[^2]erectile tissue, linked to trigeminal innervation detecting airflow and temperature; congestion and decongestion of the venous sinusoids regulate nasal resistance. Turbinates are also essential for filtration, heating and humidification of inspired air. They direct airflow to the olfactory cleft, and some areas receive direct innervation from the olfactory bulb. Hypertrophy of the turbinates in allergy or environmental irritation results in nasal obstruction.

## NASAL AIRFLOW AND THE NASAL CYCLE

## Available with the Gray's Anatomy e-book

## Nasal obstruction

Disturbances of the normal airflow pattern, whether produced by mucocutaneous or skeletal changes within the nose, affect normal nasal breathing and are usually perceived as some form of nasal obstruction.

The septum may be displaced by injury or by disproportionate growth of the cartilage that may cause it to bend; sometimes, the deviation may cause unilateral nasal obstruction. Variations in the anatomy of the lateral nasal wall, usually associated with variations in the size and position of the anterior ethmoidal cells, may obstruct frontal or maxillary sinus drainage, e.g. frontal cells, supraorbital ethmoidal cells, and infraorbital or Haller's cells, which represent an extension of anterior ethmoidal pneumatization along the infraorbital margin, sometimes within the roof of the maxillary sinus (see below).

## NASAL AND OLFACTORY MUCOSAE

## Nasal mucosa

The lining of the anterior part of the nasal cavity and vestibule is continuous with the skin, and consists of keratinized stratified squamous epithelium overlying a connective tissue lamina propria. Inferiorly, the skin bears coarse hairs (vibrissae), which curve towards the naris and help to arrest the passage of particles in inspired air. In males, after middle age, these hairs increase considerably in size. Further posteriorly, at the limen nasi, this changes into a mucosa, lined initially by nonkeratinizing stratified squamous epithelium, and then by pseudostratified ciliated (respiratory) epithelium rich in goblet cells (see Fig. 2.2D). Respiratory epithelium forms most of the surface of the nasal cavity, i.e. it covers the conchae, meatuses, septum, floor and roof, except superiorly in the olfactory cleft, where the olfactory epithelium is present. It is adherent to the periosteum or perichondrium of the neighbouring skeletal structures. In some areas, cells of the respiratory epithelium may be low columnar or cuboidal, and the proportion of ciliated to non-ciliated cells is variable.

There are numerous seromucous glands within the lamina propria of the nasal mucosa. Their secretions make the surface sticky so that it traps particles in the inspired air. The mucous film is continually moved by ciliary action (the mucociliary escalator or rejection current) posteriorly into the nasopharynx at a rate of 6 mm per minute. Palatal movements transfer the mucus and its entrapped particles to the oropharynx for swallowing, but some also enters the nasal vestibule anteriorly. The secretions of the nasal mucosa contain the bacteriocides lysozyme, $\beta$-defensin and lactoferrin, and also secretory immunoglobulins (IgA). The mucosa is continuous with the nasopharyngeal mucosa through the posterior nasal apertures, the conjunctiva through the nasolacrimal duct and lacrimal canaliculi, and the mucosa of the sphenoidal, ethmoidal, frontal and maxillary sinuses through their openings into the meatuses.

The mucosa is thickest and most vascular over the conchae, especially at their extremities, and also on the anterior and posterior parts of the nasal septum and between the conchae. The mucosa is very thin in the meatuses, on the nasal floor and in the paranasal sinuses. Its thickness reduces the volume of the nasal cavity and its apertures significantly. The lamina propria contains cavernous vascular tissue with large venous sinusoids.

## Olfactory mucosa

Olfactory mucosa (Fig. 33.8) covers approximately $5 \mathrm{~cm}^{2}$ of the posterior upper parts of the lateral nasal wall, including the upper part of the vertical portion of the middle concha (where it is interspersed with

The paired nasal valves are critical regulators of nasal airflow and resistance. Each is divided into external and internal portions, although often only the internal portion is regarded as the 'nasal valve' or flow-limiting segment. The external valve is made up of the ala, the skin of the vestibule, the nasal sill and the contour of the medial crus of the lower lateral cartilage. The external valve has a tendency to collapse at high flow rates, even in normal individuals.

The upper lateral cartilages are in continuity with the superior border of the nasal septum. A valve-like mechanism exists at its distal end that regulates nasal airflow. The nasal valve area and internal nasal valve are two entities that should not be confused. The nasal valve area is the narrowest portion of the nasal passage. It is bounded medially by the septum and the tuberculum of Zuckerkandl, and superiorly and laterally by the caudal margin of the upper lateral cartilage, its fibroadipose attachment to the piriform aperture and the anterior end of the inferior turbinate; inferiorly, it consists of the floor of the piriform aperture. The nasal valve, on the other hand, is the specific slit-like segment between the caudal margin of the upper lateral cartilage and the septum. It is measured in degrees and normally ranges between 10 and $15^{\circ}$. Dilator naris anterior and the alar part of nasalis support the nasal valves.

Airflow dynamics are recognized as playing a key role in conditioning (i.e. warming, humidifying and filtering) inspired air; however, these dynamics are still poorly understood (Churchill et al 2004, Boyce
and Eccles 2006). It is generally agreed that airflow within the nose is both laminar and turbulent. Inspired air is forced to pass through the nasal valve and then expands as it passes further into the nasal cavity, which offers little airflow resistance. This sudden change in speed and pressure produces turbulence and eddies. These currents allow adequate contact of inspired air with respiratory epithelium and facilitate odorant transport to the olfactory area. Chewing also affects nasal airflow; pulses of aroma-laden air are pumped out of the mouth into the retronasal region with each chew.

The cross-sectional area of the nasal airway depends on the dimensions of the septal partition and inferior turbinates (which are modulated by changes in the dimensions of the erectile tissue that covers them), and on the stability of the lateral nasal walls during breathing. The nasal cycle is an alternating fluctuation of nasal engorgement and airflow through the nasal passages, with period lengths ranging from 1 to 5 hours. The mechanism involves changes in sympathetic tone to the venous erectile tissue of the nasal mucosa; increased sympathetic vasoconstriction causes resistance to fall. These alterations in the thickness and contours of the mucosal surfaces are visible as a swelling or shrinkage of the nasal lining, and may serve to protect the mucosae from desiccation. The pacemaker for the cycle is believed to lie within the suprachiasmatic nucleus. The rhythmicity of the cycle decreases with age.

Fig. 33.8 C, A higher-power view of the expanded end of an olfactory receptor neurone. The electron-dense, osmiophilic material within the adjacent supporting cell $(\mathrm{S})$ is thought to contribute to the pigmentation of the olfactory epithelium. Other abbreviations: B, basal body with projecting 'feet'; C, olfactory cilium; M, microtubules. D, A section of human olfactory epithelium immunostained with anti-OMP (olfactory marker protein). An immunopositive olfactory receptor neurone lies between two unstained supporting cells (S). Other abbreviations: V, microvilli.

Fig. 33.8 A, The chief cytological features of the olfactory epithelium. Receptor cells (neurones) ( R ) are situated among columnar sustentacular cells. The axons of the receptor cells emerge from the epithelium in bundles enclosed by ensheathing glial cells (G). Rounded globose basal cells (B) and flattened horizontal basal cells (not shown) lie on the basal lamina, and the subepithelial glands (of Bowman) (S) open on to the surface via their intraepithelial ducts (I). At the surface are cilia of the receptor cells and microvilli of the supporting cells. B-D, Longitudinal sections through human olfactory epithelium. B, Ciliated olfactory receptor neurones with characteristic expanded ends ( N ) project into the nasal lumen. The edge of a Bowman's gland (BG) lies deeper in the lamina propria. Other abbreviations: B, basal cells resting on the basal lamina; M, microvillar cell; S, supporting or sustentacular cells containing electron-dense material. (B-D, Courtesy of Professor Bruce Jafek, Department of Otolaryngology, University of Colorado, Denver, USA.)
respiratory epithelium in a chequerboard fashion) and the opposite part of the nasal septum, the superior concha, the sphenoethmoidal recess, the upper part of the perpendicular plate of the ethmoid and the portion of the roof of the nose that arches between the septum and lateral wall, including the underside of the cribriform plate (constituting the olfactory cleft or groove). It consists of a yellowish-brown pigmented pseudostratified epithelium, containing olfactory receptor neurones, sustentacular cells and two classes of basal cell, lying on a subepithelial lamina propria containing subepithelial olfactory glands (of Bowman) and bundles of axons derived from the olfactory receptor neurones that course through the mucosa on their way to the cribriform plate. The glands secrete a predominantly serous fluid through ducts that open on to the epithelial surface. These secretions form a thin fluid layer in which sensory cilia and the microvilli of the sustentacular cells are embedded.

Olfactory receptor neurones Olfactory receptor neurones are bipolar. Their cell bodies and nuclei are located in the middle zone of the olfactory epithelium. Each neurone has a single unbranched apical dendrite, $2 \mu \mathrm{~m}$ in diameter, which extends to the epithelial surface; and a basally directed unmyelinated axon, $0.2 \mu \mathrm{~m}$ in diameter, which passes in the opposite direction, penetrates the basal lamina and enters the lamina propria. The tips of the dendrites project into the overlying secretory fluid and are expanded into characteristic endings (knobs) (see Fig. 33.8B). Groups of up to 20 cilia radiate from the circumference of each ending and extend for long distances parallel to the epithelial surface. Internally, the short proximal part of each cilium has the ' $9+2$ ' pattern of microtubules typical of motile cilia, while the longer distal trailing end contains only the central pair of microtubules. The olfactory cilia lack dynein arms and are thought to be non-motile; their primary purpose is to increase the surface area of sensory receptor membrane available for the efficient detection of odorant molecules transferred across the mucous layer by odorant-binding proteins. Mature olfactory neurones express olfactory marker protein (OMP), an abundant cytoplasmic protein involved in olfactory signal transduction (see Fig. 33.8D). Each olfactory receptor neurone expresses receptors for a single odorant molecule (or very few). In humans, over 1000 genes code for functional odorant receptors; the number of functional genes is much higher in macrosmotic animals (Buck and Axel 1991). Although neurones with the same receptor specificity are randomly distributed within anatomical zones of the epithelium, their axons all converge on
the same glomerulus in the olfactory bulb. Specific odours activate a unique spectrum of receptor neurones, which in turn activate restricted groups of glomeruli and their second-order neurones.

The axons form small intraepithelial fascicles among the processes of sustentacular and basal cells. The fascicles penetrate the basal lamina and are immediately surrounded by olfactory ensheathing cells. Groups of up to 50 such fascicles join to form larger olfactory nerve rootlets that pass through the cribriform plate of the ethmoid bone, wrapped in meningeal sheaths. They immediately enter the overlying olfactory bulbs, where they synapse in glomeruli with mitral cells and, to a lesser extent, with smaller tufted cells.

Microvillar cells Microvillar cells occupy a superficial position in the olfactory epithelium. They are flask-shaped and electron-lucent, and the apical end of each cell gives rise to a tuft of microvilli that project into the mucus layer lining the nasal cavity (see Fig. 33.8B). Cell counts in longitudinal sections reveal that microvillar cells occur with a density that is approximately one-tenth of the density of ciliated olfactory neurones; their function and origin have yet to be determined.

Sustentacular cells Sustentacular, or supporting, cells are columnar cells that separate and partially ensheathe the olfactory receptor neurones. Their large nuclei form a layer superficial to the neuronal nuclei within the epithelium. The cells are capped by numerous long, irregular, microvilli, which lie in the secretory fluid layer that covers the surface of the epithelium, intermingled with the trailing ends of the cilia on the olfactory receptor endings. Their expanded bases contain numerous lamellated dense bodies, which are the remnants of secondary lysosomes, and which contribute significantly to the pigmentation of the olfactory area (see Fig. 33.8B,C). The granules gradually accumulate with age, and because these cells are long-lived, the intensity of pigmentation also increases with age. Neighbouring sustentacular cells are linked by desmosomes close to the epithelial surface, an arrangement that helps to stabilize the epithelium mechanically. Sustentacular cells and olfactory receptor neurones are linked by tight junctions at the level of the epithelial surface.

Basal cells There are horizontal and globose basal cells. Horizontal basal cells are flattened against the basal lamina. Their nuclei are condensed and their darkly staining cytoplasm contains numerous intermediate filaments of the cytokeratin family, inserted into desmosomes
between the basal cells and surrounding sustentacular cells. Globose cells are rounded or elliptical in shape, and have pale, euchromatic nuclei and pale cytoplasm. They form a distinct zone that is slightly internal to the basal surface of the epithelium and characterized by mitotic figures; globose basal cells are the immediate source of new olfactory receptor neurones.

Olfactory ensheathing cells Olfactory ensheathing cells share properties with astrocytes and non-myelinating Schwann cells, but also possess distinctive features that indicate they are a separate class of glia. Developmentally, they are derived from the olfactory placode rather than the neural crest. They ensheathe olfactory axons in a unique manner throughout their entire course and accompany them into the olfactory bulb, where they contribute to the glia limitans. In recent years, olfactory ensheathing cells have been the focus of intense experimental scrutiny in the search for a source of transplantable glia capable of supporting neuronal regeneration within the central nervous system, possibly in the treatment of paraplegia.

Olfactory glands Olfactory (Bowman's) glands are branched tubuloalveolar structures that lie beneath the olfactory epithelium and secrete their products on to the epithelial surface through narrow, vertical ducts. Their secretions, which include defensive substances, lysozyme, lactoferrin, $\operatorname{IgA}$ and sulphated proteoglycans, together with odorantbinding proteins which increase the efficiency of odour detection, bathe the dendritic endings and cilia of the olfactory receptors. The fluid acts as a solvent for odorant molecules, allowing their diffusion to the sensory receptors.

Turnover of olfactory receptor neurones Olfactory receptor neurones are lost and replaced throughout life. Individual receptor cells have a variable lifespan, thought to average 1-3 months. Stem cells situated near the base of the epithelium undergo periodic mitotic division throughout life, giving rise to new olfactory receptor neurones, which then grow a dendrite to the olfactory surface and an axon to the olfactory bulb. The cell bodies of these new receptor neurones gradually move apically until they reach the region just below the supporting cell nuclei. When they degenerate, dead neurones either are shed from the epithelium or are phagocytosed by sustentacular cells. The rate of receptor cell loss and replacement increases after exposure to damaging stimuli but declines slowly with age, a phenomenon that presumably contributes to diminishing olfactory sensory function in old age. Biopsy specimens from normosmic adults have revealed that patchy replacement of olfactory with respiratory epithelium occurs even in young healthy adults (Paik et al 1992, Holbrook et al 2005).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE NASAL CAVITY

Many of the vessels and nerves supplying the nasal cavities arise within the pterygopalatine fossa and these origins are described in Chapter 32.

## Arteries

Branches of the ophthalmic, maxillary and facial arteries supply different territories within the walls, floor and roof of the nasal cavity (Fig. 33.9). They ramify to form anastomotic plexuses within and deep to the nasal mucosa. Anastomoses also occur between some larger arterial branches. The anterior and posterior ethmoidal branches of the ophthalmic artery supply the ethmoidal and frontal sinuses and the roof of the nose (including the septum). The anterior ethmoidal artery usually runs within the bone of the anterior skull base, unless this is well pneumatized with a supraorbital cell, in which case the artery is more likely to be positioned away from the skull base and to be more prone to surgical damage. The sphenopalatine branch of the maxillary artery supplies the mucosa of the turbinates, meatuses and posteroinferior part of the nasal septum, i.e. it is the principal vessel supplying the nasal mucosa. The artery comes out of a fissure (erroneously termed a foramen), and normally divides before it enters the nasal cavity behind the crista ethmoidalis into posterior lateral nasal and posterior septal branches. Sometimes, the artery may divide before it leaves the foramen. The number and distribution of its branches show great variation, with a median of three or four branches (Babin et al 2003). The greater palatine branch of the maxillary artery supplies the region of the inferior meatus. A branch crosses the sphenoidal rostrum, below its natural ostium, to supply the nasal septum. This is utilized to provide pedicled, vascularized nasoseptal flaps in skull-base reconstruction. Its terminal part ascends through the incisive canal to anastomose on the septum with branches of the sphenopalatine and anterior ethmoidal arteries, and with the septal branch of the superior labial artery. This septal region (Little's area or Kiesselbach's plexus) is a common site of bleeding from the nose. The infraorbital artery and the superior, anterior and posterior alveolar branches of the maxillary artery supply the mucosa of the maxillary sinus. The pharyngeal branch of the maxillary artery supplies the sphenoidal sinus.

## Nose bleeds

Available with the Gray's Anatomy e-book

Fig. 33.9 The arterial supply of the nasal cavity. A, The lateral wall of the left nasal cavity. B, The medial wall of the left nasal cavity. (From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

The vast majority of nose bleeds, particularly in children, occur as a result of digital trauma to the anastomosis of arterioles and veins in Little's area, on the nasal septum just inside the nasal vestibule. This area is amenable to cautery when required. In older patients, brisker bleeding may occur as a result of the spontaneous rupture of arteries further back in the nose. These may be controlled by applying pressure with a nasal pack, but where this fails, knowledge of the pattern of arterial blood supply to the nasal cavity permits interruption of the appropriate blood supply by ligation or embolization of the feeding vessel. The sphenopalatine artery may be ligated under endoscopic visualization as it enters the nose through the sphenopalatine foramen. The ethmoidal arteries may be exposed within the orbit and ligated to arrest bleeding high up in the nasal cavity. The maxillary artery may be exposed surgically behind the posterior wall of the maxillary sinus and ligated, or alternatively it may be identified radiologically, using a radiopaque dye, so that it may be blocked by embolization (Simmen and Jones 2010).

