ends of those bones that possess two epiphyses. However, experimental observations in other species have revealed that one epiphysis usually grows faster than the other after birth. Since the faster-growing end also usually fuses later with the diaphysis, its contribution to length is greater. Though faster rate has not been measured directly in human bones, later fusion has been documented radiologically. The more active end of a long limb bone is often termed the growing end but this is a misnomer.

The rate of increase in stature, which is rapid in infancy and again at puberty, demonstrates that rates of growth at epiphyses vary. The spurt at puberty, or slightly before, decreases as epiphyses fuse in postadolescent years.

Growth cartilages do not grow uniformly at all points, which presumably accounts for changes such as the alteration in angle between the humeral shaft and its neck. The junctions between epiphysis and diaphysis at growth plates are not uniformly flat on either surface. Osseous surfaces usually become reciprocally curved by differential growth, and the epiphysis forms a shallow cup over the convex end of the shaft, with cartilage intervening: an arrangement that may resist shearing forces at this relatively weak region. Reciprocity of bone surfaces is augmented by small nodules and ridges, as can be seen when the surfaces are stripped of cartilage. These adaptations emphasize the formation of many immature bones from several elements held together by epiphysial cartilages. Most human bones exhibit these complex
junctions, at which bone is bonded to bone through cartilage, throughout the active years of childhood and adolescence.

Forces at growth cartilages are largely compressive but with an element of shear. Interference with epiphysial growth may occur as a result of trauma but more frequently follows disease; the resulting changes in trabecular patterns of bone are visible radiographically as dense transverse lines of arrested growth (Harris's growth lines). Several such lines may appear in the limb bones of children afflicted by successive illnesses.

Variation in skeletal development occurs between individuals, sexes and possibly also races. The timing rather than the sequence of events varies, and females antedate males in all groups studied. Differences that are perhaps insignificant before birth may be as great as 2 years in adolescence.

## JOINTS

Joints are the regions of the skeleton where two or more bones meet and articulate. These junctions are supported by a variety of soft tissue structures, and their prime functions are either to facilitate growth or to allow movement between bones. The simplest classifications of joints relate to either the range of movement possible or the nature of the intervening soft tissues; there is no satisfactory single classification. Free movement occurs at synovial joints, whereas restricted movement occurs at synarthroses, which can be subdivided into fibrous and cartilaginous joints. The general characteristics of each type of joint will be considered next. Features that are specific to individual joints are discussed in the relevant topographical chapters.

## FIBROUS JOINTS

Bones in fibrous joints are joined by fibrous connective tissue that allows little movement. Three definable subtypes are sutures, gomphoses and syndesmoses (Fig. 5.28).

## Suture

Sutures are restricted to the skull (see Ch. 27 for descriptions of individual sutures). In a suture, the two bones are separated by a layer of membrane-derived connective tissue. The sutural aspect of each bone is covered by a layer of osteogenic cells (cambial layer) overlaid by a capsular lamella of fibrous tissue that is continuous with the periosteum on both the endo- and ectocranial surfaces. The region between the capsular coverings contains loose fibrous connective tissue and decreases with age, so that the osteogenic surfaces become apposed. On completion of growth, many sutures synostose and are obliterated. Synostosis occurs normally as the skull ages; it can begin in the early twenties and continues into advanced age. A schindylesis is a specialized suture in which a ridged bone fits into a groove on a neighbouring element, e.g. where the cleft between the alae of the vomer receives the rostrum of the sphenoid (see Fig. 5.28).

## Gomphosis

A gomphosis is a peg-and-socket junction between a tooth and its socket, where the two components are maintained in intimate contact by the collagen of the periodontium connecting the dental cement to the alveolar bone. Strictly speaking, a gomphosis is not an articulation between two skeletal structures.

## Syndesmosis

A syndesmosis is a truly fibrous connection between bones. It may be represented by an interosseous ligament (e.g. the interosseous membrane between the radial and ulnar shafts), a slender fibrous cord, or a denser fibrous membrane (e.g. the posterior region of the sacroiliac joint: see Fig. 5.28).

## CARTILAGINOUS JOINTS

Cartilaginous joints may be classified as primary (synchondrosis) or secondary (symphysis), depending on the nature of the intervening cartilage. While the distinction between fibrous and cartilaginous joints is usually clear, some degree of admixture can occur in which either a predominantly fibrous articulation contains occasional islands

Gomphosis
(dento-alveolar joint)

Schindylesis (ridge and groove)

Fig. 5.28 Examples of the principal varieties of fibrous joints, each shown in section.
of cartilage, or a predominantly cartilaginous articulation contains aligned dense bundles of collagen. These joints tend to be less rigid than the fibrous articulations and some permit restricted movement (Figs 5.29-5.30).

## Primary cartilaginous joints

Primary cartilaginous joints or synchondroses occur where advancing centres of ossification remain separated by an area of hyaline (but nonarticular) cartilage. They are present in all postcranial bones that form from more than one centre of ossification. Since hyaline cartilage retains the capability to ossify with age, synchondroses tend to synostose when growth is complete. Primary cartilaginous joints are almost exclusively associated with growth plates (see above).

## Secondary cartilaginous joints

Secondary cartilaginous joints, or symphyses, are largely defined by the presence of an intervening pad or disc of fibrocartilage interposed between the articular (hyaline) cartilage that covers the ends of two articulating bones. The pad or disc varies from a few millimetres to over a centimetre in thickness, and the whole region is generally bound by strong, tightly adherent, dense connective tissues. Collagenous ligaments extend from the periostea of the articulating bones across the symphysis. The ligaments blend with the hyaline and fibrocartilaginous perichondria but do not form a complete capsule. They contain plexuses of afferent nerve terminals, which also penetrate the periphery of the fibrocartilage. The combined strength of the ligaments and fibrocartilage can exceed that of the associated bones. A symphysis is designed to withstand a range of stresses (compression, tension, shear, bending and torsion) but the range of movement is generally limited, both by the physical nature of the articulation and by adjacent bones. Tears are usually the result of sudden stresses that occur when the body is in an inappropriate posture.

All symphyses occur in the midline (mandibular, manubriosternal, pubic and intervertebral) and all except the mandibular symphysis occur in the postcranial skeleton and resist synostosis. The mandibular symphysis (symphysis menti) is histologically different from the other symphyses; however, the widespread use of this descriptive term ensures that it remains, perhaps inappropriately, within this category.

The concept that synchondroses are temporary and concerned with growth, whereas symphyses are permanent and concerned with movement, is an oversimplification and only partly correct. Both types of joint must be strong, both are sites at which growth occurs, and both contribute either directly or indirectly to the total movement patterns of the parts involved. Movements that occur at a symphysis often depend on more than the mechanical properties of the fibrocartilaginous pad or disc, e.g. movements between vertebrae depend not only on the deformability of the intervertebral disc but also on the morphology of the apophysial joints and the properties of associated ligaments (Adams et al 2013).

The prominent role of synchondroses in skeletal growth is widely recognized, whereas growth of symphyses has received less attention. Symphysial growth may, for convenience, be considered from two interrelated aspects: namely, intrinsic growth of the fibrocartilaginous disc, and growth of the hyaline cartilaginous plates into which endochondral ossification progresses.

## SYNOVIAL JOINTS

These are freely moving joints in which the articulating bony surfaces are covered in smooth (hyaline) articular cartilage and separated by a film of viscous synovial fluid that serves as a lubricant (Fig. 5.31). Joint stability is provided by a fibrous capsule (which usually has intrinsic ligamentous thickenings), and often by internal or external accessory ligaments. Synovial fluid, which also aids metabolite transport to cells in the articular cartilages, is synthesized by the synovial membrane that lines the joint capsule.

Fig. 5.29 Examples of varieties of cartilaginous joints (see also Fig. 5.30). A, A sectional view of the principal tissues involved, more detailed architecture and main growth patterns of symmetrical and asymmetrical synchondroses. Lesser degrees of asymmetry occur in some locations. Synostosis is the normal fate of almost all synchondroses when endochondral growth has ceased. B, Intervertebral symphyses (presacral), shown in section, displaying age-related changes. Partial or complete synostosis is the normal fate of sacral and coccygeal symphyses.

Fig. 5.30 Less common interchondral and osseochondral junctions: see text for other locations. General periosteum and perichondrium omitted.

## Articular surfaces

Articular cartilage comprises a specialized type of hyaline cartilage, reflecting its origin as part of the cartilaginous 'model' of bone in embryonic life. Exceptions include the sternoclavicular, acromioclavicular and temporomandibular joints, where articulating surfaces are covered by dense fibrous tissue containing isolated groups of chondrocytes with little proteoglycan in their surrounding matrix, presumably reflecting their formation by intramembranous ossification.

The most superficial cartilage, directly adjacent to the synovial fluid, is an acellular layer approximately $3 \mu \mathrm{~m}$ thick, which contains fine collagen fibrils running parallel to the surface. It functions as an elastic and protective 'skin' for the underlying tissue, and can appear to recoil under tension if the cartilage is damaged. The deformability of articular cartilage enables opposing cartilage surfaces to flatten slightly at their area of contact, increasing contact area and decreasing contact stress (see Fig. 5.57). This load-distributing property of articular cartilage depends on the congruence of opposing joint surfaces (see Fig. 5.61). Slight undulations in the surface trap synovial fluid so that fluid-film lubrication is possible under most circumstances; effectively, the bones 'aqua-plane' on each other (Fig. 5.60). This ensures very low friction and, consequently, low wear of the cartilage.

The acellular surface layer is coated with a large glycoprotein, lubricin, which projects from the surface so that a hydrophobic region of the molecule lies in the joint space, where it repels its counterpart on the opposing articular surface. In this way, lubricin acts in the manner of a lubricant such as grease to reduce friction and wear of the surface zone. This 'boundary lubrication' mechanism becomes important when the fluid film has been squeezed out, e.g. after sustained forceful loading of the joint, and loss of lubricin can lead to cartilage degeneration (Waller et al 2013). Transmission electron microscopy shows this lubricant layer as an interrupted electron-dense surface coat $0.03-0.1 \mu \mathrm{~m}$ thick. Synovial fluid and membranous debris, the product of chondrocytic necrosis, may contribute to this surface coat, which is transient in nature. The 'lamina splendens', a structure that appears as a bright line at the free surface of articular cartilage when oblique sections are examined by negative phase contrast microscopy, may be a

Fig. 5.31 Synovial joints, some main structural features and one elementary type of classification: A, simple; B, compound; C, complex joints. For clarity, the articular surfaces are artificially separated. A and C are purely diagrammatic and not related to particular joints. B, however, is a simplified representation of some features of an elbow joint; the complicated contours due to the olecranon, coronoid and radial fossae, and profiles of articular fat pads have been omitted for clarity.
microscopical artefact at the border between regions of different refractive index, rather than an anatomically distinct surface layer. Deeper zones of articular cartilage are described on page 83.

With advancing age, undulations on the articular surfaces deepen and develop minute, ragged projections, perhaps as a consequence of wear and tear. These changes are extremely slow in healthy joints, but are accelerated in pathologically 'dry' joints and where synovial fluid viscosity is altered.

## Fibrous capsule

A fibrous capsule completely encloses each synovial joint except where it is interrupted by synovial protrusions (see descriptions of individual joints for details). It is composed of interlacing bundles of parallel fibres of collagen type I, and is attached continuously round the ends of the articulating bones. In small bones this attachment is usually near the periphery of the articular surfaces, but in long bones it varies considerably, and part or all of the attachment may be a significant distance from the articular surface. The joint capsule is perforated by vessels and nerves, and may contain apertures through which synovial membrane protrudes as bursae. It is lined by a synovial membrane that also covers all non-articular surfaces (bones, tendons and ligaments) that lie partly or wholly within the fibrous capsule. Where a tendon is attached to bone inside a synovial joint, an extension of the synovial membrane usually accompanies it beyond the capsule. Some extracapsular tendons are separated from the capsule by a synovial bursa continuous with the interior of the joint. These protrusions are potential routes for the spread of infection into joints.

A fibrous capsule usually exhibits local thickenings of parallel bundles of collagen fibres, called capsular (intrinsic) ligaments, and named by their attachments. Some capsules are reinforced or replaced by tendons of nearby muscles, or expansions from them. Accessory ligaments are distinct structures, and may be located inside or outside the joint capsule. All ligaments, although stiff in tension, are pliant in bending. They can rebound elastically from being stretched by up to $10-15 \%$, and are protected from injury by reflex contraction of appropriate muscles. They do little to resist normal movements but become taut at the end of each normal range of movement.

## Synovial membrane

Synovial membrane lines the fibrous joint capsule and exposed osseous surfaces, intracapsular ligaments, bursae and tendon sheaths (Fig. 5.32). It does not cover intra-articular discs or menisci, and stops at the margins of articular cartilages in a transitional zone that occupies the peripheral few millimetres of cartilage. Synovial membrane secretes and absorbs a fluid that lubricates the movement between the articulating surfaces.

Pink, smooth and shining, the internal synovial surface displays a few small synovial villi that increase in size and number with age. Folds and fringes of membrane may also project into a joint cavity; some are

Fig. 5.32 A section of a synovial joint and its associated highly vascular synovial membrane in a human fetal hand. The two articular cartilage surfaces ( $A$, arrows) are separated on the right by a layer of synovial fluid (S) secreted by the synovial membrane (SM), which extends a short distance into the joint space from the capsule (C).
sufficiently constant to be named, e.g. the alar folds and ligamentum mucosum of the knee. Synovial villi are more numerous near articular margins and on the surfaces of folds and fringes, and become prominent in some pathological states.

Accumulations of adipose tissue (articular fat pads) occur within the synovial membrane in many joints. These pads, and also synovial folds and fringes, are deformable cushions that occupy potential spaces and irregularities in joints that are not wholly filled by synovial fluid. During movement they accommodate to the changing shape and volume of the irregularities, a function they share with intra-articular discs and menisci. They also increase the area of synovial membrane, and may help to spread synovial fluid over the articular surfaces.

The synovial membrane has two layers: a highly cellular intimal layer resting on a fibrous and vascular subintimal layer (subsynovial tissue). The subintima is often composed of loose, irregular connective tissue, but also contains organized collagen and elastin fibres lying parallel to the membrane surface, interspersed with occasional fibroblasts, macrophages, mast cells and fat cells. The elastic component may prevent formation of redundant folds during joint movement. Subintimal adipose cells form compact lobules surrounded by highly vascular fibroelastic interlobular septa that provide firmness and compressive turgor.

The intimal layer consists of pleomorphic synovial cells embedded in a granular, amorphous matrix. In normal human joints, synovial cells form an interlacing, discontinuous layer, 1-3 cells and 20-40 $\mu \mathrm{m}$ thick, between the subintima and the joint cavity. They are not separated from
the subintima by a basal lamina, and are distinguished from subintimal cells only because they associate to form a superficial layer. In many locations, but particularly over loose subintimal tissue, areas are commonly found that are free from synovial cells. Over fibrous subintimal tissue the synovial cells may be flattened and closely packed, forming endothelium-like sheets. Human synovial cells are generally elliptical, with numerous cytoplasmic processes. Neighbouring cells are often separated by gaps, but their processes may interdigitate where they lie closer together. There is considerable regional variation in cell morphology and numbers.

There are at least two morphologically distinct populations of synovial cells or synoviocytes: type A and type B. Type A synoviocytes are macrophage-like cells characterized by surface ruffles or lamellipodia, plasma membrane invaginations and associated pinocytotic vesicles, a prominent Golgi apparatus but little rough endoplasmic reticulum. They probably synthesize and release lytic enzymes and phagocytose joint debris from synovial fluid. Type B synoviocytes, which predominate, resemble fibroblasts and have abundant rough endoplasmic reticulum but fewer vacuoles and vesicles, and a less ruffled plasma membrane than type A synoviocytes. They probably synthesize some of the hyaluronan of synovial fluid, the boundary lubricant lubricin, and inhibitors of the degradative enzymes synthesized by type A cells, limiting their potential to damage joint tissues. Synoviocytes do not divide actively in normal synovial membranes, but may do so in response to trauma and haemarthrosis. Under such conditions, type B synoviocytes divide in situ, while type A cells increase by immigration of bone marrow-derived precursors.

## Synovial fluid

Synovial fluid occupies synovial joints, bursae and tendon sheaths. In synovial joints it is clear or pale yellow, viscous and slightly alkaline at rest (the pH lowers during activity), and contains a small mixed population of cells and metachromatic amorphous particles. Fluid volume is low: usually less than 0.5 ml can be aspirated from a large joint such as the knee.

The composition of synovial fluid is consistent with it being mainly a transudate of blood plasma: it contains protein (approximately $0.9 \mathrm{mg} / 100 \mathrm{ml}$ ) derived from the blood. It also contains hyaluronan, which is thought to be a significant determinant of the viscoelastic and thixotropic (flow rate-dependent) properties of synovial fluid. A small proportion (approximately 2\%) of synovial fluid protein differs from plasma protein and is probably produced by type B synoviocytes. An even smaller proportion (approximately $0.5 \%$ ) of synovial fluid protein appears to be a specialized lubricating glycoprotein, lubricin. Synovial fluid contains a few cells (approximately 60 per ml in resting human joints), including monocytes, lymphocytes, macrophages, synovial intimal cells and polymorphonuclear leukocytes; higher counts are found in young individuals. The amorphous metachromatic particles and fragments of cells and fibrous tissue found in synovial fluid are presumed to be the by-products of wear and tear.

## Intra-articular menisci, discs and fat pads

An articular disc or meniscus can occur between articular surfaces where congruity (conformity of opposing articular surfaces) is low. The term meniscus should be reserved for incomplete discs, like those in the knee joint and, occasionally, in the acromioclavicular joint. Complete discs, such as those in the sternoclavicular and inferior radio-ulnar joints, extend across a synovial joint, thereby dividing it structurally into two synovial cavities; they often have small perforations. The disc in the temporomandibular joint may be complete or incomplete.

The main part of a disc is relatively acellular, but the surface may be covered by an incomplete stratum of flat cells, continuous at the periphery with adjacent synovial membrane. Discs are usually connected to their fibrous capsule by vascularized connective tissue, so that they become invaded by blood vessels and afferent and vasomotor postganglionic sympathetic nerves. The union between disc and capsule may be closer and stronger, as occurs in the knee and temporomandibular joints. Discs and menisci are composed of fibrocartilage containing crimped type I collagen fibres, and are not covered by synovial membrane.

The functions of intra-articular fibrocartilages are uncertain. Evidence from structural or phylogenetic data, aided by mechanical analogies, suggests that functions include: improvement of fit between articulating surfaces; deployment of weight over larger surface areas; shock absorption; facilitation of combined movements; limitation of translational (gliding) movements at joints such as the knee; protection
of articular margins; facilitation of rolling movements; and spread of lubricant. The temporomandibular disc has attracted particular attention because of its exceptional, perhaps unique, design and biomechanical properties.

The functions of labra and fat pads, two other quite common types of intra-articular structure, are also uncertain. A labrum is a fibrocartilaginous anular lip, usually triangular in cross-section, attached to an articular margin such as the glenoid fossa or acetabulum. It deepens the socket and increases the area of contact between articulating surfaces, and may act as a lubricant spreader. Like menisci, labra may reduce the synovial space to capillary dimensions, thus limiting drag. Unlike menisci, labra are not compressed between articular surfaces. Small fibrous labra have been described along the ventral or dorsal margins of the zygapophysial joints at lumbar levels, as have meniscusshaped fibroadipose meniscoids at the superior or inferior poles of the same joints. Fat pads are soft and change shape to fill joint recesses that vary in dimension according to joint position.

## Vascular supply and lymphatic drainage

Numerous branches from peri-articular arterial plexuses pierce the fibrous capsules to form subsynovial vascular plexuses. Some synovial vessels end near articular margins in an anastomotic fringe, the circulus articularis vasculosus. A lymphatic plexus in the synovial subintima drains along blood vessels to the regional deep lymph nodes.

Articular cartilage, intra-articular menisci and cartilaginous discs are all avascular, presumably because high mechanical pressures in these deformable tissues would collapse any blood vessels inside them. Laboratory experiments show that proteoglycans inhibit vascular growth, so the high concentration of proteoglycans in the cartilaginous tissues of joints may help to exclude blood vessels. However, injury and disease can alter both the mechanical and chemical environment within cartilage (Adams 2013), allowing revascularization in peripheral and disrupted regions. The blood supply to subchondral bone is described on page 89.

## Innervation

A movable joint is innervated by articular branches of the nerves that supply the muscles acting on the joint and that also supply the skin covering the joint (Hilton's law). Although there is overlap between the territories of different nerves, each nerve innervates a specific part of the capsule. The region made taut by muscular contraction is usually innervated by nerves that supply the antagonists. For example, during abduction, stretching the portion of the capsule of the hip joint supplied by the obturator nerve elicits reflex contraction of the adductors that is usually sufficient to prevent damage.

Myelinated axons in articular nerves innervate Ruffini endings, lamellated articular corpuscles, and structures resembling Golgi tendon organs. Ruffini endings respond to stretch and adapt slowly, whereas lamellated corpuscles respond to rapid movement and vibration, and adapt rapidly; both types of receptor register the speed and direction of movement. Golgi tendon organs, innervated by the largest myelinated axons ( $10-15 \mu \mathrm{~m}$ diameter), are slow to adapt; they mediate position sense and also are concerned in stereognosis, i.e. recognition of shape of held objects. Simple endings are numerous at the attachments of capsules and ligaments, and are thought to be the terminals of unmyelinated and thinly myelinated nociceptive axons (see p. 59 for an account of sensory receptors).

Many unmyelinated postganglionic sympathetic axons terminate near vascular smooth muscle, and are presumably either vasomotor or vasosensory. The nerve endings in synovial membrane are believed to supply blood vessels exclusively, from which it is assumed that synovial membrane is normally relatively insensitive to pain.

Cartilaginous structures within joints normally have no nerve supply, partly because they are avascular and partly because axonal growth is inhibited by a high concentration of proteoglycans. However, when fibrocartilage is injured or diseased, nerves may accompany the consequent ingrowth of blood vessels and give rise to pain (Freemont et al 1997). Subchondral bone is normally innervated and is a likely source of pain in the spine (Peng et al 2009).

## Classification

Synovial joints can be classified according to their shape (Fig. 5.33). While this has some practical value, it should be remembered that they are merely variations, sometimes extreme, of basic forms. Articular

4 Ellipsoid joint

Fig. 5.33 Types of synovial joint, with selected examples.
surfaces are never truly flat, or complete spheres, cylinders, cones or ellipsoids.

## Plane joints

Plane joints, such as intermetatarsal and some intercarpal joints, have almost flat surfaces. Slight curvature is often disregarded, although it is usual, and movements are considered to be pure translations or sliding between bones.

## Hinge joints

These resemble hinges because movement takes place about a single stationary axis, and so is largely restricted to one plane. Examples are interphalangeal and humero-ulnar joints. However, the surfaces of biological hinges are not truly cylindrical, and actual motion can occur in more than one plane. Hinge joints possess strong collateral ligaments.

Bicondylar joints are predominantly uniaxial hinge joints, but the presence of two condyles side by side allows limited rotation about a second axis orthogonal to the first. These joints are formed from two convex condyles that articulate with concave or flat surfaces. The condyles may lie within a common fibrous capsule (as in the knee), or in separate capsules that necessarily cooperate in all movements as a condylar pair (as in the temporomandibular joints).

## Pivot joints

These are uniaxial joints in which an osseous pivot inside an osteoligamentous ring allows rotation only around the axis of the pivot. Pivots may rotate in rings (e.g. the head of the radius rotates within the anular ligament and ulnar radial notch), or rings may rotate around pivots (e.g. the atlas rotates around the dens of the axis).

## Ellipsoid joints

Ellipsoid joints are biaxial, and consist of an oval, convex surface apposed to an elliptical concavity. Examples are the radiocarpal and
metacarpophalangeal joints. Primary movements occur around two orthogonal axes, such as flexion-extension and abduction-adduction, and may be combined as circumduction. Rotation around the third axis is largely prevented by general articular shape.

## Saddle joints

Saddle joints are biaxial joints in which the articular surfaces have both concave and convex regions. Each surface is maximally convex in one direction and maximally concave in another, at right angles to the first. The convexity of the larger surface is apposed to the concavity of the smaller surface and vice versa. Primary movements occur in two orthogonal planes but articular shape also causes axial rotation of the moving bone. Such 'coupled' rotation is never independent, and can be functionally significant in habitual positioning and limitation of movement. The most familiar saddle joint is the carpometacarpal joint of the thumb; other examples include the ankle and calcaneocuboid joints.

## Ball-and-socket joints

These multiaxial joints are formed by a globoid 'head' articulating with an opposing cup. Prime examples are the hip and shoulder joints. Although their surfaces resemble parts of spheres, they are not strictly spherical but slightly ovoid, and consequently congruence is not perfect in most positions. Indeed, it occurs in only one position, at the end of the most common movement.

## Factors influencing movement

Movements at synovial joints depend on a number of factors, including the complexity and number of articulating surfaces, and the number and position of the principal axes of movement.

## Complexity of form

Most synovial joints are simple articulations between two articular surfaces. A joint with more than two articular surfaces is called a

Fig. 5.34 The shoulder joint is multiaxial and possesses three degrees of freedom. The three mutually perpendicular axes are shown, around which the principal movements of flexion-extension ( $\mathbf{A}$ ), abduction-adduction (B) and medial and lateral rotation (C) occur. Note that these axes are referred to the plane of the scapula and not to the coronal and sagittal planes of the erect body. Although an infinite variety of additional movements may occur at such a joint, e.g. movements involving intermediate planes or combinations, they can always be resolved mathematically into components related to the three axes illustrated.

Fig. 5.35 A profile of a section through an ovoid surface showing that it may be considered as a series of segments of circles of changing radius. The radius of curvature of joint surfaces often changes from one location to another.
compound joint, e.g. the knee and the elbow (see Fig. 5.31). In all compound joints, articulating territories remain distinct. A synovial joint that contains an intra-articular disc or meniscus is called a complex joint, e.g. the tibiofemoral joint of the knee, and the temporomandibular joints.

## Degrees of freedom

Joint motion can be described by rotation and translation about three orthogonal axes. There are three possible rotations (axial, abductionadduction, flexion-extension) and three possible translations (proximodistal, mediolateral, anteroposterior). Each is a degree of freedom. For most joints, translations are small and can be neglected (Fig. 5.34). A few joints have minor but pure translatory movements, but most joint motion is by rotation.

When movement is practically limited to rotation about one axis (e.g. the elbow), a joint is termed uniaxial and has one degree of freedom. If independent movements can occur around two axes (e.g. flexion-extension and axial rotation in the knee), the joint is biaxial and has two degrees of freedom. Since there are three axes for independent rotation, joints may have up to three degrees of freedom. This apparently simple classification is complicated by the complexity of joint structure and has consequent effects on motion. Even though a true 'ball-and-socket' joint is multiaxial and can rotate about many chosen axes, for each position there is a maximum of three orthogonal planes, which means that it can have, as a maximum, three degrees of freedom.

For a uniaxial hinge joint with a single degree of freedom, a single unchanging axis of rotation would be predicted. However, because the shapes of joint surfaces are complex, there is a variable radius of curvature (Fig. 5.35) and consequently the axis of rotation will vary as joint movement progresses. When the variation is minor, e.g. in the elbow, it is often appropriate to describe a mean position for the axis, whereas in other joints, e.g. the knee, the situation is more complex.

Motion in one direction is often linked to motion in another. Coupled (or conjunct) movements occur as an integral and inevitable accompaniment of the main movement. Adjunct movements can occur independently and may or may not accompany the principal movement.

## Types of joint movement

Joint surfaces move by translation (gliding) and angulation (rotation), usually in combination, to produce gross movements at the joint.

Where movement is slight, the reciprocal surfaces are of similar size; where it is wide, the habitually more mobile bone has the larger articular surface.

## Translation

Translation is the simplest motion and involves gliding or sliding without appreciable angulation. Although frequently combined with other movements, it is often considered the only motion permitted in some carpal and tarsal articulations. However, cineradiography reveals that considerable angulation occurs during movements of the small carpal and tarsal bones.

## Flexion

Flexion is an example of angulation, where there is a change in angle between the topographical axes of the articulating bones. Although a widely used term, flexion is difficult to define. It often means approximation of two ventral surfaces around a transverse axis. However, the thumb is almost at right angles to the fingers: its 'dorsal' surface faces laterally so that flexion and extension at its joints occur around anteroposterior axes. At the shoulder, flexion is referred to an oblique axis through the centre of the humeral head in the plane of the scapular body, the arm moving anteromedially forwards and hence nearer to the ventral aspect of the trunk. At the hip, which has a transverse axis, flexion brings the morphologically dorsal (but topographically ventral) surface of the thigh to the ventral aspect of the trunk. Description of flexion at the ankle joint is complicated by the fact that the foot is set at a right angle to the leg. Elevation of the foot diminishes this angle and is usually termed flexion; however, it involves the approximation of two dorsal surfaces so might equally be called extension. Flexion has also been defined as the fetal posture, implying that elevation of the foot is flexion, a view supported by withdrawal reflexes in which elevation is always associated with flexion at the knee and hip. Definitions based on morphological and physiological considerations are thus contradictory; to avoid confusion, dorsiflexion and plantar flexion are used to describe ankle movements.

## Abduction and adduction

Abduction and adduction occur around anteroposterior axes except at the first carpometacarpal and shoulder joints. The terms generally imply lateral or medial angulation, except in digits, where arbitrary planes are chosen (midlines of the middle digit of the hand and second digit of the foot), because these are least mobile in this respect. Abduction of the thumb occurs around a transverse axis and away from the palm. Similarly, abduction of the humerus on the scapula occurs in the scapular plane around an oblique axis at right angles to it.

## Axial rotation

Axial rotation is a widely, but often imprecisely, used term. Its restricted sense denotes movement around some notional 'longitudinal' axis, which may even be in a separate bone, e.g. the dens of the second cervical vertebra, on which the atlas rotates. An axis may approximate to the centre of the shaft of a long bone, as in medial and lateral humeral rotation (see Fig. 5.34). Alternatively, the axis may be at an angle to the topographical axis of a bone, as in movement of the radius on the ulna in pronation and supination, where the axis joins the centre of the radial head to the base of the ulnar styloid process. In these examples, rotations can be independent adjunct motions, constituting a degree of freedom, or obligatory (coupled) rotations, which always accompany some other main movement as a consequence of articular geometry. Obligatory coupled motion is frequently combined with a degree of voluntary adjunct motion, the latter dictating what proportion of the motion occurs above the minimum obligatory component.

## Circumduction

Circumduction combines successive flexion, abduction, extension and adduction, and occurs when the distal end of a long bone circumscribes the base of a cone that has its apex at the joint in question. Examples are circular movements of the hand and foot about the shoulder and hip joints, respectively.

## DEVELOPMENT OF JOINTS

The development of joints is described in the context of limb development on page 222.

## MUSCLE

Most cells possess cytoskeletal elements that are capable of lengthening or shortening and so enable the cell to change its shape. This capacity is important in a variety of cellular functions, including locomotion, phagocytosis and mitosis. Slow movements can be effected by polymerization-depolymerization mechanisms involving actin and tubulin, but much faster and more forceful movements can be created by the so-called 'motor proteins', which use energy from the hydrolysis of adenosine 5 '-triphosphate (ATP). Of these ATP-dependent systems, one of the most widespread is based on the interaction of the motor protein myosin with actin.

In muscle cells the filaments of actin, myosin and other associated proteins are so abundant that they almost fill the interior of the cell. Moreover, they align predominantly in one direction, so that interactions at the molecular level are translated into linear contraction of the whole cell. The ability of these specialized cells to change shape has thus become their most important property. Assemblies of contractile muscle cells, the muscles, are machines for converting chemical energy into mechanical work. Muscle forces move limbs and drive many of the functions of the human body, and muscle tissue constitutes 40-50\% of body mass.

## CLASSIFICATION OF MUSCLE

Muscle cells (fibres) are also known as myocytes (the prefixes myo- and sarco- are frequently used in naming structures associated with muscle). They differentiate along one of three main pathways to form skeletal, cardiac or smooth muscle. Both skeletal and cardiac muscle (Ch. 6) may be called striated muscle, because their myosin and actin filaments are organized into regular, repeating structures (sarcomeres), which give the cells a finely cross-striated appearance when viewed microscopically. Cardiac muscle fibres are relatively short, with branched ends, and are joined to adjacent fibres at intercellular junctional complexes called intercalated discs, which skeletal muscle lacks. Smooth muscle cells lack striations because their actin and myosin are not organized into sarcomeres.

Other contractile cells, including myofibroblasts and myoepithelial cells, are different in character and developmental origin. They contain smooth muscle-like contractile proteins and are found singly or in small groups.

## SKELETAL MUSCLE

Skeletal muscle (striated, voluntary) is the most common muscle tissue. It consists of long, parallel multinucleate cells bundled together by collagenous sheaths. Its regular organization enables skeletal muscle to generate powerful contractions, with a power output of approximately 100 watts per kilogram of tissue. However, the price paid for this organization is a limited contractile range: skeletal muscle can shorten by only $30 \%$. If a larger range of movement is required, it must be achieved through the amplification provided by lever systems, as described in Figure 5.63. Skeletal muscle is innervated by somatic motor nerves and is sometimes referred to as voluntary muscle, because its contractions are often initiated under conscious control. However, this is a misleading term because skeletal muscle is involved in many movements, such as breathing, blinking and swallowing, which are often initiated at an unconscious level.

## MICROSTRUCTURE OF SKELETAL MUSCLE

Skeletal muscle fibres are enormous multinucleate cells (Figs 5.365.37), which develop by fusion of individual myoblasts (see below).

Fig. 5.36 Skeletal muscle fibres from human lateral rectus in longitudinal section, showing transverse striations representing the sarcomeric organization of actin and myosin filaments. The variation in fibre diameter is typical of extraocular muscles. Capillaries (C) and nerves ( N ) lie between the fibres, orientated mainly in parallel and so are also sectioned longitudinally. Toluidine blue stained resin section. (Provided by courtesy of the Department of Optometry and Visual Science, City University, London.)

Individual fibres are long, cylindrical structures that tend to be consistent in size within a given muscle, but in different muscles may range from 10 to $100 \mu \mathrm{~m}$ in diameter, and from a few millimetres to many centimetres in length. The cytoplasm of each fibre, the sarcoplasm, is surrounded by a plasma membrane often called the sarcolemma. The bulk of the sarcoplasm comprises the contractile machinery, organized into myofibrils (see Fig. 5.37) 1-2 $\mu \mathrm{m}$ in diameter, which extend the length of the fibre. Numerous moderately euchromatic, oval nuclei usually occupy a thin transparent rim of sarcoplasm between the myofibrils and the sarcolemma, and are especially numerous in the region of the neuromuscular junction (see Fig. 3.34). In transverse section, a muscle fibre may reveal only one or two nuclei, but it may contain several hundred along its entire length. Myogenic satellite cells lie between the sarcolemma and the surrounding basal lamina (see below).

## Sarcomeres

Although myofibrils are too tightly packed to be visible by routine light microscopy, their presence can be inferred from transverse striations across the tissue. Cross-striations may be demonstrated more effectively using special stains (see Fig. 5.36) or under polarized light, which can differentiate dark, anisotropic A-bands (which are birefringent and rotate the plane of polarized light strongly) from lighter, isotropic I-bands (rotate the plane of polarized light to a negligible degree). In transverse section, skeletal muscle fibres are usually polygonal (Fig. 5.38 ) and their sarcoplasm often has a stippled appearance, because transversely sectioned myofibrils are resolved as dots. The packing density of muscle fibres varies, from low (in the extrinsic muscles of the larynx) to high (in the group of muscles that elevate the mandible).

Most detail is revealed by transmission electron microscopy (Fig. 5.39). Myofibrils, approximately $1 \mu \mathrm{~m}$ in diameter, are the dominant ultrastructural feature. In longitudinal sections they appear as ribbons that are interrupted at regular intervals by thin dark transverse lines, which correspond to discs in the parent cylindrical structure. These are the Z-lines or, more properly, Z-discs (Zwischenscheiben = interval discs) that divide each myofibril into a linear series of repeating contractile units, the sarcomeres. A sarcomere is typically $2.2 \mu \mathrm{~m}$ long in resting muscle. At higher power, it can be seen to consist of two types of filament, thick and thin, organized into regular arrays (see Figs 5.37 and 5.39). Thick filaments, which are approximately 15 nm in diameter, are composed mainly of myosin. Thin filaments, which are 8 nm in diameter, are composed mainly of actin. The arrays of thick and thin filaments form a partially overlapping structure in which electron density (as seen in the electron microscope) varies according to the amount of protein present. The A-band consists of the thick filaments, together with lengths of thin filaments that interdigitate with, and thus overlap, the thick filaments at either end (see Fig. 5.39; Fig. 5.40). The central, paler region of the A-band, which is not penetrated by the thin filaments, is called the H-zone (Helle = light). At their centres, the thick filaments are linked together transversely by material that constitutes

Fig. 5.40 B, The arrangement of titin and nebulin in a skeletal muscle sarcomere. A single titin molecule spans from the Z-disc to the M-band and contains a spring-like 'elastic' region that develops force when the sarcomere is stretched. Nebulin extends from the $Z$ disc for the full length of each actin filament. (From Prado LG et al. Isoform Diversity of Giant Proteins in Relation to Passive and Active Contractile Properties of Rabbit Skeletal Muscles. J Gen Physiol 2005;126:461-480.)

Fig. 5.37 Levels of organization within a skeletal muscle, from whole muscle to fasciculi, single fibres, myofibrils and myofilaments.
the M -line (Mittelscheibe = middle [of] disc), which is visible in most muscles. The I-band consists of the adjacent portions of two neighbouring sarcomeres in which the thin filaments are not overlapped by thick filaments. The thin filaments of adjacent sarcomeres are anchored in the Z-disc, which bisects the I-band.

Fig. 5.38 A transverse cryostat section of adult human skeletal muscle. Note the tight packing of the fibres and the peripheral location of the dark-stained nuclei. (Photograph by Professor Stanley Salmons, from a specimen provided by courtesy of Tim Helliwell, Department of Pathology, University of Liverpool.)

The high degree of organization of thick and thin filaments is equally evident in transverse sections (see Fig. 5.40; Fig. 5.41). The thick myosin filaments form a hexagonal lattice. In the regions where they overlap the thin filaments, each myosin filament is surrounded by six actin filaments at the trigonal points of the lattice. In the I-band, the thin filament pattern changes from hexagonal to square as the filaments approach the Z-disc, where they are incorporated into a square lattice structure.

The banded appearance of individual myofibrils is a function of the regular alternation of the thick and thin filament arrays. The size of myofibrils places them at the limit of resolution of light microscopy; cross-striations are only visible at that level because of the alignment in register of the A- and I-bands in adjacent myofibrils across the width of the whole muscle fibre. In suitably stained relaxed material, the A-, I - and H -bands are quite distinct, whereas the Z -discs, which are such a prominent feature of electron micrographs, are thin and much less conspicuous in the light microscope, and M-lines cannot be resolved.

## Muscle proteins

Myosin, the protein of the thick filament, constitutes $60 \%$ of the total myofibrillar protein and is the most abundant contractile protein. The thick filaments of skeletal and cardiac muscle are $1.5 \mu \mathrm{~m}$ long. Their composition from myosin heavy and light chain assemblies is described on page 12. The other components of myosin, the regulatory proteins tropomyosin and troponin, play a major part in the control of contraction.

Actin is the next most abundant contractile protein and constitutes $20 \%$ of the total myofibrillar protein. In its filamentous form, F-actin, it is the principal protein of the thin filaments. A number of congenital myopathies result from gene mutations in components of the thin filament assembly (Clarkson et al 2004).

A third type of long sarcomeric filament (not shown in Fig. 5.40) connects the thick filaments to the Z-disc, and is formed by the giant protein, titin, which has a molecular mass in the millions (Gregorio et al 1999). Single titin molecules span the half-sarcomere between the M -lines and the Z-discs, into which they are inserted. They have a tethered portion in the A-band, where they are attached to thick filaments as far as the M-line, and an elastic portion in the I-band. The elastic properties of titin endow the relaxed muscle fibre with passive resistance to stretching, and with elastic recoil.

A number of proteins that are neither contractile nor regulatory are responsible for the structural integrity of the myofibrils, particularly their regular internal arrangement. A component of the Z-disc, $\alpha$-actinin, is a rod-shaped molecule that anchors the plus-ends of actin filaments from adjacent sarcomeres to the Z-disc. Nebulin inserts into the Z-disc, associated with the thin filaments, and regulates the lengths of actin filaments. Desmin, an intermediate filament protein characteristic of muscle, encircles the myofibrils at the Z-disc and, with the linking molecule plectrin, forms a meshwork that connects myofibrils together within the muscle fibre and to the sarcolemma. Myomesin holds myosin filaments in their regular lattice arrangement in the region of the M-line. Dystrophin is confined to the periphery of the muscle fibre, close to the cytoplasmic face of the sarcolemma. It binds to actin

Fig. 5.39 The electron microscopic appearance of skeletal muscle in longitudinal section. A, A low-power view of parts of two adjacent muscle fibres, separated by endomysium (E) containing capillaries (C) and a peripherally placed nucleus $(\mathrm{N})$ in the fibre. Mitochondria (arrows) are situated peripherally and between myofibrils (M). Myofibrils pack the cytoplasm, with their sarcomeres (contractile units) in register, as seen by the alignment of Z-discs (dark transverse lines) across each muscle fibre. B, A sarcomere within a
$\stackrel{\text { O }}{0}$ myofibril, and parts of two others. (A sarcomere is the distance between adjacent Z-discs.) Also seen are the A-band, bisected by the M-line, and I-band, which here is almost obliterated in the contracted state (see Fig. 5.40). A triad is visible between myofibrils, comprised of a T-tubule (long arrow) and two terminal cisternae of sarcoplasmic reticulum (short arrows). A
Fig. 5.40 A, Sarcomeric structures. The drawings below the electron micrograph (of two myofibrils sectioned longitudinally and with their long axes orientated transversely) indicate the corresponding arrangements of thick and thin filaments. Relaxed and contracted states are shown to illustrate the changes that occur during shortening. Insets at the top depict the electron micrographic appearance of transverse sections through the myofibril at the levels shown. Note that the packing geometry of the thin filaments changes from a square array at the Z-disc to a hexagonal array where they interdigitate with thick filaments in the A-band. (Photographs by Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.) ( B , continued online)
intracellularly and is also associated with a large oligomeric complex of glycoproteins, the dystroglycan/sarcoglycan complex that spans the membrane and links specifically with merosin, the $\alpha_{2}$-laminin isoform of the muscle basal lamina. This stabilizes the muscle fibre and transmits forces generated internally on contraction to the extracellular matrix.

Dystrophin is the product of the gene affected in Duchenne muscular dystrophy, a fatal disorder that develops when mutation of the gene leads to the absence of the protein (Batchelor and Winder 2006). A milder form of the disease, Becker muscular dystrophy, is associated
with a reduced size and/or abundance of dystrophin. Female carriers (heterozygous for the mutant gene) of Duchenne muscular dystrophy may also have mild symptoms of muscle weakness. At about 2500 kb , the gene is one of the largest yet discovered, which may account for the high mutation rate of Duchenne muscular dystrophy (approximately $35 \%$ of cases are new mutations). Other muscular dystrophies may involve deficiencies in proteins functionally associated with dystrophin, such as the dystroglycan/sarcoglycan complex or $\alpha_{2}$-laminin; they may also be the result of mutations in proteins of the inner nuclear membrane (Azibani et al 2014; Koch and Holaska 2014).

Fig. 5.41 An electron micrograph of skeletal muscle in transverse section, showing parts of two muscle fibres. Part of a capillary (C) is seen in transverse section in the endomysial space. The variation in the appearance of myofibrils in cross-section is explained in Figure 5.40. (Photograph by Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.)

## Other sarcoplasmic structures

Although myofibrils are the dominant ultrastructural feature, skeletal muscle fibres contain other organelles essential for cellular function. Ribosomes, Golgi apparatus and mitochondria are located around the nuclei, between myofibrils and the sarcolemma, and, to a lesser extent, between the myofibrils. Mitochondria, lipid droplets and glycogen provide the metabolic support needed by active muscle. The mitochondria are elongated and their cristae are closely packed. The number of mitochondria in an adult muscle fibre is not fixed, but can increase or decrease quite readily in response to sustained changes in activity. Spherical lipid droplets, approximately $0.25 \mu \mathrm{~m}$ in diameter, are distributed uniformly throughout the sarcoplasm between myofibrils. They represent a rich source of energy that can be tapped only by oxidative metabolic pathways; they are therefore more common in fibres that have a high mitochondrial content and good capillary blood supply Small clusters of glycogen granules are dispersed between myofibrils and among the thin filaments. During brief bursts of activity, they provide an important source of anaerobic energy that is not dependent on blood flow to the muscle fibre.

Tubular invaginations of the sarcolemma penetrate between the myofibrils in a transverse plane at the limit of each A-band (see Fig. 5.39; Fig. 5.42). The lumina of these transverse (T-)tubules are thus in continuity with the extracellular space. At the ends of the muscle fibre, where force is transmitted to adjacent connective tissue structures, the sarcolemma is folded into numerous finger-like projections that strengthen the junctional region by increasing the area of attachment.

The sarcoplasmic reticulum (SR) is a specialized form of smooth endoplasmic reticulum and forms a plexus of anastomosing membrane cisternae that fills much of the space between myofibrils (see Fig. 5.42). The cisternae expand into larger sacs, junctional sarcoplasmic reticulum or terminal cisternae, where they come into close contact with T-tubules, forming structures called triads (see Figs 5.39 and 5.42). The membranes of the SR contain calcium-ATPase pumps that transport calcium ions into the terminal cisternae, where the ions are bound to calsequestrin, a protein with a high affinity for calcium, in dense storage granules. In this way, calcium can be accumulated and retained in the terminal cisternae at a much higher concentration than elsewhere in the sarcoplasm. $\mathrm{Ca}^{2+}$-release channels (ryanodine receptors) are concentrated mainly in the terminal cisternae and form one half of the junctional 'feet' or 'pillars' that bridge the SR and T-tubules at the triads. The other half of the junctional feet is the T-tubule receptor that constitutes the voltage sensor.

Fig. 5.42 A three-dimensional reconstruction of a mammalian skeletal muscle fibre, showing in particular the organization of the transverse ( T ) tubules and sarcoplasmic reticulum. Mitochondria lie between the myofibrils. Note that transverse tubules are found at the level of the $A / I$ junctions, where they form triads with the terminal cisternae of the sarcoplasmic reticulum.

## Connective tissues of muscle

The endomysium is a delicate network of connective tissue that surrounds muscle fibres and forms their immediate external environment. It is the site of metabolic exchange between muscle and blood, and contains capillaries and bundles of small nerve fibres. Ion fluxes associated with the electrical excitation of muscle fibres take place through its proteoglycan matrix. The perimysium is a more substantial connective tissue structure that is continuous with the endomysium, and ensheathes groups of muscle fibres to form parallel bundles, or fasciculi. It carries larger blood vessels and nerves, and accommodates neuromuscular spindles. Perimysial septa are themselves the inward extensions of a collagenous sheath, the epimysium, which forms part of the fascia that invests whole muscle groups.

Epimysium consists mainly of type I collagen; perimysium contains type I and type III collagen; endomysium contains collagen types III and IV. Collagen IV is associated particularly with the basal lamina that invests each muscle fibre. The epimysial, perimysial and endomysial sheaths coalesce where the muscles connect to adjacent structures at tendons, aponeuroses and fasciae (see below).

## NEUROVASCULAR SUPPLY OF MUSCLE

## Vascular supply and lymphatic drainage

In most muscles, the major source artery enters on the deep surface, frequently in close association with the principal vein and nerve, forming a neurovascular hilum. The vessels subsequently course and branch within the connective tissue framework of the muscle. Smaller arteries and arterioles ramify in the perimysial septa and give off capillaries that run in the endomysium. The smaller vessels lie mainly parallel to the muscle fibres, but also branch and anastomose around the fibres, forming an elongated mesh.

The gross vascular anatomy of muscles has been classified into five types according to the number and relative dominance of vascular pedicles that enter the muscle (Mathes and Nahai 1981) (Fig. 5.43). This classification has important surgical relevance in determining which muscles will survive, and therefore be useful for pedicled or free tissue transfer procedures in plastic and reconstructive surgery. Type I

Fig. 5.43 Classification of muscles according to their blood supply. (With permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd edn. Edinburgh: Churchill Livingstone.)
muscles possess a single vascular pedicle supplying the muscle belly, e.g. tensor fasciae latae (supplied by the ascending branch of the lateral circumflex femoral artery) and gastrocnemius (supplied by the sural artery). Type II muscles are served by a single dominant vascular pedicle and several minor pedicles, and can be supported on a minor pedicle as well as the dominant pedicle, e.g. gracilis (supplied by the medial circumflex femoral artery in the dominant pedicle). Type III muscles are supplied by two separate dominant pedicles, each from different source arteries, e.g. rectus abdominis (supplied by the superior and inferior epigastric arteries) and gluteus maximus (supplied by the superior and inferior gluteal arteries). Type IV muscles have multiple small pedicles that, in isolation, are not capable of supporting the whole muscle, e.g. sartorius and tibialis anterior; about $30 \%$ survive reduction on to a single vascular pedicle. Type V muscles have one dominant vascular pedicle and multiple secondary segmental pedicles, e.g. latissimus dorsi (supplied by the thoracodorsal artery as the primary pedicle, thoracolumbar perforators from the lower six intercostal arteries and the lumbar arteries as the segmental supply) and pectoralis major (supplied by the pectoral branch of the thoraco-acromial axis as the dominant pedicle, and anterior perforators from the internal thoracic vessels as the segmental supply).

In cross-sections of muscle, the number of capillary profiles found adjacent to fibres usually varies from 0 to 3 . Muscle fibres involved in sustained activities, such as posture, are served by a denser capillary network than fibres that are recruited only infrequently. It is common for muscles to receive their arterial supply via more than one route. The accessory arteries penetrate the muscle at places other than the hilum, and ramify in the same way as the principal artery, forming vascular territories. The boundaries of adjacent territories are spanned by anastomotic vessels, sometimes at constant calibre, but more commonly through reduced-calibre arteries or arterioles that are referred to as 'choke vessels'. These arterial arcades link the territories into a continuous network.

Veins branch in a similar way, forming venous territories that correspond closely to the arterial territories. In the zones where the arterial territories are linked by choke vessels, the venous territories are linked by anastomosing veins: in this case, without change of calibre. On either side of these venous bridges, the valves in the adjacent territories direct flow in opposite directions towards their respective pedicles, but the connecting veins themselves lack valves and therefore permit flow in either direction.

Because of the potential for relative movement within muscle groups, vessels tend not to cross between muscles, but radiate to them from more stable sites or cross at points of fusion. Where a muscle underlies the skin, blood vessels bridge between the two. These may be primarily cutaneous vessels, which supply the skin directly but contribute small branches to the muscle as they pass through it, or they may be the terminal branches of intramuscular vessels, which leave the muscle to supplement the cutaneous blood supply. The latter are less frequent where the muscle is mobile under the deep fascia. Correspondence between the vascular territories in the skin and underlying tissues gave rise to the concept of angiosomes, which are composite blocks of tissue supplied by named distributing arteries and drained by their companion veins (see Taylor and Pan (1998) for further analyses of muscle angiosomes).

Pressure exerted on valved intramuscular veins during muscle contraction functions as a 'muscle pump' that promotes venous return to the heart. In some cases this role appears to be amplified by veins that pass through the muscle after originating elsewhere in superficial or deep tissues. The extent to which the muscle capillary bed is perfused can be varied in accordance with functional demand. Arteriovenous anastomoses, through which blood can be returned directly to the venous system without traversing the capillaries, provide an alternative, regulated pathway.

The lymphatic drainage of muscles begins as lymphatic capillaries in epimysial and perimysial, but not endomysial, sheaths. These converge to form larger lymphatic vessels that accompany the veins and drain to the regional lymph nodes.

## Innervation

Every skeletal muscle is supplied by one or more nerves. Muscles in the limbs, face and neck are usually innervated by a single nerve, even though the axons it contains may be derived from neurones located in several spinal cord segments and their associated ganglia. Muscles such as those of the abdominal wall, which originate from several embryonic segments, are supplied by more than one nerve. In most cases, the nerve travels with the principal blood vessels within a neurovascular bundle
(see Fig. 2.9), approaches the muscle near to its least mobile attachment, and enters the deep surface at a position that is more or less constant for each muscle.

Nerves supplying muscle are frequently referred to as 'motor nerves' but they contain both motor and sensory components. The motor component is mainly composed of large, myelinated $\alpha$-efferent axons, which supply the muscle fibres, supplemented by small, thinly myelinated $\gamma$-efferents, or fusimotor fibres, which innervate the intrafusal muscle fibres of neuromuscular spindles (see p. 60), and fine, unmyelinated autonomic efferents, which innervate vascular smooth muscle. The sensory component consists of large, myelinated IA and smaller group II afferents from the neuromuscular spindles, large myelinated IB afferents from the Golgi tendon organs (see p. 59), and fine myelinated and unmyelinated axons that convey pain and other sensations from free terminals in the connective tissue sheaths of the muscle.

Within muscles, nerves travel through the epimysial and perimysial septa before entering the fine endomysial tissue around muscle fibres. Alpha-motor axons branch repeatedly before they lose their myelinated sheaths to terminate in a narrow zone towards the centre of the muscle belly, known as the motor point. Clinically, this is the place on a muscle from which it is easiest to elicit a contraction with stimulating electrodes. Long muscles generally have two or more terminal (end-plate) bands because many muscle fibres do not run the full length of an anatomical muscle. The terminal branch of an $\alpha$-motor axon contacts a muscle fibre at a specialized synapse, the neuromuscular junction (see Fig. 3.34). It gives off several short, tortuous branches, each ending in an elliptical area, the motor end-plate. The underlying discoidal patch of sarcolemma, the sole plate or subneural apparatus, is thrown into deep synaptic folds. This discrete type of neuromuscular junction (en plaque ending) is found on muscle fibres that are capable of propagating action potentials. A different type of ending is found on slow tonic muscle fibres that do not have this capability, e.g. in the extrinsic ocular muscles, where slow tonic fibres form a minor component of the anatomical muscle. In this case the propagation of excitation is taken over by the nerve terminals, which branch over an extended distance to form a number of small neuromuscular junctions (en grappe endings). Some muscle fibres of this type receive the terminal branches of more than one motor neurone. The terminals of the $\gamma$-efferents that innervate the intrafusal muscle fibres of the neuromuscular spindle also take a variety of different forms.

The terminal branches of $\alpha$-motor axons are normally in a 'one-toone' relationship with their muscle fibres: a muscle fibre receives only one branch, and any one branch innervates only one muscle fibre. When a motor neurone is excited, an action potential is propagated along the axon and all of its branches to all of the muscle fibres that it supplies. The motor neurone and the muscle fibres that it innervates can therefore be regarded as a functional unit: the 'motor unit'. This arrangement accounts for the more or less simultaneous contraction of a number of fibres within the muscle. The size of a motor unit varies considerably. In muscles used for precision tasks, such as the extraocular and intrinsic laryngeal muscles, each motor neurone innervates perhaps ten muscle fibres. In a large limb muscle, a motor neurone may innervate several hundred muscle fibres. Within a muscle, fibres belonging to one motor unit are distributed over a wide territory, without regard to fascicular boundaries, and they intermingle with the fibres of other motor units. Motor units become larger in cases of nerve damage because denervation induces collateral or terminal sprouting of the remaining axons. Each new branch can reinnervate a fibre, thus increasing the territory of its parent motor neurone.

## MUSCLE CONTRACTION

The arrival of an action potential at the motor end-plate of a neuromuscular junction causes acetylcholine (ACh) to be released from storage vesicles into the highly infolded $30-50 \mathrm{~nm}$ synaptic cleft that separates the nerve ending from the sarcolemma (see Fig. 3.34). ACh is rapidly bound by receptor molecules located in the junctional folds, triggering an almost instantaneous increase in the permeability, and hence conductance, of the postsynaptic membrane. This generates a local depolarization (the end-plate potential), which initiates an action potential in the surrounding sarcolemma. The activity of the neurotransmitter is rapidly terminated by the enzyme acetylcholinesterase (AChE), which is bound to the basal lamina in the sarcolemmal junctional folds. The sarcolemma is an excitable membrane, and action potentials generated at the neuromuscular junction propagate rapidly over the entire surface of the muscle fibre.

Action potentials are conducted radially into the interior of the fibre via the T-tubules, which are extensions of the sarcolemma, ensuring that
all parts of the muscle fibre are activated rapidly and almost synchronously. Excitation-contraction coupling is the process whereby an action potential triggers the release of calcium from the terminal cisternae of the sarcoplasmic reticulum into the cytosol. This activates a calcium-sensitive switch in the thin filaments and so initiates contraction. At the end of excitation, the T-tubular membrane repolarizes, calcium release ceases, calcium ions are actively transported back to the calsequestrin stores in the sarcoplasmic reticulum by the calciumATPase pumps, and the muscle relaxes.

The lengths of the thick and thin filaments do not change during muscle contraction. The sarcomere shortens by the sliding of thick and thin filaments past one another, which draws the Z-discs towards the middle of each sarcomere (see Fig. 5.40). As the overlap increases, the I- and H-bands narrow to near-extinction, while the width of the A-bands remains constant. Filament sliding depends on the making and breaking of bonds (cross-bridge cycling) between myosin head regions and actin filaments. Myosin heads 'walk' or 'row' along actin filaments using a series of short power strokes, each resulting in a relative movement of 5-10 nm. Actin filament binding sites for myosin are revealed only by the presence of calcium, which is released into the sarcoplasm from the sarcoplasmic reticulum, causing a repositioning of the troponin-tropomyosin complex on actin: this is the calcium-sensitive switch. Myosin head binding and release are both energy-dependent and require ATP. In the absence of ATP (as occurs post mortem) the bound state is maintained, and is responsible for the muscle stiffness known as rigor mortis.

The summation of myosin power strokes leads to an average sarcomere shortening of up to $1 \mu \mathrm{~m}$; an anatomical muscle shortens by a centimetre or more, depending on the muscle, because each muscle has thousands of sarcomeres in series along its length.

## Slow-twitch versus fast-twitch fibres

The passage of a single action potential through a motor unit elicits a twitch contraction where peak force is reached within $25-100 \mathrm{~ms}$, depending on the motor unit type involved. However, the motor neurone can deliver a second nervous impulse in less time than it takes for the muscle fibres to relax. When this happens, the muscle fibres contract again, building the tension to a higher level. Because of this mechanical summation, a sequence of impulses can evoke a larger force than a single impulse and, within certain limits, the higher the impulse frequency, the more force is produced ('rate recruitment'). An alternative strategy is to recruit more motor units. In practice, the two mechanisms appear to operate in parallel, but their relative importance may depend on the size and/or function of the muscle; in large muscles with many motor units, motor unit recruitment is probably the more important mechanism.

With the exception of rare tonic fibres, skeletal muscles are composed entirely of fibres of the twitch type. These fibres can all conduct action potentials but they differ in other respects. Some fibres obtain their energy very efficiently by aerobic oxidation of substrates, particularly of fats and fatty acids. They have large numbers of mitochondria; contain myoglobin, an oxygen-transport pigment related to haemoglobin; and are supported by a well-developed network of capillaries that maintains a steady nutrient supply of oxygen and substrates. Such fibres are well suited to functions such as postural maintenance, in which moderate forces need to be sustained for prolonged periods. At the other end of the spectrum, some fibres have few mitochondria, little myoglobin and a sparse capillary network, and store energy as cytoplasmic glycogen granules. Their immediate energy requirements are met largely through anaerobic glycolysis, a route that provides prompt access to energy but that is less sustainable than oxidative metabolism. They are capable of brief bursts of intense activity that must be separated by extended quiescent periods during which intracellular pH and phosphate concentrations are restored to normal values, and glycogen and other reserves are replenished.

In some animals, different types of muscle fibre tend to be segregated into different muscles. This causes some muscles to have a conspicuously red appearance, reflecting their rich blood supply and high myoglobin content associated with a predominantly aerobic metabolism, whereas other muscles have a much paler appearance, reflecting a more anaerobic character. These variations in colour led to the early classification of muscle into red and white types. This classification has now been largely superseded by myosin-based typing and the presence of specific disease-related enzymes.

In humans, all muscles are mixed, with fibres specialized for aerobic working conditions intermingling with fibres of a more anaerobic or intermediate metabolic character. Different types of fibre are not readily

Table 5.1 Physiological, structural and biochemical characteristics of the major histochemical fibre types

| Characteristic | Fibre types |  |  |
| :--- | :--- | :--- | :--- |
|  | TYPE I | TYPE IIA | TYPE IIX |
| Physiological |  |  |  |
| Function | Sustained forces, | Powerful, fast movements |  |
|  | as in posture |  |  |
| Motor neurone firing threshold | Low | Intermediate | High |
| Motor unit size | Small | Large | Large |
| Firing pattern | Tonic, | Phasic, high-frequency |  |
|  | low-frequency |  |  |
| Maximum shortening velocity | Slow | Fast | Fast |
| Rate of relaxation | Slow | Fast | Fast |
| Resistance to fatigue | Fatigue-resistant | Fatigue-resistant | Fatigue-susceptible |
| Power output | Low | Intermediate | High |
| Structural |  |  |  |
| Capillary density | High | Intermediate | Low |
| Mitochondrial volume | High | Narrow | Narrow |
| Z-disc | Broad |  | Extensive |
| T-tubule and sarcoplasmic | Sparse |  |  |
| reticulum systems |  |  | High |
| Biochemical |  |  | Intermediate |
| Myosin ATPase activity | Low | Ligh |  |
| Oxidative metabolism |  |  |  |
| Anaerobic glycolysis | Low |  |  |
| Calcium transport ATPase | Low |  |  |

distinguished in routine histological preparations but are clear when specialized enzyme histochemical techniques are used. On the basis of metabolic differences, individual fibres can be classified as oxidative slow-twitch (red) fibres or glycolytic fast-twitch (white) fibres. Muscles composed mainly of oxidative slow-twitch fibres correspond to the red muscles of classical descriptions. Muscles that are predominantly oxidative in their metabolism contract and relax more slowly than muscles relying on glycolytic metabolism. This difference in contractile speed is due in part to the activation mechanism (volume density of the sarcotubular system and proteins of the calcium 'switch' mechanism), and in part to molecular differences between the myosin heavy chains of these types of muscle. These differences affect the ATPase activity of the myosin head, which in turn alters the kinetics of its interaction with actin, and hence the rate of cross-bridge cycling. Differences between myosin isoforms can be detected histochemically, and ATPase histochemistry continues to play a significant role in diagnostic typing (Table 5.1). Two main categories have been described: type I fibres, which are slow-contracting, and type II, which are fast-contracting. Molecular analyses have revealed that type II fibres can be further subdivided according to their content of myosin heavy-chain isoforms into types IIA and IIX. Muscle fibres may contain only one (i.e. a pure fibre) or a combination (i.e. a hybrid fibre) of these isoforms; the five most prevalent muscle fibre types in humans are I, I/IIA, IIA, IIA/IIX, IIX. (For further reading, see Galpin et al (2012), Holland and Ohlendieck (2013).) There is a correlation between categories and fatigue resistance, such that type I fibres are generally oxidative (slow oxidative) and resistant to fatigue; type IIA are moderately oxidative, glycolytic (fast oxidative glycolytic) and fatigue-resistant; and type IIX largely rely on glycolytic metabolism (fast glycolytic) and so are easily fatigued.

## Fibre type transformation

Fibre type proportions in a named muscle may vary between individuals of different age or athletic ability. Fibre type grouping, where fibres with similar metabolic and contractile properties aggregate, increases after nerve damage and with age. Grouping occurs as a result of reinnervation episodes, where denervated fibres are 'taken over' by a sprouting motor neurone and adopt its type properties. If the nerves to fast white and slow red muscles are cut and cross-anastomosed in experimental animals, so that each muscle is reinnervated by the other's nerve, the fast muscle becomes slower-contracting, and the slow muscle fastercontracting. There is evidence that such fibre type transformation may be a response to the patterns of impulse traffic in the nerves innervating the muscles (Minetto et al 2013). If fast muscles are stimulated continuously for several weeks at 10 Hz , a pattern similar to that normally experienced by slow muscles, they develop slow contractile characteristics and acquire a red appearance and a resistance to fatigue even greater than that of slow muscles.

The initial phase of slowing can be explained by less rapid cycling of calcium, resulting from reduced sarcoplasmic reticulum and changes in the amount and molecular type of proteins involved in calcium transport and binding. Chronic stimulation also triggers the synthesis of myosin heavy and light chain isoforms of the slow muscle type; the associated changes in cross-bridge kinetics result in a lower intrinsic speed of shortening. The muscle becomes more resistant to fatigue through changes in the metabolic pathways responsible for the generation of ATP and a reduced dependence on anaerobic glycolysis. There is a switch to oxidative pathways, particularly those involved in the breakdown of fat and fatty acids, and an associated increase in capillary density and in the fraction of the intracellular volume occupied by mitochondria. If stimulation is discontinued, the sequence of events is reversed and the muscle regains, over a period of weeks, all of its original characteristics. The reversibility of transformation is one of several lines of evidence that the changes take place within existing fibres, and not by a process of degeneration and regeneration.

Many of the changes in the protein profile of a muscle that are induced by stimulation are now known to be the result of transcriptional regulation. For example, analysis of the messenger RNA species encoding myosin heavy chain isoforms shows that expression of the fast myosin heavy chain mRNA is downregulated within a few days of the onset of chronic stimulation, while the slow myosin heavy chain mRNA is upregulated. Although myosin isoform expression is responsive to the increase in use induced by chronic stimulation, it tends to be stable under physiological conditions unless these involve a sustained departure from normal postural or locomotor behaviour.

## DEVELOPMENT AND GROWTH OF SKELETAL MUSCLE

Most information about the early development of the skeletal musculature in humans has been derived from other vertebrate species. However, where direct comparisons with the developing human embryo have been made, the patterns and mechanisms of muscle formation have been found to be the same.

The majority of the skeletal muscle in the body develops from paraxial mesenchyme and its segmental derivatives, the somites. A small portion forming the extraocular muscles is derived from prechordal mesenchyme, which joins with the most rostral paraxial mesenchyme and which has been demonstrated to have a myogenic fate. Skeletal muscle precursor myoblasts are derived from dermomyotomes, the lateral portion of the somites (see Fig. 44.3).

## Myogenic determination factors

Myogenic determination factors, which can be detected in somites prior to morphogenetic changes, are a family of nuclear phosphoproteins that includes Myf-5, myogenin, MyoD and Myf-6 (herculin). They have in common a 70-amino-acid, basic helix-loop-helix (bHLH) domain that is essential for protein-protein interactions and DNA binding. Outside the bHLH domain there are sequence differences between the factors that probably confer some functional specificity. The myogenic bHLH factors play a crucial role in myogenesis. Forced expression of any of them diverts non-muscle cells to the myogenic lineage. They activate transcription of a wide variety of muscle-specific genes by binding directly to conserved DNA sequence motifs (-CANNTGknown as E-boxes) that occur in the regulatory regions (promoters and enhancers) of these genes. Their effect may be achieved cooperatively and can be repressed, e.g. by some proto-oncogene products. Some of the bHLH proteins can activate their own expression. Accessory regulatory factors, whose expression is induced by the bHLH factors, provide an additional tier of control.

Myogenic factors do not all appear at the same stage of myogenesis (Buckingham et al 2003). In the somites, Myf-5 is expressed early, before myotome formation, and is followed by expression of myogenin. MyoD is expressed relatively late, together with the contractile protein genes. Myf-6 is expressed transiently in the myotome and becomes the major transcript postnatally. Whether this specific timing is important for muscle development is not yet clear. The creation of mutant ('knockout') mice deficient in the bHLH proteins has shown that myogenin is crucial for the development of functional skeletal muscle, and that while neither $M y f-5$ nor $M y o D$ is essential to myogenic differentiation on its own, lack of both results in a failure to form skeletal muscle. In the limb bud the pattern of expression of the bHLH genes is generally later than in the somite: $M y f-5$ is expressed first but transiently, followed by myogenin and MyoD, and eventually Myf-6. These
differences provide evidence at the molecular level for the existence of distinct muscle cell populations in the limb and somites. It may be that the myogenic cells that migrate to the limb buds differ at the outset from those that form the myotome, or their properties may diverge subsequently under the influence of local epigenetic factors.

## Formation of muscle fibres

In both myotomes and limb buds, myogenesis proceeds in the following way. Myoblasts become spindle-shaped and begin to express muscle-specific proteins. The mononucleate myoblasts aggregate and fuse to form multinucleate cylindrical syncytia, or myotubes, in which the nuclei are aligned in a central chain (Fig. 5.44). These primary myotubes attach at each end to the tendons and developing skeleton.

Fig. 5.44 Stages in formation of skeletal muscle. Mononucleate myoblasts fuse to form multinucleate primary myotubes, characterized initially by central nuclei. Subsequently, other myoblasts align along the primary myotubes and begin to fuse with one another, forming secondary myotubes. In large animals, such as humans, further generations of new muscle fibres are similarly formed. As the contractile apparatus is assembled, the nuclei move to the periphery, cross-striations become visible and primitive features of the neuromuscular junction emerge. Later, small adult-type myoblasts - satellite cells - can be seen lying between the basal lamina and the sarcolemma of the mature muscle fibre. These too appear to be derived from cells that originated in the somites during early development. (Redrawn from a figure provided by Terry Partridge, Department of Genetic Medicine, Children's National Medical Center, Washington DC.)

The initiation of fusion does not depend on the presence of nerve fibres, since these do not penetrate muscle primordia until after the formation of primary myotubes.

Although synthesis of the contractile machinery is not dependent on fusion of myoblasts, it proceeds much more rapidly after fusion. Sarcomere formation begins at the Z-disc, which binds actin filaments constituting the I-band to form I-Z-I complexes. The myosin filaments assemble on the I-Z-I complexes to form A-bands. Nebulin and titin are among the first myofibrillar proteins to be incorporated into the sarcomere, and may well determine the length and position of the contractile filaments. Desmin intermediate filaments connect the Z-discs to the sarcolemma at an early stage, and these connections are retained.

Myogenic cells continue to migrate and to divide, and during weeks 7-9 there is extensive de novo myotube formation. Myoblasts aggregate near the midpoint of the primary myotubes and fuse with each other to form secondary myotubes, a process that may be related to early neural contact. Several of these smaller-diameter myotubes may be aligned in parallel with each of the primary myotubes. Each develops a separate basal lamina and makes independent contact with the tendon. Initially, the primary myotube provides a scaffold for the longitudinal growth of the secondary myotubes but eventually they separate. At the time of their formation, the secondary myotubes express an 'embryonic' isoform of the myosin heavy chains, whereas the primary myotubes express a 'slow' muscle isoform apparently identical to that found in adult slow muscle fibres. In both primary and secondary myotubes, sarcomere assembly begins at the periphery of the myotube and progresses inwards towards its centre. Myofibrils are added constantly and lengthen by adding sarcomeres to their ends. T-tubules are formed and grow initially in a longitudinal direction; since they contain specific proteins not found in plasma membranes, they are probably assembled via a different pathway from that which supports the growth of the sarcolemma. The sarcoplasmic reticulum wraps around the myofibrils at the level of the I-bands.

By 9 weeks, the primordia of most muscle groups are well defined, contractile proteins have been synthesized and the primitive beginnings of neuromuscular junctions can be observed, confined initially to the primary myotubes. Although some secondary fibre formation can take place in the absence of a nerve, most is initiated at sites of innervation of the primary myotubes. The pioneering axons branch and establish contact with the secondary myotubes. By 10 weeks these nerve-muscle contacts have become functional neuromuscular junctions and the muscle fibres contract in response to impulse activity in the motor nerves. Under this new influence, the secondary fibres express fetal (sometimes referred to as neonatal) isoforms of the myosin heavy chains. At this stage, several crucial events take place, which may be dependent on, or facilitated by, contractile activity. As the myofibrils encroach on the centre of the myotube, the nuclei move to the periphery and the characteristic morphology of the adult skeletal muscle myofibre is established. The myofibrils become aligned laterally, and A- and I-bands in register across the myotube produce cross-striations that are visible at the light microscopic level. T-tubules change from a longitudinal to a transverse orientation and adopt their adult positions; they may be guided in this process by the sarcoplasmic reticulum, which is more strongly bound to the myofibrils.

The myotubes and myofibres are grouped into fascicles by growing connective tissue sheaths, and fascicles are assembled to build up entire muscles. As development proceeds, the increase in intramuscular volume is accommodated by remodelling of the connective tissue matrix.

At 14-15 weeks, primary myotubes are still in the majority, but by 20 weeks the secondary myotubes predominate. During weeks $16-17$, tertiary myotubes appear; they are small and adhere to the secondary myotubes, with which they share a basal lamina. They become independent by 18-23 weeks, their central nuclei move to the periphery, and they contribute a further generation of myofibres. The secondary and tertiary myofibres are always smaller and more numerous than the primary myofibres. In some large muscles, higher-order generations of myotubes may be formed.

Late in fetal life, a final population of myoblasts appears, which will become the satellite cells of adult muscle. These normally quiescent cells lie outside the sarcolemma beneath the basal lamina (see Fig. 5.44; Fig. 5.45). M-cadherin, a cell adhesion protein of possible regulatory significance, occurs at the site of contact between a satellite cell and its muscle fibre. In a young individual, there is one satellite cell for every 5-10 muscle fibre nuclei. The latter are incapable of DNA synthesis and mitosis, and satellite cells are therefore important as the sole source of additional muscle fibre nuclei during postnatal growth of muscle (to maintain the ratio of cytoplasmic volume per nucleus as fibres increase
in mass). After satellite cells divide, one of the daughter cells fuses with the growing fibre, the other remaining as a satellite cell capable of further rounds of division. In adult skeletal muscle, satellite cells provide a reservoir of cells that enable exercise-induced hypertrophy, and regeneration of muscle after damage (see below).

## Development of fibre types

Developing myotubes express an embryonic isoform of myosin that is subsequently replaced by fetal and adult myosin isoforms. The major isoform of sarcomeric actin in fetal skeletal muscle is cardiac $\alpha$-actin; only later is this replaced by skeletal $\alpha$-actin. The significance of these developmental sequences is not known.

The pattern of expression is fibre-specific and changes over time. In primary myotubes, embryonic myosin is replaced by adult slow myosin from about 9 weeks onwards. In secondary and higher-order myotubes, the embryonic myosin isoform is superseded first by fetal and then by adult fast myosin, and a proportion go on to express adult slow myosin. Other fibre-specific, tissue-specific and species-specific patterns of myosin expression have been described in mammalian limb muscles and jaw muscles.

The origin of this diversity in the temporal patterns of expression of different fibres, even within the same muscle, is far from clear. It has been suggested that intrinsically different lineages of myoblast emerge at different stages of myogenesis or in response to different extracellular cues. If this is the case, their internal programmes may be retained or overridden when they fuse with other myoblasts or with fibres that have already formed. The fibres that emerge from this process go on to acquire a phenotype that will depend on the further influence of hormones and neural activity.

Fig. 5.45 An electron micrograph of a satellite cell. Note the two plasma membranes that separate the cytoplasm of the satellite cell from that of the muscle fibre, and the basal lamina (arrows) of the transversely sectioned muscle fibre, which continues over the satellite cell (see also Fig. 5.39a). Compare this appearance with the normal muscle nucleus, which is seen in the adjacent fibre at the top of the micrograph. (Photograph by Dr Michael Cullen, School of Neurosciences, University of Newcastle upon Tyne.)

In humans, unlike many smaller mammals, muscles are histologically mature at birth, but fibre type differentiation is far from complete. In postural muscles, the expression of type I ('slow') myosin increases significantly over the first few years of life. During this same period, the proportions of fibre types in other muscles become more divergent. The presence in adult muscles of a small proportion of fibres with an apparently transitional combination of protein isoforms reinforces the view that changes in fibre type continue to some extent in all muscles and throughout adult life. Fibre type transitions also occur in relation to damage or neuromuscular disease; under these conditions, the developmental sequence of myosins may be recapitulated in regenerating fibres.

## Growth and regulation of fibre length

Muscle fibres grow in length by addition of sarcomeres to the ends of myofibrils. In order for the mean sarcomere length, and hence filament overlap, to be optimized for maximum force, the number of sarcomeres must be regulated throughout life. This is achieved by the addition or removal of sarcomeres in response to any prolonged change of length. For example, if a limb is immobilized in a plaster cast, the fibres of muscles that have been fixed in a shortened position lose sarcomeres, while those that have been fixed in a lengthened position add sarcomeres; the reverse process occurs after the cast has been removed.

## Satellite cells and muscle repair

Until the mid-20th century, the mechanisms responsible for maintenance and repair of skeletal muscle were unclear. These issues were largely resolved by the discoveries that multinucleated muscle fibres were formed by the fusion of mononucleated precursors, myoblasts, and that a population of satellite cells, so called because of their position on the edge of the fibre, exist between the basal lamina of the mature muscle fibre and its sarcolemma, where they constitute 2-5\% of the nuclei enclosed by the basal lamina.

Studies in mouse models, where genetic analysis is possible, have shown that the functional properties of postnatal satellite cells depend on the expression of the Pax7 gene, whereas the prenatal development of muscle is not similarly dependent. This implies that satellite cells are not simply the relics of prenatal myogenic cells, even though they appear to be derived from the same embryonic source in the somites. Moreover, satellite cells are not a homogeneous population: no two differentiation markers concur completely. This is also the situation in human tissue (Fig. 5.46). It has yet to be determined whether this variation reflects a difference in position in the lineage, functional status or adjacent environment.

The satellite cell has been established rigorously in mice as being both necessary and sufficient for effective regeneration of damaged skeletal muscle (Relaix and Zammit 2012). These cells proliferate to replace their resident region of muscle in 3-4 days and to replenish the quiescent satellite cell population. In humans, there is histological evidence of the rapid accumulation of myoblasts, presumably derived from local satellite cells, at sites of muscle damage. The presumed central role of satellite cells in muscle growth and adaptation has, however, been questioned by some recent research. Satellite cells are undoubtedly important during early postnatal development and growth, and in muscle regeneration following acute injury or eccentric damage. In other situations, however, regulation of protein synthesis

Fig. 5.46 Two adjacent sections, fluorescenceimmunolabelled, of a regenerating muscle fibre in a power lifter's trapezius. A, Anti-laminin antibody (red) shows basal lamina. Anti-CD56 (green) is a marker of myogenic cells and of newly formed myotubes. B, Basal lamina (red) and myogeninpositive nuclei (green). Basal laminae outline transversely sectioned muscle fibres, including the original outline of the regenerating fibre (centre field). Numerous small blood vessels, also outlined by basal laminae, are present and probably reflect local inflammation. Within the CD56-positive zone, several nuclei (one arrowed) are positive for myogenin, indicating their terminally differentiated status. Numerous other nuclei (Hoechst dye, blue) within the basal lamina surrounding the area of regeneration probably include proliferating myogenic cells and inflammatory cells. (Courtesy of Ms Mona Lindström and Professor Lars-Eric Thornell, Department of Anatomy, Umeå University, Sweden.)
and degradation may be more important determinants of muscle mass （Schiaffino et al 2013）．
A detail of wide pathological interest is the demonstration that the failing regenerative potency of satellite cells in ageing muscle seems in large part to be attributable to age－related changes in the systemic envi－ ronment rather than a decline in the intrinsic capabilities of the satellite cells themselves（Conboy et al 2005）．

## Regulation of muscle mass

Muscles respond to resistance exercise in training，or rehabilitation fol－ lowing illness or injury，by increasing in mass．This process is termed hypertrophy，particularly when applied to the increased muscle bulk that occurs in response to intense physical activity．Individual muscle fibres increase in size by the synthesis of new myofibril proteins， increased protein turnover rates and the recruitment of satellite cells to provide new nuclei for existing fibres or to form new myotubes．In inactivity，as seen in those confined to bed or wheelchair，in immobi－ lized limbs，and in patients with disorders of voluntary movement， muscles decrease in mass．This is termed atrophy，or disuse atrophy，in contrast to the pathological wasting of skeletal muscle associated with some disease states，including cancer cachexia，heart failure，diabetes and obesity．It is also recognized that loss of skeletal muscle mass and function may be a consequence of normal healthy ageing，when it is termed sarcopenia．There is experimental evidence that this process may be associated with apoptosis of satellite cells and capillary endothelial cells（Wang et al 2014）．

## FORM AND FUNCTION OF SKELETAL MUSCLE

The names given to individual muscles are usually descriptive and are based on their shape，size，number of heads or bellies，position，depth， attachments or actions．The meanings of some of the terms used are summarized in Table 5．2．The functional roles implied by the names should be interpreted with caution because they are often oversimpli－
fied，and terms denoting action may emphasize only one of a number of usual actions．A given muscle may play different roles in different movements and these roles may change if the movements are assisted or opposed by gravity．

## Fibre architecture

Muscles can be classified according to their general shape and the pre－ dominant orientation of their fibres relative to the direction of pull（Fig． 5．47）．Muscles with fibres（cells）that are largely parallel to the line of pull vary in form from flat，short and quadrilateral（e．g．thyrohyoid） to long and strap－like（e．g．sternohyoid，sartorius）．In such muscles， individual fibres may run for the entire length of the muscle，or over

Table 5．2 Terms used in naming muscles

| Shape | Depth | Position |
| :--- | :--- | :--- |
| Deltoid（triangular） | Superficialis（superficial） | Anterior，posterior，medial， |
| Quadratus（square） | Profundus（deep） | lateral，superior，inferior， |
| Rhomboid | Externus／externi（external） | supra－，infra－ |
| （diamond－shaped） | Internus／interni（internal） | Interosseus（between |
| Teres（round） | Attachment | bones） |
| Gracilis（slender） | Sternocleidomastoid（from | Aorsi（of the back） |
| Rectus（straight） | Abdominis（of the abdomen） |  |
| Lumbrical（worm－like） | mastoid and clavicele to | Pectoralis（of the chest） |
| Size | Coracobrachialis（from the | Brachii（of the arm） |
| Memoris（of the thigh） |  |  |
| Mrevis，minor，longus（long） | coracoid process to the | Oris（of the mouth） |
| Latissimus（broadest） | arm） | Oculi（of the eye） |
| Longissimus（longest） |  | Action |
| Number of heads or |  | Extensor，flexor |
| bellies |  | Abductor，adductor |
| Biceps（two heads） |  | Levator，depressor |
| Triceps（three heads） |  | Supinator，pronator |
| Quadriceps（four heads） |  |  |
| Digastric（two bellies） |  |  |

Fig．5．47 Morphological＇types＇of muscle based on their general form and fascicular architecture．

Fig. 5.48 The 'detorsion' or untwisting that results from the contraction of a spirally arranged muscle.
shorter segments when there are transverse, tendinous intersections at intervals (e.g. rectus abdominis). In a fusiform muscle, the fibres may be close to parallel in the 'belly', but converge to a tendon at one or both ends. Where fibres are oblique to the line of pull, muscles may be triangular (e.g. temporalis, adductor longus) or pennate (feather-like) in construction. The latter vary in complexity from unipennate (e.g. flexor pollicis longus) and bipennate (e.g. rectus femoris, dorsal interossei) to multipennate (e.g. deltoid). Fibres may pass obliquely between deep and superficial aponeuroses, in a type of 'unipennate' form (e.g. soleus), or they may start from the walls of osteofascial compartments and converge obliquely on a central tendon in circumpennate fashion (e.g. tibialis anterior). Muscles may exhibit a spiral or twisted arrangement (e.g. sternocostal fibres of pectoralis major or latissimus dorsi, which undergo a $180^{\circ}$-twist between their medial and lateral attachments). Muscles may spiral around a bone (e.g. supinator, which winds obliquely around the proximal radial shaft), or contain two or more planes of fibres arranged in differing directions, a type of spiral sometimes referred to as cruciate (sternocleidomastoid, masseter and adductor magnus are all partially spiral and cruciate). Many muscles display more than one of these major types of arrangement, and show regional variations that correspond to contrasting, and in some cases independent, actions.

## Direction of force

Although muscles differ in their internal architecture, the resultant force must be directed along the line of the tendon, so forces transverse to this direction must be in balance (see Fig. 5.47; Fig. 5.48). In strap-like muscles, the transverse component is negligible. In fusiform, bipennate and multipennate muscles, symmetry in the arrangement of the fibres produces a balanced opposition between transverse components, whereas in asymmetrical muscles (e.g. unipennate muscles), the fibres generate an unopposed lateral component of force that is balanced by intramuscular pressure.

Muscles that incorporate a twist in their geometry unwind it as they contract, so that they tend not only to approximate their attachments but also to bring them into the same plane. Muscles that spiral around a bone tend to reduce the spiral on contraction, causing rotation.

## Force versus range of contraction

Muscle fibre architecture varies because some muscles are required to develop a large force on their tendinous insertion, whereas other muscles are required to move their insertion through a considerable distance. These demands are largely incompatible and require different muscle architecture.

The force developed by an active muscle depends on the tension developed in each muscle fibre. If all of the muscle fibres are parallel (as in the strap-like muscle in Figure 5.47), then the muscle force is equal to the sum of the tension in each fibre, and so will be proportional to the total cross-sectional area of those fibres. The range of contraction generated by an active muscle depends on the relative motion that can take place between the overlapping proteins in the sarcomere, and this sets a natural limit (approximately 30\%) to the amount of fibre shortening that can take place. Hence, the movement of the tendinous insertion is proportional to the length of the muscle fibres.

Fig. 5.49 Force vectors in an idealized pennate muscle. The increase in effective cross-sectional area made possible by this architecture outweighs the small reduction in the component of force acting in the direction of the tendon.

If these principles are applied to a long, strap-like muscle in which the fibres are predominantly parallel to the line of pull (see Fig. 5.47), it will be evident that the whole muscle will be able to contract by $30 \%$ of its length (the same as each muscle fibre). However, such a strap-like muscle contains relatively few muscle fibres, so the maximum tension it can develop will not be great. Compare this to the bipennate muscle in Figure 5.49, which contains perhaps three times as many muscle fibres, all set at an angle (typically $30^{\circ}$ ) to the axis of the tendon. Each short fibre will not be able to contract very far, and the contraction of the tendon will be even less, because the muscle fibres are pulling on it obliquely. So, the bipennate muscle has a poor contraction distance. However, the total force its fibres can generate will be approximately three times as great as the tension in the strap-like muscle. Even after this force is reduced to allow for its obliquity (in this case by $\cos 30^{\circ}$, which equals 0.87 ), the overall tension in the direction of the tendon will exceed that in the strap-like muscle by a factor of $2.6(3 \times 0.87)$. So, the bipennate muscle sacrifices contraction distance for greater maximum force. This effect would be much greater in the multipennate muscle shown in Figure 5.47.

## Force, strength and power

In descriptions of muscle performance, 'force', 'strength' and 'power' are often used interchangeably but these terms are not synonymous. When considering human performance, it is possible for strength to increase without a concomitant increase in the true force-generating capacities of the muscles involved. Strength is usually measured under circumstances that require the participation of several muscles, and so depends on skilful coordination of these muscles as well as the forces they generate. This disparity can be marked during the early stages of physical training.

Power is the rate at which a muscle can perform external work, and is equal to force multiplied by contraction velocity. Since force depends on the total cross-sectional area of muscle fibres, and velocity (the rate of muscle shortening) depends on muscle fibre length, powerful muscles tend to be long as well as fat. A prime example is the quadriceps, which is the prime mover when someone stands up from a seated position. A lack of power in this and other muscles is the critical factor that limits the ability of many elderly people to live independently (Reid and Fielding 2012).

## Actions of muscles

Historically, the actions of specific muscles were estimated from simple observation. Muscle attachments were identified by dissection, and their probable action deduced from the line of pull. With the use of localized electrical stimulation it became possible to study the actions of selected muscles systematically in the living subject. This approach was pioneered by Duchenne de Boulogne in the mid-19th century. However, the study of isolated muscles cannot reveal the manner in which they interact during voluntary movements. Duchenne appreciated this, and supplemented electrical stimulation with observations of patients with partial paralysis to make more accurate deductions about the way in which muscles cooperate. Manual palpation can be used to detect muscle contraction, but only in superficial muscles under quasi-static conditions. Modern knowledge of muscle action has
been acquired almost entirely by recording the electrical activity that accompanies mechanical contraction, a technique known as electromyography (EMG). This technique can be used to study activation of deep as well as superficial muscles, under static and dynamic conditions. Multiple channels of EMG can reveal coordination between different muscles that participate in a movement. These data can be further supplemented by monitoring joint angle and ground reaction force, and by recording the movement on camera or with a three-dimensional motion analysis system.

Conventionally, the action of a muscle is defined as the movement that takes place when it contracts. However, this is an operational definition: equating 'contraction' with shortening, and 'relaxation' with lengthening is too simple in the context of whole muscles and real movements. Whether a muscle approximates its attachments on contraction depends on the degree to which it is activated, and the forces against which it has to act.

Movements that involve shortening of an active muscle are termed concentric, e.g. contraction of biceps/brachialis while raising a weight and flexing the elbow. Movements in which the active muscle undergoes lengthening are termed eccentric, e.g. in lowering the weight previously mentioned, biceps/brachialis 'pays out' length as the elbow extends. Eccentric contractions stretch the collagenous tissue sheaths within muscle (see below), which increases the risk of tears in muscles such as the hamstrings, and of a more general delayed-onset muscle soreness (Proske and Morgan 2001). Muscle contraction that does not involve change in muscle length is isometric.

Natural movements are accomplished by groups of muscles. Each muscle may be classified, according to its role in the movement, as a prime mover, antagonist, fixator or synergist. It is usually possible to identify one or more muscles that are consistently active in initiating and maintaining a movement: these are its prime movers. Muscles that wholly oppose the movement, or initiate and maintain the opposite movement, are antagonists. For example, brachialis is the prime mover in elbow flexion, and triceps is the antagonist. To initiate a movement, a prime mover must overcome passive and active resistance and impart an angular acceleration to a limb segment until the required angular velocity is reached; it must then maintain a level of activity sufficient to complete the movement.

When prime movers and antagonists contract together they behave as fixators, stabilizing the corresponding joint by increased transarticular compression, and creating an immobile base on which other prime movers may act. For example, flexors and extensors of the wrist co-contract to stabilize the wrist when an object is grasped tightly in the fingers.

Acting across a uniaxial joint, a prime mover produces a simple movement. Acting at multiaxial joints, or across more than one joint, prime movers may produce more complex movements that contain elements that have to be eliminated by contraction of other muscles. The latter assist in accomplishing the movement and are considered to be synergists, although they may act as fixators, or even as partial antagonists of the prime mover. For example, flexion of the fingers at the interphalangeal and metacarpophalangeal joints is brought about primarily by the long flexors, superficial and deep. However, these also cross intercarpal and radiocarpal joints, and if movement at these joints were unrestrained, finger flexion would be less efficient. Synergistic contraction of the carpal extensors eliminates this movement, and even produces some carpal extension, which increases the efficiency of the desired movement at the fingers.

In the context of different movements, a given muscle may act as a prime mover, antagonist, fixator or synergist. Even the same movement may involve a muscle in different ways if it is assisted or opposed by gravity. For example, in thrusting out the hand, triceps is the prime mover responsible for extending the forearm at the elbow, and the flexor antagonists are largely inactive. However, when the hand lowers a heavy object, the extensor action of the triceps is replaced by gravity, and the movement is controlled by active lengthening (eccentric 'contraction') of the flexors. It is important to remember that all movements take place against the background of gravity and its influence must not be overlooked.

## TENDONS AND LIGAMENTS

Forces developed by skeletal muscles are transferred to bone by tendons, aponeuroses and fasciae, whereas ligaments prevent excessive separation of adjacent bones. All of these structures comprise dense fibrous connective tissues containing a high proportion of type I collagen.

Fig. 5.50 The attachment of a tendon (pink) to skeletal muscle (orange). The regular dense connective tissue of the tendon consists of parallel bundles of type I collagen fibres, which are orientated in the long axis of the tendon and the muscle to which it is attached. A few elongated fibroblast nuclei are visible in the tendon. (Trichrome stain.)

## TENDONS

## Gross structure and function

Tendons take the form of whitish-looking cords or straps, with a round or oval cross-section. They are composed of dense, regular connective tissue; $60 \%$ of their dry weight consists of large crimped fibres of collagen type I (Fig. 5.50). Other components of their matrix include collagen types II and V, elastin, glycoproteins and proteoglycans (Wang 2006). Fascicles (bundles) of collagen fibres are orientated mainly parallel to the long axis of the tendon but are to some extent interwoven; they may be conspicuous enough to give tendons a longitudinally striated appearance to the unaided eye. Tendons generally have smooth surfaces, although large tendons may be ridged longitudinally by coarse fasciculi (as in the osseous aspect of the angulated tendon of obturator internus). Loose connective tissue between fascicles provides a conduit for small vessels and nerves; it condenses on the surface as a sheath or epitendineum, which may contain elastin and irregularly arranged collagen fibres. The loose attachments between this sheath and the surrounding tissue present little resistance to movements of the tendon. In situations where greater freedom of movement is required, a tendon is separated from adjacent structures by a synovial sheath.

Tendons are slightly elastic and can be stretched by 6-15\% of their length without damage (Wang 2006). Some of this extensibility is attributable to the reorientation of collagen type I fibres, some to the straightening of the crimped (wave-like) structure of these fibres, and some to sliding between adjacent collagen fibrils and fibres (Screen et al 2004). Sliding is possible because discrete collagen fibres appear to reinforce connective tissue in the manner of a 'chopped fibre-composite' material such as fibre glass (Hukins and Aspden 1985), rather than by forming a fixed scaffold (which would make growth difficult). It takes a great deal of energy to stretch a long and strong tendon, and most of this elastic 'strain energy' can be recovered when the tension is released. During locomotion, the rhythmic storing and releasing of strain energy in stretched tendons helps to smooth the movement, so that tendons (rather than cartilage) act as the body's natural shock absorbers. This energy storage and release also reduces the metabolic cost of locomotion. Tendons are sufficiently flexible that they can be diverted around osseous surfaces or deflected under retinacula to redirect the angle of pull.

The vascular supply of tendon is sparse but not negligible. Small arterioles from adjacent muscle tissue pass longitudinally between the fascicles, branching and anastomosing freely, and are accompanied by venae comitantes and lymphatic vessels. This longitudinal plexus is augmented by small vessels from adjacent loose connective tissue or synovial sheaths. Vessels rarely pass between bone and tendon at osseous attachments, and the junctional surfaces are usually devoid of foramina. A notable exception is the calcaneal (Achilles) tendon, which does receive a blood supply across its osseotendinous junction. During postnatal development, tendons enlarge by interstitial growth, particularly at myotendinous junctions, where there are high concentrations of fibroblasts. Growth decreases along a tendon from the muscle to the osseous attachments. The thickness finally attained by a tendon depends on the size and strength of the associated muscle, but also appears to

Fig. 5.51 The microstructure of bone at entheses. A, B, The cortical shell of bone (short arrows) is very thin at fibrocartilaginous attachment sites. In these examples showing the attachment of the tendons of triceps brachii (TB) and of fibularis longus (FL), the cortical shell is approximately the same thickness as the underlying trabeculae ( T ). Note that in A, the superficial trabeculae (long arrows) are aligned along the direction of pull of the tendon of triceps. C, In marked contrast, the layer of cortical bone (CB) at the fibrous attachment site of pronator teres (PT) to the mid-shaft of the radius, is much thicker.
D, Higher-power view of the cortical calcified shell of tissue at a fibrocartilaginous attachment site (the calcaneal or Achilles tendon), which consists of bone (B) and calcified fibrocartilage (CF). In this specimen, there are two tidemarks, TM1 and TM2, associated with the cortical shell of calcified tissue. TM1 is adjacent to the zone of uncalcified fibrocartilage (UF), and marks the mechanical boundary between hard and soft tissues. TM2 lies nearer the bone and indicates an earlier phase of calcification. Note the relative straightness of the tidemarks but the highly irregular interface between calcified fibrocartilage and bone (arrows), which is important in anchoring the tendon to the bone. Sections of human cadaveric bone stained with Masson's trichrome. (Photographs courtesy of Professor Michael Benjamin, Cardiff University, from sections cut and stained by S. Redman.)
be influenced by additional factors such as the degree of pennation of the muscle. The cellularity, and hence the metabolic rate, of large adult tendons is very low, but increases during infection or injury. Repair involves an initial proliferation of fibroblasts followed by interstitial deposition of new collagen fibres (Wang 2006). Complete remodelling (replacement) of the tissue, as seen in bone, does not occur in adult tendons, so healing tendons do not quite recover their original strength. Tendons can adapt their stiffness and strength to match prevailing mechanical demands, but the process is slow and may be incomplete (Rumian et al 2009).

The nerve supply to tendons is largely sensory and there is no evidence of any capacity for vasomotor control. Golgi tendon organs, specialized endings that are sensitive to force, are found near myotendinous junctions; their large myelinated afferent axons run within branches of muscular nerves or in small rami of adjacent peripheral nerves. They play an important role in 'tendon reflexes', which serve to protect the musculoskeletal system from injury.

## Tendon attachments

Muscles connect to bones by means of tendons, aponeuroses and fasciae. The epimysial, perimysial and endomysial sheaths within muscle coalesce at these attachments, and interdigitate with adjacent collagenous structures to form strong connections in which force transmission is aided by shear stress transfer.

At the myotendinous junction, muscle fibres separate into finger-like processes separated by insertions of tendinous collagen fibres. Although there are no desmosomal attachments at these junctions, other specializations assist in the transmission of force from the interior of the fibre to the extracellular matrix. Actin filaments from the adjacent sarcomeres, which would normally insert into a Z-disc at this point, instead penetrate a dense, subsarcolemmal filamentous matrix that provides attachment to the plasma membrane. This matrix is similar in character to the cytoplasmic face of an adherens junction. The structure as a whole is homologous to the intercalated discs of cardiac muscle. Integrins at the extracellular surface of the junctional sarcolemma provide contact with the basal lamina, which adheres closely to collagen and reticular fibres (type III collagen) of the adjacent tendon or other connective tissue structure.

Tendinous attachments to bone (also known as entheses or osteotendinous junctions) have been broadly categorized as either fibrocar-
tilaginous or fibrous (Benjamin et al 2006). In fibrocartilaginous entheses, four zones of tissue can be distinguished: pure dense fibrous connective tissue (continuous with and indistinguishable from the tendon), uncalcified fibrocartilage, calcified fibrocartilage, and bone (continuous with and indistinguishable from the rest of the bone). There are no sharp boundaries between zones, and the proportions of each component vary between entheses. A fibrocartilaginous enthesis is usually found where a tendon approaches the bone at a high angle, e.g. triceps brachii (Fig. 5.51A,B,D). At fibrous entheses, which are characteristic of the shafts of long bones, the tendon approaches the bone at an acute angle and merges with the periosteum before attaching to bone by dense fibrous connective tissue, e.g. pronator teres (Fig. 5.51C). Fibrous entheses generally attach to a greater area of bone compared to fibrocartilaginous entheses, enabling them to reduce stress.

## LIGAMENTS

The microstructure and biology of ligaments is broadly similar to that of tendons (Rumian et al 2007). Ligaments consist mostly of large crimped fibres of collagen type I, and their cells are predominantly elongated fibroblasts. However, there are two major differences between tendons and ligaments: one relating to gross structure, the other to composition. Structurally, ligaments tend to have fibres orientated in a range of directions because they must resist the separation of bones in more than one direction, whereas collagen fibres in a tendon must align with tension in the adjacent muscle. More diverse mechanical roles of ligaments are also reflected in their composition. For example, the ligamentum flavum, which joins adjacent vertebrae in the spine, has a very high elastin content which enables it to be stretched more than $80 \%$ when the spine is flexed, and yet remain under tension in all postures. Maintaining tension is important because this ligament lies adjacent to the spinal cord, and could impinge on it if it became slack (and buckled) when the spine was moved into extension.

## BIOMECHANICS

The purpose of this section is to explain, in a non-mathematical way, how mechanical principles shape the human musculoskeletal system. Mechanical considerations explain why bones are stiff and tendons are tough, why the surfaces of some synovial joints are imperfectly matched,

Fig. 5.52 The effects of different types of loading on a solid object (A) are illustrated in B-F.
and why some tendons insert closer to joints than others. The emerging subject of 'mechanobiology' considers how cells adapt their matrix to prevailing mechanical demands and explains why some tissues are better at doing this than others.

## MECHANICAL CONCEPTS

## Forces, moments and torques

A force is an action that deforms an object, or that causes it to move, and can be termed compressive, tensile or shear, according to the manner in which it deforms that object (Fig. 5.52). A force F acting at the end of a lever of length $L$ will generate a bending moment $(F \times L)$ acting about the pivot point of the lever. A torque or torsional moment (Fig. 5.52 F) may be quantified in similar terms. The combined influence of several forces can be calculated as shown in Figure 5.53. If the forces all act in the same direction, they may be added. However, if they act in different directions, each force must be resolved into two imaginary components that act in two anatomically convenient directions at $90^{\circ}$ to each other, using simple trigonometry. All components acting in the same direction are added to form two forces ( S and C in Fig. 5.53), which can be used to calculate the magnitude and direction of the single resultant force (which has a similar effect to all of the individual forces combined). Forces acting on a stationary object are analysed according to the principle that all forces acting in any given direction must balance each other (i.e. add to zero), and all moments or torques acting about a given pivot point must also balance each other.

## Mechanical properties of structures

Most anatomical structures deform readily when a sufficient force is applied to them, but their resistance to deformation increases steadily as the magnitude of the force increases. The resulting graph of force against deformation resembles the one shown in Figure 5.54. Stiffness is the ratio of force to deformation (typical units $\mathrm{N} / \mathrm{mm}$ ) and so is represented by the gradient of the graph. The initial region of low stiffness, or 'toe region', is followed by a stiffer region in which the graph is almost linear. In many biological structures, the 'toe region' can be explained by the straightening out of the zig-zag 'crimped' structure of collagen type I fibres, whereas the linear region represents direct stretching of the straightened collagen fibres and some slipping between them. If the deformed structure springs back immediately to its original

Fig. 5.54 A typical force-deformation graph for a skeletal structure subjected to mechanical loading. In the initial 'toe region', deformation increases rapidly with force, but this is followed by a linear region in which the deformation increases more slowly, and in proportion to the applied force. The gradient of the graph indicates the stiffness of the structure at any given load. Strength is the force at which an object becomes damaged, and this is usually interpreted either as the force at which the gradient first reduces (the elastic limit) or as the force when the gradient falls to zero (the ultimate strength).
dimensions when the deforming force is removed, the deformation is termed 'elastic'; a deformation that shows no sign of recovering is plastic; a deformation that recovers eventually, but gradually, is viscoelastic (see below). 'Strength' is the force at which an object becomes damaged, and is usually interpreted either as the force at which the gradient of the graph first reduces (the elastic limit) or as the force when the gradient falls to zero (the ultimate strength).

## Properties of materials

The properties of materials must be expressed in such a way that they are independent of the size and shape of the structure they constitute. A force divided by the area over which that force is applied gives a stress value (force per unit area); the resulting deformation divided by the original length of the object gives a strain value (fractional or percentage deformation). Stress divided by strain is the size-independent material equivalent of the stiffness of an object, and is an important physical property termed the 'modulus' (sometimes 'Young's modulus'). There are different types of modulus but essentially they are measures of stiffness, or resistance to deformation.

Fig. 5.55 This force-deformation graph shows how an object deforms when a force is applied to it (upward arrow) and how it recovers its shape when the force is gradually released (downward arrow). The area under the loading curve represents the strain energy that has been expended in deforming the object. The area under the unloading curve represents the energy that is given up when the object is allowed to spring back to its original shape. The small area in between represents energy that cannot be recovered but is dissipated as heat. This is the hysteresis energy.

## Energy and shock absorption

Deforming an object may require a considerable expenditure of energy. Technically, the work done (i.e. energy expended) is proportional to the average force exerted, multiplied by the distance moved. This is mathematically equivalent to the area under the graph in Figure 5.55, and is referred to as the strain energy, i.e. the energy expended in deforming the object. If the object has elastic properties, it will spring back to its original shape when the deforming force is removed, and all the strain energy is then released. (This release of strain energy explains why a stretched rope can recoil violently if it snaps.) Structures such as coiled springs, which can resist high forces and also deform extensively, are capable of storing large amounts of energy, and so can act as shock absorbers when they are continually compressed and stretched. Tendons act in a similar manner during locomotion: they store strain energy when they are stretched by muscle contraction, and release most of this energy when the muscles relax later in the gait cycle. A small fraction of the stored strain energy, the hysteresis energy, is dissipated as heat (see Fig. 5.55). This heat can cause the temperature to rise by several degrees centigrade in large tendons that are involved in vigorous repetitive activity. Any material or structure that is capable of absorbing large amounts of strain energy before failure is termed tough; otherwise it is brittle. From Figure 5.55 it is apparent that tough materials must be both strong and extensible. In contrast, brittle materials such as glass and tooth enamel undergo minimal deformation and so absorb little strain energy, even though they are strong. The shock-absorbing characteristics of tendons are important during locomotion, making movements smoother and reducing metabolic cost (Alexander 1988).

## Liquids

A liquid has negligible rigidity and so deforms readily to take the shape of its container. When compressed, it maintains practically the same volume, but it flows to equalize the intensity of loading within it. As a result, a static liquid under load exhibits a single internal pressure (force per unit area) that does not vary with location or direction. Even delicate objects are not deformed when immersed in a high-pressure liquid if they themselves are filled with liquid, because the internal and external pressures on them are exactly equal; this explains why cells can survive high pressures in liquids without damage to their delicate plasma membrane. Of the musculoskeletal tissues, only the nucleus pulposus of intervertebral discs exhibits true liquid behaviour (Adams 2013). Some other tissues, including bone and cartilage, contain liquid that is able to move through pores in the solid matrix.

Fig. 5.56 The deformation of viscoelastic materials varies with time. In this example, a load is applied at zero time, which causes an immediate elastic deformation, followed by a slowly increasing time-dependent deformation (creep). When the load is removed, some deformation is recovered immediately, but full recovery is achieved only slowly.

Table 5.3 Tensile material properties of skeletal tissues*

|  | Cortical bone | Tendon (ligament) | Articular cartilage |
| :--- | :--- | :--- | :---: |
| Strength $(\mathrm{MPa})$ | 130 | $50-110$ | $5-20 ?$ |
| Modulus $(\mathrm{MPa})$ | 17,000 | $500-1800(150-800)$ | $4-10$ |
| Failure strain $(\%)$ | $1-2.5$ | $10-20$ | $30-100$ |

*For comparison, alloy steel has a strength of 600 MPa and a modulus of $20,000 \mathrm{MPa}$.

## Viscoelasticity

Materials are said to be viscoelastic if they behave partly like a thick (viscous) fluid and partly like an elastic solid. Viscoelastic deformations change with time, even when the deforming stress is constant, and complete recovery from such deformations also takes some time after the stress is removed (Fig. 5.56). In most biological materials, viscous behaviour occurs because applied loading causes fluid to flow from the most heavily loaded regions to the least loaded, by percolating through very small (nanometre-scale) pores in the matrix, a process that can take hours; for this reason, the term poroelastic is often preferred to viscoelastic when referring to tissues such as cartilage.

Creep and stress relaxation are two important manifestations of viscoelasticity. Creep may be described as continuing deformation under constant load (see Fig. 5.56), whereas stress relaxation is a gradual decrease in force resisted by a viscoelastic material when it is initially deformed by a certain amount, and then held with the same constant deformation. Creep can reduce the thickness of loaded articular cartilage and intervertebral discs, typically by $20 \%$ in 5 minutes and 3 hours, respectively. Creep deformation is reversed over a similar timescale when the compressive loading is reduced and water is reabsorbed. Bone creeps at a much slower rate, but in old osteoporotic vertebrae, creep probably contributes to vertebral deformity (Luo et al 2012).

## MATERIAL PROPERTIES OF SKELETAL TISSUES

The material properties of several skeletal tissues are compared in Table 5.3.

## Bone

Bone consists mainly of collagen type I and microcrystals of the mineral hydroxyapatite. Collagen gives bone considerable tensile strength, and renders it very tough when fractured, whereas the mineral component gives bone a very high compressive modulus and high compressive
strength. Rigidity (stiffness) is the defining characteristic of bone; it enables the tissue to provide precisely shaped surfaces in synovial joints that will deform very little under load, and it also enables fast locomotion when muscles pull on bones. If bones were strong and tough but not rigid, rapid muscle contractions would cause them to bend alarmingly and would slow the angular movement of limbs.

## Tendon, ligament and fascia

Tendons, ligaments and fascia consist primarily of densely packed collagen type I fibres, giving these tissues high tensile strength. The crimped nature of the collagen fibres allows them to be stretched by up to $15 \%$ before failure, and this combination of strength and extensibility enables tendons, ligaments and fascia to absorb more strain energy per unit weight than any other biological material. An important difference between tendons and ligaments is that ligaments often contain bundles of collagen fibres orientated in a range of directions, presumably because bones can be moved apart in a range of directions, whereas the fibres in a tendon are all aligned with the direction of muscle tension. Fascia usually contains collagen fibres aligned in adjacent sheets to resist forces in at least two different directions.

## Hyaline cartilage

Hyaline cartilage consists mainly of very fine collagen type II fibrils and large proteoglycan molecules, which have the property of attracting water and swelling. Collagen gives cartilage its tensile strength and stiffness, and the proteoglycans give the tissue a high water content that confers compressive 'turgor'. During growth and healing, proteoglycans enable the growing cartilage to swell and occupy space that later will be strengthened by other components of the matrix. Articular cartilage is a particular type of hyaline cartilage that covers the ends of articulating bones; its high water content enables it to distribute loading evenly on the underlying bone. Since cartilage is softer than bone, it deforms more when loaded, increasing the area of contact between articular surfaces and reducing contact stress (Fig. 5.57). Cartilage creep (see above) causes the area of contact to increase, and further reduces contact stress. Creep in articular cartilage also causes water to be exuded into the joint cavity, assisting in fluid-film lubrication (see below). Articular cartilage 'wear' (loss of material) during high and repetitive loading is minimized because the collagen type II fibrils in the superficial zone are aligned parallel to the surface, an arrangement that provides maximal resistance to surface splitting and the subsequent loss of tissue.

## Fibrocartilage and elastic cartilage

Fibrocartilage and elastic cartilage combine the high proteoglycan and water content that characterizes cartilage with a high proportion of either collagen type I (fibrocartilage) or elastin (elastic cartilage). Collagen type I confers extra tensile strength and toughness, whereas elastin fibres provide elastic recoil, i.e. the ability to spring back to shape after large deformations.

Fig. 5.57 Articular cartilage in a synovial joint is not as stiff as the underlying bone, so the presence of cartilage in a loaded joint increases the area of contact (B) compared to a joint without cartilage (A).

## MECHANICAL PROPERTIES OF SKELETAL STRUCTURES

## Long bones

Long bones are characterized by enlarged ends covered in cartilage, a long hollow shaft and various bony protuberances. The enlarged ends serve to reduce contact stress where long bones meet in synovial joints, and to increase the stability of such joints (Fig. 5.58). A different relationship between stability and mobility can exist in different anatomical planes, even for the same joint, e.g. the knee joint favours stability in the frontal plane and mobility in the sagittal plane. The hollow shaft of a long bone confers high strength in bending for a given mass of material, but also minimizes bone mass and so increases the speed of movement. Bending strength is increased by having as much bone mass as possible far from the axis of bending (Fig. 5.59). The precise crosssectional shape of a long bone therefore gives a clear indication of the planes in which the shaft is most likely to be subjected to severe bending. Bony prominences or processes on long bones serve to increase the lever arm of muscles that are attached to them: if a large prominence is close to the centre of rotation of a joint, then it can increase the lever arm by over $100 \%$, and the maximum torque developed by the muscle about that centre of rotation would increase by the same amount.

Fig. 5.58 In synovial joints, the shapes of the opposing bone ends largely determine how much movement is possible, and the stability of the joint. Tapered bone ends (A) lead to high mobility but low stability (in the plane of the page). Conversely, very wide bone ends (C) lead to low mobility and high stability. Some joints resemble (A) in one plane but (B) or $(\mathbf{C})$ in others.

Fig. 5.59 A cross-section through the shaft of a long bone, showing how the irregular shape gives information about the bone's strength in bending about different axes. Strength will be greatest about the axis A-B because a high proportion of bone mass is located a long distance from this axis, and so will resist bending very strongly. Strength will be minimal about the axis C-D for a similar reason.

## Synovial joints

Typically，synovial joints are designed for full and free movements，but they must also provide some stability in specific planes（see Fig．5．58）． In a joint with a small range of movement，intrinsic stability provided by the articular surfaces and ligaments of that joint may be more impor－ tant than the extrinsic stability provided by surrounding muscles．Low－ friction movement is facilitated by the smooth surfaces of articular cartilage being made slippery by the presence of the boundary lubricant lubricin，which is bound to the cartilaginous surfaces．This boundary lubrication reduces friction during slow movements，especially when forces are high．During rapid movements，microscopic undulations in the cartilage surface trap small quantities of synovial fluid between the articular surfaces，so that fluid－film lubrication（akin to aquaplaning） can also occur（Fig．5．60），and friction and wear are greatly reduced． The sticky，viscous nature of synovial fluid enables it to persist between the cartilage surfaces for longer than water，which would be squeezed out much too quickly．Fluid－film lubrication is assisted by joint incon－ gruity，in which the opposing articular surfaces have slightly different curvatures（Fig．5．61），producing a potential fluid－filled gap that moves as the joint moves，washing synovial fluid across the cartilage surfaces． Incongruity can also help to reduce peak loading on the apex of the joint．

## Intervertebral discs

Intervertebral discs are composed of three tissues：the anulus fibrosus （fibrocartilage），the nucleus pulposus（a hydrated collagen－proteoglycan gel）and the end－plates（hyaline cartilage）．The water content of the nucleus pulposus can reach $90 \%$ in children and young adults，enabling the tissue to behave like a fluid．When compressive loading is applied to the vertebral column，the fluid pressure in the nucleus presses evenly on the adjacent vertebral bodies，even when they are orientated at small angles to each other．The anulus resists radial expansion of the nucleus and can deform vertically to facilitate spinal bending in various planes． The relatively dense hyaline cartilage end－plate helps to maintain a fluid pressure in the nucleus by slowing down water loss into the vertebral body through perforations in the vertebral end－plate．Nevertheless，discs lose approximately $20 \%$ of their water gradually，in the course of each day．This net loss of water is regained at night when，in recumbency， the load on the spine is relieved．Diurnal variations in disc water content cause adults to be approximately 2 cm taller in the early morning，and more flexible in the evening．

Fig．5．60 The articular cartilage surfaces of synovial joints contain microscopic undulations that trap small quantities of synovial fluid between the surfaces，enabling fluid－film lubrication to occur．Boundary lubrication at the points of contact between cartilage asperities （roughness）is facilitated by lubricants adhering to the cartilage surface．

Fig．5．61 Some synovial joints are incongruent in the sense that the opposing articular surfaces have slightly different curvatures．This ensures that there is a fluid－filled gap between them when the joint is subjected to low loading（A）．Under high loading（B）this gap disappears，but peak loading at the apex of the joint remains lower than it would be if the surfaces had the same curvature，and this is a major advantage for an incongruent joint．The shape of the concave articular surface is sometimes referred to as a Gothic arch．Abbreviation：$F=$ loading force．

## MUSCLES AND LEVER SYSTEMS

Collagenous architecture of muscle
Muscles are supported by a hierarchy of collagenous sheaths（endomy－ sium，perimysium and epimysium），which surround individual muscle fibres，fascicles and whole muscles respectively．Muscles are bound together into functional groups by collagenous fascia．Together，these sheaths create a strong honeycomb structure that contributes to the muscle＇s resistance to tension．When muscle is stretched during eccen－ tric（lengthening）contractions，high tensile forces in the collagenous structures add to the tension generated by muscle fibre contraction， leading to high and potentially damaging forces acting on the musc－ ulotendinous junction．

## Internal muscle forces

Generally speaking，muscle forces exert greater mechanical loading on the skeleton than does body weight．For example，during relaxed standing， $50 \%$ of the compressive force acting on the lumbar spine arises from the antagonistic activity of the muscles of the back and abdomen，and $50 \%$ comes from superincumbent body weight（Adams 2013）．However，when bending the trunk to lift weights from the ground，more than $90 \%$ of the compressive force acting on the spine can be attributed to muscle tension（Fig．5．62）．Similarly，muscle forces acting on the knee can exceed body weight by a factor of 200－ $400 \%$ during stair climbing and during deep squatting movements． Muscle forces can exceed the strength of adjacent bones if they contract in alarm，so that normal inhibitory reflexes are suppressed；it is not uncommon for vertebrae to be crushed by muscle tension during major epileptic fits．According to Newton＇s 2nd Law of motion（force $=$ mass $\times$ acceleration），muscle forces also rise to high levels when attempting to accelerate body parts，e．g．during jumping or throwing． It follows that any attempt to achieve maximum acceleration will natu－ rally require maximal muscle tension．The size and potential dangers of internal muscle forces are often overlooked，leading some authors to draw spurious distinctions between weight－bearing and non－weight－ bearing joints，and to suggest erroneously that only the former are subjected to high loading．It is likely that a watchmaker＇s finger joints are subjected to stresses as high，and as often，as those applied to his ankles．

Fig．5．62 During manual labour，muscle tension often rises to high levels in order to generate sufficient bending moment to move external objects． In this example，the back muscles act only a short distance（d）from the pivot point in the intervertebral discs（ O ），whereas the weight being lifted acts on a much bigger lever arm（D）．In order for the moments to balance， the back muscle tension（F）must exceed the weight being lifted（W）by the ratio of $\mathrm{D} / \mathrm{d}$ ．In practice，this can lead to the lumbar spine being compressed by approximately 500 kg during moderate manual handling． （For simplicity，the above analysis disregards the weight of the upper body．）

Fig．5．63 Muscle lever systems can be classified as first－class（A），second－class（B）or third－class（C），according to the relative positions of the fulcrum（or pivot），the muscle insertion，and the externally applied load．

## Muscle lever systems

Muscle tension generates bending moments and torques about joints． Moments and torques depend on lever arms as well as muscle forces． It is conventional（although not particularly illuminating）to distin－ guish between three types of muscle lever system（Fig．5．63）．Generally， the length of the lever arm（the perpendicular distance between the line of action of the muscle and the centre of rotation of the joint）is more important than lever type（Fig．5．64）．If the lever arm is short，then a given muscle contraction will move the joint through a large angle，so the lever system is suited to large and／or rapid movements of that joint． Conversely，a long lever arm leads to small and／or slow movements but greater moment generation．Elite weightlifters may have muscle inser－ tions with particularly large lever arms about particular joints．

## MOVEMENTS

## Movements of bones

Movement of a bone is referred to as translation if it does not involve any change in orientation relative to a fixed frame of reference（or to another bone）．A pure rotation involves no translation，merely a pivot－ ing of the bone about some fixed point or centre of rotation．Spin is the rotation of a bone about its mechanical axis，which for a long bone would coincide with its long axis．Spin can occur in conjunction with other joint rotations（Fig．5．65）．Most body movements involve some combination of rotation，translation and spin，although the transla－ tional component is often small．

## Movements at articular surfaces

Opposing joint surfaces are never perfectly congruent，but substantial regions of these surfaces may fit together exactly in a certain position known as the close－packed position，in which the joint is most stable． For example，the close－packed position of the knee joint corresponds

Fig．5．64 The precise location of a muscle insertion relative to a joint greatly influences the function of that joint．A，If the perpendicular distance（d）between the muscle＇s line of action and the centre of rotation of the joint $(\bullet)$ is large，then the joint is suited to slow but forceful movements．B，If $d$ is small，then the joint is suited to rapid but less forceful movements．Abbreviation：F，force，showing line of muscle action．

Fig. 5.65 Complex movements of the body's joints are sometimes required to produce apparently simple movements of the limbs. In this example, moving the hand as shown from $A$ to $B$ to $C$ requires a hidden 'spin' movement of the arm of $90^{\circ}$ about its mechanical (long) axis.

Fig. 5.66 The surfaces of incongruent joints move relative to each other by various combinations of spin, roll and slide.
to full extension. In other (loose-packed) positions, the surfaces of incongruent joints are not perfectly matched, and are able to move relative to each other by a combination of spin, roll and slide (Fig. 5.66). In final close-packing, surfaces are fully congruent, in maximal contact and tightly compressed or 'screwed home', the fibrous capsule and ligaments are maximally spiralized and tensed, and no further movement is possible. Close-packed surfaces cannot be separated by normal external force (as they may be in other positions), and bones can be regarded as temporarily locked, as if no joint existed. Close-packing is a final, limiting position, and any force that tends to further change can only be resisted by contraction of appropriate muscles. Failure to stop further movement results in injury to joint structures. Therefore, movement just short of close-packing is physiologically most important.

Ligaments and articular cartilage are, to a small degree, elastically deformable: in the final stages of close-packing the articular position is an equilibrium between the external moments and torques applied (often by gravity) and resistance to tissue deformation by the tense, twisted capsule and compressed cartilage surfaces. In symmetrical standing, the knee and hip joints approach close-packed positions sufficiently to maintain an erect posture with minimal energy. In all other positions, the articular surfaces are not congruent and parts of the capsule are lax; the joint is said to be loose-packed. Close- and loosepacked positions of several major joints are shown in Table 5.4 (see MacConaill and Basmajian (1977)). Capsules are sufficiently lax near the mid-range of many movements to allow separation of the articulating surfaces by external forces. Opinions may vary in connection with some of the positions in Table 5.4, e.g. a close-packed position may possibly occur in occasional joints at both extremes of the range of movement. It is difficult to assess the situation in small tarsal and carpal joints and the first carpometacarpal joints. Intervertebral movements are the result of integrated simultaneous changes at all elements that make up the intervertebral articular complex, and perhaps should not

Table 5.4 The close- and loose-packed positions of joints

| Joint | Close-packed position | Loose-packed position |
| :--- | :--- | :--- |
| Shoulder | Abduction + lateral rotation | Semi-abduction |
| Ulnohumeral | Extension | Semi-flexion |
| Radiohumeral | Semi-flexion + semi-pronation | Extension + supination |
| Wrist | Dorsiflexion | Semi-flexion |
| 2nd-5th | Full flexion | Semi-flexion + ulnar deviation |
| metacarpophalangeal |  |  |
| Interphalangeal (fingers) | Extension | Semi-flexion |
| 1st carpometacarpal | Full opposition | Neutral position of thumb |
| Hip | Extension + medial rotation | Semi-flexion |
| Knee | Full extension | Semi-flexion |
| Ankle | Dorsiflexion | Neutral position |
| Tarsal joints | Full supination | Semi-pronation |
| Metatarsophalangeal | Dorsiflexion | Neutral position |
| Interphalangeal (toes) | Dorsiflexion | Semi-flexion |
| Intervertebral | Extension | Neutral position |

Data from MacConaill MA, Basmajian JV 1977 Muscles and Movements, 2nd edn. New York: Kriger.

Fig. 5.67 When a bone is rotated, the centre of rotation (CoR) can be located by drawing lines between the initial and final positions of anatomical landmarks on the bone, and then determining where the perpendicular bisectors of these lines meet. The CoR may not correspond to a precise anatomical landmark.
be included in Table 5.4. However, most of the positions given do correspond with postures adopted when maximal stress is encountered.

## Centre of rotation

The centre of rotation is a theoretical concept and may not correspond closely to any anatomical landmark or natural pivot. For a finite movement of one bone relative to a fixed reference (perhaps an anatomical plane), the centre of rotation can be located by drawing theoretical lines between the initial and final positions of two anatomical landmarks on the bone, and determining where the perpendicular bisectors of these two lines meet (Fig. 5.67). Real movements of real joints often involve varying combinations of rotation and translation as the movement progresses. It can be instructive to break the whole movement down into a series of small movements, calculate the centre of rotation for each one, and then join up the centres to create the locus of the instantaneous centre of rotation for the whole movement. Joint disease sometimes leads to an abnormally long and tortuous locus of the centre of rotation, because degenerative changes can reduce the restraint to motion offered by one or more tissues.

## Coupled movements

An attempt to move a joint in one plane sometimes causes articular surfaces to meet at an oblique angle, creating small rotations in other planes. These secondary rotations, which are usually smaller than the primary rotations, are referred to as coupled movements, e.g. lateral bending of the lumbar spine, which occurs in the coronal plane, also normally produces coupled axial rotations. Joint pathology can lead to abnormal coupled movements.

Fig. 5.68 Adaptive remodelling is the process by which musculoskeletal tissues adapt to prevailing mechanical demands. If a tissue is subjected to increased mechanical loading (right), it deforms more. Cells respond to this increased strain by depositing more matrix and increasing its modulus (stiffness) until strain levels return to normal. Similarly, reduced loading leads to reduced tissue strain (left), reduced modulus and reduced matrix deposition until strain levels rise to normal.

## MECHANOBIOLOGY

## Adaptive remodelling

Skeletal tissues are generally able to adapt their mechanical properties to match the forces applied to them. This process is best understood for bone, and bone biologists refer to this general principle as Wolff's Law. As illustrated in Figure 5.68, the amount of deformation of a tissue (i.e. the strain) is proportional to the mechanical loading to which it is subjected. Cells detect this increased strain and respond by producing more extracellular matrix, which increases the modulus (stiffness) of the tissue and returns strain levels to normal. Similarly, reduced loading leads to reduced tissue strain, reduced matrix synthesis and reduced modulus, so that tissue strain increases to normal values. This negative feedback system ensures that bone adapts (remodels) to suit its mechanical environment (Currey 2002). Animal experiments suggest that as few as 36 relatively severe loading cycles per day are sufficient to produce a maximal hypertrophic response in bone, whereas fewer than four loading cycles per day leads to tissue resorption (Rubin and Lanyon 1984). Evidently, bone cells respond to maximal loading rather than time-averaged loading. There is some experimental evidence that cartilage adapts similarly to its mechanical environment (Hall et al 1991). It would be unlikely that they did not, because the mechanical properties of adjacent tissues would rapidly become mismatched, increasing the risk of damage to one of them. However, it is equally evident that different tissues cannot adapt at the same rates. Highly vascularized tissues such as muscle and bone have the potential to adapt rapidly, whereas poorly vascularized tissues such as large tendons do not. Avascular tissues such as articular cartilage and intervertebral discs can adapt only very slowly, so that turnover times for some matrix macromolecules can be as long as 100 years. Large differences in adaptive potential between adjacent musculoskeletal tissues could lead to problems in the less well-vascularized tissue when levels of mechanical loading increase abruptly (Adams et al 2013).

## Mechanotransduction

Various mechanisms have been proposed to explain how cells in musculoskeletal tissues detect mechanical loading. Cells in bone respond
to tissue strain, possibly by detecting the resulting fluid flow within the microscopic canaliculi of the matrix. Cells in cartilage and ligaments also detect tissue strain, possibly because it deforms the cells in shear (see Fig. 5.52). Cells in articular cartilage and in the nucleus pulposus of intervertebral discs appear to be able to detect hydrostatic pressure in their surrounding medium, although only the cells in the nucleus pulposus would normally experience such a pressure in life. (The pore pressure in a 'biphasic' solid such as articular cartilage can vary from place to place and is not equivalent to a single hydrostatic pressure.) Muscle cells respond to strain and microinjury, possibly disturbing intracellular proteins such as titin. Mechanotransduction appears to be mediated by matrix molecules such as fibronectin pulling on transmembrane proteins such as integrins, which in turn disturb the cell cytoskeleton.

## Degeneration, injury and frustrated repair

Numerous theories have been propounded to explain degenerative changes in skeletal tissues. Most presume that the cells behave abnormally, possibly because of an unfavourable genetic inheritance, so that the matrix becomes weakened and physically disrupted. Alternatively, degenerative changes may represent an attempt by the cells to repair a matrix where the primary cause of damage has been excessive mechanical loading (Adams et al 2013). Excessive loading does not necessarily imply trauma; normal loading is excessive if the matrix has become abnormally weak on account of an unfavourable genetic inheritance or age. In poorly vascularized tissues, such as cartilage and tendon, low cell density and inadequate transportation of metabolites could lead to a vicious circle of minor injury, frustrated repair, tissue weakening and further injury.

# Smooth muscle and the cardiovascular and lymphatic systems 

The cardiovascular system carries blood from the heart to all parts of the body through a series of tubes, all but the smallest of which are muscular. The muscle in these tubes is of two types: smooth muscle is characteristic of the walls of blood vessels, whereas cardiac muscle provides the walls of the heart chambers with their powerful contractile pumping action. The general characteristics and classification of muscle tissues are given on page 103. Smooth muscle also forms an important contractile element in the walls of many other organ systems of the body, e.g. the gastrointestinal tract and the airways.

## SMOOTH MUSCLE

In smooth muscle tissue, the contractile proteins actin and myosin are not organized into regular sarcomeres, visible as transverse striations, and so the cytoplasm has a smooth (unstriated) appearance. Smooth muscle is also referred to as involuntary muscle because its activity is neither initiated nor monitored consciously. It is much more variable, in both form and function, than either striated or cardiac muscle, a reflection of its varied roles in different systems of the body.

Smooth muscle is typically found in the walls of tubular structures and hollow viscera. It regulates diameter (e.g. in blood vessels, and branches of the bronchial tree); propels liquids or solids (e.g. in the ureter, hepatic duct and intestines); or expels the contents (e.g. in the urinary bladder and uterus). The actual arrangement of the cells varies with the tissue. The account that follows will therefore be concerned with the generic properties of smooth muscle. The more specialized morphologies of smooth muscle are described in the appropriate regional chapters.

## MICROSTRUCTURE OF SMOOTH MUSCLE

Smooth muscle cells (fibres) are smaller than those of striated muscle. Their length can range from $15 \mu \mathrm{~m}$ in small blood vessels to $200 \mu \mathrm{~m}$, and even to $500 \mu \mathrm{~m}$ or more in the uterus during pregnancy. The cells are spindle-shaped, tapering towards the ends from a central diameter of $3-8 \mu \mathrm{~m}$ (Fig. 6.1). The nucleus is single, located at the midpoint, and often twisted into a corkscrew shape by the contraction of the cell. Smooth muscle cells align with their long axes parallel and staggered

Fig. 6.1 Smooth muscle cells (fibres) in longitudinal (bottom) and transverse (top) section at the boundary of circular and longitudinal muscle layers in the human intestinal wall. Individual cells are spindle-shaped with a single central nucleus, aligned in parallel with neighbouring cells in a fasciculus. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
longitudinally, so that the wide central portion of one cell lies next to the tapered end of another. Such an arrangement achieves both close packing and a more efficient transfer of force from cell to cell. In transverse section, smooth muscle is seen as an array of circular or slightly polygonal profiles of very varied size, and nuclei are present only in the centres of the largest profiles (Fig. 6.2). This appearance contrasts markedly with that of skeletal muscle cells, which show a consistent diameter in cross-section and peripherally placed nuclei throughout their length.

Smooth muscle has no attachment structures equivalent to the fasciae, tendons and aponeuroses associated with skeletal muscle. There is a special arrangement for transmitting force from cell to cell and, where necessary, to other soft tissue structures. Cells are separated by a gap of $40-80 \mathrm{~nm}$. Each cell is covered almost entirely by a prominent basal lamina, which merges with a reticular layer consisting of a network of fine elastin, reticular fibres (collagen type III) and type I collagen fibres (Fig. 6.3). These elements bridge the gaps between adjacent cells and provide mechanical continuity throughout the fascicle. The cell attaches to components of this extracellular matrix at dense plaques (Figs 6.3A and 6.4), where the basal lamina is thickened; cell-cell attachment occurs at intermediate junctions or desmosomes, formed of two adjacent dense plaques. At the boundaries of fascicles, the connective tissue fibres become interwoven with those of interfascicular septa, so that the contraction of different fascicles is communicated throughout the tissue and to neighbouring structures. The components of the reticular network, the ground substance and collagen and elastic fibres, are synthesized by the smooth muscle cells themselves, not by fibroblasts or other connective tissue cells, which are rarely found within fasciculi.

Fig. 6.2 A transmission electron micrograph showing smooth muscle fibres in transverse section, two at the level of their single central nucleus. In several places, the plasma membranes of adjacent cells are closely approximated at gap junctions (arrows).

Fig. 6.3 A, A three-dimensional representation of smooth muscle cells. For clarity, some structural features have been separated for illustration in different cells. The spindle-shaped cells interdigitate with their long axes parallel; mechanical continuity between the cells is provided by a reticular layer of elastin and collagen fibres. The cytoskeletal framework consists of intermediate filament arrays (mainly longitudinal) and bundles of actin and myosin filaments (shown in separate cells) inserted into cytoplasmic dense bodies and submembraneous dense plaques to form a three-dimensional network. The sarcolemma contains anchoring desmosomes (adherens junctions), gap junctions and caveolae. B, The concertina-like change in shape of smooth muscle cells as they contract.

Fig. 6.4 Transmission electron micrographs showing the characteristic features of smooth muscle cells. Vascular smooth muscle in human kidney tissue, showing a cytoplasm packed densely with microfilaments (actin and myosin), cytoplasmic dense bodies (arrows) and submembraneous dense plaques (arrowheads). A basal lamina encloses the cell. The inset shows four caveolae (C) (vesicular invaginations of the cell surface at high magnification). These are associated with receptors, enzymes and ion channels important in smooth muscle function. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK. Inset courtesy of Professor Chun Y Seow, University of British Columbia.)

The membrane of smooth muscle cells contains molecules such as proteoglycans, glycoproteins and glycolipids on its exterior surface that form a thin, negatively charged network, the glycocalyx. Whilst less studied than that of endothelial cells, the smooth muscle cell glycocalyx has been shown to be important for mechanotransduction in small blood vessels. There are also a number of cell membrane-spanning proteins that extend through the glycocalyx and interact with the extracellular matrix, including cadherins and integrins. These provide structural and signalling links with the extracellular matrix and other cells, e.g. at desmosomes. The cytosolic ends of these proteins interact with components of the cytoskeleton via a complex of other proteins and kinases, and provide an important signalling pathway linking cell function to the exterior, which can modulate, for example, gene transcription and phenotype (Stegemann 2005).

Discontinuities occur in the basal lamina between adjacent cells, and here the cell membranes approach to $2-4 \mathrm{~nm}$ of one another to form a gap junction (see Fig. 6.2). These junctions are structurally similar to their counterparts in cardiac muscle, and are formed by binding of adjacent connexon complexes on the surface of the two cells. They provide a low-resistance channel through which electrical excitation and small molecules can pass, e.g. enabling a coordinated wave of contraction. The incidence of gap junctions varies with the anatomical site of the tissue: they appear more abundant in the type of smooth muscle that generates rhythmic (phasic) activity and they link the endothelium functionally with the underlying smooth muscle (myoendothelial gap junctions) in small resistance arteries and arterioles.

Caveolae, cup-like invaginations of the plasma membrane with a resemblance to endocytotic vesicles, are a characteristic feature of smooth muscle cells, and may form up to $30 \%$ of the membrane (see Fig. 6.4). They are associated with many receptors, ion channels, kinases and the peripheral sarcoplasmic reticulum, and may thus act as highly localized signalling microdomains. They may also act as specialized pinocytotic structures involved in fluid and electrolyte transport into the cell. Other organelles (mitochondria, ribosomes, etc.) are largely confined to the filament-free perinuclear cytoplasm, although in some smooth muscle types, including vascular smooth muscle, peripheral mitochondria, sarcoplasmic reticulum and sarcolemma form signalling microdomains.

## NEUROVASCULAR SUPPLY OF SMOOTH MUSCLE

## Vascular supply

The blood supply of smooth muscle is less extensive than that of striated muscle. Where the tissue is not too densely packed, afferent and efferent vessels gain access via connective tissue septa, and capillaries run in the connective tissue between small fascicles. However, unlike striated muscle, capillaries are not found in relation to individual cells.

## Innervation

Smooth muscle may contract in response to nervous or hormonal stimulation, or electrical depolarization transferred from neighbouring cells. Some muscles receive a dense innervation to all cells; these are often referred to as multi-unit smooth muscles, and most blood vessels are of this type. Such innervation can precisely define contractile activity; e.g. in the iris, specific nervous control can produce either pupillary constriction or dilation. Other muscles are more sparsely innervated. They tend to display myogenic activity, initiated spontaneously or in response to stretch, which may be markedly influenced by hormones. In these muscles, which include those in the walls of the gastrointestinal tract, urinary bladder, ureter, uterus and uterine tube, innervation tends to exert a more global influence on the rate and force of intrinsically generated contractions. These muscles have been referred to as unitary smooth muscles. The terms multi-unit and unitary smooth muscles are widely used, but in practice such distinctions are better regarded as the extremes of a continuous spectrum.

Smooth muscles are innervated by unmyelinated axons whose cell bodies are located in autonomic ganglia, either in the sympathetic chain or, in the case of parasympathetic fibres, closer to the point of innervation (Fig. 6.5). They ramify extensively, spreading over a large area of the muscle and sending branches into the muscle fasciculi. The terminal portion of each axonal branch is beaded and consists of expanded portions, varicosities, packed with vesicles and mitochondria, separated by thin, intervaricose portions. Each varicosity is regarded as a transmitter release site and may be considered as a nerve ending in the functional sense. In this way the axonal arborization of a single autonomic neurone

bears a very large number of nerve endings (up to tens of thousands), as opposed to a maximum of a few hundred in somatic motor neurones. The neuromuscular terminals of autonomic efferents are considered in more detail on page 64 .

The neuromuscular junctions in smooth muscles do not show the consistent appearance seen in skeletal muscles. The neurotransmitter diffuses across a gap that can vary from 10 to 100 nm ; even separations of up to $1 \mu \mathrm{~m}$ may still allow neuromuscular transmission to take place, although more slowly. The nerve ending is packed with vesicles but the adjacent area of the muscle cell is not structurally differentiated from that of non-junctional regions, i.e. there is no distinct synapse.

Intramuscular afferent nerves are the peripheral processes of small sensory neurones in the dorsal root ganglia. Since they are unmyelinated, contain axonal vesicles and have a beaded appearance, they are difficult to distinguish from efferent fibres, except by differential staining for neurotransmitters.

## STRUCTURAL BASIS OF CONTRACTION

Although electron microscopy revealed the presence of filaments in smooth muscle some years ago, this observation alone provided little insight into their mode of function because of the lack of any obvious organization of the filaments. More recent work, using high-resolution immunocytochemistry, has revealed further details of the internal architecture of the cell and suggests a structural basis for contractile function. The model, which is illustrated in Figure 6.3, depends on the mutual interaction of two systems of filaments, one forming the cytoskeleton and the other the contractile apparatus.

Excluding the perinuclear region, the cytoplasm of a smooth muscle cell effectively consists of two structural domains. The cytoskeleton forms a structural framework that maintains the spindle-like form of the cell and provides an internal scaffold with which other elements can interact. Its major structural component is the intermediate filament desmin, with the addition of vimentin (which may also be present alone) in vascular smooth muscle. The intermediate filaments are arranged mainly in longitudinal bundles, but some filaments interconnect the bundles with each other and with the sarcolemma to form a three-dimensional network. The bundles of intermediate filaments insert into focal, electron-dense bodies, approximately $0.1 \mu \mathrm{~m}$ in diameter, which are distributed uniformly throughout the cytoplasm and also attach to dense plaques underlying the plasma membrane (see Fig. 6.3A). The cytoplasmic dense bodies and submembraneous dense plaques are equivalent to the Z-discs of striated muscle cells. They contain the actin-binding protein $\alpha$-actinin and thus also anchor the actin filaments of the contractile apparatus. These form a lattice of obliquely arranged bundles throughout the cytoplasm, which transmit force to the plasma membrane and thus the basal lamina and extracellular matrix via dense plaques. These are associated with a highly structured arrangement of ancillary proteins, including vinculin and talin,

In some blood vessels, notably those of the pulmonary circulation, and in the airways and probably in other smooth muscle types, there is evidence for heterogeneity of cell phenotype. The smooth muscle cells of small blood vessels and bronchioles exhibit different functional properties from those in larger vessels and airways, and may differ in morphology, expression of signalling proteins such as ion channels, and excitation-contraction coupling mechanisms. Even within individual tissues there is evidence of heterogeneity. Some myofibroblast-like cells have a function that is more secretory than contractile. The secretory phenotype is often increased in disease (e.g. chronic severe asthma, pulmonary hypertension) and is associated with increased proliferation and remodelling, and with secretion of cytokines and other mediators. Many smooth muscles seem to exhibit considerable phenotypic plasticity between these contractile and secretory phenotypes (Halayko and Solway 2001).
which in turn attach to integrins that cross the membrane and provide attachment to components of the extracellular matrix (Gunst and Zhang 2008).

An analogous arrangement underlies cell-cell attachment at desmosomes, but here the attachment between dense plaques is provided by transmembrane cadherin glycoproteins and intracellular catenins instead of integrins and talin. Mechanical deformation of the cell may be linked to cell signalling mechanisms via focal adhesion kinase (FAK) and its substrate paxillin; phosphorylation of talin and paxillin may modulate the deformability of the smooth muscle cell. Other regulatory proteins also associate specifically with actin, such as caldesmon and calponin. The cytoskeleton is not a passive structure. It adapts dynamically to load and is modulated by cell surface receptors including integrins and agonist binding to G-protein coupled receptors, and so contributes to contraction (Gunst and Zhang 2008). This presumably contributes to the low energy requirements of smooth muscle contraction because dynamic reorganization of the cytoskeleton following active contraction allows cell shortening to be maintained without further energy expenditure.

The ratio of actin to myosin is about eight times greater in smooth compared to striated muscle, reflecting the greater length of actin filaments in smooth muscle. Smooth muscle myosin filaments are $1.5-2 \mu \mathrm{~m}$ long, somewhat longer than those of striated muscle. Although smooth muscle cells contain less myosin, the longer filaments are capable of generating considerable force. The myosin filaments of smooth muscle are also assembled differently, such that their head regions lie symmetrically on either side of a ribbon-like filament, rather than imposing a bipolar organization on the filament. Actin filaments, to which they bind, can thus slide along the whole length of the myosin filament during contraction. In addition, dynamic polymerization of both myosin and actin monomers during activation can alter the length of the contractile filaments. These differences underpin the ability of smooth muscle to undergo much greater changes in length than striated muscle. Actin-myosin filament sliding generates tension, which transmits to focal regions of the plasma membrane, changing the cell to a shorter, more rounded shape (see Fig. 6.3B) and often deforming the nucleus to a corkscrew-like profile.

Although some smooth muscles can generate as much force per unit cross-sectional area as skeletal muscle, the force always develops much more slowly than in striated muscle. Smooth muscle can contract by more than $80 \%$, a much greater range of shortening than the $30 \%$ or so to which striated muscle is limited. The significance of this property is illustrated by the urinary bladder, which is capable of emptying completely from an internal volume of 300 ml or more. Smooth muscles can maintain tension for long periods with very little expenditure of energy. Many smooth muscle structures are able to generate spontaneous contractions; examples are found in the walls of the intestines, ureter and uterine tube.

## EXCITATION-CONTRACTION COUPLING IN SMOOTH MUSCLE

Excitation-contraction coupling in smooth muscle is more complex than in skeletal or cardiac muscle, and may be electromechanical or pharmacomechanical. Electromechanical coupling involves depolarization of the cell membrane by an action potential, and may be generated when a membrane receptor, usually linked with an ion channel, is occupied by a neurotransmitter, hormone or other blood-borne substance. It is most commonly seen in unitary and phasic smooth muscles such as those of the viscera, with transmission of electrical excitation from cell to cell via gap junctions. In some types of smooth muscle depolarization may be the consequence of other stimuli, such as cooling, stretch and even light.

Pharmacomechanical coupling is a receptor-mediated and G-protein coupled process, and is the major mechanism in tonic smooth muscles such as in the vasculature and airways. It may involve several pathways, including formation of inositol trisphosphate, which triggers intracellular calcium release from the sarcoplasmic reticulum, activation of voltage-independent calcium channels in the sarcolemma, and depolarization causing activation of voltage-dependent calcium channels (reviewed in Berridge (2008)). In addition, many receptors also couple to kinases that modulate contraction in a calcium-independent fashion, either via myosin phosphatase (see below) or via the actin cytoskeleton (see above). The extent to which any of these pathways contributes to activation varies between different types of smooth muscle.

Whilst the regulation of contraction of smooth muscle is largely calcium-dependent, in contrast to cardiac and skeletal muscle, the effects of an elevation of intracellular calcium are mediated via myosin
rather than actin/tropomyosin. Most smooth muscles contain little or no troponin, and instead calcium binds to calmodulin. The calciumcalmodulin complex regulates the activity of myosin light chain kinase, which phosphorylates myosin regulatory light chains and initiates the myosin-actin adenosine $5^{\prime}$-triphosphatase (ATPase) cycle. The enzymatic activation process is therefore inherently slow. Myosin phosphatase dephosphorylates myosin and thus promotes relaxation. The degree of myosin phosphorylation and therefore contraction depends on the relative activities of myosin light chain kinase and myosin phosphatase. Thus inhibition of the phosphatase, e.g. by Rho kinase, increases phosphorylation for any level of calcium (i.e. increases calcium sensitivity). The latter is a central component of the response to many constrictor agonists.

## Regulation of smooth muscle intracellular calcium

Intracellular calcium is a key determinant of smooth muscle function, including contraction and also proliferation, migration and secretion of mediators. Its regulation in smooth muscle is particularly complex, and involves calcium entry via both voltage-dependent and independent ion channels, release from and reuptake into intracellular stores such as the sarcoplasmic reticulum, and modulation by mitochondria.

## ORIGIN OF SMOOTH MUSCLE

It was thought that all smooth muscle cells developed in situ exclusively from the splanchnopleuric mesenchyme in the walls of the anlagen of the viscera and around the endothelium of blood vessels. However, endothelial and tunica media smooth muscle cells arise from the epithelial plate of individual somites (Scaal and Christ 2004), and the smooth muscle of the sphincter and dilator pupillae is derived from neurectoderm.

Following a period of proliferation, clusters of myoblasts become elongated in the same orientation. Dense bodies, associated with actin and cytoskeletal filaments, appear in the cytoplasm, and the surface membrane starts to acquire its specialized features, i.e. caveolae, adherens junctions and gap junctions. Cytoskeletal filaments extend to insert into the submembraneous dense plaques and cytoplasmic dense bodies. Thick filaments are seen a few days after the first appearance of thin filaments and intermediate filaments, and from this time the cells are able to contract. During development, dense bodies increase in number and further elements of the cytoskeleton are added. In addition to synthesizing the cytoskeleton and contractile apparatus, the differentiating cells express and secrete components of the extracellular matrix.

In a developing smooth muscle, all the cells express characteristics of the same stage of differentiation and there are no successive waves of differentiation. From its earliest appearance to maturity, a smooth muscle increases several hundred-fold in mass, partly by a $2-4$-fold increase in the size of individual cells, but mainly by a very large increase in cell number. Growth occurs by division of cells in every part of the muscle, not just at its surface or ends. Mitosis occurs in cells in which differentiation is already well advanced, as evidenced by the presence of myofilaments and membrane specializations. Mitotic smooth muscle cells may be found at any stage of life but their numbers peak before birth, at a time that differs for different muscles; they are rare in the adult unless the tissue is stimulated to hypertrophy (as in the pregnant uterus) or to repair. The ability of mature cells to undergo mitosis therefore differs between the three major types of muscle: skeletal muscle cells cannot divide at all after differentiation; cardiac muscle cells can divide but only before birth; and smooth muscle cells appear to remain capable of division throughout life.

During the early stages of development, smooth muscle expresses embryonic and non-muscle isoforms of myosin. The proportions of these isoforms decrease progressively. Initially, SM-1 is the dominant or exclusive smooth muscle heavy chain isoform and the SM-2 isoform becomes more established later. For a review of the development of vascular smooth muscle, see Owens et al (2004).

## SMOOTH MUSCLE REMODELLING IN DISEASE

The ability of smooth muscle cells to divide and change phenotype throughout life means that smooth muscle has significant plasticity and can adapt to changing needs and stimuli, e.g. in the walls of the uterus during pregnancy. This can, however, have detrimental consequences in disease.

The arrangement of peripheral signalling microdomains (see above) is vital to this process. Sequential release from inositol trisphosphate receptors and calcium-sensitive ryanodine receptors (calcium release channels) in the sarcoplasmic reticulum, together with reuptake via the sarco-endoplasmic reticulum calcium ATPase (SERCA), give rise to slow calcium oscillations; it is now thought that the rate of oscillations, rather than the average level of calcium, is the prime driver for smooth muscle function, including contraction and activation of gene transcription (Berridge 2008).

Sustained stress (physical or oxidative), tissue damage, inflammatory mediators and other stimuli can promote enhanced growth, apoptosis (programmed cell death, p. 26) and switching to a more secretory phenotype (see above). Increased mediator release as a result of switching to a more secretory phenotype can potentiate such changes and attract inflammatory cells, resulting in a positive feedback loop. Chronic disease and inflammation can therefore lead to extensive smooth muscle remodelling, a major contributing factor to, for example, chronic asthma and pulmonary hypertension, which significantly worsens the conditions (Mahn et al 2010, Stenmark et al 2006). Peripheral vascular remodelling may also occur in essential hypertension and diabetes.

## CARDIOVASCULAR AND LYMPHATIC SYSTEMS

## GENERAL ORGANIZATION

Cells of peripheral blood, suspended in plasma, circulate through the body in the blood vascular system. Fluid and solutes exchange between the plasma and interstitium across capillaries and small venules. Excess interstitial fluid from peripheral tissues returns to the blood vascular system via the lymphatic system, which also provides a channel for the migration of leukocytes and the absorption of certain nutrients from the gut.

The cardiovascular system carries nutrients, oxygen, hormones, etc. throughout the body and the blood redistributes and disperses heat. As a consequence of the hydrostatic pressure, the system also has mechanical effects, such as maintaining tissue turgidity. Blood circulates within a system made up of the heart, the central pump and main motor of the system; arteries, which lead away from the heart and carry the blood to the periphery; and veins, which return the blood to the heart. The heart is essentially a pair of muscular pumps, one feeding the pulmonary circulation, which is responsible for gas exchange in the lungs and has a low hydrostatic pressure, and the other feeding the systemic circulation, which has a high hydrostatic pressure and serves the rest of the body. With limited exceptions, both circulations form a closed system of tubes, so that blood per se does not usually leave the circulation.

From the centre to the periphery, the vascular tree shows three main modifications. The arteries increase in number by repeated bifurcation and by sending out side branches, in both the systemic and the pulmonary circulation. For example, the aorta, which carries blood from the heart to the systemic circulation, gives rise to about $4 \times 10^{6}$ arterioles and four times as many capillaries. The arteries also decrease in diameter, although not to the same extent as their increase in number, so that a hypothetical cross-section of all the vessels will show an increase in total area with increasing distance from the heart. At its emergence from the heart, the aorta of an adult man has an outer diameter of approximately 30 mm (cross-sectional area of nearly $7 \mathrm{~cm}^{2}$ ). The diameter decreases along the arterial tree until it is as little as $10 \mu \mathrm{~m}$ in arterioles (each with a cross-sectional area of about $80 \mu \mathrm{~m}^{2}$ ). However, given the enormous number of arterioles, the total cross-sectional area at this level is approximately $150 \mathrm{~cm}^{2}$, more than 200 times that of the aorta. As a result, blood flow is faster near the heart than at the periphery.

The walls of arteries decrease in thickness towards the periphery, although this is not as substantial as the reduction in vessel diameter. Consequently, in the smallest arteries (arterioles), the thickness of the wall represents about half the outer radius of the vessel, whereas in a large vessel it represents between one-fifteenth and one-fifth, e.g. in the thoracic aorta the radius is approximately 17 mm and the wall thickness 1.1 mm .

Venules, which return blood from the capillaries, converge on each other, forming a progressively smaller number of veins of increasingly large size. As with arteries, the hypothetical total cross-sectional area of all veins at a given level reduces nearer to the heart. Eventually, only the two largest veins, the superior and inferior venae cavae, open into the heart from the systemic circulation. A similar pattern is found in the pulmonary circulation but here the vascular loop is shorter and has fewer branch points, and consequently, the number of vessels is smaller than in the systemic circulation. The total end-to-end length of the vascular network in a typical adult is twice the circumference of the earth.

Large arteries, such as the thoracic aorta and subclavian, axillary, femoral and popliteal arteries, lie close to a single vein that drains the same territory as that supplied by the artery. Other arteries are usually flanked by two veins, satellite veins (venae comitantes), which lie on either side of the artery and have numerous cross-connections; the whole is enclosed in a single connective tissue sheath. The artery and the two satellite veins are often associated with a nerve, and when they are surrounded by a common connective tissue sheath they form a neurovascular bundle.

The close association between the larger arteries and veins in the limbs allows counterflow exchange of heat. This mechanism promotes heat transfer from arterial to venous blood and thus helps to preserve body heat. Counterflow heat exchange systems are found in certain organs, e.g. in the testis, where the pampiniform plexus of veins surrounds the testicular artery (this arrangement not only conserves body heat, but also maintains the temperature of the testis below average body temperature). Counterflow exchange mechanisms are found in the microcirculation, as in the arterial and venous sinusoids of the vasa recta in the renal medulla. Here, countercurrent exchange retains solutes at a high concentration in the medullary interstitium, with efferent
venous blood transferring solutes to the afferent arterial supply; this mechanism is essential for concentration of the urine.

Arteries and veins are named primarily according to their anatomical position. In functional terms, four main classes of vessel are described: conducting and distributing vessels (large arteries), resistance vessels (small arteries but mainly arterioles), exchange vessels (capillaries, sinusoids and small venules) and capacitance vessels (veins). Structurally, arteries can also be divided into elastic and muscular types. Although muscle cells and elastic tissue are present in all arteries, the relative amount of elastic material is greatest in the largest vessels, whereas the relative amount of smooth muscle increases progressively towards the smallest arteries.

The large conducting arteries that arise from the heart, together with their main branches, are characterized by the predominantly elastic properties of their walls. Distributing vessels are smaller arteries supplying the individual organs, and their walls are characterized by a well-developed muscular component. Resistance vessels include the smallest arteries and arterioles, and are highly muscularized. They provide the major part of peripheral resistance to blood flow and so cause the largest drop in blood pressure before the blood flows into the tissue capillary beds.

Capillaries, sinusoids and small (postcapillary) venules are collectively termed exchange vessels. Their thin walls allow exchange between blood and the interstitial fluid that surrounds all cells: this is the essential function of a circulatory system. Arterioles, capillaries and venules constitute the microvasculature, the structural basis of the microcirculation.

Larger venules and veins form an extensive but variable, largevolume, low-pressure system of vessels conveying blood back to the heart. Their high capacitance is due to the significant distensibility (compliance) of their walls, so that the content of blood is high even at low pressures. Veins contain the greatest proportion of blood, reflecting their large relative volume.

Blood from the gastrointestinal tract (with the exception of the lower part of the anal canal) and from the spleen, pancreas and gallbladder drains to the liver via the portal vein. The portal vein ramifies within the substance of the liver like an artery and ends in the hepatic sinusoids. These drain into the hepatic veins, which in turn drain into the inferior vena cava. Blood supplying the abdominal organs thus passes through two sets of capillaries before it returns to the heart. The first provides the organs with oxygenated blood, and the second carries deoxygenated blood, rich in absorption products from the intestine, through the liver parenchyma. A venous portal circulation also connects the median eminence and infundibulum of the hypothalamus with the adenohypophysis. In essence, a venous portal system is a capillary network that lies between two veins, instead of between an artery and a vein, which is the more usual arrangement in the circulation. A capillary network may also be interposed between two arteries, e.g. in the renal glomeruli, where the glomerular capillary bed lies between afferent and efferent arterioles. This maintains a relatively high-pressure system, which is important for renal filtration.

A parallel circulatory system is provided by the lymphatic vessels and lymph nodes. Lymphatic vessels originate in peripheral tissues as blindended endothelial tubes that collect excess fluid from the interstitial spaces between cells and conduct it as lymph. Lymph is returned to the blood vascular system via lymphatic vessels, which converge on the large veins in the root of the neck.

The development of blood vessels is described in Chapter 13.

## General features of vessel walls

All blood vessels, with the exception of capillaries and venules, have walls consisting of three concentric layers (tunicae) (see Fig. 6.8). The intima (tunica intima) is the innermost layer. Its main component, the endothelium, lines the entire vascular tree, including the heart and lymphatic vessels. The media (tunica media) contains muscle cells, elastic fibres and collagen. While it is by far the thickest layer in arteries, the media is absent in capillaries and is comparatively thin in veins. The adventitia (tunica adventitia) is the outer coat of the vessel and consists of connective tissue, nerves and vessel capillaries (vasa vasorum). It links the vessels to the surrounding tissues. Vessels differ in the relative thicknesses and detailed compositions of these layers.

## Large elastic arteries

The aorta and its largest branches (brachiocephalic, common carotid, subclavian and common iliac arteries) are large elastic arteries that conduct blood to the medium-sized distributing arteries.

The intima is made of an endothelium, resting on a basal lamina, and a subendothelial connective tissue layer. The endothelial cells are flat, elongated and polygonal in outline, with their long axes parallel to the direction of blood flow (see Fig. 6.17). The subendothelial layer is well developed, contains elastic fibres and type I collagen fibrils, fibroblasts and small, smooth muscle-like myointimal cells. The latter accumulate lipid with age, and in an extreme form this contributes to atherosclerosis. Thickening of the intima progresses with age and is more marked in the distal than in the proximal segment of the aorta.

A prominent internal elastic lamina, sometimes split, lies between intima and media. This lamina is smooth, measures about $1 \mu \mathrm{~m}$ in thickness, and, with the elastic lamellae of the media, is stretched under the effect of systolic pressure, recoiling elastically in diastole. Elastic arteries can thus sustain continuous blood flow despite the pulsatile cardiac output, and smooth out the cyclical pressure wave. The media has a markedly layered structure, in which fenestrated layers of elastin (elastic lamellae) alternate with interlamellar smooth muscle cells (Fig. 6.6), collagen and fine elastic fibres. The arrangement is very regular, such that each elastic lamella and adjacent interlamellar zone is regarded as a 'lamellar unit' of the media. In the human aorta there are approximately 52 lamellar units, measuring about $11 \mu \mathrm{~m}$ in thickness. Number and thickness of lamellar units increases during postnatal development, from 40 at birth.

The adventitia is well developed. In addition to collagen and elastic fibres, it contains flattened fibroblasts with extremely long, thin processes, macrophages and mast cells, nerve bundles and lymphatic vessels. The vasa vasorum is usually confined to the adventitia.

## Muscular arteries

Muscular arteries are characterized by the predominance of smooth muscle in the media (Fig. 6.7). The intima consists of an endothelium, similar to that of elastic arteries, which rests on a basal lamina and subendothelial connective tissue. The internal elastic lamina (see Fig. 6.7; Fig. 6.8) is a distinct, thin layer, sometimes duplicated and occasionally absent. It is thrown into wavy folds as a result of contraction of smooth muscle in the media. Some $75 \%$ of the mass of the media consists of smooth muscle cells that run spirally or circumferentially around the vessel wall. The relative amount of extracellular matrix is therefore less than in large arteries, although fine elastic fibres that run mainly parallel to the muscle cells are present. An external elastic lamina, composed of sheets of elastic fibres, forms a less compact layer than the internal lamina, and separates the media from the adventitia in larger muscular arteries. The adventitia is made of fibroelastic connective tissue, and can be as thick as the media in the smaller arteries. The inner part of the adventitia contains more elastic than collagen fibres.

## Arterioles

In arterioles (Figs 6.9-6.10), the endothelial cells are smaller than in large arteries, but their nuclear region is thicker and often projects markedly into the lumen. The nuclei are elongated and orientated parallel to the vessel length, as is the long axis of the cell. The basal surface of the endothelium contacts a basal lamina, but an internal elastic lamina is either absent or highly fenestrated and traversed by cytoplasmic processes of muscle or endothelial cells. The muscle cells are larger in cytoplasmic volume than those in the walls of large arteries and form a layer one or two cells thick. They are arranged circumferentially and are tightly wound around the endothelium. In the smallest arterioles each cell makes several turns, producing extensive apposition between parts of the same cell. Contraction of the muscle constricts the lumen, and so controls blood flow into the capillary bed; arterioles thus act functionally as precapillary sphincters, even though the absence of an anatomically delineated sphincter means that the term is no longer commonly used. Contraction of arterioles is primarily regulated by local vasoactive and metabolic factors, but can also be controlled by central mechanisms.

Arterioles are usually densely innervated by sympathetic fibres, via small bundles of varicose axons packed with transmitter vesicles, mostly of the adrenergic type. The distance between axolemma and muscle cell membrane can be as little as $50-100 \mathrm{~nm}$ and the gap is occupied only by a basal lamina. Autonomic neuromuscular junctions are very common in arterioles. Arteriolar adventitia is very thin.

## Capillaries

The capillary wall (Fig. 6.11) is formed by an endothelium and its basal lamina, plus a few isolated pericytes. Capillaries are the vessels closest

Fig. 6.6 Elastic artery (human aorta), stained for elastic fibres. The dense staining of the internal elastic lamina is seen close to the luminal surface (top); elastic lamellae fill the tunica media and merge with the external elastic lamina at its junction with the collagenous adventitia (red fibres, below). to the tissue they supply and their wall constitutes a minimal barrier between blood and the surrounding tissues. Capillary structure varies in different locations. Capillaries measure $4-8 \mu \mathrm{~m}$ in diameter (much more in the case of sinusoids) and are hundreds of microns long. Their lumen is just large enough to admit the passage of single blood cells, usually with considerable deformation. Typically a single endothelial cell forms the wall of a capillary, and there are junctional complexes between extensions of the same cell.

Endothelial cells are joined by tight junctions (occluding junctions, zonulae adherentes), forming a diffusion barrier. Capillary permeability varies greatly among tissues and is correlated largely with the type of endothelium. The majority of tissues, including brain, muscle, lung and connective tissues, contain capillaries with a continuous, unbroken layer of endothelium (continuous endothelium). This is impermeable to proteins, although electrolytes can diffuse through the tight junc-

Fig. 6.11 Transmission electron micrograph of a capillary in a human muscle biopsy specimen. An endothelial cell with its nucleus in the plane of section forms adherens junctions (long arrows) with either a second cell or an extension of itself. The cytoplasm contains numerous transcytotic vesicles (short arrows). A basal lamina surrounds the capillary. Fig. 6.12 Expanded sinusoids (S), typical of endocrine glands and certain other tissues, are seen here containing erythrocytes (orange) in the adenohypophysis. Endocrine cells stain either blue or reddish-brown, or are poorly stained in this trichrome preparation.
tions, albeit relatively slowly. Their passage is further limited in brain, thymic cortex and testis by particularly tight junctions.

Endothelial cells of some capillaries have fenestrations, or pores, through their cytoplasm, which facilitate diffusion. Fenestrations are approximately circular and $50-100 \mathrm{~nm}$ in diameter, and at their edge the luminal and abluminal membranes of the endothelial cell come into contact. The fenestration itself is usually occupied by a thin, electron-dense diaphragm containing glycoprotein PV-1, which restricts passage of large molecules such as proteins. Fenestrated capillaries occur in intestinal mucosae, endocrine and exocrine glands, and renal glomeruli, where they may lack a diaphragm. Fenestrations are almost invariably present in capillaries that lie close to an epithelium, including the skin.

## Sinusoids

Sinusoids are expanded capillaries (Fig. 6.12), and are large and irregular in shape. They have true discontinuities in their walls, allowing intimate contact between blood and the parenchyma. The discontinuities are formed by gaps between fenestrated endothelial cells, such that the sinusoidal lining, and sometimes also the basal lamina, is incomplete. Sinusoids occur in large numbers in the liver (where a basal
lamina is completely absent), spleen, bone marrow, adenohypophysis (see Fig. 6.12) and suprarenal medulla.

## Venules

When two or more capillaries converge, the resulting vessel is larger ( $10-30 \mu \mathrm{~m}$ ) and is known as a venule (postcapillary venule). Venules (see Fig. 6.9) are essentially tubes of flat, oval or polygonal endothelial cells surrounded by basal lamina and, in the larger vessels, by a delicate adventitia of a few fibroblasts and collagen fibres mainly running longitudinally. Pericytes (see Fig. 6.21) support the walls of these venules.

Postcapillary venules are sites of leukocyte migration. In venules of mucosa-associated lymphoid tissue (MALT), particularly of the gut and bronchi, and in the lymph nodes and thymus, endothelial cells are taller and have intercellular junctions through which lymphocytes and other blood components can readily pass. These are known as high endothelial venules (HEVs) (see Figs 6.18-6.19). Elsewhere, venules are believed to be a major site where migration of neutrophils, macrophages and other leukocytes into extravascular spaces occurs, and where neutrophils may temporarily attach, forming marginated pools.

In general, the endothelium of venules has few tight junctions and is relatively permeable. The intercellular junctions of venules are sensitive to inflammatory agents, which increase their permeability to fluids and defensive cells, and facilitate leukocyte extravasation by diapedesis.

Venules do not acquire musculature until they are about $50 \mu \mathrm{~m}$ in outer diameter, when they are known as muscular venules. This distinction is important because postcapillary venules, which lack muscle in their walls, are as permeable to solutes as capillaries and are thus part of the microcirculatory bed. At the level of the postcapillary venule the cross-sectional area of the vascular tree is at its maximum, and there is a dramatic fall in pressure (from 25 mmHg in the capillary to approximately 5 mmHg ). Muscular venules converge to produce a series of veins of progressively larger diameter. Venules and veins are capacitance vessels, i.e. they have thin distensible walls that can hold a large volume of blood and accommodate luminal pressure changes.

## Fluid exchange in the microvasculature

The microvasculature is important for the creation and maintenance of the interstitial fluid that bathes the cells. The thin walls of capillaries and small venules allow easy diffusion of fluid and most small molecules, but the endothelial barrier prevents movement of proteins; consequently, plasma and interstitial fluid have almost identical compositions, except that the latter contains very little protein. Fluid transfer across these exchange vessels is driven by the balance between the hydrostatic pressure (i.e. blood pressure within them) forcing fluid into the tissues, and the oncotic pressure (colloidal osmotic pressure, reflecting the difference in protein concentrations) drawing fluid back into the vessels. These 'Starling forces' are normally closely balanced, so differences in hydrostatic pressure mean that fluid tends to be filtered into the tissue at the arterial side of the exchange vessels and largely reabsorbed at the venous side. The balance forms lymph. Disruption of the balance (e.g. high venous pressure in the feet) can lead to accumulation of tissue fluid (oedema) and swelling.

## Inflammation and endothelial permeability

Inflammatory mediators increase the permeability of capillaries and small venules by causing contraction of endothelial cells and so loosening tight junctions. This facilitates leukocyte extravasation by diapedesis but also disrupts normal barrier function, allowing extravasation of protein and fluids. The consequence is tissue oedema and the swelling that is commonly associated with inflammation. There is considerable cross-talk between endothelial cells and cells of the immune system.

## Veins

Veins are characterized by a relatively thin wall in comparison to arteries of similar size and by a large capacitance. Wall thickness is not correlated exactly with the size of the vein and varies in different regions, e.g. the wall is thicker in veins of the leg than it is in veins of a similar size in the arm.

The structural plan of the wall is similar to that of other vessels, except that the amount of muscle is considerably less than in arteries, while collagen and, in some veins, elastic fibres predominate. In most veins, e.g. those of the limbs, the muscle is arranged approximately circularly. Longitudinal muscle is present in the iliac, brachiocephalic, portal and renal veins and in the superior and inferior venae cavae. Muscle is absent in the maternal placental veins, dural venous sinuses,
pial and retinal veins, veins of trabecular bone and the venous spaces of erectile tissue; these veins consist of endothelium supported by variable amounts of connective tissue. Distinction between the media and adventitial layers is often difficult, and a discrete internal elastic lamina is absent.

Tethering of some veins to connective tissue fasciae and other surrounding tissues may prevent collapse of the vessel even under negative pressure (e.g. in the cranium). Pressure within the venous system does not normally exceed 5 mmHg , and it decreases as the veins grow larger and fewer in number, approaching zero close to the heart. As they contain only a small amount of muscle and commonly have a large calibre, veins have limited influence on blood flow. However, venoconstriction is an important component of the baroreceptor reflex because it reduces vein compliance and therefore capacity, effectively mobilizing blood to maintain or increase central venous pressure, and hence cardiac output. A sudden fall in blood volume, e.g. following a haemorrhage, also initiates the elastic recoil and reflex constriction of veins, in order to compensate for the blood loss and maintain central venous pressure and venous return to the heart. Vasoconstriction in cutaneous veins in response to cooling is important in thermoregulation.

Most veins have valves to prevent reflux of blood (Figs 6.13-6.14). A valve is formed by an inward projection of the intima, strengthened by collagen and elastic fibres, and covered by endothelium that differs in orientation on its two surfaces. Surfaces facing the vessel wall have transversely arranged endothelial cells, whereas on the luminal surface of the valve, over which the main stream of blood flows, cells are arranged longitudinally in the direction of flow. Most commonly two, or occasionally three, valves lie opposite one another; sometimes only one is present. They are found in small veins or where tributaries join

Fig. 6.13 The upper portions of the femoral and long saphenous veins laid open to show the valves, at about two-thirds of their natural size.

Fig. 6.14 A valve in a human small vein, formed from flap-like extensions of the intima that close when pressure increases on the proximal side, preventing backflow. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 6.15 A, A microcirculatory unit, showing a terminal arteriole, thoroughfare channels (TC) formed of metarterioles, capillaries (C) and collecting venule. Note the thick wall of the anastomotic channel composed of layers of modified smooth muscle cells.
larger veins. The valves are semilunar (cusps) and attached by their convex edges to the venous wall. Their concave margins are directed with the flow and lie against the wall as long as flow is towards the heart. When blood flow reverses, the valves close and blood fills an expanded region of the wall, a sinus, on the cardiac side of the closed valve. This may give a 'knotted' (varicose) appearance to the distended veins, if these have many valves. In the limbs, especially the legs where venous return is against gravity, valves are of great importance in aiding venous flow. Blood is moved towards the heart by the intermittent pressure produced by contractions of the surrounding muscles (the muscle pump). Valves are absent in the veins of the thorax and abdomen.

## VASCULAR SHUNTS AND ANASTOMOSES

## Arteriovenous shunts and anastomoses

Communications between the arterial and venous systems are found in many regions of the body. In some parts of the microcirculation (e.g. in the mesenteries), the capillary circulation can be bypassed by wider thoroughfare channels formed by metarterioles (Fig. 6.15A). These have similarities to both capillaries and the smallest arterioles, and have a discontinuous layer of smooth muscle in their walls. Metarterioles can deliver blood directly to venules or to a capillary bed, according to local demand and conditions. When functional demand is low, blood flow is largely limited to the bypass channel. Periodic opening and closing of different arterioles irrigates different parts of the capillary network. The number of capillaries in individual microvascular units and the size of their mesh determine the degree of vascularity of a tissue; the smallest meshes occur in the lungs and the choroid of the eye.

Arteriovenous anastomoses (Fig. 6.15B) are direct connections between smaller arteries and veins. Connecting vessels may be straight or coiled, and often possess a thick muscular tunic. Under sympathetic control, the vessel is able to close completely, diverting blood into the capillary bed. When patent, the vessel carries blood from artery to vein, partially or completely excluding the capillary bed from the circulation. Simple arteriovenous anastomoses are widespread and occur notably in the skin of the nose, lips and ears, nasal and gastrointestinal mucosae, erectile tissue, tongue, thyroid gland and sympathetic ganglia. In the

Fig. 6.16 A digital arteriovenous anastomosis, prepared by intravascular perfusion of stain in a full-thickness specimen of skin, followed by clearance. The heavily stained, thick-walled, tortuous anastomotic channels (AC) contrast with the central arterial stem (A) and the thinwalled venous (V) outflow channels. (Courtesy of the late Professor RT Grant, GKT School of Medicine, London.)
newborn child, there are few arteriovenous anastomoses but they develop rapidly during the early years. In old age they atrophy, sclerose and diminish in number. These factors may contribute to the less efficient temperature regulation that occurs at the two extremes of age.

In the skin of the hands and feet, especially in digital pads and nail beds (see Fig. 7.18), anastomoses form a large number of small units termed glomera. Each glomus organ has one or more afferent arteries, stemming from branches of cutaneous arteries that approach the surface. The afferent artery gives off a number of fine periglomeral branches and then immediately enlarges, makes a sinuous curve, and narrows again into a short, funnel-shaped vein that opens at right angles into a collecting vein (Fig. 6.16).

## Arterial anastomoses

Arteries can be joined to each other by an anastomosis, so that one can supply the territory of the other. An end-to-end anastomosis occurs when two arteries communicate directly, e.g. the uterine and ovarian arteries, the right and left gastro-epiploic arteries, the ulnar artery and the superficial palmar branch of the radial artery. Anastomosis by convergence occurs when two arteries converge and merge, as happens when the vertebral arteries form the basilar artery at the base of the brain. A transverse anastomosis occurs when a short arterial vessel links two large arteries transversely, e.g. the anastomoses between the two anterior cerebral arteries; the posterior tibial artery and the fibular artery; and the radial and ulnar arteries at the wrist.

## The angiosome concept and vascular territories

The blood supply to the skin and underlying tissues has been mapped using ink injection studies, corrosion casts, dissection, perforator mapping and two- and three-dimensional radiographic analyses of fresh cadavers and isolated limbs injected with solutions containing lead oxide.

Findings from these different studies all support the clinically important concept of the angiosome, a three-dimensional block of tissue supplied by a source artery, its perforating branches and their accompanying veins (Taylor and Palmer 1987, Levy et al 2003, Taylor 2003, Pan and Taylor 2009). Angiosomes form a complex three-dimensional jigsaw puzzle; some pieces have a predominantly cutaneous component while others are predominantly muscular. Each consists of arteriosomes and venosomes linked to neighbouring angiosomes by either similar calibre (true) or reduced calibre (choke) anastomoses. Anastomoses between adjacent angiosomes may occur within the skin or within muscle. Some muscles are supplied by a single artery and its accompanying veins and therefore lie within one angiosome, while other muscles are supplied by more than one vessel and therefore cross more than one angiosome. A detailed knowledge of anatomical vascular territories and spatial angiosome architecture is essential in designing, evaluating and raising axial flaps based on vascular connections in plastic and reconstructive surgery.

## MICROSTRUCTURE OF BLOOD VESSELS

## Intima

The intimal lining of blood vessels consists of an endothelium, and a variable amount of subendothelial connective tissue, depending on the vessel.

## Endothelium

The endothelium is a monolayer of flattened polygonal cells that extends continuously over the luminal surface of the entire vascular tree (see Fig. 6.10; Fig. 6.17). Its structure varies in different regions of the vascular bed.

The endothelium is a key component of the vessel wall and subserves several major physiological roles. Endothelial cells are in contact with the blood stream and thus influence blood flow. They regulate the diffusion of substances and migration of cells out of and into the circulating blood. In the brain, endothelial cells of small vessels actively transport substances, e.g. glucose, into the brain parenchyma. Endothelial cells play an important role in haemostasis because they produce von Willebrand factor, which promotes platelet adhesion (see below); secrete prostacyclin and thrombomodulin, which limits clot formation; and promote fibrinolysis by secreting tissue plasminogen activator. They have selective phagocytic activity and are able to extract substances from the blood. For example, the endothelium of pulmonary vessels removes and inactivates several polypeptides, biogenic amines, bradykinin, prostaglandins and lipids from the circulation, and converts the precursor of angiotensin II to its active form.

Endothelial cells secrete vasoconstrictor (thromboxane) and vasodilator (prostacyclin) prostaglandins, nitric oxide (NO) and endothelin (a vasoconstrictor). They respond to stretch (e.g. increased pressure) and the shear effect of blood flow via stretch-sensitive ion channels in the cell membrane. Endothelial cells synthesize components of the basal lamina. They proliferate to provide new cells during growth of blood vessels, to replace damaged endothelium, and to provide solid cords of cells that develop into new blood vessels (angiogenesis). Angiogenesis, which may be stimulated by endothelial production of

Fig. 6.17 A scanning electron micrograph of the luminal surface of the basilar artery. The tightly packed endothelial cells are elongated in the direction of blood flow. (Courtesy of Masoud Alian, University College, London.)
autocrine growth factors in response to local hypoxia, is important in wound healing and in the growth of tumours. Endothelial cells are also active participants in, and regulators of, inflammatory processes (Pober and Sessa 2007).

Although endothelial cells are thin, they extend over a relatively large surface area. They are thickest at the nucleus, where they can reach $2-3 \mu \mathrm{~m}$, causing a slight bulge into the lumen (see Fig. 6.10). Elsewhere, they are thin and laminar, and are often as little as $0.2 \mu \mathrm{~m}$ thick in capillaries. They are generally elongated in the direction of blood flow, especially in arteries (see Fig. 6.17).

Except in sinusoids, endothelial cells usually adhere to each other at their edges, so there is no discontinuity in the lining of the lumen. They adhere to adjacent cells through the junctional complex, an area of apposition where adherent and tight junctions are found. They also communicate via gap junctions, which are most marked in continuous capillaries. Cell contacts and myoendothelial gap junctions between endothelial and smooth muscle cells are common in small resistance arteries and arterioles, where the separation between endothelium and media is reduced and the inner elastic lamina is either very thin or absent. Myoendothelial gap junctions play an important role in the integration and regulation of vascular function (Figueroa and Duling 2009).

Transcytotic (pinocytotic) vesicles (see Fig. 6.11) are present in all endothelial cells but are particularly numerous in exchange vessels; they include caveolae (see Fig. 6.4) typical of smooth muscle cells. They shuttle small amounts of interstitial fluid or plasma across the endothelial cytoplasm and thus facilitate bulk exchange of nutrients and metabolites between these compartments. They are normally the only means by which protein can cross the endothelium. Endothelial cells secrete many factors but they do not have the morphological characteristics of secretory cells.

The Wiebel-Palade body is characteristic of endothelial cells. It is an elongated cytoplasmic vesicle, $0.2 \times 2-3 \mu \mathrm{~m}$ in length, which contains regularly spaced tubular structures parallel to its long axis. WiebelPalade bodies play a role in both inflammation and haemostasis because they store the adhesion molecule P-selectin (see below) and von Willebrand factor, which mediates platelet adhesion to the extracellular matrix after vascular injury.

## Von Willebrand factor

Von Willebrand factor (vWF) is a very large, multimeric glycoprotein consisting of at least 80 monomers of 250 kDa each, responsible for the characteristic appearance of Wiebel-Palade bodies. Its function is to bind to other proteins and provide a bridge between them.

## Endothelial cell-leukocyte interactions

The luminal surface of endothelial cells does not normally support the adherence of leukocytes or platelets. However, many functions of human vascular endothelial cells are dynamic rather than fixed. Activated endothelial cells and the characteristic endothelium of high endothelial venules (HEVs) of lymphoid tissues are sites of leukocyte attachment and diapedesis (see below).

On release from endothelial cells, vWF binds to collagen in the subendothelial matrix; when this is exposed following vascular damage, vWF facilitates platelet adhesion by binding to platelet glycoprotein receptors. This is particularly efficient in high-flow/shear-stress conditions, when it also causes platelet activation. Although the major source of vWF is probably endothelial cells, it is also produced by megakaryocytes and stored in platelet $\alpha$-granules. vWF is present in plasma, where it binds and stabilizes factor VIII, a clotting protein secreted into the blood stream by hepatocytes. Hereditary deficiency or defective function of vWF causes defective haemostasis and a tendency to bleed (von Willebrand disease) (reviewed in Sadler (2005)).

HEVs (Fig. 6.18) are located within the T-cell domains, between and around lymphoid follicles in all secondary lymphoid organs and tissues except the spleen. They are specialized venules of $7-30 \mu \mathrm{~m}$ diameter, which possess a conspicuous cuboidal endothelial lining. The luminal aspect of HEVs shows a cobblestone appearance. The endothelial cells rest on a basal lamina and are supported by pericytes and a small amount of connective tissue (Fig. 6.19). They are linked by discontinuous adhesive junctions at their apical and basal aspects; the junctions are circumnavigated by migrating lymphocytes. Ultrastructurally, the endothelial cells have the characteristics of metabolically active secretory cells. Thus they contain large, rounded, euchromatic nuclei with one or two nucleoli, prominent Golgi complexes, many mitochondria, ribosomes and pinocytotic vesicles. Typically, they also possess WiebelPalade bodies (see above).

Many of the adhesion molecules that mediate interactions between blood leukocytes and HEVs or cytokine-activated endothelium have been identified. They can be divided into three general families: selectins, integrins and the immunoglobulin supergene family. Selectins and

Fig. 6.18 A high endothelial venule in a human lymph node, sectioned longitudinally, lined by cuboidal endothelium (arrow). Fig. 6.19 A high endothelial venule in transverse section in a human palatine tonsil. The lumen is completely filled by a neutrophil ( N ). Cuboidal endothelial cells (EC) line the vessel. Two lymphocytes (L) with heterochromatic nuclei are seen below, in transit within the wall of the vessel. (Courtesy of Dr Marta Perry, Department of Anatomy, St Thomas's Hospital Medical School, London.)
integrins are expressed on leukocytes and mediate adhesion of circulating cells to the endothelium, which expresses selectins and members of the immunoglobulin supergene family. Regulated expression of these molecules by both cell types provides the means by which leukocytes recognize the vessel wall (leukocyte homing antigens and vascular addressins), adhere to it and subsequently leave the circulation.

The first step in this cascade is the loose binding or tethering of leukocytes, and this is initiated via L-, P- or E-selectin. This weak, reversible adhesion allows leukocytes to roll along the endothelial surface of a vessel lumen at low velocity, making and breaking contact, and sampling the endothelial cell surfaces. Recognition of chemokines (chemotactic signalling molecules) presented by the endothelium leads to 'inside-out' signalling and conversion of integrins at the leukocyte surface into actively adhesive configurations that bind strongly to their endothelial ligands, resulting in stable arrest. Finally, the leukocyte migrates through the vessel wall (diapedesis), passing either between (paracellular migration) or across (transcellular migration) endothelial cells. Transcellular migration is thought to be the preferred pathway; endothelial transcytotic vesicles (caveolae), intermediate filaments (vimentin) and F-actin are important in the creation of transient transcellular channels through which leukocytes pass. They then cross the basal lamina and migrate into the surrounding tissue by mechanisms that involve CD31 antigen and matrix metalloproteinases (reviewed in Vestweber (2007)).

## Cell adhesion molecules

There are three known members of the selectin family of adhesive proteins: L-selectin (also known as lymphocyte homing receptor), E-selectin and P-selectin. L-selectin is expressed on most leukocytes. Endothelial cells of HEVs in lymphoid organs express its oligosaccharide ligand, although other molecules such as mucins may be alternative ligands. L-selectin mediates homing of lymphocytes, especially to peripheral lymph nodes, but also promotes the accumulation of neutrophils and monocytes at sites of inflammation. E-selectin is an inducible adhesion molecule that mediates adhesion of leukocytes to inflammatory cytokine-activated endothelium, and is only transiently expressed on endothelium. P-selectin is rapidly mobilized from WiebelPalade bodies, where it is stored, to the endothelial surface after endothelial activation. It binds to ligands expressed on neutrophils, platelets and monocytes, and, like E-selectin, tethers leukocytes to endothelium at sites of inflammation. P-selectin is quickly endocytosed by the endothelial cells and so its expression is short-lived.

The integrins are a large family of molecules that mediate cell-to-cell adhesion as well as interactions of cells with extracellular matrix. Certain $\beta_{1}$ integrin heterodimers are expressed on lymphocytes 2-4 weeks after antigenic stimulation (very late antigens, VLAs) and bind to the extracellular matrix. Additionally, VLA-4, present on resting lymphocytes (expression increases after activation), monocytes and eosinophils, binds to the vascular cell adhesion molecule-1 (VCAM-1), the ligand on activated endothelium. In contrast to $\beta_{1}$ integrins, which many cells express, the expression of $\beta_{2}$ integrins is limited to white blood cells. Although the leukocyte integrins are not constitutively adhesive, they become highly adhesive after cell activation and therefore play a key role in the events required for cell migration. The endothelial ligands for one such $\beta_{2}$ integrin are the intercellular adhesion molecules-1 and 2 (ICAM-1 and ICAM-2), which belong to the immunoglobulin superfamily.

Three members of the large immunoglobulin superfamily of proteins are involved in leukocyte-endothelial adhesion, providing integrin counter-receptors on the endothelial cell membrane. ICAM-1 and ICAM-2 are constitutively expressed but upregulated by inflammatory cytokines. VCAM-1 is absent from resting endothelium but is induced by cytokines on activated endothelium and promotes extravasation of lymphocytes at sites of inflammation.

## Subendothelial connective tissue

The subendothelial connective tissue, also termed the lamina propria, is a thin but variable layer. It is largely absent in the smallest vessels, where the endothelium is supported instead by pericytes (see Fig. 6.21). It contains a typical fibrocollagenous extracellular matrix, a few fibroblasts and occasional smooth muscle cells. Endothelial von Willebrand factor concentrates in this layer and participates in haemostasis and platelet adhesion when the overlying endothelium is damaged.

## Media

The media consists chiefly of concentric layers of circumferentially or helically arranged smooth muscle cells with variable amounts of elastin and collagen.

## Smooth muscle

Smooth muscle forms most of the media of arteries (see Fig. 6.7) and arterioles. A thinner layer of smooth muscle is also found in venules and veins; small segments of the pulmonary veins nearest to the heart contain striated cardiac muscle. Contraction of the smooth muscle in arteries and arterioles reduces the calibre of the vessel lumen, reducing blood flow through the vessel. This is particularly effective in small resistance vessels, where the wall is thick relative to the diameter of the vessel. Smooth muscle activation also increases the rigidity of the vessel wall, reducing its compliance. In arteries this affects propagation of the pulse, whereas in veins it effectively reduces their capacity.
The smooth muscle cells synthesize and secrete elastin, collagen and other extracellular components of the media, which bear directly on the mechanical properties of the vessels. The mechanics of the musculature of the media are complex. Distensibility, strength, self-support, elasticity, rigidity, concentric constriction, etc. are interrelated functions and are finely balanced in the different regions of the vascular bed.

In large arteries, where the blood pressure is high, the muscle cells are shorter ( $60-200 \mu \mathrm{~m}$ ) and smaller in volume than in visceral muscle. In arterioles and veins, smooth muscle cells more closely resemble those from the viscera. The cells are packed with myofilaments and other elements of the cytoskeleton, including intermediate filaments. Vascular muscle cells contain intermediate filaments of either vimentin alone or both vimentin and desmin, whereas the intermediate filaments of visceral smooth muscle are exclusively of desmin. Intercellular junctions are mainly of the adhesive (adherens) type, coupling cells mechanically Gap junctions couple cells electrically and allow passage of small signalling molecules. Junctions between muscle cells and the connective tissue matrix are particularly numerous, especially in arteries.

The muscle cells of the arterial media can be regarded as multifunctional mesenchymal cells. After damage to the endothelium, muscle cells migrate into the intima and proliferate, forming bundles of longitudinally orientated cells that reform the layer. In certain pathological conditions, muscle cells (and macrophages) undergo fatty degeneration and participate in the formation of atheromatous plaques.

## Collagen and elastin

Components of the extracellular matrix (see Ch. 2) are major constituents of vessel walls; in large arteries and veins they make up more than half of the mass of the wall, mainly in the form of collagen and elastin. Other fibrous components such as fibronectin, and amorphous proteoglycans and glycosaminoglycans, are present in the interstitial space.

Elastin is found in all arteries and veins and is especially abundant in elastic arteries (see Fig. 6.6). Individual elastic fibres ( $0.1-1.0 \mu \mathrm{~m}$ in diameter) anastomose with each other to form net-like structures, which extend predominantly in a circumferential direction. More extensive fusion produces lamellae of elastic material, which, though usually perforated and thus incomplete, separate the layers of muscle cells. The internal elastic lamina is a conspicuous elastic lamella in arteries, between intima and media, which allows the vessel to recoil after distension. When the intraluminal pressure falls below physiological limits (post mortem), it is compressed and coils up into a regular corrugated shape (Fig. 6.20; see Figs 6.7, 6.10), reducing but not obliterating the lumen; the profile of the artery remains circular. Fenestrations in the elastic lamina, which may also be split in thickness, allow materials to diffuse between intima and media. An outer elastic lamina, similar in appearance to, but markedly less well developed and less compact than, the internal elastic lamina, lies at the outer aspect of the media at its boundary with the adventitia (see Fig. 6.7). These laminae are less evident in elastic arteries, where elastic fibres occupy much of the media (see Fig. 6.6).

Collagen fibrils are found in all three vessel layers. Type III collagen (reticulin) occupies much of the interstitial space between the muscle cells of the media and is also found in the intima. Collagen is abundant in the adventitia, where type I collagen fibres form large bundles that increase in size from the junction with the media to the outer limit of the vessel wall. In veins, collagen is the main component of the vessel wall and accounts for more than half its mass.

In general terms, collagen and elastic fibres in the media run parallel to, or at a small angle to, the axes of the muscle cells, and they are therefore arranged mainly circumferentially. In contrast, the predominant arrangement of collagen fibres in the adventitia is longitudinal. This arrangement imposes constraints on length change in large vessels under pressure, e.g. in large arteries, in which the radial distension under the effect of the pulse far exceeds the longitudinal distension. The outer sheath of type I collagen in the adventitia therefore has a structurally supportive role. The more delicate type III collagen network of the media provides attachment to the muscle cells and its role is to

Fig. 6.20 The wall of a human muscular artery, stained for elastin (black), showing the internal elastic lamina (IEL). Fine, incomplete elastic lamellae are interspersed between smooth muscle cells of the tunica media. The endothelium is partly detached in this postmortem specimen. van Gieson stain.
transmit force around the circumference of the vessel. In a distended vessel, the elastic fibres store energy and, by recoiling, help to restore the resting length and calibre.

The extracellular material of the media, including collagen and elastin, is produced by the muscle cells. Its turnover is slow compared to that in other tissues. In the adventitia, collagen is synthesized and secreted by fibroblasts, as in other connective tissues. During postnatal development, while vessels increase in diameter and wall thickness, there is an increase in elastin and collagen content. Subsequent changes in vessel structure, seen during ageing, include an increase in the ratio of collagen to elastin, with a reduction in vessel elasticity.

## Adventitia

The adventitia is formed of general connective tissue, varying in the thickness and density of its collagen fibre bundles.

## Vasa vasorum

In smaller vessels, the nourishment of the tissues of the vessel wall is provided by diffusion from the blood circulating in the vessel itself. The wall thickness at which simple diffusion from the lumen becomes insufficient is 1 mm . Large vessels have their own vascular supply within the adventitia (see Fig. 6.8), in the form of a network of small vessels, the vasa vasorum. These originate from, and drain into, peripheral branches of the vessel they supply. They ramify within the adventitia and, in the largest of arteries, penetrate the outermost part of the media. The vasa vasorum of the pulmonary artery arise from adjacent systemic arteries. The larger veins are also supplied by vasa vasorum but these may penetrate the wall more deeply, perhaps because of the lower oxygen tension.

## Nervi vasorum

Blood vessels are innervated by efferent autonomic fibres that regulate the state of contraction of the musculature (muscular tone) and thus the diameter of the vessels, particularly the resistance arteries and arterioles. Perivascular nerves branch and anastomose within the adventitia of an artery, forming a meshwork around it. Nerves are occasionally found within the outermost layers of the media in some of the large muscular arteries.

Nervi vasorum are small bundles of axons, which are almost invariably unmyelinated and typically varicose. Most are postganglionic axons derived from neurones in sympathetic ganglia. The density of innervation varies in different vessels and in different areas of the body; it is usually sparser in veins and larger lymphatic vessels. Large veins with a pronounced muscle layer, such as the hepatic portal vein, are well innervated. Some vessels in the brain may be innervated by intrinsic cerebral neurones, although neural control of brain vessels is of minor importance compared with metabolic and autoregulation (local response to stretch stimuli).

The control of vascular smooth muscle is complex. Vasoconstrictor adrenergic fibres release noradrenaline (norepinephrine), which acts on $\alpha$-adrenergic receptors in the muscle cell membrane. In addition,
circulating hormones and factors such as nitric oxide, prostaglandins and endothelin, which are released from endothelial cells, exert a powerful effect on the muscle cells. Neurotransmitters reach the muscle from the adventitial surface of the media, whereas hormonal and endothelial factors diffuse from the intimal surface. In a few tissues, sympathetic cholinergic fibres inhibit smooth muscle contraction and induce vasodilation. Vascular smooth muscle exhibits endogenous (myogenic) activity in response to stretch and shear.

Most arteries are accompanied by nerves that travel in parallel with them to the peripheral organs that they supply. However, these paravascular nerves are quite independent and do not innervate the vessels they accompany.

## Pericytes

Pericytes are present at the outer surface of capillaries and the smallest venules (postcapillary venules), where an adventitia is absent and there are no muscle cells. They are elongated cells, whose long cytoplasmic processes are wrapped around the endothelium. Pericytes are scattered in a discontinuous layer around the outer circumference of capillaries. They are generally absent from fenestrated capillaries but form a more continuous layer around postcapillary venules (Fig. 6.21). They are gradually replaced by smooth muscle cells as vessels converge and increase in diameter.

Pericytes are enclosed by their own basal lamina, which merges in places with that of the endothelium. Most display areas of close apposition with endothelial cells, and occasionally form adherens junctions where their basal laminae are absent. Pericyte cytoplasm contains actin, myosin, tropomyosin and desmin, which suggests that they are capable of contractile activity. They also have the potential to act as mesenchymal stem cells, and participate in repair processes by proliferating and giving rise to new blood vessel and connective tissue cells. Pericytes, or closely related cells, may be the source of myofibroblasts that contribute to fibrosis in disease processes (reviewed in Duffield (2012)).

## Cerebral vessels

Major branches of cerebral arteries that lie in the subarachnoid space over the surface of the brain have a thin outer coating of meningeal cells, usually one layer thick, where adjacent meningeal cells are joined by desmosomes and gap junctions. These arteries have a smooth muscle media and a distinct elastic lamina. Veins on the surface of the brain have very thin walls, and the smooth muscle layers in the wall are often discontinuous. They are coated externally by a monolayer of meningeal cells.

As arteries enter the subpial space and penetrate the brain, they lose their elastic laminae, and consequently the cerebral cortex and white matter typically contain only arterioles, venules and capillaries. The exceptions are the large penetrating vessels in the basal ganglia, where many arteries retain their elastic laminae and thick smooth muscle media. Enlarged perivascular spaces form around these large arteries in ageing individuals. Arterioles and venules in the cortex and white matter can be distinguished from each other because arterioles are surrounded by a smooth muscle coat, whereas veins and venules have larger lumina and thinner walls.

Fig. 6.21 A scanning electron micrograph of capillary (C) and pericytes (P) supporting the vessel wall. (Courtesy of T. Fujiwara and Y. Uehara, Department of Anatomy, Ehime University School of Medicine, Japan.)

Cerebral capillaries are the site of the blood-brain barrier. They are lined by endothelial cells, which are joined by tight junctions. The endothelial cytoplasm contains a few pinocytotic vesicles. The cells are surrounded by a basal lamina (see Fig. 3.12); at points of contact with perivascular astrocytes, the intervening basal lamina is formed by fusion of the endothelial and glial basal laminae. Pericytes, completely surrounded by basal lamina, are present around capillaries. Perivascular macrophages are attached to the outer walls of capillaries and to other vessels; they are phenotypically distinct from parenchymal microglia, which are also of monocytic origin. A thin layer of meningeal cells derived from the pia mater surrounds arterioles but disappears at the level of capillaries. For further descriptions of cerebral vessels, see Chapter 19.

## LYMPHATIC VESSELS

Lymphatic capillaries form wide-meshed plexuses in the extracellular matrices of most tissues. They begin as dilated, blind-ended tubes with larger diameters and less regular cross-sectional appearances than those of blood capillaries. Their basal laminae are incomplete or absent and they lack associated pericytes. The smaller lymphatic vessels are lined by endothelial cells, which have numerous transcytotic vesicles within their cytoplasm and so resemble blood capillaries. However, unlike capillaries, their endothelium is generally quite permeable to much larger molecules: they are readily permeable to large colloidal proteins and particulate material such as cell debris and microorganisms, and also to cells. Permeability is facilitated by gaps between the endothelial cells, which lack tight junctions (discontinuous endothelium), and by pinocytosis. The lymphatic system provides an important transport pathway for leukocytes and defence against infection (reviewed in Saharinen et al (2004)).

Lymph is formed from interstitial fluid, which is derived from blood plasma via filtration in the microcirculation. Much of the filtered fluid is reabsorbed by the time the blood leaves the venules, but about $15 \%$ or 8 litres per day enters the lymphatics. Lymphatic vessels take up this residual fluid by passive diffusion and the transient negative pressures in their lumina, which are generated intrinsically by contractile activity of smooth muscle in the largest lymphatic vessel walls, and extrinsically by compression of the lymph vessels as a result of contraction of adjacent muscle or arterial pulsation. The unidirectional flow of lymph is maintained by the presence of valves in the larger vessels (Fig. 6.22). Lymphatic capillaries are prevented from collapsing by anchoring filaments, which tether their walls to surrounding connective tissue structures and exert radial traction.

In most tissues, lymph is clear and colourless; in the lymphatic capillaries it has an identical composition to interstitial fluid. In contrast, lymph from the small intestine is dense and milky, reflecting the presence of lipid droplets (chylomicrons) derived from fat absorbed by the mucosal epithelium. The terminal lymphatic vessels in the mucosa of the small intestine are known as lacteals and the lymph as chyle. Lymphatic capillaries are not ubiquitous: they are not present in cornea, cartilage, thymus, the central or peripheral nervous system or bone marrow, and there are very few in the endomysium of skeletal muscles.

Lymphatic capillaries join into larger vessels that pass to local lymph nodes. Typically, lymph percolates through a series of nodes before

Fig. 6.22 A valve $(V)$ in a lymphatic vessel (L), accompanying a small venule (Ven) and arteriole (A) in human connective tissue. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
reaching a major collecting duct. There are exceptions to this arrangement: the lymph vessels of the thyroid gland and oesophagus, and of the coronary and triangular ligaments of the liver, all drain directly to the thoracic duct without passing through lymph nodes. In the larger vessels, a thin external connective tissue coat supports the endothelium. The largest lymphatic vessels $(200 \mu \mathrm{~m})$ have three layers, like small veins, although their lumen is considerably larger than that of veins with a similar wall thickness. The tunica media contains smooth muscle cells, mostly arranged circumferentially. Elastic fibres are sparse in the tunica intima, but form an external elastic lamina in the tunica adventitia.

The larger lymphatic vessels differ from small veins in having many more valves (see Fig. 6.22). The valves are semilunar, generally paired and composed of an extension of the intima. Their edges point in the direction of the current, and the vessel wall downstream is expanded into a sinus, which gives the vessels a beaded appearance when they are distended. Valves are important in preventing the backflow of lymph.

Deep lymphatic vessels usually accompany arteries or veins, and almost all reach either the thoracic duct or the right lymphatic duct, which usually joins the left or right brachiocephalic veins respectively at the root of the neck.

The thoracic duct is structurally similar to a medium-sized vein but the smooth muscle in its tunica media is more prominent. Most lymphatic vessels anastomose freely. Larger vessels have their own plexiform vasa vasorum and accompanying nerve fibres. If their walls are acutely infected (lymphangitis) this vascular plexus becomes congested, marking the paths of superficial vessels by red lines that are visible through the skin and tender to the touch.

Lymphatic vessels repair easily. New vessels form readily after damage, beginning as solid cellular sprouts from the endothelial cells of persisting vessels that subsequently become canalized.

## Lymphoedema

Insufficient lymphatic drainage leads to accumulation of fluid in the tissues (oedema) and swelling, typically in the limbs.

## CARDIAC MUSCLE

In cardiac muscle, as in skeletal muscle, the contractile proteins are organized structurally into sarcomeres that are aligned in register across the fibres, producing fine cross-striations that are visible in the light microscope. Both types of muscle contain the same contractile proteins (although commonly different isoforms), which are assembled in a similar way. The molecular basis for contraction, but not its regulation, is the same. Elevation of cytosolic calcium triggers contraction, corresponding to cardiac systole and the pumping phase of the heart cycle. Removal of cytosolic calcium induces relaxation, corresponding to diastole and cardiac filling. Despite the similarities, there are major functional, morphological and developmental differences between cardiac and skeletal muscle.

## MICROSTRUCTURE OF CARDIAC MUSCLE

The myocardium, the muscular component of the heart, constitutes the bulk of its tissues. It consists predominantly of cardiac muscle cells, which are usually $120 \mu \mathrm{~m}$ long and $20-30 \mu \mathrm{~m}$ in diameter in a normal adult. Each cell has one or two large nuclei occupying the central part of the cell, whereas skeletal muscle has multiple, peripherally placed nuclei. The cells are branched at their ends, and the branches of adjacent cells are so tightly associated that their appearance under light microscopy is of a network of branching and anastomosing fibres (Fig. 6.23). Cells are bound together by elaborate junctional complexes, the intercalated discs (Fig. 6.24; see Figs 6.23, 6.26).

Fine fibrocollagenous connective tissue is found between cardiac muscle fibres. Although this is equivalent to the endomysium of skeletal muscle, it is less regularly organized because of the complex threedimensional geometry imposed by the branching cardiac cells. Numerous capillaries and some nerve fibres are found within this layer. Coarser connective tissue, equivalent to the perimysium of skeletal muscle, separates the larger bundles of muscle fibres, and is particularly well developed near the condensations of dense fibrous connective tissue that form the 'skeleton' of the heart. The ventricles of the heart are composed of spiralling layers of fibres that run in different directions. Consequently, microscope sections of ventricular muscle inevitably contain the profiles of cells cut in a variety of orientations. A linear arrangement of cardiac muscle fibres is found only in the papillary muscles and trabeculae carneae.

Fig. 6.23 Cardiac muscle fibres in human myocardium, sectioned longitudinally. Cell branching and fine cross-striations are clearly visible and indicate the intracellular organization of sarcomeres. The dark transverse lines are intercalated discs (D). Endomysium (E) contains nuclei of endothelial cells and fibroblasts.

Fig. 6.24 A three-dimensional reconstruction of cardiac muscle cells in the region of an intercalated disc, a junctional complex between neighbouring cells. The interdigitating transverse parts of the intercalated disc form a fascia adherens, with numerous desmosomes; gap junctions are found in the longitudinal parts of the disc. The organization of the transverse tubules and sarcoplasmic reticulum is also shown.

In the developed world, secondary lymphoedema is most commonly the consequence of treatment for cancer, particularly breast cancer, following either surgical removal of lymph nodes and vessels, or their damage by radiation therapy. Tumours can themselves cause lymphoedema if they compress and block lymph vessels. Lymph node infections can also restrict lymph flow. In tropical regions, invasion of the lymphatic vessels by thread-like nematode worms (filariasis) can lead to severe swelling, particularly in the legs and genitals (elephantiasis) (Pfarr et al 2009). Podoconiosis is a non-filarial elephantiasis endemic to tropical highland areas of Africa and elsewhere. It is thought to be due to an abnormal inflammatory reaction to volcanic red clay soils (Fuller 2005). Both filariasis and podoconiosis have a large socioeconomic impact. Primary lymphoedema is a rare inherited condition, most common in females, and may involve abnormal development of lymph nodes or valves in the lymphatic vessels.

Electron micrographs of cardiac muscle cells in longitudinal section show that the myofibrils separate before they pass around the nucleus, leaving a zone that is occupied by organelles, including sarcoplasmic reticulum, Golgi complex, mitochondria, lipid droplets and glycogen (Fig. 6.25). At the light microscopic level, these zones appear in longitudinal sections as unstained areas at the poles of each nucleus. They often contain lipofuscin granules, which accumulate there in individuals over the age of 10 ; the reddish-brown pigment may be visible even in unstained longitudinal sections.

The cross-striations of cardiac muscle are less conspicuous than those of skeletal muscle. This is because the contractile apparatus of cardiac muscle lies within a mitochondria-rich sarcoplasm. The myofibrils are also less well delineated in cardiac muscle; in transverse sections they often fuse into a continuous array of myofilaments, irregularly bounded by mitochondria and longitudinal elements of sarcoplasmic reticulum. The large mitochondria, with their closely spaced cristae, reflect the highly developed oxidative metabolism of cardiac tissue. The proportion of the cell volume occupied by mitochondria (approximately 35\%) is even greater in cardiac muscle than it is in slow twitch skeletal muscle fibres. The high demand for oxygen is also reflected in high levels of myoglobin and an exceptionally rich network of capillaries around the fibres.

The force of contraction is transferred through the ends of the cardiac muscle cells via the junctional strength provided by the intercalated discs. As in skeletal muscle, force is also transmitted laterally to the sarcolemma and extracellular matrix via vinculin-containing elements that bridge between the Z-discs of peripheral myofibrils and the plasma membrane. The actin-binding proteins spectrin and dystrophin, important components of the cardiac muscle cell cytoskeleton, associate independently with the sarcolemma to provide mechanical support. Both protein complexes form components of the costamere (Peter et al 2011; Samarel 2005), which, in addition to transmitting force from sarcomeres to the sarcolemma and extracellular matrix, is central to mechanically generated signalling mechanisms.

Atrial muscle cells are smaller than ventricular cells. The cytoplasm near the Golgi complexes at the poles of the nuclei exhibits dense membrane-bound granules that contain the precursor of atrial natriuretic peptide. This hormone promotes loss of sodium and water in the kidneys, reducing blood volume and thereby lowering blood pressure. It is released into the blood in response to stretch of the atrial wall. Atrial natriuretic peptide and aldosterone have antagonistic effects on renal sodium and water handling, via independent mechanisms.

Fig. 6.25 A low-power transmission electron micrograph of cardiac muscle in longitudinal section, including the perinuclear zone of one of the fibres. Note the abundant large mitochondria $(\mathrm{M})$ between myofibrils (My), and an intercalated disc (circled). (Courtesy of Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.)

The sarcolemma of ventricular cardiac muscle cells invaginates to form T-tubules with a wider lumen than those of skeletal muscle; atrial muscle cells have few or no T-tubules. Unlike skeletal muscle, most T-tubules penetrate the sarcoplasm at the level of the Z-discs (see Fig. 6.24). The T-tubules are interconnected at intervals by longitudinal branches to form a complex network. They serve a similar function in skeletal and cardiac muscle, i.e. to carry the wave of depolarization into the cores of the cells.

The sarcoplasmic reticulum is a membrane-bound tubular plexus that surrounds and defines, sometimes incompletely, the outlines of individual myofibrils. Its main role, as in skeletal muscle, is the storage, release and reaccumulation (sequestration) of calcium ions. The calcium-binding protein calsequestrin allows large amounts of calcium to be stored within the sarcoplasmic reticulum and modulates activity of the calcium release channels (ryanodine receptors) (Györke and Terentyev 2008). The sarcoplasmic reticulum is separated from the T-tubules by a 15 nm gap spanned by structures termed junctional processes, which are thought to be the cytoplasmic part of the calcium release channels; similar processes are found in skeletal muscle at the junctional surface of the terminal cisternae. Sarcoplasmic reticulum bearing junctional processes is termed junctional sarcoplasmic reticulum to distinguish it from free sarcoplasmic reticulum, which forms a longitudinal network. Junctional sarcoplasmic reticulum makes contact with both the T-tubules and the sarcolemma (of which the T-tubules are an extension). Sarcoplasmic reticulum forms small globular extensions (corbular sarcoplasmic reticulum) in the vicinity of the Z-discs, but not in immediate relation to T-tubules or the sarcolemma. Since the junctions between T-tubules and sarcoplasmic reticulum usually involve only one structure of each type, the corresponding profiles in electron micrographs are referred to as dyads, rather than triads as in skeletal muscle.

## Intercalated discs

Intercalated discs are unique, complex junctions between cardiac myocytes. In the light microscope they are seen as transverse lines crossing the tracts of cardiac cells (see Fig. 6.23). They may step irregularly within or between adjacent tracts, and may appear to jump to a new position as the plane of focus is altered. Ultrastructurally, they are seen to have transverse and lateral portions (see Fig. 6.24; Fig. 6.26). The transverse portions occur wherever myofibrils abut the end of the cell, and each takes the place of the last Z-disc. At this point, the actin filaments of the terminal sarcomere insert into a dense subsarcolemmal matrix that anchors them, together with other cytoplasmic elements such as intermediate filaments, to the plasma membrane. Prominent desmosomes, often with a dense line in the intercellular space, occur at intervals along each transverse portion. This junctional region is

Fig. 6.26 An intercalated disc in cardiac muscle, with several zones of electron-dense fascia adherens (FA) and a gap junction (arrow). (Courtesy of Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.)
homologous with, and probably similar in composition to, the structure found on the cytoplasmic face of the myotendinous junction, and is a type of fascia adherens junction. It provides firm adhesion between cells, and a route for the transmission of contractile force from one cell to the next.

The lateral portions of an intercalated disc run parallel to the myofilaments and the long axis of the cell, for a distance that corresponds to one or two sarcomeres before turning again to form another transverse portion. They are therefore responsible for the stepwise progression of the intercalated disc, which is seen microscopically. The lateral portions contain gap junctions between adjacent cells (see Fig. 6.26), which provide electrical coupling and so enable the electrical impulse to propagate from one cell to the next, spreading excitation and contraction rapidly along the branching tracts of interconnected cells. The activity of the individual cells of the heart is thus coordinated so that they function as if they were a syncytium.

## Contractile protein isoforms <br> of cardiac muscle

As in skeletal muscle, the contractile proteins of cardiac muscle exist in a number of tissue- and stage-specific forms.

## Endocardium

The whole inner surface of the heart is covered by a thin layer of cells forming the endocardium, which separates the myocardium from the blood. These cells are very similar to the endothelial cells that line blood vessels, with a similar biological activity and embryological origin. They are now recognized as playing an important signalling role in cardiac muscle function (reviewed in Brutsaert (2003)).

## NEUROVASCULAR SUPPLY OF CARDIAC MUSCLE

## Vascular supply

The activity of the heart is equivalent to a constant power expenditure of 1.3 watts under basal conditions, and escalates to 3 watts or more during physical exertion. Cardiac muscle cells contain glycogen, which is a reserve during peaks of activity, but the majority of their energy requirement is continuous and supplied only through a highly developed oxidative metabolism, as is evident from the high proportion of the cell volume that is occupied by mitochondria. This metabolism has to be supported by a rich blood supply. Myocardium has a very high perfusion rate of $0.5 \mathrm{ml} / \mathrm{min} / \mathrm{g}$ of tissue ( 5 times that of liver and 15 times that of resting skeletal muscle). No cardiac muscle cell is more than $8 \mu \mathrm{~m}$ from a capillary, and vascular channels occupy a high proportion of the total interstitial space. Cardiac muscle is supplied by the coronary vessels. Although there is some variation in the detailed distribution of the arterial branches, the left ventricle, which has the highest workload and largest mass, receives the highest arterial blood flow. Branches run in the myocardium along the coarser aggregations of connective tissue and ramify extensively in the endomysial layer, creating a rich plexus of anastomosing vessels. This plexus includes lymphatic as well as blood capillaries, which is not the case in skeletal muscle.

The high oxygen requirement of the myocardium makes it vulnerable to ischaemic damage arising from atheroma or embolism in the coronary arteries. This vulnerability is exacerbated in the left ventricle because embedded coronary arteries are compressed by contraction of the myocardium, limiting perfusion during systole. Arterial anastomoses, often more than $100 \mu \mathrm{~m}$ in diameter, are found throughout the heart and are an important factor in determining whether an adequate collateral circulation may develop after a coronary occlusion.

## Innervation

Although the impulse-generating and conducting system of the heart establishes an endogenous rhythm, the rate and force of contraction are under neural influence. Both divisions of the autonomic nervous system supply unmyelinated postganglionic fibres to the heart. The innervation is derived bilaterally but it is functionally asymmetrical. Activation of the left stellate ganglion (sympathetic) has little effect on heart rate but increases ventricular contractility, whereas activation of the right stellate ganglion influences both rate and contractility. Activation of the right vagus nerve (parasympathetic) slows heart rate mainly through its
influence on the pacemaker region, the sinuatrial (SA) node, whereas activation of the left vagus slows propagation of the impulse mainly through its effect on the atrioventricular (AV) node. Vagal activity has little direct effect on ventricular contractility.

Postganglionic sympathetic nerve fibres from the cervical sympathetic ganglia reach the heart via the recurrent cardiac nerves. Parasympathetic fibres in the heart are derived from ganglion cells in the cardiac plexuses and atrial walls that are innervated by preganglionic cardiac branches of the vagus. Adrenergic, cholinergic and peptidergic endings have been demonstrated in the myocardium. Fibres often end close to muscle cells and blood vessels, but junctional specializations are not seen, and a gap of at least 100 nm remains between myocyte and axon. It is probable that neurotransmitters diffuse across this gap to the adjacent cells. Some of the endings represent efferent nerve terminals, while others function as pain receptors, mechanoreceptors or chemoreceptors.

## EXCITATION-CONTRACTION COUPLING IN CARDIAC MUSCLE

The molecular interaction between actin and myosin that underlies the generation of force is initiated by elevation of cytosolic calcium in both cardiac and skeletal muscle. However, there are significant differences in both the mechanisms by which this occurs and the physical arrangement and molecular composition of the contractile elements (reviewed in Bers (2002)).

One of the major functional differences between cardiac and skeletal muscle is the way in which contractile force is regulated. Smoothness and gradation of contraction in skeletal muscle depend on recruitment and asynchronous firing of different numbers of motor units. Individual motor units can also build up a contraction through a brief series of re-excitations. In the heart, the entire mass of muscle must be activated almost simultaneously, and mechanical summation by re-excitation is not possible, because the cells are electrically refractory until mechanical relaxation has taken place (see below).

As in skeletal muscle, cardiac muscle contraction is initiated when calcium binds to troponin- C , a component of the regulatory protein complex on the thin filaments. During basal activity of the heart, the amount of calcium bound to troponin-C during each systole induces less than half-maximal activation of the contractile apparatus. Contractile force can therefore be increased by increasing cytosolic calcium and thus the amount bound to troponin-C. This is achieved by controlling the amount of free calcium that is released into the cytosol during systole.

A special feature of the cardiac muscle cell is the long duration of its action potential. This is due to activation of voltage-dependent L-type calcium channels in the sarcolemma by the initial depolarization, through which calcium enters the cell, sustaining the depolarization and so causing a long-lasting electrical plateau of equivalent length to the contraction. However, calcium influx during the plateau only accounts for about $25 \%$ of the elevation of cytosolic calcium; the rest is released from the sarcoplasmic reticulum.

Action potentials are conducted into the T-tubules, where they activate L-type channels and calcium influx. This causes a localized increase in free calcium in the narrow space between the T-tubules and junctional sarcoplasmic reticulum, which activates calcium release channels on the latter, causing calcium to flood out into the cytosol. This 'calcium-induced calcium release' is a vital component of cardiac muscle activation and is the principal or only mechanism by which calcium can be released from the sarcoplasmic reticulum in the myocardium. This major difference between cardiac and skeletal muscle is reflected in tissue-specific isoforms of calcium release channels.

Systolic activation is terminated on repolarization of the action potential by reuptake (sequestration) of calcium from the cytosol back into the sarcoplasmic reticulum. This is mediated by a high-affinity sarco-endoplasmic reticulum calcium ATPase (SERCA), which rapidly reduces cytosolic free calcium to resting levels. The activity of this ATPase controls the rate of decay of the calcium transient and is therefore a determinant of the rate of relaxation of the heart. The sarcoplasmic reticulum contains a cardiac form of calsequestrin, a homologue of the proteins found in skeletal and smooth muscle. This calciumbinding protein buffers the free calcium concentration inside the sarcoplasmic reticulum, allowing it to store considerable amounts of total calcium without increasing the gradient against which SERCA must pump. It may also modulate the activity of the calcium release channels (Györke and Terentyev 2008).

Whilst SERCA therefore allows rapid relaxation of the myocardium, the calcium that entered the cell during the action potential must also

The cardiac isoform of $\alpha$-actin is not identical to the skeletal muscle form and is encoded by a different gene, although the two are so similar as to be functionally interchangeable. Both skeletal and cardiac isoforms of sarcomeric actin are expressed in fetal ventricular muscle. The mRNA for skeletal $\alpha$-actin increases postnatally and exceeds that of cardiac actin in the adult.

The myosin heavy chain of human cardiac muscle exists in two isoforms, $\alpha$ and $\beta$, both of which are present in the fetal heart. The $\alpha$ form persists as the adult isoform in atrial muscle, whereas the $\beta$-form (which is associated with a slower rate of contraction) predominates in ventricular muscle. Interestingly, the $\beta$-form of myosin heavy chain in cardiac muscle is identical to the isoform in slow twitch skeletal muscle. This identity between cardiac and slow twitch skeletal protein isoforms is true of several proteins, including ventricular myosin light chains and cardiac troponin-C. Other proteins, such as troponin-I and T, exist in cardiac-specific forms in the adult, although skeletal isoforms are expressed in the fetus and neonate. The appearance of cardiac-specific isoforms of troponin-I and T in the blood, following their release from damaged cardiac cells, is now a standard diagnostic test for myocardial infarction.
be transported out again to prevent calcium overload. This is accomplished primarily by a sodium-calcium exchanger (NCX) in the sarcolemma, and to a much lesser extent by a sarcolemmal calcium ATPase. These act more slowly than SERCA, continuously removing calcium from the cell during the diastolic interval as calcium slowly leaks from the sarcoplasmic reticulum.

The extent of the elevation of cytosolic calcium and therefore force generation during systole is determined by both the size of the initial stimulus (amount of calcium entering through L-type channels) and the amount of calcium stored within the sarcoplasmic reticulum. The greater the amount stored, the more is available for release. This provides an intrinsic mechanism for matching any increase in heart rate with a progressive increase in contractile force. At higher heart rates, more calcium enters per unit time, but as the diastolic interval is reduced there is less time for calcium to be removed from the cell by the sarcolemmal sodium-calcium exchanger. The amount of calcium stored in the sarcoplasmic reticulum therefore increases, so more can be released during systole. Increased heart rate is therefore coupled with an increase in force, a phenomenon called the staircase response.

The most potent physiological means of enhancing cardiac contractility is through the action of $\beta$-adrenergic agents, specifically the sympathetic neurotransmitter noradrenaline (norepinephrine) and circulating adrenaline (epinephrine). Activation of $\beta$-adrenergic receptors produces cyclic adenosine monophosphate (cAMP), which enhances calcium influx via L-type calcium channels during depolarization, so stimulating greater release from the sarcoplasmic reticulum. In addition, cyclic AMP enhances the activity of SERCA via promoting phosphorylation of an associated protein, phospholamban. This enables a more rapid reduction of the cytosolic calcium pump and accelerated relaxation, which is important when the heart rate is increased. Phosphorylation of troponin-I on the thin filaments also increases the rate of cross-bridge cycling, further accelerating relaxation.

## Dysfunction of cardiac muscle: excitationcontraction coupling in disease

In coronary heart disease the myocardium may be inadequately perfused (myocardial ischaemia), leading to energy deficit, loss of contractility and eventually cell death. The process may culminate in irretrievable myocardial damage and progress to heart failure, which is the inability to provide adequate cardiac output for the tissues.

## ORIGIN OF CARDIAC MUSCLE

Cardiac myocytes differentiate from the splanchnopleuric coelomic epithelial cells of the pericardium initially subjacent to the endoderm (see Fig. 52.6). As the primitive heart tube is formed, the presumptive myocardial cells start to express genes that encode characteristic myocardial proteins, including myosin, actin, troponin and other components of the contractile apparatus. Myofibrils begin to appear in the developing myoblasts, and the first functional heart beats start soon afterwards.

Committed cardiac myoblasts do not fuse to form multinucleated myotubes, as occurs in skeletal muscle, but remain as single cells coupled physically and electrically through intercellular junctions. Differentiated cardiac myocytes continue to divide during fetal develop-
ment and withdraw from the cell cycle only after birth. This is markedly different from skeletal muscle development, when differentiation, including the activation of muscle-specific genes, coincides with withdrawal from the cell cycle. During fetal maturation, successive changes in gene expression give rise to the characteristics of fetal, neonatal and adult myocardium, and are responsible for the divergence of the properties of atrial and ventricular muscle cells.