## Veins

A rich submucosal cavernous plexus is especially dense in the posterior part of the septum and in the middle and inferior turbinates (Fig. 33.10). Numerous arteriovenous anastomoses are present in the deep layer of the mucosa and around the mucosal glands. The cavernous turbinate plexuses resemble those in erectile tissue; the nasal cavity is susceptible to blockage, should they become engorged. Veins from the posterior part of the nose generally pass to the sphenopalatine vein that runs back through the sphenopalatine foramen to drain into the

Fig. 33.10 The venous drainage of the nasal cavity: the lateral wall of the left nasal cavity. (From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
pterygoid venous plexus. The anterior part of the nose is drained mainly through veins accompanying the anterior ethmoidal arteries, and these veins subsequently pass into the ophthalmic or facial veins. Injection of vasoconstrictive agents or corticosteroids during surgery, particularly to the inferior turbinates, may permit access to the intracranial and ophthalmic circulations. Blindness has been reported in rare cases following such injections. A few veins pass through the cribriform plate to connect with those on the orbital surface of the frontal lobes of the brain. When the foramen caecum is patent, it transmits a vein from the nasal cavity to the superior sagittal sinus.

## Lymphatic drainage

Lymph vessels from the anterior region of the nasal cavity pass superficially to join those draining the external nasal skin and end in the submandibular nodes. The rest of the nasal cavity, paranasal sinuses, nasopharynx and pharyngeal end of the pharyngotympanic tube all drain to the upper deep cervical nodes, either directly or through the retropharyngeal nodes. The posterior nasal floor probably drains to the parotid nodes.

## INNERVATION OF THE NASAL CAVITY

Olfaction is mediated via the olfactory nerves. General sensation (touch, pain and temperature) from the nasal mucosa is carried by branches of the ophthalmic and maxillary divisions of the trigeminal nerves (Fig. 33.11). Trigeminal fibres close to, and within, the epithelial layer are sensitive to noxious chemicals, e.g. ammonia and sulphur dioxide. Autonomic fibres innervate mucous glands and control cyclical and reactive vasomotor activity.

## Trigeminal innervation

The anterior ethmoidal branch of the nasociliary nerve leaves the cranial cavity through a small slit near the crista galli and enters the roof of the nasal cavity, where it runs in a groove on the inner surface of the nasal bone, supplying the roof of the nasal cavity. It gives off a lateral internal branch to supply the anterior part of the lateral wall, and a medial internal branch to the anterior and upper parts of the septum, before emerging at the inferior margin of the nasal bone as the external nasal nerve to supply the skin of the external nose to the nasal tip; damage following nasal trauma may result in paraesthesia of the tip. The infraorbital nerve supplies the nasal vestibule. The anterior superior alveolar nerve supplies part of the septum, the floor near the anterior

Fig. 33.11 The innervation of the nasal cavity. A, The lateral wall of the left nasal cavity. B, The medial wall of the left nasal cavity. (From Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
nasal spine and the anterior part of the lateral wall as high as the opening of the maxillary sinus; the lateral posterior superior nasal and the posterior inferior nasal branches of the greater palatine nerve together supply the posterior three-quarters of the lateral wall, roof and floor; the medial posterior superior nasal nerves and the nasopalatine nerve supply the inferior part of the nasal septum; and branches from the nerve of the pterygoid canal supply the upper and posterior part of the roof and septum.

## Autonomic innervation

The deep petrosal nerve (postganglionic sympathetic fibres) and the greater petrosal nerve (preganglionic parasympathetic fibres) converge to form the nerve of the pterygoid canal (Vidian nerve in the Vidian canal). The canal enters the pterygopalatine fossa, and the nerve joins the pterygopalatine ganglion, where the parasympathetic fibres synapse, but the sympathetic fibres pass through without synapsing (Ch. 32). The nerve of the pterygoid canal is an important landmark to the petrous portion of the internal carotid artery, and may also rarely be transected to treat intractable rhinorrhoea. Sympathetic postganglionic vasomotor fibres are distributed to the nasal blood vessels. Postganglionic parasympathetic fibres derived from the pterygopalatine ganglion provide the secretomotor supply to the nasal mucous glands, and are distributed via branches of the maxillary nerves.

## Olfactory nerves

Olfactory nerves are bundles of very small axons derived from olfactory receptor neurones in the olfactory mucosa. The axons are unmyelinated, and in varying stages of maturity, reflecting the constant turnover of olfactory neurones that takes place in the olfactory epithelium. Bundles of axons surrounded by olfactory ensheathing cells form a plexiform network in the subepithelial lamina propria of the mucosa. The bundles unite into as many as 20 branches that cross the cribriform plate in lateral and medial groups, and enter the overlying olfactory bulb, where they end in glomeruli. Each branch is ensheathed by dura mater and pia arachnoid as it passes through the cribriform plate (Fig. 33.12). The dura subsequently becomes continuous with the nasal periosteum, and the pia arachnoid merges with the connective tissue sheaths surrounding the nerve bundles, an arrangement that may favour the spread of infection into the cranial cavity from the nasal cavity.

In severe injuries involving the anterior cranial fossa, the olfactory bulb may be separated from the olfactory nerves or the nerves may be torn, producing anosmia, i.e. loss of olfaction. Fractures may involve the meninges, so that cerebrospinal fluid may leak into the nose, resulting in cerebrospinal rhinorrhoea. Such injuries open up avenues for intracranial infection from the nasal cavity.

## Vomeronasal organ

Available with the Gray's Anatomy e-book

## PARANASAL SINUSES

The paranasal sinuses are the frontal, ethmoidal, sphenoidal and maxillary sinuses, housed within the bones of the same name (see Fig. 33.1; Figs 33.13-33.15). They all open into the lateral wall of the nasal cavity by small apertures that permit both the equilibration of air between the various air spaces and the clearance of mucus from the sinuses into the nose via a mucociliary escalator. The detailed position of these apertures, and the precise form and size of each of the sinuses, vary enormously between individuals (Lang 1989, Beale et al 2009, Navarro 1997). Respiratory epithelium extends through the apertures of the paranasal sinuses to line their cavities, a feature that unfortunately favours the spread of infections. Sinus mucosa is thinner and less vascular, and has fewer goblet cells, than nasal mucosa. Cilia are always present in the mucosa near the apertures but less evenly distributed elsewhere within the sinuses.

The functions of the paranasal sinuses remain speculative. They clearly add some resonance to the voice, and also allow the enlargement of local areas of the skull while minimizing a corresponding increase in bony mass. It is likely that such growth-related changes serve to strengthen particular regions, e.g. the alveolar processes of the maxillae when the secondary dentition erupts, but they may also function in

In most amphibians, reptiles and mammals, the vomeronasal organ is the peripheral sensory organ of the accessory olfactory system. In these animals, paired vomeronasal organs are located either at the base of the nasal septum or in the roof of the mouth, and are involved in chemical communication that is often, but not exclusively, mediated via pheromones. In many macrosomatic animals, the vomeronasal organ consists of a vomeronasal duct that contains chemosensory cells, and a vomeronasal nerve that terminates centrally in the accessory olfactory bulb. The vomeronasal organ exists in the developing human fetus but its existence in the adult has long been controversial. A bilateral structure in the anteroinferior wall of the nasal septum just dorsal to the paraseptal cartilages, which is presumed to be analogous to the vomeronasal organ of other vertebrates, has been demonstrated in adult human tissue; while there is no evidence that this structure has any neuroreceptive function, it has been suggested that it might have an as yet unknown endocrine function (Wessels et al 2014).

contouring the head to provide visual signals indicating the individual's status in a social context (e.g. gender, sexual maturity and group identity).

Most sinuses are rudimentary or absent at birth, but enlarge appreciably during the eruption of the permanent teeth and after puberty, events that significantly alter the size and shape of the face.

## DEVELOPMENT OF THE PARANASAL SINUSES, AND ANATOMICAL VARIATIONS IN CHILDHOOD

At birth, both small ethmoidal and maxillary sinuses are present, but the frontal sinus is nothing more than an out-pouching from the nasal cavity, and there is no pneumatization of the sphenoid bone.

Understanding the development of the sinuses at each stage of childhood is essential for interpreting pathology and planning surgery. Cadaveric and radiological studies have provided normative data for sinus development.

## FRONTAL SINUS

The paired frontal sinuses are posterior to the superciliary arches, between the outer and inner tables of the frontal bone (see Figs 33.13, $33.15 \mathrm{~A}, \mathrm{~B}$ ). Each usually underlies a triangular area on the surface of the face, its angles formed by the nasion, a point 3 cm above the nasion and the junction of the medial third and lateral two-thirds of the supraorbital margin. The two sinuses are rarely symmetric, since the septum between them usually deviates from the median plane. Each sinus may be further divided into a number of communicating recesses by incomplete bony septa.

The average dimensions of an adult frontal sinus are: height 3.2 cm ; breadth 2.6 cm ; and depth 1.8 cm . Each usually has a frontal portion that extends upwards above the medial part of the eyebrow, and an orbital portion that extends back into the medial part of the roof of the orbit. One or both sinuses may rarely be hypoplastic or even absent; racial differences have been reported. The prominence of the superciliary arches is no indication of the presence or size of the frontal sinuses.

The turbinates at birth are usually bulky and the inferior and middle meatuses are underdeveloped. The uncinate, hiatus semilunaris and ethmoidal bulla are already well-defined, fixed landmarks, and both the anterior and posterior ethmoidal cells are already almost completely developed in terms of number but not size. The cells are separated by connective tissue, which becomes compressed with subsequent expansion of the cells. The ethmoid complex ranges from 8 to 12 mm in length, 1 to 3 mm in width and 1 to 5 mm in height; the complexes expand rapidly in size in the first few years of life. The maxillary sinus is roughly spherical, with a volume of $6-8 \mathrm{~cm}^{3}$, and measures 10 mm in length, 4 mm in height and 3 mm in width. It lies initially medial to the orbit, but projects laterally under the orbit by the end of the first year of life. The sphenoid is devoid of air, although a blind mucosal sac may sometimes be identified. At birth, the sphenoid has two major ossification centres; failure of fusion between the two may give rise to anatomical variations such as a persistent 'craniopharyngeal canal'. The Eustachian tube is found within the nasal cavity, behind the posterior end of the inferior turbinate. The frontal sinus is no more than a small out-pouching that drains into the infundibulum.

The supreme turbinate has usually disappeared, while the remaining three turbinates reduce relatively in size. The inferior meatus develops and contributes to the nasal airway. The maxillary sinus enlarges rapidly up to the age of 4 years, reaching laterally as far as the infraorbital canal, and inferiorly to the attachment of the inferior turbinate; it ranges between 22 and 30 mm in length, 12 and 18 mm in height and 11 and 19 mm in width. The ethmoidal cells enlarge in all directions, starting anteriorly and then progressing posteriorly. By the age of 4, they are well developed; variants such as the agger nasi cell, infraorbital cell and concha bullosa are identifiable. Sphenoidal pneumatization commences around 7 months of age; a distinct cell is visible by the age of 2 years. By 4 years of age, it is roughly pea-sized, with a diameter of $4-8 \mathrm{~mm}$. The frontal sinus is the last to develop and is imperceptible in infants less than 1 year old. It begins to pneumatize after the age of 2, gradually enlarging as an out-pouching from the anterior ethmoids. Early growth is slow; by 4 years, the vertical height reaches only half the height of the orbit (between 6 and 9 mm in height) (Wolf et al 1993).
By 8 years, the sinuses have expanded in all directions. The maxillary sinus has reached the maxillary bone laterally and the plane of the hard palate, becoming tetrahedral in shape. It ranges from 34 to 38 mm in length, 22 to 26 mm in height and 18 to 24 mm in width. The dental buds of unerupted teeth are closely related to the floor of the sinus. The ethmoidal cells continue to enlarge, but more slowly than before; the posterior cells become larger than the anterior cells.

Pneumatization into the vertical plate of the frontal bone does not usually begin until the fifth year, at which time the frontal sinus may be identified radiologically. The frontal sinus pneumatizes rapidly and begins to pneumatize into the vertical plate of the frontal bone; its height reaches the orbital roof at 8 years (Ruf and Pancherz 1996).

By 12 years, the sinuses have almost reached adult proportions. The maxillary sinus pneumatizes into the maxillary alveolus after eruption of the permanent dentition, so that the floor of the sinus now sits $4-5 \mathrm{~mm}$ below the level of the floor of the nasal cavity. The ethmoidal sinuses reach adult size, and the frontal sinuses extend into the frontal bone, continuing to enlarge until puberty. The sphenoidal sinus reaches its full size by the age of 14 years.

Asymmetry in the size and shape of the sinuses, hypoplasia and anatomical variants are common (Navarro 1997). Unilateral or bilateral maxillary hypoplasia occurs infrequently; the condition is rarely bilateral. Pneumatization of an ethmoidal cell into the middle concha creates a concha bullosa, and inferolaterally creates an infraorbital cell. The degree of pneumatization of the sphenoid is highly variable but aplasia is very rare. In contrast, unilateral aplasia of the frontal sinus is present in $15 \%$ of adults, and present bilaterally in $5 \%$.

Fig. 33.15 A-B, Sagittal CT scans showing the frontal, ethmoidal and sphenoidal sinuses. Arrows indicate the hiatus semilunaris in A. (A, Courtesy of Professor D Bell.)

They are more prominent in males, and lend the forehead an obliquity that contrasts with the vertical or convex profile typical of children and females.

The aperture of each frontal sinus opens either into the anterior part of the corresponding middle meatus by the ethmoidal infundibulum as a frontonasal recess (rather than a duct), or medial to the hiatus semilunaris if the uncinate process is attached to the lateral nasal wall or an agger nasi cell (Kuhn 2002). The frontal recess is actually the most anterior part of the anterior ethmoidal complex but is described here because of its importance in the drainage of the frontal sinus. Its lateral wall is the lamina papyracea; the medial wall is formed by the middle turbinate; and posteriorly, the wall is made up of either the cranial base, in a suprabullar recess, or the insertion of the bulla, if this reaches the cranial base. Anteriorly, the wall extends from the frontal sinus proper to the anterior attachment of the middle turbinate. In its simplest form, it takes the shape of an inverted funnel, forming an hourglass shape with the floor of the frontal sinus. However, the frontal recess is often narrowed both from in front and from behind by anterior ethmoidal cells, such that it may be highly convoluted (Fig. 33.16). These frontoethmoidal cells are classified with regard to their attachments to the inner walls of the frontal sinus and relationship to the frontal recess as anterior or posterior, medial or lateral (Lund et al 2014).

Fig. 33.18 A horizontal section of the head showing the ethmoidal and sphenoidal sinuses. (With permission from Berkovitz BKB, Moxham BJ 2002 Head and Neck Anatomy. London: Martin Dunitz.)

## Vascular supply, lymphatic drainage and innervation

The frontal sinuses receive their arterial supply from the supraorbital and anterior ethmoidal arteries. The veins drain into an anastomotic vein in the supraorbital notch that connects the supraorbital and superior ophthalmic veins. Lymphatic drainage is to the submandibular nodes. The sinuses are innervated by branches of the supraorbital nerves (general sensation) and the orbital branches of the pterygopalatine ganglia (parasympathetic secretomotor fibres).

## SPHENOIDAL SINUS

The sphenoidal sinuses are two large, irregular cavities within the body of the sphenoid and therefore lie posterior to the upper part of the nasal cavity (see Figs 33.14-33.15; Figs 33.17-33.18). Each opens into the

Fig．33．16 A，A coronal CT demonstrating the frontal sinus（F），agger nasi cell（blue arrow）and uncinate process inserting into the middle turbinate （yellow arrow）．B，An absent frontal sinus（asterisk）．C，A coronal CT demonstrating variations in the frontal sinus with multiple cells within the frontal recess．
corresponding sphenoethmoidal recess via an aperture high on the anterior wall of the sinus. The sphenoid ostium is usually medial to the superior turbinate, although the height of the ostium is highly variable. The average dimensions of the adult sphenoid are: vertical height 2 cm ; transverse breadth 1.8 cm ; and anteroposterior depth 2.1 cm . The sinuses are usually separated by a septum that usually deviates from the midline, so that they are unequal in size and form. Their lumina may be further partially divided by bony laminae and accessory septa, especially in the region of former synchondroses, and these septa commonly insert on to the internal carotid artery. Occasionally, one sinus overlaps the other above and, rarely, they intercommunicate. Bony ridges, produced by the internal carotid artery, pterygoid canal, maxillary branch of trigeminal and sometimes the optic nerve, may project into the sinuses from their lateral walls. The sphenoidal sinuses are related above to the optic chiasma and hypophysis cerebri, and on each side to the internal carotid artery and cavernous sinus. One or both sinuses may partially encircle the optic canal. Dehiscences in the osseous walls may occasionally leave their mucosa in contact with the overlying dura mater, optic nerve or carotid artery.

The extent of pneumatization of surrounding bone is highly variable. Sometimes, a lateral recess may extend into the greater and lesser wings of the sphenoid or the pterygoid processes, separating the pterygoid (Vidian) canal and foramen rotundum, and may even invade the basilar part of the occipital bone almost to the foramen magnum. A posterior ethmoidal sinus may extend posterosuperior to the relatively smaller sphenoidal sinuses. In such cases, the sphenoid is medial and inferior to this sphenoethmoidal cell (Onodi cell), which itself will be closely related to the optic nerve and carotid artery. An attempt to approach the sphenoid through a sphenoethmoidal cell places these structures at risk of injury. Sphenoethmoidal cells are readily identified on computed tomographic (CT) imaging, where a horizontal bar can be seen in the coronal plane. The anterior clinoid process may be pneumatized in up to $15 \%$ of sphenoidal cells.

The shape and position of the sphenoidal sinus are of clinical importance in an endoscopic trans-sphenoidal surgical approach to the hypophysis cerebri. The sinuses may be classified into three main types: sellar, the most common type, in which the sinus extends for a variable distance beyond the tuberculum sellae; presellar, in which the sinus occasionally extends posteriorly towards, but not beyond, the tuberculum sellae; and conchal, the rarest type, in which a small sinus is separated from the sella turcica by approximately 10 mm of trabecular bone. The anterior midline septum often becomes deviated to one side posteriorly; identification of this septation is important prior to surgery (Fig. 33.19).

## Vascular supply, lymphatic drainage and innervation

The sphenoidal sinuses receive their arterial supply from the posterior ethmoidal branches of the ophthalmic arteries and nasal branches of the sphenopalatine arteries. Venous drainage is through the posterior ethmoidal veins draining into the superior ophthalmic veins. Lymph drainage is to the retropharyngeal nodes. The sinuses are innervated by the posterior ethmoidal branches of the ophthalmic nerves (general sensation) and the orbital branches of the pterygopalatine ganglia (parasympathetic secretomotor fibres).

## ETHMOIDAL SINUSES

The ethmoidal sinuses differ from the other paranasal sinuses in that they are formed of multiple thin-walled cavities in the ethmoidal labyrinth (see Figs 33.13, 33.15-33.18). The number and size of the cavities vary, from 3 large to 18 small sinuses on each side. They lie between the upper part of the nasal cavity and the orbit, and are separated from the latter by the paper-thin lamina papyracea or orbital plate of the ethmoid (this presents a poor barrier to infection, which may therefore spread into the orbit). Pneumatization may extend into the middle concha, or into the body and wings of the sphenoid bone lateral to the sphenoidal sinus. (There is a view that the ethmoidal sinuses are aerated after birth, rather than pneumatized, as happens with the other paranasal sinuses (Jankowski 2013).)

The ethmoidal sinuses are divided clinically into anterior and posterior groups on each side, distinguished by their embryological development, sites of communication with the nasal cavity, their mucociliary drainage, and their relation to the basal lamella of the middle turbinate. (Cells wrongly designated previously as belonging to a middle group are now included with the anterior group (Stammberger and Kennedy 1995).) The anterior and posterior groups are separated from each other by the basal lamella; this may be indented by cells from either group
and therefore it forms a rather tortuous barrier between them. Within each group, the sinuses are only partially separated by incomplete bony septa.

## Anterior ethmoidal sinuses

Up to 11 anterior ethmoidal air cells drain into the ethmoidal infundibulum, a three-dimensional, funnel-shaped cleft between the uncinate and lateral wall of the nose, by one or more orifices. The most anterior group, developmental remnants of the first ethmoturbinals, are the agger nasi cells. These cells are almost always present. They are medial relations of the lacrimal sac and duct, and invaginate beneath the frontal sinus on the lateral wall of the nasal cavity anteriorly. Removal of the superior walls of the agger nasi, 'uncapping the egg', is a key part of surgery of the frontal recess. The ethmoidal bulla, arising from the second ethmoturbinal of the nose, consists of a group of the largest and least variable anterior ethmoidal cells. The cleft between the posterior edge of the uncinate bone and the face of the ethmoidal bulla is known as the hiatus semilunaris. When the bullar lamella reaches the cranial base, this forms the posterior wall of the frontal recess. In other cases, a suprabullar recess may be found. Infraorbital (Haller) cells may develop medially beneath the orbital floor (Fig. 33.20).

## Posterior ethmoidal sinuses

Up to seven posterior ethmoidal air cells usually drain by a single orifice into the superior meatus; one may drain into the supreme meatus when present, and one or more into the sphenoidal sinus (Fig. 33.21). The posterior group lies very close to the optic canal and optic nerve; optic nerve injury is a devastating potential complication of endoscopic sinus surgery, particularly if a sphenoethmoidal cell (Onodi cell) is present. The reported incidence varies widely ( 3.5 to $51 \%$ ), according to racial group; it is more common in non-Caucasians. The sphenoethmoidal cell is usually regarded as the most posterior ethmoidal cell that pneumatizes lateral and superior to the sphenoidal sinus, and is intimately associated with the optic nerve; it may contain a tuberculum nervi optici, where the optic canal bulges into the wall of the cell.

## Roof of the ethmoid

The ethmoid bone is open superiorly; the roof is closed by the orbital plate of the frontal bone. Ethmoidal air cells indent this plate; each one is a 'fovea ethmoidalis'. The thin, lateral cribriform lamella (one of the thinnest parts of the cranial base) forms the medial wall of the roof, extending from the middle turbinate to the cribriform plate, and the lateral wall of the olfactory fossa or niche. The olfactory fossa varies in depth and is frequently asymmetrical; it is at risk during sinus surgery.

## Uncinate process

The uncinate process in a thin, hook-shaped bone that articulates with the perpendicular plate of the palatine bone and the ethmoidal process of the inferior concha. Its posterosuperior margin is free, forming the hiatus semilunaris with the ethmoidal bulla. It may sometimes reflect medially into the middle meatus and usually overlies the ostium of the maxillary sinus. It is frequently removed during sinus surgery (Becker 1994).

## Vascular supply and innervation

The ethmoidal sinuses receive their arterial supply from nasal branches of the sphenopalatine artery and the anterior and posterior ethmoidal branches of the ophthalmic artery. Venous drainage is by the corresponding veins. The lymphatics of the anterior group drain to the submandibular nodes, and those of the posterior group to the retropharyngeal nodes. The sinuses are innervated by the anterior and posterior ethmoidal branches of the ophthalmic nerves (general sensation) and the orbital branches of the pterygopalatine ganglia (parasympathetic secretomotor fibres).

## MAXILLARY SINUS

The maxillary sinus is the largest of the paranasal sinuses. It usually fills the body of the maxilla and is pyramidal in shape (see Figs 30.8B, 33.13, 33.17; Fig. 33.22). The base is medial and forms much of the lateral wall of the nasal cavity. The floor, which often lies below the nasal floor, is formed by the alveolar process and part of the palatine process of the maxilla. It is related to the roots of the teeth, especially the second premolar and first molar, but may extend posteriorly to the third molar tooth and/or anteriorly to incorporate the first premolar, and sometimes the canine. Defects in the bone overlying the roots are

Fig. 33.19 A, A coronal CT demonstrating a normal right-sided sphenoidal sinus and a small left-sided sphenoidal sinus (S). The left sphenoethmoidal cell is also shown (asterisk). Pneumatization of the left anterior clinoid process (green arrow) means that the optic nerve (yellow arrow) lies exposed within the sphenoethmoidal cell. The foramen rotundum (blue arrow) and pterygoid (Vidian) canal (red arrow) can also be seen. B, An endoscopic view of a right Onodi cell; the optic nerve is visible in the posterolateral wall of the cell (asterisk). C, A coronal CT demonstrating well-pneumatized sphenoidal sinuses. The foramen rotundum (asterisk) and internal carotid artery (arrow) are also shown. D, A sagittal CT demonstrating the sphenoidal sinus (S), pituitary fossa (arrow) and posterior sphenoethmoidal cell (asterisk).

Fig. 33.20 A, The anterior ethmoidal air cells (E). B, An endoscopic view showing a partially opened agger nasi cell (asterisk). C, An infraorbital ethmoidal cell (Haller cell, asterisk), seen as a variation of anterior ethmoidal anatomy.

Fig. 33.21 A, A coronal CT demonstrating the posterior ethmoidal cells.
A bony spur can be seen in the nasal septum. B, The posterior ethmoidal air cells and the sphenoethmoidal recess (arrow).
not uncommon. The roof of the sinus forms the major part of the floor of the orbit. It contains the infraorbital canal, which may exhibit dehiscences. The lateral truncated apex of the pyramid extends into the zygomatic process of the maxilla, and may reach the zygomatic bone, in which case it forms the zygomatic recess, which throws a V-shaped shadow over the antrum on a lateral radiograph.

The facial surface of the maxilla forms its anterior wall, and is grooved internally by a delicate canal (canalis sinuosus) that houses the anterior superior alveolar nerve and vessels as they pass forwards from the infraorbital canal. The posterior wall is formed by the infratemporal surface of the maxilla; it contains alveolar canals that may produce ridges in the sinus and that also conduct the posterior superior alveolar vessels and nerves to the molar teeth. The medial wall is deficient posterosuperiorly at the maxillary hiatus, a large opening that is partially closed in an articulated skull by portions of the perpendicular plate of the palatine bone, the uncinate process of the ethmoid bone, the inferior nasal concha, the lacrimal bone and the overlying nasal mucosa, to form an ostium and anterior and posterior fontanelles. The ostium usually opens into the inferior part of the ethmoidal infundibulum, and thence into the middle meatus, via the hiatus semilunaris (the hiatus forms the area above the superior edge of the uncinate process). The ostium is not normally visible on examination of the nose, without prior resection of the uncinate process. The fontanelles are covered only by periosteum and mucosa, and may contain accessory ostia that may be visible on nasendoscopy and CT. All of the openings are nearer the roof than the floor of the sinus, which means that the natural drainage of the maxillary sinus is reliant on an intact mucociliary escalator; the cilia of the sinus mucoperiosteum normally beat towards the ostium.

The maxillary sinus may be incompletely divided by septa; complete septa are very rare. The thinness of its walls is clinically significant in determining the spread of tumours from the maxillary sinus. A tumour may push up the orbital floor and displace the eyeball; project into the nasal cavity, causing nasal obstruction and bleeding; protrude on to the cheek, causing swelling and numbness if the infraorbital nerve is damaged; spread back into the infratemporal fossa, causing restriction of mouth opening due to pterygoid muscle damage and pain; or spread down into the mouth, loosening teeth and causing malocclusion. Extraction of molar teeth may damage the floor, and impact may fracture its walls. Rarely, hypoplasia of one maxillary antrum is present.

## Ostiomeatal complex

The term ostiomeatal complex, or ostiomeatal unit, refers to the area that includes the maxillary sinus ostium, ethmoidal infundibulum and the hiatus semilunaris (see Fig. 33.17); it is a functional complex rather than a clearly defined anatomical structure (see Fig. 33.22A). The complex is the common pathway for drainage of secretions from the maxillary and anterior group of ethmoidal sinuses; where the uncinate process attaches to the lateral nasal wall, the complex also drains the frontal sinus.

## Vascular supply, lymphatic drainage and innervation

The arterial supply of the maxilla is derived mainly from the maxillary arteries via the anterior, middle and posterior superior alveolar branches and from the infraorbital and greater palatine arteries. Branches of the
posterior superior alveolar artery and the infraorbital artery form an anastomosis in the bony wall of the sinus, which also supplies the mucous membrane that lines the nasal chambers. An extraosseous anastomosis frequently exists between the posterior superior alveolar artery and the infraorbital artery. The intra- and extraosseous anastomoses form a double arterial arcade that supplies the lateral antral wall and, partly, the alveolar process. Veins corresponding to the arteries drain into the facial vein or pterygoid venous plexus on either side. Lymph drainage is to the submandibular nodes. The sinuses are innervated by the infraorbital and anterior, middle and posterior superior alveolar branches of the maxillary nerves (general sensation), and nasal branches of the pterygopalatine ganglia (parasympathetic secretomotor fibres).

## IMAGING OF THE PARANASAL SINUSES

Standard radiological images are no longer recommended in the diagnosis of rhinosinusitis because of their poor specificity and sensitivity, although they may be used to confirm the presence of acute frontal or maxillary sinusitis that has failed to respond to medical treatment and requires urgent drainage. CT defines anatomical variations but should not be used in isolation for diagnosis because 1 in 3 asymptomatic individuals show incidental mucosal changes. Spiral CT provides goodquality axial, coronal and sagittal images that facilitate an appreciation of the size and relationship of the paranasal sinuses (Fig. 33.23).

## SPREAD OF INFECTION FROM THE SINUSES

Uncontrolled paranasal sinus infection can cause very significant morbidity. In the pre-antibiotic era, it was often associated with mortality from meningitis and brain abscess. Paranasal sinus infection has the potential to spread to the orbit, cavernous sinuses, meninges and brain. The ability to overcome infection at this site depends on the virulence of the infecting organism, the speed with which appropriate treatment is delivered, innate immunity and individual anatomical aspects of the sinuses that may predispose to spread of infection. Normal mucociliary clearance of the nasal and paranasal mucosa becomes paralysed or uncoordinated very quickly with the onset of infection and patent or potentially patent drainage pathways become paramount. The middle meatus forms the common drainage pathway for the anterior ethmoidal, frontal and maxillary sinuses. The posterior ethmoidal and sphenoidal sinuses drain into the superior meatus and sphenoethmoidal recess. Endoscopic examination will usually show infected mucus draining from these areas in this situation (Simmen and Jones 2005).

The bony walls of the sinuses are paper-thin in places and dehiscences of them, particularly of the lamina papyracea and cribriform plate of the ethmoids, the lateral wall of the sphenoid, and the orbital and posterior walls of the frontal sinus, bring infected sinus mucosa into direct contact with orbital periosteum, the dura of the anterior cranial fossa and the cavernous sinus. Septic thrombophlebitis then develops and infection spreads rapidly by this route. Sequelae can include blindness, intra- and extradural collections, cavernous sinus thrombosis, meningitis, frontal lobe abscess and osteomyelitis of the cranial vault if diploic veins are involved.

## Pharynx

The pharynx is a $12-14 \mathrm{~cm}$ long musculomembranous tube shaped like an inverted cone. It extends from the cranial base to the lower border of the cricoid cartilage (the level of the sixth or seventh cervical vertebra), where it becomes continuous with the oesophagus. The width of the pharynx varies constantly because it is dependent on muscle tone, especially of the constrictors; at rest, the pharyngo-oesophageal junction is closed as a result of tonic closure of the upper oesophageal sphincter, and during sleep, muscle tone is low and the dimensions of the pharynx are markedly decreased (which may give rise to snoring and sleep apnoea). The pharynx is limited above by the posterior part of the body of the sphenoid and the basilar part of the occipital bone, and it is continuous with the oesophagus below. Behind, it is separated from the cervical part of the vertebral column and the prevertebral fascia, which covers longus colli and longus capitis, by loose connective tissue in the retropharyngeal space above and the retrovisceral space below.

The muscles of the pharynx are three circular constrictors and three longitudinal elevators. The constrictors may be thought of as three overlapping cones that arise from structures at the sides of the head and neck, and pass posteriorly to insert into a midline fibrous band, the pharyngeal raphe. The arterial supply to the pharynx is derived from
branches of the external carotid artery, particularly the ascending pharyngeal artery, but also from the ascending palatine and tonsillar branches of the facial artery, the maxillary artery (greater palatine and pharyngeal arteries and the artery of the pterygoid canal) and dorsal lingual branches of the lingual artery. The pharyngeal veins begin in a plexus external to the pharynx, receive meningeal veins and a vein from the pterygoid canal, and usually end in the internal jugular vein. Lymphatic vessels from the pharynx and cervical oesophagus pass to the deep cervical nodes, either directly or through the retropharyngeal or paratracheal nodes. The motor and sensory innervation is principally via branches of the pharyngeal plexus.

The pharynx lies behind, and communicates with, the nasal, oral and laryngeal cavities via the nasopharynx, oropharynx and laryngopharynx, respectively (Figs 34.1-34.2). Its lining mucosa is continuous with that lining the pharyngotympanic tubes, nasal cavity, mouth and larynx. The retropharyngeal and parapharyngeal spaces surround the pharynx; the retropharyngeal space lies anterior to the prevertebral and alar fascia and thus to the alar, danger space that lies between them. For further reading, including reviews of some of the more important historical literature, see Flint et al (2010), Graney et al (1998), Hollinshead (1982), Wood-Jones (1940).