The regulatory mechanisms underlying differentiation of cardiac muscle appear to be distinct from those of skeletal muscle. It is anticipated that counterparts will be found for the transcriptional factors Myf-5, myogenin, MyoD and Myf-6, which are responsible for inducing differentiation of skeletal muscle. It is known that Tbx5 and Nkx2-5 are required for formation of atrial and ventricular myocardium (see Fig. 52.13).

Concurrent with the development of contractile proteins, cardiac myocytes develop numerous specific intracellular vesicles containing substances shown to induce natriuresis and diuresis, and a family of polypeptides generally known as atrial natriuretic peptides. These vesicles develop from the Golgi complex in both atria and ventricles during fetal life but become restricted to atrial muscle in the adult. Atrial natriuretic peptide is measurable when the heart is recognizably four-chambered; almost all cells within the atria are capable of its synthesis.

The impulse-generating (AV node) and conducting systems of the heart (AV node; bundle of His, Purkinje fibres) are formed from cardiac myocytes that differ in their morphology from the working myocardium of the heart chambers. Cells of the SA and AV nodes tend to be smaller with slow cell-to-cell electrical conduction, whilst those of the bundle of His and Purkinje fibres are larger in diameter with very rapid electrical conduction.

## CARDIAC PLASTICITY AND REGENERATION OF CARDIAC MUSCLE

The heart exhibits a significant degree of plasticity. Physiological and pathophysiological stimuli can initiate cardiac remodelling (reviewed in Hill and Olson (2008)). For example, increased loads as a result of exercise training or pregnancy induce physiological hypertrophy of the heart, where the ventricular walls thicken due to an increase in the size (but not number) of cardiac muscle cells. Conversely, hypertrophy resulting from cardiac damage, high blood pressure and/or extended activation of neurohumoral compensatory mechanisms (e.g. sympathetic stimulation, production of angiotensin II and aldosterone) can be maladaptive, increasing the risk and rate of progression of heart failure and sudden death due to arrhythmias.

In skeletal muscle, a population of precursor cells (satellite cells) is retained in adult life, constituting a pool of myoblasts capable of dividing, fusing with existing muscle fibres and initiating regeneration after damage. It was thought that cardiac muscle lacked an equivalent population of cells and was therefore incapable of regeneration. There is some evidence that the heart does contain endogenous progenitor cells capable of regenerating myocardial function (Oh et al 2004), although to a very limited extent compared to skeletal muscle and insufficient to restore heart function after ischaemic or other injury. It has been suggested that there is a slow but continuous renewal of cardiac muscle cells throughout life even in healthy individuals, with a turnover of between 0.4 and $1 \%$ per year (Bergmann et al 2009).

The body responds to this challenge with a variety of neurohumoral mechanisms, including increased sympathetic stimulation to the heart, increasing heart rate and contractility via noradrenaline (norepinephrine; see above). Treatment includes administration of positive inotropic agents (drugs that increase contractility) such as $\beta$-adrenergic agonists and phosphodiesterase inhibitors that prevent the breakdown of cyclic AMP. The classical positive inotropic drug is digitalis (digoxin), which at therapeutic doses causes partial inhibition of the sodium pump (sodium-potassium ATPase) that maintains the ionic gradient across the sarcolemma. This leads to a reduced sodium concentration gradient, impairing operation of the sarcolemmal sodium-calcium exchanger. Less calcium is therefore extruded from the cell, so more is left in the sarcoplasmic reticulum for release during systole, increasing force. However, positive inotropes are now only used in the short term because, if used chronically, they can hasten progression of the disease. The following explains why this is the case.

An energy deficit has far-reaching consequences beyond the inhibition of actin and myosin interactions. ATP is vital for many cellular processes: in particular, the activities of the sodium pump and SERCA. Impaired operation of the sodium pump leads to reduced extrusion of calcium (see above). Inhibition of SERCA impairs calcium reuptake into the sarcoplasmic reticulum and relaxation at the end of systole. The net effect is calcium overload. Mitochondria can mitigate the effects by taking up calcium, but eventually this causes mitochondrial damage and so worsens the energy deficit. As ATP falls further, operation of the sodium pump declines, the ionic gradient is dispersed and the cell depolarizes, causing calcium entry through L-type channels, which worsens the calcium overload and leads to cell death. Positive inotropes, by increasing both cytosolic calcium and energy requirements, will clearly worsen the situation.

This sequence of events has led to development of agents that act via increasing the binding of troponin- C to calcium, rather than by increasing calcium. However, therapy for chronic heart failure is still currently focused on limiting disease progression, largely by interrupting neurohumoral compensation mechanisms. Paradoxically, this includes $\beta$-adrenergic receptor antagonists, and also antagonists to angiotensin II and aldosterone (reviewed in Francis (2001)), which may inhibit cardiac remodelling (see below).

Both increased mechanical stress and circulating or local mediators can initiate the gene transcription and protein synthesis associated with cardiac hypertrophy and remodelling. At least part of the response is mediated through calcium-dependent mechanisms involving calcineurin, and isoforms of protein kinase $C$ and calcium-calmodulindependent kinase, but growth factors, inflammatory cytokines and other humoral mediators also activate complex signalling cascades that modify activity of transcription factors. Notably, physiological and pathological cardiac remodelling show significant differences in gene transcription and expression of certain proteins; pathological hypertrophy is associated with phenotypic switching towards fetal and less efficient isoforms of contractile proteins such as myosin heavy chain (Hill and Olson 2008).

Chronic heart failure is regarded as irreversible and progressive, and pathological cardiac remodelling plays a major role in its progression. Therapy is largely focused on agents that suppress pro-remodelling pathways (e.g. $\beta$-blockers, angiotensin converting enzyme inhibitors, aldosterone antagonists) and therefore slow progression (Francis 2001). However, recent developments have raised hope for future treatments that might reverse cardiac damage.

## Skin and its appendages

In this chapter, the types and functions of skin in different parts of the body are described first, followed by the microstructure of the epidermis and dermis, and the appendages of skin, including the pilosebaceous units and the sweat glands and nails. The development of skin, natural skin lines and age-related changes, and clinical aspects of skin, e.g. grafts, surgical skin flaps and wound healing, are also described. The integumental system includes the skin and its derivatives, hairs, nails, sweat and sebaceous glands; subcutaneous fat and deep fascia; the mucocutaneous junctions around the openings of the body orifices; and the breasts. Mucocutaneous junctions and breast tissues are covered in the appropriate regional sections.

## TYPES AND FUNCTIONS OF SKIN

The skin is the largest organ of the human body and constitutes approximately $15 \%$ of the total body weight. In an average 70 kg person, the skin weighs approximately 13 kg and has a surface area of about $2 \mathrm{~m}^{2}$. It covers the entire external surface of the body, including the external auditory meatus, the lateral aspect of the tympanic membrane and the vestibule of the nose. It is continuous with the mucosae of the alimentary, respiratory and urogenital tracts, and fuses with the conjunctiva at the margins of the eyelids, and with the lining of the lacrimal canaliculi at the lacrimal puncta. The thickness of the skin ranges from 1.5 to 5.0 mm and depends mainly on its location.

The skin forms a self-renewing interface between the body and its environment. It provides an effective barrier against microbial organisms, and protects against mechanical, chemical, osmotic, thermal and ultraviolet radiation damage. It is an important site of immune surveillance against the entry of pathogens and the initiation of primary immune responses. For instance, the skin produces various antimicrobial peptides such as human cathelicidin LL-37, a small cationic peptide that can prevent the immunostimulatory effects of bacterial wall molecules such as lipopolysaccharide and therefore protect against endotoxaemia. It can inhibit neutrophil apoptosis and stimulate angiogenesis, tissue regeneration, and release of cytokines such as interleukin (IL)-8. Specific innate immune defences in the skin are present throughout the epidermis, dermis, hair follicles and appendages, and in the absence of skin diseases or trauma, provide a resilient buffer against external microorganisms.

Skin performs many biochemical synthetic processes, including the formation of vitamin $D$ under the influence of ultraviolet B (UVB) radiation and synthesis of cytokines and growth factors. Skin is the target of a variety of hormones such as thyroxine, androgens and oestrogens. These activities can affect the appearance and function of individual skin components, such as the sebaceous glands, the hairs and the pigment-producing cells.

Control of body temperature is an important function of skin, and is effected mainly by regulation of heat loss from the cutaneous circulation through the rapid increase or reduction in the flow of blood to an extensive external surface area. This process is also assisted by sweating. In disorders such as erythroderma, in which more than $90 \%$ of the skin is inflamed and red, insensible fluid losses can exceed several litres per days and can result in shock if treatment is not initiated promptly. Skin is involved in socio-sexual communication and can signal emotional states by means of muscular and vascular responses. It is a major sensory organ, richly supplied by nerve terminals and specialized receptors for touch, temperature, pain and other stimuli.

Skin has good frictional properties, assisting locomotion and manipulation by its texture. It is elastic, and can be stretched and compressed within limits. The outer surface is covered by skin lines, some of which are large and conspicuous while others are microscopic, or are only revealed after manipulation or incision of the skin.

The colour of human skin is derived from, and varies with, the amount of blood (and its degree of oxygenation) in the cutaneous circulation, the thickness of the cornified layer, and the ratio of eumelanin (brown/black) and pheomelanin (red/yellow). Melanin has a protective role against UV radiation and acts as a scavenger of harmful free radicals. Racial variations in colour are mainly due to differences in the amount, type and distribution of melanin and are genetically determined. These genetic variants may also determine the prevalence of benign skin lesions such as freckles, as well as susceptibility to common forms of non-melanoma skin cancers.

The appearance of skin is affected by many other factors, e.g. size, shape and distribution of hairs and of skin glands (sweat, sebaceous and apocrine), and changes associated with maturation, ageing, metabolism and pregnancy. The general state of health is reflected in the appearance and condition of the skin, and the earliest signs of many systemic disorders may be apparent in the skin.

## CLASSIFICATION OF SKIN

Although skin in different parts of the body is fundamentally of similar structure, there are many local variations in parameters such as thickness, mechanical strength, softness, flexibility, degree of keratinization (cornification), size and number of hairs, frequency and types of glands, pigmentation, vascularity and innervation. There are two main types of skin: the thick, hairless (glabrous) skin, which forms the surfaces of the palms of the hands, soles of the feet, and flexor surfaces of the digits; and the thinner, hairy type, which covers large areas of the body (Figs 7.1-7.2; see Fig. 7.4).

## MICROSTRUCTURE OF SKIN AND SKIN APPENDAGES

## EPIDERMIS

The epidermis (see Fig. 7.2; Fig. 7.3) is a self-renewing stratified epithelial tissue consisting mainly of keratinocytes. Other cells within the epidermis include melanocytes (pigment-forming cells from the embryonic neural crest), Langerhans cells (immature antigen-presenting dendritic cells derived from bone marrow), lymphocytes and Merkel cells. Merkel cells may function as sensory mechanoreceptors or possibly as part of the dispersed neuroendocrine system and many are associated with nerve endings. Free sensory nerve endings are sparsely present within the epidermis. In routine histological preparations, the nonkeratinocyte cells are almost indistinguishable, and appear as clear cells surrounded by a space produced by shrinkage during processing. Their cytoplasm lacks prominent filament bundles.

The population of keratinocytes undergoes continuous renewal throughout life. This turnover of keratinocytes is mediated by stem cells that reside in the basal layer of the epidermis. These basal cells generate daughter cells, which undergo a series of biochemical and physical changes as they migrate towards the surface of the skin to form the various layers of the epidermis. They transform from polygonal living cells to non-viable flattened squames full of intermediate filament proteins (keratins) embedded in a dense matrix of cytoplasmic proteins to form mature keratin. The process is known as cornification.

The epidermis consists of several layers: the innermost layer is the basal layer (stratum basale) and is succeeded by the spinous or prickle cell layer (stratum spinosum), granular layer (stratum granulosum), clear layer (stratum lucidum) and cornified layer (stratum corneum), which is the most superficial (Fig. 7.4). The first three of these layers are metabolically active compartments through which cells pass and change their morphology as they undergo cellular differentiation. The

Fig. 7.2 The interfollicular epidermis of human thin skin. Note the thin cornified layer (C) in comparison with the thick cornified layer in Figure 7.4 (which is at a lower magnification). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
more superficial layers of cells undergo terminal keratinization, or cornification, which involves not only structural changes in keratinocytes, but also molecular and biochemical changes within the cells and their surroundings.

The epidermal appendages (pilosebaceous units, sweat glands and nails) are formed developmentally by the ingrowth of the epidermis.

## Keratinocytes

## Basal layer

The basal layer or stratum basale is the innermost layer of the epidermis and is adjacent to the dermis. It is the site of epidermal cellular proliferation. This layer is in contact with a basal lamina (Fig. 7.5; see Fig. 2.8), which is a thin layer of specialized extracellular matrix, not usually visible by light microscopy. By transmission electron microscopy, the basal lamina consists of a clear lamina lucida (adjacent to the basal cell plasma membrane) and a darker electron-dense lamina densa. The basal plasma membrane of the basal keratinocytes, the extracellular basal lamina (lamina lucida and lamina densa) and anchoring fibrils composed of type VII collagen within the subjacent dermal matrix (the lamina fibroreticularis), which insert into the lamina densa, collectively form the basement membrane zone (BMZ) at the dermal-epidermal junction. This is a highly convoluted interface, particularly in thick, hairless skin, where dermal papillae (rete ridges) project into the epidermis, interlocking with adjacent downward projections of the epidermis (rete pegs) (see Fig. 7.4).

The majority of basal keratinocytes (see Fig. 7.3) are columnar to cuboidal in shape, with large (relative to their cytoplasmic volume), mainly euchromatic nuclei and prominent nucleoli. The cytoplasm contains variable numbers of melanosomes and keratin filament bundles corresponding to the keratin tonofilaments of classic electron microscopy. In the basal keratinocytes, these keratins consist mostly of keratin 5 (K5) and keratin 14 (K14) proteins. The plasma membranes of interconnecting cells are coupled by desmosomes while those of the basal keratinocytes are linked to the basal lamina by hemidesmosomes (see Figs 7.5, 1.19). Melanocytes (see Fig. 7.9), Langerhans cells (see Figs 7.3 and 7.11) and Merkel cells (see Fig. 3.27) are interspersed

Fig. 7.3 The main features of the epidermis, including its cell layers and different cell types.

Fig. 7.4 The epidermis and papillary dermis $(P)$ of human thick skin, showing the thick cornified layer ( $C$, stratum corneum) , the eosinophilic clear layer (L, stratum lucidum), the granular layer (G, stratum granulosum), the prickle cell layer ( S , stratum spinosum) and the basal layer ( $B$, stratum basale). Capillary loops (arrows) are seen entering the deep papillae (rete ridges) of the dermis, between downward-projecting epidermal rete pegs. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
among the basal keratinocytes. Merkel cells are connected to keratinocytes by desmosomes, but melanocytes and Langerhans cells lack these specialized contacts. Intraepithelial lymphocytes are present in small numbers.

Keratinocyte stem cells are found within the basal layer of the epidermis. These cells divide into progeny cells called transit (or transient) amplifying cells, which also reside within the basal layer. Transit amplifying cells undergo a few rounds of proliferation before undergoing terminal differentiation. The activity of stem cells and transit amplifying cells in the basal layer provides a continuous supply of differentiating cells, which move suprabasally, eventually forming the cornified or corneocyte layer of the epidermis. Stem cells are thought to reside mainly in the interfollicular epidermis in the troughs of rete pegs, in the outer root sheath bulge of the hair follicle and in sebaceous glands. The distribution of stem cells and the size of their proliferative units (see below) may be quite variable in human skin.

The epidermal stem cells and their differentiated progeny are organized into columns named epidermal proliferation units. Several layers of prickle and granular cells overlie a cluster of $6-8$ basal cells, forming a columnar proliferative unit. Each group of basal cells consists of a central stem cell with an encircling ring of transit amplifying proliferative cells and postmitotic maturing cells. From the periphery of this unit, postmitotic cells transfer into the prickle cell layer. The normal total epidermal turnover time is between 52 and 75 days. In some skin disorders, the turnover rates and transit times are significantly shortened, e.g. in psoriasis, the total epidermal turnover time may be as little as 8 days. The control of keratinocyte proliferation and differentiation is beyond the scope of this publication but is reviewed in Fuchs (2007).

Fig. 7.6 The superficial layers of human thick skin, showing the deeply stained keratohyalin granule-containing cells of the granular layer (G) between the prickle cell or spinous layer (S) and the clear (or lucid, L) and cornified (C) layers above. Note that the clear layer is only translucent in unstained preparations and appears eosinophilic, as here, after staining. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

## Prickle cell layer

The prickle cell layer, also known as the stratum spinosum (see Fig. 7.3; Fig. 7.6), consists of several layers of closely packed keratinocytes. These cells are connected to each other by desmosomes, specialized cell-cell junctions that provide tensile strength and cohesion to the layer. When skin is stained by haematoxylin and eosin and viewed by routine light microscopy, intercellular bridges corresponding to the locations of desmosomes are seen between the dehydrated keratinocytes. This appearance gives these suprabasal keratinocytes their characteristic spiny appearance. The cytoplasm of the keratinocytes in the prickle cell layer contains prominent bundles of cytokeratin filaments, mostly cytokeratins 1 (K1) and 10 (K10), arranged concentrically around a euchromatic nucleus and attached to the dense plaques of the desmosomes. The cytoplasm also contains melanosomes, either singly or aggregated within membrane-bound organelles (compound melanosomes). Langerhans cells (see Fig. 7.11) and occasional lymphocytes are also present in the prickle cell layer.

## Granular layer

Extensive changes in keratinocyte structure occur in the 3-4 layers of flattened cells in the granular layer, also known as the stratum granulosum. The nuclei become pyknotic and begin to disintegrate. Organelles such as ribosomes and membrane-bound mitochondria and Golgi bodies degenerate. Cytokeratin filament bundles become more compact and associated with irregular, densely staining keratohyalin granules (see Fig. 7.6). Small round granules ( $100 \times 300 \mathrm{~nm}$ ) with a lamellar internal structure (lamellar granules, Odland bodies, keratinosomes) also appear in the cytoplasm. Keratohyalin granules contain a histidine-rich, sulphur-poor protein profilaggrin, which becomes modified to filaggrin as the cell reaches the stratum corneum. The lamellar granules release their hydrophobic glycophospholipid contents into the intercellular space within this layer and between the granular layer and the cornified layer. These glycophospholipids form an important component of the permeability barrier of the epidermis. Defects in the filaggrin protein, as a result of loss-of-function mutations in the filaggrin (FLG) gene, have been shown to cause ichthyosis vulgaris, a common dry scaly skin condition, as well as being a major risk factor for atopic eczema. In addition, copy number variation in the FLG gene may influence the amount of filaggrin in the skin and also contribute to the pathogenesis of both dry skin and eczema. The degradation products of filaggrin, including urocanic acid, contribute to the formation of natural moisturizing factor, a key component of the epidermal barrier function. The functions of filaggrin are reviewed in Brown and McLean (2012).

## Clear layer

The clear layer is only found in thick palmar or plantar skin. It represents a poorly understood stage in keratinocyte differentiation. It stains more strongly than the cornified layer with acidic dyes (see Fig. 7.6). It is more optically refractile and often contains nuclear debris. Ultrastructurally, the cells contain compacted keratin filaments and resemble the incompletely keratinized cells that are occasionally seen in the innermost part of the cornified layer of thin skin.

Fig. 7.7 A scanning electron micrograph showing the epidermal surface surrounding the aperture of a sweat duct. Note the polygonal, scale-like keratinocytes (squames) of the superficial cornified layer.

## Cornified layer

The cornified layer (see Figs 7.3, 7.6) is the final product of epidermal differentiation. It consists of closely packed layers of flattened polyhedral squames or corneocytes (Fig. 7.7), ranging in surface area from 800 to $1100 \mu \mathrm{~m}^{2}$. These cells overlap at their lateral margins and interlock with cells of apposed layers by ridges, grooves and microvilli. In thin skin, this layer may be a few cells deep, but in thick skin it may be more than 50 cells deep. The plasma membrane of the corneocytes appears thicker than that of other keratinocytes, partly due to the crosslinking of a soluble precursor, involucrin, at the cytoplasmic face of the plasma membrane, in the complex insoluble cornified envelope. The outer surface is also covered by a monolayer of bound lipid. The intercellular region contains extensive lamellar sheets of glycolipid derived from the lamellar granules of the granular layer. The cells lack a nucleus and membranous organelles, and consist solely of a dense array of keratin filaments embedded in a cytoplasmic matrix, which is partly composed of filaggrin derived from keratohyalin granules.

Under normal conditions, the production of epidermal keratinocytes in the basal layer is matched by the loss of corneocytes from the cornified layer. Desquamation of these cells is normally imperceptible. When excessive, it may appear as dandruff on the scalp or the flaking or peeling skin that follows sunburn. In certain skin disorders such as psoriasis, there is extensive scaling. The thickness of the cornified layer can be influenced by local environmental factors including chronic scratching, which can lead to a considerable thickening of the whole epidermis including the cornified layer. The soles of the feet become much thickened if an individual habitually walks barefoot, and calluses develop in areas of frequent pressure, e.g. on various parts of the feet from wearing tight shoes; palmar calluses in manual workers; and digital calluses in guitar players.

## Keratins

Epidermal keratinization has historically been the term applied to the final stages of keratinocyte differentiation and maturation, during which cells are converted into tough cornified squames. However, this is now regarded as ambiguous because the term keratin is assumed to refer to the protein of epithelial intermediate filaments, rather than to the whole complement of proteins in the terminally differentiated cell of the stratum corneum.

Keratins are the intermediate filament proteins found in all epithelial cells. There are two types: namely, type I (acidic) and type II (neutral/ basic). They form heteropolymers, are co-expressed in specific pairs and are assembled into 10 nm intermediate filaments. Fifty-four different functional keratin genes are recognized in humans. These are expressed in highly specific patterns and also according to the stage of cellular differentiation. Antibodies to individual keratins are useful analytical tools (Fig. 7.8). Keratins K5 and K14 are expressed by basal keratinocytes. Keratins K1 and K10 are synthesized suprabasally. In the granular

Fig. 7.8 Immunofluorescence microscopy of human skin showing the epidermis (E), cytokeratin 14 (green staining) in the basal layer, the dermis (D) and the dermal-epidermal junction (dotted line).
layer the filaments become associated with keratohyalin granules containing profilaggrin, a histidine-rich phosphorylated protein. As the cells pass into the cornified layer, profilaggrin is cleaved by phosphatases into filaggrin, which causes aggregation of the filaments and forms the matrix in which they are embedded. Other types of keratin expression occur elsewhere, particularly in hair and nails, where highly specialized hard keratin is expressed. This becomes chemically modified and is much tougher than in the epidermis. For a recent review of keratin function, see Pan et al (2013).

## Epidermal lipids

The epidermis serves as an important barrier to transepidermal loss of water and other substances through the body surface (apart from in sweating and sebaceous secretion). This is possible in part because of the presence of an epidermal lipid layer that consists of a variety of lipids that are synthesized in the epidermis. These include triglycerides, fatty acids, phospholipids, cholesterol, cholesterol esters, glycosphingolipids and ceramides. Furthermore, 7-dehydrocholesterol, an intermediate molecule in the cholesterol biosynthesis pathway and a precursor of vitamin D, is synthesized in the skin. The content and composition of epidermal lipids change with differentiation. Phospholipids and glycolipids first accumulate within keratinocytes above the basal layer, but higher up they are broken down and are practically absent from the cornified layer. Cholesterol and its esters, fatty acids and ceramides accumulate towards the surface and are abundant in the cornified layer. The lamellar arrangement of the extracellular lipids is a major factor in their barrier function. For further reading on cornified layer lipids, see Elias et al (2014).

## Melanocytes

Melanocytes are melanin pigment-producing cells derived from the neural crest (Figs 7.9-7.10). They are present in the epidermis and its appendages, oral epithelium, some mucous membranes, uveal tract (choroid coat) of the eyeball, parts of the middle and internal ear, and in the pial and arachnoid meninges, principally over the ventrolateral surfaces of the medulla oblongata. The cells of the retinal pigment epithelium, developed from the outer wall of the optic cup, also produce melanin, and neurones in different locations within the brainstem (e.g. the locus coeruleus and substantia nigra) synthesize a variety of melanin called neuromelanin. In humans there are two classes, the brown-black eumelanin and the red-yellow pheomelanin, both derived from the substrate tyrosine. Most natural melanins are mixtures of eumelanin and pheomelanin; pheomelanic pigments, trichochromes, occur in red hair.

Melanocytes are dendritic cells and lack desmosomal contacts with apposed keratinocytes, though hemidesmosomal contacts with the basal lamina are present. In routine tissue preparations, melanocytes appear as clear cells in the basal layer of the epidermis. The numbers

Fig. 7.9 Melanocytes in the basal layer of thin skin, including that of the follicular epidermis, in a biopsy of peri-auricular skin in a Caucasian male. The pigmented melanocytes, visualized immunocytochemically using antibody against a differentiation marker (Melan A/MART-1), extend dendritic processes between keratinocytes of the basal and lower prickle cell layers. Melanocytes are relatively inactive in this specimen; no melanosomes are visible in the surrounding keratinocytes. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 7.10 An electron micrograph of a basal epidermal melanocyte, showing its nucleus and cytoplasm containing melanosomes (white arrows). There are no desmosomes connecting it with apposed keratinocytes. The cytoplasm of the keratinocytes is full of dense keratin filaments (which are absent from the melanocyte) and transferred melanosomes. The dermo-epidermal junction is indicated (black arrows). Human tissue. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)
per unit area of epidermis range from 2300 per $\mathrm{mm}^{2}$ in cheek skin to 800 per $\mathrm{mm}^{2}$ in abdominal skin. It is estimated that a single melanocyte may be in functional contact via its dendritic processes with up to 30 keratinocytes. The nucleus is large, round and euchromatic, and the cytoplasm contains intermediate filaments, a prominent Golgi complex and vesicles and associated rough endoplasmic reticulum, mitochondria and coated vesicles, together with a characteristic organelle, the melanosome.

The melanosome is a membrane-bound structure that undergoes a sequence of developmental stages during which melanin is synthesized and deposited within it by a tyrosine-tyrosinase reaction. Mature melanosomes move into the dendrites along the surfaces of microtubules and are transferred to keratinocytes through their phagocytic activity (reviewed in Wu and Hammer (2014)). Each melanocyte supplies melanin to approximately 35-40 neighbouring basal keratinocytes. Keratinocytes engulf and internalize the tip of the dendrite with the subsequent pinching-off of melanosomes into the keratinocyte cytoplasm. Here, they may exist as individual granules in heavily pigmented skin, or be packaged within secondary lysosomes as melanosome complexes in lightly pigmented skin. In basal keratinocytes they can be seen to accumulate in a crescent-shaped cap over the distal part of the nucleus. As the keratinocytes progress towards the surface of the
epidermis, melanosomes undergo degradation, and melanin remnants in the cornified layer form dust-like particles. Melanosomes are degraded more rapidly in light-skinned than in dark-skinned individuals, in whom melanosomes persist in cells of the more superficial layers. Melanosomes are acidic, which explains why the larger melanosomes present in dark skin types are associated with a more acidic skin surface ( $\mathrm{pH}=4.3$ ), compared to lighter skin types $(\mathrm{pH}=5.3)$.

Melanin protects the skin against the harmful effects of UV radiation on DNA and is also an efficient scavenger of damaging free radicals. However, a high concentration of melanin may adversely affect synthesis of vitamin D in darker-skinned individuals living in northern latitudes. Melanin pigmentation is both constitutive and facultative Constitutive pigmentation is the intrinsic level of pigmentation and is genetically determined, whereas facultative pigmentation represents reversible changes induced by environmental agents, e.g. UV and Xradiation, chemicals and hormones. Racial variations in pigmentation are due to differences in melanocyte morphology and activity rather than to differences in number or distribution. In skin with naturally heavy pigmentation, the cells tend to be larger and more dendritic, and to contain more large, late-stage melanosomes than the melanocytes of paler skins. The keratinocytes in turn contain more melanosomes, individually dispersed, whereas in light skins the majority are contained within secondary lysosomes to form melanosome complexes.

The response to UV light includes immediate tanning with pigment darkening and can occur within minutes as a result of photo-oxidation of pre-existing melanin. Delayed tanning occurs after about 48 hours, and involves stimulation of melanogenesis within the melanocytes, and transfer of additional melanosomes to keratinocytes. There may also be some increase in size of active melanocytes, and in their apparent numbers, mainly through activation of dormant cells. Freckles in the skin, particularly of red-haired individuals, are usually thought to be induced by UV, though they do not appear until several years after birth, despite exposure. Paradoxically, melanocytes are significantly fewer in freckles than in adjacent paler epidermis, but they are larger and more active.

Adrenocorticotrophin (ACTH) is thought to affect melanocyte activity, and is probably responsible for the hyperpigmentation associated with pituitary and adrenal disorders. In pregnancy, higher levels of circulating oestrogens and progesterone are responsible for the increased melanization of the face, abdominal and genital skin, and the nipple and areola, much of which may remain permanently.

In albinism, the tyrosinase required for melanin synthesis is either absent or inactive, and melanocytes, though present, are relatively quiescent cells in an otherwise normal epidermis. Melanocytes decrease significantly in numbers in old age and are absent from grey-white hair. For further reading on melanocyte function in health and disease, see Hearing (2011).

## Langerhans cells

Langerhans cells (Fig. 7.11) are dendritic antigen-presenting cells that are distributed throughout the basal and prickle cell layers of the epidermis and its appendages. They are also present in other stratified

Fig. 7.11 Langerhans cells immunolabelled using a peroxidase method for the marker protein S100, extending dendrites between keratinocytes, mainly in the prickle cell layer of human thin skin. Basal layer melanocytes and scattered dermal cells (possibly of neural origin) are also positive for S100. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
squamous epithelia, including the buccal, tonsillar and oesophageal epithelia, as well as the cervical and vaginal mucosae, and the transitional epithelium of the bladder. They are found in the conjunctiva but not in the cornea. In routine haematoxylin and eosin histological preparations, they appear as clear cells. They enter the epidermis from the bone marrow during development to establish the postnatal population (460-1000/ $\mathrm{mm}^{2}, 2-3 \%$ of all epidermal cells, with regional variations), which is maintained by continual replacement from the marrow.

The nucleus is euchromatic and markedly indented, and the cytoplasm contains a well-developed Golgi complex, lysosomes (which often contain ingested melanosomes) and a characteristic organelle, the Birbeck granule, which is the ultrastructural hallmark of the Langerhans cell. The latter are discoid or cup-shaped, or have a distended vesicle resembling the head of a tennis racket; in section they often appear as a cross-striated rod $0.5 \mu \mathrm{~m}$ long and 30 nm wide. When stimulated by antigen, Langerhans cells migrate out of the epidermis to lymphoid tissues (see Fig. 4.14). Their numbers are increased in chronic skin inflammatory disorders, particularly of an immune aetiology, such as some forms of dermatitis.

## Merkel cells

Merkel cells (see Commentary 1.3) are present as clear oval cells, singly or in groups, in the basal layer of the epidermis. They are also present in the outer root sheath of some large hair follicles. Merkel cells are thought to derive embryologically from the epidermis, although a neural crest origin has been considered. They can be distinguished histologically from other clear cells (melanocytes and Langerhans cells) only by immunohistochemical and ultrastructural criteria.

The plasma membrane of a Merkel cell has short, stiff processes that interdigitate with adjacent basal keratinocytes to which it is attached by small desmosomes. The cytoplasm contains numerous closely packed intermediate filaments (mostly K8 and K18, and also K19 and K20) and characteristic $80-110 \mu \mathrm{~m}$ dense-core granules. The basal plasma membrane of many Merkel cells is closely apposed to the membrane of an axonal terminal, which conveys the sensation of touch. Merkel cells are thought to function as neuroendocrine sensory receptors. They are slowly adapting mechanoreceptors that respond to directional deformations of the epidermis and the direction of hair movement by releasing a transmitter from their dense-core cytoplasmic granules. There is evidence that a subpopulation of Merkel cells lacks axonal contact and may serve a neuroendocrine function locally. For further reading on Merkel cells, see Lucarz and Brand (2007).

Merkel cells can undergo malignant transformation (see Commentary 1.3), possibly triggered by the Merkel cell polyomavirus, and give rise to a rare and aggressive tumour called a Merkel cell carcinoma that typically presents with a painless, rapidly growing nodule on sunexposed sites.

## DERMIS

Beneath the epidermis is the dermis (see Figs 7.1, 7.4, 7.17), which is an irregular, moderately dense connective tissue composed of an interwoven collagenous and elastic network in an amorphous ground substance of glycosaminoglycans, glycoproteins and bound water. The dermis also contains nerves, blood vessels, lymphatics and epidermal appendages. Mechanically, the dermis provides considerable strength to the skin by virtue of the number and arrangement of its collagen fibres (which give it tensile strength) and its elastic fibres (which allow it to stretch and recoil). The density of its fibre meshwork, and therefore its physical properties, varies with different parts of the body, and with age and gender. The dermis is vital for the survival of the epidermis, and important morphogenetic signals are exchanged at the interface between the two both during development and postnatally. The dermis can be divided into two zones: a narrow, superficial papillary layer and a deeper reticular layer. The boundary between these two zones is indistinct.

Adult dermal collagen is mainly of types I and III, in proportions of $80-85 \%$ and $15-20 \%$ respectively. Type I collagen fibres are coarse and found predominantly in the deeper reticular dermis, and the finer type III collagen is found in the papillary dermis and around blood vessels. Type IV collagen is found in the basal lamina between epidermis and dermis, and around Schwann cells of peripheral nerves and endothelial cells of vessels. Types V, VI and VII are minor collagenous components of the dermis. Elastic fibres form a fibrous network interwoven between the collagen bundles throughout the dermis and are more prominent
in some regions, e.g. the axilla. Deficiency of type XVII collagen and type VII collagen, as a result of pathogenic mutations in the COL17A1 and COL7A1 genes, leads to junctional and dystrophic epidermolysis bullosa, respectively, which manifest as trauma-induced skin fragility.

Two major categories of cell are present in postnatal dermis, permanent and migrant, as is typical of all general connective tissues. The permanent resident cells include cells of organized structures such as nerves, vessels and cells of the arrector pili muscles, and the fibroblasts, which synthesize all components of the dermal extracellular matrix. The migrant cells originate in the bone marrow (see Fig. 4.12) and include macrophages, mast cells, eosinophils, neutrophils, T and B cells (including antibody-secreting plasma cells), and dermal interstitial dendritic cells, which are capable of immune surveillance and antigen presentation.

## Layers of the dermis

## Papillary layer

The papillary layer is immediately subjacent to the epidermis (see Fig. 7.4). It provides mechanical anchorage, metabolic support and trophic maintenance to the overlying epidermis, as well as supplying sensory nerve endings and blood vessels. The cytoskeleton of the basal epidermal keratinocytes is linked to the fibrous matrix of the papillary dermis through the attachment of keratin filament bundles to hemidesmosomes, then via anchoring filaments of the basal lamina, to the anchoring fibrils of type VII collagen, which extend into the papillary dermis (see Fig. 7.5). This arrangement provides a mechanically stable substratum for the epidermis.

The superficial surface of the dermis is shaped into numerous papillae or rete ridges, which interdigitate with rete pegs in the base of the epidermis and form the dermal-epidermal junction at their interface. The papillae have round or blunt apices, which may be divided into several cusps. In thin skin, especially in regions with little mechanical stress and minimal sensitivity, papillae are few and very small, while in the thick skin of the palm and sole of the foot they are much larger, closely aggregated, and arranged in curved parallel lines following the pattern of ridges and grooves on these surfaces (see Fig. 7.1). Lying under each epidermal surface ridge are two longitudinal rows of papillae, one on either side of the epidermal rete pegs, through which the sweat ducts pass on the way to the surface. Each papilla contains densely interwoven, fine bundles of types I and III collagen fibres and some elastic fibrils. Also present is a capillary loop (see Fig. 7.4), and in some sites, especially in thick hairless skin, Meissner's corpuscle nerve endings.

## Reticular layer

The reticular layer merges with the deep aspect of the papillary layer. Its bundles of collagen fibres are thicker than those in the papillary layer and form a strong but deformable three-dimensional lattice that contains a variable number of elastic fibres. The predominant parallel orientation of the collagen fibres may be related to the local mechanical forces on the dermis and may be involved in the development of skin lines.

## Hypodermis

The hypodermis (tela subcutanea; subcutaneous tissue) is a layer of loose connective tissue of variable thickness that merges with the deep aspect of the dermis. It is often adipose, particularly between the dermis and musculature of the body wall. It mediates the increased mobility of the skin, and its adipose component contributes to thermal insulation, acts as a shock absorber and constitutes a store of metabolic energy. Subcutaneous nerves, vessels and lymphatics travel in the hypodermis, their main trunks lying in its deepest layer, where adipose tissue is sparse. In the head and neck, the hypodermis also contains striated muscles, such as platysma, which are remnants of more extensive sheets of skin-associated musculature found in other mammals (panniculus adiposus).

The amount and distribution of subcutaneous fat varies according to gender: it is generally more abundant and more widely distributed in females, whereas it diminishes from the trunk to the extremities in males. The total amount of subcutaneous fat tends to increase in both males and females in middle age. (At any age, the amount of adipose tissue reflects the quantity of lipid stored in adipocytes rather than a change in the number of cells.) There is an association with climate (rather than race): superficial fat is more abundant in colder geographical regions. The hypodermis is most distinct on the lower anterior abdominal wall, where it is rich in elastic tissue and appears many-
layered as it passes through the inguinal regions into the thighs. It is well differentiated in the limbs and the perineum, but is thin where it passes over the dorsal aspects of the hands and feet, the sides of the neck and face, around the anus, and over the penis and scrotum. It is almost absent from the external ears and atypical in the scalp and in the palms and soles.

## PILOSEBACEOUS UNIT

The pilosebaceous unit consists of the hair and its follicle with an associated arrector pili muscle, sebaceous gland and sometimes an apocrine gland (see Figs 7.1, 7.12). Not all elements of the unit occur together in all body regions.

## Hairs

Hairs are filamentous cornified structures present over almost the entire body surface. They grow out of the skin at an angle (see Fig. 43.1), as is evident in the sloping of the hairs on the dorsum of forearm, hand and fingers towards the ulnar side. Hairs are absent from several areas of the body, including the thick skin of the palms, soles, the flexor surfaces of the digits, the thin skin of the umbilicus, nipples, glans penis and clitoris, the labia minora and the inner aspects of the labia majora and prepuce. The presence, distribution and relative abundance of hair in certain regions such as the face (in males), pubis and axillae, are secondary sexual characteristics that play a role in socio-sexual communication. There are individual and racial variations in density, form, distribution and pigmentation. Hairs assist in thermoregulation, e.g. on the scalp they provide some protection against injury and the harmful effects of solar radiation. They also have a sensory function.

Hair density varies from approximately 600 per $\mathrm{cm}^{2}$ on the face to 60 per $\mathrm{cm}^{2}$ on the rest of the body. In length, hairs range from less than a millimetre to more than a metre, and in width from 0.005 to 0.6 mm . They can be straight, coiled, helical or wavy, and differ in colour depending on the type and degree of pigmentation. Curly hairs tend to have a flattened cross-section, and are weaker than straight hairs. Over most of the body surface, hairs are short and narrow (vellus hairs) and in some areas these hairs do not project beyond their follicles, e.g. in eyelid skin. In other regions they are longer, thicker and often heavily pigmented (terminal hairs); these include the hairs of the scalp, the eyelashes and eyebrows, and the postpubertal skin of the axillae and pubis, and the moustache, beard and chest hairs of males. The presence in females of coarse terminal hairs in a male-like pattern is termed hirsutism and can be familial or a sign of an endocrine disorder involving excess androgen production.

## Hair follicle

The hair follicle (see Fig. 7.1; Figs 7.12-7.13A) is a downgrowth of the epidermis containing a hair. It may extend deep ( 3 mm ) into the hypodermis, or may be superficial ( 1 mm ) within the dermis. Typically, the long axis of the follicle is oblique to the skin surface; with curly hairs it is also curved. There are cycles of hair growth and loss, during which the follicle presents with different appearances. In the anagen phase, the hair is actively growing and the follicle is at its maximal extent of

Fig. 7.12 A
pilosebaceous unit in thin, hairy skin seen at low magnification. The hair follicle, hair shaft and hair root extend almost vertically through the field, the follicle joining the interfollicular epidermis (E). The acini (A) of a sebaceous gland, which is also sectioned tangentially through its capsule (centre bottom, below the portion of the hair follicle in section), open into the follicle in centre field. Note the associated arrector pili smooth muscle (AP). Compare with Figure 7.15.

A

Fig. 7.13 A, The major structural features of the base of a hair follicle, showing the organization of the major layers of the hair and surrounding sheath, arising from the hair bulb. A dermal hair papilla invaginates the bulb, and along the basal layer of the epidermis, at its interface with the dermis, melanocytes insert their dendrites among the keratinocytes forming the hair. B, The hair bulb at the base of the human hair follicle. The dermal hair papilla invaginates the bulb from its fibrous outer sheath, carrying a loop of capillaries. Melanocytes in the germinal matrix (equivalent to the basal layer of interfollicular epidermis) extend dendrites into the adjacent layers of keratinocytes, to which they pass melanosomes. The layers of the hair shaft and root sheaths are also indicated. (B, Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
development. In the involuting or catagen phase, hair growth ceases and the follicle shrinks. During the resting or telogen phase, the inferior segment of the follicle is absent. This is succeeded by the next anagen phase. Further details of the hair growth cycle are given below.

## Anagen follicle

The anagen follicle has several regions. The innermost part is the inferior segment, which includes the hair bulb region extending up to the level of attachment of the arrector pili muscle at the follicular bulge. Between this point and the site of entry of the sebaceous duct is the isthmus, above which is the infundibulum, or dermal pilary canal, which is continuous with the intraepidermal pilary canal. Below the sebaceous duct, the hair shaft and follicular wall are closely connected, and towards the upper end of the isthmus the hair becomes free in the pilary canal. Below the infundibulum, the follicle is surrounded by a thick perifollicular dermal coat containing type III collagen, elastin, sensory nerve fibres and blood vessels, and into which the arrector pili muscle fibres blend. A thick, specialized basal lamina, the glassy membrane, marks the interface between dermis and the epithelium of large hair follicles.

## Hair bulb

The hair bulb forms the lowermost portion of the follicular epithelium and encloses the dermal hair papilla of connective tissue cells (Fig. 7.13B). The dermal hair papilla is an important cluster of inductive mesenchymal cells, which is required for hair follicle growth in each cycle throughout adult life; it is a continuation of the layer of adventitious mesenchyme that follows the contours of the hair follicle. The hair bulb generates the hair and its inner root sheath. A hypothetical line drawn across the widest part of the hair bulb divides it into a lower germinal matrix and an upper bulb. The germinal matrix is formed of closely packed, mitotically active pluripotential keratinocytes, among which are interspersed melanocytes and some Langerhans cells. The upper bulb consists of cells arising from the matrix. These migrate apically and differentiate along several lines. Those arising centrally form the hair medulla. Radially, successive concentric rings of cells give rise to the cortex and cuticle of the hair and, outside this, to the three layers
of the inner root sheath. The latter are, from innermost to outer, the cuticle of the inner root sheath, Huxley's layer and Henle's layer. Henle's layer is surrounded by the outer root sheath, which forms the cellular wall of the follicle (see Fig. 7.13). Differentiation of cells in the various layers of the hair and its inner root sheath begins at the level of the upper bulb and is asynchronous, beginning earliest in Henle's layer and Huxley's layer.

## Structure of hair and its sheaths

A fully developed hair shaft consists of three concentric zones, which are, from outermost to inner, the cuticle, cortex and medulla. Each has different types of keratin filament proteins and different patterns of cornification. In finer hairs the medulla is usually absent. The cuticle forms the hair surface and consists of several layers of overlapping cornified squames directed apically and slightly outwards (Fig. 7.14). Immature cuticle cells have dense amorphous granules aligned predominantly along the outer plasma membrane with a few filaments. The cortex forms the greater part of the hair shaft and consists of numerous closely packed, elongated squames, which may contain nuclear remnants and melanosomes. Immature cortical cells contain bundles of closely packed filaments but no dense granules, and when fully cornified, they have a characteristic thumbprint appearance with filaments arranged in whorls. The medulla, when present, is composed of loosely aggregated and often discontinuous columns of partially disintegrated cells containing vacuoles, scattered filaments, granular material and melanosomes. Air cavities lie between the cells or even within them.

Henle's layer and Huxley's layer of the inner root sheath contain irregular dense keratohyalin granules and associated filaments in the precornified state. At the level of the upper bulb, Henle's layer begins to cornify, as does Huxley's layer at the middle of the inferior follicle. When fully differentiated, cells of both layers have a thickened cornified envelope enclosing keratin filaments embedded in a matrix. The cells of the inner root sheath cuticle undergo terminal differentiation at a level closer to the hair bulb than that of Huxley's layer, but lack a clearcut filament pattern such as is seen in the cortical cells of the hair shaft. As they cornify, the cuticle cells of the inner root sheath and hair become interlocked. At about the level of entry of the sebaceous duct,

Fig. 7.14 A scanning electron micrograph of a scalp hair, showing details of its surface structure. Note that the cuticular cells overlap each other; their free ends point towards the apex of the hair. (Courtesy of Michael Crowder MD.)
above the isthmus, the inner root sheath undergoes fragmentation, and the hair then lies free in the pilary canal.

The outer root sheath, beginning at the level of the upper bulb, is a single or double layer of undifferentiated cells containing glycogen. Higher up the follicle it becomes multilayered. At the isthmus all remaining cell layers of the follicle sheath become flattened, compressed and attenuated. On emerging from the isthmus, the outer root sheath assumes the stratified, differentiating characteristics of interfollicular epidermis, with which it becomes continuous. At the level of entry of the sebaceous duct, it forms the wall of the pilary canal.

## Hair cycle and growth of hair

Recurrent cyclic activity of hair follicles involves growth, rest, and shedding of hair in phases. In humans, these occur in irregular cycles of variable duration; there are regional and other variations in the length of the individual phases. In the growing or anagen phase, follicle and hair are as described above. Melanocytes are active only in mid-anagen, and are capable of producing both pheo- and eumelanosomes, which they pass to precortical and medullary keratinocytes. Changes in hair colour of an individual, usually in adolescence, are due to alterations in the dominant type of melanosome produced.

Anagen is followed by the involuting or catagen phase, during which mitotic activity of the germinal matrix ceases, the base of the hair condenses into a club that moves upwards to the level of the arrector pili muscle, and the whole inferior segment of the follicle degenerates. The dermal papilla also ascends and remains close to the base of the shortened follicle and its enclosed club hair, a situation that persists during the resting or telogen phase. During telogen, melanocytes become amelanotic and can be identified only ultrastructurally. At the beginning of the next anagen, the epithelial cells at the base of the follicle divide to form a secondary hair rudiment, which envelops the dermal papilla to form a new hair bulb. This grows downwards, reforming the inferior segment of the follicle, from which a new hair grows up alongside the club hair, which is eventually shed.

Postnatally, hairs exhibit regional asynchrony of cycle duration and phase leading to an irregular pattern of growth and replacement. In some regions, such as the scalp, the cycle is measured in years; in others, such as general body hair, the cycle is much shorter and hairs are therefore limited in length. At puberty, hair growth and generation of much thicker hairs occurs on the pubes and axillae in both sexes, and on the face and trunk in males. The actions of hormones on hair growth are complex, and involve not only sex hormones, but also those of the thyroid, suprarenal cortex and pituitary glands. Androgens stimulate facial and general body hair formation. After about the first 30 years, they tend to cause the thick terminal hairs of the scalp to change to small vellus hairs, which produces recession from the forehead and sometimes almost complete male pattern baldness. In females, oestrogens tend to maintain vellus hairs; postmenopausal reduction of oestrogens may permit stronger facial and bodily hair growth. In mid-pregnancy, hair growth may be particularly active but later, often post partum, an unusually large number of hairs enter the telogen phase

Fig. 7.15 A sebaceous gland, showing a group of secretory acini opening into a hair follicle (top right). The distended sebocytes are filled with their oily secretion (sebum), which is discharged into the hair follicle by the holocrine disintegration of secretory cells.
Compare with
Figure 7.12.
and are shed before the growth cycle recommences. In older men, growth of hairs on the eyebrows and within the nostrils and external ear canals increases, whereas elsewhere on the body, growth slows and the hairs become much finer.

Measurements of the rate of growth of individual hairs vary considerably, probably because of the influence of the factors mentioned above. A rate of $0.2-0.44 \mathrm{~mm}$ per 24 hours in males is usually given; the higher rate occurs on the scalp. Contrary to popular myth, shaving does not appear to affect the growth rate and hair growth ceases after death.

## Sebaceous glands

Sebaceous glands are small saccular structures (see Figs 7.1, 7.12; Fig. 7.15) found in the dermis. Most associate with the hair follicle and arrector pili muscle to form the pilosebaceous unit. They are present over the whole body except the thick, hairless skin of the palm, soles and flexor surfaces of digits. Typically, they consist of a cluster of secretory acini, which open by a short common duct into the dermal pilary canal of the hair follicle. They release their lipid secretory product, sebum, into the canal by a holocrine mechanism. In some areas of thin skin that lack hair follicles, their ducts open instead directly on to the skin surface, e.g. on the lips and corners of the mouth, the buccal mucosa, nipples (Montgomery's glands), areolae of the female breast, penis, inner surface of the prepuce, clitoris and labia minora. At the margins of the eyelids, the large, complex palpebral tarsal glands (Meibomian glands) are of this type. They are also present in the external auditory meatus (ceruminous glands).

In general, the numbers of sebaceous glands in any given area reflect the distribution of hair follicles, ranging from an average of $100 / \mathrm{cm}^{2}$ over most of the body to as many as $400-900 / \mathrm{cm}^{2}$ on the face and scalp. They are also numerous in the midline of the back. Individual sebaceous glands are particularly large on the face, around the external auditory meatus, chest and shoulders, and on the anogenital surfaces. Those on the face are often related to very small vellus hairs whose follicles have particularly wide apertures.

Microscopically, the glandular acini are enclosed in a basal lamina supported by a thin dermal capsule and a rich capillary network. Each acinus is lined by a single layer of small, flat, polygonal epithelial cells (sebocytes), which, when terminally differentiated, produce and accumulate sebum. They possess euchromatic nuclei and large nucleoli, scattered keratin filaments, free ribosomes, smooth endoplasmic reticulum and rounded mitochondria, and are attached to each other by desmosomes. Mitotically active cells give rise to progeny that move gradually towards the centre of the acinus, increasing in volume and accumulating increasingly large lipid vacuoles. The nuclei become pyknotic as the cells mature. The huge distended cells ultimately disintegrate, filling the central cavity and its duct with a mass of fatty cellular debris (holocrine secretion; see Figs 2.6, 7.15). The process takes 2-3 weeks. The secretory products pass through a wide duct lined with keratinized stratified squamous epithelium into the infundibulum of
the hair follicle and then to the surface of the hair and the general epidermis.

While the full range of functions in the skin remains to be clarified, sebum is a key component of the epidermal barrier, as well as having a key role in the skin's immune system. Sebum also contributes to a characteristic body odour. When first formed, sebum is a complex mixture of over $50 \%$ di- and triglycerides, with smaller proportions of wax esters, squalene, cholesterol esters, cholesterol and free fatty acids. At birth, sebaceous glands are quite large, regressing later until stimulated again at puberty. At that time, sebaceous gland growth and secretory activity increase greatly in both males and females, under the influence of androgens (testicular and suprarenal), which act directly on the gland. Excessive amounts of sebum may become impacted within the duct and this, associated with hyperkeratinization, may lead to blockage and formation of a comedone. This may become infected and inflamed, and is the primary lesion of acne. Acne is the most common disease caused by dysfunction of the sebocyte. Oestrogens have an effect opposite to that of androgens, and sebum secretion is considerably lower in women, becoming greatly decreased after the age of 50 years.

## Apocrine glands

Apocrine glands are particularly large glands found in the dermis or subcutaneous fat. They are classed as a type of sweat gland. In the adult, they are present in the axillae, perianal region, areolae, periumbilical skin, prepuce, scrotum, mons pubis and labia minora

An apocrine gland consists of a basal secretory coil and a straight duct that opens into either the pilary canal above the duct of the sebaceous gland, or directly on to the skin surface if there is no associated hair. The secretory region may be as much as 2 mm wide and its coils often anastomose to form a labyrinthine network. Each coil is lined by cuboidal secretory cells whose apical cytoplasm projects into the lumen and basally is in contact with a layer of myoepithelial cells within a thick basal lamina. The secretory cells contain vacuoles, vesicles and dense granules of varying size and internal structure; the numbers and character vary with the cycle of synthesis and discharge. The mechanism of secretion is still not clear but may involve merocrine secretion of granules, apocrine secretion or complete holocrine disintegration of the cells (see Fig. 2.6).

Apocrine activity is minimal before puberty, after which it is androgen-dependent and responsive to emotional stimuli. It is controlled by adrenergic nerves and is sensitive to adrenaline (epinephrine) and noradrenaline (norepinephrine). The secretion is initially sterile and odourless, but it undergoes bacterial decomposition to generate odorous and musky compounds, including short-chain fatty acids, and steroids such as $5 \alpha$-androstenone. In many animals these are potent pheromonal signals but their role in humans is less certain. Obstruction of apocrine sweat ducts and associated upper hair follicles in the axillae, breast areolae and pubic region, mainly in women, is thought to underlie Fox-Fordyce disease. Chronic inflammation involving the skin bearing apocrine glands leads to a painful, occasionally debilitating condition called hidradenitis suppurativa.

## Arrector pili muscles

The arrector pili muscles are small bundles of closely packed smooth muscle cells that form oblique links between the dermal sheaths of hair follicles and the papillary layer of the dermis (see Figs 7.1, 7.12). They show the typical features of smooth muscle cells and are separated by narrow spaces containing collagen fibres and unmyelinated noradrenergic sympathetic axons.

The muscles are attached to the bulge region of the follicles by elastin fibrils, and are directed obliquely and towards the side to which the hair slopes superficially. The sebaceous gland occupies the angle between the muscle and the hair follicle, and muscle contraction helps to expel the gland contents. Contraction tends to pull the hair into a more vertical position and to elevate the epidermis surrounding it into a small hillock (goose bump), dimpling the skin surface where the muscle is inserted superficially. Arrector pili muscles are absent from facial, axillary and pubic hairs, eyelashes and eyebrows, and from the hairs around the nostrils and the external auditory meati.

## SWEAT GLANDS

The vast majority of sweat glands (Fig. 7.16) are eccrine, although their mode of secretion includes typical merocrine mechanisms. The glands

Fig. 7.16 The coiled secretory portion of a sweat gland (SG) in the reticular dermis. The deeper-stained profiles (above) are the origins of the duct. An autonomic nerve fibre (NF) and accompanying arteriole (A) and venule $(\mathrm{V})$ are seen below.

Fig. 7.17 A sweat duct in a trichrome-stained section of thick skin. The duct (SD) spirals through the dermis and epidermis, and is visible most clearly in the cornified superficial layer.
are long, unbranched, tubular structures, each with a highly coiled, secretory portion up to 0.4 mm in diameter, situated deep in the dermis or hypodermis. From there, a narrower, straight or slightly helical ductal portion emerges (see Fig. 7.1). The walls of the duct fuse with the base of epidermal rete pegs and the lumen passes between the keratinocytes, often in a tight spiral, particularly in thick hairless skin (Fig. 7.17), and opens via a rounded aperture (pore) on to the skin surface (see Fig. 7.7). In thick hairless skin, sweat glands discharge along the centres of friction ridges, incidentally providing fingerprint patterns for forensic analysis. Sweat glands have an important thermoregulatory function, and their secretion enhances grip and sensitivity of the palms and soles.

Eccrine sweat glands are absent from the tympanic membrane, margins of the lips, nail bed, nipple, inner preputial surface, labia minora, penis and clitoris, where apocrine glands are located. They are numerous elsewhere, their frequency ranging from 80 to over $600 / \mathrm{cm}^{2}$, depending on position and genetic variation. The total number is estimated to be between 1.6 and 4.5 million, and is greatest on the plantar skin of the feet. There are many sweat glands on the face and flexor aspects of the hands, and least on the surfaces of the limbs. People indigenous to warmer climates tend to have more sweat glands than those indigenous to cooler regions.

Microscopically, the secretory coil consists of a pseudostratified epithelium enclosing a lumen. Three types of cell have been described: clear cells, from which most of the secretion is derived; dark cells, which share the same lumen; and myoepithelial cells. Clear cells are approximately pyramidal in shape, and their bases rest on the basal lamina or are in contact with the myoepithelial cells. Their apical plasma membranes line lateral intercellular canaliculi, which connect with the main lumen. The basolateral plasma membranes are highly folded, interdigitating with apposed clear cells, and they have the basal membrane infoldings typical of cells involved in transcytotic fluid and ion transport from the interstitial fluid to the glandular lumen. Their cytoplasm contains glycogen granules, mitochondria, rough endoplasmic reticulum and a small Golgi complex, but few other organelles. The nucleus is round and moderately euchromatic. Dark cells are pyramidal and lie closer to the lumen, such that their broad ends form its lining. Their cytoplasm contains a well-developed Golgi complex, numerous vacuoles and vesicles, and dense glycoprotein granules, which they secrete by a typical merocrine mechanism. Myoepithelial cells (see Figs 2.3, 2.4) resemble those associated with secretory acini of the salivary glands and breast, and contain abundant myofilaments.

The intradermal sweat duct is composed of an outer basal layer and an inner layer of luminal cells connected by numerous desmosomes. The intraepidermal sweat duct (acrosyringium) is coiled and consists of two layers of cells, which, developmentally, are different from the surrounding keratinocytes and can be distinguished from them by the presence of keratin K19. The outer cells near the surface contain keratohyalin granules and lamellar granules, and undergo typical cornification. The inner cells, from a mid-epidermal level, contain numerous vesicles, undergo an incomplete form of cornification, and are largely shed into the lumen at the level of the cornified epidermal layer.

Sweat is a clear, odourless fluid, hypotonic to tissue fluid, and contains mainly sodium and chloride ions, but also potassium, bicarbonate, calcium, urea, lactate, amino acids, immunoglobulins and other proteins. Excessive sweating can lead to salt depletion. Heavy metals and various organic compounds are eliminated in sweat. When first secreted, the fluid is similar in composition to interstitial fluid. It is modified as it passes along the duct by the action mainly of the basal cells, which resorb sodium, chloride and some water. The hormone aldosterone enhances this activity. The sweat glands are capable of producing up to 10 litres of sweat per day, in response to thermal, emotional and taste stimuli, mediated by unmyelinated sympathetic cholinergic fibres. The glands also respond to adrenaline (epinephrine). Thermoregulation is coordinated via a heat centre in the preoptic region, in and near the rostral hypothalamus, which reacts to changes in blood temperature and afferent stimuli from the skin by initiating appropriate responses such as controlling cutaneous blood supply, the rate and volume of sweat secretion (for evaporation at the surface) and shivering.

## NAIL APPARATUS

Nails (Fig. 7.18) are homologous with the cornified layer of the general epidermis. They consist of compacted, anucleate, keratin-filled squames in two or three horizontal layers. Ultrastructurally, the squames contain closely packed filaments that lie transversely to the direction of proximodistal growth, and are embedded in a dense protein matrix. Unlike the general epidermis, squames are not shed from the nail plate surface. A variety of mineral elements including calcium are present in nail. The hardness of nail is determined by the arrangement and cohesion of the layers of squames and their internal fibres, and not by the calcium content. The water content of nail is low but nail is 10 times more permeable to water than the general epidermis. The softness and elasticity of the nail plate are related to its degree of hydration.

The nail apparatus consists of the nail plate, proximal and lateral nail folds, nail matrix, nail bed and hyponychium.

## Nail plate

The nail plate is embedded within the proximal and lateral nail folds. It is approximately rectangular in shape and is mostly convex in both longitudinal and transverse axes. There is considerable inter- and intraindividual variation (see Fig. 7.18). The thickness of the plate increases proximodistally from about 0.7 mm to 1.6 mm , although the terminal thickness varies between individuals. The surface of the nail plate may show fine longitudinal ridges, and its undersurface is grooved by corresponding ridges in the nail bed. Disturbances of growth pattern or disease may lead to transverse ridging or grooves. Minute trapped air

Fig. 7.18 The organization and terminology of the structures associated with a fingernail. (With permission from Paus R, Peker S 2003 Biology of hair and nails. In: Bolognia JL, Jorizzo JL, Rapini RP (eds) Dermatology. London: Mosby.)
bubbles may produce white flecks. These defects move distally with the growth of the nail plate.

The nail plate arises from compacted cornified epithelial cells derived from the dorsal, intermediate and ventral nail matrices. It is densely adherent to the matrices on its undersurface but becomes a free structure distal to the onychodermal band, where it separates from the nail bed. The dorsal aspect of the nail plate originates from the more proximal regions of the germinal matrix, i.e. dorsal and intermediate matrices, whereas the deeper, volar aspect of the plate originates from the ventral matrix.

## Nail folds

The sides of the nail plate are bordered by the lateral nail folds, which are continuous with the proximal fold (see Fig. 7.18). They are bounded by the attachment of the skin to the lateral aspect of the distal phalanx margin and the lateral nail. The proximal nail fold provides the visible proximal border to the nail apparatus. It consists of a superficial and a deep epidermal layer. These two layers are separated by a core of dermis. The epidermis of the superficial layer lacks hair follicles and epidermal ridges, and its cornified distal margin extends over the nail plate as the cuticle or eponychium. The deep layer merges with the nail matrix.

The eponychium is bounded by the fascial attachment of the skin to the base of the distal phalanx，distal to the insertion of the extensor tendon，and its distal free edge．It adheres to the dorsal aspect of the nail plate and overlies the root of the nail．

## Nail matrix

The nail matrix is the main source of the nail plate and it can be sub－ divided into three parts．Proximally，the dorsal matrix is defined as the volar surface（undersurface）of the proximal nail fold．The intermediate matrix（germinal matrix）starts where the dorsal matrix folds back on itself and extends as far as the distal portion of the lunula．The ventral matrix（sterile matrix）is the remainder of the nail bed；it starts at the distal border of the lunula and ends at the hyponychium．

The matrix epithelium consists of typical basal and prickle layer keratinocytes，among which are scattered melanocytes and Langerhans cells．Cornified cells of the dorsal and ventral aspects of the matrix are steadily extruded distally to form the nail plate．The proximal $50 \%$ of the nail matrix contributes approximately $80 \%$ of the nail plate．This process continues into the nail bed at the distal edge of the lunula， which is formed where the distal portion of the ventral matrix underlies the nail plate．

The lunula is pale，opaque and convex，and is more prominent in the thumb than the other digits．It is not known why the lunula is so pale compared with the more distal translucent pink nail bed．The lack of colour may reflect the thickness of the epidermis in the lunula and／ or a paucity of capillaries in the dermis of the lunula．

## Nail bed

The epidermis of the nail bed extends from the distal margin of the lunula to the hyponychium．The distal margin of the nail bed，which is the point where the nail plate becomes free of the nail bed，is called the onychodermal band．The surface of the nail bed is ridged and grooved longitudinally，corresponding to a similar pattern on the undersurface of the nail plate．This results in a tight interlocking between the nail plate and the underlying nail bed，protecting against microbial invasion and the collection of debris underneath the nail． The epidermis of the nail bed is thin and lacks a stratum granulosum． It consists of 2－3 layers of nucleated cells that lack keratohyalin gran－ ules，and a thin cornified layer that moves distally with the growing nail plate．It contains an occasional sweat gland distally．

The dermis of the nail bed is anchored to the periosteum of the distal phalanx without an underlying subcutaneous layer．It forms a tight compartment，which means that infections involving the nail bed or an increase in pressure，e．g．resulting from a haematoma，may cause severe pain，which may be relieved by the removal of part or all of the nail plate．The dermis of the nail bed is richly vascularized．The blood vessels are arranged longitudinally and display numerous glomus bodies，which are encapsulated arteriovenous anastomoses involved in the physiological control of peripheral blood flow in relation to tem－ perature．The dermis is well innervated and contains numerous sensory nerve endings，including Merkel endings and Meissner＇s corpuscles． Nail bed cells differentiate towards the nail plate and contribute to its thickness ventrally．

## Hyponychium

The hyponychium is the area under the free nail between the onychoder－ mal band proximally and the distal groove．It is an epidermal ridge that demarcates the junction between the finger pulp and the subungual structures．

## Nail growth

Nail growth is determined by the turnover rate of the matrix cells，which varies with digit，age，environmental temperature and season，time of day，nutritional status，trauma and various diseases．Generally，the rate of growth is related to the length of the digit，being fastest（approxi－ mately 0.1 mm per day）in the middle finger of the hand and slowest in the little finger．Fingernails grow 3－4 times faster than toenails，more quickly in summer than in winter，and faster in the young than in the old．A fingernail grows out in about 6 months，whereas a toenail is replaced，on average，in 18 months．

Genetic keratin disorders（see Haines and Lane（2012））may lead to nail dystrophies such as pachyonychia congenita，where the nails become grossly thickened．In addition，germline mutations in the

RSPO4 gene，which encodes R－spondin 4，have been shown to cause recessive anonychia（absence of all fingernails and toenails）．Further－ more，mutations in the FZD6 gene，which encodes the Wnt receptor protein frizzled 6，have been shown to underlie the molecular basis of autosomal recessive nail dysplasia，as well as twenty－nail dystrophy（a condition that affects the nails of all the fingers and toes）．

## VASCULAR SUPPLY，LYMPHATIC DRAINAGE AND INNERVATION

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Cutaneous blood flow amounts to approximately $5 \%$ of the cardiac output．The cutaneous circulation has an important thermoregulatory function，and is organized so that its capacity can be rapidly increased or decreased by as much as 20 times，in response to a need to lose or conserve body heat．The ability to control skin blood flow decreases with ageing，making older adults less able to thermoregulate adequately． Lifestyle factors，such as physical activity，diet and smoking，might interact with the ageing process to modulate＇normal＇age－associated changes in the cutaneous microcirculation．

The blood supply to the skin originates from three main sources：the direct cutaneous，musculocutaneous and fasciocutaneous systems．The direct cutaneous system of vessels is derived from the main arterial trunks and accompanying veins．These vessels course in the subcutane－ ous fat parallel to the skin surface and are confined to certain areas of the body，e．g．the supraorbital artery，the superficial circumflex iliac artery and the dorsalis pedis artery．The musculocutaneous perforators arise from the intramuscular vasculature，pass through the surface of the muscle，and pierce the deep fascia to reach the skin by spreading out in the subcutaneous tissues．The fasciocutaneous system consists of perforating branches from deeply located vessels（deep to the deep fascia）that pass along intermuscular septa and then fan out at the level of the deep fascia to reach the skin．Examples include the fasciocutane－ ous perforating vessels from the radial and ulnar arteries．

The direct cutaneous vessels，musculocutaneous perforators and fasciocutaneous perforators each contribute to six anastomosing hori－ zontal reticular plexi of arterioles（Fig．7．19），which have vascular con－ nections between them and which ultimately provide the blood supply to the skin．Three plexi are located in the skin itself and supply all ele－ ments including the sweat glands and pilosebaceous units．The subpap－ illary plexus is located at the junction of the papillary and reticular layers of the dermis and gives off small branches that form perpendicu－ lar capillary loops in the dermal papillae（usually one loop per papilla） （see Figs 7．1，7．4；Fig．7．20）．The reticular dermal plexus is located in the middle portion of the dermis and is primarily venous．The deep dermal plexus is located in the deepest part of the reticular dermis and on the undersurface of the dermis．The close association between arte－ riolar and venous plexi allows the countercurrent heat exchange between bloods at different temperatures．

The remaining three plexi are the subcutaneous plexus，and two plexi associated with the deep fascia．The deep fascia has a plexus on its deep surface and a more extensive plexus superficially．This arrangement is much more pronounced in the limbs than it is in the trunk．

The general structure and arrangement of the microvasculature is described in detail in Chapter 6 and so only features particular to skin will be considered here．In the deeper layers of the dermis，arterio－ venous anastomoses are common，particularly in the extremities （hands，feet，ears，lips，nose），where vessels are surrounded by thick muscular coats．Under autonomic vasomotor control，these vascular shunts，when relaxed，divert blood away from the superficial plexus and so reduce heat loss，while at the same time ensuring maintenance of some deep cutaneous circulation and preventing anoxia of structures such as nerves．Extensive capillary anastomoses are present．Generally， cutaneous blood flow is regulated according to thermoregulatory need and also，in some areas of the body，according to emotional state．In very cold conditions，the peripheral circulation is greatly reduced by vasoconstriction，but intermittent spontaneous vasodilation results in periodic increases in temperature that prevent cooling to the level at which frostbite might occur．This is thought to be due to a direct effect of oxygen lack on the arteriolar constrictor muscle，rather than to a neural influence．

The lymphatics of the skin，as elsewhere，are small terminal vessels that collect interstitial fluid and macromolecules for return to the cir－ culation via larger vessels．They also convey lymphocytes，Langerhans cells and macrophages to regional lymph nodes．They begin as blind－ ended，endothelial－lined tubes or loops just below the papillary dermis．

A

B

Fig. 7.19 Vascular supply to the skin. A, Note the various horizontal plexuses fed by direct cutaneous, fasciocutaneous and musculocutaneous arteries. Compare with Figure 79.6. B, Higher magnification of vascular supply. (A, Redrawn from McCarthy JG (ed) 1990 Chapter 9 in Plastic Surgery, Vol 1. Philadelphia: Saunders. B, Redrawn from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd edition. Edinburgh: Churchill Livingstone.)

Fig. 7.20 A thick vertical section through palmar skin: the arteries, arterioles and capillaries have been injected with red gelatin to demonstrate the pattern of dermal vascularization. At the base of the dermis a broad, flat arterial plexus supplies a more superficial papillary plexus, which in turn gives off capillary loops that enter the dermal papillae.

These drain into a superficial plexus below the subpapillary venous plexus, which drains via collecting vessels into a deeper plexus at the junction of the reticular dermis and subcutis, and this, in turn, drains into larger subcutaneous channels.

## INNERVATION

Skin is a major sensory organ, with regional variations in its sensitivity to different stimuli. It is richly innervated and is also involved with autonomic functions such as thermoregulation. Information about the external environment is relayed through receptors that are responsive to various stimuli, which may be mechanical (rapid or sustained touch, pressure, vibration, stretching, bending of hairs, etc.), thermal (hot and cold) or noxious (perceived as itching, discomfort or pain). Pacinian corpuscles subserve deep pressure and vibrational sensation, and are located deep in the dermis or in the hypodermis, particularly of the digits. Meissner's corpuscles are highly specialized mechanore-
ceptors found in hairy and glabrous skin. They are located in dermal papillae close to the dermal-epidermal junction. They are rapidly adapting mechanoreceptors and are responsible for sensing light touch. These receptors are particularly suited to detecting shape and texture during active exploratory touch and are numerous in the finger pads.

The primary input is transmitted by neurones whose cell bodies lie in the spinal and cranial ganglia, and whose myelinated or unmyelinated axons are terminally distributed, mainly within the dermis. Efferent autonomic fibres are unmyelinated and can be either noradrenergic or cholinergic. They innervate the arterioles, arrector pili muscles, and the myoepithelial cells of sweat and apocrine glands. In the scrotum, labia minora, perineal skin and nipples they also supply the smooth muscle fasciculi of the dermis and adjacent connective tissue. Except in the nipples and genital area, the activity of the autonomic efferent nerves is mainly concerned with regulation of heat loss by vasodilation and vasoconstriction, sweat production and pilo-erection (although this last is a minor function in humans).

On reaching the dermis, the nerve fasciculi branch extensively to form a deep reticular plexus that innervates much of the dermis, including most sweat glands, hair follicles and the larger arterioles. Many small fasciculi pass from this plexus to ramify in another superficial papillary plexus at the junction between the reticular and papillary layers of the dermis. Branches from this pass superficially into the papillary layer, ramifying horizontally and vertically, and terminate either in relation to encapsulated receptors, or as terminals reaching the level of the basal lamina. In some instances, they enter the epidermis as free endings that are responsive to light pressure and touch sensation or to nociceptive stimuli. As these fasciculi terminate, they lose their epineurial and perineurial sheaths, leaving the Schwann cell-axonal complexes or naked axons enveloped only by basal lamina, in direct contact with the matrix. These naked distal axonal terminals may be vulnerable to pathogens entering via a skin abrasion. The structure and classification of sensory endings are described in detail on page 59.

The segmental arrangement of the spinal nerves is reflected in the sensory supply of the skin: a dermatome is the area supplied by all the cutaneous branches of an individual spinal nerve through its dorsal and ventral rami (p. 233 and Fig. 16.10). Typically, dermatomes extend round the body from the posterior to the anterior median line. The upper half of each zone is supplemented by the nerve above, the lower half by the nerve below. Dermatomes of adjacent spinal nerves overlap markedly, particularly in the segments least affected by development of the limbs (Ladak et al 2014). The interrelationship between the skin and the nervous system is important in the pain seen in certain polyneuropathies and after injury to nerve or skin.

## DEVELOPMENT OF SKIN AND SKIN APPENDAGES

The skin develops from the surface ectoderm and its underlying mesenchyme. The surface ectoderm gives rise to the epidermis and its appendages such as the pilosebaceous units, sweat glands and nail units. Interactions between ectoderm and mesenchyme give rise to the oral and nasal epithelia, as well as teeth. Ectodermal cells differentiate mainly into the keratinocytes and probably Merkel cells. Melanocytes are derived from the neural crest while Langerhans cells and lymphocytes originate from the bone marrow.

The dermis is derived from the somatopleuric mesenchyme (in the limbs and trunk), and possibly the somitic mesenchyme (covering the epaxial musculature), and from the neural crest (in the head). Angiogenic mesenchyme gives rise to the blood vessels of the dermis. Nerves and associated Schwann cells, which are derived from the neural crest, enter and traverse the dermis during development.

## EPIDERMIS AND APPENDAGES

## General (interfollicular) epidermis

In the first 4-5 weeks, embryonic skin consists of a single layer of ectodermal cells overlying a mesenchyme containing cells of stellate dendritic appearance interconnected by slender processes and sparsely distributed in a loosely arranged microfibrillar matrix (Fig. 7.21). The interface between ectoderm and mesenchyme, known as the basement membrane zone (BMZ), is an important site of mutual interactions on which the maintenance of the two tissues depends, both in prenatal and postnatal life. Ectodermal cells, which characteristically contain glycogen deposits, contact each other at gap and tight junctions (occluding junctions, zonae occludentes). The layer so formed soon develops into a bilaminar epithelium, and desmosomes also appear. The basal germinative layer gives rise to the postnatal epidermis, and the superficial layer to the periderm, a transient layer confined to fetal life. The periderm maintains itself, expresses different keratin polypeptides, and grows by the mitotic activity of its own cells, independent of those of the germinative layer. Originally flattened, the periderm cells increase in depth; the central area containing the nucleus becomes elevated and projects as a globular elevation towards the amniotic cavity. The plasma membrane develops numerous surface microvilli with an extraneous
coat of glycosaminoglycans, and cytoplasmic vesicles become prominent deep to it. These developments reach a peak between 12 and 18 weeks of gestation, at which time the periderm is a major source of the amniotic fluid to which it may contribute glucose; it also has an absorptive function. From about 20 weeks onwards, the globular protrusions become undermined and pinched off to float free in the amniotic fluid. The now-flattened periderm cells undergo terminal differentiation to form a temporary protective layer for the underlying developing epidermis, against an amniotic fluid of changing composition as a result of the accumulation of products of fetal renal excretion. Up to parturition, the periderm squames continue to be cast off into the amniotic fluid and they contribute to the vernix caseosa, a layer of cellular debris that covers the fetal skin at birth.

Proliferation in the germinative layer leads to a stratified appearance with successive layers of intermediate cells between it and the periderm. From an early stage, cells of all layers are packed with glycogen granules. Differentiation of these layers is not synchronous throughout all regions of the developing skin, being more advanced cranially than caudally, and progressing on the body from the mid-axillary line ventrally. Reduction in glycogen content of the cells is associated with a shift towards biosynthetic activity connected with terminal (cornifying) differentiation, manifested by the presence of different enzymes and expression of keratins. Simple epithelial keratins present from before implantation (K8 and K18) are replaced by typical keratinocyte basal cell keratins (K5 and K14), followed in the first suprabasal cell layer by those of higher molecular weight associated with differentiation (K1 and K10) at 10-12 weeks. This is soon followed by the expression of profilaggrin and filaggrin, and the appearance of keratohyalin granules among filamentous bundles of the uppermost intermediate layer cells at approximately 20 weeks. The first fully differentiated keratinocytes appear shortly afterwards. By 24-26 weeks a definite cornified layer exists in some areas, and by approximately 30 weeks, apart from some residual glycogen in intermediate cells, the interfollicular epidermis is essentially similar to its postnatal counterpart.

Non-keratinocytes are present in developing epidermis from about 8 weeks' gestation. Langerhans cells can be seen in the epidermis by $5-6$ weeks and are fully differentiated by 12-14 weeks. Their numbers increase at least partially by mitotic division in situ, but at 6 months are only $10-20 \%$ of those in the adult. It is not known if Langerhans cells function in immune surveillance in fetal skin. Melanocytes are present in the bilaminar epidermis of cephalic regions as early as 8 weeks. By $12-14$ weeks they can reach a density of 2300 per $\mathrm{mm}^{2}$, reducing to

Fig. 7.21 Development of the skin.

800 per $\mathrm{mm}^{2}$ just before birth. Keratinocytes regulate the final ratio between themselves and melanocytes via growth factors, cell-surface molecules and other signals. Fetal melanocytes produce melanized melanosomes and transfer them to keratinocytes. This is an intrinsic activity independent of UV irradiation and suggests that melanin has functions other than photoprotection.

Merkel cells begin to appear in the epidermis of the palm and sole of the foot between 8 and 12 weeks, and later in association with some hairs and with dermal axonal-Schwann cell complexes.

## Pilosebaceous unit

Pilosebaceous units develop in a cranio-caudal direction at about 9 weeks' gestation, first in the regions of the eyebrows, lips and chin. The hair placode is a collection of cells in the basal layer of the epidermis and develops adjacent to a local concentration of mesenchymal cells, which will eventually become the dermal papilla. Further proliferation and elongation of the cells lead to a hair germ, which protrudes downwards into the mesenchyme in association with the primitive dermal papilla during weeks $13-15$. The hair germ becomes a hair peg as it migrates downwards within the developing skin, and when its bulbous lower portion envelops the dermal papilla it becomes known as a bulbous peg. Melanocytes are individually present at the hair peg stage, and abundantly so and quite active in the bulbous peg. At this stage (approximately week 15), two or three swellings appear on the posterior wall. The uppermost is the rudiment of the apocrine gland (present only in some follicles), the middle forms the sebaceous gland and the lower one is the bulb, to which the arrector pili muscle (arising from underlying mesenchyme) later becomes attached. The cells of the lowermost region of the bulb, the matrix, divide actively and produce a pointed hair cone. This grows upwards to canalize a developing hair tract, along which the fully formed hair, derived by further differentiation of cells advancing from the matrix, reaches the surface at approximately week 18 of gestation.

Sebaceous glands develop independently of hair follicles in the nostrils, eyelids (as tarsal glands) and the anal region. Apocrine sweat glands are formed at the same time as eccrine (merocrine) glands and are at first widely distributed over the body. Their number diminishes from 5 months' gestation, producing the distribution seen in adult skin.

Hairs produced prenatally are called lanugo hairs, which are short and downy, lack a medulla, and in certain parts of the body are arranged in a vortex-like manner into tracts. Late in pregnancy, lanugo hairs are replaced by vellus hairs, and these in turn by intermediate hairs, which are the predominant type until puberty. New follicles do not develop in postnatal skin.

## Eccrine sweat glands

Eccrine (merocrine) sweat glands are one type of sudoriferous gland. Sweat gland rudiments appear in the second and third months of gestation as cell buds associated with the primary epidermal ridges of the finger and toe pads of terminal digits. They elongate into the dermis and by 16 weeks the lower portion begins to form the secretory coil, within which, by 22 weeks, secretory and myoepithelial cells are present. The solid cord of cells connecting the coil to the epidermis becomes the intradermal duct, and the lumina of both are formed by dissolution of desmosomal contacts between the cells. The intraepidermal duct is foreshadowed by a column of concentrically arranged inner and outer cells within which a lumen is formed and opens on the surface at 22 weeks. As with hair follicles, no new eccrine sweat glands develop postnatally. Emotional sweating occurs in preterm infants from 29 weeks' gestational age.

## Epidermal ridges

The primary epidermal ridges develop as regularly spaced, small downgrowths of epidermal cells separated by corresponding dermal ridges during the second and third months of gestation. In the fifth month secondary ridges develop, with the pattern becoming evident on the surface; this pattern is finalized through further remodelling postnatally.

## Nails

Fields of proliferative ectoderm appear on the tips of the terminal segments of the digits. They progressively reach a dorsal position, where,
at approximately 9 weeks, a flattened nail field limited by proximal, distal and lateral nail grooves is apparent. The nail field ultimately forms the nail bed, and the primordium of the nail is formed of a wedge of cells that grows diagonally, proximally and deeply into the mesenchyme from the proximal groove towards the underlying terminal phalanx. The deeper cells of this wedge form the primordium of the matrix, which gives rise to the nail plate. The latter emerges from under the now proximal nail fold at about 14 weeks and grows distally over an already keratinized nail bed. The nail matrix is usually considered to have dorsal and ventral (intermediate) components, but there are conflicting opinions as to the extent to which each contributes to the nail, both in ontogeny and postnatally. It is generally agreed that the ventral matrix contributes the major part.

At 20 weeks, the nail plate entirely covers the nail field (nail bed), now limited distally by a distal ridge, which, when the plate projects beyond the tip, becomes the hyponychium beneath it. At birth, the microstructure of the main nail unit components is similar to that postnatally.

## DERMIS

The embryonic dermis is more cellular than the adult dermis, and many of these mesenchymal cells are involved in signalling pathways that regulate ectodermal differentiation. The mesenchymal cells underlying the surface ectoderm and early bi- and trilaminar epidermis contact each other by slender processes to form an intercommunicating network. They secrete a matrix that is rich in ions, water and macromolecules, proteoglycan/glycosaminoglycans, fibronectin, collagenous proteins of various types and elastin. Further development of these intrinsic components involves the differentiation of individual cell types, fibroblasts, endothelial cells, mast cells and the assembly of matrix components into organized fibrillar collagen fibres and elastic fibres. During embryogenesis, the matrix is heterogeneous with regard to its biochemical and macromolecular components. The main glycosaminoglycans of embryonic and fetal skin are glycuronic acid and dermatan sulphate. Types I, III, V and VI collagens are distributed more or less uniformly, regardless of fetal age, with some local concentrations of type III and V collagens, the levels of which are higher than in postnatal skin. Collagens of types IV and VII are found predominantly in the BMZ.

The progressive morphological differentiation of the dermis involves its separation from the subcutis at about the third month; changes in composition and size of collagen fibrils and their organization into bundles, amongst which cells become relatively fewer; downgrowth of epidermal appendages; the organization of nervous and vascular plexuses; and the relatively late appearance of elastic networks. The papillary and reticular regions are present as early as 14 weeks but the overall organization of the dermis continues to develop postnatally.

## Vascular supply and lymphatic drainage

The dermal vasculature is generally thought to be developed in situ by the transformation of angiogenic mesenchymal cells. Closed endothelium-lined channels containing nucleated red cells are present by 6 weeks underneath the ectoderm, and by the eighth week are arranged in a single plane parallel to the epidermis; these ultimately form the subpapillary plexus. A second, deeper horizontal plexus is evident by 50-70 days. Both plexuses extend by budding and give rise to the final patterns of arterioles, venules and capillaries, which are established shortly after birth. Pericytes also develop from mesenchymal cells. Lymphatic vessels are formed by mesenchymal cells, which become organized to enclose pools of proteinaceous fluid leaking from the developing capillaries.

## Innervation

Sensory cutaneous nerves (axons and Schwann cells) are derived from the neural crest (via dorsal root and cranial sensory ganglia). Motor fibres to vessels and glands arise from neurones in sympathetic ganglia. As individual parts of the embryo grow, the nerves grow and lengthen with them. Small axons are present superficially at a stage when the epidermis is bilaminar, and by 8 weeks of gestation a functioning cutaneous plexus is already present. By the fourth gestational month, the dermal plexuses are richly developed and Meissner and Pacinian corpuscles have appeared.

## EPITHELIAL-MESENCHYMAL INTERACTIONS IN DEVELOPING SKIN

Epidermal-mesenchymal (dermal) interactions at the BMZ occur during development and throughout life. At the ectodermal stage, the BMZ consists of the basal plasma membrane of an ectodermal cell, paralleled on its cytoplasmic side by various cytoskeletal filaments, and beneath it by a layer ( $0.1-0.2 \mu \mathrm{~m}$ ) of microfibrillar-amorphous material deposited by the cell. At the bilaminar stage, a continuous lamina densa is present, separated from the basal plasma membrane by a lamina lucida traversed by loosely fibrillar material; similar filaments extend from the lamina densa into the mesenchymal matrix.

Hemidesmosomes (see Fig. 1.19) begin to appear at 8 weeks as stratification starts, and anchoring fibrils at $9-10$ weeks. By the end of the third month, the basic morphology of the interfollicular BMZ is essentially similar to that of the postnatal BMZ.

Laminin and type IV collagen are present in the developing basal lamina at 6 weeks; bullous pemphigoid antigen (BPAG, in hemidesmosomes) and anchoring fibril proteins are expressed later. These immunocytochemical and morphological observations are of importance for the prenatal diagnosis of genetically determined diseases such as epidermolysis bullosa. The basal lamina provides a physical supporting substrate and attachment for the developing epidermis, and is thought to be selectively permeable to macromolecules and soluble factors regulating epidermal-dermal morphogenetic interactions.

## NEONATAL GROWTH

The surface area of the skin increases with growth. It is estimated that the surface area of a premature neonate weighing 1505 g is approximately $1266 \mathrm{~cm}^{2}$, whereas a neonate of 2980 g has a surface area of $2129 \mathrm{~cm}^{2}$. The skin of the neonate is thinner than that of older infants and children. It cornifies over a period of 2-3 weeks, which provides protection. In the premature infant the even thinner epidermal layer allows absorption of a variety of substances such as chlorhexidine and permits a significantly higher transepidermal water loss than occurs in full-term neonates. At birth the skin is richly vascularized by a dense subepidermal plexus. The mature pattern of capillary loops and of the subpapillary venous plexus is not present at birth but develops as a result of capillary budding with migration of endothelia at some sites and the absorption of vessels from other sites. Some regions mature faster than others. With the exceptions of the palms, soles and nail beds, the skin of the neonate has almost no papillary loops. It has a disordered capillary network, which becomes more orderly from the second week when papillary loops appear; defined loops are not present until the fourth or fifth week, and all areas possess loops by $14-17$ weeks postnatally.

Neonates exhibit a regional sequence of eccrine gland maturation. The earliest sweating occurs on the forehead, followed by the chest, upper arm and, later, more caudal areas. Acceleration of maturation of the sweating response occurs in premature babies after delivery.

## NATURAL SKIN CREASES AND WRINKLES

## SKIN LINES

The surface of the skin and its deeper structures show various linear markings, seen as grooves, raised areas and preferred directions of stretching.

## Surface pattern lines, tension lines and skin creases

[^0]

Fig. 7.22 The surface of hairless skin from the palm of the hand, showing epiderma friction (papillary) ridges and larger flexure lines (left).

Fig. 7.23 A scanning electron micrograph of the surface of thin skin of the back, showing an interlacing network of fine creases and predominantly triangular areas between them.
e.g. on the cheek the primary creases radiate from the hair follicles, on the scalp they form hexagons, while on the calf and thigh they form parallelograms. There is a relationship between the type of pattern and local skin extensibility.

## Wrinkle lines

Wrinkle lines are caused by contraction of underlying muscles and are usually perpendicular to their axis of shortening. On the face they are known as lines of expression, and with progressive loss of skin elasticity due to ageing, they become permanent. Occupational lines are creases produced by repeated muscular contractions associated with particular trades or skills. Contour lines are lines of division at junctions of body planes, e.g. the cheek with the nose, and lines of dependency are produced by the effect of gravity on loose skin or fatty tissue, e.g. the creases associated with the pendulous fold beneath the chin in older age.

## Flexure (joint) lines

Flexure (joint) lines are major markings found in the vicinity of synovial joints, where the skin is attached strongly to the underlying deep fascia (see Fig. 7.22). They are conspicuous on the flexor surfaces of the palms, soles and digits, and in combination with associated skin folds they facilitate movement. The skin lines do not necessarily coincide with the associated underlying joint line. For example, the flexure lines demarcating the extended fingers from the palm lie approximately 12 mm distal to the metacarpophalangeal joints, the positions of which are more closely related to the distal palmar crease. The patterns of

Fig. 7.24 The palmar aspect of a terminal phalanx to show fingerprint ridges. Note the interphalangeal flexure line (IPFL).

Fig. 7.25 A scanning electron micrograph of the surface of thick hairless skin from the volar surface of a human digit, showing friction ridges along which lines of sweat ducts open as pores (one pore is arrowed). (Courtesy of Professor Lawrence Bannister and Dr Caroline Wigley.)
flexure lines on the palms and soles may vary and are, to some extent, genetically determined.

## Papillary ridges

Papillary ridges are confined to the palms and soles and the flexor surfaces of the digits, where they form narrow parallel or curved arrays separated by narrow furrows (Figs 7.24-7.25). The apertures of sweat ducts open at regular intervals along the summit of each ridge. The epidermal ridges correspond to an underlying interlocking pattern of dermal papillae, an arrangement that helps to anchor the two layers firmly together. The pattern of dermal papillae determines the early development of the epidermal ridges. This arrangement is stable throughout life, unique to the individual, and therefore significant as a means of identification. The ridge pattern can be affected by certain abnormalities of early development, including genetic disorders such as Down's syndrome, and skeletal malformations such as polydactyly. Absence of epidermal ridges is extremely rare. Functionally, epidermal ridges increase the gripping ability of hands and feet, preventing slipping. The great density of tactile nerve endings beneath them means that they are also important sensory structures.

The analysis of ridge patterns by studying prints of them (fingerprints) is known as dermatoglyphics and is of considerable forensic
importance. Measurable parameters include the frequency of ridges in particular patterns and the disposition of tri-radii, which are junctional areas where three sets of parallel ridges meet. Fingerprint ridge patterns can be separated into three major types (see Fig. 7.24): arches (5\%), loops ( $70 \%$ ) and whorls ( $25 \%$ ). Arches have no tri-radii, loops have one tri-radius, and whorls have two or more. Whorl finger patterns are more common on the right hand, and males generally have more whorls and fewer arches than females, in whom the ridges are relatively narrower. The frequency of individual patterns varies with particular fingers. Similar patterns are seen on the toes. Adermatoglyphia is an extremely rare autosomal dominant condition in which fingerprint ridges are absent, and is caused by mutations in the SMARCAD1 gene. Other genetic disorders may also have reduced or absent dermatoglyphics as part of the clinical features.

If the mechanical demands placed on the skin are greater than the skin creases and the dermis can accommodate, the lateral cohesion of dermal collagen fibres becomes disrupted with associated haemorrhage and cellular reaction, and, eventually, the formation of poorly vascularized scar tissue. These changes are termed intrinsic to distinguish them from scars formed by external wounding. Sites of dermal rupture are visible externally as lines or striae. They are initially pink in colour, later widen and become a vivid purple or red (striae rubrae), and eventually fade, becoming paler than the surrounding intact skin (striae albae). They develop on the anterior abdominal wall of some women in pregnancy, when they are termed striae gravidarum (stretch marks).

Variation in pigmentation can also produce externally visible lines on the surface of the skin. Futcher's or Voigt's lines mark differences in pigmentation between the darker extensor and paler flexor surfaces of the arms, and occur along the anterior axial lines, extending from the sternum to the wrist. They are more common in darker-skinned people.

## Lines detectable after manipulation or incision

In certain regions of the body, surgical wounds heal with a better and less conspicuous scar if they are orientated in a particular direction. This finding is related to a number of factors including skin tension and naturally formed wrinkle lines. Skin is normally under tension and the direction in which this is greatest varies regionally. Tension is dependent on the protrusion of underlying structures, the direction of underlying muscles, and on joint movements. Many anatomists and surgeons have therefore attempted to produce a body map to indicate the best direction in which to make an elective incision to obtain the most aesthetic scar. These maps frequently differ, especially in the region of the face. Out of the multitude of described cleavage lines, the most commonly referred to are relaxed skin tension lines (RSTLs), Langer's lines and Kraissl's lines. Of these, the RSTLs and Kraissl's lines are probably more appropriate lines for surgical incision.

## Relaxed skin tension lines

Relaxed skin tension lines (RSTLs) are those that correspond to the directional pull (which forms furrows) when the skin is relaxed; they do not always correspond to wrinkle lines. The tension across the RSTL is constant even during sleep but can be altered (increased, decreased or abolished) by underlying muscle contraction. The direction of the RSTLs can be determined by pinching the skin in different directions. Pinching at right angles to the RSTLs will result in fewer and higher furrows than pinching parallel to these lines.

## Lines of Langer and KraissI

Langer punctured the skins of cadavers with a circular awl and noted the subsequent elliptical-shaped openings that this protocol produced. By connecting the long axes of the holes, he produced the cleavage lines named after him. These lines represent skin tension in rigor mortis but they frequently do not relate to the lines of choice in making elective incisions, e.g. Langer's lines often run at right angles to the RSTLs on the face.

Kraissl's lines are essentially exaggerated wrinkle lines obtained by studying the loose skin of elderly faces whilst contracting the mimetic muscles of the face. For the most part, these lines do correspond to RSTLs but slight variation exists on the face, especially on the lateral side of the nose, the lateral aspect of the orbit, and the chin.

## Blaschko's lines

Blaschko's lines represent a pattern of cutaneous mosaicism that can be observed in a range of congenital and acquired skin conditions. They do not appear to correspond to vascular or neural elements of the skin, and may be related to earlier developmental boundaries of a 'mosaic' nature.

## AGE-RELATED SKIN CHANGES

Two main factors, chronological and environmental, are involved in skin ageing. Chronological changes are physiological or intrinsic in origin. A major environmental factor is chronic exposure to the sun, referred to as photoageing, which is to some extent preventable.

## Intrinsic ageing

From about the third decade onwards there are gradual changes in the appearance and mechanical properties of the skin, which reflect natural ageing processes. These become very marked in old age. Normal ageing is accompanied by epidermal and dermal atrophy, which result in changes in the appearance, microstructure and function of the skin. Alterations include wrinkling, dryness, loss of elasticity, thinning and easy bruising. Epidermal atrophy is manifested by general thinning and loss of the basal rete pegs and flattening of the dermal-epidermal junction. Flattening of the junction decreases resistance to shear, leading to poor adhesion of epidermis and its separation following minor injury The thickness of the cornified layer is not reduced in old age, and its permeability characteristics seem little affected. Epidermal proliferative activity and rate of cell replacement decline with age, being reduced by up to $50 \%$ in elderly skin. Synthesis of vitamin D is also reduced. After middle age, there is a $10-20 \%$ decline in the number of melanocytes, and Langerhans cells become sparser, a change which is associated with a reduction in immune responsiveness. Depigmentation and loss of hair, as well as some local increases (eyebrows, nose and ears in males, and face and upper lip in females), are commonly observed. Alterations in non-keratinocytes may be aggravated by chronic exposure to UV irradiation.

Dermal changes are mainly responsible for the appearance of aged skin, its stiffness, flaccidity and wrinkling, as well as loss of extensibility and elasticity. Its general, thickness diminishes as a result of the decline in collagen synthesis by a reduced population of fibroblasts, though the relative proportion of type III collagen increases. Senile elastosis is a degenerative condition of collagen, which may be partly due to excessive exposure to sun. Vascularization of the skin is reduced, the capillary loops of the dermal papillae are particularly affected, and the tendency towards small spontaneous purpuric haemorrhages indicates a general fragility of the cutaneous microvasculature. A decrease in sensitivity of sensory perception, associated with some loss of specialized receptors, occurs. Ageing is also associated with fat redistribution, which may contribute to the physical characteristics of loose, sagging skin.

## Photoageing

Skin ageing is also influenced by external factors, such as tobacco exposure, malnutrition, airborne particulate matter and UV radiation. Photoageing, also known as extrinsic skin ageing, occurs as a result of the hazardous effect of UV radiation on human skin. It is a major concern because of an association with skin cancer. Ultraviolet light B (UVB) is primarily absorbed in the epidermis and has been shown to induce angiogenesis and lymphatic dysfunction in skin. It causes DNA damage by generating cyclobutane pyrimidine dimers and 6,4photoproducts, which are photocarcinogenic. Ultraviolet A is absorbed by cellular chromophores such as melanin, riboflavin and urocanic acid, resulting in the formation of reactive oxygen species, which in turn damage lipids, DNA and proteins (for review, see Kohl et al (2011)).

## CUTANEOUS WOUND HEALING AND SCARRING

The end-point of healing of mammalian skin wounds is usually scar formation. Cutaneous scars result from injury to both the epidermis and the underlying dermis. The epidermis largely regenerates, but dermal architecture is abnormal after repair and the undulating pattern of rete ridges at the dermal-epidermal junction is not reproduced. Scar tissue is biomechanically inferior to unwounded skin. Appendages such as hair follicles, sebaceous and sweat glands, which are derived from the epidermis, do not regenerate after wounding.

The molecular biology of cutaneous repair involves the coordination of numerous cell types, signalling molecules and matrix proteins. Many of these signalling molecules have pleiotropic effects and it is the complex balance of these mediators, rather than their individual action, that determines events in wound repair. Wound healing is often considered in four overlapping temporal phases: namely, haemostasis, inflammation, proliferation and remodelling (Fig. 7.26). These events will be discussed separately for clarity, although this is an artificial
division of the complex, interrelated processes that constitute the wound healing response. For further reading, see Miller and Nanchahal (2005) and Rozen et al (2009).

## HAEMOSTASIS

Wounding causes vascular injury and initiates fibrin-fibronectin clot formation. The clot consists of platelets (promoted to aggregate by fibrillar collagens type I and III) embedded in a mesh of cross-linked fibrin and fibronectin fibres. It serves as a haemostatic plug, protects the denuded wound with a temporary physical shield, and forms a provisional matrix through and over which cells migrate during the repair process. The clot also acts as a reservoir of growth factors and cytokines, which are released as platelets degranulate, and contribute to inflammatory cell recruitment.

## INFLAMMATION

Neutrophils and monocytes are recruited to wound sites within minutes of injury by a variety of chemotactic signals, including complement factors, bacterial polysaccharides, cytokines and growth factors such as tumour necrosis factor alpha (TNF- $\alpha$ ), interleukin (IL)-1, plateletderived growth factor (PDGF), transforming growth factor alpha (TGF$\alpha$ ) and TGF- $\beta 1,2$, basic fibroblast growth factors (bFGF/FGF-2), serotonin and monocyte chemotactic protein-1 (MCP-1).

Neutrophils are active against contaminating bacteria. Monocytes differentiate into macrophages that phagocytose not only pathogenic organisms, but also expended neutrophils, cell and matrix debris. Both neutrophils and macrophages act as a further source of cytokines and growth factors to amplify stimuli already present in the wound site. Macrophages are also a source of additional factors such as TGF- $\alpha$, FGF and vascular endothelial growth factor (VEGF) that activate resident fibroblasts, endothelial cells and keratinocytes, which in turn are central to the processes of re-epithelialization and formation of granulation tissue, as discussed below.

## PROLIFERATION

The proliferation phase of wound healing involves re-epithelialization and granulation tissue formation, which take place more or less simultaneously.

## Re-epithelialization

Re-epithelialization begins within hours of wounding as a result of keratinocyte migration and proliferation from the wound edges and skin appendages. Cytokines such as epidermal growth factor (EGF), FGF, keratinocyte growth factor (KGF/FGF-7), insulin-like growth factor-1 (IGF-1) and TGF- $\alpha$ are released by activated fibroblasts and keratinocytes, and stimulate the re-epithelialization process. The mechanisms of keratinocyte migration are not fully understood, although disruption of desmosomes and hemidesmosomes, extracellular matrix contact, formation of cytoplasmic actin filaments and degradation of the fibrin matrix are all likely to be important. There is evidence that keratinocyte expression of matrix metalloproteinases (MMPs) is associated with re-epithelialization. During this phase of cutaneous wound healing, keratinocyte proliferation is thought to be upregulated after migration has started; dividing and migrating cells are found in the first suprabasal as well as basal keratinocyte layers. MMP activity is regulated by the production of tissue inhibitors of MMPs (TIMPs), and a relative imbalance, with upregulation of certain MMPs, may be associated with impaired wound healing. When the denuded wound surface has been covered by a monolayer of keratinocytes, migration ceases. A stratified epidermis with an underlying basal lamina is re-established from the margins of the wound inwards. Anchoring fibrils linking the basal lamina to the underlying connective tissue mark neo-epidermal maturity.

## Granulation tissue formation

The term granulation tissue refers to the macroscopic appearance of wound connective tissue, which appears pink and granular. It contains numerous capillaries that invade the initial wound clot and become organized into a microvascular network (angiogenesis), together with the cells and molecules necessary to stimulate neo-matrix deposition.

Fig. 7.26 The processes involved in the healing of a normal cutaneous wound. Abbreviations: EGF, epidermal growth factor; FGF, fibroblast growth factor; KGF, keratinocyte growth factor; PDGF, platelet-derived growth factor: TGF, transforming growth factor; VEGF, vascular endothelial growth factor.

Angiogenesis is a complex process, promoted by dynamic interactions between endothelial cells, angiogenic cytokines (including FGF-2, VEGF (mainly from keratinocytes), PDGF and TGF- $\beta 1,2$ ) and the extracellular matrix environment.

Electron microscopic studies have shown that the epidermis, basal lamina and papillary dermis all develop on the surface of the granulation tissue. Wounds that fail to granulate do not heal satisfactorily, suggesting that granulation tissue formation is a key aspect of wound repair. Excessive granulation is also associated with delayed re-epithelialization.

Activated fibroblasts in the healing wound proliferate in response to growth factors, notably TGF- $\beta 1$, IGF-1, PDGF, FGF and EGF. Within 72 hours of injury, these fibroblasts synthesize components of the new extracellular matrix, which are deposited in an orderly sequence. The neo-matrix initially includes fibronectin and hyaluronan, which form a provisional substratum for cellular migration. Fibronectin acts as an initiation site for collagen fibrillogenesis, and as anchorage for myofibroblasts to effect wound contraction. Hyaluronan forms a highly hydrated matrix that is easily penetrated by migrating cells. Ultimately this and other neo-matrix components are replaced, first by collagen type III, and subsequently by collagen type I, which imparts strength to the mature scar (see remodelling, below). Non-structural proteins such as tenascin are also found in the neo-matrix of healing wounds and provide signals that orchestrate the repair process.

Cellularity decreases during the evolution of granulation tissue into a mature scar (and during other phases of wound healing), mainly as a result of apoptosis.

## REMODELLING

Remodelling of the extracellular matrix is important throughout the wound healing process and persists for some time after closure of the defect. Fibroblasts are responsible for matrix remodelling, as well as deposition. Initially they replace hyaluronan in the neo-matrix with sulphated proteoglycans, such as decorin, biglycan and versican, which
contribute to tissue resilience. Increased wound strength coincides with new collagen deposition. Approximately 3 weeks after injury, collagen breakdown and synthesis equilibrate; subsequent, more gradual increases in wound strength reflect collagen remodelling, with the formation of intermolecular cross-links and larger collagen bundles. Scar maturation is associated with proportional increases in collagen type I relative to collagen type III. Collagen fibres of the dermis in scars are arranged in an irregular fashion and scarred skin only reaches a maximum tensile strength of about $70 \%$ that of unwounded skin.

## Wound contraction

An important part of remodelling is wound contraction. Once granulation tissue has been laid down, a proportion of activated fibroblasts (or other mesenchymal cells) transform into myofibroblasts, which play a key role in wound contraction; they are thought to generate forces that pull normal dermal and adipose tissue into the wound defect.

## SCARLESS WOUND HEALING

Wounds heal with reduced or absent scarring in certain circumstances, notably cutaneous wounds in the early fetus. The development of a major inflammatory response at a wound site appears to be a significant determinant of whether scarring occurs. Scarless fetal wound healing is characterized by fewer inflammatory cells (which are less differentiated than their adult counterparts and which remain in the wound for a shorter time), rapid re-epithelialization, reduced angiogenesis and restoration of the connective tissue architecture in which collagen is arranged in the normal reticular pattern.

An ontogenic transition period, during which cutaneous healing changes from scar-free to scar-forming, has been identified in the third trimester of gestation. Studies of this transition period have led to the identification of molecules of key importance in the scarring process; the most extensively characterized factor to date is TGF- $\beta$. Three mammalian TGF- $\beta$ isoforms have been identified: TGF- $\beta 1,2$ and 3 .

Comparisons of fetal scar-free and adult scar-forming wounds show that TGF- $\beta 1$ and 2 are not present in fetal wounds, suggesting that scarless wound healing is associated with TGF- $\beta 3$ activity, rather than TGF$\beta 1$ and 2. The $\beta 1$ and 2 isoforms are dominant in fetal, neonatal and adult wounds that form scars. The main sources of TGF- $\beta 3$ are fibroblasts and keratinocytes, whilst TGF- $\beta 1$ and 2 are produced from degranulating platelets and subsequently from monocytes and macrophages; the low levels of TGF- $\beta 1$ seen in fetal wounds have been attributed to a relative lack of platelet degranulation and fibrin clot formation.

## SKIN GRAFTS AND FLAPS

A graft is a piece of tissue that has been detached from its blood supply and therefore needs to regain a blood supply from the bed in which it is placed in order to survive. In contrast, a flap is a piece of tissue that is surgically raised and transferred from one location in the body to another while maintaining its blood supply, which enters the base (pedicle) of the flap when it is transplanted.

## GRAFTS

Grafts can be composed of skin, fat, fascia or bone, either separately or together as a composite piece of tissue. Skin grafts can be either fullthickness grafts or split-thickness grafts. Full-thickness grafts consist of the epidermis and the full thickness of the dermis. Split-thickness grafts consist of the epidermis and a variable quantity of the dermis. An essential difference is that the donor site following the harvest of a fullthickness graft has no epidermal elements from which new skin can regenerate. These grafts therefore tend to be taken from sites of the body where the donor defect can be primarily closed. The donor site from split-thickness grafting contains adnexal remnants (hair follicles in particular), which have the propensity to divide and regenerate new epidermis, and so resurface the donor defect.

Revascularization of grafts is dependent on early and direct connection between host and graft vessels (inosculation), before which graft survival depends on fluid absorption (imbibition). Revascularization, which occurs as early as 48 hours post-transplantation, is by both anastomosis, whereby the severed ends of pre-existing graft vessels link up with vessels of the underlying wound bed; and neovascularization, which involves the de novo angiogenic ingrowth of vessels from the wound bed into the graft. During the first 2 weeks, blood vessels from the recipient site invade the graft edges along previous vascular channels in the direction of an ischaemic stimulus, whereas native graft vasculature begins to regress. Endothelial progenitor cells appear to play an important role in blood vessel formation, attracted by ischaemic gradients. Inosculation occurs, restoring blood flow to the graft microcirculation. By the start of the third week, complete blood flow in the graft vasculature has been established and, in the absence of a continuing ischaemic stimulus, neovascularization ends.

## FLAPS

Flaps are named according to the type of tissue transferred, e.g. a fasciocutaneous flap contains skin and fascia, and a musculocutaneous flap contains both muscle and the overlying skin, whereas a skin flap, fascial flap and muscle flap contain only the separate elements that their names imply. The blood supply to a skin flap can be randomly orientated, which limits the flap length-to-breadth proportions to no more than $2: 1$ (except on the face, where longer flaps can be performed). Much longer skin flaps can be raised elsewhere if the blood supply to the flap is a direct cutaneous artery and vein; these are called axial pattern flaps and are usually based on the local angiosome. An
angiosome is an anatomical territory supplied by a source artery and drained by accompanying veins and lymphatic vessels (p. 132). It may include fascia, nerve, muscle and bone, as well as skin. The concept is important in analysis of patterns of ischaemia and in planning incisions, and enables the raising of free, composite, vascularized tissue flaps. (For further reading about the angiosome concept, see Taylor and Palmer (1987), Taylor et al (1994) and Yin et al (2013)).

A free flap (free tissue transfer) is a specific type of flap in which the tissue, whether skin, fascia, muscle or bone, or a combination of these, is completely removed from its original location in the body along with a single identifiable artery and vein, and transferred to a remote site. The blood vessels in the flap are anastomosed to vessels located in the new site using microsurgical techniques. This often allows for greater flexibility in performing reconstructive surgery.

## SKIN STEM CELLS

To maintain, repair and regenerate itself, the skin contains stem cells, which reside in various parts of the hair follicles, including the bulge area and isthmus, the basal layer of interfollicular epidermis, the base of sebaceous glands and within sweat glands. Stem cells are able to self-renew, as well as give rise to differentiating cells. However, it is not clear whether every basal keratinocyte or only a proportion of cells is a stem cell. Two possible hypotheses have emerged concerning epithelial renewal. One theory, known as symmetrical cell division, divides basal keratinocytes into epidermal proliferation units, which comprise one self-renewing stem cell and about 10 tightly packed transit amplifying cells, each of which is capable of dividing a limited number of times before exiting the basal layer to undergo terminal differentiation. This unit gives rise to a column of larger and flatter cells, which culminates in a single hexagonal surface. The alternative theory, known as asymmetrical cell division, is that some interfollicular stem cells (perhaps up to $70 \%$ of cells) can shift their spindle orientation from lateral to perpendicular, such that one daughter cell is committed to terminal differentiation while the other maintains its proliferative capacity. Asymmetrical cell divisions can therefore bypass the need for transit amplifying cells.