## NASOPHARYNX

## Boundaries

The nasopharynx lies above the soft palate and behind the posterior nares, which allow free respiratory passage between the nasal cavities and the nasopharynx (see Figs 34.1-34.2). The nasal septum separates
the two posterior nares, each of which measures approximately 25 mm vertically and 12 mm transversely. Just within these openings lie the posterior ends of the inferior and middle nasal conchael/turbinates (Ch. 33). The nasopharynx has a roof, a posterior wall, two lateral walls and a floor. These are rigid (except for the floor, which can be raised or lowered by the soft palate), and the cavity of the nasopharynx is therefore never obliterated by muscle action, unlike the cavities of the oro- and laryngopharynx. The nasal and oral parts of the pharynx

Fig．34．3 A，The interior of the pharynx，exposed by removal of the mucous membrane，sagittal section．The bodies of the cervical vertebrae have been removed，the cut posterior wall of the pharynx retracted dorsolaterally and palatopharyngeus reflected dorsally to show the cranial fibres of the inferior constrictor．The dorsum of the tongue has been pulled ventrally to display a part of styloglossus in the angular interval between the mandibular and the lingual fibres of origin of the superior constrictor．B，Muscles of the left half of the soft palate and adjoining part of the pharyngeal wall，sagittal section．
communicate through the pharyngeal isthmus，which lies between the posterior border of the soft palate and the posterior pharyngeal wall． Elevation of the soft palate and constriction of the palatopharyngeal sphincter close the isthmus during swallowing．

The roof and posterior wall form a continuous concave slope that leads down from the nasal septum to the oropharynx．It is bounded above by mucosa overlying the posterior part of the body of the sphen－ oid，and further back by the basilar part of the occipital bone as far as the pharyngeal tubercle．Further down，the mucosa overlies the pharyn－ gobasilar fascia and the upper fibres of the superior constrictor，and behind these，the anterior arch of the atlas．A lymphoid mass，the pha－ ryngeal tonsil（adenoid，nasopharyngeal tonsil），lies in the mucosa of the upper part of the roof and posterior wall in the midline．

The lateral walls of the nasopharynx display a number of important surface features．On either side，each receives the opening of the pha－ ryngotympanic tube（auditory or Eustachian tube），situated $10-12 \mathrm{~mm}$ behind and a little below the level of the posterior end of the inferior nasal concha（see Fig．34．2）．The tubal aperture is approximately trian－ gular in shape，and is bounded above and behind by the tubal elevation that consists of mucosa overlying the protruding pharyngeal end of the cartilage of the pharyngotympanic tube．A vertical mucosal fold，the salpingopharyngeal fold，descends from the tubal elevation behind the aperture（see Fig．34．2）and covers salpingopharyngeus in the wall of the pharynx（Fig．34．3）；a smaller salpingopalatine fold extends from the anterosuperior angle of the tubal elevation to the soft palate in front of the aperture．As levator veli palatini enters the soft palate，it produces an elevation of the mucosa immediately around the tubal opening（see Fig．34．3）．A small variable mass of lymphoid tissue，the tubal tonsil， lies in the mucosa immediately behind the opening of the pharyngo－ tympanic tube．Further behind the tubal elevation is a variable depres－ sion in the lateral wall，the lateral pharyngeal recess（fossa of Rosenmüller），located between the posterior wall of the nasopharynx and the salpingopharyngeal fold．The floor of the nasopharynx is formed by the nasal，upper surface of the soft palate．

The relations of the nasopharynx are important in understanding the spread of nasopharyngeal carcinoma（Chong and Ong 2008）．The mucosa of the nasopharynx is separated from the masticator space by the parapharyngeal space．The carotid sheath，containing the carotid space，lies posterior and lateral to the parapharyngeal space．The
glossopharyngeal，vagus，accessory and hypoglossal nerves lie within the upper part of the carotid sheath and they come to lie within the superior part of the parapharyngeal space，along with the sympathetic chain．The foramen lacerum lies superolateral to the fossa of Rosen－ müller；in life，the foramen is closed by cartilage，over which the internal carotid artery runs．The foramen ovale，which transmits the mandibular division of the trigeminal nerve，lies still further laterally；the mandibu－ lar nerve passes through the parapharyngeal space and then the masti－ cator space in order to innervate the muscles of mastication．The retropharyngeal space is posterior to the nasopharynx．

Microstructure of non－tonsillar nasopharynx The nasopha－ ryngeal epithelium anteriorly is ciliated，pseudostratified respiratory in type with goblet cells（see Fig．2．2D）．The ducts of mucosal and sub－ mucosal seromucous glands open on to its surface．Posteriorly，the respiratory epithelium changes to non－keratinized stratified squamous epithelium which continues into the oropharynx and laryngopharynx． The transitional zone between the two types of epithelium consists of columnar epithelium with short microvilli instead of cilia．Superiorly， this zone meets the nasal septum；laterally，it crosses the orifice of the pharyngotympanic tube；and it passes posteriorly at the union of the soft palate and the lateral wall．Numerous mucous glands surround the tubal orifices．

Innervation Much of the mucosa of the nasopharynx behind the pharyngotympanic tube is supplied by the pharyngeal branch of the pterygopalatine ganglion，which traverses the palatovaginal canal with a pharyngeal branch of the maxillary artery．

## PHARYNGEAL TONSIL

The pharyngeal tonsil（adenoid，nasopharyngeal tonsil）is a median mass of mucosa－associated lymphoid tissue（MALT；see Ch．4）situated in the roof and posterior wall of the nasopharynx（Fig．34．4）．At its maximal size（during the early years of life），it is shaped like a truncated pyramid，often with a vertically orientated median cleft，so that its apex points towards the nasal septum and its base to the junction of the roof and posterior wall of the nasopharynx（Papaioannou et al 2013）．

Fig. 34.4 A, A pharyngeal tonsil following adenoidectomy by curettage. The rostral surface is to the left; surface folds radiate forwards from a median recess (arrow). In this example, the impression left by contact with the left Eustachian cushion is evident laterally (arrowhead). B, A transnasal endoscopic view of a pharyngeal tonsil. Key: 1, pharyngeal tonsil (in posterior naris); 2,
inferior concha (posterior view); 3, posterior end of nasal septum. (A, Specimen provided by Professor MJ Gleeson, School of Medicine, King's College London. B, Courtesy of Mr Simon A Hickey.)

The free surface of the pharyngeal tonsil is marked by folds that radiate forwards and laterally from a median blind recess, the pharyngeal bursa (bursa of Luschka), which extends backwards and up. The recess is present in the fetus and the young but only occasionally present in the adult, and marks the rostral end of the embryological notochord. The number and position of the folds and of the deep fissures that separate them vary. A median fold may pass forwards from the pharyngeal bursa towards the nasal septum, or instead a fissure may extend forwards from the bursa, dividing the nasopharyngeal tonsil into two distinct halves that reflect its paired developmental origins (see Fig. 34.4).

The prenatal origins of the pharyngeal tonsil are described on page 615. After birth, it initially grows rapidly, but usually undergoes a degree of involution and atrophy from the age of 8-10 years (although hypoplasia may still occur in adults up to the seventh decade). Relative to the volume of the nasopharynx, the size of the tonsil is largest at 5 years, which may account for the frequency of nasal breathing problems in preschool children, and the incidence of adenoidectomy in this age group.

Vascular supply and lymphatic drainage The arterial supply of the pharyngeal tonsil is derived from the ascending pharyngeal and ascending palatine arteries, the tonsillar branches of the facial artery, the pharyngeal branch of the maxillary artery and the artery of the pterygoid canal (see Figs 34.6-34.7). In addition, a nutrient or emissary vessel to the neighbouring bone, the basisphenoidal artery, which is a branch of the inferior hypophysial arteries, supplies the bed of the pharyngeal tonsil and is a possible cause of persistent postadenoidectomy haemorrhage in some patients.

Numerous communicating veins drain the pharyngeal tonsil into the internal submucous and external pharyngeal venous plexuses. They emerge from the deep lateral surface of the tonsil and join the external palatine (paratonsillar) veins, and pierce the superior constrictor either to join the pharyngeal venous plexus, or to unite to form a single vessel that enters the facial or internal jugular vein; they may also connect with the pterygoid venous plexus.

Microstructure The pharyngeal tonsil is covered laterally and inferiorly mainly by ciliated respiratory epithelium that contains scattered small patches of non-keratinized stratified squamous epithelium. Its superior surface is separated from the periosteum of the sphenoid and occipital bones by a connective tissue hemicapsule. The fibrous framework of the tonsil, consisting of a mesh of collagen type III (reticular) fibres supporting a lymphoid parenchyma similar to that in the palatine tonsil, is anchored to the hemicapsule.

The nasopharyngeal epithelium lines a series of mucosal folds around which the lymphoid parenchyma is organized into follicles and extrafollicular areas. Internally, the tonsil is subdivided into 4-6 lobes by connective tissue septa, which arise from the hemicapsule and penetrate the lymphoid parenchyma. Seromucous glands lie within the connective tissue, and their ducts extend through the parenchyma to reach the nasopharyngeal surface.

Functions The pharyngeal tonsil forms part of the circumpharyngeal lymphoid ring (Waldeyer's ring) and therefore presumably contributes to the defence of the upper respiratory tract. The territories served by its lymphocytes are uncertain but may include the nasal cavities, nasopharynx, pharyngotympanic tubes and the middle and inner ears.

Adenoidectomy Surgical removal of the pharyngeal tonsil (adenoid) is commonly performed to clear nasopharyngeal obstruction and as part of the treatment of chronic secretory otitis media. A variety of methods are employed, including suction diathermy, suction micro-
debridement and, most commonly, blind curettage. When using the latter, it is important to avoid hyperextension of the cervical spine, as this throws the arch of the atlas into prominence and may result in damage to the prevertebral fascia and anterior spinal ligaments, with resultant infection and cervical instability. Extreme lateral curettage can result in damage to the tubal orifice and excessive bleeding because the vasculature is denser laterally. Removal of the pharyngeal tonsil in children can result in an impairment in the ability of the soft palate to close the pharyngeal isthmus fully (velopharyngeal insufficiency, VPI), causing excessive nasality of speech (Gray and Pinborough-Zimmerman 1998)

## PHARYNGOTYMPANIC TUBE

The pharyngotympanic tube (see Figs 34.9A, B, 37.6-37.7) connects the tympanic cavity to the nasopharynx. It has several functions related to maintaining the health of the middle ear, including pressure equalization on both aspects of the tympanic membrane, mucociliary clearance and 'drainage', and protection from the influences of the nasopharyngeal environment and loud sounds. Approximately 36 mm long, it descends anteromedially from the tympanic cavity to the nasopharynx at an angle of approximately $45^{\circ}$ with the sagittal plane and $30^{\circ}$ with the horizontal (these angles increase with age and elongation of the cranial base). It is formed partly by cartilage and fibrous tissue, and partly by bone.

The cartilaginous part, which is approximately 24 mm long, is formed by a triangular plate of cartilage, the greater part of which is in the posteromedial wall of the tube. Its apex is attached by fibrous tissue to the circumference of the jagged rim of the bony part of the tube, and its base is directly under the mucosa of the lateral nasopharyngeal wall, forming a tubal elevation (torus tubarius; Eustachian cushion) behind the pharyngeal orifice of the tube (see Fig. 31.1). The upper part of the cartilage is bent laterally and downwards, producing a broad medial lamina and narrow lateral lamina. In transverse section, it is hook-like and incomplete below and laterally, where the canal is composed of fibrous tissue. The cartilage is fixed to the cranial base in the groove between the petrous part of the temporal bone and the greater wing of the sphenoid, and ends near the root of the medial pterygoid plate. In adults, the cartilaginous and bony parts of the tube are not in the same plane, the former descending a little more steeply than the latter. The diameter of the tube is greatest at the pharyngeal orifice and least at the junction of the two parts (the isthmus), increasing again towards the tympanic cavity. At birth, the pharyngotympanic tube is about half its adult length; it is more horizontal and its bony part is relatively shorter but much wider.

The bony part, approximately 12 mm long, is oblong in transverse section, with its greater dimension in the horizontal plane. It starts from the anterior tympanic wall and gradually narrows to end at the junction of the squamous and petrous parts of the temporal bone, where it has a jagged margin for the attachment of the cartilaginous part. The carotid canal lies medially.

The mucosa of the pharyngotympanic tube is continuous with the nasopharyngeal and tympanic mucosae. The bony canal is lined by a prolongation of the low cuboidal, ciliated mucosa that lines the middle ear. The histology changes to pseudostratified, ciliated, columnar epithelium typical of the upper respiratory tract after the bony/cartilaginous junction. Within the cartilaginous tube, the floor contains numerous mucus-producing goblet cells and is heavily rugated, whereas the walls in the upper half of the tube contain fewer goblet cells and are generally smooth. Mucosal folding is a feature of the childhood tube; the increased surface area and concomitant increased numbers of ciliated

Thornwaldt's cyst is an embryonic remnant of the persisting cranial end of the notochord that sometimes develops if the pharyngeal bursa is occluded (Fig. 34.5). Usually benign and asymptomatic, these cysts can become infected; symptoms include halitosis, occipital headache and postnasal drip (Yuca and Varsak 2012).

Fig. 34.5 Thornwaldt's cyst. A, axial view; B, sagittal view.
cells are presumed to facilitate improved clearance of the mucociliary blanket. Folds decrease with age up to the age of 20 years, when adult characteristics are reached. Mucous glands predominate in neonates; mucous, serous and mixed glands are present in equal amounts in young children; and serous glands predominate in later life (Orita et al 2002). The smoothness of the wall in the upper half of the tube may function in pressure equalization and gas exchange. The pharyngeal orifice is a narrow slit, level with the palate and without a tubal elevation. A lymphoid mass, the tubal tonsil, is found near the pharyngeal orifice; it is variable and sometimes considerable. (For further reading see Sade (1989), Bluestone (1998), O'Reilly and Sando (2010).)

Relations Salpingopharyngeus is attached to the inferior part of the cartilaginous tube near its pharyngeal opening. Posteromedially are the petrous part of the temporal bone and levator veli palatini, which arises partly from the medial lamina of the tube. Anterolaterally, tensor veli palatini separates the tube from the otic ganglion, the mandibular nerve and its branches, the chorda tympani nerve and the middle meningeal artery.

Vascular supply The osseous part of the pharyngotympanic tube is supplied by the tubal artery (a branch of the accessory meningeal artery) and the caroticotympanic branches of the internal carotid artery. The cartilaginous part of the tube is supplied by the deep auricular and pharyngeal branches of the maxillary artery, the ascending palatine artery (usually a branch of the facial artery but sometimes branching directly from the external carotid artery) and the ascending pharyngeal branch of the external carotid artery. The veins of the pharyngotympanic tube usually drain to the pterygoid venous plexus.

Innervation The pharyngotympanic tube is innervated by filaments from the tympanic plexus and from the pharyngeal branch of the pterygopalatine ganglion. The tympanic plexus ramifies on the promontory in the middle ear cavity and is formed by the tympanic branch of the glossopharyngeal nerve and caroticotympanic nerves of sympathetic origin (see Fig. 37.13).

Equalization of pressure At rest, the cartilaginous part of the pharyngotympanic tube is closed at the nasopharyngeal orifice. In normal individuals, the tube opens in order to equalize middle ear pressure to ambient pressure. Analysis of slow-motion video-endoscopy reveals four stages in tubal opening. Initially, the soft palate is elevated, the lateral pharyngeal wall moves medially and the medial lamina of the pharyngotympanic tube rotates medially (levator veli palatini is thought to open the distal part of the tube). The lateral wall of the pharyngotympanic tube moves laterally, so that the orifice is dilated both laterally and vertically. Tubal dilation propagates from distal to proximal by the action of dilator tubae. Finally, the proximal cartilaginous tube adjacent to the junctional region opens. Opening usually lasts for $0.3-0.5 \mathrm{sec}$ but is prolonged during yawning. Closure depends on adhesion of the intraluminal mucous blanket, elastic forces of the supporting tissues, and hydrostatic pressure of venous blood.

## OROPHARYNX

## Boundaries

The oropharynx extends from below the soft palate to the upper border of the epiglottis (see Figs 34.1-34.2). It opens into the mouth through the oropharyngeal isthmus, demarcated by the palatoglossal arch, and faces the pharyngeal aspect of the tongue. Its lateral wall consists of the palatopharyngeal arch and palatine tonsil (see Fig. 31.3). Posteriorly, it is level with the bodies of the second, and upper part of the third, cervical vertebrae (see Fig. 34.2).

## SOFT PALATE

The soft palate is a mobile flap suspended from the posterior border of the hard palate, sloping down and back between the oral and nasal parts of the pharynx (see Figs 34.2-34.3). The boundary between the hard and soft palate is readily palpable and may be distinguished by a change in colour, the soft palate being a darker red with a yellowish tint. The soft palate is a thick fold of mucosa enclosing an aponeurosis, muscular tissue, vessels, nerves, lymphoid tissue and mucous glands; almost half its thickness is represented by numerous mucous glands that lie between the muscles and the oral surface of the soft palate. The latter is covered by a stratified squamous epithelium, while the nasal
surface is covered with a ciliated columnar epithelium. Taste buds are found on the oral aspect of the soft palate.

In most individuals, two small pits, the fovea palatini, may be seen, one on each side of the midline; they represent the orifices of ducts from some of the minor mucous glands of the palate. In its usual relaxed and pendant position, the anterior (oral) surface of the soft palate is concave and has a median raphe. The posterior aspect is convex and continuous with the nasal floor, the anterosuperior border is attached to the posterior margin of the hard palate, and the sides blend with the pharyngeal wall. The inferior border is free and hangs between the mouth and pharynx. A median conical process, the uvula, projects downwards from its posterior border (see Fig. 31.3). It may be congenitally bifid and associated with submucous cleft palate, hypoplastic orifice of the pharyngotympanic tube and absence of the salpingopharyngeal folds.

The anterior third of the soft palate contains little muscle and consists mainly of the palatine aponeurosis. This region is less mobile and more horizontal than the rest of the soft palate and is the chief area acted on by tensor veli palatini.

A small bony prominence, produced by the pterygoid hamulus, can be felt just behind and medial to each upper alveolar process, in the lateral part of the anterior region of the soft palate. The pterygomandibular raphe (a tendinous band between buccinator and the superior constrictor) passes downwards and outwards from the hamulus to the posterior end of the mylohyoid line (see Fig. 34.8). When the mouth is opened wide, this raphe raises a fold of mucosa that indicates the internal, posterior boundary of the cheek; it is an important landmark for an inferior alveolar nerve block (Ch. 31). (For further reading, see Wood-Jones (1940).)
Palatine aponeurosis A thin, fibrous, palatine aponeurosis, composed of the expanded tendons of the tensor veli palatini muscles, strengthens the soft palate. It is attached to the posterior border and inferior surface of the hard palate behind any palatine crests, and extends medially from behind the greater palatine foramina. It is thick in the anterior two-thirds of the soft palate but very thin further back. Near the midline, it encloses the musculus uvulae. All the other palatine muscles are attached to the aponeurosis.

Palatoglossal and palatopharyngeal arches The lateral wall of the oropharynx presents two prominent folds, the palatoglossal and palatopharyngeal folds (anterior and posterior pillars of the fauces, respectively) (see Figs 31.3, 34.6). The palatoglossal arch, the anterior fold, runs from the soft palate to the side of the tongue and contains palatoglossus. The palatopharyngeal arch, the posterior fold, projects more medially and passes from the soft palate to merge with the lateral wall of the pharynx; it contains palatopharyngeus. A triangular tonsillar fossa (tonsillar sinus) lies on each side of the oropharynx between the diverging palatopharyngeal and palatoglossal arches, and contains the palatine tonsil.

Vascular supply The arterial supply of the soft palate is usually derived from the ascending palatine branch of the facial artery. Sometimes, this is replaced or supplemented by a branch of the ascending pharyngeal artery, which descends forwards between the superior border of the superior constrictor and levator veli palatini, and accompanies the latter to the soft palate. The veins of the soft palate usually drain to the pterygoid venous plexus.

Innervation General sensation from most of the soft palate is carried by branches of the lesser palatine nerve (a branch of the maxillary nerve) and from the posterior part of the palate by pharyngeal branches from the glossopharyngeal nerve and from the plexus around the tonsil (formed by tonsillar branches of the glossopharyngeal and lesser palatine nerves). The special sensation of taste from taste buds in the oral surface of the soft palate is carried in the lesser palatine nerve; the taste fibres initially travel in the greater petrosal nerve (a branch of the facial nerve) and pass through the pterygopalatine ganglion without synapsing. The lesser palatine nerve also carries the secretomotor supply to most of the mucosa of the soft palate, via postganglionic branches from the pterygopalatine ganglion. Postganglionic secretomotor parasympathetic fibres may pass to the posterior parts of the soft palate from the otic ganglion (which receives preganglionic fibres via the lesser petrosal branch of the glossopharyngeal nerve). Postganglionic sympathetic fibres run from the carotid plexus along arterial branches supplying the palate.

## Uvulopalatopharyngoplasty

The pharyngeal airway is kept patent in awake individuals by the combined dilating action of genioglossus, tensor veli palatini, geniohyoid and stylohyoid, which act to counter the negative pressure generated in the lumen of the pharynx during inspiration. The tone in the muscles is reduced during sleep, and is also affected by alcohol and other sedatives, hypothyroidism and a variety of neurological disorders. If the dilator muscle tone is insufficient, the walls of the pharynx may become apposed. Intermittent pharyngeal obstruction may cause snoring, and complete obstruction may cause apnoea, hypoxia and hypercarbia, which lead to arousal and sleep disturbance. Obstructive sleep apnoea (OSA) is a serious syndrome affecting up to $4 \%$ of middle-aged people; it has potentially life-threatening consequences. The pathophysiological causes of OSA include an anatomically small upper airway, in which augmented pharyngeal dilator muscle activation can maintain airway patency when the individual is awake but not when asleep, coupled with instability in the respiratory control system. Individuals with OSA may demonstrate some or all of the following anatomical features: an increase in soft palate length and thickness; a shortened mandible; a lowered hyoid bone position; and increases in the volume of fat in soft palate and parapharyngeal fat pads in the retropalatal and retroglossal region. While these studies differ in their assessment of the relative incidence and significance of these factors, they all confirm that the anatomical changes in OSA have the combined effect of both narrowing and shortening the airway. At the same time, physiological mechanisms that exist to ensure that the airways remain dilated and patent seem to suffer a sleep-induced fall in activity in OSA sufferers. The muscles primarily responsible for maintaining a dilated airway under normal conditions are the muscles affecting the position of the hyoid bone, the infrahyoid and suprahyoid muscles, the muscles of the tongue, especially genioglossus, and the muscles that move the soft palate. (For further reading, see Ison et al (1997), Fogel et al (2004), Johal et al (2007), Malhotra and White (2002).)

Surgical techniques involving reduction in the length of the soft palate, removal of the tonsils and plication of the tonsillar pillars can be used to raise the intrinsic dilating tone in the pharyngeal wall and to reduce the bulk of (and to stiffen) the soft palate. This will reduce the tendency of the soft palate to vibrate and generate noise during periods of incipient collapse of the pharynx. An alternative treatment is to deliver air to the pharynx at above atmospheric pressure via a closely fitting facemask, thus inflating the pharynx and countering its tendency to collapse.

Fig. 34.6 The tonsillar bed, sagittal section.

## PALATINE TONSIL

The right and left palatine tonsils form part of the circumpharyngeal lymphoid ring. Each tonsil is an ovoid mass of lymphoid tissue situated in the lateral wall of the oropharynx (Fig. 34.6; see Figs 31.3, 31.5). Size varies according to age, individuality and pathological status (tonsils may be hypertrophied and/or inflamed). It is therefore difficult to define the normal appearance of the palatine tonsil. For the first 5 or 6 years of life, the tonsils increase rapidly in size. They usually reach a maximum at puberty, when they average $20-25 \mathrm{~mm}$ in vertical, and $10-15 \mathrm{~mm}$ in transverse, diameters, and they project conspicuously into the oropharynx. Between the ages of 1 and 11 years, the tonsil and adenoid grow proportionally to the lower facial skeleton (Arens et al 2002). Tonsillar involution begins at puberty, when the reactive lymphoid tissue begins to atrophy, and by old age only a little tonsillar lymphoid tissue remains.

The long axis of the tonsil is directed from above, downwards and backwards. Its medial, free, surface usually presents a pitted appearance. The pits, $10-20$ in number, lead into a system of blind-ending, often highly branching, crypts that extend through the whole thickness of the tonsil and almost reach the connective tissue hemicapsule. In a healthy tonsil, the openings of the crypts are fissure-like and the walls of the crypt lumina are collapsed so that they are in contact with each other. The human tonsil is polycryptic. The branching crypt system reaches its maximum size and complexity during childhood. The mouth of a deep tonsillar cleft (intratonsillar cleft, recessus palatinus) opens in the upper part of the medial surface of the tonsil. It is often erroneously called the supratonsillar fossa, and yet it is not situated above the tonsil but within its substance. The mouth of the cleft is semilunar, curving parallel to the convex dorsum of the tongue in the sagittal plane. The upper wall of the recess contains lymphoid tissue that extends into the soft palate as the pars palatina of the palatine tonsil. After the age of 5 years, this embedded part of the tonsil diminishes in size. There is a tendency for the whole tonsil to involute from the age of 14 years, and for the tonsillar bed to flatten out. During young adult life, a mucosal fold, the plica triangularis, stretches back from the palatoglossal arch down to the tongue. It is infiltrated by lymphoid tissue and frequently represents the most prominent (anteroinferior) portion of the tonsil. It rarely persists into middle age.

The lateral or deep surface of the tonsil spreads downwards, upwards and forwards. Inferiorly, it invades the dorsum of the tongue; superiorly, it invades the soft palate; and, anteriorly, it may extend for some distance under the palatoglossal arch. This deep, lateral aspect is covered
by a layer of fibrous tissue, the tonsillar hemicapsule. The latter is separable with ease for most of its extent from the underlying muscular wall of the pharynx, which is formed here by the superior constrictor, and sometimes by the anterior fibres of palatopharyngeus, with styloglossus on its lateral side. Anteroinferiorly, the hemicapsule adheres to the side of the tongue and to palatoglossus and palatopharyngeus. In this region, the tonsillar artery, a branch of the facial artery, pierces the superior constrictor to enter the tonsil, accompanied by venae comitantes. An important and sometimes large vein, the external palatine or paratonsillar vein, descends from the soft palate lateral to the tonsillar hemicapsule before piercing the pharyngeal wall. Haemorrhage from this vessel from the upper angle of the tonsillar fossa may complicate tonsillectomy. The muscular wall of the tonsillar fossa separates the tonsil from the ascending palatine artery, and, occasionally, from the tortuous facial artery itself, which may lie near the pharyngeal wall at the lower tonsillar level. The glossopharyngeal nerve lies immediately lateral to the muscular wall of the tonsillar fossa (see Figs 34.3A, 34.6); it is at risk if the wall is pierced, and is commonly temporarily affected by oedema following tonsillectomy. The internal carotid artery lies approximately 25 mm behind and lateral to the tonsil. In some individuals, the styloid process may be elongated and deviate towards the tonsillar bed.

## Microstructure

Each tonsil is a mass of lymphoid tissue associated with the oropharyngeal mucosa and fixed in its position, unlike most other examples of mucosa-associated lymphoid tissue. It is covered on its oropharyngeal aspect by non-keratinized stratified squamous epithelium. The whole of the tonsil is supported internally by a delicate meshwork of fine collagen type III (reticulin) fibres which are condensed in places to form more robust connective tissue septa that also contain elastin. These septa partition the tonsillar parenchyma, and merge at their ends with the dense irregular fibrous hemicapsule on the deep aspect of the tonsil and with the lamina propria on the pharyngeal surface. Blood vessels, lymphatics and nerves branch or join within the connective tissue condensations. The hemicapsule forms its lateral boundary with the oropharyngeal wall, and with the mucosa that covers its highly invaginated free surface.

The 10-20 crypts formed by invagination of the free surface mucosa are narrow tubular epithelial diverticula that often branch within the tonsil and frequently are packed with plugs of shed epithelial cells, lymphocytes and bacteria, which may calcify. The epithelium lining the crypts is mostly similar to that of the oropharyngeal surface, i.e. stratified squamous, but there are also patches of reticulated epithelium, which is much thinner, and which has a complex structure that is of great importance in the immunological function of the tonsil.

Reticulated epithelium Reticulated epithelium lacks the orderly laminar structure of stratified squamous epithelium. Its base is deeply invaginated in a complex manner so that the epithelial cells, with their slender branched cytoplasmic processes, provide a coarse mesh to accommodate the infiltrating lymphocytes and macrophages. The basal lamina of this epithelium is discontinuous. Although the oropharyngeal surface is unbroken, the epithelium may become exceedingly thin in places, so that only a tenuous cytoplasmic layer separates the pharyngeal lumen from the underlying lymphocytes. Epithelial cells are held together by small desmosomes, anchored into bundles of keratin filaments. Interdigitating dendritic cells (antigen-presenting cells, APCs) are also present (Ch. 4). The intimate association of epithelial cells and lymphocytes facilitates the direct transport of antigen from the external environment to the tonsillar lymphoid cells, i.e. reticulated epithelial cells are functionally similar to the microfold (M) cells of the gut. The total surface area of the reticulated epithelium is very large because of the complex branched nature of the tonsillar crypts, and has been estimated at $295 \mathrm{~cm}^{2}$ for an average palatine tonsil.

Tonsillar lymphoid tissue There are four lymphoid compartments in the palatine tonsils. Lymphoid follicles (Ch. 4), many with germinal centres, are arranged in rows roughly parallel to neighbouring connective tissue septa. Their size and cellular content varies in proportion to the immunological activity of the tonsil. The mantle zones of the follicles, each with closely packed small lymphocytes, form a dense cap, always situated on the side of the follicle nearest to the mucosal surface. These cells are the products of B-lymphocyte proliferation within the germinal centres. Extrafollicular, or T-lymphocyte, areas contain a specialized microvasculature including high endothelial venules (HEVs), through which circulating lymphocytes enter the tonsillar parenchyma. The lymphoid tissue of the reticulated crypt epithelium contains predominantly IgG- and IgA-producing B lymphocytes (including some

Fig. 34.7 The arterial supply to the palatine tonsil.
mature plasma cells), T lymphocytes and antigen-presenting cells. There are numerous capillary loops in this subsurface region.

## Vascular supply and lymphatic drainage

The arterial blood supply to the palatine tonsil is derived from branches of the external carotid artery (see Fig. 34.6; Fig. 34.7). Three arteries enter the tonsil at its lower pole. The largest is the tonsillar artery, which is a branch of the facial, or sometimes the ascending palatine, artery. It ascends between medial pterygoid and styloglossus, perforates the superior constrictor at the upper border of styloglossus, and ramifies in the tonsil and posterior lingual musculature. The other arteries found at the lower pole are the dorsal lingual branches of the lingual artery, which enter anteriorly, and a branch from the ascending palatine artery, which enters posteriorly to supply the lower part of the palatine tonsil. The upper pole of the tonsil also receives branches from the ascending pharyngeal artery, which enter the tonsil posteriorly, and from the descending palatine artery and its branches, the greater and lesser palatine arteries. All of these arteries enter the deep surface of the tonsil, branch within the connective tissue septa, narrow to become arterioles and then give off capillary loops into the follicles, interfollicular areas and the cavities within the base of the reticulated epithelium. The capillaries rejoin to form venules, many with high endothelia, and the veins return within the septal tissues to the hemicapsule as tributaries of the pharyngeal drainage. The tonsillar artery and its venae comitantes often lie within the palatoglossal fold, and may haemorrhage if this fold is damaged during surgery.

Unlike lymph nodes, the palatine tonsils do not possess afferent lymphatics or lymph sinuses. Instead, dense plexuses of fine lymphatic vessels surround each follicle and form efferent lymphatics, which pass towards the hemicapsule, pierce the superior constrictor, and drain to the upper deep cervical lymph nodes directly (especially the jugulodigastric nodes) or indirectly through the retropharyngeal lymph nodes. The jugulodigastric nodes are typically enlarged in tonsillitis, when they project beyond the anterior border of sternocleidomastoid and are palpable superficially $1-2 \mathrm{~cm}$ below the angle of the mandible; when enlarged, they represent the most common swelling in the neck.

## Innervation

The tonsillar region is innervated by tonsillar branches of the maxillary and glossopharyngeal nerves (see Fig. 34.6). The fibres from the maxil-
lary nerve pass through, but do not synapse in, the pterygopalatine ganglion; they are distributed through the lesser palatine nerves and form a plexus (the circulus tonsillaris) around the tonsil together with the tonsillar branches of the glossopharyngeal nerve. Nerve fibres from this plexus are also distributed to the soft palate and the region of the oropharyngeal isthmus. The tympanic branch of the glossopharyngeal nerve supplies the mucous membrane lining the tympanic cavity. Infection, malignancy and postoperative inflammation of the tonsil and tonsillar fossa may therefore be accompanied by pain referred to the ear.

## Tonsillectomy

Surgical removal of the pharyngeal tonsils is commonly performed to prevent recurrent acute tonsillitis or to treat airway obstruction by hypertrophied or inflamed palatine tonsils. Occasionally, the tonsil may be removed to treat an acute peritonsillar abscess, which is a collection of pus between the superior constrictor and the tonsillar hemicapsule. Many methods have been employed, the most common being dissection in the plane of the fibrous hemicapsule, followed by ligation or electrocautery to the vessels divided during the dissection. The nerve supply to the tonsil is so diffuse that tonsillectomy under local anaesthesia is performed successfully by local infiltration rather than by blocking the main nerves. Surgical access to the glossopharyngeal nerve may be achieved by separating the fibres of superior constrictor.

## Waldeyer's ring

Waldeyer's ring is a circumpharyngeal ring of mucosa-associated lymphoid tissue that surrounds the openings into the digestive and respiratory tracts. It is made up anteroinferiorly by the lingual tonsil, laterally by the palatine and tubal tonsils, and posterosuperiorly by the pharyngeal tonsil and smaller collections of lymphoid tissue in the intertonsillar intervals.

## LARYNGOPHARYNX

## Boundaries

The laryngopharynx is situated behind the entire length of the larynx (known clinically as the hypopharynx) and extends from the superior border of the epiglottis, where it is delineated from the oropharynx by the lateral glossoepiglottic folds, to the inferior border of the cricoid cartilage, where it becomes continuous with the oesophagus (see Figs $34.1-34.2$ ). The laryngeal inlet lies in the upper part of its incomplete anterior wall, and the posterior surfaces of the arytenoid and cricoid cartilages lie below this opening.

Piriform fossa A small piriform fossa lies on each side of the laryngeal inlet, bounded medially by the aryepiglottic fold and laterally by the thyroid cartilage and thyrohyoid membrane. Branches of the internal laryngeal nerve lie beneath its mucous membrane. At rest, the laryngopharynx extends posteriorly from the lower part of the third cervical vertebral body to the upper part of the sixth. During deglutition, it may be elevated considerably by the hyoid elevators.

Inlet of larynx The obliquely sloping inlet of the larynx lies in the anterior part of the laryngopharynx and is bounded above by the epiglottis, below by the arytenoid cartilages of the larynx, and laterally by the aryepiglottic folds (see Fig. 34.1). Below the inlet, the anterior wall of the laryngopharynx is formed by the posterior surface of the cricoid cartilage.