Hair follicle stem cells (see Hsu et al (2011) for recent research) are found in the bulge regions below the sebaceous glands but also in other parts of the hair follicle. These stem cells undergo varying degrees of growth, degeneration and rest, which are governed, in part, by Wnt signalling and bone morphogenetic protein (BMP) inhibition. The bulge area stem cells generate cells of the outer root sheath, which drive the highly proliferative matrix cells next to the mesenchymal papillae. After proliferating, matrix cells differentiate to form the hair channel, the inner root sheath and the hair shaft. Hair follicle stem cells can also differentiate into sebocytes and interfollicular epidermis. Despite this multipotency, the follicle stem cells only function in pilosebaceous unit homeostasis and do not contribute to the interfollicular epidermis unless the skin is wounded. Stem cells are also found in the base of sebaceous glands; the progeny of these cells differentiate into lipidfilled sebocytes. Stem cells in sweat glands can differentiate into epithelial, luminal or myo-epithelial daughter cells to maintain skin integrity and homeostasis.

Apart from epithelial stem cells, other cells in the dermis and subcutis may have stem cell properties. Some stem cells, termed dermal sheath cells, reside close to hair follicles; other stem cells in the dermis, known as MUSE (multi-lineage differentiating stress-enduring) cells, are pluripotent stem cells (see Commentary 1.2). Trauma and/or hypoxia in the skin, e.g. during wound healing or skin grafting, may induce recruitment of epithelial and endothelial progenitors from stem cell sources beyond the skin, such as bone marrow, predominantly from the mesenchymal stromal cell pool. For review of epidermal stem cells, see Beck and Blanpain (2012) and Ghadially (2012).

# Fluorescence microscopy in cell biology today 

Dylan M Owen

Fluorescence microscopy is one of the most widely used tools in cell biology today. Its major strength is that it allows the distributions of individual, specific protein species to be mapped at submicron resolution in living cells and even whole organisms. There are several technologies that came together in the 1990s and early years of the twenty-first century to make this possible. These are the development of fluorescent fusion protein constructs based on genetically encoded fluorescent proteins; advances in excitation and detector technology allowing new levels of specificity, speed and signal-to-noise; the development of multiphoton excitation permitting imaging deep within tissues; and new image analysis and computing techniques for the manipulation and quantification of the resulting data. These advances combined to make fluorescence a standard research tool, found within most laboratories working in the biological sciences. However, a new wave of technological development arrived in the last 5-10 years and is only now beginning to be adopted by the biological sciences community. New fluorescent probes, optical technology and imageprocessing algorithms have led to the development of super-resolution microscopy in which fluorescence images can be obtained with resolution approaching the molecular scale. In effect, this allows the mapping of all fluorescent molecules in a sample with nanometre accuracy, a possibility that is changing the way we think about what microscope images mean.

Fluorescent fusion constructs allow a protein species of interest to be genetically fused to a fluorescent protein so that it can be visualized in a microscope (Chudakov et al 2010). Originally, this meant fusion to the green fluorescent protein (GFP) from the Pacific jellyfish Aequoria victoria (Tsien 1998). For the development of this technology, the 2008 Nobel Prize for Chemistry was shared between Osamu Shinomura, who identified and purified GFP; Martin Chalfie, who created and imaged the first fluorescent fusion (Chalfie et al 1994); and Roger Tsien, who mutated GFP to create a whole palate of possible colours - a palate that is now vast (Shaner et al 2005, Giepmans et al 2006). Unlike immunostaining, in which fluorescently tagged antibodies to the protein of interest are introduced into the cell, GFP is genetically encoded and is therefore compatible with live cell imaging, so allowing the investigation of protein dynamics under physiological conditions. The newest fluorescent protein technology includes photoactivatable and colourswitchable proteins, which are useful for tracking intracellular events (Patterson and Lippincott-Schwartz 2002), and as timers (Subach et al 2009) and sensors of various environmental parameters, such as pH (Tantama et al 2011). On the hardware side, advances in laser technology have allowed more specific excitation of the sample. Unlike mercury arc lamps, laser light is monochromatic: that is, it contains only a single wavelength. This specificity greatly expanded the scope for multichannel imaging and the visualization of several fluorescent species simultaneously. The latest developments in this field centre on white light lasers and tuneable lasers for more flexible imaging (McConnell 2004) Simultaneously, detectors have become faster and more sensitive. The charge-coupled device (CCD) camera evolved into the electronmultiplying CCD, which was sensitive enough to detect individual photons and therefore image and track single molecules within cells. Currently, compound metal-oxide semiconductor (CMOS) camera technology is transforming microscopy with its very high frame rates and huge fields of view. For point detectors such as those used on confocal and multiphoton systems, new hybrid detectors are being implemented, offering the Holy Grail of extremely high sensitivity and large dynamic range.

While GFP advanced imaging into the domain of live cells, multiphoton excitation allowed imaging in living organisms (Denk et al 1990, Helmchen and Denk 2005). Here, two low-energy photons from a pulsed laser combine at the sample to excite the fluorophores, rather than a single high-energy photon as is normally used. Low-energy (red) photons are scattered less by complex biological tissue, which means that high resolution can be maintained at greater imaging depths
(Fig. 1.1.1a). Model organisms, such as nematodes, zebrafish and fruit flies, can be studied in this way. The newest developments in in vivo imaging that are currently transforming the field are based on light sheets. Termed SPIM (selective plane illumination microscopy), a flat sheet of excitation light is projected through the sample and imaged by a perpendicularly arranged lens (Huisken et al 2004) (Fig. 1.1.1b). This allows high-resolution three-dimensional imaging at high speed and with minimal photo-damage to the sample.

In all the above techniques, the resolution of the final fluorescence image is limited by the diffraction of light to be 200-300 nm; two fluorescent objects separated by less than this distance would not be distinguishable as two separate entities. In 2008, the emerging field of super-resolution far-field microscopy or nanoscopy was named Method of the Year by Nature Methods, and in 2014 the Nobel Prize for Chemistry was awarded for the development of the techniques. By a combination of new fluorophores, optics and image analysis, the diffraction limit was circumvented by three new methodologies. Broadly, these are techniques based on structured illumination microscopy (SIM), in which a grid pattern of excitation light is projected on to the sample (Gustafsson 2000) (Fig. 1.1.2a); stimulated emission depletion (STED) microscopy, in which a 'doughnut'-shaped depletion beam is used to de-excite fluorophores and narrow the excitation spot used in confocal microscopy (Hell and Wichmann 1994, Vicidomini et al 2011) (Fig. 1.1.2b); or single-molecule localization techniques such as photoactivated localization microscopy (PALM), in which individual molecules

Fig. 1.1.1 Illustration of in vivo imaging by multiphoton and selectiveplane microscopy. A, In multiphoton microscopy, excitation only occurs where the excitation photons are most dense - at the focus. Not only does this generate intrinsic optical sectioning but also the low scattering of long-wavelength (red/infra-red) light means that focus can be deep into tissue. B, Selective-plane illumination creates a flat light sheet projected from the side by a cylindrical lens, with fluorescence collected by a standard objective and imaged using a camera. This allows extremely high-speed three-dimensional imaging.

Fig. 1.1.2 The main techniques for super-resolution imaging. A, Structured illumination microscopy (SIM) projects a pattern of excitation light (blue lines) on to the sample (green). Multiple acquisitions with different pattern positions and orientations allow a super-resolution image to be reconstructed computationally. B, Stimulated emission depletion (STED) uses a red-wavelength depletion laser beam to cancel out fluorophore excitation at the periphery of a standard confocal excitation spot, leading to a narrower effective excitation area. C, Single-molecule localisation microscopy (SMLM) uses special fluorophores or chemicals to image a sparse set of molecules in any one frame exclusively, leading to individual point spread functions that can be imaged and centroided to find the true position of the molecule. Over many thousands of frames, the positions of all fluorophores in the sample can be mapped.
are imaged and localized in sequence (Betzig and Chichester 1993) (Fig. 1.1.2c).

SIM achieves resolutions of around 100 nm and is compatible with conventional fluorophores and live cell imaging. STED typically achieves $50-100 \mathrm{~nm}$ in biological samples but is more challenging for live cell imaging because of the damaging laser powers used. PALM and the related technique of direct stochastic optical reconstruction microscopy (dSTORM) (Rust et al 2006, Heilemann et al 2008) deliver the highest resolution of $20-30 \mathrm{~nm}$, but are relatively slow and therefore mainly used on fixed cells where new switchable fluorophores allow fluorescent molecules to be turned on stochastically. Individual molecules are then imaged and their coordinates recorded before the fluorophores are bleached and a new subset of molecules is activated. In this way, all molecules in the sample are imaged in sequence, circumventing the diffraction limit. Using PALM, the ability to acquire tables of the $x, y$ and z coordinates of all individual fluorescent molecules, rather than images per se, requires new ways of thinking about the analysis and quantification of data sets; this challenge is only just beginning. Example images acquired with these three super-resolution methods are shown in Figure 1.1.3.

While work on new improved fluorophores, laser technology, optical components and processing algorithms continues, more radical breakthroughs in microscopic techniques and data analysis are likely. They will focus on further enhancements to resolution, imaging speeds and applicability to whole-organism imaging: for example, PALM is beginning to be applied to live cells when the biological structure is relatively stable (Shroff et al 2008) and the speed of STED has been greatly improved (Chmyrov et al 2013). There is no doubt that these advances will make fluorescence microscopy an even more valuable tool within the biological sciences.

# Stem cells in regenerative medicine 

## COMMENTARY <br> 1.2

Jonathan M Fishman, Paolo De Coppi, Martin A Birchall

## Introduction

There is a great deal of hype, hope and optimism surrounding the use of stem cells in regenerative medicine. Historically and in recent years, stem cell successes have attracted widespread media attention, which has further fuelled the public perception of stem cells and what they are capable of achieving. Although significant breakthroughs have been made in the past decade in stem cell research and the resulting scientific output has increased exponentially, so far, only a small proportion of this research has been successfully translated into the clinical arena. Scientific effort is therefore now focusing on translating this research from 'bench' to 'bedside' and on testing the clinical efficacy and safety of stem cell therapies through clinical trials. (For further reading, see Dimmeler et al (2014).)

## What are stem cells?

Stem cells may be defined as cells that exhibit properties of multilineage differentiation and self-renewal (Thomson et al 1998). The term 'multilineage differentiation' means that cells have the potential to differentiate into any of the three embryonic germ layers - ectoderm, mesoderm or endoderm. By self-renewing, stem cells are able to generate further stem cells, thereby propagating themselves.

## Types of stem cell

Stem cells can be broadly categorized into embryonic or adult stem cells. The different types of stem cell are depicted in Figure 1.2.1. From an immunological perspective, stem cells can also be syngeneic (from identical twins), autologous (from the same individual), allogeneic (from a different member of the same species) or xenogeneic (from a different species altogether). Syngeneic and autologous cells have obvious advantages since they are unlikely to be rejected following transplantation. The advantages and disadvantages of the different types of stem cell are outlined in Table 1.2.1.

## Embryonic stem cells (ESCs)

Embryonic stem cells are the archetypal pluripotent stem cells, derived from the embryonic inner cell mass of the blastocyst and capable of differentiating into any cell type (Thomson et al 1998). However, current limitations on using ESCs include immunological rejection, safety concerns about the formation of tumours (teratomas) and ethical dilemmas concerning the utilization of cells derived from aborted fetuses. A recent trial of ESCs in spinal cord injury patients has been halted due to financial constraints, although clinical trials are currently under way in the UK and USA within the field of retinal research (Schwartz et al 2012, Watts 2011). Evidence suggests that human ESCs may be generated through somatic cell nuclear transfer (cloning) techniques, a challenge previously believed to be insurmountable (Tachibana et al 2013). This has the potential of generating patient-specific (matched) ESCs in future that will not be rejected by the patient's immune system. Preliminary data suggest that reprogramming by nuclear transfer may be slightly more effective than reprogramming by transcription factors (Krupalnik and Hanna 2014, Ma et al 2014).

## Amniotic fluid stem cells (AFSCs)

The amniotic fluid that surrounds the developing fetus contains a rich stem cell population that was first discovered in 2007 (De Coppi et al 2007). Such cells are c-kit ${ }^{+}\left(\mathrm{CD} 117^{+}\right)$and fulfil the criteria of true stem cells, in that they are pluripotent and exhibit self-renewal. Although not in clinical trials as yet, these cells offer the prospect of correcting fetal defects either in utero or at the time of birth.

Fig. 1.2.1 Different types of stem cell.

## Umbilical cord stem cells

Umbilical cord blood is a potential source of stem cells that may be used to treat a variety of different diseases, including haemopoietic and genetic diseases. Cord blood stem cells display embryonic stem cell markers but are negative for blood cell lineage markers. The main advantages they offer are ease of procurement with minimal risk to the donor; ease of cryopreservation and banking for future use; and minimal ethical concerns.

## Adult stem cells

## Mesenchymal stem cells (MSCs)

Mesenchymal stem cells (MSCs) are broadly multipotent stem cells that are capable of differentiating into a variety of different tissue types, being fairly restricted towards differentiation along the mesodermal lineage. Their potential to differentiate into cartilage, bone or adipose tissue depends on the ability to create the appropriate microenvironment in which this might occur, a goal that continues to be the focus of intense study. MSCs are often derived from bone marrow but can also be enriched from a variety of other sources, including adipose tissue, synovium, skeletal muscle and placental tissues. They have the advantage of generating large numbers of cells and their application in

Table 1.2.1 Comparison of the different types of stem cell

|  | Advantages | Disadvantages |
| :---: | :---: | :---: |
| Embryonic stem cells | Pluripotency | Fear of immunological rejection <br> Safety concerns - tumour (teratoma) formation <br> Ethical dilemmas surrounding aborted fetuses <br> Oocytes required |
| Amniotic fluid stem cells | Pluripotency <br> Non-tumorigenic Can be harvested (through amniocentesis) and manipulated prenatally so that defect can be corrected either in utero or at the time of birth | Low yield - $1 \%$ of amniotic fluid cells are c-kit ${ }^{+}$(CD117 ${ }^{+}$) stem cells Further research concerning origin of cells and characterization required |
| Umbilical cord stem cells | Ease of procurement with minimal donor morbidity <br> Ease of cryopreservation and banking for future use Minimal ethical concerns | Low yield of stem cells and only finite number of cells available from donor Problems of storage - long-term storage may affect cell quality; cost implications; quality control issues |
| Mesenchymal stem cells | Multipotent <br> Large numbers can be harvested Can be enriched from a variety of different tissues including bone marrow, adipose tissue, etc Easily expanded in tissue culture for tissue engineering purposes Autologous and possess immunomodulatory properties Appear safe in clinical trials Minimal ethical concerns | Differentiation dependent on an appropriate microenvironment Optimal mode of delivery unclear Limited long-term therapeutic potential |
| Induced pluripotent stem cells | Pluripotent <br> Can be derived from any cell type Probably non-immunogenic | Low efficiency of reprogramming with current techniques ( $<1 \%$ ) Safety concerns - viral vector transduction commonly required (risks of viral infection and genetic manipulation) and risk of tumours |

vivo should encounter few ethical concerns when compared to the use of ESCs, given that their utilization is comparable to bone marrow transplantation, which is already in widespread clinical use. MSCs are currently in numerous clinical trials for a variety of different diseases, including the treatment of myocardial infarction, where initial results have been promising.

## Induced pluripotent stem cells (iPSCs)

Induced pluripotent stem cells are a relatively novel type of stem cell. Following their discovery in 2006 (Takahashi and Yamanaka 2006), Yamanaka was awarded the 2012 Nobel Prize in Physiology or Medicine. If several critical transcription factors are introduced into a cell Oct3/4, Sox2, Klf4, c-Myc (so-called 'Yamanaka' or 'stemness' factors), any cell (e.g. a fibroblast) can be reverted to a pluripotent state. More recently, it has been demonstrated that such cells may be reprogrammed to totipotency (ability of a cell to differentiate into any cell type, including the extra-embryonic membranes and tissues) (Abad et al 2013). Limitations of the iPSC approach include the low efficiency of the process, safety concerns around viral transduction, immunogenicity of the iPSCs and the risk of tumour formation. Current research is aimed at generating iPSCs without the use of viruses, through the employment of drug molecules (Hou et al 2013). In addition, contrary to earlier opinion, it appears that iPSCs, being an autologous cell source, are indeed non-immunogenic (Araki et al 2013). Phase I/II clinical trials involving iPSCs are eagerly awaited to determine their overall efficacy and safety in disease states.

## Somatic cell reprogramming - stimulustriggered acquisition of pluripotency (STAP): fact or fantasy?

Two papers in Nature in 2014 reported that differentiated mouse somatic cells were able to revert to a pluripotent, or possibly even a totipotent, phenotype after transient exposure to low pH . The reprogramming did not require either nuclear transfer or genetic manipulation and was remarkably rapid, unlike the time taken to prepare iPSCs (Obokata et al 2014a, Obokata et al 2014b). The reprogrammed cells were named STAP (stimulus-triggered acquisition of pluripotency) cells. Not surprisingly, the papers were headline news around the world. However, what seems to be too good to be true usually is just that; within weeks of publication, the methodology and the nature of the cells used in the studies were called into serious question and both papers were subsequently retracted (Nature editorial 2014).

Fig. 1.2.2 Tissue-engineering an organ for transplantation.

## Regenerative medicine through tissue engineering

Tissue engineering is an interdisciplinary field that applies the principles and methods of engineering and the life sciences towards the development of biological substitutes that can restore, maintain or improve tissue function (Langer and Vacanti 1993). The main approach to tissue engineering includes using the various types of stem cell mentioned above and seeding them, either on or within scaffolds, to create 'off-the-shelf' organs and tissues for transplantation (Fig. 1.2.2). Seeding of stem cells on to scaffolds may be undertaken either in vitro

Fig. 1.2.3 Blastocyst complementation to generate human organs for transplantation.

## Box 1.2.1 Clinical highlights

Several patients have now received a new trachea using tissueengineering techniques. The patient's own (autologous) stem cells were harvested from the bone marrow and respiratory epithelium, and seeded on to either decellularized (Elliott et al 2012, Macchiarini et al 2008) or synthetic (Jungebluth et al 2011) scaffolds before being transplanted back into the patient. Early results have been encouraging and clinical trials of full-scale partial laryngotracheal implants are anticipated in the near future.
in a bioreactor, or in vivo using the host as a 'living' bioreactor. Tissue engineering has the potential to overcome existing organ shortages and generate organs and tissues that are not rejected by the patient's immune system (Fishman et al 2013). The trachea was the first stem-cellbased, tissue-engineered organ successfully transplanted into humans (Fishman et al 2011) (Box 1.2.1).

## Using stem cells to replace organs and tissues through blastocyst complementation

A complementary approach to organ and tissue replacement using interspecific blastocyst complementation has been reported recently. In this technique, iPSCs home to developmentally deficient niches, where they regenerate tissues of the donor cell species (Kobayashi et al 2010). Using two transgenic pig lines, normal fluorescently-labelled pig pluripotent stem cells have been transplanted into genetically altered pigs lacking pancreata, resulting in the development of chimeric pigs
with fluorescent orange pancreata derived from donor cells (Matsunari et al 2013). This is an important step towards the generation of human organs in large animals by complementing pig embryos with human iPSCs (Fig. 1.2.3). The clinical possibilities of using blastocyst complementation as a means of generating transplantable human organs may offer one solution to the current shortfall in organs for transplantation: by growing human organs in livestock animals such as pigs, an unlimited supply of immunologically matched human organs might be made available for transplantation. Concerns have been raised over possible immunological rejection (targeting porcine-derived vasculature surrounding the new organ), and ethical and safety issues associated with injecting human iPSCs, capable of differentiating into any cell and/or tissue type, into pigs (and so theoretically generating a new human-pig hybrid species, especially if such cells home to the brain or the germline).

## Conclusion

At present, the jury is still out as to which stem cell is most effective and safest for tissue regeneration. For this reason, all of the above stem cells are being explored as viable options for future therapies without relying on a single stem cell at the present time. iPSCs probably offer most potential for the future, although it may be that different stem cells perform differently under different conditions (e.g. some stem cells may be better at generating one tissue than another). In addition, for tissue engineering purposes, a stem cell is required that can generate large numbers of cells in a relatively short period of time. Either way, well-conducted clinical trials will be required to determine the stem cell's efficacy, safety and cell fate prior to its widespread use in medicine.

## Ellen A Lumpkin

The epidermis, our outermost layer of skin, serves as a protective barrier and sensory interface with the environment. In vertebrates, these functions are accomplished through the work of only four conserved cell types. Keratinocytes form a water-tight barrier, melanocytes protect against ultraviolet damage and Langerhans cells perform immune surveillance. Merkel cells, which constitute less than $1 \%$ of the epidermis, are an enigmatic cell type whose function and developmental origin have long been debated; however, recent advances show that mammalian Merkel cells are epithelial derivatives that collaborate with sensory neurones to initiate touch sensation.

As early as the nineteenth century, Merkel cells were proposed to contribute to skin's sensory function. These cells were first described by Friedrich Sigmund Merkel, who named them touch cells (Tastzellen), based on contacts with nerve terminals (Merkel 1875). Merkel cells are found in highly touch-sensitive skin areas, including glabrous (hairless) skin of fingertips and lips, some hair follicles, and touch domes on the trunk (Fig. 1.3.1). Most Merkel cells are innervated by a particular class of myelinated ( $\mathrm{A} \beta$ ) sensory neurones called slowly adapting type I (SAI) afferents (Iggo and Muir 1969). These touch receptors are unusual because they produce biphasic discharges of action potentials that send two types of information to the brain (see Fig. 1.3.1): dynamic responses to moving stimuli represent an object's spatial features (e.g. edges and curvature), whereas sustained action-potential trains signify steady pressure (e.g. contact with clothing; Johnson 2001).

Merkel cells were initially proposed to serve as sensory receptor cells based on their synapse-like contacts with nerve terminals and densecore vesicles filled with neurotransmitters (Halata et al 2003). Sensory receptor cells, such as taste-bud cells or hair cells of the inner ear, transduce the energy of a sensory stimulus into electrical signals, which then trigger neurotransmitter release to excite sensory afferents. The hypothesis that Merkel cells are mechanosensory receptors was challenged by neurophysiological studies that reported touch sensitivity after Merkel-cell loss, which suggested that Merkel cells act in a non-sensory capacity.

Recent studies in rodent models have reconciled these views by demonstrating that both Merkel cells and their sensory afferents are mechanosensory cells. Three lines of evidence support this two-receptorsite model, which was proposed more than two decades ago (Yamashita and Ogawa 1991).

First, Merkel cells are touch-sensitive. Like inner-ear hair cells, Merkel cells display fast mechanotransduction currents that convert cellular displacements into electrical signals (Ikeda et al 2014, Maksimovic et al 2014, Woo et al 2014). Piezo2, a large, mechanically activated membrane protein, is required for mechanotransduction currents in Merkel cells. Thus, Piezo2 is a leading candidate gene to encode sensory transduction channels for touch (see Fig. 1.3.1).

Second, Merkel cells are excitatory cells. This was established with a state-of-the-art technique called optogenetics, which uses light-gated molecules derived from Archea to activate or inhibit electrical signalling in specific cells. Transgenic mice were engineered to selectively express light-gated membrane proteins in Merkel cells (Maksimovic et al 2014). When the skin is illuminated to activate Merkel cells in these mice, their sensory afferents produce sustained volleys of action potentials that mimic the response to static pressure (see Fig. 1.3.1). Conversely, neuronal firing is inhibited when Merkel cells are optogenetically silenced. These results confirm that Merkel cells are sensory cells capable of exciting afferents.

Third, Merkel cells are necessary for sustained, but not for dynamic, firing in SAI afferents. Prototypical SAI responses are abolished in transgenic mouse strains that lack either Merkel cells or epidermal Piezo2 expression (Maricich et al 2009, Maksimovic et al 2014, Woo et al 2014). Instead, sustained touch produces only transient bursts of action potentials in these mice (see Fig. 1.3.1). This finding indicates that Merkel cells are essential for conveying information about static pressure to the nervous system. Importantly, they also show that sensory afferents are independently capable of transducing dynamic touch,

Fig. 1.3.1 The Merkel cell-neurite complex is a compound touch receptor. The schematic shows the innervation of a touch dome. Merkel cells (blue) cluster in these highly touch-sensitive spots in humans and other mammals. Merkel cells are mechanosensory receptor cells derived from epidermal progenitors. Adjacent Merkel cells are innervated by a myelinated sensory afferent (yellow) that produces slowly adapting type I (SAI) responses. This response has two phases: (1) Dynamic firing. During a moving stimulus (blue bar), mechanotransduction channels located in the SAI afferent open to excite a transient neuronal volley (blue action potentials). (2) Sustained firing. Static pressure (green bar) activates the Merkel cells' Piezo2-dependent mechanotransduction channels to excite electrical signalling. Merkel cells then signal to SAI afferent terminals to produce sustained action-potential firing (green). Although numerous neuroactive molecules localize to dense-core vesicles, the
neurotransmitters and receptors (orange) that mediate excitatory signalling have not been identified. (Receptor and channel symbols © motifolio.com.)
albeit with reduced activity．Finally，touch－driven behaviours are com－ promised in rodents lacking functional Merkel cells，which indicates that Merkel cells are important for the perception of touch（Maricich et al 2012，Ikeda et al 2014，Woo et al 2014）．

Together，these studies demonstrate that the Merkel cell－neurite complex is a compound touch receptor with two mechanosensory cell types arranged in series（see Fig．1．3．1）．A key open question is：which neurotransmitters convey information between Merkel cells and sensory afferents？

Transgenic mouse studies have also clarified the Merkel cell＇s onto－ geny．Although embedded in a stratified epithelium，Merkel cells express simple epithelial keratins（e．g．keratin－8，keratin－20）and produce dozens of neurochemical markers（Moll et al 1984，Halata et al 2003， Haeberle et al 2004）．Due to this unusual assortment of epithelial and neuronal markers，it was unclear whether Merkel cells derive from epithelial precursors or neural crest．These competing models were tested in transgenic mice by genetically marking specific cell lineages based on selective expression of Cre recombinase．Wnt1 ${ }^{\text {Cre }}$ ，which marks all neural crest cells，failed to label Merkel cells；however， $\mathrm{Krt14}{ }^{\mathrm{Cre}}$ ，a marker of keratinocyte－derived cells，labelled Merkel cells in all skin areas（Morrison et al 2009，Van Keymeulen et al 2009）．Moreover， Merkel cells are replenished from epidermal progenitors in mature skin （Van Keymeulen et al 2009，Woo et al 2010，Doucet et al 2013）．Finally， Merkel cells were abolished by conditional deletion of a developmental transcription factor，Atoh1，driven by Krt14 ${ }^{\text {Cre }}$ but not Wnt1 ${ }^{\text {Cre }}$（Morrison et al 2009，Van Keymeulen et al 2009）．Together，these studies provide a starting point to define transcriptional networks that bestow a neuro－ sensory fate in epidermal cells（Bardot et al 2013，Lesko et al 2013）．

Despite remarkable progress in Merkel－cell biology，important ques－ tions about human Merkel cells remain unanswered．Do Merkel cells
serve additional，non－sensory functions in skin？This is particularly important in human skin，where a substantial fraction of Merkel cells appear to lack innervation．Are human Merkel cells derived from epi－ dermis and renewed throughout life？If so，how are these processes disrupted during ageing，which is accompanied by loss of touch recep－ tors in extremities？This condition is proposed to contribute to the decline of tactile acuity，grip strength and postural stability in the elderly．

Mechanisms of Merkel－cell specification may also be important in a very different human pathology－Merkel cell carcinoma（MCC）．This highly aggressive，non－melanoma skin cancer is linked to Merkel cells based on ultrastructure，neurosecretory markers and keratin－20 immu－ noreactivity（Bhatia et al 2011）．Recent genomic profiling studies confirm that human MCC cells express many of the same genes as mouse Merkel cells（Haeberle et al 2004，Harms et al 2013）．An impor－ tant unresolved question is whether Merkel cells or their epidermal progenitors act as cells of origin for MCC．Immune suppression is a probable risk factor for MCC because it is prevalent on sun－exposed skin and in immunocompromised patients．Intriguingly，MCC has been linked to a newly described virus，Merkel cell polyomavirus（Feng et al 2008），raising the possibility that viral infection plays a role in MCC pathogenesis．Active areas of investigation include identifying a causal link between MCC and polyoma viral infection，and defining mecha－ nisms that underlie the aggressiveness of MCC．

## Metaplasia

## COMMENTARY <br> 1.4

## Jonathan MW Slack, Leonard P Griffiths, David Tosh

Metaplasia is the appearance, in adult life, of a patch of tissue that normally belongs elsewhere in the body (Slack 1985, Slack 2007). Generally, it is understood that the metaplasia originated in situ and has not migrated from elsewhere. Therefore, metastatic tumour deposits, for example, are not considered to be metaplasias, and neither are tissues misplaced during embryonic development, such as thyroid residues in the thyroglossal duct.

Metaplasias are very diverse (Willis 1962). They include ectopic bone and cartilage arising from connective tissue, squamous metaplasia of glandular epithelia, and substitution of one glandular tissue for another. The latter group is of particular interest from a biological point of view. These metaplastic transformations are normally between tissue types that originated in embryonic development as neighbours in a common cell sheet. They may remain neighbours into adult life or may become separated. For example, intestinal metaplasia of the stomach is a wellstudied type of metaplasia in which patches of small intestine-like epithelium are found in the stomach (Stemmermann and Hayashi 1968, Gutierrez-Gonzalez and Wright 2008). Intestinal metaplasia found in the urinary bladder contains cell types and markers normally found in the colon (Sung et al 2006). The bladder is not part of a common cell sheet with the intestine in the adult, but in the embryo it is, originating from the allantoic diverticulum of the hindgut. Glandular metaplasias are particularly common in the alimentary canal and in the female reproductive tract (Kurita 2011), perhaps because these are both
examples of structures in which a number of different tissue types arise from a simple epithelial tube in the embryo.

The clinical importance of metaplasias stems from the fact that they often predispose to cancer. For example, carcinomas of the bronchus usually arise within areas of squamous metaplasia (Auerbach et al 1961) and carcinomas of the stomach usually arise in regions of intestinal metaplasia (Busuttil and Boussioutas 2009).

Metaplasias arise because the combination of gene activities that defines the tissue type in embryonic development becomes altered in adult life. The genes in question encode a limited number of key transcription factors. For example, the transcription factor p63 is essential for the formation of squamous epithelia (Koster et al 2004) and is always found to be expressed in patches of squamous metaplasia. In experiments with mice, ectopic expression of the Cdx2 gene, normally necessary for intestinal development, leads to patches of intestinal tissue in the stomach (Silberg et al 2002, Mutoh et al 2002). Conversely, deletion of Cdx2 from the intestine leads to oesophagus-like or stomach-like patches in the intestine (Gao et al 2009, Stringer et al 2012). In tissues that are maintained by continuous renewal from a population of stem cells, it is the stem cells whose character becomes switched in an initiating event. Once the change has occurred, it is irreversible.

A well-studied example of metaplasia is Barrett's metaplasia, commonly known as Barrett's oesophagus (Falk 2002, Gilbert et al 2011) (Fig. 1.4.1). This is characterized by the presence of columnar

Fig. 1.4.1 Barrett's metaplasia. A, Normal endoscopic appearance showing the junction between gastric columnar and oesophageal squamous epithelium (Z-line). B-C, Endoscopies showing two cases of Barrett's oesophagus. The Z-line has moved proximally and is very irregular. There are islands of squamous tissue within the columnar region. D, Histological view, haematoxylin and eosin. E, Histological view, immunostained for CDX2 (brown). Scale bar 200 microns. Abbreviations: BM, metaplastic epithelium (Barrett's metaplasia); SSQE, stratified squamous epithelium.
epithelium in the distal oesophagus，of which some resembles intesti－ nal epithelium possessing goblet cells．Barrett＇s metaplasia is important because it is a risk factor for the development of oesophageal adeno－ carcinoma，a cancer whose incidence rose considerably in the late twen－ tieth century（Hvid－Jensen et al 2011）．In less developed countries，most oesophageal cancers are squamous cell carcinomas，arising from the normal squamous lining of the oesophagus but，in the Western world， adenocarcinomas are now more common．

At least some metaplasias are monoclonal，i．e．a particular focus consists of tissue all derived from a single cell．This is the case for intes－ tinal metaplasia of the stomach，where neighbouring metaplastic crypts arise by fission（Gutierrez－Gonzalez et al 2011）．In Barrett＇s metaplasia， patches of crypts can also be monoclonal（Nicholson 2012），although the lesion as a whole is polyclonal．A key property of metaplastic foci is that the new tissue is in a situation of competitive growth with the old tissue that surrounds it．Unless the metaplastic tissue can outgrow the surrounding tissue，then the transformation of a single stem cell would not give rise to a macroscopic lesion．However，this aspect of epithelial biology remains poorly understood．

The exact cell of origin of Barrett＇s metaplasia is still not known （Barbera and Fitzgerald 2010）．The columnar lined epithelium of Bar－ rett＇s metaplasia is in continuation with the columnar lined gastric mucosa and appears as a proximal displacement of the junction with the stratified squamous epithelium（the Z－line）．However，it is generally thought not to be a phenomenon of cell migration alone，as animal experiments indicate that it is possible to elicit patches of metaplasia separated from the gastric epithelium（Gillen et al 1988，Goldstein et al 1997）．The normal oesophagus originates from an endodermal tube lined with columnar epithelium，which becomes squamous between about 6－7 weeks of gestation．Although lined with squamous
epithelium，the tissue also contains mucous glands connected by ducts to the lumen，which are located in the submucosa but originate from the original embryonic oesophageal epithelium．Barrett＇s metaplasia probably arises by transformation of the basal cells of the squamous epithelium，or from the mucous glands，or both（Nicholson et al 2012， Leedham et al 2008）．

The predisposing cause of Barrett＇s metaplasia is gastro－oesophageal reflux，in which stomach acid，and bile from the intestine，enter the oesophagus（Souza 2010）．It is known that this environment can induce in oesophageal cells expression of some of the key genes involved in intestinal development，such as those encoding CDX factors and hepatocyte nuclear factors（Eda et al 2003，Debruyne et al 2006，Piessen et al 2007）．Obesity is a well－known risk factor for reflux，partly because of effects on intra－abdominal pressure and probably also through the effects of cytokines released from fat（Corley et al 2007）．Barrett＇s meta－ plasia may progress to dysplasia and to adenocarcinoma．Progression is associated with loss of the tumour suppressor gene CDKN2A，encod－ ing the protein p16，which is an inhibitor of cell division；and TP53， encoding the protein p53，required for death of abnormal cells （Spechler et al 2010，Chen et al 2011）．Studies of the clonal structure of Barrett＇s metaplasia have shown that is it complex，containing cell populations derived from several original progenitors，with various combinations of abnormalities arising from somatic mutation （Leedham et al 2008）．

Gastro－oesophageal reflux is normally treated with proton pump inhibitors that reduce the levels of stomach acid．This improves associ－ ated oesophagitis but does not usually result in regression of any Bar－ rett＇s metaplasia．Barrett＇s metaplasia as such is not normally treated but，if it progresses to dysplasia，it may be extirpated by a variety of endoscopic techniques（Lim and Fitzgerald 2013）．

# Electron microscopy in the twenty-first century 

## COMMENTARY <br> 1.5

Roland A Fleck

## Introduction

Biological electron microscopy (EM) is pivotal in life science research. A measure of its ubiquity is the diversity of its capacity, e.g. threedimensional structural information about proteins and viruses at $\AA$ resolution; three-dimensional reconstructions of cellular organelles and tissues (from a few tens of nanometres to hundreds of micrometres); and two-dimensional and topographic information and elemental microanalysis at subcellular resolution. The capacity of EM is now further enhanced by correlative light and electron microscopy (CLEM) workflows, where light microscopy (LM) events are co-localized with underlying ultrastructure. In its simplest form, LM generates a 'Google Earth'-like map to identify areas of interest, which are then studied at the ultrastructural level by EM, so overcoming both the physical size limitations imposed on samples by EM and the diffraction limits of resolution imposed by LM (Williams and Carter 2009). CLEM can also be combined with advanced EM sample preparation and imaging techniques to provide previously unheralded levels of cytoarchitectural insight into biological systems (McDonnald 2009, Plitzko et al 2009, Sartori et al 2007).

However, biological EM is not without its challenges. The electron beam is generated under vacuum at pressures and temperatures that are nominally incompatible with liquid water, yet water is the most abundant cellular constituent. Moreover, carbon-based life forms also have poor contrast in the electron microscope because they are composed mainly of light elements. In fact, carbon is so 'transparent' in the electron microscope that it is often employed as a film to support biological samples. To overcome these caveats, hydrated 'live' tissue is converted to a 'fixed' state; conventional protocols employ a series of steps, including chemical fixation, alcohol dehydration and resin infiltration. Heavy metal salts are added for positive staining of fixed and embedded specimens or negative staining of whole structures that have been deposited on a support film (Glauert and Lewis 1998). More recently, cryo-fixation has been adopted to allow the 'solidification of a biological specimen by cooling with the aim of minimal displacement of its components' (Steinbrecht and Zierold 1987). By using low temperature as a physical fixation strategy, the morphology and dimensions of the living material are retained and soluble cellular components are not displaced, which means that processing artefacts commonly encountered in more conventional room-temperature EM techniques are either reduced or removed. Cryo-EM often allows direct observation of specimens that have not been stained or chemically fixed.

## EM in pathology

Despite the decline in diagnostic histopathology by EM from the height of its popularity in the 1980s, EM remains an important diagnostic tool in several well-defined areas. Indeed, guidance issued by the UK's Royal College of Pathologists cites and supports the Association of Clinical Pathologists Best Practice No. 160, which states that 'Many respondents [to a review of laboratory practice in renal pathology] expressed the opinion that to carry out evaluation of renal biopsy specimens without at least having the availability of electron microscopy is negligent' (de Haro and Furness 2012). Other specialized areas include the diagnosis of primary ciliary dyskinesia; certain skin/connective tissue disorders, e.g. inherited bullous lesions and Ehlers-Danlos syndrome; and specialized areas of ophthalmic pathology (de Haro and Furness 2012). Diagnostic transmission electron microscopy (TEM) in the clinical setting has been largely stagnant and there has been little change in procedures or application for decades. In marked contrast, TEM in the research setting has experienced an explosion in capacity and capability, and there is considerable opportunity for twenty-first century EM to

Fig. 1.5.1 A Masson trichrome stain of a renal biopsy taken for diagnostic histopathology. The arrow highlights a glomerular capillary, fringed with foot processes, which would be selected for investigation at higher resolution by transmission electron microscopy (see Video 1.5.1). For diagnostic pathology, the whole glomerulus would be examined. Key: red, keratin; blue/green, collagen; light red/pink, cytoplasm. (Image courtesy of M Balys.)
translate to, and to advance, clinical research and diagnostic pathology (Fig. 1.5.1, Video 1.5.1).

## Limitations of traditional processing techniques and current protocols

Traditional EM processing strategies introduce artefacts (perturbations to structure) (Fig. 1.5.2) that affect tissue structure, e.g. by shrinkage or swelling of the tissue under examination, the shrinkage of cellular organelles, and/or the extraction or redistribution of cellular constituents such as lipids, proteins and DNA (Boyde and Maconnachie 1979). Most chemical fixatives react with proteins and cross-link peptide chains as part of their action (Glauert and Lewis 1998). These reactions can be highly deleterious to epitopes, significantly compromising immunohistochemical studies.

Cryo-fixation has two distinct advantages over chemical fixation (Nermut and Frank 1971, Nermut 1991). It is rapid (measured in milliseconds), which means that the sample is preserved, hydrated and in a 'close-to-life' state at the point of initiating fixation, and ensures simultaneous immobilization of all macromolecular components (Robards and Sleytr 1995). Many protein networks are labile and prone to disruption with even a slight osmotic or temperature change; cryo-fixation minimizes these deleterious effects. Cryo-techniques allow the study of biological samples with improved ultrastructural preservation and may facilitate the study of dynamic processes. Rapid freezing prevents artefactual aggregations of proteins because tissue fixation and processing can be performed with no or minimal use of cross-linking fixatives, which means that samples retain higher antigenicity (Kellenberger 1991, Hayat 2000, Claeys et al 2004).

This level of preservation relies on vitrification (the transformation of water from a liquid to an amorphous state without inducing the

Fig. 1.5.2 An overview of electron microscopy specimen preparation workflow. Areas to the left of the dashed line are at room temperature, indicating that samples can be handled without the requirement for specialist cryo-operating procedures. Samples to the right of the dashed line must be handled in a manner suitable for vitreous biological samples, taking specific care to pre-cool tools before approaching or manipulating samples. Arrows denote the direction of workflow and key stages required to process a sample from 'living/close to life' state to final image. Vitreous thin film (VTF) is a technique in which a liquid sample is pipetted ( $4-6 \mu \mathrm{l}$ ) on to a transmission electron microscopy (TEM) grid and blotted to create a thin, even liquid film across the surface of the grid. Ideally, the TEM grid should have a holey carbon film and, following blotting, the liquid sample will be held as a monolayer (approximately 12 nm thick) of particles supported within the holes. This film is then plunged rapidly into a liquid cryogen (ethane) to vitrify the sample, generating a vitreous ice film that is amorphous (no long-range structure) and thus a desirable support phase for cryo-electron microscopy of the encased particles (Cheng et al 2012). Other abbreviations: CEMOVIS, cryo-electron microscopy of vitreous sections; SEM, scanning electron microscopy. (Adapted from Fleck RA 2015 Low-temperature electron microscopy. In: Wolkers W, Oldenhof H (eds), Methods in Cryopreservation and Freeze-Drying Protocols. Methods in Molecular Biology. Berlin: Springer.)
nucleation of ice crystals). The nucleation of ice crystals is temperatureand pressure-dependent. Crystallization depends on the cooling rate, itself dependent on the thermal properties of water, the sample thickness, and the heat extraction flow at the surface of the specimen. Freezing is a time-dependent process. Vitrification sits at the beginning of a workflow where the sample is either subsequently processed to a stable room-temperature state for imaging or maintained in its vitreous state throughout (see Fig. 1.5.2) (Fleck 2015).

There are a variety of methods for rapid freeze fixation of tissues. However, the depth of vitrification is often limited (e.g. a few microns for samples plunged into liquid cryogen). Of the available technologies, high-pressure freezing (HPF) is by far the most effective. First introduced by Moor and Riehle in 1968, HPF exploits the physical benefit of high pressure ( 210 MPa ) to reduce the cooling rate required for the vitrification of water from several $100,000 \mathrm{~K} . \mathrm{s}^{-1}$ to a few $1,000 \mathrm{~K} . \mathrm{s}^{-1}$, making vitrification of relatively thick samples practicable (Moor and Riehle 1968, Studer et al 2008). HPF machines synchronize pressurization and cooling of the sample (to below the glass transition temperature ( Tg ) ) within 20 ms , in a highly reproducible manner (Müller and Moor 1984, Riehle 1968, Studer et al 2001), extending the depth of vitrification to as much as $200 \mu \mathrm{~m}$ (Studer et al 1995, Studer et al 2008).

Tissue samples prepared this way require further modification to make them compatible with the transmission electron microscope. They must either be converted to a room-temperature stable state (e.g. by freeze substitution into a resin), or be sectioned whilst remaining below the glass transition temperature $\left(\mathrm{T}_{\mathrm{g}}\right)$; when this is done, images close to the native structure of biological specimens can be achieved. However, despite its benefits, cryo-electron microscopy of vitreous sections (CEMOVIS) has not been routinely adopted, principally because of the technical difficulty of producing a ribbon of frozen sections and
transferring it on to an EM grid. A double micromanipulator tool that guides the ribbon using an electrically conductive fibre, and then positions and attaches the ribbon to an EM grid has recently been developed (Studer et al 2014) (Fig. 1.5.3).

## Advances in instrumentation and detector technology

EM has undergone a revolution in recent years, largely coincident with the advent of digital charge-couple device (CCD) cameras and increasing personal computer (PC) processing power. What was principally a two-dimensional technique is now one that readily embraces three dimensions by electron tomography (Gan and Jensen 2011). In this technique, a specimen is tilted through the incident beam, sequential images are acquired, and, after alignment, a weighted backprojection is used to generate a three-dimensional tomographic volume (see Video 1.5.1). These techniques have stimulated instrument changes. In conventional TEM, low accelerating voltages ( $80-120 \mathrm{keV}$ ) provide a strong beam-to-specimen interaction in order to increase contrast from electron scattering. Cryo-TEM and tomography require higher accelerating voltages ( $200-300 \mathrm{keV}$ ), which reduce the beam-tospecimen interaction; the contribution of chromatic aberration to the image is also reduced, theoretically improving resolution (Williams and Carter 2009).

Changing the emission source has been another major technical advance. A field emission gun (FEG) is becoming the preferred source of the electron beam because it provides a beam of smaller diameter, higher coherence and a current density (brightness) of up to three orders of magnitude greater than was achieved with conventional thermionic emitters (e.g. tungsten or lanthanum hexaboride

Fig. 1.5.3 Cryo-electron microscopy of vitreous sections (CEMOVIS) performed using a cryo-ultramicrotome. The cryo-chamber (Leica EM FC6, Leica Microsystems, Austria) is mounted on a conventional room-temperature ultramicrotome (Leica EM UC6, Leica Microsystems, Austria). The double manipulators (Manip, Diatome, Switzerland) are then attached to the top of the cryo-chamber, allowing precise control of both the vitreous ribbon and the transmission electron microscopy grid. The system is located within a glove box to maintain a low-humidity environment around the sample that will reduce contamination during sectioning.
( $\mathrm{LaB}_{6}$ )-tipped filaments) (Kersker 2001). The net results for both scanning electron microscopy (SEM) and TEM have been greatly improved signal-to-noise ratio and spatial resolution, coupled with a significant increase in emitter life and reliability. FEG has had a major impact on the practicality of cryo-SEM and resolution in cryo-TEM studies, although these higher accelerating voltages carry a penalty of decreased contrast.

## Overcoming the challenges of contrast in the transmission electron microscope

Zero-loss energy filtering is employed to improve image contrast in the transmission electron microscope. The filter may be positioned either in-column or post-column. Increased scattering contrast and the exclusion of the blurred background (as a consequence of the interception of inelastically scattered electrons) allow specimens to be imaged closer to focus, and increases high-resolution contrast and image resolution (Grimm et al 1997, Grimm et al 1998).

Energy filtered transmission electron microscopy (EFTEM) imaging to remove the contributions of inelastically scattered electrons is advantageous when imaging thick biological samples. Han et al (1995) demonstrated that only elastically scattered electrons contributed to the coherent image component when imaging biological specimens of more than $0.5 \mu \mathrm{~m}$ thick at 200 keV ; optimization of the zero-loss signal required operation at intermediate to high primary accelerating voltages (over 200 keV ). The gain due to EFTEM increases with specimen thickness, with a linear dependence for light-scattering elements (Grimm et al 1998). These results are important for the accurate recording of images of thick biological specimens by tomography and to demonstrate the increasing importance of high accelerating voltages in biological TEM (Grimm et al 1998).

New technologies are overcoming previous limitations of low contrast in the transmission electron microscope. Zernike phase plates (ZP), which are well accepted for imaging with the light microscope, represent a novel approach to imaging in the transmission electron microscope. Despite technical hurdles to their use, the potential reward in greater contrast has driven research into this technology (Fukuda et al 2009, Glaeser 2013). An approximate five-fold increase in contrast is possible with a $\pi / 2$ ZP that shifts the phase of only the scattered electrons (these phase-shifted electrons interfere with the unscattered electrons in the image plane), resulting in amplitude contrast rather than phase contrast. Indirect scintillator-coupled charge-coupled-device (SCCD) cameras replaced film cameras and revolutionized EM because they provided a near-instant digital readout and obviated the physical limitation of a fixed number of image plates. Direct detection devices (DDD) avoid the fundamental inefficiencies of the electron-to-light conversion process of a scintillator and achieve unmatched sensitivity
and resolution with superior detective quantum efficiency (DQE) relative to a conventional CCD camera (Milazzo et al 2010). Moreover, direct exposure to the incident electron beam significantly improves the signal-to-noise ratio in comparison to an SCCD (Milazzo et al 2010). Perhaps more importantly, DDD allow images to be recorded as movies, which means that movement caused by the electron beam can be corrected computationally (Grigorieff 2013). As an example, images of ribosomes of sufficient quality to permit alignment at an accuracy that approaches near-atomic resolution have been obtained using approximately 30,000 images (Bai et al 2013).

When combined, ZP, EFTEM and DDD offer a paradigm shift in the capability of the transmission electron microscope and are likely to drive further advances in EM-based research. Whether in isolation or combination, these techniques will translate from cutting edge to routine instrumentation, heralding generic benefits to the field. Phase contrast electron microscopy utilizing ZP has already been applied to histochemically stained strong-phase (high-contrast heavy-metalstained) biological specimens (Atsuzawa et al 2009). In sections of various thicknesses specifically stained for the Golgi apparatus, a highcontrast gain was observed even for strong-phase objects, indicating that phase contrast electron microscopy has an application for traditional strong-phase-contrasted biological specimens (Atsuzawa et al 2009), as well as for low-phase cryo-fixed biological specimens (e.g. the visualization of cyanophage Syn5 inside its host, Synechococcus, using ZP in combination with cryo-tomography (cryo-ET) to enhance image contrast over conventional cryo-ET) and will permit direct identification of subcellular components (Dai et al 2013).

## Advances in the scanning electron microscope

Cryo-FEGSEM has become well established as a research tool. The stability and emitter life of a FEG source, coupled with the stability and low keV sensitivity of a modern scanning electron microscope, is a powerful tool. Unlike TEM, in which high accelerating voltages are used to transmit the electrons through the specimen, SEM benefits from low accelerating voltages that limit beam interaction with the specimen. This is key to successful cryo-SEM but creates a challenge around generating sufficient signal for high-resolution imaging. Modern FEGSEM systems (with improved detector sensitivity and signal-to-noise ratios) are now achieving sub-nm resolution at 1 keV , making them highly capable tools for life science research, particularly when combined with high-resolution coating and fracture techniques (Fleck 2015) (see Fig. 1.5.2; Fig. 1.5.4).

Large three-dimensional volumes may be generated by the assembly of sequential two-dimensional images acquired in the scanning electron microscope. There are essentially three strategies, each with unique strengths and weaknesses: focused ion beam (FIB), serial block face SEM (SBFSEM) and array tomography (AT). FIB involves milling of material in a dual-beam scanning electron microscope using a focused beam of gallium ions to cut (mill) away layers of material. After each cut, the surface is imaged, ultimately producing a stack of twodimensional images that can be aligned to generate a three-dimensional volume. Although FIB can be combined with cryo-preparation techniques, elemental microanalysis and the range of imaging modes available within the SEM, it can be challenging (problems include achieving registry between slices, gallium contamination of the sample, and damage to structural information caused by the milling process).

SBFSEM takes a different approach from FIB and incorporates a microtome within the scanning electron microscope chamber (Denk and Horstmann 2004). The microtome cuts a thin section from the block, an image is taken, and the procedure is repeated until a threedimensional volume is generated (Video 1.5.2). SBFSEM is less prone to registration issues because the sample essentially remains locked in position below the detector. However, like FIB, this technique is destructive since, once sectioned, the sample is lost. SBFSEM uses room temperature processing techniques with high levels of en bloc heavy metal staining that are required to generate a sufficiently robust back-scattered electron signal to form an image. The processing steps, and the limitations of the back-scattered electron detector, mean that SBFSEM is currently incompatible with elemental microanalysis or cryo-techniques. However, this is a nascent technology that is advancing rapidly. Novel applications will emerge with advances in detectors, improved resins (e.g. conductive resins) and the exploitation of charge suppression approaches in the SEM (e.g. beam deceleration).

Unlike FIB and SBFSEM, AT is not destructive and material may be recovered and re-imaged. The technique allows samples to be prepared by any TEM preparation strategy. Material is sectioned at room temperature by ultramicrotomy; the sections are collected in order as a ribbon and may then be stained to enhance contrast, or are immunolabelled.

Fig. 1.5.4 Cryo-scanning electron microscopy (SEM) images. A, Fractured Plasmodium falciparum-infected erythrocytes. A cross-fractured infected erythrocyte is shown; the insert depicts a high-magnification image of the p-face of the infected erythrocyte with membrane proteins visible on the fracture plane. The scale bar represents $1 \mu \mathrm{~m}$ (main image) and 100 nm (inset). B, Cross-fractured Neisseria meningitidis showing surface membrane protein organization and polysaccharide coat. The scale bar represents 100 nm . Images were taken with a cold-field emission gun cryo-SEM (JSM$7401 F$, JEOL, Japan), equipped with a Baltec/Leica VCT100 vacuum transfer system and cryo-stage. Coating was applied after fracturing (3 nm Pt/C) using multi-angle rotational coating (BAF060, Baltec/Leica Microsystems, Austria).

Ribbons may be imaged by LM or SEM; individual sections can be identified, recovered and imaged at the higher spatial resolution of the transmission electron microscope. Successful AT requires high-precision $x-y-z$ sample stages that can perform programmed, sequential (in focus) imaging of serial sections. Arguably the most challenging aspect of the workflow is the serial sectioning of the sample; to date, this is undertaken almost exclusively by highly skilled operators. However, the ATUMtome (RMC, USA) employs a tape system to automate the serial sectioning process and has recently been commercialized (Fig. 1.5.5). New multibeam-multidetector SEMs (e.g. 61 concurrent beams) are being developed that will allow images of up to 1.2 billion pixels to be acquired in 1 s (Marx 2013) and will further speed data acquisition.

Developments in thin-film technology and microfabrication are facilitating the design of liquid cells that will permit improved imaging of samples in the liquid phase (de Jonge and Ross 2011). In combination with recent advances in ZP, EFTEM and DDD, the new generation of liquid cells offers considerable potential for the study of complex dynamic cellular processes.

Fig. 1.5.5 ATUMtome and tape. The ATUMtome is mounted on an PT-PC PowerTome (RMC, USA), showing the tape being transferred from a delivery spool (top) to receiving spool (bottom) through the boat, which maintains a water reservoir behind the edge of the diamond knife (blue) to float the sections and allow their capture by tape. Tape tension is maintained throughout by a series of tensioning springs and guides. The insert shows individual sections on tape mounted on carbon tape and silicon wafer (to help dissipate specimen charging during imaging) ready for viewing in the scanning electron microscope.

# The reaction of peripheral nerves to injury 

Rolfe Birch

Main nerve trunks contain many thousands of axons. When a trunk is stretched, but not ruptured, by dislocation of, say, the femoral or humeral heads, or by the nearby passage of a bullet, the axons within that nerve may respond in different ways. The degree of injury may vary along the length of a particular nerve or transversely across its crosssection: some axons will remain intact, some will sustain conduction block but recover rapidly, and yet others will degenerate throughout their entire extent distal to the injury because they have been ruptured. A proportion recover spontaneously whilst the remainder never recover.

Seddon (1943) introduced the terms neurapraxia for conduction block, axonotmesis for a degenerative lesion of favourable prognosis, and neurotmesis for a degenerative lesion of unfavourable prognosis. Sunderland (1951) expanded this classification to five degrees of peripheral nerve injury by subdividing neurapraxia according to the degree of connective tissue disruption, and MacKinnon and Dellon (1988) subsequently added a sixth category. However, the fundamental distinction between neurapraxia and either axonotmesis or neurotmesis remains the persistence of conduction in the distal segment of the nerve in neurapraxia, and the absence of conduction in axonotmesis or neurotmesis. In clinical practice, neurotmesis usually signifies transection of an entire nerve trunk, its constituent fascicles and their surrounding investments of perineurium and epineurium; the proximal and distal nerve stumps are frequently separated by an inter-stump gap of varying length (Fig. 1.6.1). The early disappearance of conduction indicates impending or actual critical ischaemia and is probably the most important indicator that a lesion is deepening (see below).

## Neurapraxia/conduction block

Conduction block exhibits certain characteristic features: paralysis exceeds loss of sensation; proprioceptive nerves are more deeply affected than those responsible for light touch; and sympathetic nerves to the smooth muscles of the blood vessels and sweat glands are least affected. There are distinct patterns of conduction block. Anoxia is important in all of them and there are often elements of mechanical deformation, inducing alterations of the nodal and paranodal apparatus in myelinated axons, and subsequent demyelination either of whole internodes or of paranodes.

Fig. 1.6.1 Axonotmesis (centre) and neurotmesis (bottom) at the moment of injury. Note the preservation of the Schwann cell basal lamina in axonotmesis. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Transient ischaemia Lying in one position without moving for a long time (e.g. during coma, inebriation or anaesthesia), prolonged sitting with the legs crossed or prolonged leaning on the elbows are all situations in which a limb nerve may be transiently compressed against a bone or a hard surface. The ischaemia thus induced in the compressed nerves causes an anoxic, physiological, block of both axoplasmic transport and ion channel functions along affected axons. This is seen during operation for the exposure of limb nerves with an inflated cuff in position: stimulation of a nerve evokes a brisk muscular response by transmission through the neuromuscular junction, which then diminishes before disappearing after about 30 minutes, whereas conduction within the nerve itself can be detected for about another 30 minutes. On the other hand, direct stimulation of the muscle provokes a twitch that can be elicited for about another 2 hours; loss of this direct response signals impending muscle death. The selective vulnerability of different populations of nerve fibres is demonstrated by the classical experiment of applying an inflated cuff about the arm (Lewis et al 1931). The observer experiences first a loss of superficial sensibility, then a graduated loss of muscle power. The first pain response is lost soon after superficial sensibility fails; the delayed pain response is still detectable after 40 minutes of ischaemia. Large myelinated axons are first affected; unmyelinated axons and autonomic fibres escape; and pilo- and vasomotor functions are scarcely affected. All modalities recover within a few minutes of release of the cuff; the unpleasant quality of the residual delayed pain sensation, and the burst of painful 'pins and needles' after release of the cuff, give an insight into the feelings of patients affected by dysaesthesiae.

Slowly progressing ischaemia Conduction block caused either by a haematoma or aneurysm, or by bleeding into compartments produces early and deep autonomic paralysis and loss of power that extends over hours or days, whilst deep pressure sense and some joint position sense persist. These symptoms are seen in war wounds, when nerves become compressed and strangled by scar tissue or by the cicatrix deep to split skin grafts, and may progress over a period of weeks or months. The recovery of function and relief of pain are rapid - at times, dramatic - after removal of the cause in most of these cases.

Prolonged conduction block associated with focal demyelination Severe prolonged pressure causes local demyelination and a conduction block that is not directly attributable to anoxia and that may last for weeks or months (Fig. 1.6.2). Compression-induced focal paranodal myelin deformation may be involved; experimental studies using a cuff inflated to high pressure around a limb produced slippage of paranodal myelin at nodes of Ranvier lying under the edges of the cuff, i.e. where the pressure gradient between compressed and noncompressed portions of the nerve was likely to be greatest (Ochoa et al 1972, Dyck et al 2005). Clinically, local demyelination and conduction

Fig. 1.6.2 The effect of mechanical compression: paranodal and juxtaparanodal myelin slippage under the edges of an inflated pressure cuff (after Ochoa J, Fowler TJ, Gilliatt RW 1972). (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 1.6.3 Hourglass 'constriction' of the lateral root of the median nerve: the result of traction injury. There was full spontaneous recovery. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
block will persist until the source of the external irritation, e.g. a bony projection, is removed (Birch and St Clair Strange 1990). Relief of pain and recovery follow rapidly in lesions that have persisted for many months, or even years. Mechanical deformation is the likely explanation for the conduction block seen in cases of 'hourglass' constriction of fascicles within a nerve trunk, where axons may be focally constricted within affected fascicles (Fig. 1.6.3).

Prolonged conduction block of war wounds The characteristic features of classical neurapraxia (see above), caused by the nearby passage of a missile, are likely to be provoked by a momentary displacement or stretching of the nerve trunks. However, a different pattern of conduction block has been recognized in recent conflicts, where the patient is exposed, at close range, to the shock wave of an explosion without any wound or fracture, or signs of significant injury to the soft tissues at the level of the nerve lesion. In these cases, the smallest fibres are most deeply affected and they may not recover. Pain is rare in both of these variants of conduction block (Birch et al 2012).

## Degenerative lesions

There are essentially two types of degenerative lesion, with very different potentials for recovery. In the first, which approximates to axonotmesis, the tubes of Schwann cell basal lamina that surround each axonSchwann cell unit remain intact, which means that axons may regenerate in an orderly fashion across the lesion site and into the distal stump, providing that the causative agent is removed and that the length of the distal stump (i.e. the distance from the site of injury to the end organ) is not so long that it compromises axonal regrowth. In the second, which approximates to neurotmesis, not only the Schwann cell basal lamina tubes, but also the connective tissue sheaths around the fascicle are interrupted; spontaneous axonal regeneration following this type of injury will be imperfect and disorderly, or may not occur at all.

## Deepening of a lesion in a nerve that has not been divided

Unrelieved activity of a noxious agent on an intact nerve is signified by pain and increasing neurological deficit, indicating that the lesion is deepening. Nerves within a swollen ischaemic limb or tense compartment become compressed and anoxic. Nerves displaced by an expanding haematoma become stretched and anoxic. Nerves that have become displaced into a fracture or joint are tethered and become subjected to compression, stretching and anoxia. These nerves are not severed by the initial injury; the first lesion is axonotmesis and spontaneous recovery is probable if the cause is removed. However, if this does not happen, the lesion continues to deepen into that of neurotmesis and spontaneous recovery will not occur. The speed of deepening of a lesion is related to the cause: (i) A nerve crushed by a plate or strangled by an encircling suture may recover if the cause is removed within a few minutes (Fig. 1.6.4). (ii) A nerve that has become compressed and anoxic within a swollen ischaemic limb will recover if perfusion of the tissues is restored within 3 hours; the likelihood of full spontaneous recovery diminishes with the passage of every hour after that time (Fig.

Fig. 1.6.4 The appearance of a radial nerve after extrication from beneath a compression plate 48 hours after the first operation. There was relief of pain but only incomplete recovery so that subsequent flexor to extensor transfer was necessary. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 1.6.5 Volkmann's ischaemic contracture. A, The ulnar nerve exposed during flexor muscle slide 8 weeks after supracondylar fracture. The epineurial vessels and also the ulnar recurrent collateral vessels are occluded, and the nerve is compressed by the swollen infarcted muscle. B, The appearance of the hand 14 years later. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
1.6.5). (iii) A nerve displaced into a fracture or joint will usually recover if it is extricated within a few days, but will be destroyed if a compression device has been used to stabilize the skeleton without retrieving the nerve (Fig. 1.6.6). (iv) Function may be retained for a long time in a nerve exposed to continuing traction from a malunited fracture. (v) Nerves may continue to work for months or years before failing when they are exposed to the progressing fibrosis caused by radiotherapy, by overlying split skin graft or by other examples of deep scar. (vi) Pain is the cardinal symptom of the unrelieved action of a noxious agent.

## Wallerian degeneration

Trauma that physically separates axons from their cell bodies produces Wallerian degeneration (WD). All affected axons in the extreme tip of

Fig. 1.6.6 Deepening of a lesion. A, A median nerve extricated from a supracondylar fracture in a 9-year-old girl 3 days after injury; there was complete recovery. B, A median nerve extricated from a supracondylar fracture in a 13-year-old girl 8 weeks after injury; there was no recovery. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
the proximal stump and throughout the distal stump degenerate, irrespective of their calibre or functional modality; recovery is often slow and incomplete, and there may be considerable residual loss of function. Moreover, although research has tended to address issues associated with the molecular and cellular events that occur at the lesion site and target tissues, it is important to remember that injury to a peripheral nerve that induces WD also initiates significant and often longlasting central changes in sensory ganglia and ascending and descending pathways within the spinal cord and brain; these changes also have a significant impact on the likelihood of recovery. Studies of cell bodies of human dorsal root ganglia (DRG) have revealed changes in the expression of a wide range of receptors and a remarkable alteration in the expression of genes regulating neuronal activity (Lawson 2005, Rabert et al 2004, Anand et al 2008). There is an extensive literature on WD in both central and peripheral nervous systems, and only a brief summary of the response in the peripheral nervous system is presented here (see Gordon (2015))

Neuronal cell body and proximal stump The central and the peripheral effects of WD are profound and, in neurotmesis, ultimately irreversible. Not only is the neuronal cell body separated from its continual supply of retrogradely transported neurotrophins, but also its central connections rapidly alter; many neurones thus isolated will die Amputation provides a model of the effect of permanent axonotomy on the spinal cord: there is extensive loss of neurones in the dorsal root ganglia and in the anterior horn, and a diminution of the large myelinated axons in the ventral and dorsal roots (Dyck et al 1984, Suzuki et al 1993). Neuronal death is more severe in more proximal neurotmesis, and less marked after axonotmesis than after neurotmesis. Neurotmesis in the neonate produces a more rapid and much greater incidence of sensory and motor neurone death than in the adult. Surviving neurones rapidly upregulate a series of genes involved in repair and neuroprotection mechanisms following injury (repair-associated genes, RAGs), which direct many of the changes seen during WD and subsequent recovery (e.g. Calenda et al 2012). (For a review of the molecules
involved in retrograde signalling to initiate expression of RAGs, particularly the family of glycoprotein 130 (gp130) cytokines, see Zigmond (2011).) Changes in the expression of ion channels and receptors in the neuronal cell bodies in human DRGs can be detected within a few minutes of an injury to the nerve (Lawson 2005).

Tip of proximal stump Within a few hours of injury, the cut ends of a transected axon seal off, forming end bulbs. The end bulb that forms at the proximal tip of axons in the proximal stump is transformed into a growth cone from which multiple needle-like filopodia and broader sheet-like lamellipodia grow out. The filopodia are rich in actin, and may extend or retract within a matter of minutes. Each axon forms new branches or sprouts: collateral sprouts arise from nodes of Ranvier at levels where the axons are still intact; terminal sprouts arise from the tips of the surviving axons. The axon sprouts and fine cytoplasmic processes derived from their associated Schwann cells form clusters, regenerating units, surrounded by Schwann cell basal laminae. Sprouts within one regenerating unit represent the regenerative effort of one neurone and its axon. Within a few days of injury, the calibre of axons in the proximal stumps is reduced and nerve conduction velocity in the proximal segment falls.

Distal stump During the first 2 or 3 weeks after injury, the constitutive tissue response within a denervated distal stump involves numerous events: some sequential, others consecutive. These include the production of debris, as axons and their myelin sheaths are degraded; an increase in local blood flow; activation of resident macrophages, and recruitment and influx of exogenous macrophages; and proliferation of fibroblasts and Schwann cells. The gliotic response produces a population of dedifferentiated daughter Schwann cells that remain within the basal lamina tubes secreted by their parent cells, forming what are now called Schwann tubes but which were previously known as bands of Büngner. They behave acutely as the 'presumed targets' of the regrowing axons until the actual targets (muscle or sensory end organ) have been reinnervated: they secrete proteins that collectively facilitate axonal regrowth, whether by providing trophic support or by establishing a supportive growth matrix (for further reading on these interactions, see Hall (2005), Webber et al (2011), Arthur-Farraj et al (2012), Gordon (2015)). There is a growing consensus that Schwann cells express distinct motor and sensory phenotypes, and that this fundamental difference affects the ability of Schwann cell tubes to selectively support regenerating neurones. For example, expression of osteopontin and clusterin is upregulated in Schwann cells in transected peripheral nerves: the two secreted factors appear to facilitate regeneration of motor or sensory neurones, respectively (Wright et al 2014).

While the microenvironment of an acutely denervated distal stump facilitates axonal regrowth because it provides a vascularized segment of longitudinally orientated, laminin-rich basal lamina tubes filled with axon-responsive Schwann cells, a chronically denervated distal stump is associated with poor axonal regeneration and poor functional recovery (Sulaiman and Gordon 2009). Biopsies taken during late repairs, especially when the injury has been complicated by arterial injury or by sepsis, often show remarkably few Schwann cells lying within a densely collagenous matrix. Myelin fragments are detectable in such cases many months after the injury. The residual Schwann cells become progressively less receptive to ingrowing regenerating axons with time; experimental studies have shown that they downregulate expression of axon-responsive receptors that are normally important in Schwann cell-axon signalling (Li et al 1997, Li et al 1998). These findings underscore the clinical observation that there is a relatively narrow window of opportunity when surgical intervention is most likely to produce positive results (Lundborg 2000).

## The special case of preganglionic injury

The preganglionic lesion is all too common in severe traction injuries to the brachial and lumbosacral plexuses. The roots of the spinal nerves are torn from the spinal cord, which means that the somatic afferent pathway is interrupted between the dorsal root ganglion and the spinal cord (see Fig. 1.6.6). The neuronal cell bodies and their axons, investing Schwann cells and associated basal laminae remain intact, healthy and conducting for a long time after the injury. The surviving axons include all those with cell bodies in the dorsal root ganglion, including many 'recurrent' fibres in the ventral root that derived from cells in the dorsal root ganglion (Figs 1.6.7-1.6.9). Somatic efferent fibres, being separated from their cell bodies, degenerate; postganglionic autonomic efferent axons also degenerate, as a result of damage to their grey rami communicantes. Carlstedt (2007) reckons that about one-half of all motor neurones in the affected spinal cord segment have disappeared by 2 weeks after avulsion of the ventral root and he urges 'a swift

Fig. 1.6.7 Intact (afferent) myelinated and unmyelinated fibres in a suprascapular nerve, 6 weeks after an avulsion lesion of the brachial plexus; efferent fibres have degenerated. Magnification $\times 6600$. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. SpringerVerlag, London.)

Fig. 1.6.8 Wallerian degeneration in the ventral root of the eighth cervical nerve, 6 weeks after avulsion from the spinal cord. A degenerate efferent myelinated fibre (right) compared with a healthy myelinated afferent fibre (left). Magnification $\times 11115$. intervention to re-establish contact between the injured nerve cells and the periphery with its supply of neurotrophic substances to counteract nerve cell loss'. After avulsion injury, human dorsal root ganglion neurones show dramatic changes in the expression of genes involved in neurotransmission, trophism, cytokine function, signal transduction, myelination, transcription regulation and apoptosis (Rabert et al 2004).

## Regeneration and recovery of function

'But the journey of the axon tip to an end organ is only the most dramatic of the phases in the process of regeneration, and its arrival is alone no guarantee of the return of useful function.'

Young (1942)
The cellular microenvironment of a normal peripheral nerve does not ordinarily support axonal regrowth; indeed, there appear to be 'molecular brakes' that prevent axonal sprouting. Somewhat counterintuitively, it appears that their expression may be upregulated after injury. WD transforms the environment throughout the distal stump of a transected nerve to one that facilitates axonal regrowth, albeit for a relatively short period (Christie and Zochodne 2013). Manipulating the many cellular and molecular responses that occur during the injury response in the peripheral nervous system remains an as yet unachieved goal of reconstructive surgery.

Fig. 1.6.9 Afferent and efferent fibres in a ventral root. Healthy myelinated and unmyelinated fibres in the ventral root of the eighth cervical nerve avulsed from the spinal cord 6 weeks previously. The myelinated efferent fibres have undergone Wallerian degeneration and there is a notable increase in the amount of endoneurial collagen. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

## Regeneration of end organs

Reinnervation of muscle spindles and Golgi tendon receptors is generally good after crush lesions (axonotmesis). Regeneration after repair of a divided nerve is much less orderly. A muscle spindle may become reinnervated by afferents normally destined for the Golgi tendon organ; many tendon organs remain denervated and the regenerated endings are frequently abnormal in appearance. The reorganization of motor units after repair causes significant alterations in the mechanical input to an individual tendon organ.

Muscles usually exhibit weakness, impaired coordination and reduced stamina after nerve repair. There may be selective failure of regeneration of the largest-diameter fibres and of coactivation of the $\alpha$ and $\gamma$ efferents. The normal movement of joints is brought about by smoothly coordinated and controlled activity in muscles that is precisely and delicately regulated by inhibition and facilitation of the motor neurones. The conversion of an antagonist to an agonist is the basis of musculotendinous transfer; it is common to see patients actively extending the knee or the ankle and toes as soon as the postoperative splint is removed after hamstring to quadriceps transfer or anterior transfer of tibialis posterior. Reinnervated muscles usually fail to convert after muscle transfer, irrespective of their power. Perhaps the defective reinnervation of the deep afferent pathways from the muscle spindles and the tendon receptors blinds muscles, which are, after all, sensory as well as effector organs.

Cutaneous sensory receptors similarly undergo a slow degenerative change after denervation and after 3 years they may disappear. Reinnervation tends to reverse these changes, although the longer the period of denervation, the less complete will be the regeneration. It is usual to find numerous myelinated axons in the tissues bridging nerve stumps in the human, even in failed sutures or in grafts coming to revision (Fig. 1.6.10) (Terenghi et al 1998); these findings encapsulate the difference between regeneration and recovery of function.

## Plasticity in the central nervous system

Nerve transfer involves connecting the proximal stump of a healthy nerve to the distal stump of one that has been injured in such a way that direct repair is not possible.

There is considerable adaptation of the central receptor and effector mechanisms after nerve transfer (Fig. 1.6.11). Independent flexion of the elbow without associated activity in the flexor muscles of the forearm is usual by 24 months after transfer from the ulnar nerve to the nerve to biceps brachii. Reinnervation of the muscle spindles and corresponding reorganization and remapping of the somatosensory cortex have been confirmed after transfer of intercostal nerves to the musculocutaneous nerve in adult patients with severe lesions of the brachial plexus (Malessy et al 2003, Sai et al 1996). These central phenomena may explain the remarkably good recovery of sensation within the hand

Fig. 1.6.10 Useless regeneration in a median nerve sutured 3 years previously. Proximal to the suture line, the endoneurium contains thinly remyelinated axons, some in regenerating clusters, and extensive collagenization; there was no recovery of function. Magnification $\times 4300$. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 1.6.11 A 13-year-old boy with a right-sided lesion: avulsion of C5, 6 and 7. Repair was undertaken at 2 months as follows: accessory to suprascapular transfer; one bundle of the ulnar nerve to the nerve to biceps and the nerve to the medial head of triceps; medial cutaneous nerve of the forearm to the lateral root of the median nerve. Results at 18 months show a full range of lateral rotation; abduction to $60^{\circ}$; power of elbow flexion, Medical Research Council (MRC) grade 4; power of elbow extension, MRC grade $3+$. There is a full range of active flexion and extension without obvious co-contraction. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
after repair of severe birth lesions of the brachial plexus. Indeed, the sensory recovery is far better than that of skeletal muscle and sympathetic function. Thus, there is accurate localization to the dermatomes of avulsed spinal nerves that had been reinnervated by intercostal nerves transferred from remote spinal segments (Anand and Birch 2002).

## Case report

Operation in a 6-month-old boy confirmed rupture of C 5 with avulsion of C6, 7, 8 and T1. The lesion was repaired by transfers of the accessory nerve to the suprascapular nerve, of C5 to C8 and T1, and of intercostal nerves T3, 4 and 5 to the lateral cord of the brachial plexus. At the age of 5 years, he was able to localize cotton wool and pinprick sensation accurately in both hands and was able to feel a pin in the affected side. Monofilament, vibration thresholds and joint position sense were identical in both hands. The thresholds for warming were $3.1^{\circ} \mathrm{C}(\mathrm{C} 5), 0.8^{\circ} \mathrm{C}$ (C6), $4.1^{\circ} \mathrm{C}(\mathrm{C} 7), 3.6^{\circ} \mathrm{C}(\mathrm{C} 8)$ and $3.3^{\circ} \mathrm{C}(\mathrm{T} 1)$ on the affected side. The thresholds for cooling were $2{ }^{\circ} \mathrm{C}(\mathrm{C} 5), 3.9^{\circ} \mathrm{C}(\mathrm{C} 6), 3.8^{\circ} \mathrm{C}(\mathrm{C} 7), 2.3^{\circ} \mathrm{C}$ (C8) and normal in T1. In the unaffected hand, the thresholds were less than $3.4^{\circ} \mathrm{C}$ for warm sensation and less than $2.2^{\circ} \mathrm{C}$ for cool sensation. Sweating was $70 \%$ of that of the intact palm. It seems likely that afferent impulses from the thumb, index and, probably, the middle fingers entered the spinal cord through the three intercostal nerves,

Fig. 1.6.12 The method of repair and the likely pathways for afferent function. Abbreviations: CS, cool sensation; CW, cotton wool; JPS, joint position sense; PP, pinprick; Vib, vibration threshold; WS, warm sensation. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 1.6.13 Birth lesions of the brachial plexus. This boy had a group 4 lesion with rupture of C 5 and avulsion of $\mathrm{C} 6,7,8$ and T 1 at birth. At 10 weeks of age, C5 was grafted to the upper trunk and to the ventral root of C8 and T1; accessory nerve was transferred to the ventral root of C7; the sensory divisions of intercostal nerves T3 and T4 were transferred to the lateral root of the median nerve. He regained a useful grasp between thumb and index finger, and is an extremely well-adjusted sportsman and musician. The photograph was taken at 10 years of age. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)
whilst afferent impulses from the little and, probably, the ring fingers entered the spinal cord through the fifth cervical nerve as shown in Figure 1.6.12. Similar findings have been observed in four other cases after transfer of intercostal nerves to the lateral cord (Fig. 1.6.13). The situation in the adult is very different. After transfer of the intercostal nerves to the lateral or medial cords, it is usual to find that stimulation of the reinnervated skin is referred to the chest wall and only rarely to the skin of the hand (Htut et al 2006). Concepts of the mechanisms underlying cortical plasticity following nerve injury and the importance of maintaining an active sensory map of the affected part in the somatosensory cortex during the deafferentation period are considered further by Lundborg (2003), Rosén and Lundborg (2007), Björkman et al (2009), Rosén et al (2011) and Knox et al (2015).

## Laboratory and clinical studies

There are major differences between a laboratory investigation, in which a controlled, precise and limited lesion is inflicted on a peripheral nerve in an anaesthetized experimental animal, and the situation faced by the clinician presented with a patient with a massive wound involving soft tissues (including blood vessels and muscles) and skeletal
elements, and sometimes with other injuries that threaten life and limb. That said, the fundamental cellular processes that underlie subsequent regeneration are similar in the laboratory, in the injuries of civilian practice and in the wounds of war, although in clinical practice they are modified by the violence of the injury, by the effects of injury on associated tissues and, in particular, by ischaemia and by delay before repair. Some general conclusions may be drawn from extensive clinical and laboratory studies.

The concept of retrograde degeneration of the axon extending to the first internode applies only to the most benign lesion: that of experimentally crushing the nerve between the tips of a jeweller's forceps. The extent of longitudinal damage to a nerve is greater in a rupture caused by traction than it is in 'tidy' transections caused by knife or glass; this effect worsens with increasing delay before repair, is worse still when healing has been complicated by sepsis, and worst of all in neglected ischaemia.

Failure to repair main vessels and to ensure perfusion of tissues is profoundly deleterious to regeneration and rules out worthwhile recovery of function.

As time goes by, the cellular response in both stumps changes from one that facilitates regeneration to one that is less favourable. Dense collagenization, a profusion of fibroblasts and a loss of Schwann cells are characteristics of the chronically denervated distal stump and are typical of late cases.

The normal architecture of a nerve is most closely restored to normal in a well-executed, tension-free primary suture.

Regeneration through a graft falls away along its length and not solely at the suture lines.

Delay before repair leads to increasing fibrosis and to shrinking of the distal segment so that it becomes impossible to ensure an accurate topographical match.

Destruction of the target tissues, of muscle and skin, limits function even when there is strong regeneration.

Chronological age plays an important role: for example, signalling mechanisms involved in the reinnervation of skeletal muscle may become impaired with age (Kawabuchi et al 2011).

## Preimplantation development

Understanding the spatial and temporal developmental processes that take place within an embryo as it develops from a single cell into a recognizable human is the challenge of embryology. The control of these processes resides within the genome; fundamental questions remain concerning the genes and interactions involved in development.

## STAGING OF EMBRYOS

For the purposes of embryological study, prenatal life is divided into an embryonic period and a fetal period. The embryonic period covers the first 8 weeks of development (weeks following ovulation and fertilization resulting in pregnancy). The ages of early human embryos have previously been estimated by comparing their development with that of monkey embryos of known postovulatory ages. Because embryos develop at different rates and attain different final weights and sizes, a classification of human embryos into 23 stages occurring during the first 8 weeks after ovulation was developed most successfully by Streeter (1942), and the task was continued by O'Rahilly and Müller (1987). An embryo was initially staged by comparing its development with that of other embryos. On the basis of correlating particular maternal menstrual histories and the known developmental ages of monkey embryos, growth tables were constructed so that the size of an embryo (specifically, the greatest length) could be used to predict its presumed age in postovulatory days (synonymous to postfertilizational days). O'Rahilly and Müller $(2000,2010)$ emphasize that the stages are based on external and internal morphological criteria and are not founded on length or age. Ultrasonic examination of embryos in vivo has necessitated the revision of some of the ages related to stages, and embryos of stages $6-16$ are now thought to be up to 3 to 5 days older than the previously used embryological estimates (O'Rahilly and Müller 1999, 2010). Within this staging system, embryonic life commences with fertilization at stage 1 ; stage 2 encompasses embryos from two cells, through compaction and early segregation, to the appearance of the blastocele. The developmental processes occurring during the first 10 stages of embryonic life are shown in Figure 8.1.

Much of our knowledge of the early developmental processes is derived from experimental studies on amniote embryos, particularly the chick, mouse and rat. Figure 8.2 shows the comparative timescales of development of these species and human development up to stage 12. The size and age, in postovulatory days, of human development from stage 10 to stage 23 is given in Figure 8.3.

Information on developmental age after stage 23 (8 weeks post ovulation) is shown in Figure 14.3, where the developmental staging used throughout this text is juxtaposed with the obstetric estimation of gestation that is used clinically. A critique of staging terminology and the hazards of the concurrent use of gestational age and embryonic age is given in Chapter 14; sizes and ages of fetuses towards the end of gestation are illustrated in Fig. 14.9.

## FERTILIZATION

The central feature of reproduction is the fusion of the two gamete pronuclei at fertilization. In humans, the male gametes are spermatozoa, which are produced from puberty onwards. Female gametes are released as secondary oocytes in the second meiotic metaphase, usually singly, in a cyclical fashion. The signal for the completion of the second meiotic division is fertilization, which stimulates the cell division cycle to resume, completing meiosis and extruding the second polar body (the second set of redundant meiotic chromosomes).

Fertilization normally occurs in the ampullary region of the uterine tube, probably within 24 hours of ovulation. Very few spermatozoa reach the ampulla to achieve fertilization. They must undergo capacitation, a process that is still incompletely understood, and which may
involve modifications of membrane sterols or surface proteins. They traverse the cumulus oophorus and corona radiata, then bind to specific glycoprotein receptors on the zona pellucida, ZP3 and ZP2. Interaction of ZP3 with the sperm head induces the acrosome reaction, in which fusion of membranes on the sperm head releases enzymes, such as acrosin, which help to digest the zona around the sperm head, allowing the sperm to reach the perivitelline space. In the perivitelline space, the spermatozoon fuses with the oocyte microvilli, possibly via two disintegrin peptides in the sperm head and integrin in the oolemma (Figs 8.4, 8.5A).

Fusion of the sperm with the oolemma causes a weak membrane depolarization and leads to a calcium wave, which is triggered by the sperm at the site of fusion and crosses the egg within 5-20 seconds. The calcium wave amplifies the local signal at the site of sperm-oocyte interaction and distributes it throughout the oocyte cytoplasm. The increase in calcium concentration is the signal that causes the oocyte to resume cell division, initiating the completion of meiosis II and setting off the developmental programme that leads to embryogenesis. The pulses of intracellular calcium that occur every few minutes for the first few hours of development also trigger the fusion of cortical granules with the oolemma. The cortical secretory granules release an enzyme that hydrolyses the ZP3 receptor on the zona pellucida and so prevents other sperm from binding and undergoing the acrosome reaction, thus establishing the block to polyspermy. The same cortical granule secretion may also modify the vitelline layer and oolemma, making them less susceptible to sperm-oocyte fusion and providing a further level of polyspermy block.

The sperm head undergoes its protamine $\rightarrow$ histone transition as the second polar body is extruded. The two pronuclei grow, move together and condense in preparation for syngamy and cleavage after approximately 24 hours (Fig. 8.5B). Nucleolar ribosomal ribonucleic acid (rRNA), and perhaps some messenger RNA (mRNA), are synthesized in pronuclei. A succeeding series of cleavage divisions produces eight even-sized blastomeres at approximately 55 hours, when embryonic mRNA is transcribed.

Several examples of cells that contain male and female pronuclei, termed ootids, have been described. Pronuclear fusion as such does not occur; the two pronuclear envelopes disappear and the two chromosome groups move together to assume positions on the first cleavage spindle. No true zygote containing a membrane-bound nucleus is formed.

The presence of the pronuclei from both parental origins is crucial for spatial organization and the controlled growth of cells, tissues and organs. In the mouse, embryos in which the paternal pronucleus has been removed and replaced with a second maternal pronucleus develop to a relatively advanced state ( 25 somites), but with limited development of the trophoblast and extraembryonic tissues. In contrast, embryos in which the maternal pronucleus has been replaced by a second paternal pronucleus develop very poorly, forming embryos of only six to eight somites, but with extensive trophoblast. Thus it seems that the maternal genome is relatively more important for the development of the embryo, whereas the paternal genome is essential for the development of the extraembryonic tissues that would lead to placental formation.

This functional inequivalence of homologous parental chromosomes is called parental imprinting. The process causes the expression of particular genes to be dependent on their parental origin; some genes are expressed only from the maternally inherited chromosome and others from the paternally inherited chromosome. The genes involved are called imprinted genes. The requirement for both parental genomes is limited to a subset of the chromosomes. Uniparental disomy can arise through meiotic and mitotic non-disjunction events, and results in individuals who are completely disomic or who exhibit mosaicism of disomic and non-disomic cells. If imprinted genes reside on the affected chromosomes, then the uniparental disomic cells will either express a

Fig. 8.1 Developmental processes occurring during the first 10 stages of development. In the early stages, a series of binary choices determine the cell lineages. Generally, the earliest stages are concerned with formation of the extraembryonic tissues, whereas the later stages are concerned with the formation of embryonic tissues.
double dose of the gene or have both copies repressed. For example, the gene encoding the embryonal mitogen insulin-like growth factor II is expressed from the paternally inherited chromosome, and repressed when maternally inherited.

## In vitro fertilization

In vitro fertilization (IVF) of human gametes is a successful way of overcoming most forms of infertility (Video 8.1). Controlled stimulation of the ovaries (e.g. pituitary downregulation using gonadotrophinreleasing hormone superactive analogues, followed by stimulation with purified follicle stimulating hormone or urinary menopausal gonadotrophins) enables many preovulatory oocytes (often 10 or more) to be recruited and matured, and then aspirated transvaginally using ultrasound guidance, 34-38 hours after injection of human chorionic gonadotrophin (which is given to mimic the luteinizing hormone surge). These oocytes are then incubated overnight with motile spermatozoa in a specially formulated culture medium, in an attempt to achieve successful in vitro fertilization. In cases of severe male-factor infertility, in which there are insufficient normal spermatozoa to achieve in vitro fertilization, individual spermatozoa can be directly injected into the oocyte in a process known as intracytoplasmic sperm injection (ICSI), which is as successful as routine IVF. In cases in which there are no spermatozoa in the ejaculate, suitable material can sometimes be directly aspirated from the epididymis or surgically retrieved from the testes, and the extracted sperm are then used for intracytoplasmic injection of sperm.

It is also now possible, in some cases, to test embryos for the presence of a particular genetic or chromosomal abnormality by preimplan-
tation genetic diagnosis (PGD). A sample (biopsy) is removed from either the oocyte (polar bodies), the embryo itself (a blastomere) or the blastocyst (small piece of trophectoderm), and subjected to specific genetic testing. Oocytes and embryos can also be biopsied and screened for aneuploidy (errors in chromosome copy numbers) in preimplantation genetic screening (PGS). Unaffected embryos can then be identified for transfer to the patient. Embryos that are surplus to immediate therapeutic requirements can also be cryopreserved in liquid nitrogen for later use. Propanediol or dimethylsulphoxide are commonly used as cryoprotectants for early embryos, and, like glycerol, may be used for blastocysts. Conception rates per cycle using ovarian stimulation, IVF and successive transfers of fresh and cryopreserved embryos exceed those obtained during non-assisted, or natural, conception.

## PREIMPLANTATION DEVELOPMENT

## Cleavage

The first divisions of the zygote are termed cleavages. They distribute the cytoplasm approximately equally among daughter blastomeres, so, although the cell number of the preimplantation embryo increases, its total mass actually decreases slightly (Fig. 8.6). Cell division can be asynchronous and daughter cells may retain a cytoplasmic link through much of the immediately subsequent cell cycle via a midbody, as a result of the delayed completion of cytokinesis. No centrioles are present until 16-32 cells are seen, but amorphous pericentriolar material is present and serves to organize the mitotic spindles, which are characteristically more barrel- than spindle-shaped at this time.

Fig. 8.2 Within developmental biology, evidence concerning the nature of developmental processes has come mainly from studies in vertebrate embryos, most commonly amniote embryos of the chick, mouse and rat. This chart illustrates the comparative timescale of development in these animals and in humans.

Fig. 8.3 Human developmental stages 10-23. The greatest embryonic length in mm (ordinate) is plotted against age in postfertilizational weeks (abscissa), with the stages superimposed according to current information. (Data provided by courtesy of Professor R O'Rahilly. See also O'Rahilly and Müller (2010).)

All cleavage divisions after fertilization are dependent on continuing protein synthesis. In contrast, passage through the earliest cycles, up to eight cells, is independent of mRNA synthesis. Thereafter, experimental inhibition of transcription blocks further division and development, indicating that activation of the embryonic genome is required. There is also direct evidence for the synthesis of embryonically encoded proteins at this time. As the genes of the embryo first become both active and essential, the previously functional maternally derived mRNA is destroyed. However, protein made on these maternal templates does persist at least during blastocyst growth. Spontaneous developmental arrest of embryos cultured in vitro seems to occur during the cell cycle of gene activation, but it is not caused by total failure of that activation process. Early cleavage, up to the formation of eight cells, requires pyruvate or lactate as metabolic substrates, but thereafter more glucose is metabolized and may be required.

The earliest time at which different types of cells can be identified within the cleaving embryo is when $8-16$ cells are present. Up to the formation of eight cells, cells are essentially spherical, touch each other loosely, and have no specialized intercellular junctions or significant extracellular matrix; the cytoplasm in each cell is organized in a radially symmetric manner around a centrally located nucleus. Once eight cells have formed, a process of compaction occurs. Cells flatten on each other to maximize intercellular contact, initiate the formation of gap and focal tight junctions, and radically reorganize their cytoplasmic conformation from a radially symmetric to a highly asymmetric phenotype. This latter process includes the migration of nuclei towards the centre of the embryo, the redistribution of surface microvilli and an underlying mesh of microfilaments and microtubules to the exposed surface, and the localization of endosomes beneath the apical cytoskeletal mesh. As a result of the process of compaction, the embryo forms a primitive protoepithelial cyst, which consists of eight polarized cells, in which the apices face outwards and basolateral surfaces face internally. The focal tight junctions, which align to become increasingly linear, are localized to the boundary between the apical and basolateral surfaces.

Fig. 8.4 The fertilization pathway: a succession of steps. After a sperm binds to the zona pellucida, the acrosome reaction takes place (see detail at top). The outer acrosomal membrane (blue), an enzyme-rich organelle in the anterior of the sperm head, fuses at many points with the plasma membrane surrounding the sperm head. Then those fused membranes form vesicles, which are eventually sloughed off from the head, exposing the acrosomal enzymes (red). The enzymes digest a path through the zona pellucida, enabling the sperm to advance. Eventually, the sperm meets and fuses with the secondary oocyte plasma membrane and this triggers cortical and zona reactions. First, enzyme-rich cortical granules in the oocyte cytoplasm release their contents (yellow) into the zona pellucida, starting at the point of fusion and progressing right and left. Next, in the zona reaction, the enzymes modify the zona pellucida, transforming it into an impenetrable barrier to sperm as a guard against polyspermy (multiple fertilization).

Fig. 8.5 A, An unfertilized human secondary oocyte surrounded by the zona pellucida; the first polar body can be seen. Spermatozoa are visible outside the zona pellucida. B, A fertilized human ootid before fusion of the pronuclei. Two polar bodies can be seen beneath the zona pellucida.

Gap junctions form between apposed basolateral surfaces and become functional.

The process of compaction involves the cell surface and the calcium dependent cell-cell adhesion glycoprotein, E-cadherin (also called L-CAM or uvomorulin). Neutralization of its function disturbs all three
elements of compaction. The entire process can function in the absence of both mRNA and protein synthesis. Post-translational controls are sufficient and seem to involve regulation through protein phosphorylation. Significantly, although E-cadherin is not synthesized and present on the surface of cleaving blastomeres, it first becomes phosphorylated when eight cells are visible, at the initiation of compaction.

The process of compaction is important for the generation of cell diversity in the early embryo. As each polarized cell divides, it retains significant elements of its polar organization, so that its daughter cells inherit cytocortical domains, the nature of which reflects their origin and organization in the original parent cell in the eight-celled embryo. Thus, if the axis of division is aligned approximately at right angles to the axis of cell polarity, the more superficially placed daughter cell inherits all the apical cytocortex and some of the basolateral cytocortex and is polar, whereas the more centrally placed cell inherits only basolateral cytocortex and is apolar. In contrast, if the axis of division is aligned approximately along the axis of the cell polarity, two polar daughter cells are formed. In this way, two-cell populations are formed in the 16 -cell embryo that differ in phenotype (polar, apolar) and position (superficial, deep). The number of cells in each population in any one embryo will be determined by the ratio of divisions along, and at right angles to, the axis of eight-cell polarity. The theoretical and observed limits of the polar to apolar ratio are $16: 0$ and $8: 8$. The outer polar cells contribute largely to the trophectoderm, whereas the inner

Fig. 8.6 Successive stages of cleavage of a human ootid. A, The two-cell stage. B, The three-cell stage. C, The five-cell stage. D, The eight-cell stage.
apolar cells contribute almost exclusively to the inner cell mass in most embryos.

In cleavage, the generation of cell diversity, to either trophectoderm or inner cell mass, occurs in the 16 -cell morula and precedes the formation of the blastocyst. During the 16 -cell cycle, the outer polar cells continue to differentiate an epithelial phenotype, and display further aspects of polarity and intercellular adhesion typical of epithelial cells, while the inner apolar cells remain symmetrically organized. During the next cell division (16-32 cells), a proportion of polar cells again divide differentiatively, as in the previous cycle, each yielding one polar and one apolar progeny, which enter the trophectoderm and inner cell mass lineages, respectively. Although differentiative division at this time is less common than at the 8 - to 16 -cell transition, it has the important function of regulating an appropriate number of cells in the two tissues of the blastocyst. Thus, if differentiative divisions were relatively infrequent at the 8 - to 16 -cell transition, they will be more frequent at the 16- to 32-cell transition, and vice versa.

After division to 32 cells, the outer polar cells complete their differentiation into a functional epithelium, display structurally complete zonular tight junctions and begin to form desmosomes. The nascent trophectoderm engages in vectorial fluid transport in an apical to basal direction to generate a cavity that expands in size during the 32- to 64-cell cycles and converts the ball of cells, the morula, to a sphere, the blastocyst (Fig. 8.7). Once the blastocyst forms, the diversification of the trophectoderm and inner cell mass lineages is complete, and trophectoderm differentiative divisions no longer occur. In the late blastocyst, the trophectoderm is referred to as the trophoblast, which can be divided into polar trophoblast, lying in direct contact with the inner cell mass, and mural trophoblast, surrounding the blastocyst cavity (Fig. 8.8).

## Blastocyst

The blastocyst 'hatches' from its zona pellucida at $6-7$ days, possibly assisted by an enzyme similar to trypsin (see Figs 8.7C, 8.8). Trophoblast oozes out of a small slit; many embryos form a figure-of-eight shape bisected by the zona pellucida, especially if it has been hardened during oocyte maturation and cleavage. Such half-hatching could result in the formation of identical twins. Hatched blastocysts expand and differentiation of the inner cell mass proceeds (see Fig. 8.8).

The outer cells of the blastocyst - the trophoblast or trophectoderm - are flattened polyhedral cells, which possess ultrastructural features typical of a transporting epithelium. The trophoblast covering the inner cell mass is the polar trophoblast and that surrounding the blastocyst cavity is the mural trophoblast. The free, unattached blastocyst is assigned to stage 3 of development at approximately 4 days post ovulation, whereas implantation (before villus development) occurs within a period of 7-12 days post ovulation and over the next two stages of

Fig. 8.7 Human embryos. Formation of a morula and blastocyst within the zona pellucida and blastocyst hatching from the zona pellucida. $\mathbf{A}, \mathrm{A}$ ball of cells, the morula, with the cells undergoing compaction. B, The blastocyst cavity is developing and the inner cell mass can be seen on one side of the cavity. C, The blastocyst is beginning to hatch from the zona pellucida.

Fig. 8.8 A human blastocyst nearly completely hatched from the zona
pellucida. The blastocyst can now expand to its full size.
development. Even at this early stage, cells of the inner cell mass are already arranged into an upper layer (i.e. closest to the polar trophoblast), the epiblast, which will give rise to the embryonic cells, and a lower layer, the hypoblast, which has an extraembryonic fate. Thus, the dorsoventral axis of the developing embryo and a bilaminar arrangement of the inner cell mass are both established at or before implantation. (The earliest primordial germ cells may also be defined at this stage.)

## Attachment to the uterine wall

On the sixth postovulatory day, the blastocyst adheres to the uterine mucosa and the events leading to the specialized, intimate contact of trophoblast and endometrium begin. Implantation, which is the term used for this complicated process, includes the following stages: dissolution of the zona pellucida; orientation and adhesion of the blastocyst on to the endometrium; trophoblastic penetration into the endometrium; migration of the blastocyst into the endometrium; and spread and proliferation of the trophoblast, which envelops and specifically disrupts
and invades the maternal tissues (Ch. 9). The interactions between the hatched blastocyst and the maternal endometrium are not well understood. Developmentally competent embryos appear to enhance the uterine environment and promote their own implantation (Brosens et al 2014, Macklon and Brosens 2014).

The site of implantation is normally in the endometrium of the posterior wall of the uterus, nearer to the fundus than to the cervix; it may be in the median plane or to one or other side, but may occur elsewhere in the uterus, or in an extrauterine or ectopic site.

## Ectopic implantation

The conceptus may be arrested at any point during its migration through the uterine tube and implant in its wall. Previous pelvic inflammation damages the tubal epithelium and may predispose to such delay in tubal transport. The presence of an intrauterine contraceptive device or the use of progesterone-based oral contraceptives may also predispose to ectopic pregnancy, probably because of alteration in the normal tubal transport mechanisms.

Nidation of the embryo as an ectopic pregnancy most frequently occurs in the wider ampullary portion of the uterine tube, but may also occur in the narrow intramural part or even in the ovary itself. Most ectopic pregnancies are anembryonic, although the continuing growth of the trophoblast will produce a positive pregnancy test, and may cause rupture of the uterine tube and significant intraperitoneal haemorrhage. Ectopic pregnancies with a live embryo are the most dangerous because they grow rapidly and may be detected only when they have eroded the uterine tube wall and surrounding blood vessels, as early as 8 weeks of pregnancy. Similarly, cornual ectopics (in the intramural part of the tube) may present with catastrophic haemorrhage because there is a substantial blood supply in the surrounding muscularis.

Ovarian or abdominal pregnancies are exceptionally rare. Although some are presumed to have been caused by fertilization occurring in the vicinity of the ovary (primary), most are probably caused secondarily and result from an extrusion of the conceptus through the abdominal ostium of the tube.

Apart from their important clinical implications, these conditions emphasize the fact that the conceptus can implant successfully into tissues other than a normal progestational endometrium. Prolonged development can occur in such sites and is usually terminated by a mechanical or vascular accident and not by a fundamental nutritive or endocrine insufficiency or by an immune maternal response. Abdominal implantation may occur on any organ, e.g. bowel, liver or omentum. If such a pregnancy continues, this makes removal of the placenta at delivery or abortion hazardous as a result of haemorrhage; consequently, the placenta is usually left in situ to degenerate spontaneously.

## Twinning

Spontaneous twinning occurs once in about every 80 births. Monozygotic twins arise from a single ovum fertilized by a single sperm. At some stage up to the establishment of the axis of the embryonic area and the development of the primitive streak, the embryonic cells separate into two parts, each of which gives rise to a complete embryo. The process of hatching of the blastocyst from the zona pellucida may result in constriction of the emerging cells and separation into two discrete entities. There is a gradual decrease in the average thickness of the zona pellucida with increasing maternal age, which may be causally related to the increase in frequency of monozygotic twinning with increased maternal age. The resultant twins have the same genotype but the description 'identical twins' is best avoided, since most monozygotic twins have differences in phenotypes. Late separation of twins from a single conceptus may result in conjoined twins; these may be equal or unequal, as in acardia. After twinning, monozygotic embryos enter a period of intense catch-up growth. Despite starting out at half the size, each twin embryo or fetus is of a size comparable to a singleton fetus in the second trimester of pregnancy, but declines in relative size in the last 10 weeks of pregnancy. The sex of monozygotic twins will be the same. Monoamniotic, monochorionic, monozygotic twins are most likely to be female, as are acardiac twins. The male to female ratio for all monozygotic twins is 0.487 , and for monoamniotic, monochorionic twins it is 0.231 .

Dizygotic twins represent the most frequent form of twinning. They result from multiple ovulations, which can be induced by gonadotrophins or drugs commonly used in patients with infertility. Dizygotic twins may be different sexes; like-sex pairs are more common. The male to female ratio is 0.518 . Multiple births greater than twinning, such as triplets or quadruplets, can arise from multiple ovulations, or from a

Fig. 8.9 Relationships of the extraembryonic membranes in different types of twinning. A, Diamnionic, dichorionic separated; i.e. separation of the first two blastomeres results in separate implantation sites. B, Diamnionic, dichorionic fused; here the chorionic membranes are fused but the fetuses occupy separate choria. C, Diamnionic, monochorionic; reduplication of the inner cell mass can result in a single placenta and chorionic sacs but separate amniotic cavities. D, Monoamnionic, monochorionic; duplication of the embryonic axis results in two embryos sharing a single placenta, chorion and amnion. E, Incomplete separation of the embryonic axis results in conjoined twins. $\mathbf{F}$, Unequal division of the embryonic axis or unequal division of the blood supply may result in an acardiac monster.
single ovum, or both. It is most likely to be seen in women treated with drugs to stimulate ovulation.

The range of separation of twin embryos is reflected in the separation of the extraembryonic membranes. The types of placentation that can occur are shown in Figure 8.9. Monoamniotic, monochorionic placentae are associated with the greatest perinatal mortality (50\%), caused both by entanglement of the umbilical cords impeding the blood supply and by various vascular shunts between the placentae, which may divert blood from one fetus to the other. Artery-artery anastomoses are the most common, followed by artery-vein anastomoses. If the shunting of blood across the placentae from one twin to the other is balanced by more than one vascular connection, development may proceed unimpaired. However, if this is not the case, one twin may receive blood from the other, leading to cardiac enlargement, increased urination and polyhydramnios in the recipient, and anaemia, oligohydramnios and atrophy in the donor.

Dizygotic twins have either completely separate chorionic sacs or sacs that have fused. Such placentae are separated by four membranes, two amnia and two choria; in addition, these placentae have a ridge of firmer tissue at the base of the dividing membranes, caused by the abutting of two expanding placental tissues against each other.

## FORMATION OF EXTRAEMBRYONIC TISSUES

The earliest developmental processes in mammalian embryos involve the production of those extraembryonic structures that will support and nourish the embryo during development. Production of these layers
begins before implantation is complete. At present, it is unclear where the extraembryonic cell lines arise. The trophoblast was considered to be a source but evidence now points to the inner cell mass as the site of origin. Figure 8.1 shows the sequence of development of various tissues in the early embryo.

## Epiblast and amniotic cavity

Epiblast cells are closest to the implanting face of the trophoblast and have a definite polarity; they are arranged in a radial manner with extensive junctions near the centre of the mass of cells, supported by supranuclear organelles. A few epiblast cells are contiguous with cytotrophoblast cells; apart from this contact, a basal lamina surrounds what is initially a spherical cluster of epiblast cells, and isolates them from all other cells. Those epiblast cells adjacent to the hypoblast become taller and more columnar than those adjacent to the trophoblast, and this causes the epiblast sphere to become flattened and the centre of the sphere to be shifted towards the polar trophoblast. Amniotic fluid accumulates at the eccentric centre of the now lenticular epiblast mass, which is bordered by apical junctional complexes and microvilli. As further fluid accumulates, an amniotic cavity forms, roofed by low cuboidal cells that possess irregular microvilli. The cells share short apical junctional complexes and associated desmosomes, and rest on an underlying basal lamina. The demarcation between true amnion cells and those of the remaining definitive epiblast is clear. The columnar epiblast cells are arranged as a pseudostratified layer with microvilli, frequently a single cilium, clefted nuclei and large nucleoli; the cells have a distinct, continuous basal lamina. Cell division in the epiblast tends to occur near the apical surface, causing this region to become more crowded than the basal region. At the margins of the embryonic disc, the amnion cells are contiguous with the epiblast; there is a gradation in cell size from columnar to low cuboidal within a twoto three-cell span (Fig. 8.10; see Fig. 9.1). Further development of the amnion and amniotic fluid is described on page 178.

## Hypoblast and yolk sac

Hypoblast is the term used to delineate the lower layer of cells of the early bilaminar disc, most commonly in avian embryos. This layer is also termed anterior, or distal, visceral endoderm in the mouse embryo. Just before implantation, the hypoblast consists of a layer of squamous cells that is only slightly larger in extent than the epiblast. The cells exhibit polarity, in that apical microvilli face the cavity of the blastocyst and apical junctional complexes, but they lack a basal lamina. During early implantation, the hypoblast extends beyond the edges of the epiblast and can now be subdivided into those cells in contact with the epiblast basal lamina, the visceral hypoblast, and those cells in contact with the mural trophoblast, the parietal hypoblast. The parietal hypoblast cells are squamous; they may share adhesion junctions with the

Fig. 8.10 The implanting conceptus at stage 5b. The embryo at this stage is composed only of the abutting epiblast and hypoblast layers. It is suspended within the blastocyst cavity (chorionic cavity) and surrounded by a layer of cytotrophoblast. A large mass of syncytiotrophoblast, with interconnecting lacunae, is penetrating the maternal endometrium.
mural trophoblast and, rarely, may also share gap junctions. The visceral hypoblast cells are cuboidal; they have a uniform apical surface towards the blastocyst cavity but irregular basal and lateral regions, with flanges and projections underlying one another and extending into intercellular spaces. There is no basal lamina subjacent to the visceral hypoblast, and the distance between the hypoblast cells and the epiblast basal lamina is variable.

A series of modifications of the original blastocystic cavity develops beneath the hypoblast later than those developing above the epiblast. While the amniotic cavity is enlarging within the sphere of epiblast cells, the parietal hypoblast cells are proliferating and spreading along the mural trophoblast until they extend most of the way around the circumference of the blastocyst, converging towards the abembryonic pole. At the same time, a space appears between the parietal hypoblast and the mural trophoblast that limits the circumference of the hypoblastic cavity. A variety of terms have been applied to the parietal hypoblast layer: extraembryonic hypoblast, extraembryonic endoderm and exocoelomic (Heuser's) membrane. The cavity that the layer initially surrounds is the primary yolk sac (primary umbilical vesicle), and the resultant smaller cavity lined by hypoblast is the secondary yolk sac. It has been suggested that the secondary yolk sac forms in a variety of ways, including cavitation of visceral hypoblast (a method similar to formation of the amnion), rearrangement of proliferating visceral hypoblast and folding of the parietal layer of the primary yolk sac into the secondary yolk sac. Further development of the yolk sac is described on page 177.

The visceral hypoblast cells are thought to be important in many aspects of the early specification of cell lines and control of the timing of early development. They induce the formation and position of the primitive streak in the midline of the embryo, thus establishing the first axis of the embryonic disc, and they influence the timing of epiblast epithelial-to-mesenchyme transition at the primitive streak. Hypoblast cells remain beneath the primitive streak; their experimental removal in avian embryos causes multiple embryonic axes to form. Hypoblast cells are also believed to be necessary for successful induction of the head region and for the successful specification of the primordial germ cells. With the later formation of the embryonic cell layers from the epiblast, the visceral hypoblast appears to be sequestered into the secondary yolk sac wall by the expansion of the newly formed embryonic endoderm beneath the epiblast, although there is now evidence that some hypoblast cells may remain in the final endoderm layer and contribute to the gut, and that they may also play a role in the induction of cardiogenesis. For a review of the roles of hypoblast cells, see Stern and Downs (2012).

After the formation of the secondary yolk sac, a diverticulum of the visceral hypoblast, the allantois, forms towards one end of the embryonic region and extends into the local extraembryonic mesoblast. It passes from the roof of the secondary yolk sac to the same plane as the amnion. Further development of the allantois is described on page 178.

## Extraembryonic mesoblast

By definition, extraembryonic tissues encompass all tissues that do not contribute directly to the future body of the definitive embryo and, later, the fetus. At stage 5, blastocysts are implanted but do not yet display trophoblastic villi (see Fig. 8.10); they range from 7 to 12 days in age. A feature of this stage is the first formation of extraembryonic mesoblast, which will come to cover the amnion, secondary yolk sac and the internal wall of the mural trophoblast, and will form the connecting stalk of the embryo with its contained allantoenteric diverticulum. The origin of this first mesoblastic extraembryonic layer is by no means clear; it may arise from several sources, including the caudal region of the epiblast, the parietal hypoblast and subhypoblastic cells. The trophoblastic origin of extraembryonic mesoblast is questioned because there is always a complete basal lamina underlying the trophoblast; the migration of cells out of an epithelium is usually associated with previous disruption of the basal lamina. Certainly, the origin of extraembryonic cells will change over time as new germinal populations are established.

The first mesoblastic extraembryonic layer gives rise to the layer known as extraembryonic mesoblast, arranged as a mesothelium with underlying extraembryonic mesenchymal cells; this also appears to form an extracellular structure corresponding to the magma reticulare, between the mural trophoblast and the primary yolk sac in the stage 5 embryo. Later extraembryonic mesoblast populations mushroom beneath the cytotrophoblastic cells at the embryonic pole, forming the cores of the developing villus stems, and villi and the angioblastic
cells that will give rise to the capillaries within them and the earliest blood cells.