## PHARYNGEAL FASCIA

The two named layers of fascia in the pharynx are the pharyngobasilar and buccopharyngeal fascia. The fibrous layer that supports the pharyngeal mucosa is thickened above the superior constrictor to form the pharyngobasilar fascia (see Fig. 34.10). It is attached to the basilar part of the occipital bone and the petrous part of the temporal bone medial to the pharyngotympanic tube, and to the posterior border of the medial pterygoid plate and the pterygomandibular raphe. Inferiorly, it diminishes in thickness but is strengthened posteriorly by a fibrous band attached to the pharyngeal tubercle of the occipital bone, which descends as the median pharyngeal raphe of the constrictors. This fibrous layer is really the internal epimysial covering of the muscles and their aponeurotic attachment to the base of the skull. The thinner,
external part of the epimysium is the buccopharyngeal fascia, which covers the superior constrictor and passes forwards over the pterygomandibular raphe to cover buccinator.

## PHARYNGEAL TISSUE SPACES

Pharyngeal tissue spaces can be subdivided into peripharyngeal and intrapharyngeal spaces. The anterior part of the peripharyngeal space is formed by the submandibular and submental spaces, posteriorly by the retropharyngeal space and laterally by the parapharyngeal spaces. The retropharyngeal space is an area of loose connective tissue that lies behind the pharynx and anterior to the prevertebral fascia, extending upwards to the base of the skull and downwards to the retrovisceral space in the infrahyoid part of the neck. Each parapharyngeal space passes laterally around the pharynx and is continuous with the retropharyngeal space. However, unlike the retropharyngeal space, it is a space that is restricted to the suprahyoid region. It is bounded medially by the pharynx, laterally by the pterygoid muscles (where it is part of the infratemporal fossa) and by the sheath of the parotid gland, superiorly by the base of the skull, and inferiorly by suprahyoid structures, particularly the sheath of the submandibular gland; it may be helpful to think of it as shaped like an inverted pyramid extending from the base of the skull to the greater cornu of the hyoid bone. The parapharyngeal space is divided into an anterior, or prestyloid, compartment and a posterior, or retrostyloid, compartment (Maran et al 1984). The prestyloid compartment contains the retromandibular portion of the parotid gland, fat and lymph nodes. The retrostyloid compartment contains the internal carotid artery, the internal jugular vein, the glossopharyngeal, vagus, accessory and hypoglossal nerves, the sympathetic chain, fat and lymph nodes. Any of these structures may be damaged by penetrating injuries directed posterolaterally in the region; more lateral injuries may result in penetration of the parotid gland.

An intrapharyngeal space potentially exists between the inner surface of the constrictor muscles and the pharyngeal mucosa. Infections in this space either are restricted locally or spread through the pharynx into the retropharyngeal or parapharyngeal spaces. The peritonsillar space is an important part of the intrapharyngeal space; it lies around the palatine tonsil between the pillars of the fauces. Infections in the intratonsillar space usually spread up or down the intrapharyngeal space, or through the pharynx into the parapharyngeal space.

Tissue spaces between the layers of cervical fascia are described on page 446; tissue spaces around the larynx are described on page 594.

## SPREAD OF INFECTION

Infection that spreads into the parapharyngeal space will produce pain and trismus. There may be swelling in the oropharynx that extends up to the uvula, displacing it to the contralateral side, and dysphagia. Posterior spread from the parapharyngeal space into the retropharyngeal space will produce bulging of the posterior pharyngeal wall, dyspnoea and nuchal rigidity. Involvement of the carotid sheath may produce symptoms caused by thrombosis of the internal jugular vein and cranial nerve symptoms involving the glossopharyngeal, vagus, accessory and hypoglossal nerves. If the infection continues to spread unchecked, mediastinitis will ensue. A virulent infection in the retropharyngeal space may spread through the prevertebral fascia into the underlying danger space; infection in this tissue space may descend into the thorax and even below the diaphragm, and results in chest pain, severe dyspnoea and retrosternal discomfort.

Pharyngeal infection from mucosa-associated lymph tissues such as the palatine tonsil, or as a result of a penetrating injury (e.g. from an ingested foreign body), may result in the spread of infection into the tissue spaces of the neck adjacent to the pharynx. This is an extremely serious situation because there is potential for rapid spread throughout the neck and, more dangerously, to the superior mediastinum, to cause overwhelming life-threatening infection.

## PARAPHARYNGEAL SPACE TUMOURS

Tumours that develop in the parapharyngeal tissue space may remain asymptomatic for some time. When they do present, it may be with a diffuse pattern of symptoms, reflecting the effects of compression on the lower cranial nerves, e.g. dysarthria, resulting from impairment of tongue movements secondary to hypoglossal nerve damage; dysphagia, with overspill and aspiration of ingested material into the airway, resulting from loss of sensory information from the territory of the pharyn-
geal plexus nerves; motor dysfunction of the pharynx and larynx, resulting from loss of motor innervation via the pharyngeal plexus and the recurrent laryngeal branch of the vagus to the intrinsic muscles of the larynx; and voice changes reflecting involvement of the laryngeal branches of the vagus. These tumours may also give rise to snoring as a result of narrowing of the nasopharynx.

Several surgical approaches have been described for the management of parapharyngeal space tumours, including transcervical, transparotid, transcervical-transmandibular and transoral approaches. Transoral robotic surgery uses the oral cavity as a surgical corridor; as yet, there have been relatively few studies from the transoral perspective of the relevant surgical anatomy (Dallan et al 2011, Moore et al 2012, Wang et al 2014)

## MUSCLES OF THE SOFT PALATE AND PHARYNX

The muscles of the soft palate and pharynx are levator veli palatini, tensor veli palatini, palatoglossus, palatopharyngeus, musculus uvulae, salpingopharyngeus, stylopharyngeus, and the superior, middle and inferior constrictors.

## Levator veli palatini

Levator veli palatini arises by a small tendon from a quadrilateral roughened area on the medial end of the inferior surface of the petrous part of the temporal bone, in front of the lower opening of the carotid canal (see Fig. 34.3; Figs 34.8-34.10). Additional fibres arise from the inferior aspect of the cartilaginous part of the pharyngotympanic tube and from the vaginal process of the sphenoid bone. At its origin, the muscle is inferior rather than medial to the pharyngotympanic tube and only crosses medial to it at the level of the medial pterygoid plate. It passes medial to the upper margin of the superior constrictor and

Fig. 34.8 Muscles of the pharynx, lateral view.

Fig. 34.9 Muscles of the soft palate. A, Inferior view. B, Superior view.
anterior to salpingopharyngeus. Its fibres spread in the medial third of the soft palate between the two strands of palatopharyngeus to attach to the upper surface of the palatine aponeurosis as far as the midline, where they interlace with those of the contralateral muscle. Thus, the two levator muscles form a sling above and just behind the palatine aponeurosis.

Vascular supply The blood supply of levator veli palatini is derived from the ascending palatine branch of the facial artery and the greater palatine branch of the maxillary artery (Freelander 1992).

Innervation Levator veli palatini is innervated via the pharyngeal plexus.

Actions The primary role of the levator veli palatini muscles is to elevate the almost vertical posterior part of the soft palate and pull it slightly backwards; during swallowing, the soft palate is elevated so that it touches the posterior wall of the pharynx, separating the nasopharynx from the oropharynx. By additionally pulling on the lateral walls of the nasopharynx posteriorly and medially, the levator veli palatini muscles also narrow that space. The muscle has little or no effect on the pharyngotympanic tube, although it might allow passive opening.

## Tensor veli palatini

Tensor veli palatini arises from the scaphoid fossa of the pterygoid process and posteriorly from the medial aspect of the spine of the sphenoid bone (see Figs 32.3A, B, 34.3, 34.8-34.10). Between these two sites, it is attached to the anterolateral membranous wall of the pharyngotympanic tube (including its narrow isthmus where the cartilaginous medial two-thirds meets the bony lateral third). Some fibres may be continuous with those of tensor tympani. Inferiorly, the fibres converge on a delicate tendon that turns medially around the pterygoid hamulus to pass through the attachment of buccinator to the palatine aponeurosis and the osseous surface behind the palatine crest on the horizontal plate of the palatine bone. There is a small bursa between the tendon and the pterygoid hamulus (see Fig. 131-8 in Cummings Otolaryngology Head \& Neck Surgery 5e).

The muscle is thin and triangular, and lies lateral to the medial pterygoid plate, pharyngotympanic tube and levator veli palatini. Its lateral surface contacts the upper and anterior part of medial pterygoid, the mandibular, auriculotemporal and chorda tympani nerves, the otic ganglion and the middle meningeal artery.

Dilator tubae Some fibres of tensor veli palatini that arise from the hamulus of the medial pterygoid plate are attached to the short lateral

Fig. 34.10 Muscles of the pharynx and the pharyngobasilar fascia, posterior view.
lamina of the cartilage of the pharyngotympanic, to a condensation of connective tissue lateral to the tubal wall and to a portion of Ostmann's fat pad; these fibres are sometimes referred to as dilator tubae.

Vascular supply The blood supply of tensor veli palatini is derived from the ascending palatine branch of the facial artery and the greater palatine branch of the maxillary artery (Freelander 1992).

Innervation The motor innervation of tensor veli palatini is derived from the mandibular nerve via the nerve to medial pterygoid, and reflects the development of the muscle from the first branchial arch.

Actions Tensor veli palatini is said to have three anchoring points on which it isometrically contracts: the pterygoid hamulus, Ostmann's fat pad and medial pterygoid (O'Reilly and Sando 2010). Acting together, the two tensor veli palatini muscles tauten the soft palate, principally its anterior part, and depress it by flattening its arch. Acting unilaterally, the muscle pulls the soft palate to one side. Although contraction of both muscles will slightly depress the anterior part of the soft palate, it is often assumed that the increased rigidity aids palatopharyngeal closure. A primary role of the tensor is to open the pharyngotympanic tube, e.g. during deglutition and yawning, via its dilator tubae component, and so aid equalization of air pressure between the middle ear and nasopharynx.

## Palatoglossus

Palatoglossus is narrower at its middle than at its ends (see Figs 34.3, 34.6). Together with its overlying mucosa, it forms the palatoglossal arch or fold (see Fig. 31.3). It arises from the oral surface of the palatine aponeurosis, where it is continuous with its contralateral fellow. It extends forwards, downwards and laterally in front of the palatine tonsil to the side of the tongue. Some of its fibres spread over the dorsum of
the tongue, while others pass deeply into its substance to intermingle with fibres of the intrinsic transverse muscle.

Vascular supply Palatoglossus receives its blood supply from the ascending palatine branch of the facial artery and from the ascending pharyngeal artery.

Innervation Palatoglossus is innervated via the pharyngeal plexus, and is therefore unlike all the other muscles of the tongue, which are supplied by the hypoglossal nerve.

Actions Palatoglossus elevates the root of the tongue and approximates the palatoglossal arch to its contralateral fellow, thus shutting off the oral cavity from the oropharynx.

## Palatopharyngeus

Palatopharyngeus and its overlying mucosa form the palatopharyngeal arch (see Fig. 31.3). Within the soft palate, palatopharyngeus is composed of two fasciculi that are attached to the upper surface of the palatine aponeurosis; they lie in the same plane but are separated from each other by levator veli palatini (see Figs 34.3, 34.9). The thicker, anterior fasciculus arises from the posterior border of the hard palate as well as the palatine aponeurosis, where some fibres interdigitate across the midline. The posterior fasciculus is in contact with the mucosa of the pharyngeal aspect of the palate, and joins the posterior band of the contralateral muscle in the midline. The two layers unite at the posterolateral border of the soft palate, and are joined by fibres of salpingopharyngeus. Passing laterally and downwards behind the tonsil, palatopharyngeus descends posteromedial to and in close contact with stylopharyngeus, to be attached with it to the posterior border of the thyroid cartilage. Some fibres end on the side of the pharynx, attached to pharyngeal fibrous tissue, and others cross the
midline posteriorly, decussating with those of the contralateral muscle. Palatopharyngeus thus forms an incomplete internal longitudinal muscular layer in the wall of the pharynx.

Passavant's muscle (palatopharyngeal sphincter) The existence of Passavant's muscle remains controversial (Cho et al 2013). It has been described as a part of the superior constrictor and palatopharyngeus muscles (see Fig. 34.3B). An alternative view holds that it is a distinct palatine muscle that arises from the anterior and lateral parts of the upper surface of the palatine aponeurosis, lies lateral to levator veli palatini, blends internally with the upper border of the superior constrictor, and encircles the pharynx as a sphincter-like muscle. Whatever its origin, when it contracts, it forms a ridge (Passavant's ridge) when the soft palate is elevated. The change from columnar, ciliated, 'respiratory' epithelium to stratified, squamous epithelium that takes place on the superior aspect of the soft palate occurs along the line of attachment of the palatopharyngeal sphincter to the palate. The muscle is hypertrophied in cases of complete cleft palate.

Vascular supply Palatopharyngeus receives its arterial supply from the ascending palatine branch of the facial artery, the greater palatine branch of the maxillary artery and the pharyngeal branch of the ascending pharyngeal artery.

Innervation Palatopharyngeus is innervated via the pharyngeal plexus.

Actions Acting together, the palatopharyngei pull the pharynx up, forwards and medially, and thus shorten it during swallowing. They also approximate the palatopharyngeal arches and draw them forwards.

## Musculus uvulae

Musculus uvulae arises from the posterior nasal spine of the palatine bone and the superior surface of the palatine aponeurosis, and lies between the two laminae of the aponeurosis (see Figs 34.1, 34.9). It runs posteriorly above the sling formed by levator veli palatini and inserts beneath the mucosa of the uvula. The two sides of the muscle are united along most of its length.

Vascular supply The blood supply of musculus uvulae is derived from the ascending palatine branch of the facial artery and the descending palatine branch of the maxillary artery.

Innervation The nerve supply to musculus uvulae is innervated via the pharyngeal plexus.

Actions By retracting the uvular mass and thickening the middle third of the soft palate, musculus uvulae aids levator veli palatini in palatopharyngeal closure. The two muscles run at right angles to each other and their contraction raises a 'levator eminence' that helps seals off the nasopharynx.

## Salpingopharyngeus

Salpingopharyngeus arises from the inferior part of the cartilage of the pharyngotympanic tube near its pharyngeal opening and passes downwards within the salpingopharyngeal fold to blend with palatopharyngeus (see Figs 34.1, 34.3A, 34.9).

Vascular supply Salpingopharyngeus receives its arterial supply from the ascending palatine branch of the facial artery, the greater palatine branch of the maxillary artery and the pharyngeal branch of the ascending pharyngeal artery.

Innervation Salpingopharyngeus is innervated via the pharyngeal plexus.

Actions Salpingopharyngeus elevates the pharynx, and may also assist tensor veli palatini to open the cartilaginous end of the pharyngotympanic tube during swallowing.

## Stylopharyngeus

Stylopharyngeus is a long slender muscle, cylindrical above and flat below. It arises from the medial side of the base of the styloid process, descends along the side of the pharynx, and passes between the superior and middle constrictors to spread out beneath the mucous membrane (see Figs 34.3, 34.8, 34.10, 31.6). Some fibres merge into the constrictors and the lateral glossoepiglottic fold, while others join fibres of palatopharyngeus and are attached to the posterior border of the
thyroid cartilage. The glossopharyngeal nerve curves round the posterior border and the lateral side of stylopharyngeus, and passes between the superior and middle constrictors to reach the tongue.

Vascular supply Stylopharyngeus receives its arterial supply from the pharyngeal branch of the ascending pharyngeal artery.

Innervation Stylopharyngeus is innervated by the glossopharyngeal nerve.

Actions Stylopharyngeus elevates the pharynx and larynx.

## Superior constrictor

The superior constrictor is a quadrilateral sheet of muscle and is thinner than the other two constrictors. It is attached anteriorly to the pterygoid hamulus (and sometimes to the adjoining posterior margin of the medial pterygoid plate), the posterior border of the pterygomandibular raphe, the posterior end of the mylohyoid line of the mandible and, by a few fibres, to the side of the tongue (see Figs 34.1, 34.3, 34.6, 34.8, $34.10,31.6$ ). The fibres curve back into a median pharyngeal raphe that is attached superiorly to the pharyngeal tubercle on the basilar part of the occipital bone.

Relations The upper border of the superior constrictor is separated from the cranial base by a crescentic interval that contains levator veli palatini, the pharyngotympanic tube and an upward projection of pharyngobasilar fascia. The lower border is separated from the middle constrictor by stylopharyngeus and the glossopharyngeal nerve (see Fig. 34.8). Anteriorly, the pterygomandibular raphe separates the superior constrictor from buccinator, and, posteriorly, the superior constrictor lies on the prevertebral muscles and fascia, from which it is separated by the retropharyngeal space. The ascending pharyngeal artery, pharyngeal venous plexus, glossopharyngeal and lingual nerves, styloglossus, middle constrictor, medial pterygoid, stylopharyngeus and the stylohyoid ligament all lie laterally, and palatopharyngeus, the tonsillar capsule and the pharyngobasilar fascia lie internally.

Vascular supply The arterial supply of the superior constrictor is derived mainly from the pharyngeal branch of the ascending pharyngeal artery and the tonsillar branch of the facial artery.

Innervation The superior constrictor is innervated via the pharyngeal plexus.

Actions The superior constrictor constricts the upper part of the pharynx.

## Middle constrictor

The middle constrictor is a fan-shaped sheet attached anteriorly to the lesser cornu of the hyoid and the lower part of the stylohyoid ligament (the chondropharyngeal part of the muscle), and to the whole of the upper border of the greater cornu of the hyoid (the ceratopharyngeal part) (see Figs 34.3A, 34.8, 34.10, 31.6). The lower fibres descend deep to the inferior constrictor to reach the lower end of the pharynx; the middle fibres pass transversely, and the superior fibres ascend and overlap the superior constrictor. All fibres insert posteriorly into the median pharyngeal raphe (Sakamoto 2014).

Relations The glossopharyngeal nerve and stylopharyngeus pass through a small gap between the middle and superior constrictors, and the internal laryngeal nerve and the laryngeal branch of the superior thyroid artery pass between the middle and inferior constrictors. The prevertebral fascia and longus colli and longus capitis are posterior; the superior constrictor, stylopharyngeus and palatopharyngeus are internal; and the carotid vessels, pharyngeal plexus of nerves and some lymph nodes are lateral. Near its hyoid attachment, the middle constrictor lies deep to hyoglossus, from which it is separated by the lingual artery.

Vascular supply The arterial supply of the middle constrictor is derived mainly from the pharyngeal branch of the ascending pharyngeal artery and the tonsillar branch of the facial artery.

Innervation The middle constrictor is innervated via the pharyngeal plexus.

Actions The middle constrictor constricts the middle part of the pharynx during swallowing.

## Inferior constrictor

The inferior constrictor is the thickest of the three constrictor muscles and is usually described in two parts: thyropharyngeus and cricopharyngeus (see Figs 34.3A, 34.8, 34.10, 31.6). Thyropharyngeus arises from the oblique line of the thyroid lamina, a strip of the lamina behind this, and by a small slip from the inferior cornu. Some additional fibres arise from a tendinous cord that loops over cricothyroid Cricopharyngeus arises from the side of the cricoid cartilage between the attachment of cricothyroid and the articular facet for the inferior thyroid cornu. Some authors have described cricopharyngeus as consisting of a superficial upper oblique portion - the pars oblique - and a lower, deeper, transverse portion - the pars fundiformis. The upper part attaches to the median raphe while the lower part forms a circular band that lacks a median raphe. The area demarcated by the pars oblique and pars fundiformis of cricopharyngeus is termed Killian's dehiscence (or Killian's triangle). A second triangular area, Laimer's triangle, can be identified beneath cricopharyngeus between the longitudinal fibres of the oesophagus as they pass laterally on either side to attach to the cricoid cartilage; only the circular muscle of the oesophagus forms the wall here. Both triangles are postulated to be sites of weakness in the wall of the pharynx and oesophagus, and are therefore areas where diverticula could potentially form. Both cricopharyngeus and thyropharyngeus spread posteromedially to join the contralateral muscle. Thyropharyngeus is inserted into the median pharyngeal raphe, and its upper fibres ascend obliquely to overlap the middle constrictor however, cricopharyngeus blends with the circular oesophageal fibres around the narrowest part of the pharynx.

Relations The buccopharyngeal fascia is external; the prevertebral fascia and muscles are posterior; the thyroid gland, common carotid artery and sternothyroid are lateral; and the middle constrictor, stylopharyngeus, palatopharyngeus and the fibrous lamina are internal. The internal laryngeal nerve and laryngeal branch of the superior thyroid artery reach the thyrohyoid membrane by passing between the inferior and middle constrictors. The external laryngeal nerve descends on the superficial surface of the muscle, just behind its thyroid attachment, and pierces its lower part. The recurrent laryngeal nerve and the laryngeal branch of the inferior thyroid artery ascend deep to its lower border to enter the larynx.

Vascular supply The arterial supply of the inferior constrictor is derived mainly from the pharyngeal branch of the ascending pharyngeal artery and the muscular branches of the inferior thyroid artery.

Innervation Both parts of the inferior constrictor are usually innervated via the pharyngeal plexus. Although controversial, available evidence in humans suggests that cricopharyngeus is also supplied by the recurrent laryngeal nerve and the external branch of the superior laryngeal nerve (Sakamoto 2013).

Actions Thyropharyngeus constricts the lower part of the pharynx. Cricopharyngeus is the main component of the upper oesophageal sphincter, or pharyngo-oesophageal high-pressure zone, the other parts being thyropharyngeus and the proximal cervical oesophagus. (The extent to which the lower fibres of thyropharyngeus and the upper fibres of the oesophageal musculature are involved in closing the upper end of the oesophagus appears to depend on the physiological state, whereas cricopharyngeus always participates in closure.) The upper oesophageal sphincter is defined manometrically as a region of elevated intraluminal pressure, $2-4 \mathrm{~cm}$ long, located at the junction of the hypopharynx and cervical oesophagus.

Cricopharyngeus contains about $40 \%$ of endomysial connective tissue, much of which is elastic, but it lacks muscle spindles (Bonnington et al 1988, Brownlow et al 1989). It contains both slow-twitch type I and fast-twitch type II fibres, a structural arrangement that underpins the various functions of the upper oesophageal sphincter, i.e. maintaining constant basal tone, yet being able to relax and contract rapidly during swallowing, belching and vomiting. The tonic activity of cricopharyngeus between swallows prevents influx of air during inspiration and tracheobronchial aspiration and pharyngeal reflux of oesophageal contents during oesophageal peristalsis. For further reading, see Lang and Shaker (2000).

## Hypopharyngeal diverticula

Hypopharyngeal diverticula occur in the lower portion of the pharynx through areas of weakness in the pharyngeal wall. The pharyngeal mucosa that lies between cricopharyngeus and thyropharyngeus is relatively unsupported by pharyngeal muscles and is called the dehiscence of Killian. A delay in the relaxation of cricopharyngeus, which can occur
when the swallowing mechanism becomes discoordinated, generates a zone of elevated pressure adjacent to the mucosa in the dehiscence. The result is the development of a pulsion diverticulum (a pouch of prolapsing mucosa), which breaches the thin muscle wall adjacent to the sixth cervical vertebra and expands, usually a little to the left side, into the parapharyngeal potential space. This may trap portions (or all) of the passing food bolus, resulting in regurgitation of old food, aspiration pneumonia, halitosis and weight loss. Treatment may involve open excision or inversion of the pouch to prevent it filling, coupled with division of the circular fibres of cricopharyngeus, to prevent the build-up of pressure in the region and recurrence of the pouch.

The majority of hypopharyngeal diverticula arise either between the two parts of cricopharyngeus (where the upper oblique and lower transverse fibres diverge) or below cricopharyngeus (where the longitudinal fibres of the oesophagus diverge in Laimer's triangle). Some arise between cricopharyngeus and thyropharyngeus. Diverticula are usually midline but may arise laterally below cricopharyngeus.

## PHARYNGEAL PLEXUS

Almost all of the nerve supply to the pharynx, whether motor or sensory, is derived from the pharyngeal plexus, which is formed by the pharyngeal branches of the glossopharyngeal and vagus nerves with contributions from the superior cervical sympathetic ganglion. The plexus lies on the external surface of the pharynx, especially on the middle constrictor. Filaments from the plexus ascend or descend external to the superior and inferior constrictors before branching within the muscular layer and mucosa of the pharynx.

The pharyngeal branch of the vagus supplies all the muscles of the soft palate (excluding tensor veli palatini, which is supplied by the mandibular division of the trigeminal via the nerve to medial pterygoid) and all the muscles of the pharynx (excluding stylopharyngeus, which is supplied by the glossopharyngeal nerve). It emerges from the upper part of the inferior vagal ganglion and consists of axons arising from neuronal cell bodies in the nucleus ambiguus. The nerve passes between the external and internal carotid arteries to reach the upper border of the middle pharyngeal constrictor and subsequently divides into numerous filaments that contribute to the pharyngeal plexus. It also gives off a minute filament, the ramus lingualis vagi, which joins the hypoglossal nerve as it curves round the occipital artery.

Contemporary evidence does not support the description of a cranial root of the accessory nerve as the conduit for the major motor drive to the pharyngeal plexus, albeit via the vagus nerve. The plexiform connections that may be demonstrated between the accessory nerve and the vagus nerve within the posterior cranial fossa are too variable and insubstantial to support this function.

## ANATOMY OF SWALLOWING (DEGLUTITION)

Swallowing involves a series of activities that occur within a matter of seconds. Traditionally described as a reflex, the process is more properly regarded as a programmed motor behaviour. Swallowing is initiated when food or liquid stimulates sensory nerves in the oropharynx. In a 24 -hour period, an average person will swallow between 600 and 1000 times but, of these, only some 150 will relate to feeding; the remainder occur to clear continuously produced saliva and are less frequent at night (Sato and Nakashima 2006, 2007).

Eating and drinking are basic human pleasures, and problems associated with swallowing can impact dramatically on the quality of life. Swallowing disorders are usually symptoms of other complex diseases; an inability to swallow may adversely affect nutritional status and therefore indirectly exacerbate the underlying disease. Aside from the risk of asphyxiation through choking, swallowing disorders can also be a direct cause of morbidity and mortality as a result of aspiration of food, liquid or possibly refluxed gastric acid contents, causing bacterial infection or tissue damage.

Swallowing in the adult human has usually been studied in relation to swallowing solid or liquid food carried out on command. For descriptive purposes, the process has been traditionally divided into four phases: oral preparatory, oral transit/transfer, pharyngeal and oesophageal (in this traditional view some have only recognized three phases, combining the two oral phases of preparation and transit into a single oral phase). While this sequence of events may still be appropriate for describing the swallowing of liquids, it does not accurately represent the way in which solid food is prepared for swallowing, where suitably processed food is passed in stages to the oropharynx and valleculae until a swallow is initiated. Oral and pharyngeal stages
overlap when swallowing solid food, but perhaps less so when swallowing saliva or other liquids. It therefore seems appropriate to speak of an oral preparatory and an oral transit phase when describing the swallowing of liquids, but inappropriate when considering the swallowing of solid food. (For further reading, see Hiiemae and Palmer (1999, 2003), Matsuo and Palmer (2008), Mioche et al (2002), Palmer et al (2007).)

## ORAL PREPARATORY PHASE

In the oral preparatory phase, liquids are taken into the mouth and held there either on the floor of the mouth or against the hard palate by the upward movement of the tongue. During swallowing, the muscles that dilate the pharyngotympanic tube are activated during a pause in respiration in the expiratory phase. Throughout this first phase, the soft palate is fully lowered by contraction of palatoglossus and palatopharyngeus, and the posterior part of the tongue is simultaneously elevated; the apposed soft palate and tongue form a tight seal that helps to prevent premature leakage of the bolus into the oropharynx before the airways are fully protected. Slight leakage of fluid does sometimes occur; the tendency for there to be leakage because of imperfect sealing increases with age.

## ORAL TRANSIT/TRANSFER PHASE

In the oral transit/transfer phase, the liquid in the oral cavity is transported through the palatoglossal and palatopharyngeal arches into the oropharynx. Genioglossus raises both the tongue tip and the part of the tongue immediately behind the tip so that they come into contact with the alveolar ridge. Orbicularis oris and buccinator remain contracted, keeping the lips and cheeks taut and the liquid central in the oral cavity. The liquid is accommodated in a shallow midline gutter that forms along the dorsum of the tongue, probably as a result of the co-contraction of the styloglossi and the genioglossi, aided by the superior longitudinal and transverse fibres of the intrinsic muscles. The mandible is elevated and the mouth is closed. The floor of the mouth and the anterior and middle portions of the tongue are elevated by co-contraction of the suprahyoid group of muscles (mylohyoid, digastric, geniohyoid and stylohyoid); the effectiveness of the suprahyoid muscles is increased as they contract against a fixed mandible (the mouth does not have to be closed to swallow, but it is much harder to swallow if it is open). Contraction of stylohyoid elevates the more posterior parts of the tongue and empties the longitudinal gutter. At the same time, the tongue flattens, probably as a result of the contraction of hyoglossus and some of the intrinsic lingual muscles, especially the vertical fibres. The elevated, flattened tongue pushes the liquid against the hard palate, and the sides of the tongue seal against the maxillary alveolar processes, helping to move the liquid further posteriorly. Contraction of styloglossus and mylohyoid completes the elevation of the posterior part of the tongue. At the same time, the posterior oral seal relaxes and the posterior tongue moves forwards; the overall effect is of a cam-like action of the tongue, sweeping or squeezing the liquid towards the pillars of the fauces, finally delivering it to the oropharynx and initiating the pharyngeal stage of swallowing, where the pharyngeal aperture is initially increased and then closed.

## ORAL PHASES WHEN SWALLOWING SOLIDS

When solid food is swallowed, the process is slightly different from that just described for swallowing liquids. Food is mixed with saliva and reduced to smaller pieces by the processes of chewing. When it has been converted to a suitable consistency to be swallowed, it is transferred to the oropharynx and valleculae, where it can be retained for a few seconds prior to swallowing. During this time, chewing may continue; the bolus is progressively augmented in one or more stages until a swallow is initiated and the pharyngeal phase begins. In this part of the 'oral phase for solid food', the essential action is chewing; the mandible is moved by the action of the jaw elevators and depressors (Ch. 32), and the food is reduced by the grinding action of the teeth and simultaneously mixed with saliva. The lips are maintained as a tight labial seal by the contraction of orbicularis oris; buccinator performs a similar function for the cheeks. In this way, the sulci are closed, the vestibule normally remains empty, and any food that enters the vestibule is returned to the oral cavity proper. Buccinator keeps the cheeks taut, ensuring that they are kept clear of the occlusal surfaces and that the food remains in place under the occlusal surfaces of the molar teeth.

Loss of the nerve supply to buccinator as a result of damage to the facial nerve results in painful and repeated lacerations of the cheeks. It was thought that the soft palate was depressed throughout this phase. It is now recognized that the posterior seal is not tight, and that the oral cavity and oropharynx remain in communication, permitting addition of material to the bolus while chewing continues. Spillage occurs because the soft palate is not in continuous contact with the posterior part of the tongue, as was once thought (Hiiemae and Palmer 1999). Bolus formation appears to involve several cycles of transporting food from the anterior to the posterior part of the tongue through the palatoglossal and palatopharyngeal arches until a bolus accumulates on the oropharyngeal surface of the tongue (retrolingual loading), the valleculae and within the oropharynx. Throughout this phase, the lateral and rotatory tongue movements that deliver the food to the teeth for grinding and reduction are crucial for normal bolus formation because they ensure that the food is positioned under the occlusal surfaces of the teeth. If effective tongue movements do not occur, chewing will be compromised. Movements of the tongue are also cyclical in phase with the movements of the jaw and hyoid bone. As the jaw is depressed, the tongue is also depressed and moves anteriorly. As the jaw is elevated, the tongue is retracted so that it no longer lies under the anterior teeth as they as are brought together by jaw elevation. These coordinated actions help to ensure that the tongue is not usually bitten during chewing.

Chewing continues until all the food has been moved posteriorly, a process that can last from less than 1 second to as much as 10 seconds. The oral preparatory, oral transport and pharyngeal phases of swallowing therefore overlap when solid food is being swallowed. As pieces of food are prepared in the mouth, they are moved to the posterior part of the tongue or on into the oropharynx in a similar manner to that used to transport liquids (see above). The end of this phase of swallowing is marked by the tongue propelling the prepared bolus of food to the posterior part of the oral cavity and then on into the oropharynx to initiate the swallow. Contact with either the posterior wall of the oropharynx or the mucosa overlying the palatoglossal and palatopharyngeal arches was once thought to be necessary to initiate a swallow; it is now known that there is a great degree of variability in the position of the bolus at the time at which a swallow is initiated.

## PHARYNGEAL PHASE

The delivery of the bolus to the oropharynx triggers the pharyngeal phase of the swallow. This phase, which is involuntary and is the most critical stage of swallowing, involves the pharynx changing from being an air channel (between the posterior nares and laryngeal inlet) to a food channel (from the fauces to the upper end of the oesophagus). The airway is protected from aspiration during swallowing by hyolaryngeal elevation, and by resetting respiratory rhythm so that airflow ceases briefly as the bolus passes through the hypopharynx; the total time that elapses from the bolus triggering the pharyngeal phase to the re-establishment of the airway is barely 1 second. Thus there are two aspects of the process to be examined: the transport of the food down the pharynx and through the upper oesophageal sphincter, and the absolute need to protect the airways throughout this time.

The nasopharynx is sealed off from the oropharynx by activation of the superior pharyngeal constrictor and contraction of a subset of palatopharyngeal fibres to form a variable, ridge-like structure (Passavant's ridge; Cho et al 2013), against which the soft palate is elevated. From an evolutionary perspective, this ridge represents the remnant of a sphincter that encircled a more highly placed larynx; a high laryngeal position is the norm in other mammals and in the human infant (see below), but not in the human adult. Interestingly, the pharyngeal ridge becomes hypertrophic in an infant with a cleft palate, presumably in an attempt to produce a seal to the nasal airway. Ineffective velopharyngeal closure may result in nasal regurgitation of food.