Initially, the extraembryonic mesoblast connects the amnion to the chorion over a wide area. Continued development and expansion of the extraembryonic coelom means that this attachment becomes increasingly circumvented to a connecting stalk, which is a permanent connection between the future caudal end of the embryonic disc and the chorion. The connecting stalk forms a pathway along which vascular anastomoses around the allantois establish communication with those of the chorion.

## Implantation and placentation

## IMPLANTATION

Implantation involves the initial attachment of the trophoblastic wall of the blastocyst to the endometrial luminal epithelium and its decidual response. It is now apparent that, during this process, there is an interactive dialogue between the implanting embryo and endometrial decidual stromal cells. Competent preimplantation human embryos actively enhance the uterine environment for their implantation, whereas developmentally impaired embryos induce endoplasmic reticulum stress responses in decidual cells that inhibit implantation (Brosens et al 2014).

The blastocyst/trophoblast lineage gives rise to three main cell types in the human placenta: syncytiotrophoblast cells form the epithelial covering of the villous tree and are the main endocrine component of the placenta; villous cytotrophoblast cells represent a germinative population that proliferates throughout pregnancy, fusing to generate syncytiotrophoblast; and extravillous trophoblast cells are non-proliferative and invade the maternal endometrium. The first two cell lines can be seen from stages 4 and 5 onwards. The cytotrophoblast cells that form the mural and polar trophoblast are cuboidal and covered externally with syncytial trophoblast (syncytiotrophoblast), a multinucleated mass of cytoplasm that forms initially in areas near the inner cell mass after apposition of the blastocyst to the uterine mucosa (see Fig. 8.10).

Preimplantation embryos produce matrix metalloproteinases (MMPs) that mediate penetration of the maternal subepithelial basal lamina by the syncytiotrophoblast. Trophoblast cells express L-selectin (usually seen as a mediator of neutrophil rolling and tethering in inflamed endothelium), and the maternal epithelium upregulates selectin-oligosaccharide-based ligands. Thus, differentiating cytotrophoblast cells appear to use processes that also occur in vasculogenesis
and during leukocyte emigration from the blood into the tissues. Flanges of syncytial trophoblast grow between the cells of the uterine luminal epithelium towards the underlying basal lamina without apparent damage to the maternal cell membranes or disruption of the intercellular junctions. Instead, shared junctions, including tight junctions, are formed with many of the maternal uterine epithelial cells.

Implantation continues with erosion of maternal vascular endothelium and glandular epithelium, and phagocytosis of secretory products, until the blastocyst occupies an uneven implantation cavity in the stroma (interstitial implantation) (Fig. 9.1). In the early postimplantation phase, the maternal surface is resealed by re-epithelialization and the formation of a plug, which may contain fibrin. As the blastocyst burrows more deeply into the endometrium, syncytial trophoblast forms over the mural cytotrophoblast, but never achieves the thickness of the syncytial trophoblast over the embryonic pole.

The syncytiotrophoblast, which expresses neither class I nor class II major histocompatibility complex (MHC) antigens, secretes numerous hormones; human chorionic gonadotrophin (hCG) can be detected in maternal urine from as early as 10 days after fertilization and forms the basis for tests for early pregnancy. This hCG prolongs the life of the corpus luteum, which continues to secrete progesterone and oestrogens during approximately the first 2 months of pregnancy, until these essential hormones are produced by the placenta.

Menstruation ceases on successful implantation. The endometrium, now known as the decidua in pregnancy, thickens to form a suitable nidus for the conceptus. Decidualization of the endometrial stroma may occur without an intrauterine pregnancy, e.g. in the presence of an ectopic pregnancy, after prolonged treatment with progesterone, and in the late secretory phase of a non-conception cycle.

Decidual differentiation is not evident in the stroma at the earliest stages of implantation, and it may not be until a week later that fully

Fig. 9.1 The implanting conceptus at stage 6 . The embryo is composed of epiblast, with the amniotic cavity above it, and hypoblast, with the secondary yolk sac below it (see also Figs 8.10, 10.1). Both cavities are covered externally with extraembryonic mesoblast, which also lines the larger chorionic cavity. Primary villi cover the outer aspect of the conceptus and extend into the maternal endometrium, and in places, maternal blood fills the lacunae.
differentiated cells are present. During decidualization, the interglandular tissue increases in quantity (Burton et al 2010). It contains a substantial population of leukocytes (large granular lymphocytes, macrophages and T cells) distributed amongst large decidual cells. The most numerous are uterine natural killer (NK) cells, which accumulate in the endometrium during the secretory phase of the cycle and persist until mid-pregnancy; they interact with invading extravillous trophoblast cells expressing human leukocyte antigen G and C (HLA-G, HLA-C). Decidual cells are stromal cells that contain varying amounts of glycogen, lipid and vimentin-type intermediate filaments in their cytoplasm. They are generally rounded but their shape may vary, depending on the local packing density. They may contain one, two or sometimes three nuclei, frequently display rows of club-like cytoplasmic protrusions enclosing granules, and are associated with a characteristic capsular basal lamina. Decidual cells produce a range of secretory products, including insulin-like growth factor binding protein 1 (IGFBP1) and prolactin, which may be taken up by the trophoblast. These secretions probably play a role in the maintenance and growth of the conceptus in the early part of postimplantational development, and can be detected in amniotic fluid in the first trimester of pregnancy.

Extracellular matrix, growth factors and protease inhibitors produced by the decidua all probably modulate the degradative activity of the trophoblast and support placental morphogenesis and placental accession to the maternal blood supply. Once implantation is complete, distinctive names are applied to different regions of the decidua (Fig. 9.2). The part covering the conceptus is the decidua capsularis; that between the conceptus and the uterine muscular wall is the decidua basalis (where the placenta subsequently develops); and that which lines the remainder of the body of the uterus is the decidua parietalis. There is no evidence that their respective resident maternal cell populations exhibit site-specific properties.

## DEVELOPMENT OF THE PLACENTA

Formation of the human placenta requires a developmental progression that proceeds in a specific chronological order: the development of primary, secondary and anchoring villi, and the local differentiation of haemangioblast cells within them, occur concurrently with the modification of maternal blood vessels to ensure their patency. With the onset of the embryonic heart beat, a primitive circulation exists between the embryo and the secondary yolk sac. An embryonic-placental circulation starts around week 8 of gestation; over the course of 40 weeks, the placenta develops into a highly vascular organ.

As the blastocyst implants, the syncytiotrophoblast invades the uterine tissues, including the glands and walls of maternal blood vessels (see Fig. 9.1; Fig. 9.3), and increases rapidly in thickness over the embryonic pole (Fig. 9.4). A progressively thinner layer covers the rest of the wall towards the abembryonic pole. Microvillus-lined clefts and lacunar spaces develop in the syncytiotrophoblastic envelope (days 9-11 of pregnancy) and establish communications with one another. Initially, many of these spaces contain maternal blood derived from dilated uterine capillaries and veins, as the walls of the vessels are partially destroyed. As the conceptus grows, the lacunar spaces enlarge, and become confluent to form intervillous spaces.

The projections of syncytiotrophoblast into the maternal decidua are called primary villi. They are invaded initially with cytotrophoblast and

Fig. 9.2 The gravid uterus in the second month. A placental site precisely in the uterine fundus, as indicated on the figure, is rather unusual; the dorsal, ventral or lateral wall of the corpus uteri is more usual. The maternal endometrium is now termed decidua; different regions are distinguished.

Fig. 9.3 A, The growing syncytiotrophoblast erodes decidual glands and spiral arteries, and their contents form lacunae within the syncytiotrophoblast. Cytotrophoblastic cells extend as villi into the syncytiotrophoblast. B, Cells originating from the cytotrophoblast move into the decidua, forming interstitial extravillous trophoblast cells, the third line of cytotrophoblastic cells. These surround the opened glands and spiral arteries in the decidua and inner myometrium. Cells that move through the tunicae adventitia, media and interna to enter the lumen of the vessels become endovascular extravillous trophoblast. These cells remodel the walls and plug the lumen of the spiral arteries, permitting only plasma to enter the forming intervillous space. Glandular secretions in the intervillous space provide histiotrophic nutrition to the embryo.
then with extraembryonic mesenchyme (days 13-15) to form secondary placental villi. Capillaries develop in the mesenchymal core of the villi during the third week post conception. The cytotrophoblast within the villi continues to grow through the invading syncytiotrophoblast and makes direct contact with the decidua basalis, forming anchoring villi. Further cytotrophoblast proliferation occurs laterally so that neighbouring outgrowths meet to form a spherical cytotrophoblastic shell around the conceptus (Fig. 9.5; see Fig. 9.3B). Lateral projections from the main stem villus form true villi. Elongation of growing capillaries outstrips that of the containing villi, leading to looping of vessels. This obtrusion of both capillary loops and new sprouts results in the formation of terminal villi.

As secondary villi form, single mononuclear cells become detached from the distal (anchoring) cytotrophoblast and infiltrate the maternal decidua (Fig. 9.6; see Fig. 9.3B). These extravillous cells are the third line of the original trophoblastic cells. Interstitial extravillous trophoblast cells invade the maternal spiral arteries from their adventitia. The smooth muscle and internal elastic lamina are replaced with extracellular fibrinoid deposits (Harris 2010). Those cells that pass through the endothelial basement membrane and gain access to the vessel lumen are termed endovascular extravillous trophoblast (see Figs 9.3B, 9.6). These cells plug the maternal spiral arteries until the end of the first trimester; the cells also migrate antidromically, against the flow of

Fig. 9.4 The conceptus at about stage 14. The embryonic pole shows extensive villous formation at the chorion frondosum, whereas the abembryonic pole is smooth and villous-free at the chorion laeve. (Photograph courtesy of $P$ Collins.)
maternal blood, along the spiral arteries as far as the inner myometrial region (Huppertz et al 2014).

The definitive placenta is composed of a chorionic plate on its fetal aspect and a basal plate on its maternal aspect, separated by an intervening intervillous space containing villous stems with branches in contact with maternal blood (see Fig. 9.5). During the first trimester, development takes place in a low-oxygen environment supported by histiotrophic nutrition from the endometrial glands, which discharge into the intervillous space until at least 10 weeks (see Fig. 9.3A) (Burton et al 2002, Burton et al 2007, Burton and Fowden 2012). When maternal blood bathes the surfaces of the chorion that bound the intervillous space, the human placenta is defined as haemochorial. Different grades of fusion exist between the maternal and fetal tissues in many other mammals (e.g. epitheliochorial, syndesmochorial, endotheliochorial). The chorion is vascularized by the allantoic blood vessels of the body stalk, and so the human placenta is also termed chorio-allantoic (whereas, in some mammals, a choriovitelline placenta either exists alone or supplements the chorio-allantoic variety). The human placenta is also defined as discoidal, in contrast to other shapes in other mammals, and deciduate because maternal tissue is shed with the placenta and membranes at parturition as part of the afterbirth.

## Growth of the placenta

Expansion of the entire conceptus is accompanied by radial growth of the villi and, simultaneously, an integrated tangential growth and expansion of the trophoblastic shell. Eventually, each villous stem forms a complex that consists of a single trunk attached by its base to the chorion, from which second- and third-order branches (intermediate and terminal villi) arise distally. Terminal villi are specialized for exchange between fetal and maternal circulations; each one starts as a syncytial outgrowth and is invaded by cytotrophoblastic cells, which then develop a core of fetal mesenchyme as the villus continues to grow. The core is vascularized by fetal capillaries (i.e. each villus passes through primary, secondary and tertiary grades of histological differentiation). The germinal cytotrophoblast continues to add cells that fuse with the overlying syncytium and so contribute to the expansion of the haemochorial interface. Terminal villi continue to form and branch within the confines of the definitive placenta throughout gestation, projecting in all directions into the intervillous space (see Fig. 9.5).

From the third week until about the second month of pregnancy, the entire chorion is covered with villous stems. They are thus continuous peripherally with the trophoblastic shell, which is in close apposition with both the decidua capsularis and the decidua basalis. The villi adjacent to the decidua basalis are stouter and longer, and show a greater profusion of terminal villi. As the conceptus continues to expand, the decidua capsularis is progressively compressed and thinned, the circulation through it is gradually reduced, and adjacent villi slowly atrophy and disappear. This process starts at the abembryonic pole; by the end of the third month, the abembryonic hemisphere of the

Fig. 9.5 Placental development.

Fig. 9.6 As the placenta grows, the interstitial and endovascular extravillous trophoblast cells continue to remodel the spiral arteries into large-bore, low-resistance uteroplacental vessels. These arteries remain occluded by endovascular extravillous trophoblast until the end of the first trimester, promoting a low oxygen environment.
conceptus is largely denuded. Eventually, the whole chorion apposed to the decidua capsularis is smooth and is now termed the chorion laeve; this will later become apposed to the amnion, forming chorioamnion (see Figs 9.2, 9.9). In contrast, the villous stems of the discshaped region of chorion apposed to the decidua basalis increase greatly in size and complexity, and the region is now termed the chorion frondosum (see Fig. 9.4). The chorion frondosum and the decidua basalis constitute the definitive placental site (see Fig. 9.2). Abnormalities in this process may account for the persistence of villi at abnormal sites in the chorion laeve of the gestational sac and hence the presence of accessory or succenturiate lobes within the membranes of the definitive placenta. The presence of the entire villous ring of the primitive placenta beyond the second month post-menstruation leads to the development of placenta membranacea, a giant definitive placental structure surrounding the whole gestational sac during the remainder of pregnancy.

Coincidentally with the growth of the embryo and the expansion of the amnion, the decidua capsularis is thinned and distended, and the space between it and the decidua parietalis is gradually obliterated. By the second month of pregnancy, the three endometrial strata recognizable in the premenstrual phase, i.e. compactum, spongiosum and basale, are better differentiated and easily distinguished. The glands in the spongiosum are compressed and appear as oblique slit-like fissures lined by low cuboidal cells. By the beginning of the third month of pregnancy, the decidua capsularis and decidua parietalis are in contact. By the fifth month, the decidua capsularis is greatly thinned, and it virtually disappears during the succeeding months.

Focal bleeding often occurs in the periphery of the developing placenta at the time of the formation of the membranes ( $8-12$ weeks). This complication, which is termed threatened miscarriage, is a common clinical complication of pregnancy and can lead to a complete miscarriage if the haematoma extends to the definitive placenta (Jauniaux et al 2006).

At term, the placental diameter varies from 200 to 220 mm , the mean placental weight is 470 g , its mean thickness is 25 mm and the total villous surface area is $12-14 \mathrm{~m}^{2}$, providing an extensive and intimate interface for materno-fetal exchange; the uteroplacental circulation carries approximately 600 ml of maternal blood per minute. There are no lymph vessels in the placenta and, equally, no aggregates of lymphoid cells. Systematic evaluation and careful description of the placenta after delivery have been recommended for correlation with later neonatal neurodevelopmental outcomes (Roescher et al 2014).

## Chorionic plate

The chorionic plate is covered on its fetal aspect by amniotic epithelium; on the stromal side of the epithelium, a connective tissue layer carries the main branches of the umbilical vessels (see Fig. 9.5; Fig. 9.7). Subjacent to this are a diminishing layer of cytotrophoblast and then the inner syncytial wall of the intervillous space. The connective tissue layer is formed by fusion between the mesenchyme-covered surfaces of amnion and chorion, and is more fibrous and less cellular than Wharton's jelly (of the umbilical cord), except near the larger vessels. The umbilical vessels radiate and branch from the cord attachment, with variations in the branching pattern, until they reach the bases of the trunks of the villous stems; they then arborize within the intermediate and terminal villi. There are no anastomoses between vascular trees of adjacent stems. The two umbilical arteries are normally joined at, or just before they enter, the chorionic plate, by some form of substantial transverse anastomosis (Hyrtl's anastomosis).

## Basal plate

The basal plate, from fetal to maternal aspect, forms the outer wall of the intervillous space. The trophoblast and adjacent decidua are enmeshed in layers of fibrinoid and basement membrane-like extracellular matrix to form a complex junctional zone. In different places, the basal plate may contain syncytium, cytotrophoblast or fibrinoid matrix, remnants of the cytotrophoblastic shell, and, at the site of implantation, areas of necrotic maternal decidua (the so-called Nitabuch's stria) (see Figs 9.5 and 9.7). Nitabuch's stria and the decidua basalis contain cytotrophoblast and multinucleate trophoblast giant cells derived from the mononuclear extravillous interstitial cytotrophoblast population that infiltrate the decidua basalis during the first 18 weeks of pregnancy. These cells penetrate as far as the inner third of the myometrium but can often be observed at or near the decidual-myometrial junction. They are not found in the decidua parietalis or the adjacent myometrium, suggesting that the placental bed giant cell represents a differentiative end stage in the extravillous trophoblast lineage. The striae of fibrinoid are irregularly interconnected and variable in prominence. Strands pass from Nitabuch's stria into the adjacent decidua, which contains basal remnants of the endometrial glands and large and small decidual cells scattered in a connective tissue framework that supports an extensive venous plexus.

Initially, only the central area of a placenta contains extravillous trophoblast cells, both within and around the spiral arteries. These cells

Fig. 9.7 The arrangement of the placental tissues from the chorionic plate (fetal side) to the basal plate or decidua basalis (maternal side).
gradually extend laterally, reaching the periphery of the placenta around mid-gestation; the extent of invasion is progressively shallower towards the periphery. Invaded maternal vessels show a 5 -10-fold dilation of the vessel mouth and altered responsiveness to circulating vasoactive compounds (Hung et al 2001, Burton et al 2009).

The conversion of maternal musculoelastic, spiral arteries to largebore, low-resistance uteroplacental vessels is considered key for a successful human pregnancy. Failure to achieve these changes is a feature of common complications of pregnancy, such as early-onset preeclampsia, miscarriage and fetal growth restriction.

From the third month onwards, the basal plate develops placental or cotyledonary septa, which are ingrowths of the cytotrophoblast covered with syncytium that grow towards, but do not fuse with, the chorionic plate (see Fig. 9.5). The septa circumscribe the maternal surface of the placenta into 15-30 lobes, often termed cotyledons. Each cotyledon surrounds a limited portion of the intervillous space associated with a villous trunk from the chorionic plate. From the fourth month, these septa are supported by tissue from the decidua basalis. Throughout the second half of pregnancy, the basal plate becomes thinned and progressively modified: there is a relative diminution of the decidual elements, increasing deposition of fibrinoid, and admixture of fetal and maternal derivatives.

## Intervillous space

The intervillous space contains the main trunks of the villous stems and their arborizations into intermediate and terminal villi (see Figs 9.5, 9.7). A villous trunk and its branches may be regarded as the essential structural, functional and growth unit of the developing placenta.

At term, from the inner myometrium to the intervillous space, the walls of most spiral arteries consist of fibrinoid matrix, within which cytotrophoblast is embedded. This arrangement allows expansion of the arterial diameter (and so slows the rate of arterial inflow and reduces the perfusion pressure), independent of the local action of vasoconstrictive agents. Endothelial cells, where present, are often hypertrophic. The veins that drain the blood away from the intervillous space pierce the basal plate and join tributaries of the uterine veins. The presence of a marginal venous sinus, which hitherto has been described as a constant
feature occupying the peripheral margin of the placenta and communicating freely with the intervillous space, has not been confirmed.

Recent anatomic and in vivo studies have shown that human placentation is, in fact, not truly haemochorial in early pregnancy (Video 9.1) (Jauniaux et al 2003). From the time of implantation, the extravillous trophoblast not only invades the uterine tissues but also forms a continuous shell at the level of the decidua. The cells of this shell anchor the placenta to the maternal tissue and also form plugs in the tips of the uteroplacental arteries (see Figs 9.3B, 9.6) (Burton et al 1999). The shell and the plugs act like a labyrinthine interface that filters maternal blood, permitting a slow seepage of plasma but no true blood flow into the intervillous space (Burton et al 2003). This creates a physiological placental hypoxia, which may protect the developing embryo against the deleterious and teratogenic effects of oxygen free radicals. As a result, there is a uteroplacental $\mathrm{O}_{2}$ gradient that exerts a regulatory effect on placental tissue development and function (Jauniaux et al 2003). In particular, it influences cytotrophoblast proliferation and differentiation along the invasive pathway, villous vasculogenesis and the formation of the chorion laeve. An $\mathrm{O}_{2}$ gradient persists within lobules of the placenta throughout pregnancy, with the central region well oxygenated compared to the periphery, owing to the direction of maternal blood flow (Burton and Jauniaux 2011).

At the end of the first trimester, the endovascular extravillous trophoblastic plugs are progressively dislocated, allowing maternal blood to flow progressively more freely and continuously within the intervillous space (see Figs 9.6, 9.7, Video 9.1). During the transitional phase of $10-14$ weeks' gestation, two-thirds of the primitive placenta disappears, the chorionic cavity is obliterated by the growth of the amniotic sac, and maternal blood flows progressively throughout the entire placenta (Jauniaux et al 2003). These events bring the maternal blood closer to the fetal tissues, facilitating nutrient and gaseous exchange between the maternal and fetal circulations (Gutierrez-Marcos et al 2012).

## Structure of a placental villus

Chorionic villi are the essential structures involved in exchanges between mother and fetus. The villous tissues separating fetal and

Fig. 9.8 A, A chorionic villus and its arterio-capillary-venous system carrying fetal blood. The artery carries deoxygenated blood and waste products from the fetus, and the vein carries oxygenated blood and nutrients to the fetus. B-C, Transverse sections through individual chorionic villi at 10 weeks (B) and at full term (C). The villi would be within the intervillous space, bathed externally in maternal blood. The placental membrane, composed of fetal tissues, separates the maternal blood from the fetal blood.
maternal blood are therefore of crucial functional importance. From the chorionic plate, progressive branching occurs into the villous tree, as stem villi give way to intermediate and terminal villi. Each villus has a core of connective tissue containing collagen types I, III, V and VI, as well as fibronectin. Cross-banded fibres ( $30-35 \mathrm{~nm}$ ) of type I collagen often occur in bundles, whereas type III collagen is present as thinner ( $10-15 \mathrm{~nm}$ ) beaded fibres, which form a meshwork that often encases the larger fibres. Collagens V and VI are present as $6-10 \mathrm{~nm}$ fibres closely associated with collagens I and III. Laminin and collagen type IV are present in the stroma associated with the basal laminae that surround fetal vessels and also in the trophoblast basal lamina. Overlying this matrix are ensheathing cyto- and syncytiotrophoblast cells bathed by the maternal blood in the intervillous space (see Figs 9.5, 9.7; Fig. 9.8). Cohesion between the cells of the cytotrophoblast, and also between the cytotrophoblast and the syncytium, is provided by numerous desmosomes between the apposed plasma membranes.

In earlier stages, the cytotrophoblast forms an almost continuous layer on the basal lamina. After the fourth month, it gradually expends itself producing syncytium, which comes to lie on the basal lamina over an increasingly large area (56\% at term), and becomes progressively thinner. Cytotrophoblastic cells persist until term but, because the increase in villous surface area outstrips their proliferation, they are usually disposed singly. In the first and second trimesters, cytotrophoblastic sprouts, covered in syncytium, are present and represent a stage in the development of new villi. Cytotrophoblast columns at the tips of anchoring villi extend from the villous basal lamina to the maternal decidual stroma.

The cells of the villous cytotrophoblast (Langhans cells) are palestaining with a slight basophilia. Ultrastructurally, they have a rather electron-translucent cytoplasm and relatively few organelles. They contain intermediate filaments, particularly in association with desmosomes. Between the desmosomes, the membranes of adjacent cells are separated by approximately 20 nm . Sometimes, the intercellular gap widens to accommodate microvillous projections from the cell surfaces; occasionally, it contains patches of fibrinoid. A smaller population of intermediate cytotrophoblast may also be found in the chorionic villi. This postmitotic population represents a state of partial differentiation between the cytotrophoblast stem cell and the overlying syncytium.

The syncytiotrophoblast is the multinucleated epithelium of the placenta and is an intensely active tissue layer, across which most transplacental transport must occur (Ellery et al 2009). It is a selectively permeable barrier that allows water, oxygen and other nutritive substances and hormones to pass from mother to fetus, and some of the products of excretion to pass from fetus to mother. It secretes a range of placental hormones into the maternal circulation. Syncytial cyto-
plasm is more strongly basophilic than that of the cytotrophoblastic cells and is packed with organelles consistent with its secretory phenotype. Where the plasma membrane adjoins basal lamina, it is often infolded into the cytoplasm, whereas the surface bordering the intervillous space is set with numerous long microvilli, which constitute the brush border seen by light microscopy.

Glycogen is thought to be present in both layers of the trophoblast at all stages, although it is not always possible to demonstrate its presence histochemically. Lipid droplets occur in both layers and are free in the core of the villus. In the trophoblast, they are found principally within the cytoplasm, but they also occur in the extracellular space between cytotrophoblast and syncytium, and between the individual cells of the cytotrophoblast. The droplets diminish in number with advancing age and may represent fat in transit from mother to fetus, and/or a pool of precursors for steroid synthesis. Membrane-bound granular bodies of moderate electron density occur in the cytoplasm, particularly in the syncytium, some of which are probably secretion granules. Other membrane-bound bodies, lysosomes and phagosomes, are involved in the degradation of materials engulfed from the intervillous space.

Although many nuclei are dispersed within the syncytioplasm, other are aggregated into specializations referred to as syncytial knots and syncytial sprouts (Burton et al 2003). Knots must be distinguished from syncytial sprouts, which are markers of trophoblast proliferation. In the immature placenta, syncytial sprouts represent the first stages in the development of new terminal villi, which later become invaded by cytotrophoblast and villous mesenchyme (Fogarty et al 2013). Occasionally, adjacent syncytial sprouts make contact and fuse to form slender syncytial bridges. The sprouts may become detached, forming maternal syncytial emboli, which pass to the lungs. It has been computed that some 100,000 sprouts pass daily into the maternal circulation; deported trophoblast may be a mechanism by which the maternal immune system is maintained in a state of tolerance towards paternal antigens (Chamley et al 2011). In the lungs, syncytial sprouts provoke little local reaction and apparently disappear by lysis. However, they may occasionally form foci for neoplastic growth. Syncytial sprouts are present in the term placenta. Syncytial knots are aggregates of nuclei with particularly condensed heterochromatin, and may represent a sequestration phenomenon by which senescent nuclear material is removed from adjacent metabolically active areas of syncytium.

Fibrinoid deposits are frequently found on the villous surface in areas lacking syncytiotrophoblast. They may constitute a repair mechanism in which the fibrinoid forms a wound surface that is subsequently re-epithelialized by trophoblast. The extracellular matrix glycoprotein tenascin has been localized in the stroma adjacent to these sites.

The core of a villus contains small and large reticulum cells, fibroblasts and macrophages (Hofbauer cells). Early mesenchymal cells probably differentiate into small reticulum cells, which, in turn, produce fibroblasts or large reticulum cells. The small reticulum cells appear to delimit a collagen-free stromal channel system through which Hofbauer cells migrate. Mesenchymal collagen increases from a network of fine fibres in early mesenchymal villi to a densely fibrous stroma within stem villi in the second and third trimesters. After approximately 14 weeks, the stromal channels found in immature intermediate villi are infilled by collagen to give the fibrous stroma characteristic of the stem villus.

Fetal placental vessels include arterioles and capillaries; lymphatic vessels are not present. Pericytes may be found in close association with the capillary endothelium, and from late first trimester, the vessels are surrounded externally by a basal lamina. From the second trimester (and a little later in terminal villi), dilated thin-walled capillaries are found immediately adjacent to the villous trophoblast; their respective basal laminae apparently fuse to produce a vasculosyncytial interface; the distance separating the maternal and fetal circulations may be reduced to as little as $2-3 \mu \mathrm{~m}$. The endothelial cells are non-fenestrated, display numerous caveolae, and are linked by conspicuous junctional complexes incorporating tight and adherens junctions.

## Transport across placental villi

The mechanism of transfer of substances across the placental barrier (membrane) is complex. The volume of maternal blood circulating through the intervillous space has been assessed at 500 ml per minute. Simple diffusion suffices to explain gaseous exchange. Transfer of ions and other water-soluble solutes is by paracellular and transcellular diffusion and transport; the relative importance of each of these for most individual solutes is unknown, and the paracellular pathway is morphologically undefined. Glucose transfer involves facilitated diffusion, while active transport mechanisms carry calcium and at least some amino acids. The fat-soluble and water-soluble vitamins are likely to pass the placental barrier with different degrees of facility (Jauniaux and Gulbis 2000a, Jauniaux et al 2004, Jauniaux et al 2005). The watersoluble vitamins B and C pass readily. Water is interchanged between fetus and mother (in both directions) at approximately 3.5 litres per hour. The transfer of substances of high molecular weight, such as complex sugars, some lipids and hormonal and non-hormonal proteins, varies greatly in rate and degree and is not so well understood; energy-dependent selective transport mechanisms, including receptormediated transcytosis, are likely to be involved.

Lipids may be transported unchanged through and between the cells of the trophoblast to the core of the villus. The passage of maternal antibodies (immunoglobulins) across the placental barrier confers some degree of passive immunity on the fetus; it is widely accepted that transfer is by micropinocytosis. Investigation of transplacental mechanisms is complicated by the fact that the trophoblast itself is the site of synthesis and storage of certain substances, e.g. glycogen.

The placenta is an important endocrine organ. Some steroid hormones, various oestrogens, $\beta$-endorphins, progesterone, hCG and human chorionic somatomammotropin (hCS), also known as placental lactogen (hPL), are synthesized and secreted by the syncytium. The trophoblast contains enzyme systems that are associated with the synthesis of steroid hormones, as well as enzymes that inactivate maternal hormones, allowing the fetus to develop and mature in a protected environment; for example, the fetus is protected from 10 times higher maternal glucocorticoid levels by the placental enzyme 11beta-hydroxysteroid dehydrogenase 2 (11beta-HSD2), which converts biologically active maternal cortisol to inactive cortisone (Murphy et al 1974).

It has been suggested that leukocytes may migrate from the maternal blood through the placental barrier into the fetal capillaries. It has also been shown that some fetal and maternal red blood cells may cross the barrier. The former may have important consequences, e.g. in Rhesus incompatibility.

The majority of drugs are small molecules and are sufficiently lipophilic to pass the placental barrier from 7 weeks of gestation in quantities that yield measurable concentrations in both coelomic and amniotic fluid. Many are tolerated by the fetus but some may exert grave teratogenic effects on the developing embryo/fetus, depending on the gestational age and the doses used by the mother (e.g. thalidomide, cocaine) (Ross et al 2015). A well-documented association exists between maternal alcohol ingestion and fetal abnormalities. Addiction of the fetus can occur to substances of maternal abuse such as heroin.

A wide variety of bacteria (Listeria), protozoa (Toxoplasma gondii, Plasmodium falciparum) and viruses, including cytomegalovirus (CMV), human immunodeficiency virus (HIV) and rubella, are known to pass the placental barrier from mother to fetus. Toxoplasma and CMV are transferred by cellular invasion of the villous trophoblast during the
acute phase of a newly acquired maternal infection. As the maternal circulation inside the placenta only starts to function at the end of the first trimester, transmission of Toxoplasma to the embryos is rare during that period, but highly damaging to the developing fetus. Plasmodium falciparum is transferred by villous sequestration of maternal infected erythrocytes or a breakdown of the villous barrier during labour. The presence of maternal rubella in the early months of pregnancy is of especial importance in relation to the production of congenital anomalies. (For further reading about TORCH perinatal infections, caused by Toxoplasma gondii, rubella virus, CMV and herpes simplex virus (HSV), see Stegmann and Carey (2002).)

## FETAL MEMBRANES

The implanting conceptus consists initially of three cavities and their surrounding epithelia. The original blastocyst cavity, surrounded by trophoblast, is now termed the chorionic cavity (synonymous with extraembryonic coelom). It is a large cavity containing the much smaller amniotic cavity and secondary yolk sac (see Fig. 9.1). The apposition of the latter two cavities delineates the extent of the early embryo. The chorionic cavity becomes lined with extraembryonic mesoblast, which is also reflected over the outer surface of the amnion and yolk sac. A fourth cavity, the allantois, develops later as a caudal hypoblastic diverticulum that becomes embedded within the extraembryonic mesenchyme, forming the connecting stalk of the embryo. It does not have a direct mesothelial covering.

## Chorion

The chorion consists of developing trophoblast and extraembryonic mesothelium. It varies in thickness during development, both temporally and spatially. It is thickest at the implantation site throughout gestation as the chorion frondosum and then the placenta, and thinner as gestation progresses over the remainder of its surface as the chorion laeve (see Fig. 9.4). At term, the chorion consists of an inner cellular layer containing fibroblasts and a reticular layer of fibroblasts and Hofbauer cells, which resembles the mesenchyme of an intermediate villus. The outer layer consists of cytotrophoblast 3-10 cells deep, resting on a pseudo-basement membrane, which extends beneath and between the cells. Occasional obliterated villi within the trophoblast layer are the remnants of villi present in the chorion frondosum of the first trimester. Although the interface between the trophoblast and decidua parietalis is uneven, no trophoblast infiltration of the decidua parietalis occurs.

## Yolk sac

As the secondary yolk sac forms, it delineates a cavity lined with parietal, and perhaps visceral, hypoblast, continuous with the developing endoderm from the primitive streak (Ch. 10; see Fig. 10.10). The secondary yolk sac is the first structure that can be detected ultrasonographically within the chorionic cavity (Jauniaux et al 1991). Its diameter increases slightly between 6 and 10 weeks of gestation, reaching a maximum of $6-7 \mathrm{~mm}$, after which its size decreases.

The inner cells of the yolk sac (denoted endoderm in many studies, although this layer is restricted to the embryo itself) display a few short microvilli and are linked by juxtaluminal tight junctions (Jones and Jauniaux 1995). Their cytoplasm contains numerous mitochondria, whorls of rough endoplasmic reticulum, Golgi bodies and secretory droplets, giving them the appearance of being highly active synthetic cells. With further development, the epithelium becomes folded to form a series of cyst-like structures or tubules, only some of which communicate with the central cavity. The cells synthesize several serum proteins in common with the fetal liver, such as $\alpha$-fetoprotein (AFP), $\alpha-1$-antitrypsin, albumin, pre-albumin and transferrin (Gulbis et al 1998). With rare exceptions, the secretion of most of these proteins is confined to the embryonic compartments (Jauniaux and Gulbis 2000b).

The yolk sac becomes coated with extraembryonic mesenchyme, which forms mesenchymal and mesothelial layers. A diffuse capillary plexus develops between the mesothelial layer and the underlying secondary yolk sac wall, and subsequently drains through vitelline veins to the developing liver. The mesothelial layer bears a dense covering of microvilli; the presence of numerous coated pits and pinocytotic vesicles gives it the appearance of an absorptive epithelium (Jones and Jauniaux 1995, Burke et al 2013).

The secondary yolk sac plays a major role in the early embryonic development of all mammals. In laboratory rodents, it has been
demonstrated as one of the initial sites of haemopoiesis. Human data indicate that it has an absorptive role for molecules of maternal and placental origin found in the chorionic cavity (Gulbis et al 1998), and mediates the main movement of molecules passing from the chorionic cavity to the yolk sac and, subsequently, to the embryonic gut and circulation.

After week 9, the cellular components of the wall of the secondary yolk sac start to degenerate, and their function is subsumed into exchanges at the placental chorionic plate. With embryonic development of the midgut, the connection of the yolk sac to the embryo becomes attenuated to a slender and elongated vitelline intestinal duct. Both the yolk sac and its duct remain within the extraembryonic coelom (chorionic cavity) throughout gestation, located between the amnion and chorion as they fuse, near the placental attachment of the umbilical cord.

## Allantois

The allantoenteric diverticulum (see Fig. 10.10) arises early in the third week as a solid, endodermal outgrowth from the dorsocaudal part of the yolk sac into the mesenchyme of the connecting stalk. It soon becomes canalized. When the hindgut is developed, the proximal (enteric) part of the diverticulum is incorporated in its ventral wall. The distal (allantoic) part remains as the allantoic duct and is carried ventrally to open into the ventral aspect of the cloaca or terminal part of the hindgut (Fig. 9.9A). The allantois is a site of angiogenesis, giving rise to the umbilical vessels that connect to the placental circulation. The extraembryonic mesenchyme around the allantois forms the connecting stalk, which is later incorporated into the umbilical cord.

In the fetus, the allantoic duct, which is confined to the proximal end of the umbilical cord, elongates and thins. However, it may persist as an interrupted series of epithelial strands at term, in which case the proximal strand is often continuous at the umbilicus with the median

Fig. 9.9 A, A Longitudinal section of a conceptus showing the cavities associated with development. The amniotic cavity and yolk sac are both covered with extraembryonic mesoblast and are contained within the larger chorionic cavity, which is lined with extraembryonic mesoblast. The embryo is attached to the chorion frondosum by the connecting stalk into which the allantois projects. B, A longitudinal section of a conceptus at a later stage, showing the diminution of the chorionic cavity, expansion of the amniotic cavity, relative attenuation of the yolk sac and the structures that give rise to the umbilical cord.
intra-abdominal urachus; this, in turn, continues into the apex of the bladder.

## Amnion (chorio-amnion)

The original amniotic cells develop from the edges of the epiblast of the embryonic disc, which ultimately form the interface with the skin at the umbilical region. Between the tenth and twelfth weeks of pregnancy, the amniotic cavity expands until it makes contact with the chorion to form the chorio-amnion, an avascular membrane that persists to term. The amniotic membrane extends along the connecting stalk and forms the outer covering of the umbilical cord. After birth, the site of this embryonic/extraembryonic junction is important because the extraembryonic cell lines will die, causing the umbilical cord to degenerate and detach from the body wall. In cases of anomalous development of the ventral body wall, e.g. gastroschisis and exomphalos, the reflections of the amnion along the forming umbilical cord may be incomplete (see below).

The inner surface of the amnion consists of a simple cuboidal epithelium. It has a microvillous apical surface, beneath which is a cortical web of intermediate filaments and microfilaments. There are no tight junctional complexes between adjacent cells and cationic dyes penetrate between the cells as far as the basal lamina. The intercellular clefts present scattered desmosomes, but elsewhere the clefts widen and contain interlacing microvilli. These features are consistent with selective permeability properties. The epithelium synthesizes and deposits extracellular matrix into the compact layer of acellular stroma located beneath the basal lamina, as well as the basal lamina itself.

Towards the end of gestation, increasing numbers of amniotic cells undergo apoptosis. Apoptotic cells become detached from the amnion and are found in the amniotic cavity at term. The highest incidence is in weeks 40-41, independent of the onset of labour. Apoptosis may play a role in the fragility and rupture of the fetal membranes at term.

Human amniotic epithelial cells are thought to be pluripotent because they arise so early from the conceptus. They can be distinguished from the epiblast cells from day 8. Amniotic cells lack the MHC antigen and so the amnion can be exposed to the maternal immune system without eliciting a maternal immune response. Cultured human amniotic epithelial cells express a range of neural and glial markers, including glial fibrillary acidic protein, myelin basic protein, vimentin and neurofilament proteins, suggesting that these cells may supply neurotrophic factors to the amniotic fluid. They also appear to have a hepatocyte gene expression profile, showing albumin production, glycogen storage and albumin secretion in culture. In organ culture, they have been shown to secrete 30 -fold larger amounts of albumin than in monolayer culture, and to secrete $\alpha$-1-antitrypsin (Takashina et al 2004). Amnion is used in the repair of corneas after trauma and as a graft material for reconstructing vaginas in women with cloacal abnormalities.

## Prenatal changes to the chorio-amnion

At term, the surface area of the chorio-amnion is $1000-1200 \mathrm{~cm}^{2}$, with $30 \%$ overlying the placenta and the remaining $70 \%$ in contact with the decidua (Myatt and Sun 2010). There is a diminution of the decidual component of the chorion and an increase in chorionic apoptosis towards term at the supracervical site, overlying the cervical os, which encompasses the site of rupture (Chai et al 2013). The amnion and choriodecidua show varying degrees of separation over the putative rupture site; the mean rupture strength of the zone is $60 \%$ of the remaining membranes, associated with changes in collagen organization and increase in MMP-9 (Strauss 2013). Term vaginal delivery is associated with a three-fold increase in apoptosis in the chorion close to the rupture site, compared to fetal membranes from non-labour, elective caesarean delivery (Harirah et al 2012).

In preterm, premature rupture of membranes (PPROM), the chorion is reported to be thinner at all sites (Fortner et al 2014). The presence of bacteria in the chorion at term, ascending via the vagina, has been reported without concomitant chorio-amnionitis. However, chorioamnionitis rates are higher in preterm labour and this may be a contributing cause (Harirah et al 2012, Fortner et al 2014). Loss of chorio-amnion intracellular cytokeratins, which become downregulated in infection, is thought to make the amnion vulnerable to apoptosis, shear stress and rupture (Vanderhoeven et al 2014).

There is increasing evidence that infection and inflammation of the chorio-amnion is associated with prenatal changes to the developing brain, especially the cortex, periventricular white matter and the developing cerebral blood vessels (Harteman et al 2013, Roescher et al
2014). This association also extends to the neonatal period and postnatal gut maturation (Wynn and Neu 2012). Histologically confirmed chorio-amnionitis is associated with changes in cerebral blood flow soon after birth; male infants appear to be more affected than female (Koch et al 2014).

## AMNIOTIC FLUID

The amniotic fluid, or liquor amnii, provides a buoyant medium that supports the delicate tissues of the young embryo and allows free movement of the fetus up to the later stages of pregnancy. It also diminishes the risk to the fetus of injury from outside. Amniotic fluid is derived from multiple sources throughout gestation. These include secretions from amniotic epithelium, filtration of fluid from maternal vessels via the parietal decidua and amniochorion, filtration from the fetal vessels via the chorionic plate or the umbilical cord, and fetal urine and fetal lung secretions. In early pregnancy, diffusion from intracorporeal vessels via fetal skin provides another source. Once the gut is formed, fetal swallowing of amniotic fluid is a normal occurrence; the fluid is absorbed into the fetal circulation.

Amniotic fluid volume increases logarithmically during the first half of pregnancy, from less than 10 ml at 8 weeks' gestation to 30 ml at 22 weeks and 770 ml at 28 weeks. After 30 weeks, the volume may remain unchanged to 36 weeks. It decreases towards the expected delivery date, and volumes decrease sharply in post-term gestation, averaging 515 ml at 41 weeks (Beall et al 2007, Ross and Beall 2014).

Human fetal urine output from the metanephric kidney increases from $110 \mathrm{ml} / \mathrm{kg} /$ day at 25 weeks to almost $200 \mathrm{ml} / \mathrm{kg} /$ day at term; this corresponds to almost $1000 \mathrm{ml} /$ day. The rate of human fetal lung secretion has not been measured but is presumed to be in the range of $60-100 \mathrm{ml} / \mathrm{kg} /$ day near term (Callen 2008). Animal studies indicate that lung fluid production is about one-third that of urine production, and that half of the fluid leaving the lungs enters the amniotic fluid and half is swallowed (Beall et al 2007, Ross and Beall 2014).

It is estimated that human fetuses swallow up to $760 \mathrm{ml} /$ day of amniotic fluid near term, although this decreases in the days before delivery. The remainder of the amniotic fluid is thought to be absorbed via an intramembranous pathway directly across the amniotic cavity and fetal surface of the placenta into fetal blood vessels (Beall et al 2007, Ross and Beall 2014). Intramembranous flow is thought to reach $400 \mathrm{ml} /$ day at term (Callen 2008).

Amniotic fluid volume is estimated at routine antenatal ultrasound scans, despite some concerns about its objectivity (Beattie and Rich 2007, Callen 2008, Gilbert 2012); it may be expressed as an amniotic fluid index. A deficiency of amniotic fluid is termed oligohydramnios and absent amniotic fluid is anhydramnios. Oligohydramnios in the second or third trimester is usually the result of urinary tract malformations, e.g. bilateral renal agenesis or obstruction of the lower urinary tract, uteroplacental insufficiency or premature rupture of the membranes. The urachus may play a critical role in the resolution of oligohydramnios in lower urinary tract obstruction by acting as a fistula between the bladder and the amniotic space. The major concern with oligohydramnios at less than 20 weeks is the significant risk of pulmonary hypoplasia and neonatal death. A volume of amniotic fluid in excess of 2 litres is generally considered to be abnormal and constitutes polyhydramnios (see Fig. 14.5A). Maternal causes include cardiac and renal problems and diabetes mellitus, which causes fetal hyperglycaemia and polyuria. Fetal causes include reduced fetal swallowing due to congenital malformations, e.g. anencephaly; upper intestinal tract obstruction (oesophageal and duodenal atresia); compressive pulmonary disorders (congenital diaphragmatic hernia); and neuromuscular impairment of swallowing.

Amniotic fluid has, for many years, been regarded as a medium that physically supports the developing embryo and fetus. More recently, it has also been conceptualized as part of the embryonic and early fetal extracellular matrix, and its composition throughout pregnancy has been investigated (Tong et al 2009). Techniques for biochemical analysis have revealed similarities and differences between amniotic fluid and fetal umbilical cord blood and maternal serum. Although, early in development, amniotic fluid resembles blood plasma, it also demonstrates extremely low oxygen tension, reflecting the physiological placental hypoxia noted in the first trimester (Ross and Beall 2014, Jauniaux et al 2003). In the second and third trimesters, primary electrolytes are similar in amniotic fluid, umbilical cord blood and maternal serum, whereas glucose, cholesterol and some enzymes are markedly lower in amniotic fluid. Umbilical cord blood and maternal serum contain 8 and 12.5 times more protein than amniotic fluid, respectively (Tong et al 2009). More than 100 metabolites, including cortisol and a range
of cytokines, have also been detected in amniotic fluid; the concentrations of most cytokines differ from those in maternal blood and reflect the physiological status of the fetus (Tong 2013). Proteomic analysis of human amniotic fluid at 16-18 weeks has identified more than 800 proteins and peptides (Cho et al 2007). It appears that amniotic fluid may be acting as a pathway for the transport of signalling molecules to target cells. In animal studies, substances injected into the amniotic cavity were detected within the embryos within 2 minutes, demonstrating a rapid exchange with all fetal tissues (Tong 2013).

A number of clinical markers in amniotic fluid are used as predictors of fetal health, including interleukin (IL)-10, IL-6, cell free fetal DNA and cell free fetal mRNA. Genes and proteins specific to the fetal brain, lung, kidney, blood and heart have been identified in amniotic fluid, differential gene expression investigated in a range of trisomic fetuses and lung maturity predicted by measurement of lecithin, sphingomyelin and phosphatidylglycerol (Edlow and Bianchi 2012, Ross and Beall 2014). Bacterial species have been isolated from amniotic fluid, and microbial invasion of the amniotic cavity is considered a leading cause of preterm premature delivery (DiGiulio 2012). It is thought such bacteria access the amniotic cavity via the vagina and cervix, although many oral bacteria have also been identified, suggesting that a haematogenous route is also likely. The establishment of pathogenesis is influenced by microbial adhesion, biofilm formation, and immune evasion and the maternal and fetal immune systems (DiGiulio 2012).

## UMBILICAL CORD

The formation of the connecting stalk and the early formation of the umbilical cord are described in Chapter 10. The umbilical cord ultimately consists of an outer covering of flattened amniotic epithelial cells and an interior mass of mesenchyme of diverse origins (see Fig. 9.9). It contains two tubes of hypoblastic origin, the vitelline-intestinal and allantoic ducts, and their associated vitelline and allantoic (umbilical) blood vessels. The yolk stalk and continuing duct extend the length of the cord, whereas the allantoic duct extends only into its proximal part.

The mesenchymal core is derived from the somatopleuric extraembryonic mesenchyme covering the amniotic folds, splanchnopleuric extraembryonic mesenchyme of the yolk stalk (which carries the vitelline vessels and clothes the yolk duct), and similar allantoic mesenchyme of the connecting stalk (which clothes the allantoic duct and initially carries two umbilical arteries and two umbilical veins). These various mesenchymal compartments fuse and are gradually transformed into the loose connective tissue (Wharton's jelly) that characterizes the more mature cord. The tissue consists of widely spaced elongated fibroblasts separated by a delicate three-dimensional meshwork of fine collagen fibres, which contains a variety of hydrated glycosaminoglycans and is particularly rich in hyaluronic acid.

The vitelline and allantoic (umbilical) vessels, which are initially symmetrical, become modified as a result of changes in the circulation. The vitelline vessels involute, whereas most of the allantoic (umbilical) vessels persist. The right umbilical vein disappears but the two umbilical arteries normally remain. Occasionally, one umbilical artery may disappear; there is some correlation within structural anomalies, most often cardiac, in such cases. The vessels of the umbilical cord are rarely straight, and are usually twisted into either a right- or left-handed cylindrical helix. The number of turns involved ranges from a few to over 300. This conformation may be produced by unequal growth of the vessels, or by torsional forces imposed by fetal movements. Its functional significance is obscure; perhaps the pulsations and contractions of the helical vessels assist the venous return to the fetus in the umbilical vein.

Anomalies of the fetal anterior abdominal wall, such as exomphalos and gastroschisis, may affect the arrangement of the outer covering of amnion cells along the proximal end of the umbilical cord. Exomphalos arises from a failure of the lateral folds along the ventral surface of the embryo, resulting in failure of the normal embryonic regression of the midgut from the umbilical stalk into the abdominal cavity. The abdominal contents, including intestines and liver or spleen, covered by a sac of parietal peritoneum and amnion, protrude into the base of the umbilical cord. In gastroschisis, the insertion of the umbilical cord is intact and there is evisceration of the intestine through a small abdominal wall defect that is usually located to the right of the umbilical cord; this results in free loops of bowel in the amniotic cavity. Theories concerning the aetiology of this defect include abnormal involution of the right umbilical vein or disruption of the omphalomesenteric artery by ischaemia.

Mature umbilical vessels, particularly the arteries, have a strong muscular coat that contracts readily in response to mechanical stimuli. The outermost bundles pursue an interlacing spiral course, and when they contract, they produce shortening of the vessel and thickening of the media, with folding of the interna and considerable narrowing of the lumen. This action may account for the periodic sharp constrictions of contour, the so-called valves of Hoboken, which often characterize these vessels.

The fully developed umbilical cord is, on average, some 50 cm long and $1-2 \mathrm{~cm}$ in diameter. Its length varies from 20 to 120 cm ; exceptionally short or long cords are associated with fetal problems and complications during labour. A long umbilical cord may prolapse through the cervix into the vagina once the fetal membranes rupture and this may be exacerbated by conditions that prevent the fetal head from fully occupying the maternal pelvis, e.g. pelvic tumours (fibroids), ovarian cysts, placenta praevia and prematurity. Compression of the cord by the presenting part of the fetus, or an umbilical artery spasm, will lead to fetal hypoxia and death, if untreated. The risk of perinatal death rises as the interval from diagnosis to delivery increases. The treatment is either funic replacement (pushing the cord back above the fetal head) or, more commonly, immediate caesarean section, depending on factors such as fetal viability.

The distal end of the umbilical cord usually attaches in the central portion of the placenta, but in $0.2 \%$ of pregnancies, velamentous insertion is observed (i.e. into the membranes) and this may be associated
with vulnerability to injury and fetal haemorrhage. This is especially important if the placenta is low-lying, and may be associated with vasa praevia, in which case fetal blood vessels run across the internal os. Inadvertent rupture of the fetal vessels in spontaneous labour or at the time of amniotomy (artificial rupture of membranes to induce labour) will cause fetal haemorrhage and may prove fatal. Infection of the umbilical cord, funisitis, is associated with chorio-amnionitis and later neurodevelopmental outcomes (Roescher et al 2014, Buhimschi and Buhimschi 2012).

Recent studies have examined the optimal time for cutting the umbilical cord after delivery and found that early clamping is associated with neonatal anaemia and iron deficiency. Delayed clamping, defined as ligation of the umbilical cord 2-3 minutes after birth or when cord pulsation stops, reduces the prevalence of iron deficiency at 4 months of age and results in improved ferritin levels (Andersson et al 2011, McDonald et al 2013).

## Cell populations at gastrulation

## CHAPTER

## CONCEPTUS WITH A BILAMINAR EMBRYONIC DISC

At stage 6 , the conceptus is composed of the walls of three cavities: the large chorionic cavity is surrounded by a meshwork of trophoblast and developing villi, and lined with extraembryonic mesoblast. The chorion, trophoblast and extraembryonic mesoblast enclose the extraembryonic coelom and contain the much smaller amniotic cavity and yolk sac (see Fig. 9.1). These latter cavities abut at the embryonic bilaminar disc where the epithelial epiblast and visceral hypoblast are approximated. A fourth cavity, the allantois, will form as a hypoblastic diverticulum in stage 7. The 'bilaminar disc' commonly referred to in embryology texts does not yet possess the definitive layers of embryonic ectoderm and endoderm that will give rise to embryonic structures. Only the epiblast will give rise to the embryo; all other layers produced so far are extraembryonic. The amnion and chorion (and surrounding mesoblast) are part of the extraembryonic somatopleure, whereas the yolk sac, allantois and surrounding extraembryonic mesoblast constitute extraembryonic splanchnopleure. At the junctional zone surrounding the margins of the embryonic area, where the walls of the amnion and yolk sac converge, the somatopleuric and splanchnopleuric layers of extraembryonic mesoblast are continuous.

The terms epiblast and hypoblast are used to make the distinction between the earliest bilaminar disc layers and the later embryonic layers. Epiblast and hypoblast contain mixed populations of cells with little restriction, which establish the placental structures and extraembryonic tissues before the production of embryonic cell lines at gastrulation. The older terminology depicting three germ layers that give rise to the skin, gut lining and intervening tissues is thus incorrect for the bilaminar and trilaminar embryonic disc. The application and retention of this aged terminology for the early stages of embryology continue to cause confusion and inhibit the development of more pertinent descriptive language to describe these early events. The earliest three cell lineages, not layers, that give rise to the extraembryonic membranes and the embryo are trophoblast, hypoblast and epiblast; each expresses different lineage-specific genes for its establishment, maintenance and differentiation (Artus and Hadjantonakis 2012).

At early stage 6, the epiblast is producing extraembryonic mesenchyme from its caudal margin. With the appearance of the primitive streak, a process is begun whereby cells of the epiblast either pass deep to the epiblast layer to form the populations of cells within the embryo, or remain on the dorsal aspect of the embryo to become the embryonic ectoderm. Although human embryos do not form a 'gastrula' as such, the term gastrulation is used here to denote an early period of development during which significant rearrangements, migrations and folding of the early embryo occur. The primitive streak is the site of organizer cells analogous to those found in embryos that do undergo gastrulation. The appearance of the primitive streak therefore marks the beginning of a period when gross alterations in morphology and complex rearrangements of cell populations occur. During this time, the epiblast will give rise to a complex multilaminar structure with a defined craniocaudal axis. By the end of gastrulation, cell populations from different, often widely separated, regions of the embryonic disc will become spatially related and the embryonic shape will have been produced.

## Primitive streak and node

Seen from the dorsal (epiblastic) aspect, at stage 6, the embryonic disc appears elongated. The primitive streak is first seen in the caudal region of the embryonic disc at this stage as a collection of pluripotent cells, orientated along its long axis in the median position, conferring the future craniocaudal axis of the embryo (Figs 10.1-10.2). Although the future cranial and caudal regions of the embryo are well within the boundaries of the embryonic disc, it has become the practice to term

Fig. 10.1 A longitudinal section through an early conceptus. Ingression of mesoblast is occurring at the primitive streak and the notochord is ingressing via the primitive (Hensen's) node.

Fig. 10.2 A transverse section through the embryonic plate at the level of the primitive streak to show the early movement of mesoblast between the epiblast and underlying hypoblast.
the region of the disc closest to the streak 'caudal', and the region of the disc furthest from the streak 'cranial' or 'rostral'. With the development of the streak, the terms medial and lateral can be used. The relative dimensions of the primitive streak and the fates of the cells that pass through it change with the developmental stage. Thus, the streak extends half way along the disc in the stage 6 embryo, reaching its greatest relative length in stage 7 and its maximum length in stage 8 .

Formation of the primitive streak is induced by the underlying visceral hypoblast, which remains beneath the streak even at later stages.

The primitive streak may be considered to be generally homologous with the blastopore of lower vertebrates (e.g. amphibia), with the nodal region corresponding to the dorsal lip. Experiments clearly show the lip of the blastopore to be a dynamic wave front on which cells are carried into the interior to form the roof of the archenteron, a situation analogous to ingression through the node of the prechordal plate and endoderm. The primitive streak similarly may be considered analogous to the coapted, or fused, lateral lips of the blastopore, and the cloacal membrane and its immediate environs are considered analogous to the ventral lip of the blastopore.

At the primitive streak, epiblast cells undergo a period of intense proliferation, the rate of division being much faster than that of blastomeres during cleavage. Streak formation is associated with the local production of several cell layers, extensive disruption of the basal lamina, increase in adhesive plaques and gap junctions, synthesis of vimentin, and loss of cytokeratins by the emerging cells.

As the epiblast cells proliferate, two ridges are formed on each side of the primitive streak, which appears to sink between them. The lower midline portion of the streak is termed the primitive groove. The process by which cells become part of the streak and then migrate away from it beneath the epiblast is termed ingression.

The primitive node, or Hensen's node, is the most rostral region of the primitive streak. It appears as a curved ridge of cells similar in shape to the top of an old-fashioned keyhole. Cells ingressing from the ridge pass into the primitive pit (the most rostral part of the primitive groove), and then migrate rostrally beneath the epiblast. The primitive node has been recorded in all stage 7 human embryos; it produces axial cell populations, the prechordal plate, notochord, embryonic endoderm and the medial halves of the somites. Experimental removal of the node results in complete absence of the notochord and a failure of neurulation.

Recent studies on the dynamics of ingression at the primitive streak have shown movement of the underlying extracellular tissues as well as of the overlying cells. Re-examination of the processes of cell movement relative to the surrounding extracellular molecules in embryos has found that vertical and convergent extension motion patterns, previously thought to be limited to the epiblast, also occur in sub-epiblastic extracellular matrix fibrils of fibronectin (Zamir et al 2008, Szabó et al 2011).

## Position and time of ingression through the primitive streak

Studies of cell fate have shown that epiblast cells that will pass through the streak are randomly located within the epiblast layer before their ingression, and that epiblast fate is determined at or before the time of ingression through the streak, indicating that passage through the primitive streak is the most important factor for future differentiation.

The position and time of ingression through either streak or node directly affect the developmental fate of cells. Passage through the streak is specified according to position, e.g. via the node, or rostral, middle or caudal regions of the streak. Cells that ingress through the primitive node give rise to the axial cell lines, the prechordal mesenchyme and notochord, and to the endoderm and the medial halves of the somites. The rostral portion of the primitive streak produces cells for the lateral halves of the somites, whereas the middle streak produces the lateral plate mesoblast. The adjacent caudal portion of the streak gives rise to the primordial germ cells, which can be distinguished histologically and histochemically, and the most caudal portion of the streak contributes cells to the extraembryonic mesoblast until the somites are visible. A composite of the information on the position of ingression through the streak and node is shown in Figure 10.3. The epiblast cells that do not pass through the streak but instead remain within the epiblast population give rise to the neural and surface ectoderm of the embryo.

## Prechordal plate

The earliest cells migrating through the primitive node and streak give rise to both the embryonic endoderm and the notochord. The prechordal plate is first seen at stage 7. It has been defined as a localized thickening of the endoderm rostral to the notochordal process, although it is seen as a highly developed mesenchymal mass in contact with the floor of the neural groove, rostral to the notochordal process, rather than as an epithelial layer. The prechordal plate is a temporary collection of cells that underlies the neural plate during stage 9. It is composed of cells that are similar to, or larger and more spherical than, the ingressing endodermal cells (Müller and O'Rahilly 2003). In stage 8 embryos, the prechordal plate is up to eight cells deep and extends

Fig. 10.3 The predictive fates of the epiblast cell population at the time the primitive streak is present.
along the long axis of the embryonic disc. By stages 9 and 10, the cells at the lateral edge of the plate have begun to migrate laterally as free mesenchymal cells and the plate reduces in height to two cells deep. At stage 11, the migrating prechordal mesenchyme forms bilateral premandibular mesenchymal condensations and is no longer a median structure. The extent of prechordal cells remaining within the endoderm is not clear

## Notochord

The notochord, also called chordamesoderm, the head process or chorda, arises from epiblast cells of the medial part of the primitive node. It passes through several stages during development. The cells of the early notochordal process express myogenic markers transitorily as they migrate beneath the epiblast, but later they become epithelial, forming junctions and a basal lamina. The notochordal cells are intimately mixed with endodermal cells, as both cell lines ingress at the same time (see Figs 10.1-10.2; Fig. 10.4). In the stage 8 embryo, the ingressing notochordal cells remain in the midline along the cephalocaudal axis. They form a rostral part, which is composed of a cell mass continuous with the prechordal mesenchyme; a mid portion, in which cells are arranged in a tube with a central notochordal canal; and a caudal epithelial layer of cells, the notochordal plate, which is contiguous with the embryonic endoderm and forms a roof to the secondary yolk sac. There is a transitory opening between the primitive node (and amniotic cavity) and the secondary yolk sac called the neurenteric canal (so named because its upper opening is in the future caudal floor of the neural groove, and its lower opening is into the archenteron, which is the primitive gut); it may still be found at stage 9, and the site of the neurenteric canal can be recognized in stage 10 embryos. The ingression of notochordal cells at the primitive node is matched by specification of the overlying neural ectodermal cells, and the notochordal plate is thus matched in length by the future neural floor plate. Both the notochord and the region of the floor plate of the neural tube may arise from a common progenitor cell. The early notochord is important for the maintenance and subsequent development of the neural floor plate and the induction of motor neurones. Removal of the notochord results in elimination of the neural floor plate and motor neurones, and expression of sensory cell types.

## Caudal eminence

From stages 9 and 10, the region between the neurenteric canal and the cloacal membrane (see below), including the primitive streak, is termed the caudal eminence. It consists of the caudal region of the trunk, composed of mesenchyme derived from the primitive streak and epiblast, and covered with surface ectoderm. Whereas ingression of cells through the primitive streak gives rise to the prechordal and notochordal plates, and cells rostral to the neurenteric canal (see below), the cells of the caudal eminence arise from local division of a mesenchymal population positioned caudal to the neurenteric canal. The caudal portions of the notochord, which form later in development when secondary neurulation processes begin, arise from these cell populations, sometimes termed the caudoneural hinge or junction. This tissue is thicker and

Fig. 10.4 A, The unfolded embryo, showing the disposition of the intraembryonic coelom within the embryonic disc. The lines across the embryo show the level of transverse sections through the disc shown in B-D. B-D, Transverse sections through the disc at the points indicated in $A$. E, A longitudinal section through the disc.
more advanced in differentiation than the tissues derived from the early primitive streak.

## Embryonic endoderm

Before ingression, definitive embryonic endoderm cells are found in the epiblast, located at the primitive node and rostral primitive streak. In the mouse, the endodermal cells lie beneath the epiblast mainly in the midline, interspersed with presumptive notochordal cells, forming the roof of the secondary yolk sac. The ingressing endoderm displaces the visceral hypoblast into the secondary yolk sac wall by a dramatic territorial expansion that is brought about by a change in the morphology of the cells (see Figs 10.1-10.2, 10.4). The putative endoderm cells are cuboidal epithelial cells within the node but they become squamous in the endoderm layer; this could result in a four-fold increase in the surface area covered by the cells. A complete replacement of the visceral hypoblast has not yet been confirmed and there may be a mixed population of cells in the endodermal layer in the early stages. Ingression of cells through the streak and node in the human is apparent at stage 6, and, by stage 7 , a population of endoderm and notochord cells is present beneath the epiblast (see Figs 10.1-10.2, 10.4). During stages $6-11$, the midline roof of the secondary yolk sac becomes populated mainly by the notochordal plate, which remains in direct lateral continuity with the endodermal cells. It is not until stage 11, after the definitive notochord is formed, that the endoderm cells can join across the midline. For the developmental fate of the embryonic endoderm, see Figure 12.3.

## Intraembryonic mesoblast (mesenchyme)

Epiblast cells ingress through the cranial and middle parts of the streak individually, maintaining their apical epithelial contacts while elongating ventrally. The cells become flask-shaped, with thin, attenuated apical necks and broad basal regions. Their basal and lateral surfaces form lamellipodia and filopodia, and the apical contact is released. The cells are now free mesoblast cells, their fibroblastic, stellate morphology reflecting the release from the epithelial layer. Once through the streak, the cells migrate away from it, using the basal lamina of the overlying epiblast and extracellular matrix as a substratum. The cells contact one another by filopodia and lamellipodia, with which they also contact the basal lamina. Gap junctions have been observed between filopodia and cell bodies. With the appearance of the mesoblast, spaces form between the epiblast and visceral hypoblast that are filled with extracellular matrix rich in glycosaminoglycans. The migrating mesoblast has a leading edge of cells that open up the migration routes, and the following cells seem to be pulled along behind in a coordinated mass movement. Mesoblast formed by cells migrating through the primitive node and rostral primitive streak will form the paraxial mesenchyme, whereas cells migrating through the middle to caudal streak will form the lateral plate mesenchyme (see Figs 10.1-10.2).

## Embryonic ectoderm

When the ingression of cells through the primitive streak is completed, the epithelial cells remaining in the epiblast layer are termed embryonic
ectoderm cells. This layer still contains a mixed population because both surface ectoderm cells and neural ectoderm cells are present. It is believed that these cells were originally in the cranial half of the disc when the primitive streak first appeared, at which time the neural-fated cells were closest to the streak, and the surface ectoderm cells were most cranial (see Fig. 10.3). The process of primary neurulation relocates most of the neuroepithelial cells (see below).

## Primordial germ cells

Although early studies on human embryos have reported primordial germ cells, and described their development from the early endoderm of the yolk sac and allantois, it is now clear from animal experimentation that the primordial germ cells arise from epiblast ingressing at the caudal end of the primitive streak (see Fig. 10.3). It is not known whether these cells originate from rostral regions that migrate to the streak or from local caudal regions. Extremely early segregation of the germ cells, when the epiblast layer consists of only $10-13$ cells, has been demonstrated. It has been suggested that the primordial germ cells remain sequestered in the extraembryonic mesenchyme at the caudal end of the embryo until the embryonic endoderm has been produced and gastrulation completed, and that they start to migrate along the allantoic and hindgut endoderm as the folding of the embryo begins. The formation of the tail fold brings the proximal portion of the allantois within the body, so reducing the final distance over which the cells migrate to the genital ridges. Further development of the germ cells is described in Chapter 72.

## TRILAMINAR DISC

Although the stage 8 embryo is termed a trilaminar disc, the concept of three epithelial layers forming a trilaminar disc is incorrect; the middle, mesoblast, layer is several cells thick with intervening extracellular matrix. The embryo at this stage, approximately 23 days after ovulation, is pear-shaped, and broader cranially than caudally (Fig. 10.5). The upper epiblast cells are tall and form a pseudostratified columnar epithelial layer with a basal lamina, except at the primitive streak, where the cells are ingressing to form the other layers. The more centrally placed epiblast will give rise to neural ectoderm (neurectoderm) and the more laterally placed epiblast will give rise to surface ectoderm. The future neural ectoderm is seen as a neural plate that matches the length of the notochordal plate directly beneath, being slightly wider near the prechordal plate. The lower embryonic endoderm, a simple squamous layer with a developing basal lamina, is not always complete at this stage, particularly in the midline caudal to the prechordal plate, which is still occupied by the notochordal process or plate.

The middle, mesoblast, layer is composed of free cells migrating cranially, laterally and caudally from the primitive streak (see Fig. 10.4). They produce extracellular matrix, which separates the epiblast and endoderm of the embryonic area and permits their passage. The streams of mesoblast extend between the epiblast and endoderm over all of the disc area except cranially at the buccopharyngeal membrane (where the endoderm and ectoderm become apposed once the prechordal mesenchyme has migrated laterally), and caudally at the cloacal membrane (a patch of thickened endoderm, similar to the buccopharyngeal membrane, caudal to the primitive streak). The mesoblast on each side of the notochord is termed paraxial mesenchyme.

Fig. 10.5 The extent and shape of the neural plate in an unfolded embryo.

Mesoblast that passes in a cranial direction flanks the notochordal plate and passes around the prechordal plate region, converging medially to fuse in the midline beyond its cephalic border. This transmedian mass, in which the heart and pericardium will develop, is initially termed the cardiogenic mesoblast. It fuses with the junctional zone of extraembryonic mesoblast around the extreme cephalic margin of the embryonic area. This region will eventually form the septum transversum and primitive ventral mesentery of the foregut. Mesoblast passing laterally from the streak soon approaches and becomes confluent with the extraembryonic mesoblast around the margins of the disc, i.e. at the junctional zone where the splanchnic and somatic strata of extraembryonic mesoblast merge. Mesoblast that streams caudally from the primitive streak skirts the margins of the cloacal membrane and then converges towards the caudal midline extremity of the embryonic disc to become continuous with the extraembryonic mesoblast of the connecting stalk. It is unclear if the lower layer of the cloacal membrane consists of visceral hypoblast, like the more cranial primitive streak (the hypoblast is necessary for maintaining the streak), or if it is replaced by migrating embryonic endoderm, or if there is a region for ingression of endoderm at the caudal end of the streak, similar to the node cranially.

Still further caudally, the embryonic disc develops a midline diverticulum adjacent to the cloacal membrane. This diverticulum, the allantois, projects into the extraembryonic connecting stalk (see Figs 9.9, 10.4; Fig. 10.6). There is little information about which cells form the allantois, i.e. whether it is composed of visceral hypoblast, parietal hypoblast or embryonic endoderm. The allantois later develops a rich anastomotic blood supply around it, in the manner of the yolk sac.

The generation of cells at the primitive node produces midline endoderm, notochord and the floor plate of the future neural tube. As the notochord grows and elongates, there is a matched growth of neural floor plate cells until both cell lines extend to the buccopharyngeal membrane. The epiblast lateral to the midline contains both future surface and neural ectoderm. The latter becomes arranged between the primitive node and buccopharyngeal membrane; cells destined to be in the neural plate lie medially, and those destined for the neural crest lie along the junction between the neural plate and surface ectoderm (see Fig. 10.5). A smaller subpopulation of neuronal cells, the ectodermal placodes, are arranged either close to the neural crest or within the rostral limit of the neural plate itself.

## FOLDING OF THE EMBRYO

In a diagrammatic representation of the trilaminar disc prior to folding and viewed from the ectodermal aspect, all of the future external surface of the body is delimited (see Fig. 10.5). The ends of the gut tube are specified on the ectodermal surface at the buccopharyngeal and cloacal membranes, which are regions where the ectoderm and underlying endoderm are apposed without intervening mesoblast. In the midline between these membranes, proliferation of the neural ectoderm matches the underlying migration of mesoblast from the primitive streak, so that the neural plate covers the paraxial mesenchyme on each side of the notochord (see Fig. 10.6E). As the paraxial mesenchyme segments, the formation of the epithelial somites elevates the edges of the neural plate and initiates primary neurulation (see Fig. 10.6F; Figs 10.7-10.8). The neural plate itself undergoes concurrent morphological changes. The most medial cells become wedge-shaped, forming the neural groove. Further elevation of the edges of the neural groove permits fusion of the neuronal populations in the dorsal midline to form the neural tube. The surface ectoderm forms the putative dorsal epidermis (see Figs 10.6G, 10.7-10.8). Cells at the lateral edge of the neural plate, termed neural crest cells, remain as a linearly arranged mesenchymal population between these two epithelia. Fusion of the neural tube begins in the future rhombencephalic region of the embryo and proceeds rostrally and caudally to about the level of somite 29. Neurulation is described further in Chapter 17. A population of neural epithelial cells remain within the surface ectoderm; at this stage they are termed ectodermal placodes.

The representation of a person on the trilaminar disc (Fig. 10.9) shows, to some extent, the way in which the positions of the main body structures are already specified in the unfolded embryo. Ectoderm lateral to the neural plate and the paraxial mesenchyme will form structures within the back. The portion of the disc between the buccopharyngeal membrane and the edge of the disc will become the ventral thoracic wall and the ventral abdominal wall cranial to the umbilicus. Further caudally, midway along the neural axis, the lateral portions of the disc will become the lateral and ventral abdominal walls of the

Fig. 10.6 Head and tail (A-D) and lateral (E-G) folding of the embryo. A-D, Median sagittal (longitudinal or axial) sections through the embryonic disc at successive stages; the relative positions of the buccopharyngeal and cloacal membranes have been maintained; thus, the movement of the most rostral and caudal portions of the disc can be followed. As these portions of the disc move ventrally, the initially wide-open yolk sac becomes constricted and fore- and hindgut divisions can be seen; the midgut is that region remaining in wide connection to the yolk sac. E-G, Transverse sections through the midpoint of the embryonic disc at successive stages to illustrate lateral folding that occurs as neurulation proceeds.
trunk. The portion of the disc beyond the cloacal membrane will form the ventral abdominal wall caudal to the umbilicus. The circumference of the disc, where the embryonic tissue meets the extraembryonic membranes, will become restricted to the connection between the ventral abdominal wall and the umbilical cord, i.e. the umbilicus.

Head folding begins at stage 9 , when the fusing cranial neural plate rises above the surface ectoderm and the portion of the disc rostral to the buccopharyngeal membrane (which contains the cardiogenic mesenchyme) moves to lie ventral to the developing brain (see Fig. 10.6). The prosencephalon and buccopharyngeal membrane are now the most rostral structures of the embryo. The previously flat region of endoderm, which may contain cells from the prechordal plate, is now modified into a deep tube, the primitive foregut. Tail folding can be seen in stage 10 embryos, when the entire embryo comes to rise above the level of the yolk sac. Similar movement of the part of the disc caudal to the cloacal membrane results in its repositioning ventral to the neural plate. Generally, as the embryo rises above the edges of the disc, the lateral regions of the disc are drawn ventrally and medially, contributing to the lateral folding of the embryo.

## FORMATION OF THE INTRAEMBRYONIC COELOM

At and just before stage 9 (before formation of the head fold), vesicles appear between the mesenchymal cells cranial to the buccopharyngeal membrane and within the cranial lateral plate mesenchyme. At the periphery of the vesicles, the mesenchymal cells develop junctional complexes and apical polarity, and form an epithelium. The vesicles become confluent to form a horseshoe-shaped tube, the intraembryonic coelom, which extends caudally to the level of the first somite and laterally into the lateral plate mesenchyme towards the extraembryonic mesenchyme. The lateral plate mesenchyme thus develops somatopleuric coelomic epithelium subjacent to the ectoderm, and a splanchnopleuric coelomic epithelium next to the embryonic endoderm (see Fig. $12.2 \mathrm{C}(\mathrm{iv})$ ). At this stage, the intra- and extraembryonic coeloms do not communicate.

During development of the head fold, the morphological movements that organize the foregut and buccopharyngeal membrane have a similarly profound effect on the shape of the intraembryonic coelom.

The midline portion of the originally flat, horseshoe-shaped coelom moves ventrally, leaving the caudal arms of the horseshoe in their original position. In this way, the midline part of the coelom, which was originally just rostral to the buccopharyngeal membrane, comes to lie ventral to the foregut (caudal to the buccopharyngeal membrane), and the two lateral extensions of the coelom pass close to the lateral walls of the foregut on each side. The caudal portions of the coelom (the two arms of the horseshoe), which, in the unfolded disc, communicated laterally with the extraembryonic coelom, turn $90^{\circ}$ to lie lateral to the gut, and communicate with the extraembryonic coelom ventrally.

Compartments of the coelom that will give rise to the body cavities later in development can already be seen. The midline ventral portion, caudal to the buccopharyngeal membrane, becomes the pericardial cavity. The canals lateral to the foregut (pericardioperitoneal canals) become the pleural cavities and the uppermost part of the peritoneal cavity. The remaining portion of the coelom becomes the peritoneal cavity. By stage 11, the intraembryonic coelom within the lateral plate mesenchyme extends caudally to the level of the caudal wall of the yolk sac. The intra- and extraembryonic coeloms communicate widely on each side of the midgut along the length of the embryo from the level of the fourth somite (Fig. 10.10).

In the early embryo, the intraembryonic coelom provides a route for the circulation of coelomic fluid and, with the beating of the heart tube, functions as a primitive circulation that takes nutritive fluid deep into the embryo until it is superseded by the blood vascular system. The coelomic channel, and the primitive circulation that passes through it, is of paramount importance up to stage 13 . Whereas the superficial tissues of the embryo can receive nutrients via the amniotic sac and yolk sac fluids, the deeper tissues are, until the formation of the coelom, under conditions similar to those found in tissue culture. However, from stage 10, exocoelomic fluid, propelled by the first contractions of the developing heart, is brought into contact with the deeply placed mesenchyme. This early 'circulation' ensures that an adequate supply of nutrients reaches the rapidly increasing amount of embryonic tissue, and meets most of the requirements of the deeper mesenchymal derivatives. From stage 12, the endothelial system expands and fills rapidly with plasma, which passes across the locally thinned coelomic epithelium into the large hepatocardiac channels that project into the pericardioperitoneal canals at the level of the seventh somite.

Fig. 10.7 Scanning electron micrographs of rat embryos at the time of neurulation. A, Ventral view, showing the neural fold (NF), and the heart $(H)$, with the somatopleuric pericardial membrane and surface ectoderm removed; the arrow indicates the entrance to the foregut via the cranial intestinal portal. B, Dorsolateral view; the arrows indicate the extent of rostral (to the right) and caudal (to the left) neural tube formation. (Photographs by P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)

Fig. 10.8 A human embryo at stage $10,2.1 \mathrm{~mm}$ long, with nine somites: right lateral and dorsal aspects. Nearly all the yolk sac and the caudal amnion have been excised.

Fig. 10.9 A representation of a person on the flat embryonic disc. The position of the central nervous system has been matched to the dimensions of the neural plate, and the position of the heart in the thorax to the position of the pericardial coelom. The limbs, although represented in this diagram, are not present on the disc at this stage. The usefulness of this diagram lies in its illustration of the extent of the anterior body wall both rostral to the buccopharyngeal membrane and caudal to the cloacal membrane. The future dorsal regions of the body are found medially on the disc, while the ventral regions of the body are situated laterally and peripherally on the disc. After head and tail folding and lateral folding, the peripheral edge of the disc becomes constricted as the edge of the umbilicus.

In spite of the importance of the coelom in defining the body cavities, and of the coelomic epithelium in the production of the major mesenchymal populations of the trunk (Streeter 1942, Langemeijer 1976, O'Rahilly and Müller 1987) (see Fig. 12.2), until recently the overall contribution of the coelom and its epithelium to the embryo has received relatively little attention (Carmona et al 2013). The coelom is a single, tubular organ that may be compared to the neural tube, in that it possesses a specialized wall that encloses a cavity. Like neural ectoderm, proliferating coelomic epithelium is a pseudostratified columnar epithelium with an inner germinal layer, from which cellular progeny migrate. After the germinal phase, both epithelia ultimately form the lining of a cavity, ependyma for the neural epithelium, and mesothelium for the coelomic epithelium. Coelomic epithelium, like neural epithelium, produces cells destined for different fates from different sites and at different developmental times. Coelomic cells are like the neural epithelium, in that they have apical epithelial specializations and tapering basal processes that are in direct contact with the underlying mesenchyme, without an intervening basal lamina. The possibility of the tapering processes forming directional signals for migrating progeny, similar to the radial glia of the neural tube, has not been examined.

## EMBRYONIC CELL POPULATIONS AT GASTRULATION

After gastrulation, the cells of the embryo contribute to two fundamental types of tissue, namely: epithelial and mesenchymal. Differentiation of specialized circulating blood cells and other cell types occurs in sequence. Embryonic and fetal cell types are replaced later in development or after birth.

## Epithelia

Epithelial populations in the embryo have many of the morphological characteristics of differentiated epithelia, i.e. they are composed of sheets of closely packed, polarized cells, with narrow intercellular clefts containing minimal extracellular material, and a developed basal

Fig. 10.10 A, An early stage in development of a human blastocyst. B, A blastocyst sectioned through the longitudinal axis of an embryo, showing the early formation of the allantois and the connecting stalk. C, A longitudinal section of an embryo at a later stage of development; the pericardial cavity can be seen at the most rostral part of the embryonic area. $\mathbf{D}$, A longitudinal section of an embryo at a later stage, showing formation of the head and tail folds, the expansion of the amnion and the delimitation of the umbilicus. $\mathbf{E}, \mathrm{A}$ transverse section along the line $\mathrm{a}-\mathrm{b}$ in $\mathbf{D}$; observe that the intraembryonic coelom communicates freely with the extraembryonic coelom. $\mathbf{F}$, A longitudinal section of an embryo at a later stage, showing full expansion of the amniotic cavity and the umbilical cord.
lamina containing specific proteins synthesized by the epithelium itself. The cells usually show juxtaluminal lateral surface specializations, such as desmosomes, tight junctions, gap junctions, and so on, and specializations of the apical surface, such as microvilli or cilia.

Epithelial polarity factors establish the extent of the apical, lateral and basal domains of the individual cells forming an epithelium. Three main control pathways have been identified in maintaining apicobasal polarity (St Jonston and Sanson 2011). The apical domain is specified by the Crumbs transmembrane protein; Baz/PAR-3 specifies the position and extent of the intercellular junction; and Scribble restricts the size of the junctional domains. Once established with an underlying basal lamina, the basal surface displays integrins. Changes in the morphology of an epithelial sheet will involve relative changes in the apical, lateral and basal domains of all cells. Planar polarity of epithelia is driven by intercellular cortical actin and myosin. Epithelial cells are contiguous via actomyosin contractile networks, which contact the lateral cell membrane through E-cadherin adhesion (Gorfinkiel and Blanshard 2011). Wnt/planar cell polarity signalling pathways are involved in these epithelial morphogenetic movements and also in orientated cell division which occurs in epithelial sheets (Tao et al 2009).

Embryonic epithelia differ from those in the fetus and adult. Two distinct types can be identified. Early germinal epithelia, which give rise to epithelial or mesenchymal populations of the embryo and confer
their early patterning are termed organizers, e.g. the primitive streak. Later germinal epithelia give rise to system-specific progenitor populations, e.g. the ventricular zone of the neural tube. All epithelia other than special germinal epithelia divide to produce embryonic growth throughout development and may retain stem cells that will divide throughout life.

Characteristically, epithelia clothe internal and external surfaces as simple or compound cellular sheets that separate phases of differing composition (e.g. the external environment and the subepithelial tissue fluids; intravascular and extravascular fluids, and so on). Traffic of materials in the intercellular clefts is limited. Traffic occurs across the cells because their limiting membranes, which function as energy-dependent selective barriers, enhance the passage of some materials and impede the passage of others.

## Mesenchyme

The terms mesoblast and mesenchyme are used in this text in a specific manner and are not interchangeable. Previously, cells forming a population between the epiblast and hypoblast were termed mesoderm and, more recently, mesenchyme. The terms primary and secondary mesenchyme have been used to distinguish between those cells that arise from ingression through the primitive streak and those that arise from
neural crest ingression, respectively. Primary mesenchymal cells revert to epithelia at their destinations. However, whereas some primary mesenchymal cells may become epithelial within a short timeframe, e.g. somites and lateral plate, other cells may transform later, e.g. the epithelium lining blood vessels. To address these terminological conflicts, the mixed population of epiblast cells that ingress through the primitive streak and come to lie between the epiblast and embryonic endoderm is termed mesoblast until the cells have migrated to their final position, at which time the populations of mesenchyme can be identified and their fates inferred.

Mesoblastic and mesenchymal cells have no polarity. They form junctional complexes, which are not exclusively juxtaluminal, and they produce extracellular matrix molecules and fibres from the entire cell surface. Mesenchymal populations are formed from a range of germinal epithelia and by proliferation of mesenchymal cells directly, and occupy all the regions between the various epithelial layers described above The term mesoderm is reserved for the coelomic epithelia that later form mesothelia.

Mesenchymal cells support epithelia throughout the developing body, both locally where they contribute to the basement membrane and form the lamina propria and smooth muscle of tubes, and generally where they differentiate into connective tissue. Specific mesenchymal populations control the patterning of local regions of epithelium (e.g. the zone of polarizing activity on the postaxial limb border posterior to the apical ectodermal ridge).

## Extracellular matrix

The space beneath epithelia and between mesenchyme cells is filled with extracellular matrix; both epithelial and mesenchymal cells synthesize extracellular matrix molecules and their receptors. Epithelial cells produce a two-dimensional basal lamina, which contains a variety of matrix molecules, including laminin, fibronectin, type IV collagen and various proteoglycans. The particular molecules can vary during development according to spatial and temporal patterns, resulting in changes in the behaviour of the underlying mesenchymal cells (e.g. in patterning of the basal regions of the skull). Mesenchymal cells produce extracellular matrix molecules in three dimensions. Those adjacent to an epithelial layer will connect with its basal lamina, forming a basement membrane that secures the epithelial layer to the underlying tissue. Cells deep within a mesenchymal population may synthesize matrix molecules (fibrillar or granular) to separate cells locally, open up migration routes or leave information within the matrix to act on cell populations passing at a later time.

Molecules of the extracellular matrix are complex; they include more than 19 individual types of collagen (some of which are capable of being individually spliced to give more than 100 variants), proteoglycans and glycoproteins (which come in a wide variety of forms, with and without binding proteins), and elastic fibres (see Ch. 2). Hyaluronic acid, a glycosaminoglycan, has a vast capacity to bind water molecules and so create and structure the space between the mesenchymal cells, thereby producing much of the overall shape of an embryo. Experimental removal of hyaluronic acid prevents the formation of cell migration
routes, removes the support for overlying epithelia, and disrupts the normal branching of glandular systems.

Fibronectin deposited extracellularly along a migration pathway will affect cells that touch it later, causing realignment of their intracellular actin filaments and thus of their orientation; it also induces cell migration. The receptors for extracellular matrix molecules such as fibronectin and laminin were originally termed integrins because they integrate extracellular proteins and intracellular cytoskeletal elements (via $\alpha$ and $\beta$ subunits that span the cell membrane), allowing them to act together; the binding preference of integrins depends on their combination of subunits and environmental conditions.

It is known that extracellular matrix is structured rather than random. Epithelial and mesenchymal cell populations can structure the space around them by secretion of particular matrix molecules or growth factors, which, in turn, can organize the cells that contact them. Cellmatrix interactions and matrix-cell interactions control the position of migration routes and cellular 'decisions' to migrate or to begin to differentiate. Matrix molecules propagate developmental instructions from cell to cell and form a far-reaching four-dimensional (spatial and temporal) mechanism of communication. Mapping the molecular pathways and the biomechanical processes that underlie morphogenesis, the dynamic epigenetics of early mesenchyme cells and their secreted threedimensional extracellular matrices, and the mechanisms by which the stiffness of the surrounding matrix affects the actions of the cells within it and the specific deposition of fibrillary proteins creates tissue boundaries and zones of tension, are all the subject of ongoing research (e.g. Davidson et al 2010, Loganathan et al 2012).

## Transition between epithelial and mesenchyme states

Transformations of cell morphology from epithelium to mesenchyme, and vice versa, occur in specific places and times during development, and can be seen as ways of dispersing germinal centres with increasing restriction. The first epithelial-to-mesenchyme transition occurs at the primitive streak, a germinal epithelium that confers embryonic specification on the resultant mesoblast population. The mesoblast so formed migrates and the cells undergo mesenchyme-to-epithelial transitions when they reach their final destinations. Series of small epithelial germinal centres, the somites, are formed, as are larger, more extensive, germinal epithelial sheets that line the walls of the intraembryonic coelom. The coelomic walls, especially those derived from somatopleure and splanchnopleure, form germinal epithelia that give rise to the major mesenchymal populations that form the viscera. The early epithelial somites undergo further local epithelial-to-mesenchyme transitions to form the sclerotomes, and subsequently form several germinal epithelia in the epithelial plate of each somite. Later mesenchyme-toepithelium transitions are not associated with the formation of germinal epithelia; the most common involve the transition of mesenchyme into the endothelium of the vascular system. The nephrons of the mesonephric and metanephric systems also form from mesenchyme-toepithelial transition.

## Embryonic induction and cell division

## compre 11

## EMBRYONIC INDUCTION AND CELL DIVISION

The stages of genomic activity that unfold in the fertilized zygote from cleavage onwards are not yet fully elucidated. An admittedly simplistic but useful approach likens developmental processes to a series of binary choices (see Fig. 8.1), the first being the choice between trophoblast and inner cell mass, which specifies if the future tissue will be placenta and fetal membranes or embryo.

Bioinformatic databases use embryological ontologies wherein the lineage of organs and tissues to be retraced to the earliest time (see Commentary 2.1). They provide a temporal and spatial framework against which the sequential activation of genes preceding changes in cell and tissue morphology can be matched. They also provide a means of viewing all of the complex partonomy, lineage data and temporal information occurring within embryos within a specific timeframe and of linking these to adult anatomical tissue types. As our knowledge of the complexity of early developmental events increases, ontological databases will assist the correlation of embryological information: current limitations are discussed in Bard (2012).

Our knowledge of the early events that occur in a range of mammalian species and our interpretation of the significance of particular sequences of gene expression is limited. The upregulation of early genes appears to reflect the time period of implantation. In the mouse, implantation occurs one day after blastocyst formation, thus genes relevant to implantation are expressed early, whereas in cattle, implantation occurs after 14 days, by which time gastrulation has occurred and neurulation has been initiated (Oron 2012).

Within the developing blastocyst, the position of cells relative to each other leads to epigenetic changes. The acquisition of cell polarity is fundamental, because this specifies apical and basolateral domains, cell surface specializations, the position and nature of cell:cell junctions and the concomitant positioning of intracellular organelles and cytoskeletal elements, which in turn leads to the location of future deposition of extracellular proteins. The two cell phenotypes, epithelial and non-epithelial cells, are specified during cleavage and early compaction within the zona pellucida. All relevant genes required to maintain these cell shapes and behaviours are upregulated at these very early stages. During the formation of trophoblast, hypoblast (primitive endoderm) and epiblast, the cells respond locally to their environment, specifically to other cells that are positioned lateral and basal to them. The genes operating at these early times in the mouse embryo are given in Takaoka and Hamada (2012).

Cell populations within the embryo interact to provide the developmental integration and fine control necessary to achieve tissue-specific morphogenesis. In the early embryo, such interactions may occur only if particular regions of the embryo are present, e.g. signalling centres or organizers. As the embryo matures, some interactions tend to occur between adjacent cell populations, e.g. epithelium and mesenchyme, and later between adjacent differentiating tissues, e.g. between nerves and muscle, or between muscle and skeletal elements. The interactions between adjacent epithelia and underlying connective tissue continue throughout embryonic and fetal life and extend into postnatal life. In the adult, these interactions also permit the metaplastic changes that tissues can undergo in response to local environmental conditions.

Tissue interactions result in changes or reorganization of one or both tissues, which would not have occurred in the absence of the tissue interactions. The process of tissue interaction is also called induction, i.e. one tissue is said to induce another. The ability of a tissue to respond to inductive signals is called competence, and denotes the ability of a cell population to develop in response to the environments present in the embryo at that particular stage. After a cell population has been induced to develop along a certain pathway, it will lose competence and become restricted. Once restricted, cells are set on a particular pathway of development; after a number of binary choices
(further restrictions), they are said to be determined. Determined cells are programmed to follow a process of development that will lead to differentiation. The determined state is a heritable characteristic of cells and is the final step in restriction. Once a cell has become determined, it will progress to a differentiated phenotype if the environmental factors are suitable.

The process of determination and differentiation within embryonic cell populations is reflected by the ability of these populations to produce specific proteins. Primary proteins (colloquially termed housekeeping proteins) are considered essential for cellular metabolism, whereas proteins synthesized as cells become determined, those specific to the state of determination, are termed secondary proteins; for example, liver and kidney cells, but not muscle cells, produce arginase. Fully differentiated cells produce tertiary proteins, which no other cell line can synthesize, e.g. haemoglobin in erythrocytes. The range of housekeeping, regulatory, and tissue-specific proteomes in adult cells is presented in the Human Protein Atlas (www.proteinatlas.org).

As populations of cells become progressively determined, they can be described within a hierarchy of cellular development as transiently amplifying cells, progenitor cells, stem cells and terminally differentiated cells.

Transiently amplifying cells Transiently amplifying cells undergo proliferative cell mitosis and produce cells that are equally determined. At some stage, and as a result of an inductive stimulus, these cells will enter a quantal cycle that culminates in a quantal mitosis. This will result in an increase in the restriction of their progeny, which continue to undergo proliferative mitoses at a progressive level of determination. The quantal mitosis corresponds to the time of binary choice when the commitment of the progeny is different from that of the parent.

Progenitor cells Progenitor cells are already determined along a particular pathway. They may individually follow that differentiation pathway, or may proliferate and produce large numbers of similarly determined progenitor cells that subsequently differentiate; neuroblasts or myoblasts are examples of progenitor cells.

Stem cells Either individually or as a population, stem cells can both produce determined progeny and reproduce themselves (see Commentary 1.2). It is generally believed that stem cells undergo asymmetric divisions, in which one daughter cell remains as a stem cell, while the other proceeds along a differentiation pathway; in marked contrast, proliferative cell division may be symmetrical, producing derived cells with an identical determination. Human embryonic stem cells (hESCs) are pluripotent cells that can be derived from the inner cell mass of human blastocysts in vitro; or obtained surplus to in vitro fertilization fertility programmes; or created from oocytes donated and fertilized for that purpose. Although not yet achieved, it is hoped that hESCs can be coaxed down particular pathways under appropriate pharmaceutical conditions to produce differentiated cells that will be effective in reversing some degenerative diseases (e.g. dopamine-producing neurones for Parkinson's disease, insulin-producing islet cells for diabetes), or to replace acutely damaged tissues (e.g. motor neurones for acute spinal cord injury, cardiomyocytes in acute myocardial infarction). Proof of principle has been demonstrated in some animal models, and multipotent haemopoietic progenitor stem cells from human umbilical cord blood are now used as an alternative treatment to bone marrow transplantation for the treatment of some inherited genetic disorders (thalassaemia) and blood malignancies (leukaemias).

Terminally differentiated cells By virtue of their extreme specialization, terminally differentiated cells can no longer divide, e.g. erythrocytes and neurones. Apoptosis is a particular variety of terminal differentiation in which the final outcome is the death of the individual cells or cell populations. It occurs in the developing limb, where cells
die along the pre- and postaxial limits of the apical ectodermal ridge, limiting its extent, and also between the digits, permitting their separation.

## Tissue interactions

There are two types of cell and tissue interaction, namely: permissive and instructive.

In a permissive interaction, a signal from an apposing tissue is necessary for the successful self-differentiation of the responding tissue. This means that a particular cell population (or the matrix molecules secreted by the cells that it contains) will maintain mitotic activity in an adjacent cell population. Since a variety of different cell populations may permit a specific cell population to undergo mitosis and cell differentiation, no specific instruction or signal that may limit the developmental options of the responding tissue is involved; this signal therefore does not influence the developmental pathway selected and there is no restriction. The responding tissue has the intrinsic capacity to develop, and only needs appropriate environmental conditions in order to express this capacity. Permissive interactions often occur later in development, when a tissue whose fate has already been determined is maintained and stabilized by another.

An instructive (directive) interaction (induction) changes the cell type of the responding tissue, so that the cell population becomes restricted. Wessells (1977) proposed four general principles in most instructive interactions: in the presence of tissue A, responding tissue B develops in a certain way; in the absence of tissue A , responding tissue B does not develop in that way; in the absence of tissue A, but in the presence of tissue C, tissue B does not develop in that way; and in the presence of tissue A, a tissue D, which would normally develop differently, is changed to develop like tissue B.

These principles are exemplified during induction of the lens vesicle by the optic cup. An example of last-mentioned principle is the experimental association of chicken flank ectoderm with mouse mammary
mesenchyme, which results in the morphogenesis of mammary gland-like structures; chickens do not normally develop mammary glands.

Tissue interactions continue into adult life and are probably responsible for maintaining the functional heterogeneity of adult tissues and organs. This is exemplified by the complex tissue heterogeneity, with sharply compartmentalized boundaries, that occurs in the oral cavity. The junctions between the mucosa of the vestibule and the lip, and between the vermilion border and the facial skin, are distinct boundaries of specific epithelial and mesenchymal differentiation, and are almost certainly maintained by continuing epithelial-mesenchymal interactions in adult life. Perturbation of these interactions throughout the body may underlie a wide variety of adult diseases, including susceptibility to cancer and proliferative disorders.

## Signalling between embryonic cells and tissues

Cellular interactions may be signalled by four principal mechanisms: direct cell-cell contact; cell adhesion molecules and their receptors; extracellular matrix molecules and their receptors; and growth factors and their receptors. Many of these mechanisms interact, and it is likely that combinations of them are involved in development. Figure 11.1 illustrates some ways by which mesenchymal cells could signal to epithelial cells. An additional set of identical mechanisms could operate for epithelial-mesenchymal cell signalling. Clearly, the complexity of these mechanisms will increase in reciprocal interactions; moreover, a single molecule may have different effects on epithelial and mesenchymal cells.

Direct cell-cell contact permits the construction of gap junctions, which are important for communication and the transfer of information between cells. The transient production of gap junctions is seen as epithelial somites are formed, between neuroepithelial cells within rhombomeres, and in the tunica media of the outflow tract of the heart.

1 Direct cell-cell contact by gap junctions.

2 Cell-cell contact by cell adhesion molecules.

3 A soluble factor (growth factor) reacting with a receptor for that factor on the epithelial cells.

4 Extracellular matrix molecule secreted by the mesenchyme cells interacting with a receptor on the epithelial cell.

5 A soluble factor (growth factor) secreted by a mesenchymal cell having a biphasic action interacting (i) with a receptor on an epithelial cell, causing it to express a specific extracellular matrix molecule receptor; (ii) with a receptor on a mesenchyme cell, causing it to secrete a specific extracellular matrix molecule which then interacts with the induced epithelial receptor.

6 A soluble factor (growth factor) secreted by a mesenchyme cell interacting with a receptor on an epithelial cell, causing it to express a receptor or secrete a factor, which interacts with another factor synthesized, or receptor expressed, by another mesenchyme cell.

7 A soluble factor secreted by a mesenchyme cell interacting with a receptor on an epithelial cell, causing it to synthesize an extracellular matrix molecule (or a receptor for such a molecule) which then interacts with a specific receptor for that molecule on another mesenchyme cell.

8 A soluble factor secreted from a mesenchyme cell interacting with a receptor on an epithelial cell, causing it to synthesize a molecule which stabilizes or enhances the interaction between a mesenchymal-derived factor and its epithelial receptor.

9 A soluble factor secreted by a mesenchyme cell interacting with a receptor on an epithelial cell, causing the inhibition of synthesis/assembly of a factor or receptor.

10 A soluble factor secreted by a mesenchyme cell binding to the extracellular matrix of the basal lamina, where it remains active and subsequently interacts with a receptor on an epithelial cell which appears at a later developmental time.

Fig. 11.1 The many ways by which mesenchyme cells could signal to epithelial cells. Precisely the same mechanisms can operate in reverse, i.e. epithelium to mesenchyme.

Endogenous electrical fields are also believed to have a role in cell-cell communication. Such fields have been demonstrated in a range of amphibian embryos, and in vertebrate embryos during primitive streak ingression. Neuroepithelial cells are electrically coupled, regardless of their position relative to inter-rhombomeric boundaries.

The spatial and temporal distribution of a variety of cell adhesion molecules has been localized in the early embryo. The appearance of these molecules correlates with a variety of morphogenetic events that involve cell aggregation or disaggregation; e.g. an early response of groups of cells to embryonic inductive influences is the expression of cadherins, calcium-dependent adhesion molecules typically found in epithelial populations. Other molecules found in the extracellular matrix, e.g. fibronectin and laminin, inter alia, can modulate cell adhesion by their degree of glycosylation. Self-assembly or cross-linking by matrix molecules may affect cell adhesiveness by increasing the availability of binding sites or by obscuring them.

Extracellular matrix molecules include localized molecules of the basal lamina, e.g. laminin, fibronectin, and much larger complex associations of collagen, glycosaminoglycans, proteoglycans and glycoproteins between the mesenchyme cells. Mutations of the genes that code for extracellular matrix molecules give rise to a number of congenital disorders, e.g. mutations in type I collagen produce osteogenesis imperfecta; mutations in type II collagen produce disorders of cartilage; and mutations in fibrillin are associated with Marfan's syndrome.

Growth factors are distinguished from extracellular matrix molecules. They can be delivered to, and act on, cells in a variety of ways, namely: endocrine, autocrine, paracrine, intracrine, juxtacrine and matricrine (Fig. 11.2). Many growth factors are secreted in a latent form, e.g. associated with a propeptide (latency-associated peptide) in the case of transforming growth factor beta, or attached to a binding protein, in the case of insulin-like growth factors.

## MORPHOGENESIS AND PATTERN FORMATION

Morphogenesis may be described as the assumption of form by the whole, or part, of a developing embryo. As a term, it is used to denote the movement of cell populations and the changing shape of an embryo, particularly during early development.

The most obvious examples of morphogenesis are the large migrations that occur during gastrulation; local examples include branching morphogenesis, which occurs in the developing lungs and kidneys, for example, and in most glandular organs. The development of branches from a tubular duct occurs over a period of time. An interaction between the proliferating epithelium of the duct and its surrounding mesenchyme and extracellular matrix results in a series of clefts that produce a characteristic branching pattern (Fig. 11.3). During tubular and acinar development, hyaluronidase secreted by the underlying mesenchymal cells breaks down the basal lamina produced by the epithelial cells; this increases epithelial mitoses locally and results in an expanding acinus. Cleft formation is initiated by the mesenchyme, which produces collagen III fibrils within putative clefts. (If the collagen is removed, no clefts develop, whereas if excess collagen is not removed, supernumerary clefts appear.) The collagen acts to protect the basal lamina from the effects of the hyaluronidase, which means that the overlying epithelia have a locally reduced rate of mitosis. The region of rapid mitoses
at the tip of the acinus is therefore split into two, and two branches develop from this point.

Pattern formation concerns the processes whereby the individual members of a mass of cells, initially apparently homogeneous, follow a number of different avenues of differentiation that are precisely related to each other in an orderly manner in space and time. The patterns embraced by the term apply not only to regions of regular geometric order, e.g. the crystalline lens, but also to asymmetric structures such as the limb. For such a process to occur, individual cells must be informed of their position within the embryo, and utilize that information for appropriate differentiation. Patterning of regions is seen in: the

1 Endocrine Delivery of growth factor by the blood stream from a distant biosynthetic site to the target mesenchyme cell.

2 Autocrine Synthesis of growth factor by the cell, its secretion, binding and activation of a surface receptor elsewhere on its own surface.

3 Paracrine Synthesis of growth factor by the cell, its secretion and diffusion to an adjacent cell (or group of cells) where it binds to and activates a cell surface receptor.

4 Juxtacrine Synthesis of growth factor by the cell. The growth factor remains on the cell surface and binds to and activates a receptor on an immediately adjacent cell.

5 Intracrine Synthesis of growth factor within the cytoplasm of the cell. The growth factor moves to the nucleus and binds and activates its own nuclear receptors.

6 Matricrine Synthesis and export of growth factor from the cell. The growth factor binds to the extracellular matrix where it remains active and subsequently binds to and activates a receptor for that growth factor on the same or a different cell.

Fig. 11.2 In addition to the mechanisms described in Figure 11.1, cells may also communicate by the reception, production and secretion of growth factors. A typical embryonic mesenchyme cell may receive and produce growth factors in this way.

Fig. 11.3 Branching of a tubular duct may occur as a result of an interaction between the proliferating epithelium of the duct and its surrounding mesenchyme and extracellular matrix. A, Mesenchymal cells initiate cleft formation by producing collagen III fibrils locally within the development clefts and hyaluronidase over other parts of the epithelium. Collagen III prevents local degradation of the epithelial basal lamina by hyaluronidase and slows the rate of mitosis of the overlying epithelial cells. B, In regions where no collagen III is produced, hyaluronidase breaks down the epithelial basal lamina and locally increases epithelial mitoses, forming an expanded acinus (see arrows). ## Genes in development

Two related themes have emerged from experimental studies of devel－ opment：first，that the control of embryonic morphology has been highly conserved in evolution between vertebrates and invertebrates； and second，that this control involves families of genes coding for proteins that act as transcriptional regulators．

Homeobox genes are believed to be responsible，at least in part，for the evolutionary origin of the embryonic body plan（Robert 2001）． Experimental study of transgenic animals in which the homeobox genes have been knocked out provide some evidence of their function； however，because developmental processes permit significant recovery from insult，some of the outcomes cannot be directly interpreted as demonstrating the effect of such gene loss．

Other gene families required for normal development include the T－box family，Helix－Loop－Helix transcription factors and Sox genes；the signalling factors，transforming growth factor beta（TGF－$\beta$ ），bone mor－ phogenetic proteins（BMPs），fibroblast growth factor family（FGF），the

Wnt family and hedgehog signalling molecules．A range of cell receptor molecules are also required．For details on individual members within this range of factors，see Carlson（2014）．

## Experimental approaches to embryology

One of the most exciting techniques to provide information on cell movements and fates during development is the use of chimeric embryos．Small portions of an embryo are excised and replaced with similar portions of an embryo from a different species at the same stage， and the resulting development is then studied．This technique has been particularly effective using chick and quail embryos because the nucle－ olus is especially prominent in all quail cells，whereas it is not promi－ nent in chick cells，which means that quail cells may be easily identified within a chick embryo after chimeric transplantation（Le Douarin 1969）．The technique has also confirmed the reciprocity of tissue inter－ action between the embryonic species，a phenomenon that had previ－ ously been illustrated，for a limited period，in co－cultures of embryonic avian and mammalian tissues．Somite development and vertebral for－ mation have been studied in mouse－chick chimeras（Fontaine－Pérus 2000）．The production，in vitro，of human－animal chimeric cell lines is providing new ways of studying cellular pathways，as is the introduction of human artificial chromosome vectors into animal cells to study their interaction．

# Cell populations at the start of organogenesis 

## SPECIFICATION OF THE BODY AXES AND THE BODY PLAN

Embryos may be thought of as being constructed with three orthogonal spatial axes (cephalocaudal, dorsoventral and laterolateral), plus a temporal axis. In mammalian embryos, axes cannot be specified at very early stages; embryonic axes can be defined only after the early extraembryonic structures have been formed and the inner cell mass can be seen. The position of the future epiblast can be predicted in human embryos when the hollow blastocyst has formed. The inner cell mass becomes (seemingly) randomly located on the inside of the trophectoderm and forms a population of epiblast cells subjacent to the trophoblast. This region implants first. It is not known whether the trophectoderm in contact with the inner cell mass initiates implantation, so that the future dorsal surface of the embryo is closest to the disrupted maternal vessels at the implantation site, or whether the inner cell mass can travel around the inside of the trophoblast to gain a position subjacent to the implantation site once implantation has started.

Axes may be conferred on the whole embryonic disc, which is initially flat and mainly two-dimensional. However, their subsequent orientation in the folded three-dimensional embryo will be completely different. The dorsal structures of the folded embryo form from a circumscribed central ellipse of the early flat embryonic disc (see Fig. 10.5). Lateral and ventral structures form from the remainder of the disc, and the peripheral edge of the disc eventually becomes constricted at the umbilicus (see Figs 10.9-10.10). Although the appearance of part of the epiblast is taken to specify the dorsal surface of the embryo, the inner layer, i.e. the hypoblast, is not, by default, a ventral embryonic structure.

The primary, cephalocaudal, axis is conferred by the appearance of the primitive streak in the bilaminar disc. The primitive streak patterns cells during ingression, and so also specifies the dorsoventral axis, which becomes apparent after embryonic folding. The position of ingression through the streak confers axial, medial or lateral characteristics on the forming mesenchyme cells. The axial and medial populations remain as dorsal structures in the folded embryo, and the surface ectoderm above them will exhibit dorsal characteristics. The lateral plate mesenchyme will assume lateral and ventral positions after embryonic folding, and the surface ectoderm above this population will gain ventral characteristics.

The third and last spatial axis is the bilateral, or laterolateral, axis, which appears as a consequence of the development of the former two axes. Initially, the right and left halves of the embryonic body are bilaterally symmetric. Lateral projections, the upper and lower limbs, develop in two places on each side of the body wall (somatopleure).

With the last axis established, the temporal modification of the original embryonic axes can be seen. The segmental arrangement of the cephalocaudal axis is very obvious in the early embryo and is retained in many structures in adult life. Similarly, dorsal embryonic structures remain dorsal and undergo relatively little change. However, structures that were originally midline and ventral, especially those derived from splanchnopleuric mesenchyme, e.g. the cardiovascular system and the gut, are subject to extensive shifts, and change from a bilaterally symmetric arrangement to an entire body that is now chiral, i.e. has distinct left and right sides.

The development of all the body organs and systems, organogenesis, begins after the dramatic events of gastrulation, when the embryo has attained a recognizable body plan. In human embryos, this corresponds to the end of stage 10 (Fig. 12.1). The head and tail folds are well formed, with enclosure of the foregut and hindgut (proenteron and metenteron), although the midgut (mesenteron) is only partly constricted from the yolk sac. The forebrain projection dominates the cranial end of the embryo, and the buccopharyngeal membrane and cardiac prominence are caudal and ventral to it. The cardiac prominence
contains the transmedian pericardial cavity, which communicates dorsocaudally with right and left pericardioperitoneal canals. These pass dorsally to the transverse septum mesenchyme and open caudally into the extraembryonic coelom on each side of the midgut. The intraembryonic mesenchyme has begun to differentiate and the paraxial mesenchyme is being segmented into somites. Neural groove closure is progressing caudally, so that a neural tube is forming between the newly segmenting somites. Rostrally, the early brain regions, which have not yet fused, can be discerned. The neuroepithelium is separated from the dorsal aspect of the gut by the notochord. The earliest blood vessels have appeared and a primitive tubular heart occupies the pericardium. The chorionic circulation is soon to be established, after which the embryo rapidly becomes completely dependent on the maternal blood stream for its requirements. The embryo is connected to the developing placenta by a mesenchymal connecting stalk in which the umbilical vessels develop, and which also contains the allantois, a hindgut diverticulum. The lateral body walls are still widely separated. The embryo has contact with three different vesicles: the amnion, which is in contact with the surface ectoderm; the yolk sac, which is in contact with the endoderm; and the chorionic cavity, containing the extraembryonic coelom, which is in contact with the intraembryonic coelomic lining (see Fig. 10.10).

The early body plan of the embryo is segmented. The boundaries between the segments are maintained by the differential expression of genes and proteins that restrict cell migration in these regions. Organogenetic processes either retain the segmental plan, e.g. spinal nerves, or replace it locally, e.g. the modifications of somatic intersegmental vessels by the development of longitudinal anastomoses. Abnormalities may result from improper specification of segments along the cephalocaudal axis and may fail to produce the appropriately modified segmental plan.

The degree to which vertebrate embryos are developmentally constrained at this period of development is controversial. Comparative studies on the timing at which specific embryonic structures appear, heterochrony, have shown that other embryonic species do not follow the same developmental sequence as humans (Richardson and Keuck 2002). Although some developmental mechanisms are highly conserved, e.g. the homeobox gene codes, others may have been dissociated and modified in different vertebrate species during evolution

Organogenesis, the further development of body regions and organs that is described elsewhere in this book, starts from about stage 10 (approximately 28 days). Although it is both conventional and convenient to consider the further development of each body system on an individual basis, not only do all systems develop simultaneously, but also they interact and modify each other as they develop. This necessary interdependence is supported by the evidence of experimental embryology and reinforced by the phenomena of growth anomalies, which cut across the artificial boundaries of systems in most instances. For these reasons, it is recommended that the development of an individual system or body region should be studied in relation to others, especially those most closely associated with it, whether spatiotemporally or causally.

## EMBRYONIC CELL POPULATIONS AT THE START OF ORGANOGENESIS

The developmental processes operating in the embryo between stages 5 and 9 enabled the construction of the bi- and trilaminar embryonic disc, the intraembryonic coelom and new proliferative epithelia. From the end of stage 10 , a range of local epithelial and mesenchymal populations now interact to produce viscera and appendages. The inductive influences on these tissues and their repertoire of responses are very different from those seen at the onset of gastrulation. The range of tissues present at the start of organogenesis, when the body plan is clear,

Fig. 12.1 A, The embryo at stage 11, showing the position of the intraembryonic coelom (contained by the walls coloured blue). B, The three major epithelial populations within a stage 11 embryo, viewed from a ventrolateral position. The neural tube lies dorsal to the gut. Ventrally, the intraembryonic coelom crosses the midline at the level of the foregut and hindgut, but is lateral to the midgut and a portion of the foregut.
is given below and shown in Figures 12.1 and 12.2. For a summary of the fates of the embryonic cell populations, see Figure 12.3.

## Epithelial populations in the embryo

## Surface ectoderm

During embryogenesis, the surface ectoderm shows regional differences in thickness. Ectoderm over the dorsal region of the head and trunk is thin, as is the pericardial covering; this has been interpreted as a consequence of the expansion of this epithelium over structures that are enlarging rapidly as development proceeds. After the surface ectoderm has completed a number of early interactions it forms the periderm, which remains throughout fetal life and differentiates into epidermis.

## Ectodermal ring and ectodermal placodes

The ectoderm on the head and lateral borders of the embryo shows a zone of epithelial thickening, the ectodermal ring, which can be discerned from stage 10 and is completed by stage 12. Rostrally, it contains populations of neuroectoderm that remain in the ectoderm after primary neurulation and are termed ectodermal placodes; these placodes may be considered to be neuroepithelial cells that remain within the surface ectoderm until central nervous system development has progressed sufficiently for their inclusion into sensory epithelia and cranial nerve ganglia. The neuronal placodes may invaginate in toto to form a vesicle, or remain as a neuronal layer, or contribute individually to neuronal structures with cells of other origins. The midline ectodermal thickening, the adenohypophysial placode, invaginates as Rathke's pouch and forms a vesicle immediately rostral to the buccopharyngeal membrane. The ectodermal ring then passes bilaterally to encompass the olfactory and optic placodes, which give rise to the olfactory sensory epithelium and the lens of the eye, respectively. It then overlays the pharyngeal arches, where it gives rise to epibranchial placodes; these remove themselves individually from the ectoderm at stage 10-11 and become associated with the neural crest cells within the cranial sensory ganglia supplying the arches. It also forms specializations of the ectoderm on the frontonasal, maxillary and mandibular processes, which give rise to the tooth buds and the outer coating of the teeth. The paired otic placodes overlying the rhombencephalon at the lateral portion of the second pharyngeal arch invaginate to form the otic vesicles, which give rise to the membranous labyrinth of the ear. The ectodermal ring
then passes over the occipital and cervicothoracic parts of the embryo, superficial to the four occipital somites and later to the occipitocervical junction. Further caudally, it is associated with the upper limb field, where it will give rise to the apical ectodermal ridge. O'Rahilly and Müller (1985) have called the portion of the ring between the upper and lower limbs the intermembral part. It overlies the underlying intraembryonic coelom, and later (between stages 12 and 13), the mesonephric duct and ridge. In stages 14 and 15 , this portion of the ectodermal ring gives rise to the mammary line. Caudal to the lower limb field, in the unfolded embryo, the ring passes distal to the cloacal membrane. In the folded embryo, this region becomes superior to the cloacal membrane and corresponds to the ectoderm associated with the external genitalia, particularly the genital tubercle and urogenital swellings, where it influences the internal and external descent of the testis and the formation of the inguinal canal.

## Neural ectoderm

The neuroepithelium at the time of primary neurulation is pseudostratified. It has a midline hinge region, which, with concomitant wedging of the cells in the lateral wall of the neural groove, promotes neural tube formation. The processes of the neuroepithelium abut on to internal and external limiting membranes. This epithelium proliferates to form all the cell lines of the central nervous system and, via the production of neural crest, all the cell lines of the peripheral nervous system.

## Notochord

During stage 10, the notochordal plate undergoes a process that is similar to, but a mirror image of, neurulation, and forms an epithelial tube from caudal to rostral, ending with the pharynx. The notochordal plate forms a deep groove, the vertical edges of the groove move medially and touch, and then the endodermal epithelium from each side fuses ventral to the notochord. The cells swell and develop an internal pressure (turgor) that confers rigidity on the notochord. The notochord is surrounded by a basal lamina, which is initially referred to as a perinotochordal sheath; this term is subsequently applied to mesenchymal populations that surround the notochord. After stage 11, the tubular notochord is in contact with the neural tube dorsally and the endoderm ventrally. It is not a proliferative epithelium, but it has inductive effects on the overlying neural tube and the adjacent somites, and later provides a focus for sclerotomal migration.

(iii)

(iv)

Fig. 12.2 A, Mesoblast populations within the early embryonic disc. B, A stage 11 embryo, showing the position of the intraembryonic coelom (contained by the walls coloured blue) and the positions of the sections (i)-(iv) shown in $\mathbf{C}$. $\mathbf{C}$, Transverse sections, arranged cranial to caudal, from a stage 11 embryo; the populations of mesenchyme and the sites of mesenchymal proliferation are indicated.

## Endoderm

The craniocaudal progression of development means that the endoderm of the early stomodeum develops ahead of other portions of the endodermal epithelium. The development of the pharyngeal arches and pouches (Ch. 36) is closely associated with the development of the neural ectoderm and proliferation of the neural crest. The respiratory diverticulum arises slightly later, when the postpharyngeal gut may also be distinguished. The endoderm gives rise to the epithelial lining of the respiratory and gastrointestinal tracts, the biliary system, and the bladder and urethra.

## Coelomic epithelium

The coelomic epithelium lines the intraembryonic coelom, which is subdivided into a midline pericardial cavity, two bilateral pericardioperitoneal canals, and the initially bilateral peritoneal cavities; the latter are continuous with the extraembryonic coelom. The coelomic epithelium is a germinal epithelium. It produces the myocardium and connective tissue populations for the viscera, and also gives rise to the supporting cells for the germ cells, the epithelial lining of the urogenital tracts, and the mesothelial lining of the pericardial, pleural and peritoneal cavities.

## Somites

Somites are discrete epithelial spheres formed by the transformation of paraxial mesoblast cells to epithelium once their migration is complete. Specific regions of the somitic epithelium form local proliferative centres and, like neural and coelomic epithelium, it produces cells destined for different fates, at different developmental times. Somites can be seen on each side of the fusing neural tube in the human embryo from stage 9. Development proceeds in a craniocaudal direction. The original epithelial somites form the base of the skull, and the vertebral column and ribs; the dorsolateral portion, the dermomyotome, gives rise to the majority of the skeletal muscle of the body, including that in the limbs.

The relative dispositions of the neural, endodermal and coelomic epithelia are shown in Figure 12.1.

## Mesenchymal populations in the embryo

In the stage 10 embryo, the major mesenchymal populations are in place. Mesoblast is still being generated at the primitive streak and moving into the presomitic mesenchymal population adjacent to the notochord. Some mesoblast is also contributing to the lateral regions

Fig. 12.3 Structures that will be derived from specific epithelial and mesenchymal populations in the early embryo. Abbreviation: CNS, central nervous system.
of the embryo. The different mesenchymal populations within the embryo from stage 10 onwards are described below. The relative dispositions of the early mesenchymal populations are shown in Figure 12.2.

## Axial mesenchyme

The first epiblast cells to ingress through the primitive streak form the endoderm and notochord, and initially occupy a midline position. The earliest population of endodermal cells rostral to the notochordal plate is termed the prechordal plate. The notochordal cells remain medially and the endodermal cells subsequently flatten and spread laterally. The population of cells that remain mesenchymal in contact with the floor of the neural groove, just rostral to the notochordal plate, is termed prechordal mesenchyme (Fig. 12.4). These axial mesenchyme cells are tightly packed, unlike the more lateral paraxial cells but, unlike the notochord, they are not contained in an extracellular sheath. They are displaced laterally at the time of head flexion and form bilateral premandibular mesenchymal condensations. They become associated with the local paraxial mesenchyme. Orthotopic grafting has demonstrated that these cells leave the edges of the prechordal mesenchyme and migrate laterally into the periocular mesenchyme, where they give rise to all of the extrinsic ocular muscles.

## Paraxial mesenchyme

Paraxial mesoblast is a transient structure that forms somites at its cranial end, whilst unsegmented mesoblast is added caudally by the primitive streak. Epiblast cells that migrate through the primitive node and rostral primitive streak during gastrulation form mesoblast cells that migrate to a position lateral to the notochord and beneath the developing neural plate. Cells that ingress through the primitive node form the medial part of this paraxial mesoblast, and cells that ingress through the rostral streak form the lateral part (see Fig. 10.3). The paraxial mesoblast extends cranially from the primitive streak to the prechordal plate, which is immediately rostral to the notochord. Before somite formation, this mesenchymal tissue is also termed presomitic or unsegmented mesenchyme in mammals (analogous to the segmental plate in birds). Paraxial mesoblast rostral to the otic vesicle was previously believed not to segment.

Caudal to the otic vesicle, the paraxial mesoblast on each side of the rhombencephalon segments into somites as the neural folds elevate and neurulation begins; somites are therefore post-otic. During somitogenesis, mesoblastic cells show changes in shape and in cell-cell adhesion, and become organized into epithelial somites; this process begins at the eighth somitomere, just caudal to the midpoint of the notochordal plate. Somite one is also termed the first occipital somite. The post otic paraxial cell population is termed paraxial mesoderm in contemporary literature.

Skeletal muscle throughout the body is derived from paraxial mesoblast-derived somatic epithelium, which proliferates to form myoblastic populations that migrate to the head, body and limbs.

## Septum transversum

Early mesenchyme that invaginates through the middle part of the primitive streak comes to lie rostral to the buccopharyngeal membrane, where the cells form the epithelial wall of the pericardial coelom. As this epithelium proliferates, the visceral pericardial wall gives rise to myocardium. The parietal pericardial wall forms mesenchyme, initially termed precardiac, or cardiac, mesenchyme, which is able to induce proliferation of hepatic endodermal epithelium. With further proliferation, the precardiac mesenchyme forms a ventral mass caudal to the heart, the septum transversum, separating the foregut endoderm from the pericardial coelom (see Fig. 12.2). By stage 11, the septum transversum extends dorsally on each side of the developing gut and becomes continuous with the mesenchymal populations that proliferate from the walls of the pericardioperitoneal canals. Cells of the septum transversum give rise to the sinusoids of the liver, the central portions of the diaphragm and the epicardium.

## Neural crest

The neural crest is unique: it gives rise to neural populations in the head and trunk, and also provides an extensive mesenchymal population in the head with attributes similar, in terms of patterning, to somatopleuric mesenchyme. Neural crest cells arise from cells that lie initially at the outermost edges of the neural plate, between the presumptive epidermis and the neural tube, and are committed to a neural crest lineage before the neural plate begins to fold. After neurulation, neural crest cells form a transient axial population and then disperse, in some cases migrating over considerable distances, to a variety of different developmental fates. Unlike mesoblast, which is produced from
the primitive streak, none of the cells that arise from the neural crest become arranged as epithelia. The development and fate of head and trunk neural crest cells are very different and therefore they will be considered separately.

## Head neural crest

Head neural crest migrates before the neural tube closes. Two populations of crest cells develop. Some retain a neuronal lineage and contribute to the somatic sensory and parasympathetic ganglia in the head and neck. Others produce extensive mesenchymal populations; the crest cell population arising from the head is larger than that found at any trunk level. Each brain region has its own crest population that migrates dorsolaterally around the sides of the neural tube to reach the ventral side of the head. Crest cells surround the prosencephalic and optic vesicles, and occupy each of the pharyngeal arches (Ch. 36). They provide mesenchyme cells that will produce the connective tissue in parts of the neuro- and viscerocrania. All cartilage, bone, ligament, tendon, dermal components and glandular stroma in the head are derived from the head neural crest. Head neural crest also contributes to the tunica media of the aortic arch arteries.

## Trunk neural crest

Unlike its counterpart in the head, trunk neural crest is formed as the neural tube closes craniocaudally, which means that various stages of crest development can be found in the more caudal regions of an embryo. As the neural tube begins to fuse dorsally in the midline, the neural crest cells lose their epithelial characteristics and junctional connections, and form a band of loosely arranged mesenchyme cells immediately dorsal to the neural tube and beneath the ectoderm. Initially, most of the crest cells lie with their long axes perpendicular to the long axis of the neural tube. Later, the cell population expands laterally and around the neural tube as a sheet. Trunk neural crest cells move from their position dorsal to the neural tube via three routes (see Fig. 17.11): dorsolaterally, to form dorsal root ganglia throughout the trunk; ventrally, to form sympathetic ganglia, enteric nerves and the suprarenal medulla; and rostrocaudally, along the aorta, to form the pre-aortic ganglia. In a second migration route, crest cells pass dorsolaterally between the ectoderm and the epithelial plate of the somite into the somatopleure, where they eventually form melanocytes in the skin.

## Lateral plate

Lateral plate is the term for the early unsegmented mesoblast population lateral to the paraxial mesenchyme. Mesoblastic cells, which arise from the middle of the primitive streak (primary mesenchyme), migrate cranially, laterally and caudally to reach their destinations, where they revert to epithelium and form a continuous layer that adheres to the ectoderm dorsally and the endoderm ventrally. The epithelium faces a new intraembryonic cavity, the intraembryonic coelom, which becomes confluent with the extraembryonic coelom and provides a route for the circulation of coelomic fluid through the embryo. Once formed, the intraembryonic coelomic wall becomes a proliferative epithelium that produces new populations of mesenchymal cells. The mesenchymal population subjacent to the ectoderm is termed somatopleuric mesenchyme and is produced by the somatopleuric coelomic epithelium. The mesenchymal population surrounding the endoderm is termed splanchnopleuric mesenchyme and is produced by the splanchnopleuric coelomic epithelium (see Fig. 12.2).

It is important to note that these terms are relevant only caudal to the third pharyngeal arch. Rostral to this, there is a sparse mesenchymal population between the pharynx and the surface ectoderm prior to migration of the head neural crest, and there are no landmarks with which to demarcate lateral from paraxial mesenchyme. This unsplit lateral plate is believed to contribute to the cricoid and arytenoid cartilages, the tracheal rings and the associated connective tissue.

## Somatopleuric mesenchyme

Somatopleuric mesenchyme produces a mixed population of connective tissues and has a significant organizing effect at the level of the developing limbs. The pattern of limb development is controlled by information contained in the somatopleuric mesenchyme. Regions of the limb are specified by interaction between the surface ectoderm (apical ectodermal ridge) and underlying somatopleuric mesenchyme; together, these tissues form the progress zone of the limb. The somatopleuric mesenchyme in the limb bud also specifies the postaxial border of the developing limb. Somatopleuric mesenchyme gives rise to the connective tissue elements of the appendicular skeleton, including the pectoral and pelvic girdles and the bones and cartilage of the limbs, and their associated ligaments and tendons. It also gives rise to the dermis of the skin of the ventral and lateral body walls and of the limbs.

Fig. 12.4 The organization of the head and pharynx in an embryo at about stage 14. The individual tissue components have been separated but are aligned in register through the numbered zones.

## Splanchnopleuric mesenchyme

Splanchnopleuric mesenchyme surrounds the developing gut and respiratory tubes, contributing connective tissue cells to the lamina propria and submucosa, and smooth muscle cells to the muscularis mucosae and muscularis externa. It plays a patterning role in endodermal development, specifying the region and villus type in the gut, and the branching pattern in the respiratory tract.

## Intermediate mesenchyme

Intermediate mesenchyme is a loose collection of cells found between the somites and the lateral plate (see Fig. 12.2). Its development is closely related to the progress of differentiation of the somites and the proliferating coelomic epithelium from which it is derived. Intermediate mesenchyme is not present before somitogenesis or the formation of the eighth somite. In embryos with $8-10$ somites, it is present lateral to the sixth somite but does not extend cranially. The mesenchyme cells are arranged as layers, one continuous with the dorsal side of the paraxial mesenchyme and the somatopleure, the other with the ventral side of the paraxial mesenchyme and the splanchnopleure.

As development proceeds, the intermediate mesenchyme forms a loosely packed dorsolateral cord of cells, which lengthens at the caudal end and ultimately joins the cloaca. It gives rise to the nephric system, gonads and reproductive ducts.

## Angioblastic mesenchyme

Mesenchymal cells, which give rise to the cellular elements of the blood, the endothelium and the mesenchymal layers of the tunica externa and adventitia of blood and lymphatic vessels, arise from extraembryonic and intraembryonic sources. Evidence suggests that
endodermal tissues are necessary for endothelial differentiation, particularly the early foregut. Angioblastic mesenchyme forms early in the third week of development from extraembryonic mesenchyme in the splanchnopleure of the yolk sac, in the body stalk (containing the allantois), and in the somatopleure of the chorion. The peripheral cells flatten as a vascular endothelium, whereas the central cells transform into primitive red blood corpuscles. Later, contiguous islands merge, forming a continuous network of fine vessels. Intraembryonic blood vessels are first seen at the endoderm-mesenchyme interface within the lateral splanchnic mesenchyme at the caudolateral margins of the cranial intestinal portal. Angioblastic competence has been demonstrated within the ventral (splanchnopleuric) mesenchymes with which the endoderm interacts. However, the notochord and prechordal plate do not contain angiogenic cells. Similarly, ectodermal tissues do not appear to give rise to angiogenic cells. Somites, derived from paraxial mesenchyme, have been shown to be a source of angioblasts that either differentiate with the somite derivatives, or migrate to the neural tube, ventrolateral body wall, limb buds, mesonephros and the dorsal part of the aorta.

The earliest angiogenic mesenchymal cells form blood vessels by vasculogenesis, a process in which new vessels (e.g. endothelial heart tubes, dorsal aortae, umbilical and early vitelline vessels) develop in situ (Ch. 13). Later vessels develop by angiogenesis, sprouting and branching from the endothelium of pre-existing vessels; this process is the means by which most other vessels develop. The ultimate pattern of vessels is controlled by the surrounding, non-angiogenic mesenchyme; vessels become morphologically specific for the organ in which they develop, and also immunologically specific, expressing organ-specific proteins.

## CHAPTER <br> 13

## Early embryonic circulation

The early embryonic circulation is symmetrical (Fig. 13.1). It is modified throughout development to produce a functioning fetal circulation that is connected to the placenta, and changes rapidly at birth to accommodate disconnection from the placenta and the start of gaseous exchange in the lungs. Major restructuring of early vessels occurs as the embryo grows; anastomoses form and then disappear, capillaries fuse and give rise to arteries or veins, and the direction of blood flow may reverse several times before the final arrangement of vessels is completed.

## ANGIOGENESIS

The earliest circulatory components develop by vasculogenesis in the extraembryonic tissues. The endothelial heart tubes, dorsal aortae, umbilical and early vitelline vessels arise by vasculogenesis within the embryo. Further vessel development occurs by a process of angiogenesis in which angioblasts, arising in splanchnic and somitic tissues, add endothelial sprouts and branches to earlier vessels. None of the main vessels of the adult arises as a single trunk in the embryo. A capillary network is first laid down along the course of each vessel; the larger arteries and veins are defined by selection and enlargement of definite paths in this network. Lymphatic vessels develop after the main arteries and veins are formed; they arise initially by angiogenesis from the cardinal veins and subsequently by proliferation of lymphangioblasts to form lymphatic capillaries.

Five stages have been described during angiogenesis: endothelial tip cell specification and sprout initiation; sprout elongation and local
guidance, where the distal tip cell extends supported by proximal stalk cells that may divide; sprout elongation in response to cues from the extracellular matrix; lumen formation, which is initially by the confluence of intracellular vacuoles, followed by establishment of apical basal polarity of the cells of the endothelial sprout; and fusion of the tip cell to another sprout tip with confluence of the two lumina established (Chappell et al 2012, Kuijper et al 2007). The developmental processes of angiogenesis are similar to those seen in both neoplasia and acute inflammation in adult tissue. The scientific literature on angiogenesis is extensive and the process will not be considered in detail here; the interested reader is directed to Senger and Davis (2011), Beets et al (2013), Herbert and Stainier (2011) and Eichmann and Pardanaud (2014).

Studies have considered the development of capillary beds within the surrounding mesenchymal tissues destined to become laminae propriae, but few have looked at how capillary beds form within tissues undergoing morphogenetic movements. Czirok et al (2011) discussed the temporal imperative for free-living embryos to develop rapidly in contrast to amniote embryos, which do not have to fend for themselves. They concluded that amniote vascular patterns of development, prior to the establishment of a circulation, are not predetermined by a network of patterning genes and cell signalling pathways, but rather that the tissue movements during organogenesis and the realignment and tension that develop within extracellular matrix fibres may guide cell migration and the position of early vessels.

Extracellular matrix plays a critical role in angiogenesis and vessel stabilization in the embryo and in the adult; differences in the composition and abundance of specific extracellular matrix components between

Fig. 13.2 Profile reconstructions of the blood vascular system of a stage 13 human embryo. The early circulation is now asymmetrical; the venous vessels are enlarging on the right and diminishing on the left. A, Seen from the right side, showing the main venous channels to the heart. B, Seen from the left side, showing the aortic arch arteries, the main vessels arising from the dorsal aorta and umbilical arteries. Note that only the endothelial lining of the heart chambers is shown and, because the muscular wall has been omitted, the pericardial cavity appears much larger than the contained heart.
the embryo and adult mean that there are likely to be significant differences in the process at different ages. Fibronectin is required for normal vascular development; its deposition is related to interactions between endothelial cells and pericytes, and local tensional forces that occur between blood vessel basement membrane and local extracellular matrix assembly (Davis and Senger 2005; Senger and Davis 2011). Early blood vessels are initially surrounded by a fibronectin-rich matrix that is later incorporated into the endothelial basal lamina along with laminin, a particularly early constituent. Several layers of fibronectinexpressing cells are seen around larger vessels, such as the dorsal aortae. The endothelium does not synthesize a basal lamina in those regions where remodelling and angiogenesis are active, and the mesenchyme around such endothelium does not express $\alpha$-actin or laminin until branching has stopped and differentiation of the tunica media begins (after a stable vascular pattern has formed). It is not known how differentiation of pericytes and smooth muscle cells is induced; the majority of arteries accumulate medial smooth muscle from the surrounding mesenchyme.

Although studies have elucidated the genes involved in vasculogenesis and angiogenesis, the drivers that lead to development of asymmetric vessels from an early symmetrical pattern and the specification of the position of particular arteries, veins and lymphatic vessels are still not clear. In early development, the arteries of the embryo are disproportionately large and their walls consist of little more than a single layer of endothelium. The cardiac orifices are also relatively large and the force of the cardiac contraction is weak; consequently, the circulation is sluggish, despite the rapid rate of contraction of the developing heart. However, the tissues are able to draw nourishment not only from the capillaries but also from the large arteries and the intraembryonic coelomic fluid.

It has been suggested that the rapidly expanding cardiovascular system is filled with plasma by the movement of fluid from the intraembryonic coelom to the veins. In general, the wall of the intraembryonic coelom is composed of proliferating cells that produce the splanchnopleuric and somatopleuric mesenchymal populations. However, the walls of a portion of the pericardioperitoneal canals are thinner, and possibly more permeable to coelomic fluid, at the time when the canals surround the hepatocardiac channels (veins). The latter lie between the hepatic plexus and the sinus venosus; the hepatocardiac channel on the right side is more developed and on the left it is more plexiform, with only a transitory connection to the sinus venosus. The differentiation of this specific coelomic region occurs just in advance of the expansion and filling of the right and left atria, at about stage 12 .

As the heart muscle thickens, compacts and strengthens, the cardiac orifices become both relatively and absolutely reduced in size, the valves increase their efficiency, and the large arteries acquire their muscular walls and undergo a relative reduction in size. From this time onwards, the embryo is dependent for its nourishment on the expanding capillary beds, and the function of the larger arteries becomes restricted to that of controllable distribution channels to keep the embryonic tissues constantly and appropriately supplied.

The heart starts to beat early, before the development of the conduction system, and a circulation is established before a competent valvular mechanism has formed. Cardiac output increases in proportion with the weight of the embryo and cardiac rate increases with development. However, most of the increase in cardiac output results from a geometric increase in stroke volume. When dorsal aortic blood flow is matched to embryonic weight, blood flow remains constant over a more than 150 -fold change in mass of the embryo.

After head folding, the embryo has bilateral primitive aortae, each consisting of ventral and dorsal parts that are continuous through the first embryonic aortic arches (Ch. 36). The ventral aortae are fused and form a dilated aortic sac. The dorsal aortae run caudally, one on each side of the notochord. In the fourth week, they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single definitive descending aorta (see Fig. 13.1A, C; Fig. 13.2B). In general, more mature endothelial channels are seen in the rostral, more advanced regions of the embryo whereas, more caudally, a changing capillary plexus constantly remodels until it becomes confluent with the vascular channels of the connecting stalk. The dorsal continuation of the primitive dorsal aortae directs blood into an anastomosing network around the allantois, which will form the umbilical arteries. Blood is channelled back to the developing heart from the allantois via umbilical veins, from anastomoses in the primitive yolk sac via the vitelline veins, and from the body via pre- and postcardinal veins that join to form the common cardinal veins (see Figs 13.1B,C, 13.2A).

Vascular anomalies Localized defects of vascular development, characterized by focal increases in the number of vessels that are abnormally tortuous and enlarged, have been shown to have genetic causes and mapped to the predisposing gene and chromosomal locus (Boon et al 2011). It has been suggested that a range of capillary malformations, venous malformations, telangiectasia and lymphatic malformations, including lymphoedema, is associated with factors identified in the early formation of blood and lymphatic vessels (Brouillard and Vikkula 2007, Boon et al 2011).

Fig. 13.3 The segmental and intersegmental arteries. The small red dilations indicate the positions of the longitudinal anastomoses.

## EMBRYONIC ARTERIES

Initially, the dorsal aortae are the only longitudinal vessels present. Their branches all run at right angles to the long axis of the embryo. Later, these transverse arteries become connected by longitudinal anastomosing channels that persist in part, forming arteries such as the vertebral, internal thoracic, superior and inferior epigastric, and gastroepiploic. Each primitive dorsal aorta gives off somatic arteries (intersegmental branches to the body wall), a caudal continuation that passes into the body stalk (the umbilical arteries), lateral splanchnic arteries (paired segmental branches to the mesonephric ridge), and ventral splanchnic arteries (paired segmental branches to the digestive tube).

## Somatic arteries

The somatic arteries are intersegmental in position. They persist, almost unchanged, in the thoracic and lumbar regions, as the posterior intercostal, subcostal and lumbar arteries. Each gives off a dorsal ramus, which passes backwards in the intersegmental interval and divides into medial and lateral branches to supply the muscles and superficial tissues of the back (Fig. 13.3). The dorsal ramus also gives off a spinal branch, which enters the vertebral canal and divides into a series of branches that supply the walls and joints of the osteoligamentous canal, and neural branches to the spinal cord and spinal nerve roots. After giving off its dorsal ramus, each intersegmental artery runs ventrally in the body wall, gives off a lateral branch and terminates in muscular and cutaneous rami.

## Early umbilical arteries

Initially, the umbilical arteries are the direct caudal continuation of the primitive dorsal aortae. They are present in the body stalk before any vitelline or visceral branches emerge, indicating the dominance of the allantoic over the vitelline circulation in the human embryo. (On a comparative basis, the umbilical vessels are chorio-allantoic and therefore 'somatovisceral'.) After the dorsal aortae fuse, the umbilical arteries arise from their ventrolateral aspects and pass medial to the primary excretory duct to the umbilicus. Later, the proximal part of each umbilical artery is joined by a new vessel that leaves the aorta at its termination and passes lateral to the primary excretory duct. This, possibly the fifth lumbar intersegmental artery, constitutes the dorsal root of the umbilical artery (the original stem, the ventral root). The dorsal root gives off the axial artery of the lower limb, branches to the pelvic viscera and, more proximally, the external iliac artery. The ventral root disappears entirely, and the umbilical artery now arises from that part of its dorsal root distal to the external iliac artery, i.e. the internal iliac artery.

## Lateral splanchnic arteries

The lateral splanchnic arteries supply, on each side, the mesonephros, metanephros, testis or ovary, and the suprarenal gland. All these structures develop, in whole or in part, from the intermediate mesenchyme, later termed the aorta-gonad-mesonephros region. One testicular or ovarian artery and three suprarenal arteries persist on each side. The phrenic artery branches from the most cranial suprarenal artery, and the
renal artery arises from the most caudal. Additional renal arteries are frequently present and may be regarded as branches of persistent lateral splanchnic arteries.

## Ventral splanchnic arteries

The ventral splanchnic arteries are originally paired vessels distributed to the capillary plexus in the wall of the yolk sac. After fusion of the dorsal aortae, they merge as unpaired trunks that are distributed to the increasingly defined and lengthening primitive digestive tube. Longitudinal anastomotic channels connect these branches along the dorsal and ventral aspects of the tube, forming dorsal and ventral splanchnic anastomoses (see Fig. 13.3). These vessels obviate the need for so many 'subdiaphragmatic' ventral splanchnic arteries, and these are reduced to three: the coeliac trunk and the superior and inferior mesenteric arteries. As the viscera supplied descend into the abdomen, their origins migrate caudally by differential growth: the origin of the coeliac artery is transferred from the level of the seventh cervical segment to the level of the twelfth thoracic; the superior mesenteric from the second thoracic to the first lumbar segment; and the inferior mesenteric from the twelfth thoracic to the third lumbar segment. However, above the diaphragm, a variable number of ventral splanchnic arteries persist, usually four or five, and supply the thoracic oesophagus. The dorsal splanchnic anastomosis persists in the gastroepiploic, pancreaticoduodenal and primary branches of the colic arteries, whereas the ventral splanchnic anastomosis forms the right and left gastric and the hepatic arteries.

## EMBRYONIC VEINS

The early embryonic veins are often segregated into two groups, visceral and somatic, for convenience and apparent simplicity. The visceral group contains the derivatives of the vitelline and umbilical veins, and the somatic group includes all remaining veins. It should be noted that, with time, embryonic veins change the principal tissues they drain. They may receive radicles from obviously parietal tissues, which become confluent with drainage channels that are clearly visceral, and so form a compound vessel. The arrangement of the early embryonic veins is initially symmetrical. The primitive tubular symmetric heart receives its venous return through the right and left sinual horns, which are initially embedded in the mesenchyme of the septum transversum. Each horn receives, most medially, the termination of the principal vitelline vein; more laterally, the umbilical vein; and, most laterally, having encircled the pleuroperitoneal canal, the common cardinal vein. This symmetric pattern changes as the heart and gut develop and the cardiac return is diverted to the right side of the heart.

## Vitelline veins

The vitelline veins drain capillary plexuses that develop in the splanchnopleuric mesenchyme of the secondary yolk sac. With head, tail and lateral fold formation, the upper recesses of the yolk sac are enclosed within the embryo as the splanchnopleuric gut tube, which extends from the stomodeal buccopharyngeal membrane to the proctodeal cloacal membrane. Derivatives from all these levels possess a venous drainage that is originally vitelline.

## Early umbilical veins

The umbilical veins form by the convergence of venules that drain the splanchnopleure of the extraembryonic allantois. The human endodermal allantois is very small; it projects into the embryonic end of the connecting stalk, which is therefore regarded as precociously formed allantoic mesenchyme, whereas the umbilical vessels are considered to be allantoic. The peripheral venules drain the mesenchymal cores of the chorionic villous stems and terminal villi (extraembryonic somatopleuric structures). These are the radicles of the vena umbilicalis impar (usually single), which traverses the compacting mixed mesenchyme of the umbilical cord to reach the caudal rim of the umbilicus. Here, the single cordal vein divides into primitive right and left umbilical veins. Each curves rostrally in the somatopleuric lateral border of the umbilicus, i.e. where intraembryonic and extraembryonic or amniotic somatopleure are continuous, lying lateral to the communication between both the intraembryonic and the extraembryonic coeloms. Rostrolateral to the umbilicus, the two umbilical veins reach, enter and traverse the junctional mesenchyme of the septum transversum and connect with septal capillary plexuses. They then continue, entering their corresponding cardiac sinual horns lateral to the terminations of the vitelline veins.

Fig. 13.4 Somatic venous development. A, A schematic section through the embryonic trunk. Principal longitudinal veins are colour-coded. Interconnections and intersegmental veins are uncoloured. B, The development of the principal somatic veins, from the early symmetric state, through states of increasing asymmetry, to the definitive arrangement. Abbreviations: IVC, inferior vena cava.

This early symmetric disposition of the vitelline veins and anastomoses, umbilical and common cardinal veins, and the locus of the hepatic primordial complex are summarized in Figures 13.1B and 13.2A. For further development of the vitelline and umbilical veins, see Chapter 60 (Figs 60.8-60.10).

## Cardinal veins and somatic venous complexes

The initial venous channels in the early embryo have traditionally been termed cardinal because of their importance at this stage. The cardinal venous complexes are first represented by two large vessels on each side, the precardinal portion being rostral and the postcardinal being caudal to the heart. The two veins on each side unite to form a short common cardinal vein, which passes ventrally, lateral to the pleuropericardial canal, to open into the corresponding horn of the sinus venosus (see Figs 13.1 B and 13.2 A ; Fig. 13.4B). The precardinal veins undergo remodelling as the head develops. The postcardinal veins, which, in the early embryo, drain the body wall, are insufficient channels for venous return from the developing mesonephros and gonads and for the growing body wall. As the embryo increases in size, they are supple-
mented by a range of bilateral longitudinal channels that anastomose with the posterior cardinal system and with each other. These channels are the subcardinal, supracardinal, azygos line, subcentral and precostal veins (Fig. 13.4).

## Subcardinal veins

Subcardinal veins form in the ventromedial parts of the mesonephric ridges and become connected to the postcardinal veins by a number of vessels traversing the medial part of the ridges. The subcardinal veins assume the drainage of the mesonephros and intercommunicate by a pre-aortic anastomotic plexus, which later constitutes the part of the left renal vein that crosses anterior to the abdominal aorta.

## Supracardinal veins

Supracardinal veins form dorsolateral to the aorta and lateral to the sympathetic trunk and take over the intersegmental venous drainage from the posterior cardinal vein. The supracardinal veins are also referred to as the thoracolumbar line or lateral sympathetic line veins.

## Azygos line veins

Azygos line veins form dorsolateral to the aorta and medial to the sympathetic trunk. These channels, also referred to as the medial
sympathetic line veins, gradually take over the intersegmental venous drainage from the supracardinal veins. The intersegmental veins now reach their longitudinal channel by passing medial to the autonomic trunk, a relationship that the lumbar and intercostal veins subsequently maintain. Cranially, the azygos lines join the persistent cranial ends of the posterior cardinal veins.

## Subcentral veins

Subcentral veins form directly dorsal to the aorta in the interval between the origins of the paired intersegmental arteries. These veins communicate freely with each other and with the azygos line veins; these connections ultimately form the retro-aortic parts of the left lumbar veins and of the hemiazygos veins.

## Precostal or lumbocostal venous line

A precostal or lumbocostal venous line, anterior to the vertebrocostal element and posterior to the supracardinal, is recognized by some authorities. A possible derivative is the ascending lumbar vein.

## Further development of the somatic veins

The supracardinal veins lie lateral to the aorta and the sympathetic trunks, which therefore intervene between them and the azygos lines (see Fig. 13.4). They communicate caudally with the iliac veins and cranially with the subcardinal veins in the neighbourhood of the preaortic intersubcardinal anastomosis. The supracardinal veins also communicate freely with each other through the medium of the azygos lines and the subcentral veins. The most cranial of these connections, together with the supracardinal-subcardinal and the intersubcardinal anastomoses, complete a venous ring around the aorta below the origin of the superior mesenteric artery, termed the 'renal collar'.

The ultimate arrangement of these embryonic abdominal and thoracic longitudinal cardinal veins may be summarized as follows. The terminal part of the left postcardinal vein forms the distal part of the left superior intercostal vein. On the right side, its cranial end persists as the terminal part of the azygos vein. The caudal part of the subcardinal vein is, in part, incorporated in the testicular or ovarian vein and partly disappears. The cranial end of the right subcardinal vein is incorporated into the inferior vena cava and also forms the right suprarenal vein. The left subcardinal vein, cranial to the intersubcardinal anastomosis, is incorporated into the left suprarenal vein. The renal and testicular or ovarian veins on both sides join the supracardinal-subcardinal anastomosis. On the left side, this is connected directly to the part of the inferior vena cava that is of subcardinal status via an intersubcardinal anastomosis. The right supracardinal vein forms much of the postrenal (caudal) segment of the inferior vena cava. The left supracardinal vein disappears entirely. The right azygos line persists in its thoracic part to form all but the terminal part of the azygos vein. Its lumbar part can usually be identified as a small vessel that leaves the vena azygos on the body of the twelfth thoracic vertebra and descends on the vertebral column, deep to the right crus of the diaphragm, to join the posterior aspect of the inferior vena cava at the upper end of its postrenal segment. The left azygos line forms the hemiazygos veins. The subcentral veins give rise to the retro-aortic parts of the left lumbar veins and of the hemiazygos veins (see Fig. 13.4).

## LYMPHATIC VESSELS

The earliest lymphatic vessels arise from budding of lymphatic endothelial cells from the cardinal veins to form lymph sacs (Eichmann et al 2005). Six early lymph sacs can be identified; two are paired (the jugular and the posterior lymph sacs) and two are unpaired (the retroperitoneal sac and the cisterna chyli). In lower mammals, an additional pair (subclavian) is present, but in the human embryo, these are merely extensions of the jugular sacs.

The jugular lymph sac is the first to appear, at the junction of the subclavian vein with the precardinal vein, with later prolongations along the internal and external jugular veins. The posterior lymph sac encircles the left common iliac vein. The retroperitoneal sac appears in the root of the mesentery near the suprarenal glands. The cisterna chyli appears opposite the third and fourth lumbar vertebrae (Fig. 13.5). The lymph vessels bud out from the lymph sacs along lines that correspond more or less closely with the course of embryonic blood vessels (most commonly, veins); many also arise de novo in the mesenchyme and establish connections with existing vessels. In the body wall and the wall of the intestine, the deeper plexuses are the first to be developed; the vessels in the superficial layers are gradually formed by continued growth. Lymph vessel expansion appears to be influenced by local

Fig. 13.5 Relative positions of the primary lymph sacs (as originally determined by Sabin (1912)).
mechanotransduction with lymphatic endothelial cells elongating as a consequence of high interstitial fluid volume (Planas-Paz et al 2012). For more details on the morphogenesis of lymphatic vessels, see Tatin and Makinen (2014).

The formation of jugular lymph sacs and their normal remodelling as the lymphatic system develops are of particular interest because delay or disruption is noted in aneuploidic fetuses. Increased accumulation of tissue fluid between the skin and soft tissues, posterior to the forming cervical spine - termed nuchal translucency - can be identified on ultrasound examination between 10 and 14 weeks' gestation. Approximately $75 \%$ of trisomy 21 fetuses show an increased distance of nuchal translucency at this time (see Fig. 14.4). In the majority of cases, early nuchal fluid accumulation resolves for normal and chromosomally abnormal fetuses between 14 and 20 weeks, and is thought to reflect increased lymphatic system development, the onset of urine production by the metanephric kidneys and a decrease in placental resistance (Nafziger and Vilensky 2014).

In the fetus, lymphatic flow rates appear to be higher than in the neonate, which, in turn, are higher than in the adult; overall fetal lymph flow is thought to be five times greater than in adults (Bellini et al 2006). The production of pulmonary fluid secreted into the amniotic cavity is related to the lymphatic drainage of the lungs. In the neonate, pulmonary ventilation is important in regulating lymphatic flow in the lungs. The process of parturition causes significant changes in the distribution of body water in the neonate, including movement of blood from the placenta to the fetus and a temporary shift of fluid from the intravascular compartment to the interstitial compartment; restoration of fluid balance between intravascular, lymphatic and interstitial compartments occurs concomitant with an increase in postnatal oxygenation (Bellini et al 2006).

## LYMPH NODES AND LYMPHOID TISSUES

Lymph vessels can be seen in the embryo in the cervical region from stage 16. Lymph nodes, which provide regional proliferative foci for lymphocytes, have been identified from week 9. Early lymph sacs become infiltrated by lymphoid cells, and the outer portion of each sac becomes the subcapsular sinus of the lymph node. Morphological differentiation of medullary and cortical compartments has not been observed until the end of week 10 (Tonar et al 2001). At the same time as these early lymph nodes are developing, the nasopharyngeal wall is infiltrated by lymphoid cells that are believed to herald the early development of the tubal and pharyngeal tonsils.

In the neonate, a considerable proportion of the total amount of lymphoid tissue is localized in lymph nodes; the subsequent increase in the amount of lymphoid tissues that occurs during childhood reflects the growth of these nodes. Definitive follicles with germinal centres are formed during the first postnatal year. The pharyngeal tonsil reaches its maximal development at 6 years and its subsequent involution is completed by puberty. Details of the development of gut-associated lymphoid tissue are given in Chapter 60.

Lymphatic endothelial cells in lymphatic capillaries display a discontinuous basal lamina and basement membrane. They are held by anchoring filaments to the surrounding extracellular matrix. Their differentiation in the mouse starts with expression of Sox-18 and Prox-1, a Prospero homeobox transcription factor, in a subset of cardinal veins (Park et al 2011, Zhou et al 2010). Prox-1 is the most specific and functional lymphatic marker: its disruption leads to failure of lymphatic vessel development. Abnormal or absent lymphatic development is also seen with lack of vascular endothelial growth factor 3 (VEGFR3) and lack of angiopoietin 1, respectively (Yamashita 2007). Abnormalities of development and of remodelling of primary lymphatic vessels also occur if Akt, a serine/theonine protein kinase, is absent, possibly due to insufficient recruitment of smooth muscle cells to larger lymphatic vessels (Zhou et al 2010).

## PRENATAL STAGES

The absolute size of an embryo or fetus does not afford a reliable indication of either its chronological age or the stage of structural organization, even though graphs based on large numbers of observations have been constructed to provide averages. All such data suffer from the difficulty of timing the moment of conception in humans. It has long been customary to compute the age, whether in a normal birth or an abortion, from the first day of the last menstrual period of the mother but, as ovulation usually occurs near the fourteenth day of a menstrual cycle, this 'menstrual age' is an overestimate of about 2 weeks. Where a single coitus can be held to be responsible for conception, a 'coital age' can be established, and the 'fertilization age' cannot be much less than this because of the limited viability of both gametes. It is usually held that the difference may be several days, which is a highly significant interval in the earlier stages of embryonic development. Even if the time of ovulation and coitus were known in instances of spontaneous abortion, not only would some uncertainty still persist with regard to the time of fertilization, but also there would remain an indefinable period between the cessation of development and the actual recovery of the conceptus.

To overcome these difficulties, early embryos have been graded or classified into developmental stages or 'horizons', on the basis of both internal and external features. The study of the Carnegie collection of embryos by Streeter $(1942,1945,1948)$, and the continuation of this work by O'Rahilly and Müller (1987), provided, and continues to provide, a sound foundation for embryonic study and a means of comparing stages of human development with those of the animals routinely used for experimental study, namely: the chick, mouse and rat. Recent use of ultrasound for the examination of human embryos and fetuses in utero has confirmed much of the staging data.

The development of a human from fertilization to birth is divided into two periods: embryonic and fetal. The embryonic period has been defined by Streeter as 8 weeks post fertilization, or 56 days. This timescale is divided into 23 Carnegie stages, a term introduced by O'Rahilly and Müller (1987) to replace developmental 'horizons'. The designation of stage is based on external and internal morphological criteria and not on length or age.

## Embryonic staging

Embryonic stages 1-10 are shown in detail in Figure 8.1. Estimations of embryonic length may be $1-5 \mathrm{~mm}$ less than equivalent in vivo estimates, reflecting the shrinkage caused by the fixation procedures that are inevitably used in embryological studies. O'Rahilly and Müller $(2000,2010)$ have revised some of the ages that were previously assigned to early embryonic stages, pointing out that interembryonic variation may be greater than had been thought and that, consequently, some ages may have been underestimated. They note that, as a guide, the age of an embryo can reasonably be estimated from the embryonic length within the range $3-30 \mathrm{~mm}$, by adding 29 to the length. Correlating the age of any stage of development to an approximate day may be unreliable, and a generalization using the number of weeks of development might now be more appropriate.

The stages of development encompass all aspects of internal and external morphogenetic change that occur within the embryo within the duration of the stage. They are used to convey a snapshot of the status of the development of all body systems within a particular timeframe. Figure 14.1 shows the external appearance of embryos from stage 6 to stage 23, with details of their size and age in days. The correlation of external appearance of the embryo with internal development is shown in Figure 14.2.

Obvious external features provide some guidance to the changes occurring within embryos during successive stages. Somite number is
related to early embryonic stages, and once the number of somites is too great to count with accuracy, the degree of development of the pharyngeal arches is often used. External staging becomes more obvious when the limb buds appear. The upper limb bud is clearly visible at stage 13 and, by stage 16 , the acquisition of a distal paddle on the upper limb bud is characteristic. At stage 18, the lower limb bud now has a distal paddle, whereas the upper limb bud has digit rays that are beginning to separate. By stage 23, the embryo has a head that is almost erect and rounded, and eyelids are beginning to form. The limbs look far more in proportion and fingers and toes are separate. At this stage, the external genitalia are well developed, although they may not be sufficiently developed for the accurate determination of the sex.

Historically, the onset of bone marrow formation in the humerus was used by Streeter to indicate the end of the embryonic and the beginning of the fetal period of prenatal life. The fetal period occupies the remainder of intrauterine life; growth is accentuated, although differentiative processes continue up to and beyond birth. Overall, the fetus increases in length from 30 mm to 500 mm , and increases in weight from $2-3 \mathrm{~g}$ to more than 3000 g .

## Fetal staging

Currently, there is no satisfactory system of morphological staging of the fetal period of development, and the terminology used to describe this time period reflects this confusion. The terms 'gestation', 'gestational age' and 'gestational weeks' are considered ambiguous by O'Rahilly and Müller (2000), who recommend that they should be avoided. However, they are widely used colloquially within obstetric practice. Staging of fetal development and growth is based on an estimate of the duration of a pregnancy. Whereas development of a human from fertilization to full term averages 266 days, or 9.5 lunar months ( 28 day units), the start of pregnancy is traditionally determined clinically by counting days from the last menstrual period; estimated in this manner, pregnancy averages 280 days, or 10 lunar months ( 40 weeks). Figure 14.3 shows the embryonic timescale used in all descriptions of embryonic development and the obstetric timescale used to gauge the stage of pregnancy.

The predicted date of full term and delivery is revised after routine ultrasound examination of the fetus. Early ultrasound estimation of gestation increases the rate of reported preterm delivery (delivery at $<37$ weeks) compared with estimation based on the date of the last menstrual period (Yang et al 2002), possibly because delayed ovulation is more frequent than early ovulation; the predicted age of a fetus estimated from the date of the last menstrual period may differ by more than 2 weeks from estimates of postfertilization days.

## Obstetric staging

In obstetric practice, the duration of the period of gestation is regarded as 9 calendar months, which is approximately 270 days. The period of pregnancy is divided into thirds, termed trimesters. The first and second trimesters each cover a period of 12 weeks, and the third trimester covers the period from 24 weeks to delivery. Although the expected date of delivery is computed at 40 weeks of pregnancy, the term of the pregnancy, i.e. its completion resulting in delivery, is considered normal between 37 and 42 weeks. Neonates delivered before 37 weeks are called preterm (or premature); those delivered after 42 weeks are post-term. The period from the end of week 24 and up to 7 days after birth is termed the perinatal period. Fetuses that are delivered and die before 24 weeks are considered to be miscarriages of pregnancy, although technological advances in neonatal care can now assist the delivery and support of infants younger than 24 weeks. Infants born after 24 weeks of pregnancy who subsequently die are classed as stillborn and contribute to the statistics of perinatal mortality. Studies that discuss fetal

Fig. 14.1 The external appearance and size of embryos between stages 6 and 23. Early in development, external features are used to describe the stage, e.g. somites, pharyngeal arches or limb buds. (Adapted with permission from Rodeck CH, Whittle MJ 1999 Fetal Medicine. London: Churchill Livingstone.)
development and the gestational age of neonates, particularly those born before 40 weeks' gestation, use the obstetric estimated stages and age (menstrual age), unless they specifically correct for this. If a fetal ageing system is used, it is important to remember that the age of the fetus may be 2 weeks more than a comparable fetus that has been aged from postovulatory days.

## Ultrasound staging

The difficulty of correlating the appearance of a chorionic sac, embryo or fetus on an ultrasound scan with age during the first trimester is related to the specificity of reporting the age. An age reported as within a week of pregnancy, e.g. week 12, will cover a period of 6 days ( 12 weeks 0 days up to 12 weeks 6 days). Therefore, it is recommended that sonographic estimation of age should be given as menstrual weeks and days (i.e. 12 weeks indicates 12 weeks 0 days) (Galan et al 2008).

First trimester scan An early ultrasound scan will detect implantation and viability of the embryo once a heart beat is detected, confirm multiple pregnancy and estimate the date of delivery. Cardiac activity can be identified by the sixth menstrual week (Galan et al 2008). Crownrump length measurement is the most accurate predictor of menstrual age of the embryo during the first trimester (Galan et al 2008). Nuchal translucency is measured between 10 and 14 weeks to diagnose trisomy 21. The development of three-dimensional ultrasound scanning has enabled early detection of many anomalies previously diagnosed in the second trimester, including anencephaly, hydrocephalus and encephalocele (Pretorius et al 2014). Normograms of fetal spine growth have been constructed for a Taiwan population, which show mean spine length increasing linearly between 11 and 14 weeks (Cheng et al 2010). The study also noted a tendency for spinal extension as early as 11 weeks.

Second trimester scan Routine scanning at 18-20 weeks (obstetric staging) is used to confirm the delivery date, and assess not only the position of the placenta but also the presence of fetal anomalies that would require special intervention following delivery, such as cardiac
defects, lung immaturity, renal agenesis, polyhydramnios and defects of the anterior abdominal wall (gastroschisis and exomphalos). Estimations are made of the following: biparietal skull diameter, taken through a plane of section that traverses the third ventricle and thalami; head circumference through a plane that traverses the third ventricle and thalami plus the cavum septi pellucidi anteriorly and the tentorial hiatus posteriorly; abdominal circumference through a plane where the transverse diameter of the liver is greatest, the appearance of the lower ribs is symmetrical and the junction of the left and right portal veins is identified; and femoral length, which measures the ossified portions of the diaphysis and metaphysis (Fig. 14.4).

Between 15 and 28 weeks, the biparietal diameter is the most accurate index of fetal menstrual age and the expected date of delivery. Other measurements that may also be taken include transverse cerebellar diameter and foot length. The amount and type of fetal movement, breathing movements and visceral functions, exemplified by bladder emptying, peristaltic action and colonic echogenicity, are noted. Threeand four-dimensional ultrasound scans are now routinely constructed (Video 14.1).

Gender can be identified later in development but this information is not always routinely passed on to parents.

Constructions of ultrasound biometry charts for fetal aging now take into account the ethnic population under consideration; it is recommended that locally developed charts specific to the population should be used. The use of these charts means that factors that may influence fetal biometry, including maternal age and nutritional status, maternal height, weight, parity and smoking habits, are noted, facilitating accurate prediction of small-for-date and growth-retarded fetuses. The World Health Organization (WHO) has published a protocol for the collection of data for a multicentre study of fetal growth (Merialdi et al 2014). INTERGROWTH-21st, an international, multicentre project, also aims to standardize protocols for collecting anthropometric measurements and constructing charts describing optimal fetal and preterm postnatal growth (Sarris et al 2013, Uauy et al 2013).

An outcome of routine ultrasound examination of embryos and fetuses for anomalies may be a change to the perinatal management,

Fig. 14.2 A timetable of development of the body systems. The development of individual systems can be seen progressing from left to right. Embryonic stages and weeks of development are shown. Embryonic stages are associated with external and internal morphological features rather than embryonic length. To identify the systems and organs at risk at any time of development, follow a vertical progression from top to bottom.

Fig. 14.3 The two timescales used to depict human development. Embryonic development, in the upper scale, is counted from fertilization (or from ovulation, i.e. in postovulatory days; see O'Rahilly and Müller (1987)). Throughout this book, times given for development are based on this scale. The clinical estimation of pregnancy is counted from the last menstrual period and is shown on the lower scale; throughout this book, fetal ages relating to neonatal anatomy and growth will have been derived from the lower scale. Note that there is a 2 -week discrepancy between these scales. The perinatal period is very long because it includes all preterm deliveries.

Ultrasound planes examined in 20 -week scan

Fig. 14.4 Ultrasound planes examined in a routine second-trimester antenatal scan (left) and measurements taken to predict the estimated date of delivery (right). The top three images are in the sagittal plane (A). The other planes are transverse, apart from $\mathbf{J}$, which is longitudinal. Abbreviations: Ao, aorta; DA, ductus arteriosus; DV, ductus venosus; LA, left atrium; LPV, left portal vein; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RPV, right portal vein; RV, right ventricle; SVC, superior vena cava.
i.e. to the time, method and place of delivery of the fetus, or the parents may choose to terminate the pregnancy to minimize concerns about fetal and neonatal suffering and long-term disability. Termination may be chosen for severe, untreatable inherited metabolic disorders (e.g. Tay-Sachs disease), severe chromosomal anomalies (e.g. trisomy 13), lethal bone dysplasias, lethal anomalies such as anencephaly and other extreme neurological defects, and bilateral renal agenesis (Cass 2011). Improvements in prenatal screening and diagnosis have led to an overall increase in the prevalence of reported birth defects and overall lower perinatal mortality rates, reflecting increased early terminations of pregnancy (Cass 2011).

## Magnetic resonance imaging

Advances in prenatal ultrafast magnetic resonance imaging (MRI) now provide further ways to detect fetal anomalies, capturing particularly clear images (Sepulveda et al 2012) (Fig. 14.5). MRI is considered a useful adjunct to ultrasound imaging at 20-22 weeks because it enables better management planning for known or suspected anomalies (Reddy et al 2014).

## Fetal development

Although accurate morphological stages are not available for the fetal period, the developmental progression is broadly clear. During the fourth and fifth months, the fetus has a head and upper limbs that are

Fig. 14.5 MRI scans of fetal anomalies. A, Polyhydramnios may arise as a result of oesophageal compression, impaired swallowing and lack of absorption of amniotic fluid from the gut. B, Gastroschisis with loops of bowel in the extracellular coelom (chorionic cavity) and normal insertion of the umbilical cord. (With permission from Sepulveda W, Ximenes R, Wong AE, et al 2012 Fetal magnetic resonance imaging and threedimensional ultrasound in clinical practice: Applications in prenatal diagnosis. Best Pract Res Clin Obstet Gynaecol 26:593-624.)
still disproportionately large. (Although the rates of growth of the trunk and lower limbs increase during the remainder of intrauterine life, the disproportion is present after birth and, to a diminishing degree, is retained throughout childhood and on into the years of puberty.) A covering of primary hair, lanugo, appears. Towards the end of this period, sebaceous glands become active; the sebum that is secreted blends with desquamated epidermal cells to form a cheesy covering over the skin, the vernix caseosa, which is usually considered to protect the skin from maceration by the amniotic fluid. At about this time, the mother becomes conscious of fetal movement, formerly termed 'quickening'.

In the sixth month, the lanugo darkens, the vernix caseosa is more abundant and the skin becomes markedly wrinkled. The eyelids and eyebrows are now well developed. During the seventh month, the hair of the scalp is lengthening and the eyebrow hairs and the eyelashes are well developed. The eyelids themselves separate and the pupillary membrane disappears. The body becomes more plump and rounded in contour and the skin loses its wrinkled appearance as a result of the increased deposition of subcutaneous fat. Fetal length has increased to approximately 350 mm and weight to about 1.5 kg . Towards the end of this month, the fetus is viable; if born prematurely, it may be able to survive without the technological assistance found in neonatal intensive care units and its postnatal development can proceed normally.

Throughout the remaining lunar months of normal gestation, the covering of vernix caseosa is prominent. There is a progressive loss of lanugo, except for the hairs on the eyelids, eyebrows and scalp. The bodily shape becomes more infantile but, despite some acceleration in their growth, the legs have not quite equalled the arms in length proportionately, even at the time of birth. The thorax broadens relative to the head, and the infra-umbilical abdominal wall shows a relative increase in area, so that the umbilicus gradually becomes more centrally situated. Average lengths and weights for the eighth, ninth and tenth months are 40,45 and 50 cm and 2, 2.5 and $3-3.5 \mathrm{~kg}$, respectively. The rate of fetal growth slows from 36 to 40 weeks in response to the physical limitation imposed by the maternal uterus. Birth weight thus reflects the maternal environment more than the genotype of the child. This slowing of the growth rate enables a genetically larger child developing within a small mother to be delivered successfully. After birth, the growth rate of the neonate increases; the rate of weight gain reaches a peak some 2 months postnatally.

Just before birth, the lanugo almost disappears and the umbilicus is central. The testes, which begin to descend with the processus vaginalis of peritoneum during the seventh month and are approaching the scrotum in the ninth month, are usually scrotal in position. The ovaries are not yet in their final position at birth; although they have attained their final relationship to the uterine folds, they are still above the level of the pelvic brim.

## Fetal surgery

The use of routine ultrasound examination and MRI of fetuses has led to the development of a number of prenatal surgical interventions: e.g. to correct placental or membrane anomalies resulting in twin-to-twin transfusion and the production of amniotic bands (Deprest et al 2014); or to offer improved outcomes for meningomyelocele on the basis that the neural tissue may become secondarily damaged due to exposure to amniotic fluid and mechanical traumatic injury during gestation (Adzick 2013, Danzer and Johnson 2014, Cohen et al 2014).

## GROWTH IN UTERO

Alterations in the availability of nutrients to the fetus at particular stages of pregnancy elicit adaptive responses by the fetus. These may ensure fetal coping but may also result in pathology in adult life; the nutritional status of pregnant females is therefore of fundamental importance for the health of the next generation. Under- or overnutrition during fetal life may lead to metabolic changes in childhood, adolescence and adulthood, and pass to successive generations. Poor nutrition at critical stages of fetal life permanently alters the normal developmental pattern of a range of organs and tissues, e.g. the endocrine pancreas, liver and blood vessels, resulting in their pathological responses to certain conditions in later adult life (Barker et al 1993, Catalano and Hauguel-De Mouzon 2011). Maternal hyperglycaemia leads to changes in fetal metabolism and pathology in the child and adult (Pedersen 1952).

An increase in placental size occurs in pregnancy as an adaptive response to both high altitude and mild undernutrition, particularly

Other conditions have also been treated prenatally with limited improvement in mortality. Thus, congenital diaphragmatic hernia may be treated by percutaneous fetoscopic endoluminal tracheal occlusion from 25 to 33 weeks' gestation to prevent loss of lung fluid and enhance lung growth (Deprest et al 2004). Fetal airway patency has also been preserved during birth through perinatal ex utero intrapartum (EXIT) treatment, where a portion of the fetus is delivered through a hysterectomy incision for surgery while the fetus remains attached to the uteroplacental circulation. After the airway procedure is completed, the fetus is completely delivered (Deprest et al 2014).
during mid-pregnancy. However, although a larger placenta may be better able to deliver the full nutritional requirements of the fetus, the perfusion of a larger placenta is not without problems. It may produce changes in fetal blood flow and placental enzymes, and in the normal structure of the fetal vessel wall or of its responses to circulating trophins, e.g. catecholamines or angiotensin II, which will continue into adult life. Undernutrition in later pregnancy does not produce the same sequelae and placental enlargement does not occur. However, fetal growth slows and fetal wasting may occur as oxygen, glucose and amino acids are redistributed to the placenta to maintain its function.

## Transition to extrauterine life

The type of birth confers developmental outcomes on the neonate that affect its subsequent growth. Caesarean section for preterm delivery appears not to be associated with improved neonatal outcomes but is associated with increased risk of respiratory distress syndrome due to slower postnatal movement of fluid out of the lungs (Werner et al 2012, Bhatta and Keriakos 2011, Bellini et al 2006). The dramatic rise of this delivery method is not necessarily driven by improved neonatal outcomes because caesarean section has been shown to increase the odds of developing asthma and type 1 diabetes in later life by $20 \%$. Metaanalyses indicate that the endocrine milieu during caesarean section may lead to epigenetic effects on hepatic and metabolic function and so affect immune function in adult life, leading, in some instances, to food allergy and obesity (Steer and Modi 2009, Hyde and Modi 2012, Song et al 2013).

Prior to birth, the gut is exposed to hundreds of proteins, metabolites and cytokines that are swallowed in amniotic fluid; there is some evidence for the presence of bacterial species in amniotic fluid prior to delivery. Establishment of the gut microbiota by exposure to maternal vaginal and colonic bacteria during vaginal delivery leads to normal maturation of the gut wall. Gut colonization in preterm infants is delayed (Cilieborg et al 2012). Infants born via caesarean section may have primary gut flora disturbance for up to 6 months after birth and associated delay in postnatal immune development (Neu and Rushing 2011, Neu and Mai 2012, Matamoros et al 2013).

The establishment of enteral feeding has profound effects on early postnatal maturation. Human breast milk contains many bioactive substances that enhance gut maturity. It improves gastric emptying, encourages the growth of the microbiotome and contains a range of proteins, including large amounts of secretory immunoglobulin A and cytokines (e.g. interleukin (IL)-10) (Jakaitis and Denning 2014). Feeding preterm infants human milk is associated with less feeding intolerance and is thought to provide protection against diabetes and obesity in later life (Valentine and Morrow 2012). The rate of growth of infants fed breast milk for the first 6 months of postnatal life is different to that of formula-fed infants. Delivery of low-weight preterm babies, followed by parenteral feeding with no enteral nutrition, disrupts normal gut maturation and may lead to necrotizing enterocolitis (Wynn and Neu 2012). However, a balance with the gut microbiome is necessary; although full-term neonates born in tropical countries have similar villous height to those born in temperate climates, villous length in the small intestine shortens within 2-12 months of birth as a consequence of tropical enteropathy (Ramakrishna et al 2006).

The time of transition to extrauterine life is permanently recorded in the primary teeth and can be reliably demonstrated in forensic dental identification. The circadian growth rhythm of dentine and enamel deposition in tooth germs is temporarily blocked by the metabolic stress of delivery; the resultant change in enamel prism deposition is seen as a neonatal line or ring that can be detected in all deciduous teeth and permanent first molar teeth of live births. The thickness of the line is related to birth difficulties, being thinner in caesarean section and thicker in vaginal delivery (Sabel et al 2008, Canturk et al 2014).

## NEONATE

The neonatal period extends from birth to 28 days postnatally; it is divided into an early neonatal period from birth to 7 days, and a late neonatal period from 7 to 28 days. Technological advances have enabled successful management of preterm infants, many at ages that were considered non-viable a decade or two previously. Maturational processes involving local interactions and pattern formation still drive development at local and body-system levels in preterm infants. The sudden release of such fetuses into a gaseous environment of varying temperature, with full gravity and a range of microorganisms, promotes
the rapid maturation of some systems and the compensatory growth of others (in terms of responses to the effect of gravity or enteral feeding or exposure to microorganisms).

Details of the relative positions of the viscera and the skeleton in a full-term neonate are shown in Figures 14.6-14.8. The newborn infant is not a miniature adult, and extremely preterm infants are not the same as full-term infants. There are immense differences in the relations of some structures between the full-term neonate, child and adult, and there are also major differences between the 20-week-gestation fetus and the 40 -week fetus, just before birth. The study of fetal anatomy at 20, 25, 30 and 35 weeks is vital for the investigative and life-saving procedures carried out on preterm infants today.

## Neonatal measurements and period of time in utero

The tenth to ninetieth centile ranges for length of full-term neonates are $48-53 \mathrm{~cm}$ (Fig. 14.9A). Length of the newborn is measured from crown to heel. In utero, length has been estimated either from crownrump length, i.e. the greatest distance between the vertex of the skull and the ischial tuberosities, with the fetus in the natural curved position, or from the greatest length exclusive of the lower limbs. Greatest length is independent of fixed points and thus much simpler to measure; it is generally taken to be the sitting height in postnatal life, and is the measurement recommended by O'Rahilly and Müller (2000) as the standard in ultrasound examination.

At birth, weight reflects the maternal environment, the number of conceptuses, the sex of the baby and the parity of the mother. Generally, full-term female babies are lighter than full-term males, twins are lighter than singletons, and later children tend to be heavier than the first-born. The tenth to ninetieth centile ranges for the weight of a full-term infant at parturition are $2700-3800 \mathrm{~g}$ (Fig. 14.9B), the average being 3400 g ; $75-80 \%$ of this weight is body water and a further 15-28\% is composed of adipose tissue.

Birth weight is noted against charts appropriate for ethnicity and categorized as low, normal and high. Low birth weight has been defined as less than 2500 g , very low birth weight as less than 1500 g , and extremely low birth weight as less than 1000 g . Infants may weigh less than 2500 g but not be premature by gestational age. Measurement of the range of weights that fetuses may attain before birth has led to the production of weight charts, which allow babies to be described according to how appropriate their birth weight is for their gestational age, e.g. small for gestational age, appropriate for gestational age or large for gestational age (Fig. 14.10). Small-for-gestational-age infants, also termed 'small-for-dates', are often the outcome of intrauterine growth retardation.

For both premature and growth-retarded infants, an assessment of gestational age, which correlates closely with the stage of maturity, is desirable. Gestational age at birth is predicted by its proximity to the estimated date of delivery and the results of ultrasonographic examinations during pregnancy. It is currently assessed in the neonate by evaluation of a number of external physical and neuromuscular signs. Scoring of these signs results in a cumulative score of maturity that is usually within $\pm 2$ weeks of the true age of the infant. The scoring scheme has been devised and improved over many years.

Estimation of large-for-dates infants is based on assessment of fetal weight through ultrasound evaluation and some biometrical indices. Assessment of anterior abdominal wall width is thought to predict large-for-gestational-age babies (Walsh and McAuliffe 2012). Fetal macrosomia is defined as an absolute birth weight greater than 4000 g , 4500 g or 5000 g , or as a customized birth weight centile greater than the ninetieth, ninety-fifth or ninety-seventh centile for the infant's gestation age (Walsh and McAuliffe 2012, Schwartz et al 2014). The precise definition may not necessarily be helpful, as some at-risk infants, not identified as large for dates from growth curve charts, might go unrecognized (Larma and Landon 2011). There is a correlation between macrosomia and short maternal stature; macrosomic fetuses are at risk of shoulder dystocia and brachial plexus injuries during vaginal delivery.

## GROWTH IN INFANCY AND CHILDHOOD

After birth, there is a general decrease in the total body water but a relative increase in intracellular fluid. Normally, the newborn loses about $10 \%$ of its birth weight by 3-4 days postnatally because of loss of excess extracellular fluid. By 1 year, total body water makes up $60 \%$ of the body weight.

Animal studies have verified that maternal starvation during pregnancy decreases fetal intrauterine growth factor (IGF)-I concentrations and, together with a general hypoglycaemia, impairs the development of the fetal $\beta$ cells of the pancreas. Moreover, fetal undernutrition induces insulin resistance in the tissues. The coexistence of insulin resistance and impaired $\beta$-cell development in the fetus appears to be important in the pathogenesis of type 2 diabetes. The risk of developing this type of diabetes is greatest in those individuals with low weight at birth and at 1 year, and who become obese as adults, thus challenging an already impaired glucose-insulin metabolism. Fetal IGF-I concentrations are also lower in infants who are short at birth as a result of a long period of maternal undernutrition; these individuals have an exaggerated response to growth hormone-releasing factor, which, together with low IGF-I concentrations, suggests a degree of growth hormone resistance.

It is now thought that the balance of hormonal environment in intrauterine and early postnatal life is necessary for future adult health. The presence of altered concentrations of hormones during critical periods of development may act as endogenous functional teratogens (Plagemann 2004).

Different birth phenotypes have been correlated with different pathological sequelae. Infants who are thin at birth, with a low ponderal index (weight/length ${ }^{3}$ ), tend to develop a combination of insulin resistance, hypertension, type 2 diabetes and lipid disorders, whereas those who are short in relation to head size tend to develop hypertension and high plasma fibrinogen concentrations. These associations have been reported in babies born small for dates, rather than in those born prematurely. Some babies of average weight also develop cardiovascular pathology; they are either thin at birth and small in relation to the size of their placenta, or of average weight but short in relation to head size and have below average weight gain during the first year (Barker et al 1993). For more recent views on this concept, the reader is directed to consult Godfrey and Barker (2000), Ross and Beal (2008), and Kelishadi and Poursafa (2014).

Obesity has become increasingly prevalent since the end of the twentieth century, leading to an increase in type 2 diabetes, hypertension, hyperlipidaemia, atherosclerosis and inflammation in later life. In pregnancy, an observed decrease in insulin sensitivity as pregnancy advances leads to increased nutrient transfer to the fetus. In response, the fetus increases insulin secretion, stimulates IGF-I production, and fetal growth and fat deposition are promoted (Vrachnis et al 2012). Obese females start their pregnancy with greater insulin resistance than females of normal weight, which means that their fetuses produce more IGF-I and continue to grow. The risk of fetal macrosomia is three times higher in females with poorly controlled gestational diabetes because their increased weight reflects fat mass rather than lean body mass (Catalano and Hauguel-De Mouzon 2011). Adiposity at birth is related to obesity and metabolic dysfunction in childhood, which may be perpetuated through adulthood in an ongoing cycle through the generations (Catalano and Hauguel-De Mouzon 2011, Poston 2012). A range of risk factors for pre-, peri- and postnatal issues in maternal obesity is given in McGuire et al (2010).

Oxygenated blood（red）is returned to the fetal heart via the umbilical vein，which passes from the umbilicus to the liver． The right atrium contains oxygenated blood，which mainly passes to the left atrium．The right ventricle receives some oxygenated blood from this flow and also the deoxygenated blood from the head and neck．Blood is returned to the placenta via two umbilical arteries．

From cranial to caudal，the following structures are indicated：

| $\square$ | Larynx and trachea |
| :--- | :--- |
| Gastrointestinal tract |  |
| $\square$ | Pancreas |
| $\square$ | Urinary bladder |
| $\square$ | Prostate gland |

Note that the apex of the bladder continues as the urachus to the umbilicus．

From cranial to caudal，the following structures are indicated：
Maxillae and mandible
Costal cartilages
Lungs
Suprarenal glands
Lobulated kidneys
Ureter passing to the posterior
surface of the urinary bladder
Right uterine tube，
uterus and vagina
Left testis and vas deferens

Note that the lower border of the lung is below the central， upper border of the liver．
Note that the suprarenal glands are relatively large and superomedial to the lobulated kidneys．

Fig．14．6 A－C，Topographical representations of the anatomy of a full－term neonate．The surface markings of all organs are shown，with some coloured and others only in outline．The female genital tract is shown on the right of the body，and the male tract is shown on the left．

Fig. 14.7 A topographical representation of the anatomy of a full-term female neonate. The cut surfaces of the organs are the same colours as in Figure 14.6.

Fig. 14.8 The extent of the ossified skeleton in a full-term neonate. Note the derivation of the parts of the skeleton: the skull is derived from paraxial mesenchyme and neural crest mesenchyme; the axial skeleton, vertebrae and ribs are derived from paraxial mesenchyme; and the skeletal elements in the limbs are derived from somatopleuric mesenchyme, which forms the limb buds.

Fig. 14.10 Intrauterine growth status and its appropriateness for gestational age. Gestational age is more closely related to maturity than birth weight. The mortality for the weight ranges is indicated.

Growth rates of infants born prematurely differ from those born naturally at term. Normally, fetuses grow rapidly between 20 and 40 weeks. Optimum growth of premature infants is considered to be equivalent to intrauterine rates. However, whereas, in utero, fetuses show a slowing growth velocity before term, preterm infants show linear growth. Growth charts for preterm infants have been constructed (Fenton and Kim 2013). The INTERGROWTH-21st project is collecting data for preterm growth (see above).

Growth has always been regarded as a regular process. The rates of prenatal and postnatal growth can be indicated by increments in body length or weight, which, when plotted, form a growth curve (see Fig. 14.9). Growth curves can be plotted for individuals if accurate measurements are taken, preferably by the same person, for the entire period of growth, i.e. a longitudinal study. An alternative method is to collect a series of averages for each year of age obtained from different individuals, i.e. a cross-sectional study. Cross-sectional studies are valuable for the construction of standards for height and weight attained by healthy children at specific ages, and can establish centile limits of normal growth, but they cannot reveal individual differences in either the rate of growth or the timing of particular phases of growth.

The data from longitudinal and cross-sectional studies can also be used to plot the increments in height or weight from one age to the next. This produces a velocity curve, which reflects a child's state at any particular time much better than the growth curve, in which each point is dependent on the preceding one. The oldest published longitudinal study, still of great value today, was made by Count Philibert de Montbeillard on his son (Fig. 14.11). It shows that the velocity of growth in height decreases from birth onwards, and that a marked acceleration of growth, the adolescent growth spurt, occurs from 13 to 15 years (see below; see Fig. 14.14).

Cross-sectional data permit comparison of prenatal and postnatal growth. Childhood growth charts are used to predict normal childhood development. The velocity curve for the prenatal and postnatal period (Fig. 14.12) shows that the peak velocity for length is reached at about 4 months (note that these prenatal charts use the obstetric measurements of gestational time, in which fetal age is estimated from the last menstrual period, 2 weeks before fertilization). Growth in weight usually reaches its peak velocity after birth.

Tanner (in Harrison et al (1964)) noted that the more carefully measurements are taken, the more regular is the succession of points on a growth curve. However, a longitudinal study of growth measured weekly, semi-weekly and daily recorded that growth in length and head circumference occurred by saltatory increments, with a mean amplitude of 1.01 cm for length (Lampl 2002); growth stasis, steep changes in growth and incremental growth have all been recorded in infancy, childhood and adolescence (Caino et al 2006).

Charts of height and weight correlated to age are compiled from extensive cross-sectional growth studies. Such charts show the mean height or weight attained at each age, termed the fiftieth centile, and also the centile lines for the seventy-fifth, ninetieth and ninety-seventh centiles, in addition to the twenty-fifth, ninth and second centiles. The data shown in Figure 14.13 are derived from United Kingdom crosssectional references. Any comparison of an individual growth curve

with these data must also take into account ethnicity and the nutritional and family history of that individual.

Plotting the growth of children on such charts provides guidelines for the prediction of normal growth and indicates when investigation of possible growth anomalies should occur. Children who grow in an environment that does not constrain their growth exhibit a pattern of growth that is mainly parallel to a particular centile, a phenomenon that has been termed homeorhesis or canalization (following the same imaginary 'canal' on the growth chart). After deviation from this centile as a consequence of the adolescent growth spurt, most children return to the same centile position in adulthood, a finding that suggests that this pattern is genetically determined within individuals (Cameron 2002). For a comprehensive account of all aspects of postnatal growth, the reader is directed to consult Human Growth and Development (Cameron 2002).

The WHO published growth charts for birth to 5 years and $5-19$ years (2006). The charts were derived from children considered to be growing under optimal environmental conditions: they were breastfed, raised in environments that minimized poor diets and infection, and had nonsmoking mothers. Similar growth charts have been published by WHO for specified regions (Mansourian et al 2012).

## ADOLESCENT GROWTH SPURT AND ADULT SIZE

Growth charts reveal that body length increases from a neonatal range of $48-53 \mathrm{~cm}$ to about 75 cm during the first year after birth, and increases by $12-13 \mathrm{~cm}$ in the second year. Thereafter, $5-6 \mathrm{~cm}$ is added each year. In individual longitudinal growth curves, an increase in the velocity of growth occurs between 10.5 and 11 years in girls, and 12.5 and 13 years in boys. This rapid increase in growth is the adolescent growth spurt (Fig. 14.14; see Fig. 14.13). In both sexes, it lasts for 2-2.5 years. Girls gain about 16 cm in height during the spurt, with a peak velocity at 12 years of age. Boys gain about 20 cm in height (mostly by growth of the trunk), with a peak velocity at 14 years of age, during which time they may be growing at the rate of 10 cm a year.

Humans seem to be the only species to have a long quiescent interval between the rapid growth that takes place immediately after birth and the adolescent growth spurt. This type of growth has been termed the Infancy/Childhood/Puberty (ICP) growth model (Stevens et al 2013). It has been suggested that the quiescent interval allows the brain to mature, and complex social learning to take place, before individuals pass through puberty and become sexually active.

Apart from the expected change in growth velocity that occurs during puberty, it is now apparent that taller child height is prospectively associated with elevated risk of obesity (Johnson et al 2012, Van Dommelen 2014). Growth in height continues at a slower rate after the adolescent growth spurt. Noticeable growth is said to stop at 18 years in females and 20 years in males; longitudinal studies have indicated an average figure of 16.25 years (females) and 17.75 years (males) with a normal variation of $\pm 2$ years (Harrison et al 1964). After this time, any increments that occur as a result of appositional growth at the cranial and caudal ends of the vertebral bodies and intervening intervertebral

Fig. 14.13 Standard growth charts of British boys and girls showing the ninetieth, fiftieth and tenth centiles. (© Child Growth Foundation.)
discs are so small as to be difficult to measure. There is a loss of height after middle age.

Development-related gene expression correlates with three phases of human growth (infancy/early childhood; childhood/puberty; final height); the expression of clusters of growth-related, evolutionarily conserved genes varies in a development-dependent manner in human tissues (Stevens et al 2013). The outcomes of the Human Genome Project have been linked to anthropomorphic traits in meta-analyses of genome-wide association data that have identified genetic variants at hundreds of loci relevant to growth in pre-puberty, puberty and adulthood, particularly those associated with childhood and adult obesity (Genome-wide Investigation of ANThropometric measures - GIANT). A genome-wide association study has shown genetic loci linking
pubertal timing, height and growth with childhood obesity (Cousminer et al 2013).

The phenomenal growth rates of adolescence are most obvious in the increase in height. Weight gain is more variable. The birth weight is normally tripled by the end of the first year, and quadrupled by the end of the second year. Thereafter, weight increases by $2.25-2.75 \mathrm{~kg}$ annually until the adolescent growth spurt, when boys may add 20 kg to their weight and girls 16 kg . The peak velocity for weight gain lags behind the peak velocity for height by about 3 months. Body weight does not reach adult values until some time after adult height is attained. In recent years, the global estimates of the numbers of adults who are overweight or obese in adult life has exceeded the numbers who do not have sufficient food (Mascie-Taylor and Goto 2007).

Fig. 14.15 The duration of multiplicative growth for various human tissues.

Fig. 14.16 Allometric growth in humans. The head is very large in proportion to the rest of the body during the embryonic period. After this time, the head grows more slowly than the torso and limbs and, by adulthood, the head is only one-eighth of the body length.

## INTEGRATION OF TYPES OF GROWTH DURING DEVELOPMENT AND LIFE

In the later prenatal months and in the postnatal period, the various types of growth occur in differing patterns. The extent of tissue growth in organs depends on the specific duration of multiplicative growth for the cell types (Fig. 14.15). Different cell populations complete their initial developmental proliferation and become differentiated at different times; the final stage of differentiation is usually the cessation of cell division.

Growth of a body can be described in two ways: isometric and allometric. Isometric growth implies a progressive proportional increase in
all organs and systems with time; it does not occur in the developing embryo, which displays differential rates of growth. Allometric growth describes the differences in the relative rates of growth between one part of the body and another, and is most clearly seen in the changes in body proportion between fetuses, neonates, children and adults. Between 6 and 7 weeks after fertilization, the head is nearly one-half of the total embryonic length. It subsequently grows proportionally more slowly and, at birth, it is one-quarter of the entire length. During childhood, this pattern of growth continues with lengthening of the torso and limbs until, in adults, the head is one-eighth of the total length (Fig. 14.16).

Growth of the liver, spleen, kidneys, skeletal and muscular tissues generally follows pre- and postnatal growth curves given for the

Fig．14．17 Growth curves of different tissues，regions of the body and systems．Note that the growth of lymphoid tissue，thymus，lymph nodes and intestinal lymph masses decreases after puberty．（Adapted with permission from Tanner JM 1962 Growth at Adolescence，2nd ed．Oxford： Blackwell Publishing．）
entire body．Other tissues have very different growth rates；the brain， skull，lymphoid tissues and reproductive organs all show differing growth rates during childhood and adolescence（Kappelou et al 2006） （Fig．14．17）．

Changes in growth at a tissue level are complex；differential growth rates during puberty can lead to temporal－specific associated pathology． For example， $30 \%$ of childhood fractures affect the radius，mostly the distal metaphysis，during the pubertal growth spurt，after which the incidence of these fractures decreases rapidly（Rauch 2012）．Local dif－ ferential rates of bone growth are seen in bone growth plates，peripheral and central trabecular bone，and in bone remodelling．During prepu－ bertal growth，the distal radial growth plate adds about 9 mm to the length of the radius per year；the spaces between the peripheral trabecu－ lae are filled with mineralized bone．It is suggested that incomplete trabecular coalescence during this rapid growth，rather than bone remodelling（which takes at least 6 months to complete），leads to lower bone mineral density，especially in boys，（which decreases rapidly after the pubertal growth spurt），and higher local metaphysial cortical por－ osity（Wang et al 2010，Rauch 2012）．

## Development of the limbs

## LIMB BUDS

The limbs develop from the lateral body wall; their outgrowth is initiated at defined positions along the embryonic axis where cells continue to proliferate, giving rise to local thickenings that soon develop into limb buds. These buds are encased in an ectodermal epithelium rimmed by a longitudinal ridge of columnar epithelial cells: the apical ectodermal ridge. Figure 15.1 shows the main stages in the development of a human upper limb; the stages in development of the lower limb are basically the same. The early limb bud elongates and, gradually, the different limb regions become apparent. A broad plate forms at the tip and, within it, digital rays develop that mark the position of the forming digits. The digits later separate and become tipped with nails. For further details of upper and lower limb development, see the appropriate regional chapters.

The early limb bud contains a mixed population of mesenchymal cells: somatopleuric mesenchyme cells that give rise to the connective tissues, including cartilage, bone, tendon, loose connective tissue and
dermis; and paraxial mesenchyme cells that have migrated from the somites, and which give rise to the myogenic cells of the muscles and to some of the endothelial cells that produce an extensive vascular network in the early limb bud. The ectodermal epithelium covering the limb bud gives rise to the epidermis of the skin. Motor and sensory nerves and their associated Schwann cells, together with melanocytes destined for the skin, migrate into the developing limb somewhat later; the Schwann cells and melanocytes are derived from the neural crest.

## AXES OF LIMBS

For descriptive, experimental and conceptual purposes, various 'axes', borders, surfaces and lines in relation to the developing limb bud are defined and named (Fig. 15.2). An imaginary line from the centre of the elliptical base of the bud, through the centre of its mesenchymal core to the centre of the apical ectodermal ridge, defines the proximodistal axis of the limb bud (previously known in descriptive embryology simply as the axis). Named in relation to the proximodistal axis, the

Fig. 15.1 Scanning electron micrographs to show the development of the upper limb. A, An early limb bud viewed from the postaxial border. B, A limb bud viewed from the postaxial border; the apical ectodermal ridge (arrows) can be seen. C, A limb bud, dorsolateral view; the shoulder and elbow region can be discerned, and a hand plate has formed. The apical ectodermal ridge is still obvious at the margin of the hand plate. D, Digital rays are present in the hand plate and the margin of the plate is becoming notched. $\mathbf{E}$, The fingers are nearly separated and proliferation is commencing at the distal end of each digit to form the nail bed. F, The fingers each have tactile pads distally, and nail development continues. (Photographs courtesy of P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)

Fig. 15.2 Axes of the developing limb and specification of structures along the different axes. A, Proximodistal; limb bud viewed from the dorsal side. B, Craniocaudal; limb bud viewed from the dorsal side. C, Dorsoventral; limb bud viewed from the distal end. The development of limb structures and the ectodermal specializations are controlled by the limb mesenchyme. Outgrowth of limb bud is controlled by the apical ectodermal ridge and accompanied by the laying down of structures along the proximodistal axis; craniocaudal pattern is controlled by the zone of polarizing activity (polarizing region); dorsoventral pattern is controlled by signals from dorsal and ventral ectoderm, shown in cross-section; the section taken in the plane is shown by the dotted line. The limb bud in the diagram is equivalent to that of a human embryo at approximately stage 14.
cranially placed limb border is the preaxial border and the caudally placed limb border is the postaxial border. (In vertebrate embryos used as experimental models, e.g. chick embryos, the pre- and postaxial borders are termed anterior and posterior borders, respectively.) Any line that passes through the limb bud from preaxial to postaxial border, orthogonal to the proximodistal axis, constitutes a craniocaudal axis. The dorsal and ventral ectodermal surfaces clothe their respective aspects from preaxial to postaxial borders, and any line that passes from dorsal to ventral aspect, orthogonal to both proximodistal and craniocaudal axes, constitutes a dorsoventral axis. It should be noted here that the terms dorsal and ventral axial lines are to be used exclusively in relation to developing and definitive patterns of cutaneous innervation of the limbs and their associated levels of the trunk.

The three developmental axes (proximodistal, craniocaudal and dorsoventral) can be identified in the human developing limb bud by stage 13. Experiments on chick embryos have shown that a different set of cell-cell interactions control the development of structures in relation to each of the three principal axes of the limb bud: proximodistal (e.g. humerus to fingers), craniocaudal (e.g. thumb to little finger) and dorsoventral (e.g. extensors to flexors) (see Fig. 15.2). These experiments are described in detail in Hinchcliffe and Johnson (1980).

Outgrowth of the limb bud along its proximodistal axis is controlled by interactions between the apical ectodermal ridge and underlying somatopleuric mesenchyme, and is accompanied by the sequential formation of limb structures along the proximodistal axis. Growth and development along its craniocaudal axis involves an interaction between a small population of mesenchyme cells on the postaxial border of the limb bud, termed the zone of polarizing activity, or polarizing region, and adjacent mesenchyme. The development of the dorsoventral axis of the limb involves an interaction between the surface ectoderm on the sides of the limb bud and the underlying mesenchyme. These sets of cell-cell interactions are coordinated so that the developing limb develops properly with respect to all three axes.

Early differential growth of parts of the limb bud results in two main changes to the originally symmetrical axes of the limb. The dorsal aspect of the limb grows faster than the ventral, which causes the limb bud to
curve around the body wall; the ventral surface of the limb (closest to the body wall) remains relatively flat, but the dorsal surface bulges into the amniotic cavity. The apical ectodermal ridge, originally facing laterally, becomes increasingly directed caudally (upper limb) and ventrally (lower limb) as the limbs extend around the body.

## Apical ectodermal ridge

The apical ectodermal ridge is required for limb bud outgrowth. When it is removed from a chick wing bud, outgrowth ceases and a truncated wing results, whereas when a second apical ectodermal ridge is grafted, a new outgrowth is induced that develops digits (Saunders et al 1976) (Fig. 15.3). The molecular basis of the cell-cell interactions between apical ridge and underlying mesenchyme is conserved between different vertebrates; the apical ectodermal ridge of a mouse limb bud can promote outgrowth of a chick wing bud.

There is evidence that the limb mesenchyme beneath the apical ectodermal ridge provides a factor that is essential for maintaining activity of the ridge (the so-called apical ridge maintenance factor). Thus, the craniocaudal extent of production of apical ectodermal ridge maintenance factor determines the length of the apical ectodermal ridge. When chick leg bud cells are grafted to the tip of a wing bud beneath the apical ectodermal ridge, the ridge is maintained and outgrowth continues. It should be noted that the leg cells, even though placed in a wing bud, still form distal leg structures, i.e. toes (Saunders and Gasseling 1959) (see Fig. 15.3). In addition, leg mesenchyme will pass information to local wing ectoderm, eliciting appropriate epidermal development: in this case, formation of scales rather than feathers.

For many years, it was thought that a timing mechanism linked to limb bud outgrowth specified structures along the proximodistal axis. The timing mechanism was postulated to operate at the tip of a developing limb bud beneath the apical ectodermal ridge in the zone of proliferating undifferentiated mesenchyme cells, which were therefore called the progress zone. It was assumed that, as cells left the progress

Fig. 15.3 A-C, Experimental manipulations that identified the fundamental cell-cell interactions involved in patterning the three main axes of the limb in the chick. Abbreviation: ZPA, zone of polarizing activity.
zone during limb bud outgrowth, their proximodistal fate became fixed. Thus, cells spending a short time at the tip of the limb bud would be specified to form proximal structures, while cells spending a longer time would be specified to form distal structures (Summerbell et al 1973). However, it now seems that the proximodistal pattern is specified in the very early limb bud (Dudley et al 2002) and that the prespecified structures are progressively elaborated as the bud grows out.

## ZONE OF POLARIZING ACTIVITY

The zone of polarizing activity (or polarizing region) at the postaxial border was discovered by a grafting experiment on chick wing buds (Saunders and Gasseling 1968). When a polarizing region is grafted to the preaxial border of an early chick wing bud, so that there are polarizing region cells at both borders, duplication of distal limb structures occurs, with two ulnae (instead of an anterior radius and posterior
ulna) and a mirror-image pattern of six digits (the normal chick wing has three digits (see Fig. 15.3)). The digit closest to the polarizing region is always the most postaxial digit (in the chick wing, traditionally designated as digit 4), while more preaxial digits develop further away. Thus, the signal from the polarizing region appears to control both digit number and digit pattern. Digit number is controlled by regulating the width of the limb bud: both directly, via promoting cell proliferation, and indirectly, by controlling production of the apical ectodermal ridge maintenance factor. Digit pattern is specified by concentration of a diffusible morphogen produced by the polarizing region. The width of the limb bud is also limited by zones of programmed cell death on the preaxial and postaxial borders. (It should be noted that, in the literature relating to work on animal embryos, pre- and postaxial borders are termed anterior and posterior borders, respectively, and therefore the regions in which programmed cell death occurs are termed the anterior and posterior necrotic zones.) When the length of the apical ectodermal ridge is reduced, fewer digits form (oligodactyly), while, when the apical
ectodermal ridge becomes longer, more digits form (polydactyly). Other regions of apoptotic cell death occur between the digits and result in digital separation, but these appear later than the anterior and posterior necrotic zones; the resultant debris in all of the necrotic zones is removed by macrophages.

Grafts of the zone of polarizing activity only generate mirror-image digit patterns when placed beneath or adjacent to the apical ectodermal ridge, suggesting that the ridge produces a factor that maintains polarizing region activity. A positive feedback loop, where the polarizing region and the apical ectodermal ridge mutually maintain each other's activity, would ensure that development of craniocaudal and proximodistal axes is coordinated. Like that of the apical ectodermal ridge, the function of the polarizing region is conserved across species. Thus, grafts of the postaxial border of limb buds from mammals, including human limb buds (Fallon and Crosby 1977), generate additional chick digits, showing that the polarizing region produces the same molecular signal, although its interpretation depends on the responding cells.

## ECTODERMAL INTERACTION

Signals from the ectoderm control the dorsoventral axis. It is possible to remove the surface ectodermal epithelium (like peeling off a glove) from the mesenchymal core of an early chick limb bud. When the ectodermal epithelium from a left limb bud is recombined with the mesenchymal core from a right limb bud, keeping the craniocaudal axis in register, the distal part of the limb that develops conforms to the polarity of the ectoderm rather than the polarity of the mesenchyme (MacCabe et al 1974) (see Fig. 15.3). This can be seen in the pattern of muscles, orientation of the joints and eventual characteristic differentiation of the epidermis.

## MOLECULAR BASIS OF CELL-CELL INTERACTIONS

The apical ectodermal ridge produces fibroblast growth factors, extracellular cell-cell signalling molecules that act on the underlying mesenchyme cells and are essential for limb bud outgrowth (Niswander et al 1993). Fibroblast growth factors also maintain the activity of the polarizing region. The latter expresses Sonic hedgehog (Shh), a gene encoding another class of secreted protein that acts as an extracellular signalling molecule (Riddle et al 1993). Sonic hedgehog protein (Shh) acts on adjacent mesenchyme cells, controlling their proliferation and also maintaining the expression of the Gremlin gene, encoding an extracellular antagonist of secreted bone morphogenetic proteins. Gremlin functions as the apical ectodermal ridge maintenance factor (Zuniga et al 1999). Sonic hedgehog plays a pivotal role in the specification of the craniocaudal digit pattern: it spreads across the limb bud so that cells at different positions across the craniocaudal axis are exposed to different Shh concentrations (Tickle and Barker 2013). Responding cells transduce the signal through the Gli family of transcription factors. (The Gli proteins are bifunctional effectors of Shh signalling and can lead to either activation or repression of expression of target genes.) Dorsal limb ectoderm expresses Wnt7a, encoding another extracellular signalling molecule that acts as a dorsalizing signal (Parr and McMahon 1995).

Among the genes expressed in response to cell-cell signalling molecules in the limb are $5^{\prime}$ members of the Hox-a and Hox-d complexes Hox genes code for transcription factors that act in a cell-autonomous fashion to control expression of many target genes. Hox-d gene expres sion in the distal limb bud shows a nested arrangement similar to that of Russian babushka dolls: the postaxial border of the limb bud tip expresses five Hox-d genes ( $d-13, d-12, d-11, d-10$ and $d-9$ ), while in the adjacent, more preaxial, portion, only four genes are expressed ( $d-12$, $d-11, d-10$ and $d-9$ ), and so on, moving across the limb until only Hoxd-9 is expressed at the preaxial border (Dollé et al 1989). The fact that five different Hox-d expression domains can be distinguished prompted the suggestion that this may be why we have five fingers (and toes) (Tabin 1992): an attractive but unlikely explanation because, in the chick wing bud, the digits all come from the region that expresses all five Hox-d genes. The gene encoding the transcription factor Lmxb1 is expressed in the dorsal part of the limb in response to Wnt 7a signalling by dorsal ectoderm.

The molecular basis of limb development is conserved in humans. Mutations associated with many of the genes described above are responsible for human congenital limb malformations. Details can be found in Ferretti and Tickle (2006), Zeller et al (2009) and Zuniga et al (2012).

## DEVELOPMENT OF LIMB TISSUES

## DEVELOPMENT OF BONE AND CONNECTIVE TISSUE IN THE LIMB

The first signs of the formation of skeletal elements are regions of increased cell density in the core of the limb bud. The cells in these regions go on to differentiate into chondrocytes, which produce large quantities of extracellular matrix, in which they become embedded, giving rise to a cartilage model of the bone to be developed. One centre of chondrogenesis forms in the proximal region of an early human limb bud; two centres of chondrogenesis then form more distally as the limb bud lengthens, followed by five centres in the broadened distal tip. The Sox9 transcription factor is essential for chondrocyte differentiation in mouse embryos; the Sox9 gene is expressed before and during deposition of cartilage (Wright et al 1995). Sox9 gene transcripts are expressed in the humerus and forearm skeletal elements of human embryos at approximately 44 days, and in the carpals, metacarpals and phalanges, in addition to the more proximal elements, at approximately 52 days (Fig. 15.4). Mutations in human Sox9 are associated with campomelic dysplasia, a skeletal dysmorphology syndrome (Foster et al 1994). Some bony eminences, which are sites of entheses, have been shown to derive from chondrogenic foci which form separately and later than the cartilage model of the long bones (Blitz et al 2013). The cells coexpress Sox9 and the transcription factor scleraxis (Scx). Blockage of $S c x$ or Bmp 4 expression in the limb arrests eminence development. It is suggested that as the fully formed eminences are subjected to tension whereas joint surfaces are subjected to compression, then different developmental pathways are in operation to cope with different functional parameters (Blitz 2013). Scx encoding the transcription factor

Fig. 15.4 Sox9 expression in the skeleton of developing limbs of human embryos. A, Stage 18; approximately 44 days post ovulation. Key: 1, humerus; 2, ribs; 3, heart; 4, forearm; 5, vertebral body; 6, scapula B, Stage 21; approximately 52 days post ovulation. Key: 1, carpal; 2, metacarpal; 3, phalanges; 4, humerus; 5 , scapula; 6 , rib. Sox9 transcripts are detected in sections with radioactively labelled probes followed by autoradiography. Positive signal is represented by silver grains that show up as white areas. Scale bars represent $500 \mu \mathrm{~m}$ in both A and B. (The human tissue was provided by the joint MRC-Wellcome Human Developmental Biology Resource (http://www.hdbr.org) at the Institute of Human Genetics, Newcastle upon Tyne, UK. By courtesy of Dr Susan Lindsay, Institute of Human Genetics, University of Newcastle upon Tyne, UK.)

Scleraxis is expressed in the early limb subjacent to the ectoderm. Studies of Scx knockout mice show that the differentiation of forcetransmitting tendons can be distinguished from muscle-anchoring tendons (Muchison et al 2007). A population of $S c x^{+} / S o x 9^{+}$progenitor cells have been shown to give rise to $S c x^{-} / S o x 9^{+}$chondrocytes and $S c x^{+} /$ Sox $9^{-}$tenocytes/ligamentocytes. The $S c x^{+} / S o x 9^{+}$cells contribute particularly to establishing the enthesis organ between the cartilage and tendon (Blitz et al 2013). The closer the tendon is to the cartilage primodium (anchoring tendon), the more tenocytes arise from the Sox9 ${ }^{+}$lineage In general, the number of such derived tenocytes decreases with increasing distance from the cartilage model, although there is variation between individual force-transmitting tendons (Sugimoto et al 2013).

The first evidence of bone formation is seen at the mid section of the diaphyses of long bones at $7-8$ weeks in human embryos. Vascular invasion of the cartilage matrix precedes the formation of a periostial collar, and subsequently extends proximally and distally until it reaches the future epiphysial level, where a growth plate will be established. By 10 weeks, columns of chondrocytes can be seen at the epiphysial level of most bones. However, only the lower end of the femur and upper end of the tibia develop secondary ossification centres before birth.

For further details describing the development of cartilage, see page 84; for the development of bone, see page 91. For further details describing the development of specific limb bones, see the appropriate regional chapter. It should be noted that maternal nutrition and vitamin status affects fetal bone growth and that despite vitamin supplementation in Western countries, pregnant women in northern latitudes may remain vitamin D deficient in winter pregnancies. Infant length was shorter in pregnancies with early serum 25-hydroxyvitamin D below the median value (Walsh et al 2013).

## DEVELOPMENT OF JOINTS IN THE LIMB

Regions of developing cartilage are easily recognized histologically in the developing limb because they consist of widely spaced cells surrounded by matrix. These regions are separated by transverse bands of relatively flattened cells - interzones - which mark the sites of future joints. Their subsequent development varies according to the type of joint that is formed.

In developing fibrous joints, the interzone is converted into collagen, which is the definitive medium connecting the bones involved. In developing synchondroses, the interzone becomes (growth) cartilage of the modified hyaline type; in developing symphyses, it is predominantly fibrocartilage. In developing synovial joints, the interzonal mesenchyme becomes trilaminar when a more tenuous intermediate zone appears, splitting the mesenchyme into two dense strata. As the skeletal elements chondrify, and in part ossify, the dense strata of the interzonal mesenchyme also become cartilaginous; subsequent cavitation of the intermediate zone establishes the cavity of the joint. The loose mesenchyme around the cavity forms the synovial membrane and probably also gives rise to all other intra-articular structures, such as ligaments, discs and menisci. In joints containing discs or menisci, and in compound articulations, more than one cavity may appear initially, sometimes merging later into a complex single cavity. As development proceeds, thickenings in the fibrous capsule can be recognized as the specializations peculiar to a particular joint. (In some joints, such accessions to the fibrous capsule are derived from neighbouring tendons, muscles or cartilaginous elements.) Although the initial stages in the process of cavitation of joints are independent of movements, a true joint cavity can generally form only in the presence of movements.

## DEVELOPMENT OF MUSCLE IN THE LIMB

It is now well established that all limb myogenic precursor cells originate from the somites (Chevallier et al 1977, Kardon et al 2003). These cells are committed at an early stage and can be identified in the lateral halves of the somites. After the mesenchymal sclerotome cells have migrated from the epithelial somite, the remaining dorsolateral portion is termed the epithelial plate or dermomyotome of the somite (see Fig. 44.3). Cells from the dorsomedial edge of the dermomyotomes form the axial musculature, whereas, at limb levels, cells de-epithelialize and migrate from the ventrolateral edges of the dermomyotome into the limb bud. These precursor limb myoblasts migrate through a nonrandom, structured network of extracellular fibrils. At their leading ends, the migrating cells exhibit filopodia, which are in contact with the extracellular fibrils or with other cells; it is believed that the orientation of the extracellular fibrils may direct the migration of the cells. The precursor muscle cells do not differentiate into muscle before their
migration into the limb, probably because of inhibitory signals produced by the somatopleuric mesenchyme. Muscle differentiation depends on the key activity of the MyoD family of transcription factors (Weintraub et al 1991).

The myogenic cells colonize the limb bud in a proximodistal direction but never reach the most distal portion of the limb. Experiments in chick embryos revealed that myogenic cells are still indifferent regarding their region-specific determination when they first enter the limb. Thus, when brachial-level somites are grafted opposite the legforming region, or when pelvic-level somites are grafted opposite the wing-forming region, a normal limb musculature develops, irrespective of the origin of the somites, i.e. the muscle cells, unlike the somatopleuric mesenchyme, are not specified to be wing or leg (Chevallier et al 1977). Other experiments show that the muscle pattern developed in the limb reflects the pattern of the skeletal elements: duplication or lack of digits is accompanied by the duplication or lack of the corresponding muscles (Robson et al 1994).

The first myogenic cells to arrive in the limb form the principal dorsal and ventral premuscle masses. It is believed that, in all classes of tetrapods, limb muscle development begins with these masses, which produce all the skeletal muscle in the limb. The premuscle masses undergo a stereotyped spatiotemporal sequence of divisions and subdivisions as the limb lengthens. In human embryos, this leads to the individualization of about 19 muscles in the upper limb and 14 muscles in the lower limb. The mechanisms that divide the muscle masses are not known; one suggestion is that these divisions are created by invading somatopleuric cells. In the upper limb, the premuscle masses first divide into three masses, the next division gives rise to the muscles attached to the carpus, and the final division produces the long muscles of the digits. A similar pattern is seen in the lower limb.

Each anatomical muscle appears as a composite structure. The muscle cells and myosatellite cells are of somitic origin, and the connective tissue envelopes and the tendons are of somatopleuric origin. The precise way in which the muscles become anchored to the developing bones by the tendons is not clear. For further development of skeletal muscle, see page 109.

The literature suggests that all musculoskeletal elements are in their appropriate positions in human limbs by 10 weeks. For detailed accounts of the process, consult O'Rahilly and Gardner (1975) and Uhthoff (1990). For recent reviews on limb development, including tissue formation, see Lane and Tickle (2003).

## DEVELOPMENT OF NERVES IN THE LIMB

During development, the spinal cord opposite the limbs becomes specialized, with the formation of longitudinal minicolumns (columels) along its rostrocaudal axis. The columels consist of groups of individual pools of differentiated motor neurones, precisely organized according to function (Jessell et al 2011). Motor neurones within each individual pool innervate a particular muscle. Neurones in medial pools express the transcription factor Islet1 and their axons innervate ventral limb muscles, while neurones in lateral pools express the related transcription factor, Lim1, and innervate dorsal limb muscles. Neurones also express different Hox proteins according to their position along the rostrocaudal axis of the spinal cord, and this determines their identity and their position within the spinal cord (Dasen et al 2005).

Motor axons enter the developing limbs earlier than sensory axons at the time when dorsal and ventral muscle masses have started to form. Guidance of the growing axons is not dependent on the presence of migrating myoblasts; when these are absent, the main nerve trunks in the limb still form, although the smaller motor branches that would innervate individual muscles do not form (Lewis et al 1981, Honig et al 2005). Motor axons grow into the dorsal and ventral muscle masses and innervate muscle groups in a proximo-distal progression. Correct axonal routing depends on both repulsive and attractive cues. The pathfinding of motor axons is an important model system for understanding binary axon guidance decisions: glial cell (line)-derived neurotrophic factor (GDNF) attracts motor neurone growth cones, and interacts synergistically with ephrin-As to determine growth cone directionality (Drescher 2011). Experimental studies in mice and chickens have shown that axons of neurones in lateral pools grow into the dorsal part of the limb as a result of repulsive interactions between the receptor EphA4 (expressed by these motor neurones) and its ligand, ephrinA (expressed by ventral limb cells). The axons of EphB-expressing motor neurones in medial pools grow into the ventral part of the limb as a result of repulsive interactions with ephrinB-expressing cells in the dorsal limb (Drescher 2010). The dorso-ventral differences in Ephrin expression in the limb are controlled by the system that establishes the
dorso-ventral axis of the limb and that results in dorsal expression of Lmxb1.

Sensory neurones in the dorsal root ganglia opposite the limbs send axons peripherally to terminate in the skin and to innervate proprioceptors in the limb muscles. The trajectories of sensory axons into the limb can be influenced by interaction with motor axons. When sensory axons grow into the developing limb, it has already been invaded by motor axons and the environment will have been altered by any extracellular factors they may have secreted. If motor axons are removed before sensory axons extend into the limb, those sensory axons, which would normally terminate in muscle (Ia afferent axons), appear unable to do so and instead become cutaneous nerves (Honig et al 1986, Honig and Rutishauser 1996, Honig et al 1998).

The developing skin (ectoderm and immediately underlying somatopleuric mesenchyme) is essential for the normal development of cutaneous sensory axons. If the ectoderm is removed, the cutaneous nerves that would project to it are absent. This can be prevented by applying the signalling molecule BMP4 (Honig et al 2004, Honig et al 2005). Cutaneous sensory axons are not matched to particular regions of skin in the limb and can innervate regions outside their usual anatomical dermatomes, or expand into regions of skin where the cutaneous innervation is eliminated (Wang and Scott 2002).

Proprioceptive sensory neurones are characterized by expression of the transcription factor Runx3 and also express a neurotrophic factor receptor (TrkC) that binds specifically to the neurotrophic factor NT-3. NT-3 is expressed in the limb bud and may serve as a short-distance guide to the ingrowing axons (Genc et al 2004). There is a reciprocal interaction with the neuronal soma: in the absence of NT-3, proprioceptive neurones in the dorsal root ganglia die. The central processes of the proprioceptive sensory neurones innervating limb muscle form monosynaptic connections to motor neurones in the spinal cord after their peripheral axons have extended into the limbs. However, the pattern for these sensory/motor connections appears to be specified early. The proximo-distal position of the sensory endings in the limb is linked to the dorso-ventral location of the target motor neurones in the spinal cord, such that proximal sensory axons will connect to ventral motor columels (Sürmeli et al 2011). NT-3 is also expressed in ventral neural tube and, as in the periphery, may help guide the axons to the correct location in the spinal cord.

The different types of sensory endings show activation at different developmental times; mechanoreceptors and proprioceptors are active ahead of nociceptive neurones prenatally. A third wave of mechanosensitivity acquisition by the remaining nociceptors occurs just after birth (Lechner et al 2009).

## EMBRYONIC MOVEMENTS

Embryonic movements are vital for development of the musculoskeletal system (Pitsillides 2006, Nowlan et al 2010). Simple movements of an extremity have been observed sporadically as early as the seventh week of gestation in human embryos. Combined movements of limb, trunk and head commence between 12 and 16 weeks of gestation. Movements of the embryo and fetus encourage normal skin growth and flexibility, in addition to the progressive maturation of the musculoskeletal system.

## FETAL MOVEMENTS

Fetal movements have been detected by ultrasonography in the second month of gestation. Those related to trunk and lower limb movements are perceived consistently by the mother from about 16 weeks' gestation (quickening). Movements of the fetus often involve slow and asymmetric twisting and stretching movements of the trunk and limbs, which resemble athetoid movements. There may also be rapid, repetitive, wide-amplitude limb movements, similar to myoclonus.

By 32 weeks' gestation, symmetric flexor movements are most frequent. By term, the quality of the movements has generally matured to smooth, alternating movement of the limbs, with medium speed and intensity. The reduced effect of gravity in utero may cause certain fetal movements to appear, on ultrasonography, more fluent than the equivalent movements observed postnatally. The number of spontaneous
movements decreases after the thirty-fifth week of gestation and, from this time, there is an increase in the duration of fixed postures. This restriction of normal fetal movements in late gestation reflects the degree of compliance of the maternal uterus; there is a slowing of growth at this time.

In addition to promoting normal musculoskeletal development, movements of the fetus encourage skin growth and flexibility indirectly. Fetuses with in utero muscular dystrophies, or other conditions that result in small or atrophied muscles, have webs of skin, pterygia, which pass across the flexor aspect of the joints and severely limit movement. Multiple pterygium syndrome is characterized by webbing across the neck, the axillae and antecubital fossae. Usually, the legs are maintained straight and webbing is not seen at the hip and knee. A group of congenital disorders, collectively termed 'multiple congenital contractures', may result from genetic causes, or limitations of embryonic and fetal joint mobility, or may be secondary to muscular, connective tissue, skeletal or neurological abnormalities. These conditions may be recognized on prenatal ultrasound examination by the appearance of fixed, immobile limbs in bizarre positions, or by webbing in limb flexures. Specific syndromes, lethal multiple pterygium syndrome and congenital muscular dystrophy, have been described.

The workload undertaken by the musculoskeletal system before birth is relatively light because the fetus is supported by the amniotic fluid and, therefore, under essentially weightless conditions. The load on the muscles and bones is generated by the fetus itself, with little gravitational effect. The reduction of gravitational force afforded by the supporting fluid means that all parts of the fetus are subject to relatively equal forces and that the position assumed by the fetus relative to gravity is of little consequence. This is important to ensure the normal modelling of fetal bones, especially the skull. Skulls of premature babies may become distorted as a result of the weight of the head on the mattress, despite regular changes in position, and the application of oxygen therapy via a mask attached by a band around the head can cause dysostosis of the occipital bone.

## VASCULATURE OF THE LIMB

## ARTERIES

The early limb bud receives blood via intersegmental arteries that contribute to a primitive capillary plexus. At the tip of the limb bud, there is a terminal plexus, which is constantly renewed in a distal direction as the limb grows (see Figs 47.1, 79.1). Later, one main vessel, the axial artery, supplies the limb and the terminal plexus.

The development of the vasculature in the limb precedes the morphological and molecular changes that occur within the limb mesenchyme as tissues begin to form. Cartilage differentiation within the chick limb bud occurs only after local vascular regression begins, and only in areas with few or no capillaries (Hallmann et al 1987). It is not known whether the presence, or lack, of blood vessels affords different local environmental stimuli for mesenchymal cells (by varying the supply of nutrients to the tissue), or whether the local environment is controlled by the endothelial cells. Similarly, it is not clear whether inductive factors from the limb mesenchyme cause the changes that occur in the pattern of blood vessels. Work on chick wing buds suggests that the position of the central artery in the primitive limb bud vasculature depends on Shh signalling from the polarizing region (Davey et al 2007).

## VEINS

At the tip of the early limb bud, blood in the terminal capillary plexus returns to the body via a marginal vein that develops along the pre- and postaxial borders of the limb. As the limb enlarges, the marginal vein can be subdivided into pre- and postaxial veins, which run along their respective borders and which are the precursors of the superficial veins of the limb. Generally, the preaxial (superficial) veins join the deep veins at the proximal joint, and the postaxial (superficial) veins join the deep veins at the distal joint of the limb. Deep veins develop in situ alongside the arteries.

## COMMENTARY 2.1

# Human anatomy informatics 

Jonathan B L Bard, Paul N Schofield

## Introduction

Formal description of anatomy, both adult and developmental, has become a necessary component of informatics in the biomedical sciences because it provides the natural infrastructure for integrating very large amounts of tissue-associated data. This effort started with the formalizations of human, fruit fly and mouse anatomy in the 1990s and now includes all the major model organisms (Bard 2005, Druzinsky et al 2013). The types of data that are associated with tissues currently include gene expression, diseases and abnormal phenotypes.

Although most users do not need to know in detail how anatomy is handled within a computational context, there are two key aspects that should be appreciated. First, the sort of formal knowledge held online in databases is structured as a collection of triadic statements ('triples') of the general style:

$$
\text { <A }>\text { <relationship }><\mathrm{B}>
$$

For an anatomical fact, A and B might represent tissues and typical relationships would include part_of, derives_from (embryonic lineage), starts_at and ends_at (developmental stages) and is_a (tissue-type classification). Part_of, in particular, has several meanings and these may or may not need to be distinguished (e.g. connected parts such as the bones of a limb, and distributed parts such as the components of the glandular system). The great advantage of this approach is that the triples can be easily linked (the interventricular septum is part_of the heart is part_of the cardiovascular system) to make a hierarchy or network (more formally, this is a mathematical graph made of nodes and edges). Such graphs are the normal way of handling complex sets
of knowledge in an informatics context, and readers will already have come across them through, for example, Linnaean classifications (relationship: is_a) and evolutionary clades (relationship: descends_with_ modification_from). These relationships enable specific queries about the knowledge included in the ontology to be answered (e.g. what are the parts of the heart?). Graphs that deal with a specific domain of knowledge (e.g. anatomy, cell or tissue type) are known as ontologies, and a large number of bio-ontologies are available at the OBO Foundry site. Ontologies are not meant to be read as text but, if written in the OBO format, a list of triples based on IDs can be visualized in browsers such as OBO-Edit (see Fig. 2.1.3). Details of all online resources are included in Table 2.1.1.

Second, every term in such bio-ontologies - be it a tissue, a gene, a disease or any other entity - has associated with it a unique identity of the general form $a b c d: w x y z$, where $a b c d$ is a unique marker for the ontology (its namespace) and $w x y z$ is a number associated with the item (thus, EHDAA2:0002091 represents the trophectoderm of the human embryo). Users never need to know such IDs but it is these that are sent from one computer to another when a user wants to access databaseassociated information (e.g. gene expression) about, say, a tissue; this is because databases use these IDs internally instead of names, as they are unambiguous.

## Formalizations of human anatomy

Adult human anatomy has been catalogued in two very different ways. The Federative International Programme on Anatomical Terminologies (FIPAT) has produced three formal and comprehensive terminologies

Table 2.1.1 Online resources associated with normal and abnormal human anatomy

| Resource | Namespace | Website | Description |
| :---: | :---: | :---: | :---: |
| DECIPHER |  | http://decipher.sanger.ac.uk/ | A Sanger-based database that links chromosomal information with disease data |
| Elements of Morphology |  | http://elementsofmorphology.nih.gov/ | A National Institutes of Health (NIH)-funded project aimed at standardization of terms used to describe human morphology. So far, the head and neck, and hands and feet have been terminologically formalized, with further regions to be developed |
| Federative International Programme on Anatomical Terminologies (FIPAT) |  | http://www.ifaa.net/index.php/fipat | Digital copies of the contents of Terminologia Anatomica, Terminologia Histologica and Terminologia Embryologica as published in books produced by IFAA |
| Foundational Model of Anatomy (FMA) Explorer | FMAID | http://sig.biostr.washington.edu/ | A viewer that shows the rich information stored in the FMA |
| Human Developmental Anatomy | EHDAA2 |  | Anatomical and tissue-associated data for Carnegie stage 1-20 embryos |
| Human Developmental Studies Network (HUDSEN) |  | http://www.hudsen.org/ | A source containing human embryological gene expression and image data |
| Human Phenotype Ontology (HPO) | HP | http://www.human-phenotype-ontology.org/ | A standardized vocabulary of phenotypic abnormalities encountered in human disease |
| OBO Foundry |  | http://www.obofoundry.org/ | A repository for bio-ontologies |
| OBO-Edit |  | http://oboedit.org/ | A downloadable Java-based viewer for analysing ontologies in the OBO format |
| Online Mendelian Inheritance in Man (OMIM) |  | http://www.omim.org/ | An online catalogue of human Mendelian genetic disease with detailed phenotype annotations |
| Orphanet |  | http://www.orpha.net/ | A portal for rare disease information with a classification and encyclopaedia of rare diseases, listing genes involved and detailed phenotypic descriptions |
| Pictures of Standard Syndromes and Undiagnosed Malformations (POSSUM) |  | http://www.possum.net.au/ | A source of information on over 4000 syndromes, including multiple malformations, chromosomal abnormalities, skeletal dysplasias and metabolic disorders, linked to over 30,000 images including photos, X-rays, scans, diagrams and histology |
| Uber-anatomy Ontology | UBERON | http://uberon.github.io/ | A cross-species anatomy ontology classified according to traditional anatomical criteria such as structure, function and developmental lineage; includes comprehensive relationships to taxon-specific anatomical ontologies bridging Drosophila to Homo sapiens |

Fig. 2.1.1 An excerpt from the Federative International Programme on Anatomical Terminologies (FIPAT) human anatomy terminology. (Courtesy of FIPAT, sponsored by the University of Fribourg (Switzerland).)
in English and Latin for embryological and adult human anatomy, and for histology (e.g. Fig. 2.1.1); translations for other languages are currently being made. These are, however, reference catalogues of standard names rather than formal ontologies (they do not include the relationships between structures); hence, they are very different from the Foundational Model of Anatomy (FMA) (Rosse and Mejino 2003 and 2007). This very rich resource includes, within a single graph, 94,000 classes and over 170,000 terms, integrated to give approximately 2.4 million relationship instances from over 227 relationship types, and is stored in its own database. It aims to provide a complete model of human anatomy, and its viewer (the Foundational Model Explorer; Fig. 2.1.2) allows a user to see structure-based anatomical information. FMA includes concepts such as anatomical spaces, non-cellular substances, boundaries and topological relations.

A little simpler is the ontology of Human Developmental Anatomy, which covers the first 20 Theiler stages of human embryogenesis (up to about 7 weeks) (Theiler 1989, Bard et al 1998, Xue et al 2011, Xue et al 2013) and includes detailed lineage, staging, cell type and tissue classification information for around 2,000 anatomical items, from simple tissues of a single cell type up to complete systems (Fig. 2.1.3). This has been written in the standard OBO format (essentially, a list of triples and definitions). Many 'facts' from this ontology and the FMA have been incorporated into the Uber-anatomy Ontology (Uberon), an ontology of comparative anatomy that allows users to integrate data from different biological databases (see below).

## Human informatics resources

For many model organisms, anatomical ontology IDs can be used to access tissue-associated data, but human data resources currently lag behind those for model organisms in implementing links to formal anatomical ontologies. There are, however, a range of resources where data can be accessed on the basis of tissue names rather than IDs. One important example is the Human Developmental Studies Network (HUDSEN) database of human development, which includes gene expression and image data. In Array Express (http://www.ebi.ac.uk/ arrayexpress/(), a database of gene expression array data, human gene expression data can be searched using a custom-built ontology (Experimental Factor Ontology) where human anatomical names are mapped to a subset of FMA terms.

The FMA is currently being used as the basis for systems model building in the Virtual Physiological Human or Physiome project and is likely to become much more familiar to medical practitioners and biomedical scientists alike as such applications become much more developed. The next few years are likely to see a rapidly increasing need for formal anatomical model annotation, and, for example, extensions to the FMA are planned for the human brain-mapping project to formalize the nomenclature of cortex parcellation.

Whilst anatomical terminology relating to the human has changed little in the last century, anatomical concepts have evolved much more rapidly and there is great value in novel descriptions and views. Intrinsic
 Fig. 2.1.2 An example of the Foundational Model
of Anatomy (FMA) Explorer: the data held for the incus bone. (With permission from the Structural Informatics Group, Foundational Model of Anatomy Ontology (FMA), University of Washington.)
to the development cycle of the biomedical ontologies are openness and flexibility, so that new terms and concepts can be added as they become useful or as there is demand. For example, the Human Phenotype Ontology grew by 600 classes between 2009 and 2010.

## Abnormal anatomy and dysmorphology

The accurate description of abnormal anatomy is much more difficult than that of canonical anatomy, or even what might be accepted as normal variation within the population. Some abnormalities are so significantly distinct from canonical anatomy that new terms have traditionally been coined to capture the abnormal qualities of the structure, such as turricephaly or brachytelephalangy. Although such terms have definitions that are obvious to humans, articulating the differences between the normal and the abnormal phenotype in ways that are comprehensive computationally turns out to be difficult, and this leads to problems of relating different abnormalities to each other and to canonical structures. What follows is a brief summary of some of the informatics resources associated with abnormal human anatomy that are currently being developed. Such is the nature of the field that some will be expanded at the expense of others, and future interested readers will need to explore the sites to see how the subject is developing.

The history and use of clinical dysmorphology terms are complex and very much dependent on the tradition of training and practice in which the practitioner is raised. This requires any resource aiming to use these terms to capture all synonyms and equivalence classes within
the terminology, if it is to be of general use. The Pictures of Standard Syndromes and Undiagnosed Malformations (POSSUM - www.possum .net.au) (Stromme 1991) and Winter-Baraitser Dysmorphology databases both use traditional terminology to describe normal and abnormal anatomy but provide rich resources of images and phenotype descriptions for genetic diseases.

While an ambitious initiative to standardize descriptions of dysmorphology has begun in the Elements of Morphology project, the most widely used approach currently is the collection and relation of synonyms. Anatomical abnormalities are formally captured in the Human Phenotype Ontology (HPO) (Kohler et al 2014), one of several speciesspecific phenotype or trait-description frameworks developed for humans and model species. The HPO was originally derived from the phenotype descriptions in Online Mendelian Inheritance in Man (OMIM) and now contains more than 9500 terms covering the whole domain of human phenotype abnormality. HPO is being adopted by an increasing number of clinical resources, including the DECIPHER database of human genetic copy number variation (Firth et al 2009) and Orphanet, and is used for indexing and searching OMIM and Orphanet through HPO project tools.

There is also the broader context to be considered; computational relations of different human phenotype concepts to each other and to those of other species are important in comparing the effects of genetic variation within and between species, and in linking phenotype variation to gene expression. This integration task will now become increasingly important, if the burgeoning data on human disease and model organism phenotypes are to be used to the greatest advantage. It is here

Fig. 2.1.3 The entry for the trophectoderm in the ontology of human developmental anatomy, shown in the OBO-Edit browser. The hierarchies showing lineage and parts are on the left and the relationships included in the ontology are on the right. (With permission from Day-Richter J, Harris MA, Haendel M et al 2007 OBO-Edit--an ontology editor for biologists. Bioinformatics 23(16):2198-2200.)
that the cross-species anatomy ontology Uberon (Mungall et al 2012) has become critical, as it can be used to define phenotype ontology terms from all species and, thus, allow crossing of the species divide. Using this approach, it is possible, for example, to assert that there is a relationship between clinodactyly in humans, bent digits in the mouse and, more distantly, pectoral fin abnormalities in zebrafish. Recent advances that use model organism data to prioritize candidate genes for rare diseases would not be possible without the formalization and integration of anatomical ontologies (Hoehndorf et al 2013).

## Prospects

The current state of human anatomy informatics is that the core ontologies are in place but their formal tissue IDs (FMAID and EHDAA2) have yet to be used to annotate data in the ways now being employed for other model organisms. Over the coming few years, we can expect a start to be made in annotating human data on gene expression and
abnormal (diseased) phenotypes to defined elements of anatomy (Schofield and Hancock 2012). Once this has happened, collating and integrating a wide range of human tissue-associated data computationally will become possible (Yue et al 2005).

In the clinic, we are now beginning to see the application of formal anatomy ontology frameworks to diagnostics and interventions. For example, the FMA has been incorporated into RadLex, the unified language of radiology terms from the Radiological Society of North America, which is used by radiologists and instrument developers for indexing and retrieval of radiology information resources (Mejino et al 2008). More recently, FMA terms have been integrated with cortical parcellation terminologies (Turner et al 2010), presaging the future penetration of ontologies through imaging, radiotherapy and surgery. Clinicians are increasingly becoming used to handling and interpreting data from highly sophisticated instrumentation, and it will be necessary to include an understanding of the informatic basis of the software used in daily practice in medical training: a topic missing now from all but the most specialized and advanced courses.

# An evolutionary consideration of pharyngeal development 

Anthony Graham, Victoria L Shone

The pharynx is a complex region of the body that is involved in numerous critical functions; in pondering its mature anatomical organization, it can be difficult to discern the rules that underpin its construction. However, there is an underlying logic that is evident if one considers how this region of the body is formed during embryogenesis. The pharyngeal apparatus has its developmental origin in a series of bulges found on the lateral surface of the head at early stages: the pharyngeal arches. In humans, there are five pharyngeal arches, numbered 1, 2, 3, 4 and 6 . It has been suggested that a fifth arch exists transiently during embryogenesis, although there is no substantive evidence to support this.

The development of the pharyngeal arches is complex, because they comprise a number of disparate embryonic cell types (see Fig. 36.3). Externally, the arches are circumscribed by ectoderm, and internally, by endoderm; each has a mesenchymal core of neural crest cells that surround a central group of cranial paraxial mesodermal cells. The different embryonic populations that constitute the arches must be coordinated so that each will form the appropriate derivative at the right time and place, and so that those derivatives have the morphology associated with their specific pharyngeal arch.

For many years, it was believed that it was the neural crest cells that directed the development of the arches. However, it was subsequently shown that rudimentary pharyngeal arches can form in the absence of neural crest cells (Veitch et al 1999). Moreover, other studies have highlighted the significance of the segmentation of the endoderm in directing pharyngeal arch development. A key event in the development of the pharyngeal arches is the formation of outpocketings within the endoderm, the pharyngeal pouches, of which there are four; mutants that fail to segment the endoderm fail to form pharyngeal arches (Piotrowski et al 2000). The pharyngeal pouches form at distinct positions along the rostrocaudal axis and will eventually contact the overlying ectoderm, which invaginates to meet the pouches (see Figs 36.3, 36.4). It should be noted that in animals and animal embryos the rostrocaudal axis is referred to as anteroposterior. These portions of the ectoderm are termed the pharyngeal clefts. It is this apposition between the pouches and clefts that will define the anterior and posterior (rostral and caudal) margins of each pharyngeal arch. Significantly, it is the formation of the pharyngeal pouches that is the first indication of pharyngeal arch formation. Thus, neural crest cells and cranial paraxial mesoderm migrate into pre-existing epithelial segments that have been previously formed by the pharyngeal pouches. The endoderm then signals to other tissues of the arches and directs their development. It has been shown that fibroblast growth factor (FGF) signalling emanating from the endoderm promotes chondrogenesis within the neural crest, and the pouches also induce the formation of the epibranchial placodes (Graham 2008). These are ectodermal thickenings that will give rise to the neurones of the geniculate, petrosal and nodose ganglia. However, in general, subsequent pharyngeal arch development will involve a complex interplay of signals from the different constituent tissues.

At later stages, this segmental origin of our pharynx is obscured as development progresses, with the majority of the arches partaking in a complex remodelling that results in their obliteration (Fig. 2.2.1; see also Table 36.1, Fig. 36.7). This process involves the posterior expansion of the second pharyngeal arch, so that it comes to cover all posterior arches (see Fig. 2.2.1) (Richardson et al 2012). This results in these posterior arches becoming enclosed in a cavity, the cervical sinus of His, which, in turn, is eliminated by the apposition and fusion of its walls, yielding a smooth outline to the external surface of the neck (see Fig. 2.2.1, Fig. 36.10). Significantly, there are instances in which this remodelling is abnormal and this can result in the presence of a cervical cyst, arising from the persistence of the sinus; this may or may not be associated with internal and/or external openings, or fistulae (see Figs 2.2.1, 36.4 C ). Such malformations represent the second most common congenital lesions of the head and neck in children.

Fig. 2.2.1 Normal and abnormal internalization of the lower posterior pharyngeal arches. A, A longitudinal section through the pharyngeal arches at the point where the second pharyngeal arch is expanding to cover the posterior arches. B, The end results of the expansion of the second pharyngeal arch. The caudal edge of the second pharyngeal arch has fused with the subjacent tissue, which results in formation of a sinus between the inner surface of the second arch and the external surface of the posterior arches. This sinus is subsequently eradicated. C, Two of the consequences that result from the incomplete loss of the sinus following the fusion of the caudal edge of the second arch; if the sinus is not lost, then this cavity persists as a cervical cyst. If the caudal edge of the second arch also does not fuse properly with the subjacent tissue, then this results in a cyst with an external opening, or fistula. D, The two other consequences that can result from incomplete loss of the sinus following fusion of the caudal edge of the second arch. A cyst will form and this can have an internal opening, or fistula, or it may have both internal and external openings, or fistulae.

It is also important to note that there are significant differences between the development of the anterior and posterior pharyngeal arches. The two most anterior pharyngeal pouches form at the same time, while the more posterior pouches form sequentially. The development of the posterior pouches is also under the control of distinct signalling pathways. It has been shown that retinoid and Wnt signalling is required for the formation of the more posterior pouches but not the anterior (Quinlan et al 2002, Choe et al 2013). One key gene for the formation of the posterior, but not anterior, pharyngeal pouches is $T b x 1$ ( Xu et al 2005). This gene is required to drive proliferation within the endoderm; in mutants that lack $T b x 1$ function, the posterior pharyngeal pouches fail to form and the neural crest fails to become segregated. Patients with DiGeorge syndrome present with defects of posterior
pharyngeal arch derivatives and this is strongly associated with muta－ tions in Tbx1，suggesting that the aetiological basis of this syndrome lies in a failure of the formation of the posterior pouches．

A pervasive influence on how the pharyngeal region is organized is its evolutionary history；it is through this that one can appreciate the significance of the differences between development of the anterior versus the posterior pharyngeal arches．In all gnathostomes，the first two pharyngeal arches form the jaw and hyoid，while the more pos－ terior arches are gill－bearing．In many fish，these are covered by a protec－ tive flap，the operculum，which helps to draw water into the pharyngeal cavity and pass it over the gills，aiding respiration．Thus，the vertebrate pharynx is fundamentally split into an anterior region primarily con－ cerned with feeding and a posterior region concerned with respiration． However，it is believed that，when the vertebrates colonized land，the pharynx was substantially remodelled；with a shift to lung－based respi－ ration，the gills and the operculum were lost．

Yet，more recently，it has been demonstrated that the gills were not lost from amniotes but were transformed into the parathyroid primor－ dia．The development of both the gills and the parathyroid glands
requires the gene $g \mathrm{~cm} 2$ ，and both arise from the posterior pharyngeal pouches where the early developmental programme for gill formation persists in the amniote posterior pharynx（Okabe and Graham 2004）． Furthermore，although as adults we do not have an operculum，this structure does exist as an embryonic entity（Richardson et al 2012）．The posteriorly expanding second arch that covers our posterior arches is homologous to the developing operculum of fish．This is driven by shh signalling in both amniotes and fish，and these structures express the same key genes．The situation in amniotes differs from that in fish， however，in that the leading edge of the caudally expanding second arch fuses with the epithelium at the level of the cardiac eminence．Crucially， this event mirrors what is seen during amphibian metamorphosis， where the gills are also internalized；significantly，both the proper fusion of the posterior edge of the second arch in amniotes and amphib－ ian metamorphosis require thyroid hormone signalling．Thus，the fact that the anterior and posterior pharyngeal arches are underpinned by different developmental programmes betrays our evolutionary history and indicates that the ancestral functional division between the anterior and posterior pharynx still exists in amniotes．

## Overview of the nervous system

## cimane <br> 16

The human nervous system is the most complex product of evolution. The activity of its billions of neurones and glia constitutes the physical basis of consciousness, experience, thought and behaviour. Research to elucidate the systems and circuits involved in normal neural development and function is one of the most active areas of contemporary biology and medicine, and yet our understanding of these processes, which is essential for translational success, remains far from complete.

The nervous system has two major divisions, the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain, spinal cord, optic nerve and retina, and contains the majority of neuronal cell bodies. The PNS includes all nervous tissue outside the CNS and consists of the cranial and spinal nerves, the peripheral autonomic nervous system (ANS) and the special senses (taste, olfaction, vision, hearing and balance). It is composed mainly of the axons of sensory and motor neurones that pass between the CNS and the body. The ANS is subdivided into sympathetic and parasympathetic components. It consists of neurones that innervate secretory glands and cardiac and smooth muscle, and is concerned primarily with control of the internal environment. Neurones in the wall of the gastrointestinal tract form the enteric nervous system (ENS) and are capable of sustaining local reflex activity that is independent of the CNS. The ENS contains as many intrinsic neurones in its ganglia as the entire spinal cord and is often considered as a third division of the nervous system.

The detailed microstructure of the nervous system is described in Chapter 3 and the development of the nervous system is described in Chapter 17.

## CENTRAL NERVOUS SYSTEM

The brain and spinal cord (see Fig. 45.1A) contain the great majority of neuronal cell bodies in the nervous system. In many parts of the CNS, neuronal cell bodies are grouped together and are, more or less, segregated from axons. The generic term for such collections of cell bodies is grey matter. Small aggregations of neuronal cell bodies, which usually share a common functional role, are termed nuclei. Neuronal dendrites and synaptic interactions are mostly confined to grey matter. Axons tend to be grouped together to form white matter, so called because axons are often ensheathed in myelin, which confers a paler colouration. Axons that pass between similar origins or destinations within the CNS tend to run together in defined pathways, or tracts. These often cross the midline (decussate), which means that one half of the body is, in many respects, controlled by, and sends information to, the opposite side of the brain.

Some groups of neurones in the spinal cord and brainstem that subserve similar functions are organized into longitudinal columns. The neurones in these columns may be concentrated into discrete, discontinuous nuclei in some areas, e.g. the cranial nerve nuclei of the brainstem, or they may form more or less continuous longitudinal bands, as in much of the spinal cord (Fig. 16.1). Efferent neurones constitute three such columns. The axons of motor neurones in the somatic motor column innervate muscles derived from head somites. The two other columns are related to specialized features of head morphology: neurones in the branchial motor column innervate muscles derived from the wall of the embryonic pharynx (branchial muscles) and the visceral motor column supplies preganglionic parasympathetic fibres to glands and visceral smooth muscle. Four longitudinal cell columns are related to sensory functions. The general somatic sensory column essentially deals with general sensory information from the head; special somatic sensory neurones are related to the special senses and receive vestibular and auditory input; general visceral sensory neurones deal with information from widespread and varied visceral
sensory endings; and special visceral sensory neurones are related to the special sense of taste.

The spinal cord and brain communicate with the rest of the body via the spinal and cranial nerves respectively. These nerves contain afferent fibres that bring information into the CNS from sensory receptors, and efferent fibres that convey instructions from the CNS to peripheral effector organs. The spinal cord and brainstem can control many aspects of bodily function by reflex action mediated via interconnections of varying complexity between the afferent and efferent components of the spinal and cranial nerves. Numerous descending connections from the brain may modulate this activity. Afferent input to the spinal cord and brainstem is channelled into various ascending pathways, some of which eventually impinge upon the cerebral cortex, conferring conscious awareness.

To provide the energy required by constant neuronal activity, the CNS has a high metabolic rate and a rich blood supply (Ch. 19). A blood-brain barrier controls the neuronal environment and imposes

Fig. 16.1 The arrangement of sensory and motor cell columns in the spinal cord and brainstem. In each of parts A, B and C, dorsal is towards the top of the diagram. A, The organization of the primitive spinal cord with a dorsal sensory column, a ventral motor column, and segmentally arranged dorsal and ventral nerve roots. B, The adult thoracic spinal cord with sensory and somatic motor columns and an additional intermediate (lateral) visceral motor column. C, The arrangement of multiple longitudinal columns in the brainstem, where the motor column is now subdivided into three, and the sensory column into four. For further information about the embryological aspects of the early nervous system, consult Chapter 17.

Fig. 16.2 A transverse section through the spinal cord, illustrating the disposition of grey and white matter and the attachment of dorsal and ventral spinal nerve roots.
severe restrictions on the types of substance that can pass from the bloodstream into nervous tissue.

## SPINAL CORD

The spinal cord lies within the vertebral column, in the upper twothirds of the vertebral canal, and is continuous rostrally with the medulla oblongata of the brainstem. For the most part, the spinal cord receives afferent input from, and controls the functions of, the trunk and limbs. Afferent and efferent connections between the periphery and the spinal cord travel in 31 pairs of segmentally arranged spinal nerves that attach to the cord as a linear series of dorsal and ventral rootlets. Adjacent groups of rootlets unite to form dorsal and ventral roots that combine to form the spinal nerves proper (Fig. 16.2). The dorsal and ventral roots are functionally distinct. Dorsal roots carry primary afferent nerve fibres from neuronal cell bodies located in dorsal root ganglia, whereas ventral roots carry efferent fibres from neuronal cell bodies located in the spinal grey matter.

Internally, the spinal cord consists of a central core of grey matter surrounded by white matter. The grey matter is configured in a characteristic H, or butterfly, shape that has projections known as dorsal (posterior) and ventral (anterior) horns (Fig. 16.3). In general, neurones situated in the dorsal horn are primarily concerned with sensory functions whilst those in the ventral horn are mostly associated with motor activities. At thoracic and upper lumbar levels of the spinal cord a small lateral horn is additionally present, marking the location of the cell bodies of preganglionic sympathetic neurones. The central canal, a vestigial component of the ventricular system, lies at the centre of the spinal grey matter and runs the length of the cord. The white matter of the spinal cord consists of ascending and descending tracts that link spinal cord segments to one another and the spinal cord to the brain.

## BRAIN

The brain (encephalon) lies within the cranium. The brain receives information from, and controls the activities of, the trunk and limbs, mainly through connections with the spinal cord. It also possesses 12 pairs of cranial nerves through which it communicates mostly with structures of the head and neck. The brain is divided into major regions on the basis of ontogenetic growth and phylogenetic principles (Figs. 16.4-16.6). Ascending in sequence from the spinal cord, the principal divisions are the rhombencephalon or hindbrain, the mesencephalon or midbrain, and the prosencephalon or forebrain.

The rhombencephalon is subdivided into the myelencephalon or medulla oblongata, metencephalon or pons, and the cerebellum. The medulla oblongata, pons and midbrain are collectively referred to as the brainstem, which lies upon the basal portions of the occipital and sphenoid bones (clivus). The medulla oblongata is the most caudal part of the brainstem and is continuous with the spinal cord below the level of the foramen magnum. The pons lies rostral to the medulla and is distinguished by a mass of transverse nerve fibres that connect it to the cerebellum. The midbrain is a short segment of brainstem, rostral to

Fig. 16.3 A transverse section through the spinal cord at lumbar level. The section has been stained for nerve fibres, leaving the grey matter relatively unstained. (Figure enhanced by B Crossman.)
the pons. The cerebellum consists of paired hemispheres united by a median vermis and lies within the posterior cranial fossa, dorsal to the pons, medulla and caudal midbrain, with all of which it has numerous fibre connections.

The prosencephalon is subdivided into the diencephalon and the telencephalon. The diencephalon equates mostly to the thalamus and hypothalamus, but also includes the smaller epithalamus and subthalamus. The telencephalon is mainly composed of the two cerebral hemispheres or cerebrum. The diencephalon is almost completely embedded in the cerebrum and is, therefore, largely hidden from the exterior. The human cerebrum constitutes the major part of the brain. It occupies the anterior and middle cranial fossae and is directly related to the cranial vault. It consists of two cerebral hemispheres. The surface of each hemisphere is convoluted into a complex pattern of ridges (gyri) and furrows (sulci). Internally, each hemisphere has an outer layer of grey matter, the cerebral cortex, beneath which lies a thick mass of white matter (Fig. 16.7). One of the most important components of the cerebral white matter, the internal capsule (see Fig. 16.9), contains nerve fibres that pass to and from the cerebral cortex and lower levels of the neuraxis. Several large nuclei of grey matter, the basal ganglia or basal nuclei, are partly embedded in the subcortical white matter. Nerve fibre connections between corresponding areas on either side of the brain cross the midline within commissures, by far the largest being the corpus callosum.

During prenatal development, the walls of the neural tube thicken greatly but never completely obliterate the central lumen. Although the latter remains in the spinal cord as the vestigial central canal, it becomes greatly expanded in the brain to form a series of interconnected cavities or ventricles (Ch. 18). In two regions, the fore- and hindbrain, parts of the roof of the neural tube do not generate nerve cells but become thin, folded sheets of highly vascular secretory tissue, the choroid plexuses. These secrete cerebrospinal fluid that fills the ventricles. The cavity of the rhombencephalon becomes expanded to form the fourth ventricle, which lies dorsal to the pons and upper half of the medulla. Caudally, the fourth ventricle is continuous with a canal in the caudal medulla and, through this, with the central canal of the spinal cord. The fourth ventricle is continuous with the subarachnoid space through three openings in its roof (the foramina of Luschka and of Magendie). At its rostral extent, the fourth ventricle is continuous with a narrow channel, the cerebral aqueduct, which passes through the midbrain. The rostral end of the cerebral aqueduct opens out into the third ventricle, a narrow, slit-like, midline cavity that is bounded laterally by the diencephalon. At the rostral end of the third ventricle, a small aperture on each side leads into the large lateral ventricle that is located within each cerebral hemisphere (see Fig. 16.4C).

## OVERVIEW OF ASCENDING SENSORY PATHWAYS

Sensory modalities are conventionally described as being either special senses or general senses. The special senses are olfaction, vision, taste, hearing and vestibular function. Afferent information is encoded by highly specialized sense organs and transmitted to the brain in cranial nerves I, II, VII, VIII and IX.

The general senses include touch, pressure, vibration, pain, thermal sensation and proprioception (perception of posture and movement). Stimuli from the external and internal environments activate a diverse range of receptors in the skin, viscera, muscles, tendons and joints (Ch. 3). Afferent impulses from the trunk and limbs are conveyed to the spinal cord in spinal nerves, while those from the head are carried to the brain in cranial nerves. The detailed anatomy of the complex pathways by which the various general senses impinge on consciousness levels is better understood by reference to certain common organizational principles. Whilst undoubtedly oversimplified and subject to exceptions, this schema is helpful in emphasizing the essential similarities that exist between the ascending sensory systems.

In essence, ascending sensory projections related to the general senses consist of a sequence of three neurones that extends from peripheral receptor to contralateral cerebral cortex (Fig. 16.8). These are often referred to as primary, secondary and tertiary neurones or first-, secondand third-order neurones. Primary afferents have peripherally located sensory endings and cell bodies that lie in dorsal root ganglia or the sensory ganglia associated with certain cranial nerves. Their axons enter the CNS through spinal or cranial nerves and terminate by synapsing on the cell bodies of ipsilateral second-order neurones; the precise location of this termination depends on the modality.

Primary afferent fibres carrying pain, temperature and coarse touch/ pressure information from the trunk and limbs terminate in the dorsal horn of the spinal grey matter, near their point of entry into the spinal cord. Homologous fibres from the head terminate in the trigeminal sensory nucleus of the brainstem. The cell bodies of second-order neurones are located in either the dorsal horn or the trigeminal sensory nucleus. Their axons decussate and ascend to the ventral posterior nucleus of the contralateral thalamus as the spinothalamic or the trigeminothalamic tract, respectively; they synapse on the cell bodies of third-order neurones in the thalamus. Axons of third-order neurones pass through the internal capsule to reach the cerebral cortex, terminating in the postcentral gyrus of the parietal lobe, which is also known as the primary somatosensory cortex.

Primary afferent fibres carrying proprioceptive information and fine (discriminative) touch from the trunk and limbs ascend ipsilaterally in the spinal cord as the dorsal columns (fasciculus gracilis and fasciculus cuneatus); they end by synapsing on second-order neurones in the dorsal column nuclei (nucleus gracilis and nucleus cuneatus) of the medulla. Axons of second-order neurones decussate in the medulla and then ascend as the medial lemniscus to the ventral posterior nucleus of

Fig. 16.6 A sagittal section of the brain. (Figure enhanced by B Crossman.)

Fig. 16.7 A section through the cerebral hemisphere and brainstem, showing the disposition of grey and white matter, the basal ganglia and the internal capsule. (Dissection by EL Rees; photograph by Kevin Fitzpatrick, London.)
the contralateral thalamus, where they synapse on the cell bodies of third-order neurones. Axons of third-order neurones pass through the internal capsule to reach the cerebral cortex, terminating in the primary somatosensory cortex. A similar homologous projection exists for afferents derived from the head.

## OVERVIEW OF DESCENDING MOTOR PATHWAYS

Corticofugal fibres descend through the internal capsule and pass into the brainstem, where many of them terminate, innervating the cranial nerve nuclei and other brainstem nuclei such as the red nucleus, reticular nuclei, olivary nuclei, etc. The term 'corticobulbar' has been used for many years to describe cortical projections to brainstem nuclei but it is a misnomer. The suffix 'bulbar' is derived from 'bulb', an obsolete name for the medulla oblongata: clearly, corticofugal fibres that terminate in the midbrain and/or pons cannot be described as corticobulbar. The term 'corticobulbar' has been replaced by 'corticonuclear'.

Fig. 16.8 The organization of general sensory pathways showing first-order, second-order and third-order neurones.

Terminologia Anatomica specifies cortical axons that innervate motor or sensory nuclei of cranial nerves according to their connections as follows: fibrae corticonucleares bulbi (medullary corticonuclear fibres); fibrae corticonuclearis pontinis (pontine corticonuclear fibres); and fibrae corticonuclearis mesencephali (mesencephalic corticonuclear fibres).

Corticospinal (pyramidal tract) fibres originate from widespread regions of the cerebral cortex, including the primary motor cortex of the frontal lobe where the opposite half of the body is represented in a detailed somatotopic fashion. The fibres descend throughout the length of the brainstem. The majority then cross to the contralateral side in the motor decussation of the pyramids in the medulla. Thereafter, they continue caudally as the lateral corticospinal tract of the spinal cord, which terminates in association with interneurones and motor neurones of the spinal grey matter (Fig. 16.9). The principal function of the corticonuclear and corticospinal tracts is the control of fine, fractionated movements, particularly of those parts of the body where delicate muscular control is required. These tracts are particularly important in speech (corticonuclear tract) and movements of the hands (corticospinal tract).

Fig. 16.9 The corticospinal and corticonuclear tracts.

The concept of 'upper' and 'lower' motor neurones is fundamental in clinical neurology because the motor signs and symptoms of damage to each category are different and are indicative of the anatomical site of the lesion. Lower motor neurones are the alpha motor neurones located in the brainstem and spinal cord that innervate the extrafusal muscle fibres of skeletal muscle. The term upper motor neurones refers collectively to all the descending pathways that impinge upon the activity of lower motor neurones but, in common parlance, the term is often equated with the corticonuclear and corticospinal tracts. The terms upper and lower motor neurone lesion are used clinically to distinguish, for example, between the effects of a stroke in the internal capsule (a typical upper motor neurone lesion) and those of motor neurone disease (a typical lower motor neurone lesion).

Lower motor neurone lesions cause paralysis or paresis of specific muscles because they have lost their direct innervation. There is also loss or reduction of tendon reflex activity and reduced muscle tone. Spontaneous muscular contractions (fasciculation) occur and affected muscles atrophy over time. Upper motor neurone lesions cause paralysis or paresis of movements as a result of loss of higher control. There is increased tendon reflex activity and increased muscle tone, and no muscle atrophy occurs. A positive plantar (Babinski) reflex is present. The combination of paralysis, increased tendon reflex activity and hypertonia is referred to as spasticity.

The pathophysiology underlying the symptoms of upper motor neurone lesions is complex. This is because many descending pathways other than the corticonuclear and corticospinal tracts exist and they also influence lower motor neurone activity. These pathways include corticofugal projections to the brainstem (e.g. corticoreticular and corticopontine) that traverse the internal capsule and numerous pathways that originate within the brainstem itself (e.g. reticulospinal, vestibulospinal). Clearly, these pathways may be compromised to varying extents, depending on the site of a lesion. Their involvement is believed to be important in the pathophysiological mechanisms that underlie the generation of spasticity. Pure corticospinal tract lesions, which are exceedingly rare in humans because corticospinal tract fibres lie in close relationship to other pathways throughout most of their course, are believed specifically to cause deficits in delicate, fractionated movements and to induce the positive plantar reflex.

Two other major systems that contribute to the control of movement are the basal ganglia and the cerebellum. The basal ganglia are a group of large subcortical nuclei, the major components being the caudate nucleus, putamen and globus pallidus (see Fig. 16.7; Ch. 24). These structures have important connections with the cerebral cortex, certain
nuclei of the thalamus and subthalamus, and with the brainstem. They appear to be involved in the selection of appropriate behavioural patterns/movements and the suppression of inappropriate ones. Disorders of the basal ganglia cause either too little movement (akinesia) or abnormal involuntary movements (dyskinesias), as well as tremor and abnormalities of muscle tone (Crossman and Neary 2014). The basal ganglia are sometimes described as being part of the so-called 'extrapyramidal (motor) system'. This term is used to distinguish between the effects of basal ganglia disease and those of damage to the 'pyramidal' (corticospinal) system. However, the progressive elucidation of the anatomy of the basal ganglia and of the pathophysiology of motor disorders has revealed the close functional interrelationship between the two 'systems', and has rendered the terms that distinguish them largely obsolete (Brodal 1981). The cerebellum (Ch. 22) has rich connections with the brainstem, particularly the reticular and vestibular nuclei, and with the thalamus. It is concerned with the coordination of movement; cerebellar disorders cause ataxia, intention tremor and hypotonia.

## PERIPHERAL NERVOUS SYSTEM

The PNS is composed mainly of spinal nerves, cranial nerves, their ganglia and their ramifications that carry afferent and efferent neurones between the CNS and the rest of the body. It also includes the peripheral part of the autonomic nervous system, notably the sympathetic trunks and ganglia, and the enteric nervous system, composed of plexuses of nerve fibres and cell bodies in the wall of the gastrointestinal tract.

## SPINAL NERVES

Spinal nerves are the means by which the CNS receives information from, and controls the activities of, the trunk and limbs. Spinal nerves are considered in detail elsewhere on a regional basis (Sections 4-9).

There are 31 pairs of spinal nerves ( 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal) and these contain a mixture of sensory and motor fibres. They originate from the spinal cord as continuous series of dorsal and ventral nerve rootlets. Adjacent groups of rootlets fuse to form dorsal and ventral roots, which then merge to form the spinal nerves proper. The dorsal roots of spinal nerves contain afferent nerve fibres from cell bodies located in dorsal root ganglia. These cells give off both centrally and peripherally directed processes and do not have synapses on their cell bodies. The ventral roots of spinal nerves contain efferent fibres from cell bodies located in the spinal grey matter. These include motor neurones innervating skeletal muscle and preganglionic autonomic neurones.

Spinal nerves exit from the vertebral canal via their corresponding intervertebral foramina. They then divide to form a large ventral (anterior) ramus and a smaller dorsal (posterior) ramus. In general terms, the ventral ramus innervates the limbs together with the muscles and skin of the anterior part of the trunk. The dorsal ramus innervates the post-vertebral muscles and the skin of the back. The nerve fibres within the ventral rami serving the upper and lower limbs are redistributed within brachial and lumbosacral plexuses, respectively.

## CRANIAL NERVES

Cranial nerves are the means by which the brain receives information from, and controls the activities of, the head and neck, and to a lesser extent the thoracic and abdominal viscera. The component fibres, their route of exit from the cranial cavity, their subsequent peripheral course and the distribution and functions of the cranial nerves are considered in detail elsewhere on a regional basis (Sections 4, 7, 8). Their origins, destinations and connections within the CNS are considered in this section.

There are 12 pairs of cranial nerves that are individually named and numbered (Roman numerals) in a rostrocaudal sequence (Table 16.1). Unlike spinal nerves, only some cranial nerves are mixed in function, carrying both sensory and motor fibres; others are purely sensory or purely motor. The first cranial nerve (I; olfactory) has an ancient lineage and is derived from the forerunner of the cerebral hemisphere. It retains this unique position through the connections of the olfactory bulb, and is the only sensory cranial nerve that projects directly to the cerebral cortex rather than indirectly via the thalamus. The areas of cerebral cortex receiving olfactory input have a primitive cellular organization and are an integral part of the limbic system, which is concerned with the emotional aspects of behaviour. The second cranial nerve (II; optic)

Table 16.1 Summary of cranial nerves

| No. | Name | Components | Cells of origin | Main central connections | Exit from skull | Distribution and function |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| I | Olfactory | Special somatic afferent | Olfactory receptor cells in nasal mucosa | To olfactory bulb, anterior perforated substance, piriform cortex | Foramina of cribriform plate | Olfaction |
| II | Optic | Special somatic afferent | Ganglion cells of retina | To lateral geniculate nucleus of thalamus, pretectal area of midbrain | Optic canal | Vision |
| III | Oculomotor | Somatic efferent | Oculomotor nucleus | From visual cortical areas, medial longitudinal fasciculus | Superior orbital fissure | Motor to medial rectus, inferior rectus, superior rectus, inferior oblique, levator palpebrae superioris |
| III | Oculomotor | General visceral efferent | Edinger-Westphal nucleus | From pretectal area of midbrain | Superior orbital fissure | Parasympathetic to sphincter pupillae and ciliary muscles, via ciliary ganglion, mediating pupillary constriction and accommodation |
| IV | Trochlear | Somatic efferent | Trochlear nucleus | From visual cortical areas, medial longitudinal fasciculus | Superior orbital fissure | Motor to superior oblique |
| Trigeminal division: |  |  |  |  |  |  |
| V | $\text { Ophthalmic }\left(V_{i}\right)$ | General somatic afferent | Trigeminal (semilunar) ganglion | To trigeminal sensory nucleus | Superior orbital fissure | Sensation from forehead, scalp, eyelids, nose and eye, including conjunctiva |
|  | Maxillary ( $\mathrm{V}_{\mathrm{ij}}$ ) | General somatic afferent | Trigeminal (semilunar) ganglion | To trigeminal sensory nucleus | Foramen rotundum | Sensation from mid-face, lower eyelid, nasal cavity and paranasal sinuses, upper lip, maxillary teeth and palate |
|  | Mandibular $\left(V_{\text {iiil }}\right)$ | General somatic afferent | Trigeminal (semilunar) ganglion | To trigeminal sensory nucleus | Foramen ovale | Sensation from lower face and scalp, tongue and floor of mouth, mandibular teeth and part of external ear |
|  |  | General somatic afferent | Mesencephalic part of trigeminal sensory nucleus | To trigeminal sensory nucleus, cerebellum | Foramen ovale | Proprioception from muscles of mastication, temporomandibular joint |
|  | Mandibular ( $\mathrm{V}_{\text {III }}$ ) | Branchial (special visceral) efferent | Trigeminal motor nucleus | From precentral gyrus | Foramen ovale | Motor to muscles of mastication (temporalis, masseter, medial and lateral pterygoids), tensor tympani |
| VI | Abducens | Somatic efferent | Abducens nucleus | From visual cortical areas, medial longitudinal fasciculus | Superior orbital fissure | Motor to lateral rectus |
| VII | Facial | General somatic afferent | Geniculate ganglion | To trigeminal sensory nucleus, cerebellum | Internal acoustic meatus | Sensation from part of tympanic membrane, external acoustic meatus and skin behind pinna. <br> Proprioception from facial muscles |
| VII | Facial | Special visceral afferent | Geniculate ganglion | To nucleus solitarius | Internal acoustic meatus | Taste from anterior two-thirds of tongue |
| VII | Facial | General visceral efferent | Superior salivatory nucleus | From olfactory areas, nucleus solitarius | Internal acoustic meatus | Parasympathetic to lacrimal gland and mucous membrane of nasal and oral cavities (via pterygopalatine ganglion) and submandibular and sublingual salivary glands (via submandibular ganglion) causing secretion and vasodilation |
| VII | Facial | Branchial (special visceral) efferent | Facial nucleus | From precentral gyrus | Internal acoustic meatus | Motor to 'muscles of facial expression', stapedius, posterior belly of digastric and stylohyoid |
| VIII | Vestibulocochlear |  |  |  |  |  |
|  | Vestibular division | Special somatic afferent | Vestibular ganglion | To vestibular nuclei, cerebellum | Internal acoustic meatus | Sensations of equilibrium and motion |
|  | Cochlear division | Special somatic afferent | Spiral ganglion | To cochlear nuclei | Internal acoustic meatus | Hearing |
| IX | Glossopharyngeal | General somatic afferent | Glossopharyngeal ganglia | To trigeminal sensory nucleus | Jugular foramen | General sensation from posterior one-third of tongue, oropharynx and middle ear |
| IX | Glossopharyngeal | General visceral afferent | Glossopharyngeal ganglia | To nucleus solitarius | Jugular foramen | Sensory from carotid body (chemoreceptors) and carotid sinus (baroreceptors) |
| IX | Glossopharyngeal | Special visceral afferent | Glossopharyngeal ganglia | To nucleus solitarius | Jugular foramen | Taste from posterior one-third of tongue |
| IX | Glossopharyngeal | General visceral efferent | Inferior salivatory nucleus | From olfactory areas, nucleus solitarius | Jugular foramen | Parasympathetic to parotid salivary gland (via otic ganglion), causing secretion and vasodilation |
| IX | Glossopharyngeal | Branchial (special visceral) efferent | Nucleus ambiguus | From precentral gyrus | Jugular foramen | Motor to stylopharyngeus |
| X | Vagus | General somatic afferent | Superior (jugular) ganglion | To trigeminal sensory nucleus | Jugular foramen | General sensation from pharynx, larynx, trachea, oesophagus, part of auricle and external auditory meatus |
| X | Vagus | General visceral afferent | Inferior (nodose) ganglion | To nucleus solitarius | Jugular foramen | Sensory from thoracic and abdominal viscera Sensory from aortic arch (baroreceptors) and aortic bodies (chemoreceptors) |
| X | Vagus | General visceral efferent | Dorsal motor nucleus of vagus | From hypothalamus, nucleus solitarius | Jugular foramen | Parasympathetic to glands and smooth muscle in the pharynx, larynx, thoracic and abdominal viscera |
| $X$ | Vagus | Branchial (special visceral) efferent | Nucleus ambiguus | From precentral gyrus, sensory nuclei of brainstem | Jugular foramen | Motor to pharyngeal, external laryngeal and oesophageal striated muscles |

General visceral afferent
Special visceral afferent
Somatic efferent
General visceral efferent
Branchial (special visceral) efferent
*The existence of a 'cranial root' of the accessory nerve, with its cell bodies in the nucleus ambiguus and a distribution as given in Table 16.1, is controversial. There is a view that the 'spinal root' of the accessory nerve should be regarded as the accessory nerve proper (sometimes called the 'spinal accessory nerve') and that the vagus nerve supplies the muscles of the soft palate and the intrinsic muscles of the larynx. See Chapter 21 for further details.
consists of the axons of second-order visual neurones and these terminate in the thalamus. The other ten pairs of cranial nerves attach to the brainstem and most of their component fibres originate from, or terminate in, the cranial nerve nuclei of the brainstem.

The sensory fibres in individual spinal and cranial nerves have characteristic, but often overlapping, peripheral distributions. As far as the innervation of the body surface is concerned, the area that is supplied by a particular spinal or cranial nerve is referred to as a dermatome (Greenberg 2003), whereas the areas of skin supplied by particular peripheral nerves are often referred to as the peripheral nerve fields (or cutaneous nerve distributions). There is marked overlap between dermatomes of adjacent spinal nerves, particularly for the segments least affected by development of the limbs, i.e. the second thoracic to the first lumbar (Ladak et al 2013). In some regions, e.g. the upper anterior thoracic wall, the cutaneous nerves that supply adjoining areas are not derived from consecutive spinal nerves and in these instances the overlap between dermatomes is minimal; these boundaries give more reliable and clinically useful borders (Apok et al 2011). Maps of dermatome distribution are useful in clinical neurology as a guide to identify the location of pathology in patients with peripheral sensory deficits, but it is important to remember that they are approximations. Dermatome maps are somewhat inconsistently reported by different authors, reflecting the fact that the maps are composites that have been compiled to a large extent by clinical observations on patients with cranial or spinal nerve pathology, and also that considerable normal individual variation exists (Fig. 16.10) (Lee et al 2008). Common to all published maps are areas of sensory overlap along borders of contiguous spinal nerves and axial lines where non-contiguous spinal nerves meet, and across which very little or no sensory overlap occurs. Detailed dermatome maps are described on a regional basis. The motor axons of individual spinal and cranial nerves tend to innervate anatomically and functionally related groups of skeletal muscles, which are referred to as myotomes.

## AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system represents the visceral component of the nervous system. It consists of neurones located within both the CNS and the PNS that are concerned with the control of the internal environment, through the innervation of secretory glands and cardiac and smooth muscle. Its functions are, however, closely integrated with those of the somatic nervous system.

Visceral efferent pathways differ from their somatic equivalents in that the former are interrupted by peripheral synapses, there being a sequence of at least two neurones between the CNS and the target structure (Fig. 16.11). These are referred to as preganglionic and postganglionic neurones, respectively. The somata of preganglionic neurones are located in the visceral efferent nuclei of the brainstem and in the lateral grey columns of the spinal cord. Their axons, which are usually finely myelinated, exit from the CNS in certain cranial and spinal nerves, and then pass to peripheral ganglia, where they synapse with postganglionic neurones. The axons of postganglionic neurones are usually unmyelinated. Postganglionic neurones are more numerous than preganglionic ones; one preganglionic neurone may synapse with $15-20$ postganglionic neurones, which permits the wide distribution of many autonomic effects.

The autonomic nervous system is divided into three major parts: sympathetic, parasympathetic and enteric. These differ in organization and structure but are functionally integrated. Most, but not all, structures innervated by the autonomic nervous system receive both sympathetic and parasympathetic fibres, whereas the enteric nervous system is a network of neurones intrinsic to the wall of the gastrointestinal tract.

Two long-held dogmas are that the sympathetic and parasympathetic nervous systems are functionally antagonistic (because activation of their respective efferents has opposing actions on target structures)

Fig. 16.10 Typical dermatome maps, illustrating some of the variations reported by different authors. A, Dermatome map based on Keegan JJ, Garrett FD 1948 The segmental distribution of the cutaneous nerves in the limbs of man. Anat Rec 102:409-439. Mainly used in literature in the USA. B, Dermatome map based on Moffat DB 1993 Lecture Notes on Anatomy, 2nd edn. Oxford: Blackwell Scientific. Mainly used in literature in the UK.

Fig. 16.11 Efferent pathways of the autonomic nervous system.
and that sympathetic reactions are mass responses whereas parasympathetic reactions are usually more localized. A better concept is that the two sets of neurones constitute an integrated system for the coordinated neural regulation of visceral and homeostatic functions. Moreover, even though widespread activation of the sympathetic nervous system may occur, e.g. in association with fear or rage, it is recognized that the sympathetic nervous system is also capable of discrete activation. In general, sympathetic activity results in the constriction of cutaneous arteries (increasing blood supply to the heart, muscles and brain), cardiac acceleration, an increase in blood pressure, contraction of sphincters and depression of peristalsis, all of which mobilize body energy stores for dealing with increased activity. Parasympathetic activity results in cardiac slowing and an increase in intestinal glandular and peristaltic activities, which may be considered to conserve body energy stores.

Autonomic activity is not initiated or controlled solely by the reflex connections of general visceral afferent pathways; nor do impulses in these pathways necessarily activate general visceral efferents. For example, in many situations demanding general sympathetic activity, the initiator is somatic and typically arises from the special senses or the skin. Rises in blood pressure and pupillary dilation may result
from the stimulation of somatic receptors in the skin and other tissues. Peripheral autonomic activity is integrated at higher levels in the brainstem and cerebrum, including various nuclei of the brainstem reticular formation, thalamus and hypothalamus, the limbic lobe and prefrontal neocortex, together with the ascending and descending pathways that interconnect these regions.

The classical concept of autonomic neurotransmission is that preganglionic neurones of both sympathetic and parasympathetic systems are cholinergic and that postganglionic parasympathetic neurones are also cholinergic while those of the sympathetic nervous system are noradrenergic. The discovery of neurones that do not use either acetylcholine or noradrenaline (norepinephrine) as their primary transmitter, and the recognition of a multiplicity of substances in autonomic nerves which fulfil the criteria for a neurotransmitter or neuromodulator, have greatly complicated neuropharmacological concepts of the autonomic nervous system (Burnstock 2013). Thus, adenosine 5'-triphosphate (ATP), numerous peptides and nitric oxide have all been implicated in the mechanisms of cell signalling in the autonomic nervous system. The principal co-transmitters in sympathetic nerves are ATP and neuropeptide Y; in parasympathetic nerves vasoactive intestinal polypeptide (VIP); and in enteric nerves ATP, VIP and substance P.

## SYMPATHETIC NERVOUS SYSTEM

The sympathetic trunks are two ganglionated nerve cords that extend on either side of the vertebral column from the cranial base to the coccyx. The ganglia are joined to spinal nerves by short connecting nerves called white and grey rami communicantes. Preganglionic axons join the trunk through the white rami communicantes while postganglionic axons leave the trunk in the grey rami. In the neck, each sympathetic trunk lies posterior to the carotid sheath and anterior to the transverse processes of the cervical vertebrae. In the thorax, the trunks are anterior to the heads of the ribs, in the abdomen they lie anterolateral to the bodies of the lumbar vertebrae, and in the pelvis they are anterior to the sacrum and medial to the anterior sacral foramina. Anterior to the coccyx the two trunks meet in a single, median, terminal ganglion. Cervical sympathetic ganglia are usually reduced to three by fusion. The internal carotid nerve, a continuation of the sympathetic trunk, issues from the cranial pole of the superior ganglion and accompanies the internal carotid artery through its canal into the cranial cavity. There are between 10 and 12 (usually 11) thoracic ganglia, 4 lumbar ganglia, and 4 or 5 ganglia in the sacral region.

The cell bodies of preganglionic sympathetic neurones are located in the lateral horn of the spinal grey matter of all thoracic segments and the upper two or three lumbar segments (Fig. 16.12). Their axons are myelinated with diameters of $1.5-4 \mu \mathrm{~m}$. They leave the cord in the corresponding ventral nerve roots and pass into the spinal nerves, but soon leave in white rami communicantes to join the sympathetic trunk (Fig. 16.13). Neurones like those in the lateral grey column exist at other levels of the cord above and below the thoracolumbar outflow and small numbers of their fibres leave in other ventral roots.

Fig. 16.12 A transverse section through the thoracic spinal cord. Preganglionic sympathetic neurones are located in the lateral horn. (Figure enhanced by B Crossman.)

Fig. 16.13 Outflow from preganglionic sympathetic neurones in the lateral horn of the spinal cord. Preganglionic axons may synapse on a postganglionic neurone in a sympathetic ganglion at the same segmental level, or may pass into the sympathetic chain to synapse on a postganglionic neurone in a more rostral or caudal sympathetic ganglion, or may pass to a ganglion in an autonomic plexus in the abdominal cavity, e.g. the coeliac ganglion.

Preganglionic sympathetic neurones release acetylcholine as their principal neurotransmitter.

On reaching the sympathetic trunk, preganglionic fibres behave in one of several ways (see Fig. 16.13). They may synapse with neurones in the nearest ganglion, or traverse the nearest ganglion and ascend or descend in the sympathetic chain to end in another ganglion. A preganglionic fibre may terminate in a single ganglion or, through collateral branches, synapse with neurones in several ganglia. Preganglionic fibres may traverse the nearest ganglion, ascend or descend and, without synapsing, emerge in one of the medially directed branches of the sympathetic trunk to synapse in the ganglia of autonomic plexuses (mainly situated in the midline, e.g. around the coeliac and mesenteric arteries). More than one preganglionic fibre may synapse with a single postganglionic neurone. Uniquely, the suprarenal gland is innervated directly by preganglionic sympathetic neurones that traverse the sympathetic trunk and coeliac ganglion without synapse.

The somata of sympathetic postganglionic neurones are located mostly either in the ganglia of the sympathetic trunk or in ganglia in more peripheral plexuses. The axons of postganglionic neurones are, therefore, generally longer than those of preganglionic neurones, an exception being some of those that innervate pelvic viscera. The axons of ganglionic cells are unmyelinated. They are distributed to target organs in various ways. Those from a ganglion of the sympathetic trunk may return to the spinal nerve of preganglionic origin through a grey ramus communicans, which usually joins the nerve just proximal to the white ramus, and are then distributed through ventral and dorsal spinal rami to blood vessels, sweat glands, hairs, etc., in their zone of supply. Segmental areas vary in extent and overlap considerably. The extent of innervation of different effector systems, e.g. vasomotor, sudomotor, etc., by a particular nerve may not be the same. Alternatively, postganglionic fibres may pass in a medial branch of a ganglion direct to particular viscera, or innervate adjacent blood vessels, or pass along them externally to their peripheral distribution. They may ascend or descend before leaving the sympathetic trunk as described above. Many fibres are distributed along arteries and ducts as plexuses to distant effectors.

The principal neurotransmitter released by postganglionic sympathetic neurones is noradrenaline (norepinephrine). The sympathetic system has a much wider distribution than the parasympathetic. It innervates all sweat glands, the arrector pili muscles, the muscular walls of many blood vessels, the heart, lungs and respiratory tree, the abdominopelvic viscera, the oesophagus, the muscles of the iris, and the nonstriated muscle of the urogenital tract, eyelids and elsewhere.

Postganglionic sympathetic fibres that return to the spinal nerves are vasoconstrictor to blood vessels, secretomotor to sweat glands and motor to the arrector pili muscles within their dermatomes. Those that accompany the motor nerves to voluntary muscles are probably only dilatory. Most, if not all, peripheral nerves contain postganglionic sympathetic fibres. Those reaching the viscera are concerned with general vasoconstriction, bronchial and bronchiolar dilation, modification of glandular secretion, pupillary dilation, inhibition of gastrointestinal muscle contraction, etc. A single preganglionic fibre probably synapses with the postganglionic neurones in only one effector system, which means that effects such as sudomotor and vasomotor actions can be separate.

## PARASYMPATHETIC NERVOUS SYSTEM

Preganglionic parasympathetic neuronal cell bodies are located in certain cranial nerve nuclei of the brainstem (see Fig. 21.1) and in the intermediate grey matter of the second to fourth sacral segments of the spinal cord. Efferent fibres, which are myelinated, emerge from the CNS only in the oculomotor, facial, glossopharyngeal and vagus nerves, and in the second to fourth sacral spinal nerves. Preganglionic parasympathetic neurones are cholinergic.

The cell bodies of postganglionic parasympathetic neurones are mostly sited distant from the CNS, either in discrete ganglia located near the structures innervated, or dispersed in the walls of viscera. In the cranial part of the parasympathetic system there are four small peripheral ganglia - ciliary, pterygopalatine, submandibular and otic - that are all described on a regional basis in Section 4. These are efferent parasympathetic ganglia, unlike the trigeminal, facial, glossopharyngeal and vagal sensory ganglia, all of which are concerned exclusively with afferent impulses and contain the cell bodies of sensory neurones. The cranial parasympathetic ganglia are also traversed by afferent fibres, postganglionic sympathetic fibres and, in the case of the otic ganglion, by branchial efferent fibres; however, none of these fibres synapse in the ganglia. Postganglionic parasympathetic fibres are usually unmyeli-
nated and shorter than their counterparts in the sympathetic system because the ganglia in which the parasympathetic fibres synapse are either in or near the viscera they supply. Postganglionic parasympathetic neurones are cholinergic.

## ENTERIC NERVOUS SYSTEM AND INTRINSIC NEURONES

Many peripheral autonomic ganglia contain neurones derived from the neural crest during embryonic development that are anatomically distinct from classical sympathetic and parasympathetic neurones. Connections between these intrinsic neurones allow them to sustain and modulate visceral activities by local reflex mechanisms. The enteric nervous system consists of many millions of neurones and enteric glial cells grouped into ganglionated plexuses lying in the wall of the gastrointestinal tract; ganglia containing neuronal cell bodies and glia are connected by bundles of axons to form myenteric and submucous plexuses that extend from the oesophagus to the anal sphincter. This intrinsic circuitry mediates numerous reflex functions including the contractions of the muscular coats of the gastrointestinal tract, secretion of gastric acid, intestinal transport of water and electrolytes, and the regulation of mucosal blood flow (Poole and Furness 2012). Although complex interactions occur between the enteric and sympathetic and parasympathetic nervous systems, the enteric nervous system is capable of sustaining local reflex activity independent of the CNS.

Since intrinsic neurones survive after section of the extrinsic sympathetic and parasympathetic nerves, organs that are transplanted are not truly denervated. Separation from their autonomic input often has no obvious impact on the non-striated muscle or glands innervated by autonomic fibres; contraction may be unaffected and no structural changes ensue. This has been variously attributed to the continued activity of local plexuses or to the intrinsic activity of visceral muscle. In some important instances, however, denervation does result in cessation of activity, e.g. in sweat glands, pilomotor muscle, orbital nonstriated muscle and the suprarenal medulla.

## VISCERAL AFFERENT PATHWAYS

Visceral afferent pathways in many ways resemble somatic afferent pathways. The peripheral processes of visceral afferents run through autonomic ganglia or plexuses, and possibly through somatic nerves. Their central processes accompany somatic afferent fibres through cranial nerves or dorsal spinal roots into the CNS, where they establish connections that mediate autonomic reflexes and visceral sensation.

General visceral afferent fibres from the viscera and blood vessels accompany their efferent counterparts, and are the peripheral processes of unipolar cell bodies located in some cranial nerve and dorsal root ganglia. They are contained in the vagus, glossopharyngeal and possibly other cranial nerves; the second to fourth sacral spinal nerves, distributed with the pelvic splanchnic nerves; and thoracic and upper lumbar spinal nerves, distributed through rami communicantes and alongside the efferent sympathetic innervation of viscera and blood vessels.

The cell bodies of vagal general visceral afferent fibres are in the superior and inferior vagal ganglia. Their peripheral processes are distributed to terminals in the pharyngeal and oesophageal walls where, acting synergistically with glossopharyngeal visceral afferents in the pharynx, they are concerned with swallowing reflexes. Vagal afferents are also believed to innervate the thyroid and parathyroid glands. In the heart, vagal afferents innervate the walls of the great vessels, the aortic bodies and pressor receptors, where they are stimulated by raised intravascular pressure. In the lungs they are distributed via the pulmonary plexuses. They supply bronchial mucosa, where they are probably involved in cough reflexes; bronchial muscle, where they encircle myocytes and end in tendrils, which are sometimes regarded as muscle spindles and which are believed to be stimulated by change in the length of myocytes; interalveolar connective tissue, where their knoblike endings, together with terminals on myocytes, may evoke HeringBreuer reflexes; the adventitia of pulmonary arteries, where they may be pressor receptors; and the intima of pulmonary veins, where they may be chemoreceptors. Vagal visceral afferent fibres also end in the gastric and intestinal walls, digestive glands and the kidneys. Fibres ending in the gut and its ducts respond to stretch or contraction. Gastric impulses may evoke sensations of hunger and nausea.

The cell bodies of glossopharyngeal general visceral afferents are in the glossopharyngeal ganglia. Their peripheral processes innervate the
posterior lingual region, the palatine tonsils and pharynx, but they do not innervate taste buds. They also innervate the carotid sinus and the carotid body, which contain receptors sensitive to tension and changes in chemical composition of the blood. Impulses from these receptors are essential to circulatory and respiratory reflexes.

Visceral afferents that enter the spinal cord through spinal nerve roots terminate in the spinal grey matter. Almost all the central processes of vagal and glossopharyngeal afferent fibres end in the nucleus solitarius of the medulla. About 5\% of the vagal afferents project directly to, and terminate in, the upper cervical spinal cord ( $\mathrm{C} 1-2$ ), where they are believed to contribute to referred sensations, as well as to propriospinal mechanisms of nociceptive modulation. Visceral afferents establish connections within the CNS that mediate autonomic reflexes. In addition, afferent impulses probably mediate visceral sensations such as hunger, nausea, sexual excitement, vesical distension, etc. Visceral pain fibres may follow these routes. Although viscera are insensitive to cutting, crushing or burning, excessive tension in smooth muscle and some pathological conditions produce visceral pain. In visceral disease, vague pain may be felt near the viscus itself (visceral pain) or in a cutaneous area or other tissue whose somatic afferents enter spinal segments receiving afferents from the viscus, a phenomenon known as referred pain. If inflammation spreads from a diseased viscus to the adjacent parietal serosa (e.g. the peritoneum), somatic afferents will be stimulated, causing local somatic pain, which is commonly spasmodic. Referred pain is often associated with local cutaneous tenderness. For further reading on visceral pain, see Bielefeldt and Gebhart (2013).

Afferent fibres in pelvic splanchnic nerves innervate pelvic viscera and the distal part of the colon. Vesical receptors are widespread; those in muscle strata are associated with thickly myelinated fibres and are believed to be stretch receptors, possibly activated by contraction. Pain fibres from the bladder and proximal urethra traverse both the pelvic splanchnic nerves and the inferior hypogastric plexus, hypogastric nerves, superior hypogastric plexus and lumbar splanchnic nerves to reach their cell bodies in ganglia on the lower thoracic and upper lumbar dorsal spinal roots; the significance of this dual sensory pathway is uncertain. Lesions of the cauda equina abolish pain from vesical overdistension, but hypogastric section is ineffective. Pain fibres from the uterus traverse the hypogastric plexus and lumbar splanchnic nerves to reach somata in the lowest thoracic and upper lumbar spinal ganglia, and hypogastric division may relieve dysmenorrhoea. Afferents from the uterine cervix traverse the pelvic splanchnic nerves to reach their somata in the upper sacral spinal ganglia; stretching the cervix uteri causes pain but cauterization and biopsy excisions do not.

In general, afferent fibres that accompany pre- and postganglionic sympathetic fibres have a segmental arrangement and end in spinal cord segments from which preganglionic fibres innervate the region or viscus concerned. General visceral afferents entering thoracic and upper lumbar spinal segments are largely concerned with pain. Nociceptive impulses from the pharynx, oesophagus, stomach, intestines, kidneys, ureter, gallbladder and bile ducts seem to be carried in sympathetic pathways. Cardiac nociceptive impulses enter the spinal cord in the first to fifth thoracic spinal nerves, mainly via the middle and inferior cardiac nerves, but some fibres pass directly to the spinal nerves. It is said that there are no general visceral afferents in the superior cardiac nerves. Peripherally, the fibres pass through the cardiac plexuses and along the coronary arteries. Myocardial anoxia may evoke symptoms of angina pectoris in which pain is typically presternal, and is also referred to much of the left chest, and radiates to the left shoulder, the medial aspect of the left arm, along the left side of the neck to the jaw and occiput, and down to the epigastrium. Cardiac afferents carried in vagal cardiac branches are concerned with the reflex depression of cardiac activity. Ureteric pain fibres, also running with sympathetic fibres, are presumably involved in the agonizing renal colic that follows obstruction by calculi. Afferent fibres from the testis and ovary run through the corresponding plexuses to somata in the tenth and eleventh thoracic dorsal root ganglia.

Some primary afferent neurones, innervating the gut, lungs, heart and blood vessels, also appear to have an efferent function in that they release transmitters from their peripheral endings during the axon reflex. The primary substances released in this way are substance P , calcitonin gene-related peptide (CGRP) and ATP. These act on target cells to produce vasodilation, increased venular permeability, changes in smooth muscle contractility, degranulation of mast cells and a variety of effects on leukocytes and fibroblasts, a process collectively known as 'peripheral neurogenic inflammation'. The local release of such substances may play a trophic role in the maintenance of tissue integrity and repair in response to injury (for further reading, see Xanthos and Sandkühler (2014)).

Fig. 16.14 The principal aggregations of 'classic' chromaffin tissue in the human neonate. The aggregates in pale blue lie deep to overlying structures.

## PARAGANGLIA

Paraganglia are extra-suprarenal aggregations of neuroepithelial cells. They are all derived from the neural crest and all synthesize and store catecholamines (Fig. 16.14). Paraganglia can be divided into two broad categories: non-chromaffin, related to the parasympathetic system, particularly in the head and neck, where they tend to be associated with the glossopharyngeal or vagus nerves (carotid body, promontory of the middle ear, tunica adventitia of the jugular bulb, facial canal, ganglion nodosum, larynx); and chromaffin, connected with the orthosympathetic system (in the sympathetic ganglia of various viscera and a variety of thoracolumbar para-aortic retroperitoneal sites). Small paraganglia have also been reported incidentally in the urinary bladder, prostate, gallbladder, splenic capsule and mesosigmoid. Their functions differ with location: some cells act as interneurones, others as sources of neuroendocrine secretion. Paraganglionic catecholamine release occurs mainly in response to chemical rather than to neural stimuli. Extrasuprarenal chromaffin tissue is prominent in the fetus, and acts as the main source of catecholamines while the suprarenal medulla is immature. Although many paraganglia degenerate soon after birth, others persist into adulthood, often as microscopic paraganglia.

Paraganglia are well vascularized and their secretory cells are usually close to one or more fenestrated capillaries. Most have a sympathetic innervation and act as endocrine organs, e.g. suprarenal medullary chromaffin cells. Those associated with the parasympathetic system probably have activities on local nerve endings, e.g. the carotid body. Paraganglia produce regulatory peptides, particularly enkephalins, and store them as cytoplasmic granules until stimulated to release them. Their secretions may exert a local paracrine action on nearby cells, in addition to having remote endocrine effects.

Paragangliomas have been found in practically every site in which normal paraganglia are known to occur; carotid body paragangliomas are the most common and important group of extra-suprarenal paragangliomas (accounting for approximately $60 \%$ of head and neck paragangliomas). For further reading, see Rosai (2011) and Lack and Wieneke (2013).

## SURFACE ANATOMY

The surface positions of cerebral structures, meningeal arteries and dural venous sinuses may be approximated via a number of standardized reference lines and planes.

## Cerebral sulci and lobes

The central sulcus (Rolandic fissure) and lateral sulcus (Sylvian fissure) of the cerebral hemispheres can be landmarked via the cranium using multiple methods, the most common being that developed by Taylor and Haughton (Fig. 16.15) (Taylor and Haughton 1900, Taylor et al 1980). Recent analysis of these methods has shown them to be accurate to within a few millimetres (Reis et al 2011). Using Taylor-Haughton craniometric lines, the lateral sulcus sits on the frontozygomatic (Sylvian) line, which passes from the frontozygomatic suture to a point $75 \%$ the way along the nasion-inion midsagittal line. The lateral sulcus extends posteroinferiorly from the Sylvian point, which is located around the region of the pterion. The lateral sulcus has also been shown to align with the anterior part of the squamosal suture in a zone $2.5-4.0 \mathrm{~cm}$ anterior to the external acoustic meatus (Rahmah et al 2011). The position of the central sulcus is approximated via a line passing from the superior Rolandic point, situated approximately 2 cm posterior to the midpoint of the nasion-inion midsagittal line, to the inferior Rolandic point, situated at the intersection of the frontozygomatic line with the pre-auricular/condylar line. Alternatively, the position of the central sulcus can be approximated using a line passing from the superior Rolandic point to the midpoint of the zygomatic arch, with the central sulcus ending at the point of intersection of this line with the frontozygomatic line (Rhoton 2002). The superior extent of the parieto-occipital sulcus sits at the point of intersection of the frontozygomatic line and the $75 \%$ point on the nasion-inion line. The approximate positions of the lobes of the brain, and of the precentral and postcentral gyri, can be determined following localization of the central, lateral and parieto-occipital sulci (Fig. 16.16).

## Vertebral column, spinal cord and meninges

The surface positions of the termination of the spinal cord and dural sac can be mapped relative to the vertebrae and their spinous processes (see Ch. 43).

## Dural venous sinuses

The superior sagittal sinus passes along the nasion-inion midsagittal line on the inner surface of the cranial vault (Fig. 16.17). In the majority of subjects it deviates to the right of the sagittal plane/superior sagittal suture by up to 11 mm (Tubbs et al 2001, Samadian et al 2011). The confluence of the dural venous sinuses (torcular herophili) sits mainly to the upper right side of the inion (Sheng et al 2012). The position of the lower border of the proximal transverse sinus is best approximated via the insertion of semispinalis capitis into the cranium (Tubbs et al 2000). The course of the transverse sinus has been shown to vary widely and no single plane or surface marking can be used to predict its route accurately (Sheng et al 2012). The asterion, found at the junction of the lambdoid, occipitomastoid and parietomastoid sutures, sits over the junction between the transverse and sigmoid sinuses in $81 \%$ of subjects, inferior to it in $15 \%$ and superior to it in $4 \%$ (Sheng et al 2012).

## Middle meningeal artery

The surface positions of the anterior and posterior branches of the middle meningeal artery can be determined relative to cranial landmarks (see Fig. 26.8A).

## Development of the nervous system

The entire nervous system and the special sense organs originate from three sources, each derived from specific cell populations of the early epiblast termed neural ectoderm. The first source to be clearly delineated is the neural plate, which gives rise to the central nervous system (CNS), the somatic motor nerves and the preganglionic autonomic nerves. The second source is from cells at the perimeter of the neural plate, neural crest cells, which remove themselves by epithelial/ mesenchymal transition from the plate and migrate away just prior to its fusion into a neural tube. These cells give rise to the majority of the neurones and glia of the peripheral nervous system (PNS), i.e. the somatic sensory nerves, the somatic and autonomic ganglia, postganglionic autonomic nerves, and suprarenal and chromaffin cells. They also give rise to significant mesenchymal populations in the head. The third source is from ectodermal placodes, which constitute a focal thickening of the ectoderm covering the embryonic head. They contribute cells to the cranial sensory neurones and form the olfactory epithelia, the epithelia of the inner ear and, by a non-neuronal contribution, the lens of the eye.

## NEURULATION

Primary neurulation begins at stage 9 and is completed during stage 12 (Fig. 17.1). The process, although continuous spatially and temporally, has been envisaged as four stages. It begins with local elongation of the ectoderm cells in a midline zone of the embryonic disc and their reorganization into a pseudostratified epithelium, the neural plate. This is followed by reshaping and bending of the neural plate into a neural groove, which subsequently closes to form a neural tube bidirectionally from the mid portion to its cranial and caudal ends. A continuous surface ectoderm forms dorsal to the tube.

Primary neurulation depends on cellular changes within the neural plate; in the trunk, it may also involve movements of the paraxial

Fig. 17.1 A scanning electron micrograph of a neurulating rat embryo comparable to a stage 10 human embryo (22-24 days). The expanded brain region can be seen at the top of the image, with somite formation occurring centrally as neurulation proceeds caudally. Caudally, the ridge of underlying neural crest cells can be seen medial to the unsegmented paraxial mesenchyme. (Photograph by P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)
mesenchyme. There is fusion initially of the surface ectoderm, followed by fusion of the neural ectoderm. The neural ectodermal cells become elongated and then wedge-shaped. It has been suggested that the forces needed to shape the neural tube are intrinsic to the cells of the neurectoderm and, indeed, it has been demonstrated that human embryonic stem cells can self-organize into three-dimensional neural structures (Sasai et al 2012, Eiraku and Sasai 2012). Epithelial populations are established in the embryo with the formation of the epiblast. Three main control pathways that maintain apicobasal polarity have been described. When the neural tube is closing, its walls consist of a pseudostratified layer of columnar neural epithelial cells (see below). The cells increase in length and develop numerous longitudinally disposed microtubules. The borders of their luminal ends are firmly attached to adjacent cells by junctional complexes; the cytoplasmic aspect of the complexes is associated with a dense paraluminal web of microfilaments. The nuclei assume basal positions, which, together with contraction of apically arranged actin, imparts a slight wedge conformation on some of the cells, and creates a hinge point.

The position of hinge points within the neural plate confers different characteristics on the formed neural tube. With a median hinge point, the neural folds remain relatively straight and the tube in this position has a slit-shaped lumen; this can be seen from the initial region of fusion rostralwards. If dorsolateral hinge points are added, the resulting neural tube is rhombic, and the hinge points describe the position of the sulcus limitans. If all the neuroepithelial cells exhibit some apical narrowing, then the resulting tube has a circular lumen. The rostral slit-shaped profile of the neural tube may depend more on support from adjacent tissues than the caudal end of the tube, where neurulation is generated by the neuroepithelium. The transition from primary to secondary neurulation (see below) continues the production of a neural tube with a circular lumen.

Fusion of the neural tube starts in embryos with 4-6 somites, at the level of somites 1 and 2, forming the future rhombencephalon. The tube closes caudally and rostrally, forming sequentially cervical and thoracic cord regions, then mesencephalic and prosencephalic brain regions. Rostrally, two sites of fusion can be seen. The initial fusion, termed $\alpha$, or the dorsal lip of the rostral neuropore, proceeds caudorostrally. A second site, termed $\beta$, or the terminal lip of the rostral neuropore, closes from the rostral end of the neural plate and proceeds rostrocaudally ( $O^{\prime}$ Rahilly and Müller 2002). Closure of these lips of the rostral neuropore is completed when 19-20 pairs of somites are present. Caudal neuropore closure starts when approximately 29 somites are present and the site of closure corresponds to the level of the future somite 31 (the level of the future second sacral vertebra) ( $O^{\prime}$ Rahilly and Müller 2004).

Secondary neurulation starts from the closure of the caudal neuropore at stage 12 and ends at about stage 17; it is the process by which the caudal portion of the neural tube is formed in the absence of a neural plate. At the time of caudal neuropore closure, the caudal midline cells are generically termed the caudal eminence ( $O^{\prime}$ Rahilly and Müller 2004). A specific population of mesenchymal cells, the caudoneural hinge or junction, shares the same molecular markers as the primitive node. These cells aggregate at the midline and undergo mesenchymal/ epithelial transformation, producing a cellular cylinder that is contiguous with the caudal end of the neural tube. Further elongation of the caudal neural tube involves cavitation of the neural cylinder. Neural crest cells delaminate from the dorsal surface of the cylinder in a rostrocaudal direction and, concurrently, the paraxial mesenchyme undergoes somitogenesis.

## EARLY BRAIN REGIONS

Prior to the closure of the neural tube, the neural folds become considerably expanded in the head region; the first indication of a brain and

Fig. 17.2 The primary brain regions, neuromeres and their expansion during neurulation.
its major divisions can be seen at stage 10 (Fig. 17.2). Regional expansions - prosencephalon (forebrain), mesencephalon (midbrain) and rhombencephalon (hindbrain) - have been called the three primary cerebral vesicles, although the term 'vesicle' in this context has been considered inappropriate to describe localized accelerations of growth in the wall of the brain. As the neural tube closes, the neural wall appears to form a series of ridges and depressions perpendicular to its long axis. These transient repeating segments are termed primary neuromeres, and initially six can be identified: the prosencephalon, mesencephalon and four subdivisions of the rhombencephalon, rhombomeres A, B, C and D. The primary neuromeres themselves become subdivided during stages 10,11 and 12 , and a total of 16 secondary neuromeres have been identified. The prosencephalon gives rise to the telencephalon, diencephalon 1 (D1) and diencephalon 2 (D2), which has three subdivisions. The mesencephalon is subdivided into mesencephalon 1 (M1) and mesencephalon 2 (M2). The rhombencephalon is subdivided into the isthmus rhombencephali and rhombomeres 1-8; the original rhombomere A gives rise to secondary rhombomeres 1,2 and 3; rhombomere B gives rise to secondary rhombomere 4; rhombomere C gives rise to secondary rhombomeres 5, 6 and 7; and rhombomere D gives rise to secondary rhombomere 8 ( $\mathrm{O}^{\prime}$ Rahilly and Müller 1999). As the rhombencephalon grows, the rhombomeric boundaries become less distinct. With the early appearance of the cerebellum from the isthmus rhombencephali and rhombomere 1, the rhombencephalon is traditionally divided into the metencephalon, which extends to about rhombomere 3, and the myelencephalon, which extends to the spinomedullary junction. A summary of the derivatives of the cerebral regions is given in Table 17.1.

The elongation of the brain occurs at the same time as the appearance of three flexures, which also appear prior to the closure of the neural tube; two are concave ventrally and one concave dorsally. During stages 13 and 14, the brain bends at the mesencephalon (mesencephalic flexure) so that the prosencephalon bends in a ventral direction around

Table 17.1 Derivatives of the cerebral regions from caudal to rostral

| Cerebral region | Derivatives |
| :---: | :---: |

Fig. 17.3 Formation of the mesencephalic, cervical and pontine flexures; human embryos, lateral views. The roof of the rhombencephalon has been removed in each case. A, 9 mm long. B, approximately 10.2 mm long. $\mathbf{C}, 13.6 \mathrm{~mm}$ long.
the cephalic end of the notochord and foregut until its floor lies almost parallel with that of the rhombencephalon (Fig. 17.3). A bend also appears at the junction of the rhombencephalon and spinal cord (cervical flexure). This increases from the fifth week to the end of the seventh by which time the rhombencephalon forms nearly a right angle to the spinal cord. However, after the seventh week, extension of the head takes place and the cervical flexure diminishes and eventually disappears. The third bend, the pontine flexure, is directed ventrally between the metencephalon and myelencephalon. It does not substantially affect the outline of the head. In this region, the roof plate thins until it is composed only of a single layer of cells and pia mater: the tela choroidea. The flexure of the neural tube at this point produces a rhombic shape in the roof, which later forms the medullary velum.

## EARLY CELLULAR ARRANGEMENT OF THE NEURAL TUBE

The dorsoventral patterning of the neural tube is initiated by the underlying notochord. As neurulation proceeds, the neural tube elongates by convergent extension (Bay and Caspary 2012). Histologically, the early neural tube is composed of a pseudostratified neuroepithelium, in which the apical surfaces of the cells face the lumen of the neural tube and their basal surfaces contact the outer limiting layer of neural crest mesenchyme, which will become the pia mater. Initially, each cell has an apical, non-motile primary cilium with an internal $9+0$ configuration of microtubules and a system of intraflagellar transport. The membrane of the primary cilium expresses receptors and ion channels, and
modulates signalling pathways for Shh, Wnt and PDGFo (Lee and Gleeson 2010).

The neuroepithelium contains stem cells that will give rise to populations of neuroblasts and glioblasts. A population of radial glia, each with a primary cilium, differentiates very early. They elongate as the epithelium develops, maintaining contact with both the lumen and the outer surface, and provide a scaffold on which cell progeny can migrate. Arl13b, a cilia-specific small guanosine triphosphatase (GTPase), is essential for the formation of radial glia (Higginbotham et al 2013).

Three zones or layers develop, termed ventricular, mantle and marginal zones (Figs 17.4-17.6). The inner, ventricular zone (germinal, primitive ependymal or matrix layer) corresponds to the apical region of the radial glial cells and contains the nucleated parts of the columnar cells and rounded cells undergoing mitosis. The mantle, or intermediate, zone contains the migrant cells from the divisions occurring in the ventricular zone. The outer, marginal zone initially consists of the external (basal) cytoplasmic processes of the radial glia. It is soon invaded by tracts of axonal processes that grow from neuroblasts developing in the mantle zone, together with varieties of non-neuronal cells (glial cells and, later, vascular endothelium and perivascular mesenchyme). For further development of these layers, see page 245.

At first, the neural tube caudal to the brain is oval in transverse section and its lumen is narrow and slit-like (see Fig. 17.4). The original floor plate and the dorsal site of fusion of the tube initially contain non-neural cells. With cellular proliferation, the lateral walls thicken and the lumen, now the central canal, widens in its dorsal part and is somewhat diamond-shaped on cross-section (see Fig. 17.6). The widening of the canal is associated with the development of a longitudinal
sulcus limitans on each side, dividing the ventricular and mantle (intermediate) zones in each lateral wall into a ventrolateral lamina or basal plate, and a dorsolateral lamina or alar plate, respectively. This separation underlies a fundamental functional difference.

Throughout the neural tube, a generic pattern in the position of the neurones is specified by the juxtaposition of the notochord to the neural tube. Experimental lateral or dorsal grafting of a notochord results in the induction of a floor plate overlying the grafted notochord and the induction of ectopic motor neurones dorsally. Similarly, lateral or dorsal grafts of a floor plate also result in the induction of a new floor plate overlying the graft and the induction of ectopic dorsal motor neurones. Removal of the notochord results in the elimination of the floor plate and the motor neurones, and the differentiation of dorsal cell types in the ventral region of the cord (Dodd et al 1998) (Fig. 17.7).

The basal plate is normally concerned predominantly with motor function, and contains the cell bodies of motor neurones that will occupy the future anterior and lateral grey columns. The alar plate receives sensory inflow from external dorsal root ganglia. Motor and sensory axons combine to form the mixed nerves.

## FAILURE OF NEURULATION

Failure of neurulation produces the conditions of craniorachischisis totalis (where the entire neural tube is unfused in the dorsal midline), cranioschisis or anencephaly (where the neural tube is fused dorsally to form the spinal cord but is not fused dorsally in the brain), and spina bifida (where local regions of the spinal neural tube are unfused, or there is failure of formation of the vertebral neural arches) (Fig. 17.8; see also Ch. 44). Anencephalic fetuses display severe disturbances in the shape, position and ossification of the basichondrocranium and in the course of the intracranial notochord, and so the condition is more complicated than 'simply' a failure of neural tube fusion. Defects in the
structure or function of the primary cilium are associated with changes in cortical formation that are thought to underlie cognitive deficits and mental retardation in a range of recessive ciliopathies (Higginbotham et al 2013).

## NEURAL CREST

The neuronal populations of the early epiblast become arranged in the medial region of the embryonic disc as the neural plate. Laterally, neural folds or crests indicate the transitional region between neural and surface ectoderm. Along most of the neuraxis, the cells at the tips of the neural folds undergo an epithelial/mesenchyme transformation. They acquire migratory properties and leave the epithelium just prior to its fusion with the contralateral fold in the dorsal midline. The migratory cells so formed are collectively termed the neural crest. Cells within the rostral prosencephalic neural fold and smaller populations of cells in bilateral sites lateral to the early brain do not form migratory neural crest cells but remain within the surface epithelium as ectodermal placodes.

Neural crest populations arise from the neural folds as primary neurulation proceeds and simultaneously progresses rostrally and caudally. Crest cells migrate from the neural folds of the brain prior to tube closure. Caudally, from approximately somite 29 , secondary neurulation processes produce the most caudal neural crest. Two distinct populations of neural crest cells are formed: a neuronal population produced throughout the brain and spinal cord, which gives rise to sensory and autonomic neurones and glia; and a non-neuronal mesenchymal population, which arises only from the brain (Figs 17.917.10). Melanocytes develop from a subpopulation of neural crest cells derived from both the head and the trunk. They form one of the three pigment cell types (the others being retinal pigment epithelium and the pigment cells of the pineal organ, which both originate from the diencephalon).

Fig. 17.4 The spinal cord of a 4-week-old human embryo. Transverse section.

Fig. 17.6 The spinal cord in the cervical region of a human embryo early in the sixth week; crown-rump length 8 mm . Transverse section.

Fig. 17.5 The early development of the neural tube. Three layers are delineated in the spinal cord and brainstem.

Fig. 17.7 A-D, Successive stages in the development of the neural tube and spinal cord. A, The neural plate consists of epithelial cells. Cells in the midline of the neural plate are contacted directly by the notochord. More lateral regions of the neural plate overlie the paraxial mesenchyme (not shown). B, During neurulation, the neural plate bends at its midline and this elevates the lateral edges of the plate as the neural folds. Contact between the midline of the neural plate and the notochord is maintained at this stage. C, The neural tube is formed when the dorsal tips of the neural folds fuse. Cells in the region of fusion form the roof plate, a specialized group of dorsal midline cells. $\mathbf{D}$, Cells at the ventral midline of the neural tube retain proximity to the notochord and differentiate into the floor plate. After neural tube closure, neuroepithelial cells continue to proliferate and eventually differentiate into defined classes of neurones at different dorsoventral positions within the spinal cord. For example, sensory relay, commissural and other classes of dorsal neurones differentiate near to the roof plate, and motor neurones differentiate ventrally near the floor plate, which, by this time, is no longer in contact with the notochord. E-H, A summary of the results obtained from experiments in chick embryos, in which either a notochord or floor plate is grafted to the dorsal midline of the neural tube, or the notochord is removed before neural tube closure. E, The normal condition: motor neurones are located ventrally and sensory relay neurones are located dorsally. F, Dorsal grafts of a notochord result in the induction of a floor plate in the dorsal midline and ectopic dorsal motor neurones. G, Dorsal grafts of a floor plate induce a new floor plate in the dorsal midline and ectopic dorsal motor neurones. H, Removal of the notochord results in the elimination of the floor plate and motor neurones, and the expression of dorsal cell types in the ventral region of the spinal cord.

Fig. 17.8 Defects caused by failure of neural tube formation. A, Total failure of neurulation. B, Failure of rostral neurulation. C, Failure of caudal neurulation. Abbreviations: CSF, cerebrospinal fluid.

In the trunk, the migration patterns of neural crest cells are channelled by the somites. As the crest cells move laterally and ventrally, they can pass between the somites and within the rostral sclerotomal half of each somite, but they cannot penetrate the caudal moiety of the sclerotomal mesenchyme. Thus, the segmental distribution of the spinal and sympathetic ganglia is imposed on the neural crest cells by a prepattern that exists within the somitic paraxial mesenchyme (Fig. 17.11). The origin of the cranial-caudal patterning of the ventral neural crest cells is not clear.

Rostral to the otic vesicle, neural crest cells arise from specific regions of the brain. Early in development, a number of transverse subdivisions perpendicular to the long axis of the brain can be seen within the rhombencephalon, dividing it into segments termed rhombomeres
(Müller and O'Rahilly 1997). Eight main rhombomeres extend from the midbrain-hindbrain boundary rostrally to the spinal cord caudally (see Fig. 17.2). Rhombomeres 8 and 7 give rise to neural crest cells that migrate into the fourth and sixth pharyngeal arches; rhombomere 6 crest cells invade pharyngeal arch 3 . Rhombomere 4 crest cells migrate into arch 2, whereas rhombomeres 5 and 3 give rise to a very small number of neural crest cells that migrate rostrally and caudally to enter the adjacent even-numbered neighbours. Rhombomeres 1 and 2 produce crest cells that invade the first pharyngeal arch. In each rhombomere, mesenchymal populations and the sensory and autonomic ganglia are formed from the crest cells (see Fig. 12.4).

Further rostrally, neural crest from the mesencephalon migrates into the first arch maxillary and mandibular processes. Crest cells are

Fig. 17.9 A, A fate map along the neural crest of the presumptive territories that yield ectomesenchyme, sensory, parasympathetic and sympathetic ganglia, and neural crest-derived mesenchyme in normal development. B, Developmental potentials for the same cell types. If neural crest cells from any level of the neural axis are implanted into the appropriate sites of a host embryo, they can give rise to almost all the cell types forming the various kinds of peripheral nervous system ganglia. This is not true for neural crest-derived mesenchyme, whose precursors are confined to the cephalic area of the crest down to the level of somite 5. Abbreviations: S, somite.
produced from the diencephalon up to the level of the pineal gland (epiphysis). Neural crest cells that are produced from this rostral portion of the brain contribute mesenchymal populations to the frontonasal process. The most rostral prosencephalic neural fold does not give rise to neural crest.

## ECTODERMAL PLACODES

Before the neural tube closes, the elevating neural folds contain two distinctive neuronal populations. The larger population, neural crest cells, migrates from the neural epithelium prior to neural tube fusion. The smaller population, neuroepithelial cells, becomes incorporated into the surface ectoderm after neural tube closure. These areas of neuroepithelium within the surface ectoderm have been termed ectodermal placodes. Although the majority of the ectodermal placodes form nervous tissue, non-neurogenic placodes also occur (Begbie and Graham 2001). After an appropriate inductive stimulus, the placodes thicken and either they generate migratory neuronal cells that will contribute to the cranial sensory ganglia, or the whole placodal region invaginates to form a vesicle beneath the remaining surface ectoderm. Neurogenic placodes undergo both processes. Paired non-neurogenic placodes invaginate to form the lens vesicles under the inductive influence of the optic vesicles (Ch. 40).

Fig. 17.10 A fate map of the rostral region of the neural primordium, as established by the quail-chick chimera system. A, The various territories yielding rostral head are indicated on the neural plate and neural fold of a 1 -3-somite embryo. B, The results obtained in the avian embryo have been extrapolated to the human head. For example, the neural fold area coloured green in A yields the epithelium of the nose, philtrum and primary palate.

Fig. 17.11 The migration routes taken by neural crest cells in the trunk.

The neural folds meet in the rostral midline adjacent to the buccopharyngeal membrane. This rostral neural fold does not generate neural crest but gives rise to the hypophysial placode, i.e. the future Rathke's pouch, which remains within the surface ectoderm directly rostral to the buccopharyngeal membrane. The rostral neural fold also gives rise to the olfactory placodes, which remain as paired, laterally placed placodes, and to the epithelium of the nasal cavity (see Fig. 17.10).

Further caudally, similar neurogenic placodes can be identified and divided into three categories: namely, the epibranchial, otic and trigeminal placodes (Fig. 17.12). The epibranchial placodes appear in the surface ectoderm immediately dorsal to the area of pharyngeal (branchial) cleft formation. The first epibranchial placode is located at the level of the first pharyngeal groove and contributes cells to the distal (geniculate) ganglion of the facial nerve; and the second and third epibranchial placodes contribute cells to the distal ganglia of the

Fig. 17.12 A scheme of a human embryo at stage 13 ( $4 \mathrm{~mm}, 32$ somites), rendered flat to eliminate the cerebral flexures. The cranial sensory ganglia and otocyst, derived from the epibranchial placodes, are shown on the left. The levels of origin of the neural crest that contribute to the cranial sensory ganglia and mesenchymal populations in the head are indicated on the right. This arrangement may vary in other species. (Courtesy of Professor R O'Rahilly and Dr F Müller.)
glossopharyngeal (petrosal) and vagus (nodose) nerves, respectively. These placodes thicken and cells begin to detach from their epithelium soon after the pharyngeal pouches have contacted the overlying ectoderm. Concurrently, the neural crest cells reach and move beyond these lateral extensions of the pharynx. Neurones migrate from the epibranchial placodes internally to the sites of ganglion formation, where they show signs of early differentiation into neurones, including the formation of neurites.

The otic placodes, located lateral to the myelencephalon, invaginate to form otic vesicles from which the membranous labyrinth of the ear develops. Neurones of the vestibulocochlear nerve ganglia arise from neurones that bud off the ventromedial aspect of the otic cup, after which they can be distinguished in the acoustic and vestibular ganglia (Ch. 39).

The profundal and maxillomandibular trigeminal placodes, which fuse in humans to form a single entity, lie rostral of the otic placodes, alongside the mesencephalic-rhombencephalic junction. Prospective neuroblasts migrate from foci dispersed throughout the surface ectoderm lateral and ventrolateral to the caudal mesencephalon and metencephalon to contribute to the distal portions of the trigeminal ganglia.

## PITUITARY GLAND (HYPOPHYSIS CEREBRI)

The hypophysis cerebri consists of the adenohypophysis and the neurohypophysis (Ch. 23). Prior to neurulation, the cell populations that give rise to these two portions of the pituitary gland are found next to each other within the rostral portion of the floor of the neural plate and the contiguous midline neural fold. As neurulation proceeds, the future neurohypophysis remains within the floor of the prosencephalon. The cells of the future adenohypophysis are displaced into the surface ectoderm, where they form the hypophysial placode in close apposition and adherent to the overlying prosencephalon.

The most rostral portion of the neural plate, which will form the hypothalamus, is in contact rostrally with the future adenohypophysis in the rostral neural ridge, and caudally with the neurohypophysis, in the floor of the neural plate (see Fig. 17.10). After neurulation, the cells of the rostral neural ridge remain in the surface ectoderm and form the hypophysial placode, which is in close apposition and adherent to the overlying prosencephalon.

Neural crest mesenchyme later moves between the prosencephalon and surface ectoderm, except at the region of the placode. Before rupture of the buccopharyngeal membrane, proliferation of the periplacodal mesenchyme means that the placode forms the roof and walls of a saccular depression. This hypophysial recess (pouch of Rathke; Figs 17.13$17.14)$ is the rudiment of the adenohypophysis. It lies immediately ventral to the dorsal border of the buccopharyngeal membrane, extending in front of the rostral tip of the notochord, and retaining contact with the ventral surface of the prosencephalon, which will become the hypothalamus. It is constricted by continued proliferation of the surrounding mesenchyme to form a closed vesicle, but remains, for a time, connected to the ectoderm of the stomodeum by a solid cord of cells, which can be traced down the posterior edge of the nasal septum. Masses of epithelial cells form, mainly on each side and in the ventral wall of the vesicle, and the development of the adenohypophysis progresses by the ingrowth of a mesenchymal stroma. Differentiation of epithelial cells into stem cells and three differentiating types is said to be apparent during the early months of fetal development. It has been suggested that different types of cells arise in succession, and that they may be derived in differing proportions from different parts of the hypophysial recess. A craniopharyngeal canal, which sometimes runs from the rostral part of the hypophysial fossa of the sphenoid to the exterior of the skull, is often said to mark the original position of the hypophysial recess. Traces of the stomodeal end of the recess are usually present at the junction of the septum of the nose with the palate. Others have claimed that the craniopharyngeal canal itself is a secondary formation caused by the growth of blood vessels, and is quite unconnected with the stalk of the adenohypophysis.

A small endodermal diverticulum, Seessel's pouch, projects towards the brain from the cranial end of the foregut, immediately caudal to the buccopharyngeal membrane. In some marsupials, this pouch forms a part of the hypophysis but, in humans, it is not well defined and disappears entirely.

Just caudal to, but in contact with, the adenohypophysial recess, a hollow diverticulum elongates towards the stomodeum from the floor of the neural plate just caudal to the hypothalamus (see Fig. 17.14B); this region of neural outgrowth is the neurohypophysis. It forms an infundibular sac; its walls increase in thickness until the lumen is obliterated, except at its upper end, where it persists as the infundibular recess of the third ventricle. The neurohypophysis becomes invested by the adenohypophysis, which extends dorsally on either side. The adenohypophysis gives off two processes from its ventral wall that grow along the infundibulum and fuse to surround it, coming into relation with the tuber cinereum and forming the tuberal portion of the hypophysis. The original lumen of Rathke's pouch remains first as a cleft, and later as scattered vesicles, and can be identified readily in sagittal sections through the mature gland. The dorsal wall of Rathke's pouch remains thin and fuses with the adjoining part of the neurohypophysis as the pars intermedia.

At birth, the hypophysis is about one-sixth of the weight of the adult gland; it increases in weight to become about one-half of the weight of the adult gland at 7 years, and attains adult weight at puberty. Throughout postnatal life, the gland appears larger in females, in both size and weight.

## NEUROGLIA

Glial cells that support neurones in the CNS and PNS are derived from three lineages: namely, neuroectoderm, neural crest and angioblastic mesenchyme. In the PNS, neural crest cells produce Schwann cells and
astrocyte-like support cells in the enteric nervous system. Angioblastic mesenchyme gives rise to a variety of blood cell types, including circulating monocytes that infiltrate the brain as microglial cells later in development (Ch. 3).

In the CNS, cells of the proliferating ventricular zone give rise to astrocytes and oligodendrocytes. After the proliferative phase, the cells remaining at the ventricular surface differentiate into ependymal cells, which are specialized in many regions of the ventricular system as circumventricular organs. Planar cell polarity ( $P C P$ ) genes are involved in the differentiation of ependymal cells into a ciliated epithelium (Tissir and Goffinet 2010). PCP signalling regulates the position of the ciliary basal bodies. Defects in basal body polarity lead to disorganized beating of cilia and impaired direction of flow of the cerebrospinal fluid (Wallingford 2010), and this may result in defects in neuronal migration as development proceeds (Sawamoto et al 2006).

The ventricular zone lining the early central canal of the spinal cord and the cavities of the brain gives rise to neurones and glial cells (see Figs 17.4-17.5). Radial glia are specialized glia with radial processes that extend both outwards to form the outer limiting membrane deep to the pia mater, and inwards to form the inner limiting membrane around the central cavity. These processes may provide contact guidance paths for cell migrations, both neuronic and glioblastic. A secondary radial glial scaffold is formed in the late developing cerebellum and dentate gyrus, and serves to translocate neurones, formed in secondary germinal centres, to their definitive adult locations. Radial glia eventually lose their connections with both inner and outer limiting membranes, except those persisting in the retina as Müller cells, in the cerebellum as Bergmann glia and in the hypothalamus as tanycytes. They can differentiate into neurones as well as astrocytes. They may partially clothe the somata of neighbouring developing neurones (between presumptive synaptic contacts), or similarly enwrap the intersynaptic surfaces of their neurites. Glial processes may expand around intraneural capillaries as perivascular end-feet. Other glioblasts retain an attachment (or form new expansions) to the pia mater, the innermost stratum of the meninges, as pial end-feet. Glioblasts also line the central canal and cavities of the brain as generalized or specialized ependymal cells, but lose their peripheral attachments. In some situations, e.g. the ventral (anterior) median fissure of the spinal cord, ependymal cells retain their attachments to both the inner and the outer limiting membranes. Glia function as perineuronal satellites, providing cellular channels that connect extracerebral and intraventricular cerebrospinal fluid, the cerebral vascular bed, the intercellular crevices of the neuropil, and the cytoplasm of all neural cell varieties.

Microglia appear in the CNS after it has been penetrated by blood vessels and invade it in large numbers from certain restricted regions; from here, they spread in what have picturesquely been called 'fountains of microglia', to extend deeply among the nervous elements (Ch. 3).

## MECHANISMS OF NEURAL DEVELOPMENT

For more than a century, the mechanisms that operate during the development of the nervous system have been studied experimentally; while much has been established, answers to many fundamental questions remain obscure. Significant advances in our understanding of the mechanisms that regulate the behaviour of early neural populations are based on work on amphibian, chicken, mouse and fish embryos, using a combination of genetic, embryological, biochemical and molecular techniques.

The CNS has a fundamental structure of layers and cells, which are all derived from a pluripotential neuroepithelium. Developing neurones produce axons that traverse great distances to reach their target organs. Within the CNS, they form myriad connections with other neurones in response to locally secreted cues.

## HISTOGENESIS OF THE NEURAL TUBE

The wall of the early neural tube consists of an internal ventricular zone (sometimes termed the germinal matrix) abutting the central lumen. It contains the apical, nucleated parts of the pseudostratified columnar neuroepithelial cells and rounded cells undergoing mitosis. The early ventricular zone also contains a population of radial glial cells, whose processes pass from the ventricular surface to the pial surface, thus forming the internal and external glia limitans (glial limiting membrane). As development proceeds, the early, pseudostratified epithelium proliferates and an outer layer, the marginal zone, devoid of nuclei but containing the external cytoplasmic processes of cells, is delineated. Subsequently, a middle, mantle layer (intermediate zone) forms as the

Mouse embryonic stem cells in three-dimensional culture, induced to form co-cultures of rostral hypothalamic neuroepithelium and oral ectoderm, spontaneously self-sort and form oral ectodermal epithelial pouches, of similar dimensions to Rathke's pouch and expressing the pituitary placode marker Lim3. Multiple pouches form under these experimental conditions, suggesting that the process of pouch formation per se (including morphogenesis and rough size determination) is driven locally by an intrinsic self-organizing mechanism, whereas the specific place and number of pituitary placodes are under the control of complex positional instructions from region-specific regulators (Sasai et al 2012).

Fig. 17.15 The cell cycle in the ventricular zone of the developing neural tube. The nuclei of the proliferating stem cells show interkinetic migration. (Reprinted with permission from Journal of Comparative Neurology 120: 37-42, S Fujita, 1963. Wiley-Liss.)
newly formed neurones migrate ventriculofugally from the ventricular zone (see Fig. 17.5).

Most CNS cells are produced in the proliferative zone adjacent to the future ventricular system; in some regions, this area is the only actively mitotic zone. According to the monophyletic theory of neurogenesis, it is assumed to produce all cell types. The early neural epithelium, including the deeply placed ventricular mitotic zone, consists of a homogeneous population of pluripotent cells whose varying appearances reflect different phases in a proliferative cycle. The ventricular zone is considered to be populated by a single basic type of progenitor cell and to exhibit three phases. The cells show an 'elevator movement' as they pass through a complete mitotic cycle, progressively approaching and then receding from the internal limiting membrane, which corresponds to the apical region of the radial glial cells (Fig. 17.15) DNA replication occurs while the cells are extended and their nuclei approach the pial surface; they then enter a premitotic resting period while the cells shorten and their nuclei pass back towards the ventricular surface. The cells now become rounded close to the internal limiting membrane and undergo mitosis. They then elongate and their nuclei move towards the outer edge during the postmitotic resting period, after which DNA synthesis commences once more and the cycle is repeated. The cells so formed may then either start another proliferative cycle or migrate outwards (i.e. radially) and differentiate into neurones as they approach and enter the adjacent stratum. This differentiation may be initiated as they pass outwards during the postmitotic resting period. The proliferative cycle continues with the production of clones of neurones and glioblasts. This sequence of events has been called interkinetic nuclear migration; it eventually declines. At the last division, two postmitotic daughter cells are produced and they differentiate at the ventricular surface into ependyma.

The progeny of some of these divisions move away from the ventricular zone to form an intermediate zone of neurones. The early spinal cord and much of the brainstem show only these three main layers, i.e. ventricular, intermediate and marginal zones. However, in the telencephalon, the region of cellular proliferation extends deeper than the ventricular zone where the escalator movement of interkinetic migration is seen, and a subventricular zone appears between the ventricular and intermediate layers (see Fig. 17.15). Here, cells continue to multiply to provide further generations of neurones and glia, which subsequently migrate into the intermediate and marginal zones. A population of cells resulting from the asymmetric division of stem cells at the ventricular zone move to the subventricular zone, where they divide symmetrically. These cells are termed intermediate neural progenitor cells or basal progenitors to emphasize the fact that they are no longer attached to the apical (ventricular) surface. They translocate their nucleus to an abventricular location for mitosis. The cells are Tbr-2-positive and appear to migrate tangentially rather than radially in the developing cortex (Miyata et al 2010, Sessa et al 2010, Fietz and Huttner 2011)

In certain regions of the nervous system (e.g. the cerebellar cortex), some mitotic subventricular stem cells migrate across the entire neural wall to form a subpial population and establish a new zone of cell division and differentiation. Many cells formed in this site remain subpial in position, but others migrate back towards the ventricle
through the developing nervous tissue, and finish their migrations in various definitive sites where they differentiate into neurones or macroglial cells. In the cerebral hemispheres, a zone termed the cortical plate is formed outside the intermediate zone by radially migrating cells from the ventricular zone. The most recently formed cells migrate to the outermost layers of the cortical plate, so that earlier-formed and migrating cells become subjacent to those migrating at a later time. The subplate zone is an additional transient stratum found deep to the early cortical plate in the forebrain.

## LINEAGE AND GROWTH IN THE NERVOUS SYSTEM

Neurones are derived from three embryonic sources: CNS neurones originate from the pluripotential neural plate and tube, whereas ganglionic neurones originate from the neural crest and ectodermal placodes. The neural plate also provides ependymal and macroglial cells. Peripheral Schwann cells and chromaffin cells arise from the neural crest. The origins and lineages of cells in the nervous system have been determined experimentally by the use of autoradiography, microinjection or retroviral labelling of progenitor cells, in cell culture.

During development, neurones are formed before glial cells. The timing of events differs in various parts of the CNS and between species. Most neurones are formed prenatally in mammals but some postnatal neurogenesis does occur, e.g. the small granular cells of the cerebellum, olfactory bulb and hippocampus, and neurones of the cerebral cortex. Gliogenesis continues after birth in periventricular and other sites. Different classes of neurones develop at specific times. Large neurones, such as principal projection neurones, tend to differentiate before small ones, such as local circuit neurones. However, their subsequent migration appears to be independent of the times of their initial formation. Neurones can migrate extensively through populations of maturing, relatively static cells, to reach their destination, e.g. cerebellar granule cells pass through a layer of Purkinje cells en route from the external pial layer to their final central position. Later, the final form of their projections, cell volume and, indeed, their continuing survival depend on the establishment of patterns of functional connection.

Initially immature neurones are rotund or fusiform. Their cytoplasm contains a prominent Golgi apparatus, many lysosomes, glycogen and numerous unattached ribosomes. As maturation proceeds, cells send out fine cytoplasmic processes that contain neurofilaments, microtubules and other structures, often including centrioles at their bases where microtubules form. Internally, endoplasmic reticulum cisternae appear and attached ribosomes and mitochondria proliferate, whereas the glycogen content progressively diminishes. One process becomes the axon and other processes establish a dendritic tree. Axonal growth, studied in tissue culture, may be as much as 1 mm per day.

Successful neuronal connectivity is the product of a series of tightly regulated, programmed events that include axon initiation, growth cone formation and navigation, formation and pruning of dendritic trees and synapses (Chiu et al 2013).

## Growth cones

During development, the growing axons of neuroblasts navigate with precision over considerable distances, often pursuing complex courses to reach their targets. Eventually, they make functional contact with their appropriate end organs (neuromuscular endings, secretomotor terminals, sensory corpuscles or synapses with other neurones). Ramón y Cajal (1890) was the first to describe the expanded growing tips of axons, naming them growth cones. These tips are constantly active, changing shape, and extending and withdrawing small protuberances, filopodia and lamellipodia that apparently 'explore' the local environment for a suitable surface over which to extend. This incessant palpatory activity depends on the organization and dynamics of actin filaments that fill the growth cone leading margin (peripheral ( $\mathrm{P}-$ ) domain) and is regulated by actin-binding proteins that control all aspects of filament assembly, turnover, interactions with other filaments and cytoplasmic components, and the production of mechanical forces. Adhesive ligands and extrinsic guidance cues bind growth cone receptors to their substratum and trigger signalling activities involving Rho GTPases, kinases, phosphatases, cyclic nucleotides, and $\mathrm{Ca}^{2+}$ fluxes. Adhesion to the substratum appears to be important for transient consolidation (stabilization) of the growth cone, elaboration of the axonal cytoskeleton in the direction of growth and transduction of mechanical forces into traction in order to pull the axon towards its next target (Gomez and Letourneau 2014). Following consolidation of the growth cone, the exploratory behaviour begins again, resembling the
behaviour at the leading edge of migratory cells such as fibroblasts and neutrophils.

Axon guidance involves the coordinate action of four types of cues: short-range, local cues and long-range, diffusible cues, each of which can be either positive (permissive or attractive) or negative (inhibitory or repellent); mechanisms may involve contact attraction or chemoattraction, contact repulsion or chemorepulsion. Changes in the local proteome enable growth cones to respond rapidly to these cues by elongating, turning or collapsing. Different axons may respond to the same cue differently, according to the distribution of receptors or components of the relevant signal transduction pathways on their surfaces. Axon extension occurs when growth cones encounter a permissive, physical substrate containing short-range cues such as appropriate extracellular matrix components, transmembrane phosphatases and cadherins; axonal repulsion requires negative cues that inhibit the progress of the growth cone. Long-range cues diffuse from distant targets down gradients of specific factors, inducing neurones to turn their axons either towards the source of an attractive signal or away from a repulsive signal. Topographic projections, such as the retinotectal pathway, are established as specific populations of growth cones follow spatial gradients of guidance cues (see Kalil et al (2011)).

Several families of signalling molecules are known to be instructive guidance cues. The original canonical group of netrins, semaphorins, slits and ephrins has now been amplified by members of three families of developmental morphogens (bone morphogenetic protein (BMP), Hedgehog and Wnt families) and a number of growth factors (hepatocyte growth factor (HGF), fibroblast growth factors (FGFs) and glial cell-derived neurotrophic factor (GDNF)) for subsets of motor axons, neurotrophins (brain-derived neurotrophic factor (BDNF) and neurotrophin 3 (NT3)) for sensory axons, neuregulins for thalamocortical axons, and vascular endothelial growth factor A (VEGFA) for commissural axons (Kolodkin and Tessier-Lavigne 2013).

## Dendritic trees and synaptogenesis

Once growth cones have arrived in their appropriate target area, they form terminals and synapses. Extensive dendritic trees are generated and subsequently shaped by dendrite retraction and pruning. Signalling mechanisms underlying these processes are poorly understood: centrosomal CaMKIIß signalling has been proposed as a mechanism restricting dendrite elaboration while promoting dendrite pruning (Puram et al 2011). The final shape of dendritic trees is influenced by patterns of afferent connections and their activity, and is necessary for the accurate formation of neuronal circuitry. Defects in dendrite patterning have been implicated in the pathology of mental retardation and autism spectrum disorders.

Activity-dependent stabilization, coupled with the selective elimination of surplus synapses, is a key mechanism for generating diversity in neuronal connectivity. Dendritic spine density in childhood exceeds adult values by two- to three-fold and begins to decrease during puberty. However, the overproduction and later pruning of supernumerary synapses continues well into the third decade of life before stabilizing (Petanjek et al 2011, Kolb et al 2013). Once established, dendritic trees appear remarkably stable; partial deafferentation usually affects only dendritic spines.

## Neurotrophins

If neurones lose all afferent connections or are totally deprived of sensory input, much of the dendritic tree, and even the whole soma, will atrophy. Different regions of the nervous system vary quantitatively in their response to such anterograde transneuronal degeneration. Similar effects occur in retrograde transneuronal degeneration. Thus, neurones are dependent on peripheral structures for their survival. Loss of muscles or sensory nerve endings, e.g. in the developing limb, will result in reduction in numbers of motor and sensory neurones. Specific factors that these target organs produce, such as the neurotrophins, are taken into nerve endings and transported back to the neuronal somata; they are necessary for the survival of many types of neurone during early development, and for the growth of their axons and dendrites, and also promote the synthesis of neurotransmitters and enzymes.

Neurotrophins belong to several families of structurally and functionally related molecules, including nerve growth factor (NGF) superfamily and GDNF family (Cirulli and Alleva 2009, Park and Poo 2013, West et al 2014). The NGF superfamily includes BDNF, NT-3 and NT-4/5, which exert their survival effects selectively on particular subsets of neurones. NGF is specific to sensory ganglion cells from the neural crest, sympathetic postganglionic neurones and basal forebrain cholin-
ergic neurones. BDNF promotes the survival of retinal ganglion cells, motor neurones, and some placode-derived neurones, such as those of the nodose ganglion, that are unresponsive to NGF. NT-3 has effects on motor neurones, limb proprioceptive neurones and both placode- and neural crest-derived sensory neurones. Other growth factors found to influence the growth and survival of neural cells include the FGFs and ciliary neurotrophic factor (CNTF), all of which are unrelated in sequence to the NGF family. Members of the FGF family support the survival of embryonic neurones from many regions of the CNS. CNTF may control the proliferation and differentiation of sympathetic ganglion cells and astrocytes.

Each of the neurotrophins binds specifically to certain receptors on the cell surface. The receptor termed $\mathrm{p} 75^{\text {NTR }}$ binds all the neurotrophins with similar affinity. By contrast, members of the family of receptor tyrosine kinases (Trks) bind with higher affinity and display binding preferences for particular neurotrophins. However, the presence of a Trk receptor seems to be required for $\mathrm{p} 75^{\mathrm{NTR}}$ function.

Nervous tissue influences the metabolism of its target tissues. If, during development, a nerve fails to connect with its muscle, both degenerate. If the innervation of slow (red) or fast (white) skeletal muscle is exchanged, the muscles change structure and properties to reflect the new innervation, indicating that the nerve determines muscle type and not vice versa. Concomitant anterograde signalling by a neurone to its target tissues and retrograde signalling from target tissues to the same neurone implies instructive interactions; they occur during development, postnatally and in adult life (Harris 2008, da Silva and Wang 2011).

## INDUCTION AND PATTERNING OF THE BRAIN AND SPINAL CORD

The generation of neural tissue involves an inductive signal from the underlying chordamesoderm (notochord), termed the 'organizer'. The observation by Spemann and Mangold in 1924 that, in intact amphibian embryos, the presence of an organizer caused ectodermal cells to form nervous tissue, whereas in its absence they formed epidermis, led to the discovery of neural induction. However, experiments performed much later in the century revealed that, when ectodermal cells were dissociated, they also gave rise to neural tissue. The paradox was resolved by the finding that intact ectodermal tissue is prevented from becoming neural by an inhibitory signal(s) that is diluted out when cells are dissociated. Many lines of evidence now indicate that this inhibitory signal is mediated by members of a family of secreted proteins, the BMPs. These molecules are found throughout ectodermal tissue during early development, and their inhibitory effect is antagonized by several neural inducers that are present within the organizer, i.e. noggin, chordin and follistatin. Each of these factors is capable of blocking BMP signalling - in some cases, by preventing it from binding to its receptor(s).

The regional pattern of the nervous system is induced before and during neural tube closure. The patterning in the ventrodorsal domain is imposed on the neural plate/tube by external signals (notochord), whereas the longitudinal patterning is based on local expression domains. Early concepts about regional patterning envisaged that regionalization within mesenchymal populations that transmit inductive signals to the ectoderm impose a similar mosaic of positional values on the overlying neural plate. For example, transplantation of caudal mesenchyme beneath the neural plate in amphibia induced spinal cord, whereas rostral mesenchyme induced brain, as assessed by the morphology of the neuroepithelial vesicles. However, later work indicated a more complex scenario, in which organizer grafts from early embryos induced mainly head structures, while later grafts induced mainly trunk structures. Subsequent molecular data have tended to support a model in which neural-inducing factors released by the organizer, such as noggin, chordin and follistatin, neuralize the ectoderm and promote a mainly rostral neural identity. Later, secreted signals then act to caudalize this rostral neural tissue, setting up an entire array of axial values along the neural tube. Candidates for these later, caudalizing, signals have been shown to be retinoic acid, FGFs and the $W N T$ secreted proteins, which are present in the paraxial mesenchyme and, later, in its derivatives, the somites. This combination of signals does not seem to be sufficient to produce the most rostral, forebrain structures. Other secreted proteins resident in the rostralmost part of the earliest ingressing axial populations of endoderm and mesenchyme are also capable of inducing markers of forebrain identity from ectodermal cells (Withington et al 2001).

As the neural tube grows and is modified in shape, a number of mechanisms refine the crude rostrocaudal pattern that has been
imposed during neurulation. Molecules that diffuse from tissues adjacent to the neural tube, such as the somites, have patterning influences. The neural tube possesses a number of intrinsic signalling centres, such as the midbrain-hindbrain boundary, which produce diffusible molecules capable of influencing tissue development at a distance. In this way, extrinsic and intrinsic factors serve to subdivide the neural tube into a number of fairly large domains, on which local influences can then act. Domains are distinguished by their expression of particular transcription factors, which, in many cases, have been causally related to the development of particular regions. Examples of such genes are the Hox family, which are expressed in the spinal cord and hindbrain, and the Dlx, Emx and Otx families of genes, which are expressed in various regions of the forebrain. All of these are developmental control genes that lie high up in the hierarchy, and are capable of initiating cascades of expression of other genes to create a more fine-grained pattern of cellular differentiation. In contrast to the aforementioned secreted molecules, these genes encode proteins that are retained in the cell nucleus, and so can act on DNA to induce or repress further gene expression.

## Segmentation in the neural tube

The early neural tube is visibly divided into segments, termed neuromeres, by shallow transverse folds that extend perpendicular to its long axis. Primary neuromeres can be identified at stage 9 , and 16 secondary neuromeres are present at stage 14 . They are especially noted in the rhombencephalon, where they are termed rhombomeres, crucial units of pattern formation (Tümpel et al 2009). Domains of expression of developmental control genes abut rhombomere boundaries; single-cell labelling experiments have revealed that cells within rhombomeres form segregated non-mixing populations (Fig. 17.16). The neural crest also shows intrinsic segmentation in the rhombencephalon, and is segregated into streams at its point of origin in the dorsal neural tube. This may represent a mechanism whereby morphogenetic specification of the premigratory neural crest cells is conveyed to the pharyngeal arches (see Fig. 12.4). Although these segmental units lose their morphological prominence with subsequent development, they represent the fundamental ground plan of this part of the neuraxis, creating a series of semi-autonomous units, within which local variations in

Fig. 17.16 Hox gene expression domains in the branchiorhombomeric area in the mouse embryo at E9.5. The arrows indicate neural crest cells migrating from the rhombencephalon and midbrain. Cells migrating from the rhombencephalon are shaded to indicate the Hox genes they express. The same combination of Hox genes is expressed in the rhombomeres and in the superficial ectoderm of the pharyngeal arches at the corresponding rostrocaudal levels. The four Hox clusters are represented below. (Modified with permission from the Annual Review of Cell and Developmental Biology, Volume 8, 1992 by Annual Reviews www.annualreviews.org.)
patterning can then develop. The consequences of early segmentation for events later in development, such as the formation of definitive neuronal nuclei within the brainstem, and of peripheral axonal projections remain to be explored.

Other brain regions are not segmented in quite the same way as the hindbrain. However, morphological boundaries, domains of cell lineage restriction and of cell mixing, and regions of gene expression that abut sharp boundaries, are found in the diencephalon and telencephalon. It is thus likely that compartmentation of cell groups with some, if not all, the features of rhombomeres plays an important role in the formation of various brain regions.

The significance of intrinsic segmentation in the hindbrain is underlined by the absence of overt segmentation of the adjacent paraxial mesenchyme. There is no firm evidence for intrinsic segmentation in the spinal cord. Instead, segmentation of the neural crest, motor axons and thus, eventually, the spinal nerves is dependent on the segmentation of the neighbouring somites. Both neural crest cell migration and motor axon outgrowth occur through only the rostral and not the caudal sclerotome of each somite, so that dorsal root ganglia form only at intervals. The caudal sclerotome possesses inhibitory properties that deter neural crest cells and motor axons from entering. This illustrates the general principle that the nervous system is closely interlocked, in terms of morphogenesis, with the 'periphery', i.e. surrounding nonnervous structures, and each is dependent on the other for its effective structural and functional maturation.

Genes such as the Hox and Pax gene families, which encode transcription factor proteins, show intriguing expression patterns within the nervous system. Genes of the Hox-b cluster, for example, are expressed throughout the caudal neural tube, and up to discrete limits in the hindbrain that coincide with rhombomere boundaries. The ordering of these genes within a cluster on the chromosome ( $5^{\prime}-3^{\prime}$ ) is the same as the caudal to rostral limits of expression of consecutive genes. This characteristic pattern is surprisingly similar in fish, frogs, birds and mammals. Hox genes play a role in patterning not only of the neural tube but also of much of the head region, consistent with their expression in neural crest cells, and within the pharyngeal arches. Disruption of Hox a-3 gene in mice mimics DiGeorge's syndrome, a congenital human disorder characterized by the absence (or near-absence) of the thymus, parathyroid and thyroid glands, by the hypotrophy of the walls of the arteries derived from the aortic arches, and by subsequent conotruncal cardiac malformations. Some Pax genes are expressed in different dorsoventral domains within the neural tube. Pax-3 is expressed in the alar lamina, including the neural crest, while Pax-6 is expressed in the intermediate plate. The Pax-3 gene has the same chromosomal localization as the mouse mutation Splotch and the affected locus in the human Waardenburg's syndrome, both of which are characterized by neural crest disturbances with pigmentation disorders and occasional neural tube defects. Both Hox and Pax genes have restricted expression patterns with respect to the rostrocaudal and the dorsoventral axes of the neural tube, consistent with roles in positional specification. (For reviews of the expression patterns of these genes, see Krumlauf et al (1993).)

While craniocaudal positional values are probably conferred on the neuroepithelium at the neural plate or early neural tube stage, dorsoventral positional values may become fixed later. The development of the dorsoventral axis is heavily influenced by the presence of the underlying notochord. The notochord induces the ventral midline of the neural tube, the floor plate. This specialized region consists of a strip of non-neural cells with distinctive adhesive and functional properties. Notochord and floor plate together participate in inducing the differentiation of the motor columns. Motor neurone differentiation occurs early, giving some grounds for the idea of a ventral to dorsal wave of differentiation. The notochord/floor plate complex may also be responsible for allotting the values of more dorsal cell types within the tube (see Fig. 17.7). For example, the dorsal domain of expression of Pax-3 extends more ventrally in embryos experimentally deprived of notochord and floor plate, while grafting an extra notochord adjacent to the dorsal neural tube leads to a repression of Pax-3 expression.

## PERIPHERAL NERVOUS SYSTEM

## SOMATIC NERVES

## Spinal nerves

Each spinal nerve is connected to the spinal cord by a ventral root and a dorsal root (Fig. 17.17). The fibres of the ventral roots grow out from

Fig. 17.17 The developing spinal cord of human embryos. Transverse sections. A, Approximately 6 weeks. B, Approximately 3 months.

Fig. 17.18 The brain and cranial nerves of a human embryo, 10.2 mm long. Note the derivation of the ganglia associated with the trigeminal, facial, vestibulocochlear, glossopharyngeal, vagus and accessory nerves.
cell bodies in the anterior and lateral parts of the intermediate zone. These pass through the overlying marginal zone and external limiting membrane. Some enter the myotomes of the somites, and some penetrate the somites, reaching the adjacent somatopleure; in both sites, they ultimately form the $\alpha-\beta$ - and $\gamma$-efferents. At appropriate levels, these are accompanied by the outgrowing axons of preganglionic sympathetic neuroblasts (segments T1-L2) or preganglionic parasympathetic neuroblasts (S2-S4).

The fibres of the dorsal roots extend from cell somata in dorsal root ganglia into the spinal cord and also extend into the periphery. Neural crest cells are produced continuously along the length of the spinal cord, but gangliogenic cells migrate only into the rostral part of each somitic sclerotome, where they condense and proliferate to form a bilateral series of oval-shaped primordial spinal ganglia (dorsal root ganglia) (see Fig. 17.11). Negative factors in the caudal sclerotome deter neural crest from entering. The rostral sclerotome has a mitogenic effect on the crest cells that settle within it. From the ventral region of each ganglion, a small part separates to form sympathochromaffin cells, while the remainder becomes a definitive spinal ganglion (dorsal root ganglion). The spinal ganglia are arranged symmetrically at the sides of the neural tube and, except in the caudal region, are equal in number to the somites. The cells of the ganglia, like the cells of the intermediate zone of the early neural tube, are glial and neuronal precursors. The glial precursors develop into satellite cells (which become closely applied to the ganglionic nerve cell somata), Schwann cells and, possibly, other cells. The neuroblasts, at first round or oval, soon become
fusiform, and their extremities gradually elongate into central and peripheral processes. The central processes grow into the neural tube as the fibres of dorsal nerve roots, while the peripheral processes grow ventrolaterally to mingle with the fibres of the ventral root, thus forming a mixed spinal nerve. As development proceeds, the original bipolar form of the cells in the spinal ganglia changes; the two processes become closer and ultimately fuse to form a single stem, producing the characteristic morphology of a unipolar neurone. The bipolar form is retained in the ganglion of the vestibulocochlear nerve. For details of the timing of spinal nerve maturation, see Ashwell and Waite (2012).

## Cranial nerves

Cranial nerves may contain motor, sensory or both types of fibres. With the exception of the olfactory and optic nerves, the cranial nerves develop in a manner similar, in some respects, to components of the spinal nerves. The somata of motor neuroblasts originate within the neuroepithelium, while those of sensory neuroblasts are derived from the neural crest, with the addition in the head of contributions from ectodermal placodes (Fig. 17.18; see Fig. 12.4).

The motor fibres of the cranial nerves that project to striated muscle are the axons of cells originating in the basal plate of the midbrain and hindbrain. The functional and morphological distinction between the neurones within these various nerves is based on the types of muscle innervated. In the trunk, the motor roots of the spinal nerves all emerge
from the spinal cord close to the ventral midline to supply the muscles derived from the somites.

In the head, the motor outflow is traditionally segregated into two pathways (see Figs 17.3B, 17.18). General somatic efferent neurones exit ventrally in a similar manner to those of the spinal cord. Thus the oculomotor, trochlear, abducens and hypoglossal nerves parallel the organization of the somatic motor neurones in the spinal cord. The second motor component, special branchial efferent, consists of the motor parts of the trigeminal, facial, glossopharyngeal and vagus nerves that supply the pharyngeal (branchial) arches, and the accessory nerve. These nerves all have nerve exit points more dorsally placed than the somatic motor system.

The cranial nerves also contain general visceral efferent (parasympathetic preganglionic) neurones that travel in the oculomotor, facial, glossopharyngeal and vagus nerves, and leave the hindbrain via the same exit points as the special branchial efferent fibres. All three categories of motor neurones probably originate from the same region of the basal plate, adjacent to the floor plate. The definitive arrangement of nuclei reflects the differential migration of neuronal somata. It is not known whether all these cell types share a common precursor within the rhombencephalon; however, in the spinal cord, somatic motor and preganglionic autonomic neurones are linearly related.

These motor neurone types have been designated according to the types of muscles or structures they innervate. General somatic efferent nerves supply striated muscle derived from the cranial (occipital) somites and prechordal mesenchyme. Myogenic cells from the ventrolateral edge of the epithelial plate of occipital somites give rise to the intrinsic muscles of the tongue, while the prechordal mesenchyme gives rise to the extrinsic ocular muscles. Special branchial efferent nerves supply the striated muscles developing within the pharyngeal (branchial) arches (see Fig. 12.4), which are derived from parachordal mesenchyme between the occipital somites and the prechordal mesenchyme. All the voluntary muscles of the head originate from axial (prechordal) or paraxial mesenchyme, which renders the distinction between somatic efferent supply and branchial efferent supply somewhat artificial. However, the obviously special nature of the arch musculature, its patterning by the neural crest cells, its particularly rich innervation for both voluntary and reflex activity, and the different origins from the basal plate of the branchial efferent nerves compared to the somatic efferent nerves make the retention of a distinction between the two of some value.

General visceral efferent (parasympathetic preganglionic) neurones innervate glands of the head, the thoracic and abdominal viscera, and sphincter pupillae and ciliaris.

The cranial sensory ganglia are derived in part from the neural crest, and in part from cells of the ectodermal placodes (see Figs 17.12, 17.18) Generally, neurones distal to the brain are derived from placodes while proximal ones are derived from the neural crest (see Fig. 17.18). Supporting cells of all sensory ganglia arise from the neural crest. The most rostral sensory ganglion, the trigeminal, contains both neural crest- and placode-derived neurones that mediate general somatic afferent functions. In the case of more caudal cranial nerves (the facial, glossopharyngeal and vagus), the same applies, but the two cell populations form separate ganglia in the case of each nerve. The proximal series of ganglia is neural crest-derived (forming the proximal ganglion of the facial nerve, the superior ganglion of the glossopharyngeal nerve and the jugular ganglion of the vagus) while the distal series is derived from placodal cells (forming the geniculate ganglion of the facial nerve, the petrosal ganglion of the glossopharyngeal nerve and the nodose ganglion of the vagus). These ganglia contain neurones that mediate special, general visceral and somatic afferent functions. The vestibular ganglion contains both crest and placodal cells, and the acoustic ganglion contains only placodal neurones; the axons from these cells are special somatic afferents and they all travel in the vestibulocochlear nerve.

The neurones and supporting cells of the cranial autonomic ganglia in the head and the trunk originate from neural crest cells. Caudal to the vagal ganglion, the occipital region of the neural crest is concerned with the 'ganglia' of the accessory and hypoglossal nerves. Rudimentary ganglion cells may occur along the hypoglossal nerve in the human embryo but they subsequently regress. Ganglion cells are found on the developing intraspinal root of the accessory nerve and are believed to persist in the adult. The central processes of the cells of these various ganglia, where they persist, enter the alar lamina of the hindbrain. Their peripheral processes join the efferent components of the nerve to be distributed to the various tissues innervated. Some incoming fibres from the facial, glossopharyngeal and vagus nerves collect to form an oval bundle, the tractus solitarius, on the lateral aspect of the myelencephalon. This bundle is the homologue of the oval bundle of the spinal cord, but in the hindbrain it becomes more deeply placed by the
overgrowth, folding and subsequent fusion of tissue derived from the rhombic lip on the external aspect of the bundle

For details of the development of sensory and cranial nerve nuclei, see Ashwell and Mai (2012).

## AUTONOMIC NERVOUS SYSTEM

Autonomic nerves, apart from the preganglionic motor axons arising from the CNS, are formed by the neural crest. For the purposes of the following description, the autonomic nervous system encompasses sympathetic and parasympathetic neurones and their accompanying glia in the peripheral ganglia, the neurones and glia of the enteric nervous system, and chromaffin cells in the suprarenal medulla.

In the trunk at neurulation, neural crest cells migrate from the neural epithelium to lie transitorily on the fused neural tube. Thereafter, crest cells migrate laterally and then ventrally to their respective destinations (see Fig. 17.11). Within the head, the neural crest cells migrate prior to neural fusion, producing a vast mesenchymal population as well as autonomic neurones.

The four major regions of neural crest cell distribution to the autonomic nervous system are cranial, vagal, trunk and lumbosacral. The cranial neural crest gives rise to the cranial parasympathetic ganglia, whereas the vagal neural crest gives rise to the thoracic parasympathetic ganglia. The trunk neural crest gives rise to the sympathetic ganglia, mainly the paravertebral ganglia, and suprarenomedullary cells. This category is often referred to as the sympathosuprarenal lineage.

Neurones of the enteric nervous system are described as arising from the vagal crest, i.e. neural crest derived from somite levels 1-7, and the sacral crest, caudal to the twenty-eighth somite. At all of these levels, the crest cells also differentiate into glial-like support cells alongside the neurones (Fig. 17.19).

Fig. 17.19 The derivatives of neural crest cells in the trunk. The fate of crest cells arising at particular somite levels is shown.

## Parasympathetic ganglia

Neural crest cells migrate from the region of the mesencephalon and rhombencephalon prior to neural tube closure. From rostral to caudal, three populations of neural crest have been noted: cranial neural crest, cardiac neural crest and vagal neural crest. The migration of the sacral neural crest and the formation of the caudal parasympathetic ganglia have attracted little research interest.

Neural crest cells from the caudal third of the mesencephalon and the rostral metencephalon migrate along or close to the ophthalmic branch of the trigeminal nerve and give rise to the ciliary ganglion. Cells migrating from the nucleus of the oculomotor nerve may also contribute to the ganglion; a few scattered cells are always demonstrable in postnatal life along the course of this nerve. Preotic myelencephalic neural crest cells give rise to the pterygopalatine ganglion, which may also receive contributions from the ganglia of the trigeminal and facial nerves. The otic and submandibular ganglia are also derived from myelencephalic neural crest and may receive contributions from the glossopharyngeal and facial cranial nerves, respectively (see Fig. 12.4).

Neural crest from the region located between the otic placode and the caudal limit of somite 3 has been termed cardiac neural crest. Cells derived from these levels migrate through pharyngeal arches 3,4 and 6, where they provide, inter alia, support for the embryonic aortic arch arteries, cells of the aorticopulmonary septum and truncus arteriosus. Some of these neural crest cells also differentiate into the neural anlage of the parasympathetic ganglia of the heart. Sensory innervation of the heart is from the inferior ganglion of the vagus, which is derived from the nodose placodes. Neural crest cells migrating from the level of somites $1-7$ are collectively termed vagal neural crest; they migrate to the gut along with sacral neural crest.

## Sympathetic ganglia

Neural crest cells migrate ventrally within the body segments, penetrate the underlying somites and continue to the region of the future paravertebral and prevertebral plexuses, where they form the sympathetic chain of ganglia and the major ganglia around the ventral visceral branches of the abdominal aorta (see Figs 17.11, 17.19). Neural crest cells are induced to differentiate into sympathetic neurones by the dorsal aorta through the actions of the signalling molecules Bmp-4 and Bmp-7. The sympathetic trunk can be seen in the lower cervical and thoracic regions by $4-5$ weeks, and the sympathetic outflow from the lumbosacral sympathetic trunk to the sciatic nerve between 18 and 21 weeks (Ashwell and Waite 2012).

There is cell-specific recognition of postganglionic neurones and the growth cones of sympathetic preganglionic neurones. They meet during their growth, and this may be important in guidance to their appropriate target. The position of postganglionic neurones, and the exit point from the spinal cord of preganglionic neurones, may influence the types of synaptic connections made, and the affinity for particular postganglionic neurones. When a postganglionic neuroblast is in place, it extends axons and dendrites, and synaptogenesis occurs. The earliest axonal outgrowths from the superior cervical ganglion occur at about stage 14; although the axon is the first cell process to appear, the position of the neurones does not apparently influence the appearance of the cell processes.

The local environment plays a major role in controlling the appropriate differentiation of the presumptive autonomic ganglion neurones. The identity of the factors responsible for subsequent adrenergic, cholinergic or peptidergic phenotype has yet to be elucidated; it has been proposed that fibronectin and basal lamina components initiate adrenergic phenotypic expression at the expense of melanocyte numbers. Cholinergic characteristics are acquired relatively early and the appropriate phenotypic expression may be promoted by cholinergic differentiation factor and ciliary neurotrophic factor.

Neuropeptides are expressed by autonomic neurones in vitro and may be stimulated by various target tissue factors in sympathetic and parasympathetic neurones. Some neuropeptides are expressed more intensely during early stages of ganglion formation.

## Enteric nervous system

The enteric nervous system is different from the other components of the autonomic nervous system because it can mediate reflex activity independently of control by the brain and spinal cord. The number of enteric neurones that develop is believed to be of the same magnitude as the number of neurones in the spinal cord, whereas the number of
preganglionic fibres that supply the intestine, and therefore modulate the enteric neurones, is much fewer.

The enteric nervous system is derived from the neural crest. The axial levels of crest origin are shown in Figure 17.19. Premigratory neural crest cells are not pre-patterned for specific axial levels; rather, they attain their axial value as they leave the neuraxis. Once within the gut wall, there is a regionally specific pattern of enteric ganglia formation, which may be controlled by the local splanchnopleuric mesenchyme. Cranial neural crest from somite levels 1-7 contributes to the enteric nervous system, forming both neuroblasts and glial support cells.

The most caudal derivatives of neural crest cells, from the lumbosacral region, somites 28 onwards, form components of the pelvic plexus after migrating through the somites towards the level of the colon, rectum and cloaca. Initially, the cells come to lie within the developing mesentery, then transiently between the layers of the differentiating muscularis externa, before finally forming a more substantial intramural plexus characteristic of the adult enteric nervous system. The gut has a partially established enteric nervous system with a full complement of enteric neurotransmitters by 24 weeks. Maturation continues into the postnatal period (Ashwell and Waite 2012).

Hirschsprung's disease appears to result from a failure of neural crest cells to colonize the gut wall appropriately. The rectum is always affected and the proximal extent of the condition is variable. The condition is characterized by a dilated segment of colon proximally (or small bowel in cases of total colonic Hirschsprung's disease) and lack of peristalsis in the segment distal to the dilation. The condition is also characterized by a transition zone with reduced innervation. It is important to be aware that the transition zone may follow an asymmetric course around the circumference of the bowel and a single biopsy may be unreliable. Neonates with Hirschsprung's disease show delay in the passage of meconium, constipation, vomiting and abdominal distension. In humans, Hirschsprung's disease is often seen associated with other defects of neural crest development, e.g. Waardenburg type II syndrome, which includes deafness and facial clefts with megacolon.

Of the neural crest cells that colonize the bowel, some in the foregut may acquire the ability to migrate outwards and colonize the developing pancreas.

## Chromaffin cells

Chromaffin cells are derived from the neural crest and found at numerous sites throughout the body. They are the classic chromaffin cells of the suprarenal medulla, bronchial neuroepithelial cells, dispersed epithelial endocrine cells of the gut (formerly known as argentaffin cells), carotid body cells, and the paraganglia (Ch. 16).

The sympathetic ganglia, suprarenal medulla and chromaffin cells are all derived from the cells of the sympathosuprarenal lineage. In the suprarenal medulla, these cells differentiate into a number of types consisting of small and intermediate-sized neuroblasts or sympathoblasts, and larger, initially rounded phaeochromocytoblasts.

Large cells with pale nuclei, thought to be the progenitors of chromaffin cells, can be detected from 9 weeks in human fetuses, and clusters of small neurones are evident from 14 weeks.

Intermediate-sized neuroblasts differentiate into the typical multipolar postganglionic sympathetic neurones (which secrete noradrenaline (norepinephrine) at their terminals) of classic autonomic neuroanatomy. The smaller neuroblasts have been equated with the small, intensely fluorescent (SIF) cells, types I and II, which store and secrete dopamine type I and are thought to function as true interneurones, synapsing with the principal postganglionic neurones. Type II cells probably operate as local neuroendocrine cells, secreting dopamine into the ganglionic microcirculation. Both types of SIF cells can modulate preganglionic/postganglionic synaptic transmission in the ganglionic neurones. The large cells differentiate into masses of columnar or polyhedral phaeochromocytes (classic chromaffin cells), which secrete either adrenaline (epinephrine) or noradrenaline (norepinephrine). These cell masses are termed paraganglia and may be situated near, on the surface of, or embedded in, the capsules of the ganglia of the sympathetic chain, or in some of the large autonomic plexuses. The largest members of the latter are the para-aortic bodies that lie along the sides of the abdominal aorta in relation to the inferior mesenteric artery. During childhood, the para-aortic bodies and the paraganglia of the sympathetic chain partly degenerate and can no longer be isolated by gross dissection, but even in the adult, chromaffin tissue can still be recognized microscopically in these various sites. Both phaeochromocytes and SIF cells belong to the amine precursor uptake and decarboxylation (APUD) series of cells and are paraneuronal in nature.

## CENTRAL NERVOUS SYSTEM

## SPINAL CORD

In the future spinal cord, the median roof plate (dorsal lamina) and floor plate (ventral lamina) of the neural tube do not participate in the cellular proliferation that occurs in the lateral walls and so remain thin. Their cells contribute largely to the formation of the ependyma.

The neuroblasts of the lateral walls of the tube are large and, at first, round or oval (apolar). Soon, they develop processes at opposite poles and become bipolar neurones. However, one process is withdrawn and the neuroblast becomes unipolar, although this is not invariably so in the case of the spinal cord. Further differentiation leads to the development of dendritic processes and the cells become typical multipolar neurones. In the developing cord, they occur in small clusters representing clones of neurones. The development of a longitudinal sulcus limitans on each side of the central canal of the cord divides the ventricular and intermediate zones in each lateral wall into a basal (ventrolateral) plate or lamina, and an alar (dorsolateral) plate or lamina (see Fig. 17.17). This separation indicates a fundamental functional difference. Neural precursors in the basal plate include the motor cells of the anterior (ventral) and lateral grey columns, while those of the alar plate exclusively form 'interneurones' (which possess both short and long axons), some of which receive the terminals of primary sensory neurones. Caudally, the central canal of the cord ends as a fusiform dilation, the terminal ventricle.

## Anterior (ventral) grey column

The cells of the ventricular zone are closely packed at this stage and arranged in radial columns (see Fig. 17.6). Their disposition may be determined in part by contact guidance along the earliest radial array of glial fibres that cross the full thickness of the early neuroepithelium. The cells of the intermediate zone are more loosely packed. They increase in number initially in the region of the basal plate. This enlargement outlines the anterior (ventral) column of the grey matter and causes a ventral projection on each side of the median plane; the floor plate remains at the bottom of the shallow groove so produced. As growth proceeds, these enlargements, which are further increased by the development of the anterior funiculi (tracts of axons passing to and from the brain), encroach on the groove until it becomes converted into the slit-like anterior median fissure of the adult spinal cord. The axons of some of the neuroblasts in the anterior grey column cross the marginal zone and emerge as bundles of ventral spinal nerve rootlets on the anterolateral aspect of the spinal cord. These constitute, eventually, both the $\alpha$-efferents that establish motor end-plates on extrafusal striated muscle fibres and the $\gamma$-efferents that innervate the contractile polar regions of the intrafusal muscle fibres of the muscle spindles.

## Lateral grey column

In the thoracic and upper lumbar regions, some intermediate zone neuroblasts in the dorsal part of the basal plate outline a lateral column Their axons join the emerging ventral nerve roots and pass as preganglionic fibres to the ganglia of the sympathetic trunk or related ganglia, the majority eventually myelinating to form white rami communicantes. The axons within the rami synapse on the autonomic ganglionic neurones, and axons of some of the latter pass as postganglionic fibres to innervate smooth muscle cells, adipose tissue or glandular cells. Other preganglionic sympathetic efferent axons pass to the cells of the suprarenal medulla. An autonomic lateral column is also laid down in the mid-sacral region. It gives origin to the preganglionic parasympathetic fibres that run in the pelvic splanchnic nerves.

The anterior region of each basal plate initially forms a continuous column of cells throughout the length of the developing cord. This soon develops into two columns (on each side): one is medially placed and concerned with innervation of axial musculature, and the other is laterally placed and innervates the limbs. At limb levels, the lateral column enlarges enormously, but regresses at other levels.

Axons arising from ventral horn neurones, i.e. $\alpha$-, $\beta$ - and $\gamma$-efferent fibres, are accompanied at thoracic, upper lumbar and midsacral levels by preganglionic autonomic efferents from neuroblasts of the developing lateral horn. Numerous interneurones develop in these sites (including Renshaw cells); it is uncertain how many of these differentiate directly from ventrolateral lamina (basal plate) neuroblasts and how
many migrate to their final positions from the dorsolateral lamina (alar plate).

In the human embryo, the definitive grouping of the ventral column cells, which characterizes the mature cord, occurs early; by the fourteenth week ( 80 mm ), all the major groups can be recognized. As the anterior and lateral grey columns assume their final form, the germinal cells in the ventral part of the ventricular zone gradually stop dividing. The layer becomes reduced in thickness until, ultimately, it forms the single-layered ependyma that lines the ventral part of the central canal of the spinal cord.

## Posterior (dorsal) grey column

The posterior (dorsal) column develops later; consequently, the ventricular zone is, for a time, much thicker in the dorsolateral lamina (alar plate) than it is in the ventrolateral lamina (basal plate) (see Figs 17.6, 17.17A).

While the columns of grey matter are being defined, the dorsal region of the central canal becomes narrow and slit-like, and its walls come into apposition and fuse with each other (see Fig. 17.17). In this way, the central canal becomes relatively reduced in size and somewhat triangular in outline.

At about the end of the fourth week, advancing axonal sprouts invade the marginal zone. The first to develop are those destined to become short intersegmental fibres from the neuroblasts in the intermediate zone, and fibres of dorsal roots of spinal nerves that pass into the spinal cord from neuroblasts of the early spinal ganglia. The earlier dorsal root fibres that invade the dorsal marginal zone arise from small dorsal root ganglionic neuroblasts. By the sixth week, they form a welldefined oval bundle near the peripheral part of the dorsolateral lamina (see Figs 17.6-17.7A). This bundle increases in size and, spreading towards the median plane, forms the primitive posterior funiculus of fine calibre. Later, fibres derived from new populations of large dorsal root ganglionic neuroblasts join the dorsal root; they are destined to become fibres of much larger calibre. As the posterior funiculi increase in thickness, their medial surfaces come into contact, separated only by the posterior medial septum, which is ependymal in origin and neuroglial in nature. It is thought that the displaced primitive posterior funiculus may form the basis of the dorsolateral tract or fasciculus (of Lissauer)

## Maturation of the spinal cord

Long intersegmental fibres begin to appear at about the third month and corticospinal fibres are seen at about the fifth month. All nerve fibres at first lack myelin sheaths. Myelination starts in different groups at different times, e.g. the ventral and dorsal nerve roots at about the fifth month, the corticospinal fibres after the ninth month. In peripheral nerves, the myelin is formed by Schwann cells (derived from neural crest cells), and in the CNS by oligodendrocytes (which develop from the ventricular zone of the neural tube). Myelination persists until overall growth of the CNS and PNS has ceased. In many sites, slow growth continues for long periods, even into the postpubertal years. The cervical and lumbar enlargements appear at the time of the development of their respective limb buds.

## Ascent of conus medullaris

In early embryonic life, the spinal cord occupies the entire length of the vertebral canal, and the spinal nerves pass at right angles to the cord. From the second trimester, the vertebral column grows more rapidly than the spinal cord; the relationship between the conus medullaris and the vertebral column therefore changes as the conus gradually ascends to lie at higher vertebral levels (Barson 1970). Most of this relative rostral migration occurs during the first half of intrauterine life. By the twenty-fifth week, the terminal ventricle of the spinal cord has altered in level from the second coccygeal vertebra to the third lumbar, a distance of nine segments. As the change in level begins rostrally, the caudal end of the terminal ventricle, which is adherent to the overlying ectoderm, remains in situ, and the walls of the intermediate part of the ventricle and its covering pia mater become drawn out to form a delicate filament, the filum terminale. The separated portion of the terminal ventricle persists for a time, but it usually disappears before birth. It does, however, occasionally give rise to congenital cysts in the neighbourhood of the coccyx. In the definitive state, the upper cervical spinal nerves retain their position roughly at right angles to the cord. Proceeding caudally, the nerve roots lengthen and become progressively more oblique. By full term ( 40 weeks), the conus medullaris lies between the first and third lumbar vertebrae.

Determining the prenatal position of the conus medullaris relative to specific vertebrae is a widely used method of identifying the termination of the spinal cord. Studies of formalin fixed foetuses, usually of preterm stillbirths that may be small for dates, have provided the main timescales; more recently, values have been derived from antenatal ultrasound and magnetic resonance imaging (MRI) examinations. The often wide discrepancies between published values attest to the fact that ageing preterm infants remains an inexact science. Measurements may be influenced by factors such as placental health, maternal diet, ethnic biometrical variation, fetal sex, and the interpretation and correlation of results obtained using differing methodologies (cadaveric dissection, ultrasound, MRI).

## BRAIN

A summary of the derivatives of the cerebral regions from caudal to rostral is given in Table 17.1.

## Rhombencephalon

By the time the midbrain flexure appears, the length of the rhombencephalon is greater than that of the combined extent of the mesencephalon and prosencephalon. Rostrally, it exhibits a constriction, the isthmus rhombencephali (see Fig. 17.3B), best viewed from the dorsal aspect. Ventrally, the hindbrain is separated from the dorsal wall of the primitive pharynx only by the notochord, the two dorsal aortae and a small amount of mesenchyme; on each side, it is closely related to the dorsal ends of the pharyngeal arches.

The pontine flexure appears to 'stretch' the thin, epithelial roof plate, which becomes widened. The greatest increase in width corresponds to the region of maximum convexity, so that the outline of the roof plate becomes rhomboidal. By the same change, the lateral walls become separated, particularly dorsally, and the cavity of the hindbrain, subsequently the fourth ventricle, becomes flattened and somewhat triangular in cross-section. The pontine flexure becomes increasingly acute until, at the end of the second month, the laminae of its cranial (metencephalic) and caudal (myelencephalic) slopes are opposed to each other (see Fig. 17.21); at the same time, the lateral angles of the cavity extend to form the lateral recesses of the fourth ventricle.

At about $41 / 2$ weeks of development, when the pontine flexure is first discernible, the association between the rhombomeres and the underlying motor nuclei of certain cranial nerves can be seen. The general pattern of distribution of motor nuclei is as follows: rhombomere 1 contains the trochlear nucleus, rhombomeres 2 and 3 contain the trigeminal nucleus, rhombomeres 4 and 5 contain the facial nucleus, rhombomere 5 contains the abducens nucleus, rhombomeres 6 and 7 contain the glossopharyngeal nucleus, and rhombomeres 7 and 8 contain the vagal, accessory and hypoglossal nuclei. Rhombomeric segmentation represents the ground plan of development in this region of the brainstem and is pivotal for the development of regional identity (see Fig. 12.4). However, with further morphogenesis, the obvious
constrictions of the rhombomere boundaries disappear, and the medulla once again assumes a smooth contour. The differentiation of the lateral walls of the hindbrain into basal (ventrolateral) and alar (dorsolateral) plates has a similar significance to the corresponding differentiation in the lateral wall of the spinal cord, and ventricular, intermediate and marginal zones are formed in the same way.

## Cells of the basal plate (ventrolateral lamina)

Cells of the basal plate form three elongated, discontinuous, columns that are positioned ventrally and dorsally with an intermediate column between (Fig. 17.20).

The most ventral column is continuous with the anterior grey column of the spinal cord and will supply muscles considered 'myotomic' in origin. It is represented in the caudal part of the hindbrain by the hypoglossal nucleus, and it reappears at a higher level as the nuclei of the abducens, trochlear and oculomotor nerves (somatic efferent nuclei). The intermediate column is represented in the upper part of the spinal cord and caudal brainstem (medulla oblongata and pons), and its neurones supply branchial (pharyngeal) and postbranchial musculature. It is discontinuous, forming the elongated nucleus ambiguus in the caudal brainstem, which gives fibres to the ninth, tenth and eleventh cranial nerves, and continues into the cervical spinal cord as the origin of the accessory nerve. At higher levels, parts of this column give origin to the motor nuclei of the facial and trigeminal nerves. The nucleus ambiguus and the facial and trigeminal motor nuclei are termed branchial (special visceral) efferent nuclei. Neurones in the most dorsal column of the basal plate (represented in the spinal cord by the lateral grey column) innervate viscera. The column is discontinuous; its large caudal part forms some of the dorsal nucleus of the vagus and its cranial part forms the salivatory nucleus. These nuclei are termed general visceral (general splanchnic) efferent nuclei, and their neurones give rise to preganglionic, parasympathetic nerve fibres.

It is important to note that the neurones of the basal plate and their three columnar derivatives are only motor in the sense that some of their number form either motor neurones or preganglionic parasympathetic neurones. The remainder, which greatly outnumber the former, differentiate into functionally related interneurones and, in some loci, into neuroendocrine cells.

## Cell columns of the alar plate (dorsolateral lamina)

Cell columns of the alar plate are discontinuous and give rise to general visceral (general splanchnic) afferent, special visceral (special splanchnic) afferent, general somatic afferent, and special somatic afferent nuclei (their relative positions, in simplified transverse section, are shown in Fig. 17.20). The general visceral afferent column is represented by a part of the dorsal nucleus of the vagus, the special visceral afferent column by the nucleus of the tractus solitarius, the general somatic afferent column by the afferent nuclei of the trigeminal nerve, and the special somatic afferent column by the nuclei of the vestibulocochlear nerve. (The relatively simple functional independence of these afferent columns implied by the foregoing classification is, in the main, an aid

Fig. 17.20 A transverse section through the developing hindbrain of a human embryo 10.5 mm long, showing the relative positions of the columns of grey matter from which the nuclei associated with the different varieties of nerve components are derived. Postganglionic neurones are associated with the general visceral efferent column, bipolar neurones are associated with the otocyst, and unipolar afferent neurones are associated with the other alar plate columns.
to elementary learning. The emergent neurobiological mechanisms are, in fact, much more complex and less well understood.) Although they tend to retain their primitive positions, some of these nuclei are later displaced by differential growth patterns, by the appearance and growth of neighbouring fibre tracts, and possibly by active migration.

It has been suggested that a neurone tends to remain as near as possible to its predominant source of stimulation, and that, to achieve this aim, it will migrate around intervening structures, towards the greatest density of stimuli. The curious paths of the axons arising from the facial nucleus and the nucleus ambiguus have been regarded as exemplars of this phenomenon of neurobiotaxis. In a 10 mm embryo, the facial nucleus lies in the floor of the fourth ventricle, occupying the position of the special visceral efferent column, and it is placed at a higher level than the abducens nucleus. As growth proceeds, the facial nucleus migrates at first caudally and dorsally, relative to the abducens nucleus, and then ventrally to reach its adult position. As it migrates, the axons to which its somata give rise elongate and their subsequent course is assumed to map out the pathway along which the facial nucleus has travelled. Similarly, the nucleus ambiguus initially arises immediately deep to the ventricular floor but, in the adult, it is more deeply placed and its efferent fibres pass first dorsally and medially before curving laterally to emerge at the surface of the medulla oblongata.

## Myelencephalon

The caudal slope of the embryonic hindbrain constitutes the myelencephalon, which develops into the medulla oblongata (see Figs 17.3, 17.18, 17.21). The nuclei of the ninth, tenth, eleventh and twelfth cranial nerves develop in the positions already indicated, and afferent fibres from the ganglia of the ninth and tenth nerves form an oval marginal bundle in the region overlying the alar (dorsolateral) lamina. Throughout the rhombencephalon, the dorsal edge of this lamina is attached to the thin, expanded roof plate and is termed the rhombic lip. (The inferior rhombic lip is confined to the myelencephalon, the superior rhombic lip to the metencephalon.) As the walls of the rhombencephalon spread outwards, the rhombic lip protrudes as a lateral edge that becomes folded over the adjoining area. The rhombic lip may later become adherent to this area, and its cells migrate actively into the marginal zone of the basal plate. In this way, the oval bundle that forms the tractus solitarius becomes buried. Alar plate cells that migrate from the rhombic lip are believed to give rise to the olivary and arcuate nuclei and to the scattered grey matter of the nuclei pontis. While this migration is in progress, the floor plate is invaded by fibres that cross the median plane (accompanied by neurones that cluster in and near this plane), and it becomes thickened to form the median raphe. Some of the migrating cells from the rhombic lip in this region do not reach the basal plate and form an oblique ridge, the corpus pontobulbare (nucleus of the circumolivary bundle), across the dorsolateral aspect of the inferior cerebellar peduncle.

The lower part (caudal half) of the myelencephalon takes no part in the formation of the fourth ventricle and, in its development, it closely resembles the spinal cord. The gracile and cuneate nuclei, and some reticular nuclei, are derived from the alar plate, and their efferent arcuate fibres and interspersed neurones play a large part in the formation of the median raphe.

At about the fourth month, the descending corticospinal fibres invade the ventral part of the medulla oblongata to initiate formation of the pyramids. Dorsally, the inferior cerebellar peduncle is formed contemporaneously, by ascending fibres from the spinal cord, and by olivocerebellar and parolivocerebellar fibres, external arcuate fibres, and two-way reticulocerebellar and vestibulocerebellar interconnections. (The reticular nuclei of the lower medulla probably have a dual origin from both basal and alar plates.) In the neonate, the brainstem is more oblique and has a distinct bend as it passes through the foramen magnum to become the spinal cord.

## Metencephalon

The rostral slope of the embryonic hindbrain is the metencephalon, from which both the cerebellum and the pons develop. Before formation of the pontine flexure, the dorsolateral laminae of the metencephalon are parallel with one another. After its formation, the roof plate of the hindbrain becomes rhomboidal and the dorsal laminae of the metencephalon lie obliquely. They are close at the cranial end of the fourth ventricle, but widely separated at the level of its lateral angles (see Figs 17.18, 17.21). Accentuation of the flexure approximates the cranial angle of the ventricle to the caudal, and the alar plates of the metencephalon now lie almost horizontally.

The basal plate of the metencephalon becomes the pons. Ventricular, intermediate and marginal zones are formed in the usual way, and the nuclei of the trigeminal, abducens and facial nerves develop in the
intermediate layer. It is possible that the grey matter of the reticular formation is derived from the basal plate and that of the nuclei pontis from the alar plate by the active migration of cells from the rhombic lip. However, at about the fourth month, the pons is invaded by corticopontine, corticonuclear and corticospinal fibres, becomes proportionately thicker, and takes on its adult appearance; it is relatively smaller in the full-term neonate.

The region of the isthmus rhombencephali undergoes a series of changes that are notoriously difficult to interpret, but which result in the incorporation of the greater part of the region into the caudal end of the midbrain. Only the roof plate, in which the superior medullary velum is formed, and the dorsal part of the alar plate, which becomes invaded by converging fibres of the superior cerebellar peduncles, remain as recognizable derivatives in the adult. Early in development, the decussation of the trochlear nerves is caudal to the isthmus, but as growth changes occur, it is displaced rostrally until it reaches its adult position.

## Fourth ventricle and choroid plexus

Caudal to the developing cerebellum, the roof of the fourth ventricle remains epithelial, and covers an approximately triangular zone from the lateral angles of the rhomboid fossa to the median obex (see Figs 17.18, 17.21). Nervous tissue fails to develop over this region and vascular pia mater is closely applied to the subjacent ependyma. At each lateral angle and in the midline caudally, the membranes break through, forming the lateral (Luschka) and median (Magendie) apertures of the roof of the fourth ventricle. These become the principal routes by which cerebrospinal fluid, produced in the ventricles, escapes into the subarachnoid space. The vascular pia mater (tela choroidea), in an inverted V formation cranial to the apertures, invaginates the ependyma to form vascular fringes, which become the vertical and horizontal parts of the choroid plexuses of the fourth ventricle.

## Cerebellum

The cerebellum develops from the rhombic lip (dorsal rhombomere 1 (r1)), the dorsal part of the alar plate of the metencephalon, which constitutes the rostral margin of the diamond-shaped fourth ventricle. This region is specified as the isthmus organizer (Yu et al 2013). Two rounded swellings develop, which, at first, project partly into the ventricle (Fig. 17.21), forming the rudimentary cerebellar hemispheres. The most rostral part of the roof of the metencephalon originally separates the two swellings, but it becomes invaded by cells derived from the alar plate, which form the rudiments of the vermis. At a later stage, extroversion of the cerebellum occurs, its intraventricular projection is reduced and the dorsal extraventricular prominence increases. The cerebellum now consists of a bilobar (dumbbell-shaped) swelling stretched across the rostral part of the fourth ventricle (see Fig. 17.21). It is continuous rostrally with the superior medullary velum, formed from the isthmus rhombencephali, and caudally with the epithelial roof of the myelencephalon. With growth, a number of transverse grooves appear on the dorsal aspects of the cerebellar rudiment: these are the precursors of the numerous fissures that characterize the surface of the mature cerebellum (Fig. 17.22).

The first fissure to appear on the cerebellar surface is the lateral part of the posterolateral fissure, which forms the border of a caudal region corresponding to the flocculi of the adult. The right and left parts of this fissure subsequently meet in the midline, where they form the boundary between the most caudal vermian lobule, the nodule, and the rest of the vermis. The flocculonodular lobe can now be recognized as the most caudal cerebellar subdivision at this stage and it serves as the attachment of the epithelial roof of the fourth ventricle. Because of the expansion of the other divisions of the cerebellum, the flocculonodular lobe comes to occupy an anteroinferior position in adults. At the end of the third month, a transverse sulcus appears on the rostral slope of the cerebellar rudiment and deepens to form the fissura prima. This cuts into the vermis and both hemispheres, and forms the border between the anterior and posterior lobes. Contemporaneously, two short transverse grooves appear in the caudal vermis. The first is the fissura secunda (postpyramidal fissure), which forms the rostral border of the uvula; the second, the pre-pyramidal fissure, demarcates the pyramid. The cerebellum now grows dorsally, rostrally, caudally and laterally, and the hemispheres expand much more than the inferior vermis, which therefore becomes buried at the bottom of a deep hollow, the vallecula. Numerous other transverse grooves develop, the most extensive being the horizontal fissure.

## Cellular development of the cerebellum

The cerebellum consists of a cortex, beneath which are buried a series of deep nuclei. The organization of the cerebellar cortex is similar to

Fig. 17.21 A, The developing brainstem of a human fetus at approximately 3 months, left dorsolateral aspect. B, The developing cerebellum in the fifth month, dorsal aspect.

Fig. 17.22 Median sagittal sections through the developing cerebellum, at four chronologically later stages.
that of the cerebral cortex, except that the latter has six layers while the former has only three. However, whereas, in the cerebral cortex, neuroblasts originate from the ventricular zone and migrate ventriculofugally towards the pial surface (in an 'inside-out' fashion), early in cerebellar development a layer of cells derived exclusively from the metencephalic rhombic lip initially migrates ventriculofugally to form a layer beneath the glia limitans over the surface of the developing cerebellum. These cells form the external germinative layer and, later in development, their progeny will migrate ventriculopetally (in an 'outside-in' manner),
into the cerebellum. Thus, the cerebellum has an intraventricular portion (cells proliferating from the ventricular zone) and an extraventricular portion (cells proliferating from the external germinative layer) during development. The extraventricular portion becomes larger at the expense of the intraventricular part, the so-called extroversion of the cerebellum. Before the end of the third month, the main mass of the cerebellum is extraventricular.

The developed cerebellar cortex contains three layers: namely, the molecular layer, the Purkinje layer and the granular layer. The early bilateral expansion of the ventricular surface reflects the production, by the metencephalic alar plate ventricular epithelium, of neuroblasts that will give rise to the radial glia, cerebellar nuclei and efferent neurones of the cerebellar cortex (the Purkinje cells) (Fig. 17.23). The radial glia play a role in guiding the Purkinje cells to the meningeal surface of the cerebellar anlage. During this early stage of cerebellar development, which is dominated by the production and migration of efferent cerebellar neurones, the surface of the cerebellar anlage remains smooth. The extroversion of the cerebellum begins later when cells of the external germinative layer, also termed the superficial matrix, begin proliferation and migration. These cells produce the granule cells, which migrate inwards along the radial glia, through the layers of Purkinje cells, settling deep to them in the granular layer. This stage coincides with the emergences of the transverse folial pattern. Proliferation and migration of granule cells lead to a great rostrocaudal expansion of the meningeal surface of the cerebellum, forming the transverse fissures and transforming the multicellular layer of Purkinje cells into a monolayer. Purkinje cells and nuclear cells are formed prior to the granule cells, and granule cells serve as the recipient of the main afferent (mossy fibre) system of the cerebellum. Thus, the development of the efferent neurones of the cerebellar cortex and nuclei precedes the development of its afferent organization.

The early bilateral cerebellar anlage is changed into a unitary structure by fusion of the bilateral intraventricular bulges and the disappearance of the ependyma at this site, the merging of the left and right primitive cerebellar cortex over the midline, and the development of the cerebellar commissure by ingrowth of afferent fibres and outgrowth of efferent axons of the medial cerebellar nucleus.

When the external germinative layer is initially formed, the multicellular Purkinje cell layer beneath is not uniform, but subdivided into clusters that form rostrocaudally extending columns (Fig. 17.24). The medial Purkinje cell clusters develop into the future vermis. These Purkinje cells will grow axons that connect to neurones in the vestibular nuclei and the fastigial nucleus. The lateral clusters belong to the future hemispheres and will grow axons terminating in the interposed and dentate nuclei. The sharp border in the efferent projections from the vermis and hemispheres is thus established at an early age. These clusters will give rise to Purkinje cell zones in the adult cerebellum, which project to a single vestibular or cerebellar nucleus.

In the developing human brain, only the external germinative layer can be seen at 17-18 weeks; the Purkinje cells become apparent between 20 and 23 weeks. After 30 weeks, four layers can be recognized: the external germinative layer (external granular layer), formed by 6-8 rows of densely packed small round cells; the Purkinje cell layer, formed by 5-6 layers of larger, round, immature neurones external to the internal granular layer; and the molecular layer, containing cells that resemble external granular layer cells in migration (Lavezzi et al 2006). The external granular layer involutes between 5 and 7 months after birth; it is only a discontinuous layer at 10 months, and is totally absent by 12 months, after which time the cerebellar cortex shows a three-layered structure. From 5 to 7 months, the Purkinje cells are reduced in number and more widely spaced, displaying mature polygonal somata with evident axons and dendrites.

Relatively little is known about the molecular mechanisms involved in cerebellar development in the human (but see Manto and Jissendi (2012), Yu et al (2013), Martinez et al (2013)). Very small preterm infants are at particular risk of later cerebellar dysfunction with consequences for cognition and behaviour. Cerebellar maturation occurs postnatally and so there is interest in therapeutic agents that may improve long-term outcomes for such infants (Manto and Jissendi 2012).

## Mesencephalon

The mesencephalon or midbrain is subdivided early in development into two neuromeres, mesencephalon 1 and mesencephalon 2. It persists for a time as a thin-walled tube enclosing a cavity of some size, separated from that of the prosencephalon by a slight constriction and from the rhombencephalon by the isthmus rhombencephali (see

Fig. 17.24 A coronal section through the cerebellum and the brainstem of 65 mm human fetus. The Purkinje cells are located in five multicellular clusters (stars) on both sides of the midline. The anlage of the dentate nucleus occupies the centre of the most lateral Purkinje cell cluster. Abbreviations: B, brainstem; D, dentate nucleus; EGL, external granular layer; m, midline; 4, fourth ventricle. (Courtesy of the Schenk Collection, Dr Johan M Kros, Division of Neuropathology, Department of Pathology, Erasmus Medical Centre, Rotterdam, The Netherlands.)

Fig. 17.3; Fig. 17.25). Later, its cavity becomes relatively reduced in diameter and, in the adult brain, it forms the cerebral aqueduct. The basal (ventrolateral) plate of the midbrain increases in thickness to form the cerebral peduncles, which are at first of small size but enlarge rapidly after the fourth month, when their numerous fibre tracts begin to appear in the marginal zone. The neuroblasts of the basal plate of mesencephalon 2 give rise to the nuclei of the oculomotor nerve and some grey masses of the tegmentum, while the nucleus of the trochlear nerve remains in the region of the isthmus rhombencephali. The cells
that give rise to the trigeminal mesencephalic nucleus arise either side of the dorsal midline, from the isthmus rhombencephali rostrally across the roof of the mesencephalon. The progenitors of these cells do not express neural crest cell markers.

The cells of the dorsal part of the alar (dorsolateral) plates proliferate and invade the roof plate, which therefore thickens and is later divided into corpora bigemina by a median groove. Caudally, this groove becomes a median ridge, which persists in the adult as the frenulum veli. The corpora bigemina are later subdivided into the superior and inferior colliculi by a transverse furrow. The red nucleus, substantia nigra and reticular nuclei of the midbrain tegmentum may first be defined at the end of the third month. Their origins are probably mixed, from neuroblasts of both basal and alar plates.

The detailed histogenesis of the tectum and its main derivatives, the colliculi, will not be followed here but, in general, the principles outlined for the cerebellar cortex, the palaeopallium and neopallium also apply to this region. A high degree of geometric order exists in the developing retinotectal projection (the equivalent of the retinogeniculate projection) and in the tectospinal projection. (For further reading, see Cang and Feldheim (2013).)

## Prosencephalon

At an early stage, a transverse section through the forebrain shows the same parts as are displayed in similar sections of the spinal cord and medulla oblongata, i.e. thick lateral walls connected by thin floor and roof plates. Each lateral wall is divided into a dorsal area and a ventral area separated internally by the hypothalamic sulcus (see Fig. 17.25). This sulcus ends rostrally at the medial end of the optic stalk. In the fully developed brain, it persists as a slight groove extending from the interventricular foramen to the cerebral aqueduct. It is analogous to, if not the homologue of, the sulcus limitans. The thin roof plate remains epithelial but invaginated by vascular mesenchyme, the tela choroidea of the choroid plexuses of the third ventricle. Later, the lateral margins of the tela undergo a similar invagination into the medial walls of the cerebral hemispheres. The floor plate thickens as the nuclear masses of the hypothalamus and subthalamus develop.

Fig. 17.25 The shape of the developing ventricular system and the expansion of the medial portion of the telencephalon. The roof of the metencephalon and myelencephalon has been removed in each case. A, A human embryo, approximately 10.2 mm long, left lateral surface of the diencephalon and telencephalon removed. B, A human embryo 13.6 mm long, median section. C, A human fetus, approximately 3 months old, median section.

At a very early period, before the closure of the rostral neuropore, the subdivision of the prosencephalon into the most rostral telencephalon and two subdivisions of the diencephalon, D1 and D2, is heralded (see Fig. 17.2). At this early time, two eye fields are separated by the future neurohypophysis in the floor of the future D1. After head folding, the eye fields expand as two lateral optic evaginations, which become optic vesicles, one on each side of the early brain. For a time, they communicate with the cavity of the prosencephalon by relatively wide openings. The distal parts of the optic vesicles expand, while the proximal parts become the tubular optic stalks. The optic vesicles (which are described with the development of the eye in Ch. 40) are thus derived from the lateral walls of the D1 subdivision of the prosencephalon before the telencephalon can be clearly identified. The optic chiasma is often regarded as the boundary between diencephalon and telencephalon.

As the most rostral portion of the prosencephalon enlarges, it curves ventrally, and two further diverticula expand rapidly from it, one on each side. These diverticula, which are rostrolateral to the optic stalks,
subsequently form the cerebral hemispheres. Their cavities are the rudiments of the lateral ventricles and they communicate with the median part of the forebrain cavity by relatively wide openings, which ultimately become the interventricular foramina. The rostral limit of the median part of the forebrain consists of a thin sheet, the lamina terminalis (see Fig. 17.25), which stretches from the interventricular foramina to the recess at the base of the optic stalks. The rostral part of the forebrain, including the rudiments of the cerebral hemispheres, consists of the telencephalon and the caudal part of the diencephalon; both contribute to the formation of the third ventricle, although the latter predominates. The fate of the lamina terminalis is described below.

## Diencephalon

The diencephalon, D2, is broadly divided by the hypothalamic sulcus into dorsal (pars dorsalis diencephali) and ventral (pars ventralis diencephali) parts; each contributes to diverse neural structures. The dorsal part develops into the (dorsal) thalamus and metathalamus along the immediate suprasulcal area of its lateral wall, while the highest

Fig. 17.26 The development of the basal nuclei and internal capsule, coronal views. (Redrawn with permission from Hamilton WJ, Boyd JD, Mossman HW 1972 Human Embryology: Prenatal Development of Form and Function. Baltimore: Williams and Wilkins.)
dorsocaudal lateral wall and roof form the epithalamus. The thalamus (see Fig. 17.25) is first visible as a thickening that involves the rostral part of the dorsal area. Caudal to the thalamus, the lateral and medial geniculate bodies, or metathalamus, are recognizable at first as surface depressions on the internal aspect and as elevations on the external aspect of the lateral wall. As the thalami enlarge as smooth ovoid masses, the wide interval between them gradually narrows into a vertically compressed cavity that forms the greater part of the third ventricle. After a time, these medial surfaces may come into contact and become adherent over a variable area, the connection (single or multiple) constituting the interthalamic adhesion or massa intermedia. The caudal growth of the thalamus excludes the geniculate bodies from the lateral wall of the third ventricle.

At first, the lateral aspect of the developing thalamus is separated from the medial aspect of the cerebral hemisphere by a cleft but, with growth, the cleft becomes obliterated (Fig. 17.26) as the thalamus fuses with the part of the hemisphere in which the corpus striatum is developing. Later, with the development of the projection fibres (corticofugal and corticopetal) of the neocortex, the thalamus becomes related to the internal capsule, which intervenes between it and the lateral part of the corpus striatum (lentiform nucleus). Ventral to the hypothalamic sulcus, the lateral wall of the diencephalon, in addition to median derivatives of its floor plate, forms a large part of the hypothalamus and subthalamus.

The epithalamus, which includes the pineal gland, the posterior and habenular commissures and the trigonum habenulae, develops in association with the caudal part of the roof plate and the adjoining regions of the lateral walls of the diencephalon. At an early period (12-20 mm crown-rump length), the epithalamus in the lateral wall projects into the third ventricle as a smooth ellipsoid mass, larger than the adjacent mass of the (dorsal) thalamus and separated from it by a well-defined epithalamic sulcus. In subsequent months, growth of the thalamus rapidly overtakes that of the epithalamus and the intervening sulcus is obliterated. Thus, structures of epithalamic origin ultimately are relatively diminutive topographically.

The pineal gland arises as a hollow outgrowth from the roof plate, immediately adjoining the mesencephalon. Its distal part becomes solid by cellular proliferation but its proximal stalk remains hollow, containing the pineal recess of the third ventricle. In many reptiles, the pineal outgrowth consists of a rostral outgrowth (parapineal organ) that develops into the pineal or parietal eye, and a glandular caudal outgrowth; the caudal outgrowth is homologous with the pineal gland in humans. The rostral outgrowth also develops in the human embryo but soon disappears entirely.

The nucleus habenulae, which is the most important constituent of the trigonum habenulae, develops in the lateral wall of the diencephalon and is, at first, in close relationship with the geniculate bodies, from which it becomes separated by the dorsal growth of the thalamus. The habenular commissure develops in the cranial wall of the pineal recess. The posterior commissure is formed by fibres that invade the caudal wall of the pineal recess from both sides.

The ventral part of the diencephalon forms the subsulcal lateral walls of the third ventricle and takes part in the formation of the hypothalamus, including the mammillary bodies, the tuber cinereum and infundibulum of the hypophysis. The mammillary bodies arise as a single thickening that becomes divided by a median furrow during the

Fig. 17.27 A coronal section of the left cerebral hemisphere in a 73 mm fetus. (Redrawn with permission from Hamilton WJ, Boyd JD, Mossman HW 1972 Human Embryology: Prenatal Development of Form and Function. Baltimore: Williams and Wilkins.)
third month. The tuber cinereum develops rostral to the mammillary bodies as a cellular proliferation that extends forwards as far as the infundibulum. In front of the tuber cinereum, a wide-mouthed diverticulum forms in the floor of the diencephalon, grows towards the stomodeal roof, and comes into contact with the posterior aspect of a dorsally directed ingrowth from the stomodeum (Rathke's pouch). These two diverticula together form the hypophysis cerebri (see Fig. 17.14). An extension of the third ventricle persists in the base of the neural outgrowth as the infundibular recess. The remaining caudolateral walls and floor of the ventral diencephalon are an extension of the midbrain tegmentum, the subthalamus. This forms the rostral limits of the red nucleus, substantia nigra, numerous reticular nuclei and a wealth of interweaving, ascending, descending and oblique nerve fibre bundles, which have many origins and destinations.

## Third ventricle and choroid plexus

The roof plate of the diencephalon rostral to the pineal gland, and continuing over the median telencephalon, remains thin and epithelial in character and is invaginated by the choroid plexuses of the third ventricle (see Fig. 17.26; Fig. 17.27). Before the development of the corpus callosum and the fornix, it lies at the bottom of the longitudinal fissure, between and reaching the two cerebral hemispheres. It extends as far rostrally as the interventricular foramina and lamina terminalis.

Here, and elsewhere, choroid plexuses develop by the close apposition of vascular pia mater and ependyma without intervening nervous tissue. With development, the vascular layer is infolded into the ventricular cavity and develops a series of small villous projections, each covered by a cuboidal epithelium derived from the ependyma. The cuboidal cells display numerous microvilli on their ventricular surfaces and complex folding of their basal plasma membranes. The early choroid plexuses secrete a protein-rich cerebrospinal fluid into the ventricular system, which may provide a nutritive medium for the developing epithelial neural tissues. As the latter become increasingly vascularized, the histochemical reactions of the cuboidal cells and the character of the fluid change to the adult type. Many regions of the lining of the third ventricle become highly specialized, and develop concentrations of tanycytes or other modified cells that are collectively termed the circumventricular organs, e.g. the subfornical organ, the organum vasculosum (intercolumnar tubercle) of the lamina terminalis, the subcommissural organ, and the linings of the pineal, suprapineal and infundibular recesses.

## Telencephalon

The telencephalon consists of two lateral diverticula connected by a median region, the telencephalon impar. The rostral part of the third ventricle develops from the impar, and is closed below and in front by the lamina terminalis. The lateral diverticula are outpouchings of the lateral walls of the telencephalon, which may correspond to the alar lamina, although this is uncertain. Their cavities are the future lateral ventricles, and their walls are formed by the presumptive nervous tissue of the cerebral hemispheres. The roof plate of the median part of the telencephalon remains thin and is continuous behind with the roof plate of the diencephalon (see Figs 17.25-17.26). The rostral parts of the hypothalamus, which include the optic chiasma, optic recess and related nuclei, develop in the floor plate and lateral walls of the prosencephalon, ventral to the primitive interventricular foramina. The chiasma is formed by the meeting, and partial decussation, of the optic nerves in the ventral part of the lamina terminalis. The optic tracts subsequently grow backwards from the chiasma to end in the diencephalon and midbrain.

## Cerebral hemispheres

The cerebral hemispheres arise as diverticula of the lateral walls of the telencephalon, with which they remain in continuity around the margins of initially relatively large interventricular foramina, except caudally, where they are continuous with the rostral part of the lateral wall of the diencephalon (see Figs 17.3, 17.25). As growth proceeds, each hemisphere enlarges forwards, upwards and backwards and acquires an oval outline, medial and superolateral walls, and a floor. As a result, the medial surfaces approach, but are separated by, a vascularized mesenchyme and pia mater, which fills the median longitudinal fissure (see Fig. 17.27). At this stage, the floor of the fissure is the epithelial roof plate of the telencephalon, which is directly continuous caudally with the epithelial roof plate of the diencephalon.

At the early oval stage of hemispheric development, regions are named according to their future principal derivatives. The rostromedial and ventral floor becomes linked with the forming olfactory apparatus and is termed the primitive olfactory lobe. The floor (ventral wall, or base) of the remainder of each hemisphere forms the anlage of the primitive corpus striatum and amygdaloid complex, including its associated rim of lateral and medial walls (the striate part of the hemisphere). The rest of the hemisphere, i.e. the medial, lateral, dorsal and caudal regions, is the suprastriate part of the hemisphere. Although it is the largest in terms of surface area, initially it possesses comparatively thin walls. The rostral end of each oval hemisphere becomes the definitive frontal pole. As the hemisphere expands, its original posterior pole moves relatively in a caudoventral and lateral direction, following a curve like a ram's horn; it curves towards the orbit in association with the growth of the caudate nucleus and other structures to form the definitive temporal pole. A new posterior part persists as the definitive occipital pole of the mature brain (Figs 17.28-17.29).

The migration and differentiation of neural progenitors to form nuclei is either minimal or limited throughout the brainstem and spinal cord; the progeny of these progenitors remain immediately extraependymal or partially displaced towards the pial exterior, and are arrested deeply embedded in the myelinated fibre 'white matter' of the region. In marked contrast, proliferation and migration of neuroblasts in the cerebral hemispheres produce a superficial layer of grey matter in both the striate and the suprastriate regions, but not in the central areas of the original medial wall (where secondary fusion with the diencephalon occurs). The superficial layer of grey matter consists of neuronal somata, dendrites, the terminations of incoming (afferent)

Fig. 17.28 Lateral views of developing brains show the formation of the basal nuclei and lateral ventricles as the telencephalon develops.
(Redrawn with permission from Hamilton WJ, Boyd JD, Mossman HW 1972 Human Embryology: Prenatal Development of Form and Function. Baltimore: Williams and Wilkins.)
axons, the stems (or the whole) of efferent axons, and glial cells and endothelial cells. Successive generations of neuroblasts migrate through the layers of earlier generations to attain subpial positions (see below and Fig. 17.32), which means that the surface of the cerebral hemispheres expands at a rate greater than that of the hemispheres as a whole; the great expansion of the cerebral hemispheres is characteristic of mammals and especially of humans. Neuroblast differentiation produces a highly organized subpial surface coat of grey matter termed the cortex or pallium. The growing hemispheres subsequently overlap, successively, the diencephalon and the mesencephalon, and then meet the rostral surface of the cerebellum. The temporal lobes embrace the flanks of the brainstem.

The terminology used to describe regions of the cortex is based on evolutionary concepts. The oldest portions of cortex receive information concerned with olfaction; they are termed the archicortex (archipallium) and palaeocortex (palaeopallium), and both are subdivisions of an overall allocortex. The archicortex is the forerunner of the hippocampal lobe, and the palaeocortex gives rise to the piriform area. The remaining cortical surface expands greatly in mammals, forming the neocortex (young cortex), which displaces the earlier cortices so that they come to lie partially internally in each hemisphere. The six-layered mammalian neocortex is also described as isocortex.

## Olfactory bulb

A longitudinal groove appears in the anteromedial part of the floor of each developing lateral ventricle at about the fifth week of embryonic development. It deepens and forms a hollow diverticulum, which is continuous with the hemisphere by a short stalk. The diverticulum becomes connected on its ventral or inferior surface to the olfactory placode. Placodal cells give rise to afferent axons that terminate in the walls of the diverticulum. As the head increases in size, the diverticulum grows forwards, loses its cavity and becomes converted into the solid olfactory bulb. The forward growth of the bulb is accompanied by elongation of its stalk, which forms the olfactory tract. The part of the floor of the hemisphere to which the tract is attached constitutes the piriform area.

## Lateral ventricles and choroid plexus

The early diverticulum or anlage of the cerebral hemisphere initially contains a simple spheroidal lateral ventricle that is continuous with the third ventricle via the interventricular foramen. The rim of the foramen is the site of the original evagination. The expanding ventricle develops the ram's horn shape of the surrounding hemisphere, becoming first roughly ellipsoid and then a curved cylinder that is convex

Fig. 17.29 A-G, The superolateral surfaces of human fetal cerebral hemispheres at the ages indicated, showing the changes in size, profile and the emerging pattern of cerebral sulci with increasing maturation. Note the changing prominence and relative positions of the frontal, occipital and, particularly, the temporal pole of the hemisphere. At the earliest stage (A), the lateral cerebral fossa is already obvious; its floor covers the developing corpus striatum in the depths of the hemisphere and progressively matures into the cortex of the insula. The fossa is bounded by overgrowing cortical regions - the frontal, temporal and parietal opercula - which gradually converge to bury the insula; their approximation forms the lateral cerebral sulcus. By the sixth month, the central, pre- and postcentral, superior temporal, intraparietal and parieto-occipital sulci are all clearly visible. In the subsequent stages shown, all the remaining principal and subsidiary sulci rapidly appear, and by 40 weeks, all the features that characterize the adult hemisphere in terms of surface topography are present in miniature. (Photographs provided by Dr Sabina Strick, The Maudsley Hospital, London.)
dorsally (see Fig. 17.28). The ends of the cylinder expand towards, but do not reach, the frontal and (temporary) occipital poles; differentiating and thickening neural tissues separate the ventricular cavities and pial surfaces at all points, except along the line of the choroidal fissure. Pronounced changes in ventricular form accompany the emergence of a temporal pole. The original caudal end of the curved cylinder expands within its substance and the temporal extensions in each hemisphere pass ventrolaterally to encircle both sides of the upper brainstem (see Fig. 17.26). Another extension may develop from the root of the temporal extension in the substance of the definitive occipital pole and pass caudomedially; it is quite variable in size, often asymmetrical on the two sides, and one or both may be absent. Although the lateral ventricle is a continuous system of cavities, specific parts are now given regional names. The central part (body) extends from the interventricular foramen to the level of the posterior edge (splenium) of the corpus callosum. Three cornua (horns) diverge from the body: anterior towards the frontal pole, posterior towards the occipital pole, and inferior towards the temporal pole.

At these early stages of hemispheric development, the term pole is preferred, in most instances, to lobe. Lobes are defined by specific surface topographical features that will appear over several months, and differential growth patterns persist for a considerable period.

The pia mater, which covers the epithelial roof of the third ventricle at this stage, is itself covered with loosely arranged mesenchyme and developing blood vessels. These vessels subsequently invaginate the roof of the third ventricle on each side of the median plane to form its choroid plexuses (see Fig. 17.26). The lower part of the medial wall of the cerebral hemisphere, which immediately adjoins the epithelial roof of the interventricular foramen and the rostral extremity of the diencephalon, also remains epithelial. It consists of ependyma and pia mater; elsewhere, the walls of the hemispheres are thickening to form the pallium. The thin part of the medial wall of the hemisphere is invaginated by vascular tissue, which is continuous in front with the choroid plexus of the third ventricle and constitutes the choroid plexus of the lateral ventricle. This invagination occurs along a line that arches upwards and backwards, parallel with and initially limited to, the rostral and upper boundaries of the interventricular foramen. This curved indentation of the ventricular wall, where no nervous tissue
develops between ependyma and pia mater, is termed the choroidal fissure (see Figs 17.25C, 17.26). The subsequent assumption of the definitive form of the choroidal fissure depends on related growth patterns in neighbouring structures. Of particular importance are the relatively slow growth of the interventricular foramen, the secondary 'fusion' between the lateral diencephalon and medial hemisphere walls, the encompassing of the upper brainstem by the forward growth of the temporal lobe and its pole towards the apex of the orbit, and the massive expansion of two great cerebral commissures (the fornix and corpus callosum). The choroidal fissure is now clearly a caudal extension of the much-reduced interventricular foramen, which arches above the thalamus and is here only a few millimetres from the median plane. Near the caudal end of the thalamus, it diverges ventrolaterally, its curve reaching and continuing in the medial wall of the temporal lobe over much of its length (i.e. to the tip of the inferior horn of the lateral ventricle). The upper part of the arch will be overhung by the corpus callosum and, throughout its convexity, it is bordered by the fornix and its derivatives.

## Basal nuclei

At first, growth proceeds more actively in the floor and the adjoining part of the lateral wall of the developing hemisphere, and elevations formed by the rudimentary corpus striatum encroach on the cavity of the lateral ventricle (see Figs 17.25-17.30). The head of the caudate nucleus appears as three successive parts - medial, lateral and intermediate - which produce elevations in the floor of the lateral ventricle. Caudally, these merge to form the tail of the caudate nucleus and the amygdaloid complex, which both remain close to the temporal pole of the hemisphere. When the occipital pole grows backwards, and the general enlargement of the hemisphere carries the temporal pole downwards and forwards, the tail of the caudate is continued from the floor of the central part (body) of the ventricle into the roof of its temporal extension, the future inferior horn (see Fig. 17.28). The amygdaloid complex encapsulates its tip. Rostrally, the head of the caudate nucleus extends forwards to the floor of the interventricular foramen, where it is separated from the developing rostral end of the thalamus by a groove; later, the head expands in the floor of the anterior horn of the lateral ventricle. The lentiform nucleus develops from two laminae
of cells, medial and lateral, which are continuous with both the medial and lateral parts of the caudate nucleus. The internal capsule appears first in the medial lamina and extends laterally through the outer lamina to the cortex. It divides the laminae into two, the internal parts join the caudate nucleus and the external parts form the lentiform nucleus (see Figs 17.26-17.27). In the latter, the remaining medial lamina cells give rise mainly to the globus pallidus and the lateral lamina cells to the putamen. The putamen subsequently expands concurrently with the intermediate part of the caudate nucleus.

## Fusion of diencephalic and telencephalic walls

As the hemisphere enlarges, the caudal part of its medial surface overlaps and hides the lateral surface of the diencephalon (thalamic part), from which it is separated by a narrow cleft occupied by vascular connective tissue. At this stage (about the end of the second month), a transverse section made caudal to the interventricular foramen would pass from the third ventricular cavity successively through the developing thalamus, the narrow cleft just mentioned, the thin medial wall of the hemisphere, and the cavity of the lateral ventricle, with the corpus striatum in its floor and lateral wall (see Fig. 17.26).

As the thalamus increases in extent, it acquires a superior surface in addition to medial and lateral surfaces. The lateral part of its superior surface fuses with the thin medial wall of the hemisphere so that this part of the thalamus is finally covered with the ependyma of the lateral ventricle immediately ventral to the choroidal fissure. As a result, the corpus striatum is approximated to the thalamus and is separated from it only by a deep groove, which becomes obliterated by increased growth along the line of contact. The lateral aspect of the thalamus is now in continuity with the medial aspect of the corpus striatum so that a secondary union between the diencephalon and the telencephalon is affected over a wide area, providing a route for the subsequent passage of projection fibres to and from the cortex (see Fig. 17.26).

## Formation of the insula

At the end of the third month, while the corpus striatum is developing, there is a relative restriction of growth between the frontal and temporal lobes. The region lateral to the striatum becomes depressed to form a lateral cerebral fossa with a portion of cortex, the insula, at its base (see Figs 17.28-17.29). As the temporal lobe continues to protrude towards the orbit, and with more rapid growth of the temporal and frontal cortices, the surface of the hemisphere expands at a rate greater than the hemisphere as a whole, and the cortical areas become folded, forming gyri and sulci. The insula is gradually overgrown by these adjacent cortical regions and they overlap it, forming the opercula, the free margins of which form the anterior part of the lateral fissure. This process is not completed until after birth. The lentiform nucleus remains deep to and coextensive with the insula.

## Olfactory nerve, limbic lobe and hippocampus

The growth changes in the temporal lobe that help to submerge the insula produce important changes in the olfactory and neighbouring limbic areas. As it approaches the hemispheric floor, the olfactory tract diverges into lateral, medial and (variable) intermediate striae. The medial stria is clothed with a thin archaeocortical medial olfactory gyrus. This curves up into further archaeocortical areas rostral to the lamina terminalis (paraterminal gyrus, prehippocampal rudiment, parolfactory gyrus, septal nuclei) and these continue into the indusium griseum. The lateral stria, clothed by the lateral olfactory gyrus, and the intermediate stria (when present) terminate in the rostral parts of the piriform area, including the olfactory trigone and tubercle, anterior perforated substance, uncus and entorhinal area of the anterior part of the future parahippocampal gyrus. The lateral limit of the lateral stria is indicated by the rhinal sulcus. The forward growth of the temporal pole and the general expansion of the neocortex cause the lateral olfactory gyrus to bend laterally, the summit of the convexity lying at the anteroinferior corner of the developing insula. During the fourth and fifth months, much of the piriform area becomes submerged by the adjoining neocortex and, in the adult, only a part of it remains visible on the inferior aspect of the cerebrum.

The limbic lobe is the first part of the cortex to differentiate and, at first, it forms a continuous, almost circular, strip on the medial and inferior aspects of the hemisphere. Below and in front, where the stalk of the olfactory tract is attached, it constitutes a part of the piriform area. The portion outside the curve of the choroidal fissure (see Fig. 17.26; Fig. 17.30) constitutes the hippocampal formation. In this region, the neural progenitors of the developing cortex proliferate and migrate. The wall of the hemisphere thickens, producing an elevation that projects into the medial side of the ventricle. The elevation is the hippocampus; it appears first on the medial wall of the hemisphere, in

Fig. 17.30 The anterior and posterior commissures in the brain of a 16 -week human fetus; medial aspect of the left half of the brain.
the area above and in front of the lamina terminalis (paraterminal area), and gradually extends backwards, curving into the region of the temporal pole, where it adjoins the piriform area. The marginal zone in the neighbourhood of the hippocampus is invaded by neurones to form the dentate gyrus. Both extend from the paraterminal area backwards above the choroidal fissure and follow its curve downwards and forwards towards the temporal pole, where they continue into the piriform area. A shallow groove, the hippocampal sulcus, crosses the medial surface of the hemisphere throughout the hippocampal formation. The efferent fibres from the cells of the hippocampus collect along its medial edge and run forwards immediately above the choroidal fissure. Rostrally, they turn ventrally and enter the lateral part of the lamina terminalis to gain the hypothalamus, where they end in and around the mammillary body and neighbouring nuclei. These efferent hippocampal fibres form the fimbria hippocampi and the fornix.

## Projection fibres, internal capsule

The growth of the neocortex, and its enormous expansion during the latter part of the third month, are associated with the initial appearance of corticofugal and corticopetal projection fibres and the internal capsule. The fibres follow the route provided by the apposition of the lateral aspect of the thalamus with the medial aspect of the corpus striatum. They divide the latter, almost completely, into a lateral part, the lentiform nucleus, and a medial part, the caudate nucleus; these two nuclei remain confluent only in their anteroinferior regions (see Figs 17.26-17.27). The corticospinal tracts begin to develop in the ninth week of fetal life, they reach the caudal medulla oblongata at 15 weeks, complete the pyramidal decussation by 17 weeks, extend to the cervical and thoracic segments of the spinal cord by 19 weeks, and reach their caudal, lumbosacral, limits by 29 weeks. The fibres destined for the cervical and upper thoracic regions, which innervate the upper limbs, are in advance of those that innervate the lower limbs, and these, in turn, are in advance of fibres that innervate the face; the timing of the appearance of reflexes associated with these three parts of the body is similarly staggered. The proportions of crossed and uncrossed fibres in each corticospinal tract vary; a dominant uncrossed corticospinal tract and a complete absence of pyramidal decussation have been found in posterior fossa malformations such as occipital encephalocele, DandyWalker malformation and Joubert's syndrome. There is evidence of substantial plastic reorganization of the motor cortex and corticospinal projections following pre- or perinatal lesions to the corticospinal system (Eyre 2007). For further reading about the development of the human pyramidal tract, see ten Donkelaar et al (2004).

The majority of subcortical nuclear masses receive terminals from descending fibres of cortical origin. These are joined by thalamocortical, hypothalamocortical and other afferent ascending bundles. The internal capsular fibres pass lateral to the head and body of the caudate nucleus, the anterior cornu and central part of the lateral ventricle, the rostroventral extensions and body of the fornix, the dorsal thalamus and dorsal choroidal fissure, and medial to the lentiform nucleus (see Figs 17.26-17.27).

## Formation of gyri and sulci

Apart from the shallow hippocampal sulcus and the lateral cerebral fossa, the surfaces of the hemisphere remain smooth and uninterrupted
until early in the fourth month (see Fig. 17.29). The parieto-occipital sulcus appears at about that time on the medial aspect of the hemisphere. Its appearance seems associated with an increase in the number of splenial fibres in the corpus callosum. Over the same period, the posterior part of the calcarine sulcus appears as a shallow groove extending forwards from a region near the occipital pole. It is a true infolding of the cortex in the long axis of the striate area and produces an elevation, the calcar avis, on the medial wall of the posterior horn of the ventricle.

During the fifth month, the cingulate sulcus appears on the medial aspect of the hemisphere, and sulci appear on the inferior and superolateral aspects in the sixth month. The central, precentral and postcentral sulci appear, each in two parts, upper and lower, which usually coalesce shortly afterwards, although they may remain discontinuous. The superior and inferior frontal, the intraparietal, occipital, superior and inferior temporal, occipitotemporal, collateral and rhinal sulci all make their appearance during the same period. By the end of the eighth month, all the important sulci can be recognized (see Fig. 17.29).

## Development of commissures

The development of the commissures causes a very profound alteration of the medial wall of the hemisphere. At the time of their appearance, the two hemispheres are connected to each other by the median part of the telencephalon. The roof plate of this area remains epithelial, while its floor becomes invaded by the decussating fibres of the optic nerves and developing hypothalamic nuclei. These two routes are thus not available for the passage of commissural fibres passing from hemisphere to hemisphere across the median plane, and these fibres therefore pass through the rostral wall of the interventricular foramen, i.e. the lamina terminalis. The first commissures to develop are those associated with the palaeocortex and archicortex. Fibres of the olfactory tracts cross in the ventral or lower part of the lamina terminalis and, together with fibres from the piriform and pre-piriform areas and the amygdaloid bodies, form the rostral part of the anterior commissure (see Fig. 17.30; Fig. 17.31). In addition, the two hippocampi become interconnected by transverse fibres that cross from fornix to fornix in the upper part of the lamina terminalis as the commissure of the fornix (hippocampal commissure). Various other decussating fibre bundles (known as the supraoptic commissures, although they are not true commissures) develop in the lamina terminalis immediately dorsal to the optic chiasma, between it and the anterior commissure.

The commissures of the neocortex develop later and follow the pathways already established by the commissures of the limbic system. Fibres from the tentorial surface of the hemisphere join the anterior commissure and constitute its larger posterior part. All the other commissural fibres of the neocortex associate themselves closely with the commissure of the fornix and lie on its dorsal surface. These fibres increase enormously in number and the bundle rapidly outgrows its neighbours to form the corpus callosum (see Figs 17.30-17.31).

The corpus callosum originates as a thick mass connecting the two cerebral hemispheres around and above the anterior commissure. (This site has been called the precommissural area, but this use has been rejected here because of the increasing use of the adjective precommissural to denote the position of parts of the limbic lobe, i.e. prehippocampal rudiment, septal areas and nuclei and strands of the fornix, in relation to the anterior commissure of the mature brain.) The upper end of this neocortical commissural area extends backwards to form the trunk of the corpus callosum. The rostrum of the corpus callosum develops later and separates some of the rostral end of the limbic area from the remainder of the cerebral hemisphere. Further backward growth of the trunk of the corpus callosum then results in the entrapped part of the limbic area becoming stretched out to form the bilateral septum pellucidum. As the corpus callosum grows backwards, it extends above the choroidal fissure, carrying the commissure of the fornix on its undersurface. In this way, a new floor is formed for the longitudinal fissure, and additional structures come to lie above the epithelial roof of the third ventricle. In its backward growth, the corpus callosum invades the area hitherto occupied by the upper part of the archaeocortical hippocampal formation, and the corresponding parts of the dentate gyrus and hippocampus are reduced to vestiges, the indusium griseum and the longitudinal striae. However, the posteroinferior (temporal) archaeocortical regions of both dentate gyrus and hippocampus persist and enlarge.

## Cellular development of the cerebral cortex

Cortical neurones are not generated within the cortex itself but in proliferative transient embryonic zones such as the ventricular (VZ) and subventricular (SVZ) zones. Precise patterns of cell division and the subsequent migration of the progeny of these divisions along the shafts

B 16 weeks

Fig. 17.31 Median sections showing the formation of the commissures. The telencephalon gives rise to commissural tracts that integrate the activities of the left and right cerebral hemispheres. Tracts include the anterior and hippocampal commissures and the corpus callosum. The small posterior and habenular commissures arise from the epithalamus.
of a transient population of radial glial cells transform the neuroepithelium of the embryonic forebrain into the adult cerebral cortex (Noctor et al 2004). Neurones are derived from a lineage of radial glia stem cells and transit amplifying intermediate progenitor cells; expansion in one or both cell populations has been proposed as a potential mechanism for neocortical expansion (Kriegstein and Gotz 2003, Lui et al 2011). The earliest-generated cortical neurones accumulate in an outside-in sequence to form the preplate. Subsequent generations of neurones migrate into the preplate, forming a series of layers called the cortical plate, which splits the preplate into a superficial layer at the pial surface, the marginal zone, and a deeper layer, the subplate. Subplate neurones integrate into the intra- and extracortical circuitry; they extend axons via the internal capsule towards the thalamus and superior colliculus at times before other cortical neurones have been born (Kanold and Luhmann 2010). In humans, the subplate is maximal at approximately 25 weeks' gestation and recedes by 6 months postnatally (Kostovic et al 2012). For a review of subplate development, modulation and demise, see Hoerder-Suabedissen and Molnar (2015). Subplate neurones are vulnerable to injury during prenatal stages; their premature loss has been implicated in the pathogenesis of chronic deficits such as cognitive delay, behavioural problems and epilepsy associated with preterm birth (Jantzie et al 2014).

Neurones migrate along radial glial processes (see Fig. 17.5). The migration of neuronal precursors from the ventricular and intermediate zones occurs radially towards the pial surface (Kriegstein and Noctor 2004). From the pial surface inwards, the following zones may be defined: marginal, cortical plate, subplate, intermediate, subventricular

Fig. 17.32 A, The layers of the developing telencephalon. The early pseudostratified arrangement of the neural tube is defined by radial glia extending from the ventricular surface to the pial surface. Neuroblasts and glioblasts divide in the ventricular and subventricular zones and migrate radially along the radial glia to form a cortical plate and then a subplate. The preplate, subplate, subventricular and ultimately the ventricular zones recede during development and early postnatal life. B, Successive migration of neuroblasts from the ventricular and subventricular zones to the cortex. The first cells to migrate to the cortical plate and subplate zone form the deep cortical laminae. Later cells migrate radially between these cells to the outer part of the developing cortex. Note the extensive early proliferation of the subventricular zone and its later diminution as the cells it contains migrate radially to the cortex. The effect of this radial cell migration towards the developing cortical surface is expansion of the cortical area rather than an increase in cortical thickness. Axons from cells in the cortex extend through the intermediate zone which becomes cerebral white matter. Once the earliest cortical layers have formed, cells originating from the ganglionic eminences migrate tangentially into the cortical layers and form interneurones.
and ventricular (Fig. 17.32). (For a review of the nomenclature of the developing zones, see Bystron et al (2008).) The marginal zone, the outermost layer of the developing cerebral cortex, will form layer 1, and the neurones of the cortical plate and subplate form the neurones of the remaining $(2-6)$ cortical laminae, the complexity varying in different locations and with further additions of neurones from the deeper zones. The intermediate zone gradually transforms into the white matter of the hemisphere. Meanwhile, other deep progenitor cells produce generations of glioblasts, which also migrate into the more superficial layers. As proliferation wanes and finally ceases in the ventricular and subventricular zones, their remaining cells differentiate into general or specialized ependymal cells, tanycytes or subependymal glial cells.

The time of the proliferation of different cortical neurones varies according to their laminar destination and cell type. The first groups of cells to migrate are destined for the deep cortical laminae and later groups pass through them to more superficial regions. The subplate zone is most prominent during mid-gestation; it contains neurones surrounded by a dense neuropil and is the site of the most intense synaptogenesis in the embryonic cortex. The cumulative effect of this radial and tangential growth is evident in a marked expansion of the surface area of the cortex without a comparable increase in its thickness (Rakic 1988, Rakic 2009).

In the pallial walls of the mammalian cerebral hemisphere, the phylogenetically oldest regions, which are the first to differentiate during ontogeny, are those that border the interventricular foramen and

Fig. 17.33 A, The ganglionic eminence of the subpallium is subdivided into three regions: lateral (LGE), medial (MGE) and caudal (CGE), according to the expression patterns of various transcription factors ( $D / x 2$, Mash1, Nksx2.1 and Lhx6) and of the cellular retinol-binding protein 1 (CRBP1). B, The main migratory paths of interneurones derived from the three subdivisions of the ganglionic eminence. MGE cells tend to migrate laterally and spread throughout the cortex, and CGE cells migrate predominantly towards the caudal telencephalon, whereas LGE cells migrate rostrally and contribute to interneurones in the olfactory bulb. It has been suggested that most MGE cells differentiate into parvalbumin (PV)- and somatostatin (SS)-immunoreactive interneurones, whereas most CGE cells differentiate into calretinin (CR)-immunoreactive interneurones. Figure based on Métin et al 2006.
its extension, the choroidal fissure, the lamina terminalis and the piriform lobe. The pallidum also contributes interneurones to the formation of the cerebral cortex. A large portion of GABAergic inhibitory (non-pyramidal) cells are not generated in the cortical ventricular zone, but migrate tangentially through the striatocortical junction to reach the cortex (Wonders and Anderson 2006, Métin et al 2006, Molnar and Butt 2013, Hansen et al 2013; Fig. 17.33).

The vast species differences between invertebrate, murine, nonhuman primate and primate nervous systems have long posed particular, sometimes intractable, problems for neuroscientists exploring the evolution of the human cerebral cortex. Current understanding of the pre- and postnatal events that regulate the numbers of neurones and their associated glia; the dynamics of neuronal migration to proper layers, columns and regions; the enormous expansion of the cortical surface; and the development of connectivity, particularly networks mediating higher cognitive functions and language, remains in its infancy for the human cortex. (For further reading on the evolution of the neocortex, see Rakic (2009), Lui et al (2011), Geschwind and Rakic (2013), Lister et al (2013).)

The Allen Human Brain Atlas (http://human.brain-map.org/) uses DNA microarrays for transcriptional profiling of several hundred locations spanning the adult human neocortex (Hawrylycz et al 2012), while the NIH Blueprint Non-Human Primate Atlas profiles individual cortical layers in therhesus monkey (http://www.blueprintnhpatlas.org/). Similarly, the BrainSpan Atlas of the Developing Human Brain (http:// www.brainspan.org/) is a resource for studying the transcriptome across human brain development, using RNA sequencing on discrete cortical regions across the entire lifespan, as well as with microarrays at higher resolution in the mid-gestational cortex on laser-microdissected individual layers of different regions of the developing neocortex.

Although the biological significance of the inside-out gradient of neurogenesis is yet to be established, it is known that, if that gradient is disturbed, by either genetic or epigenetic factors, neurones display abnormal cortical function. The consequences of failure or delay in neuronal migration cause a wide range of disorders, such as lissencephaly, schizophrenia, autism and mental retardation (Wu et al 2014).

## Neonatal brain and reflexes

The brain of the full-term neonate ranges from 300 to 400 g in weight, with an average of 350 g ; the brains of neonatal males are slightly heavier than those of females. Because the head is large at birth, measuring one-quarter of the total body length, the brain is also proportionally larger and constitutes $10 \%$ of the body weight, compared with $2 \%$ in the adult. At birth, the volume of the brain is $25 \%$ of its volume in adult life. The greater part of the increase occurs during the first year, at the end of which the volume of the brain has increased to $75 \%$ of its adult volume. The growth can be accounted for partly by increase in the size of nerve cell somata, the profusion and dimensions of their dendritic trees, axons and collaterals, and by the growth of the neuroglial cells and cerebral blood vessels, but mostly it reflects the myelination of many of the axons: the sensory pathways - visual, auditory and somatic - myelinate first, and the motor fibres later. During the second and subsequent years, growth proceeds much more slowly. The brain reaches $90 \%$ of its adult size by the fifth year and $95 \%$ by 10 years, attaining adult size by the seventeenth or eighteenth year, largely as a result of the continuing myelination of various groups of nerve fibres.

The sulci of the cerebral hemispheres appear from the fourth month of gestation (see Fig. 17.29). At full term, the general arrangement of sulci and gyri is present, but the insula is not completely covered, the central sulcus is situated further rostrally, and the lateral sulcus is more oblique than in the adult. Most of the developmental stages of sulci and gyri have been identified in the brains of premature infants. Of the cranial nerves, the olfactory nerve and the optic nerve at the chiasma are much larger than in the adult, whereas the roots of the other nerves are relatively smaller.

The brain occupies $97.5 \%$ of the cranial cavity from birth to 6 years of age, after which the space between the brain and skull increases in volume until the adult brain occupies only $92.5 \%$ of the cranial cavity. The cerebral ventricles are larger in the neonatal brain than they are in the adult. The newborn has a total of $10-15 \mathrm{ml}$ of cerebrospinal fluid when delivered vaginally and 30 ml when delivered by caesarean section. As the head moves down the birth canal and is compressed, the cerebrospinal fluid is pushed out into the venous sinuses; this does not happen in a caesarean delivery.

## Myelination

Axons from cortical neurones elongate during prenatal and postnatal life forming white matter tracts and fasciculi (Fig. 17.34). Oligodendrocyte progenitor cells are prevalent initially in the subventricular zone and later (19-22 weeks' gestation) in the subplate zone (Jakovcevski et al 2009). Studies suggest three successive stages of the human oligodendrocyte lineage (pre-oligodendrocyte, immature oligodendrocyte, and mature oligodendrocyte) in human cerebral white matter between midgestation and term birth (Back et al 2001). Ventrodorsal gradients of oligodendrocyte precursor cell density and of myelination are described in the telencephalon.

Myelination occurs over a protracted period that starts during the second trimester in the PNS. Motor roots start to myelinate before sensory roots in the PNS, whereas sensory nerves start to myelinate before motor nerves. The cranial nerves of the midbrain, pons and medulla oblongata begin to myelinate at about 6 months' gestation. For reviews of the molecular mechanisms currently known to regulate many of the stages involved in myelination in the CNS and PNS (including precursor specification, proliferation, migration, differentiation and myelination of appropriate axons), see Mitew et al (2013) and Pereira et al (2012), respectively.

The sequence of myelination of the motor pathways may explain, at least partially, the order of development of muscle tone and posture in the premature infant and neonate. Myelination of the corticospinal tracts starts some 10-14 days after birth in the internal capsule and cerebral peduncles, and then proceeds simultaneously in both tracts. Myelination of the various subcorticospinal pathways (vestibulospinal, reticulospinal, olivospinal and tectospinal) starts at 24-30 weeks' gestation for the medial tracts, and at 28-34 weeks' gestation for the lateral tracts. Evidence from diffusion tensor imaging (DTI) suggests that myelination is the dominant process during the first year of life, starting centrally and spreading peripherally, and spreading forwards from the occipital to the frontal lobe (Gao et al 2009). Myelin appears to start first around longer axons; thus, in the preterm infant, axial extension precedes flexion, whereas finger flexion precedes extension. By term, the neonate at rest has a strong flexor tone accompanied by adduction of all limbs. Neonates also display a distinct preference for a head position facing to the right, which appears to be independent of handling practices and may reflect the normal asymmetry of cerebral function at this

age. Comparison of postnatal rates of myelination in human and primate brains shows that humans achieve approximately $60 \%$ of adult myelination during adolescence (compared to $96 \%$ in chimpanzees). Myelin growth continues in humans to the end of the third decade. Miller et al (2012) suggest this schedule of neural connectivity in humans might contribute to the development of functional circuitry with greater plasticity and capacity to be shaped by postnatal environmental and social interactions. The greatest delay in myelination is seen in the prefrontal cortex, an area where many neural circuits concerned with learning and memory develop only after sexual maturity has been attained.

## Reflexes present at birth

A number of reflexes are present at birth and their demonstration is used to indicate normal development of the nervous system and responding muscles. Five tests of neurological development are most useful in determining gestational age. The pupillary reflex is consistently absent before 29 weeks' gestation and present after 31 weeks; the glabellar tap, a blink in response to a tap on the glabella, is absent before 32 weeks and present after 34 weeks; the neck-righting reflex appears between 34 and 37 weeks; the traction response, where flexion of the neck or arms occurs when the baby is pulled up by the wrists from the supine position, appears after 33 weeks; and head-turning in response to light appears between 32 and 36 weeks. The spinal reflex arc is fully developed by the eighth week of gestation and lower limb flexor tone is detectable from about 29 weeks. The Babinski response, which involves extension of the great toe with spreading of the remaining toes in response to stimulation of the lateral aspect of the sole of the foot, is elicited frequently in neonates; it reflects poor cortical control of motor function by the immature brain. Generally, reflexes develop as muscles gain tone. They appear in a sequential manner from caudal to cephalic, i.e. in the lower limb before the upper, and centripetally, i.e. distal reflexes appear before proximal ones (Allen and Capute 1990).

The usual reflexes that can be elicited in the neonate include Moro, asymmetric tonic neck response, rooting-sucking, grasp, placing (contacting the dorsum of the foot with the edge of a table produces a 'stepping over the edge' response), stepping, and trunk incurvation (elicited by stroking down the paravertebral area with the infant in the
prone position). Examination of the motor system and evaluation of these reflexes allow assessment of the nervous system in relation to gestational age. The neonate also exhibits complex reflexes, such as nasal reflexes and sucking and swallowing. Infants with a corrected gestational age of 32 weeks or more have a better-developed sucking reflex and are quicker in achieving oral feeding (Neiva et al 2014).

An auditory reflex present at term is the production of otoacoustic emissions from sensory cell activity in the inner ear in response to sound and is now routinely tested in neonates as an assessment of normal hearing.

Nasal reflexes produce apnoea via the diving reflex, sneezing, sniffing, and both somatic and autonomic reflexes. Stimulation of the face or nasal cavity with water or local irritants produces apnoea in neonates. Breathing stops in expiration, with laryngeal closure, and infants exhibit bradycardia and a lowering of cardiac output. Blood flow to the skin, splanchnic areas, muscles and kidneys decreases, whereas flow to the heart and brain is protected. Different fluids produce different effects when introduced into the pharynx of preterm infants. A comparison of the effects of water and saline in the pharynx showed that apnoea, airway obstruction and swallowing occur far more frequently with water than with saline, suggesting the presence of an upper airway chemoreflex. Reflux of gastric content into the oesophagus is a wellrecognized cause of apnoea and constitutes an acute life-threatening event in infants. Reflex responses to the temperature of the face and nasopharynx are necessary to start pulmonary ventilation. Midwives have, for many years, blown on the faces of neonates to induce the first breath.

Sucking and swallowing are a particularly complex set of reflexes, partly conscious and partly unconscious. As a combined reflex, sucking and swallowing require the coordination of several of the 12 cranial nerves. The neonate can, within the first couple of feeds, suck at the rate of once per second, swallow after five or six sucks, and breathe during every second or third suck. Air moves in and out of the lungs via the nasopharynx, and milk crosses the pharynx en route to the oesophagus without apparent interruption of breathing and swallowing, or significant misdirection of air into the stomach or fluids in the trachea.

Swallowing movements are first noted at about 11 weeks' gestation; in utero fetuses swallow 450 ml of amniotic fluid per day. Sucking and swallowing in premature infants $(1700 \mathrm{~g})$ is not associated with primary
peristaltic waves in the intestine; however, in older babies and full-term neonates, at least $90 \%$ of swallows will initiate primary peristaltic waves.

Sucking develops, generally, slightly later than swallowing, although mouthing movements have been detected in premature babies as early as 18-24 weeks' gestation, and infants delivered at 29-30 weeks' gestation make sucking movements a few days after birth. Coordinated activities are not noted before 33-34 weeks. The concept of nonnutritive and nutritive sucking has been introduced to account for the different rates of sucking seen in the neonate. Non-nutritive sucking, when rhythmic negative intraoral pressures are initiated that do not result in the delivery of milk, can be spontaneous or stimulated by an object in the mouth. This type of sucking tends to be twice as fast as nutritive sucking; the sucking frequency for non-nutritive sucking is 1.7 sucks/second in $37-38$-week premature babies, 2 sucks/second in term neonates, and 2.7 sucks/second at $7-9$ months postnatally. Corresponding times for nutritive sucking are about 1 suck/second in term neonates, increasing to 1.5 sucks/second by 7 months postnatally.

The taste of the fluid, as well as nutrient content, affects the efficiency of nutritive sucking in the early neonatal period. There is more sucking with milk than with $5 \%$ dextrose; however, sucking activities increase with solutions that are determined to be sweet by adult appraisal.

In full-term neonates, the placing of a spoon or food on to the anterior part of the tongue elicits an extrusion reflex: the lips are pursed and the tongue pushes vigorously against the object. By 4-6 months, the reflex changes and food deposited on the anterior part of the tongue is moved to the back of the tongue, into the pharynx, and swallowed (see Ch. 34 for a description of swallowing in the adult). Rhythmic biting movements occur by 7-9 months postnatally, even in the absence of teeth.

Difficulties in sucking and swallowing in infancy may be an early indication of disturbed nervous system function. There is an interesting correlation between feeding styles of neonates and later eating habits. Children who were obese at 1 and 2 years of age, as measured by triceps skin-fold thickness, had a feeding pattern in the first month of life that was characterized by sucking more rapidly, producing higher pressures during prolonged bursts of sucking, and having shorter periods between bursts of sucking. Fewer feeds and higher sucking pressure seem to be associated with greater adiposity. Infants who are unable to feed orally in the first few weeks of life as a result of a congenital anomaly such as oesophageal atresia may develop food aversion.

## Postnatal brain maturation