The airway is sealed at the laryngeal inlet by closure of the glottis. The epiglottis is retroflexed over the laryngeal aditus as a result of passive pressure from the base of the tongue and active contraction of the aryepiglottic muscles (Ch. 35). The conventional view that laryngeal closure during swallowing occurs from inferior to superior, i.e. the vocal folds adduct first and the epiglottis covers the arytenoids and glottis last, has been challenged by studies using simultaneous electromyography and fibreoptic endoscopic evaluation of swallowing (FEES), which have reported that the aryepiglottic folds close before vocal fold adduction during a swallow. The sequence of events that close the glottis may alter according to the type of swallow and consistency of the bolus (Steele and Miller 2010). To prevent aspiration of material, irrespective of its consistency, the hyoid bone and larynx are raised and
pulled anteriorly with precise timing by the suprahyoid muscles and the longitudinal muscles of the pharynx (Kendall et al 2001). In this way, the laryngeal inlet is brought forwards under the bulge of the posterior tongue, i.e. out of the path of the bolus. This action helps expand the hypopharyngeal space and relax the upper oesophageal sphincter, which is also raised by several centimetres. The bolus passes over the reflected anterior surface of the epiglottis and is swept through the laryngopharynx to the upper oesophageal sphincter

Breathing is suspended briefly during swallowing; the larynx is closed, the soft palate is elevated and there is active neural inhibition of ventilation. Swallowing is normally initiated during an expiration, which is then inhibited while swallowing occurs (typically for a period of $0.5-1.5$ seconds). The resumption of expiration provides a degree of protection against any residues of solid food that might remain uncleared within the pharynx following the swallow being inhaled into the airway. The bolus is moved by sequential contraction of the pharyngeal constrictor muscles superiorly behind the bolus. At the same time, the pharynx is shortened and elevated as palatoglossus and palatopharyngeus contract against the raised and fixed soft palate. The sequential contraction of the constrictor muscles is often assumed to be the driving force that propels the bolus towards the oesophagus. However, evidence that the head of the bolus moves faster than the wave of pharyngeal contraction suggests that, at least in some situations, the kinetic energy imparted to the bolus as it is expelled from the mouth into the oropharynx may be sufficient to carry it through the pharynx. This energy is generated by pressure gradients created within the pharynx by the tongue driving force, the hypopharyngeal suction pump, and the 'stripping action' of the pharyngeal constrictors (Nishino et al 1985).

The tongue driving force (tongue thrust pressure force) is a positive pressure that squeezes the bolus towards the laryngopharynx. It is generated by the upward movement of the tongue pressing the bolus against the contracting pharyngeal wall and requires a tight nasopharyngeal seal (created by elevation of the soft palate). There is a view that the tongue driving force is the most important factor responsible for moving the bolus down the pharynx. The hypopharyngeal suction pump is caused by the elevation and anterior movement of the hyoid and larynx, which creates a negative pressure in the laryngopharynx, drawing the bolus towards the oesophagus, aided by a more negative pressure inside the oesophagus. The pharyngeal constrictors generate a positive pressure wave behind the bolus. Their sequential contraction may facilitate clearance ('stripping') of the pharyngeal walls and piriform sinuses; if this is so, residues that remain in the valleculae must reflect inadequate tongue force generation at the end of the oral phase of swallowing.

At the end of this phase, the bolus is propelled towards the upper oesophageal sphincter. At rest, this sphincter is closed by active contraction. Cricopharyngeus relaxes prior to the bolus arriving and the sphincter is then opened actively by the combined action of the suprahyoid muscles in moving the larynx anteriorly and superiorly, and passively by pressure from the arriving bolus. The upper oesophageal sphincter thus differs in its action from that of other sphincters where opening is generally passive and a consequence of pressures generated by the movements towards them of fluids or solids.

## Gag reflex

Traditionally, the stimulus for triggering a swallow has been regarded as contact with the posterior wall of the pharynx, since this is usually where the gag reflex is triggered. However, many regions of the oropharynx, when appropriately stimulated by the presence of food or liquid, are capable of triggering a swallow, although some regions are more sensitive than others, e.g. the area over the palatoglossal arches. Moreover, there appears to be little relationship between a functioning gag reflex and the ability to swallow normally. Individuals with a reduced or absent gag reflex can swallow safely; conversely, the presence of a brisk and clear gag reflex is not always associated with the ability to swallow safely.

## OESOPHAGEAL PHASE

The third, or oesophageal, stage begins after the relaxation of the upper oesophageal sphincter has allowed the bolus to enter the oesophagus. This is a true peristaltic movement, in that a muscular relaxation in front of the bolus and subsequent constriction behind the bolus move it towards the stomach. Sequential waves of contractions of the oesophageal musculature now propel the bolus down to the lower oesophageal sphincter, which opens momentarily to admit the bolus to the stomach.

The oesophageal phase of swallowing is much more variable than the other phases and lasts between 8 and 20 seconds.

## SWALLOWING PATTERN GENERATOR

The patterning and timing of striated muscle contraction during swallowing are generated at a brainstem level in a network of neural circuits that collectively form a central swallowing pattern generator. Experimental neurophysiological and tracer studies in animals have shown that the swallowing pattern generator includes several brainstem motor nuclei and two groups of interneurones in the dorsal and ventral medulla: a dorsal swallowing group and a ventral swallowing group. The dorsal swallowing group is located in the nucleus of the solitary tract and possibly in the adjacent reticular formation, and contains neurones that generate the swallowing pattern, probably triggered by convergent information from both cortical and peripheral inputs. The afferent feedback from the branches of the superior laryngeal nerve that innervate the valleculae, epiglottis and supraglottic part of the larynx, and which relay through the nucleus of the solitary tract, facilitates laryngeal closure during swallowing (Jafari et al 2003). The ventral swallowing group is in the ventrolateral medulla above the nucleus ambiguus and contains neurones that act as 'switches', distributing the swallowing drive to motoneurone pools in the trigeminal, facial and hypoglossal nuclei and in the nucleus ambiguus.

The patterns of activation in the smooth muscle of the lower part of the oesophagus are generated locally in intramural plexuses driven by vagal autonomics.

## Supramedullary influence on swallowing

Techniques including transcranial magnetic stimulation, cortical evoked potentials, positron emission tomography and functional magnetic resonance imaging (fMRI) have all been exploited in the study of volitional swallowing in humans (Harris et al 2005, Thexton 1998, Thexton and Crompton 1998). Thus far, these studies have shown that numerous cortical and subcortical regions (primary motor and sensory cortices, operculum, supplementary motor area and cingulate cortex, insula, parietal cortical areas, basal regions and cerebellum) are recruited in swallowing, although, as yet, the functional contributions made by each region have not been established, and it is not known how they influence the swallowing pattern generator. The most consistent cortical activation occurs in the primary motor and somatosensory cortices. Perhaps not surprisingly, the greatest area of fMRI activation in the primary motor cortex occurs over the portion of the precentral gyrus where the face, tongue and pharynx are represented; there is evidence for functional asymmetry between the right and left oral sensorimotor cortices (Martin et al 2004). The activity of the swallowing pattern generator is coordinated with other medullary reflexes, e.g. it is difficult to elicit a swallow when the cortical masticatory centres are stimulated. (For further reading on the motor control of oropharyngeal swallowing, see Humbert and German (2013), and on the role of sensory feedback from the oropharynx in swallowing, see Michou and Hamdy (2009).)

## SWALLOWING IN THE NEONATE

In the adult, the tip of the epiglottis is significantly lower than the inferior edge of the soft palate. In the neonate, the larynx is high in the neck and the epiglottis may extend above the soft palate so that the laryngeal airway is in direct continuity with the posterior nares (Figs 34.11-34.12); a potential space is therefore formed between the soft palate above, the epiglottis behind and the tongue anteroinferiorly. In other mammals with an oropharyngeal anatomy similar to that of the human infant, up to 14 cycles of tongue movement or oral phases cause the accumulation of food in this space. Subsequent emptying of the space is a single event followed by movement of the bolus down the oesophagus. The ratio of accumulation cycles to swallow events in the human neonate is approximately $1.5: 1$, which is lower than in other mammals but still implies some temporary accumulation. In the case of a liquid bolus, accumulated material may be passed laterally to the epiglottis through the piriform fossae rather than over the flexed epiglottis, although it is not known whether this happens in the human infant. (For further reading, see Delaney and Arvedson (2008).)

Swallow safety is critical at all ages. In the neonate, where coordination of suckling, swallowing and breathing is not fully developed, the potential risk of airway obstruction and/or aspiration of ingested milk or other material during swallowing is reduced because the intranarial larynx prevents the bolus from entering the larynx before and after a

Dysphagia is a symptom of many diseases and can arise from anatom－ ical or functional deficits anywhere along the path from the oral cavity to the stomach or from a failure of neural control resulting from con－ genital malformations，trauma，stroke or neurodegenerative diseases within the central nervous system．Loss of muscle strength affecting tongue propulsion or pharyngeal contraction will impair the initiation of the swallow and／or bolus transport．This will result in retention of residues within the pharynx following a swallow．Residues may also accumulate in the valleculae and piriform sinuses．Failure to protect the airways adequately may result in the penetration of swallowed material food or liquid into the vestibule of the larynx．Aspiration will result if the material then passes through the vocal folds，which may result in airway obstruction or aspiration pneumonia．Penetration may some－ times occur in normal individuals．

Loss of control of the pharyngeal phase of swallowing，e．g．due to neurological disease or ablative head and neck surgery，may result in aspiration of food，especially fluids，leading to pneumonia．This problem may be addressed surgically by pharyngostomy or epiglot－ topexy．In cervical pharyngostomy，a tube may be passed through the cervical skin，fascia and platysma directly into the piriform fossa（Patil et al 2006）．This is achieved by passing a curved forcep into the piriform fossa and pushing it laterally，displacing the contents of the carotid sheath and tenting up the platysma and cervical skin from the inside． By cutting down on to the forcep，it is possible to grasp the feeding tube and pull it into the piriform fossa prior to feeding it on into the oesophagus．The tract formed by such a puncture epithelializes and may be used for long－term alimentation．In epiglottopexy，the neck and the pharynx are opened to expose the laryngeal inlet，the aryepiglottic folds are denuded of mucosa to encourage their adhesion，and the epiglottis is sutured down to the aryepiglottic folds to shield the laryngeal inlet． The resultant compromise of the airway can be offset by the creation of an alternative airway via a tracheostomy．The pharyngeal wall and cervical skin are reconstituted by suturing．

Fig. 34.11 A sagittal section of the head of a neonate. Note the relatively high position of the larynx, the opening being at the level of the soft palate (A). Other abbreviations: B, epiglottis. swallow. (Neonates born at term demonstrate an increase in suck and swallow rates over the course of the first 4 weeks; efficiency of feeding, measured as volume of nutrient per suck and per swallow, doubles over the course of the neonatal period (Qureshi et al 2002).)

The change towards adult anatomy and coordination of the phases of swallowing starts a few months after birth (Kelly et al 2007). Differential growth in length of the human pharynx causes the larynx to take up its low adult position and the epiglottis to lose contact with the soft palate; the larynx reaches its final position around the time of puberty. The adult anatomy does not allow any significant accumulation of food to occur immediately anterior to the epiglottis, which means that the transport of food through the fauces has to bear a $1: 1$ relationship to pharyngeal and oesophageal transit. Moreover, the lowered larynx compromises the previously protected airway; the hyoid and larynx are therefore raised and pulled forwards during a swallow in order to minimize the risk of deglutitive aspiration.

## cmate 35

The larynx is an air passage, a sphincter and an organ of phonation, and extends from the tongue to the trachea. It projects ventrally between the great vessels of the neck and is covered anteriorly by skin, fasciae and the infrahyoid strap muscles that lower the hyoid bone and the larynx. Above, it opens into the laryngopharynx and forms its anterior wall; below, it continues into the trachea (see Fig. 34.2). It is mobile on deglutition. At rest, the larynx lies opposite the third to sixth cervical vertebrae in adult males; it is somewhat higher in children and adult females. In infants between 6 and 12 months, the tip of the epiglottis (the highest part of the larynx) lies a little above the junction of the dens and body of the axis vertebra (Mijallili et al 2012). Until puberty, male and female larynges are similar in size. After puberty, the male larynx enlarges considerably in comparison with that of the female; all the cartilages increase in both size and weight, the thyroid cartilage projects in the anterior midline of the neck, and its sagittal diameter nearly doubles. The male thyroid cartilage continues to increase in size until 40 years of age, after which no further growth occurs. For further reading, including an introduction to the more important historical literature, see Berkovitz et al (2000), Blitzer et al (2009), Dickson and Maue-Dickson (1982), Kaplan (1971), Hollinshead (1982), Tucker (1993).

## SKELETON OF THE LARYNX

The skeletal framework of the larynx is formed by a series of cartilages interconnected by ligaments and fibrous membranes, and moved by a number of muscles (Figs 35.1-35.3). The hyoid bone is attached to the larynx; it is usually regarded as a separate structure with distinctive functional roles, and is described on page 443. The laryngeal cartilages are the midline, single thyroid, cricoid and epiglottic cartilages, and the paired arytenoid, cuneiform, corniculate and tritiate cartilages.

The thyroid, cricoid and the greater part of the arytenoid cartilages consist of hyaline cartilage and may undergo mottled calcification as age advances, starting about the twenty-fifth year in the thyroid cartilage and somewhat later in the cricoid and arytenoids. By the sixty-fifth year, these cartilages commonly appear patchily dense in radiographs. The corniculate, cuneiform, tritiate and epiglottic cartilages and the apices of the arytenoid are composed of elastic fibrocartilage, with little tendency to calcify (Munir Turk 1993).

The surface anatomy of the laryngeal cartilages is described on page 413

## EPIGLOTTIS

The epiglottis is a thin, leaf-like plate of elastic cartilage that projects obliquely upwards behind the tongue and hyoid body, and in front of the laryngeal inlet (see Figs 35.2-35.3, 35.5). Its free end, which is broad and round, and occasionally notched in the midline, is directed upwards. Its attached part, or stalk (petiolus), is long and narrow and is connected by the elastic thyroepiglottic ligament to the back of the laryngeal prominence of the thyroid cartilage just below the thyroid notch. Its sides are attached to the arytenoid cartilages by aryepiglottic folds (which contain the aryepiglottic muscle). Its free upper anterior, or lingual, surface is covered by mucosa (the epithelium is nonkeratinized stratified squamous), which is reflected on to the pharyngeal aspect of the tongue and the lateral pharyngeal walls as a median glossoepiglottic, and two lateral glossoepiglottic, folds. This arrangement produces a depression, the vallecula, on each side of the median and lateral folds. The lower part of its anterior surface, behind the hyoid bone and thyrohyoid membrane, is connected to the upper border of the hyoid by an elastic hyoepiglottic ligament, and separated from the thyrohyoid membrane by adipose tissue, which constitutes the clinically important pre-epiglottic space. The smooth posterior, or laryngeal, surface is transversely concave and vertically concavo-convex, and is covered by ciliated respiratory mucosa; its lower projecting part is called

Fig. 35.2 A posterior view of the laryngeal cartilages and ligaments.

B Cricoid cartilage

## C Arytenoid cartilage: medial aspect

Fig. 35.3 Cartilages of the larynx: thyroid (A), cricoid (B), arytenoid (C), epiglottis (D), cricoarytenoid joint (E). The attachments of the false vocal folds (vestibular ligaments; above) and the true vocal folds (vocal ligaments; below) are shown in A, posterior aspect. Note the pitted surface of the epiglottis (D).
the tubercle. This surface forms the oblique anterior wall of the laryngeal vestibule. The cartilage is posteriorly pitted by small mucous glands (see Fig. 35.3D) and is perforated by branches of the internal laryngeal nerve and fibrous tissue, which means that the posterior surface of the epiglottis is in continuity through these perforations with the preepiglottic space.

## Functions of the epiglottis

During swallowing, the hyoid bone moves upwards and forwards, and the epiglottis is bent posteriorly as a result of passive pressure from the
base of the tongue and active contraction of the aryepiglottic muscles. Normally, the epiglottis diverts food and liquids away from the laryngeal inlet and into the lateral food channels. It is not essential for respiration or phonation.

Whether downward movement of the epiglottis is a passive process, produced by a combination of the weight of food or liquid on its lingual surface and forces originating elsewhere in the hyoid and larynx, or whether it is an active process brought about by active muscular control, remains the subject of debate. Neither scheme seems to explain epiglottic movement satisfactorily. It is likely that a combination of processes is taking place, in which passive forces originating in the tongue, hyoid and larynx are transmitted to the epiglottis by the
hyoepiglottic ligaments while the base of the epiglottis is actively moved by thyroarytenoid and muscles of the laryngeal inlet (Logemann et al 1992, Vandaele et al 1994). Ardran and Kemp (1967) argue that, though safe swallowing is possible without an epiglottis, more care has to be taken whilst eating.

## THYROID CARTILAGE

The thyroid cartilage is the largest of the laryngeal cartilages (see Figs 35.1-35.3). It consists of two quadrilateral laminae with anterior borders that fuse along their inferior two-thirds at a median angle to form the subcutaneous laryngeal prominence ('Adam's apple'). This projection is most distinct at its upper end, and is well marked in men but less visible in women. Above, the laminae are separated by a V-shaped superior thyroid notch or incisure. Posteriorly, the laminae diverge, and their posterior borders are prolonged as slender horns: the superior and inferior cornua. A shallow ridge, the oblique line, curves downwards and forwards on the external surface of each lamina; it runs from the superior thyroid tubercle, lying a little anterior to the root of the superior cornu, to the inferior thyroid tubercle on the inferior border of the lamina. Often, the oblique line is barely visible or is just a faint line and only the tubercles are prominent. Sternothyroid, thyrohyoid and thyropharyngeus (part of the inferior pharyngeal constrictor) are attached to the oblique line, usually as little more than a tendon (see Fig. 35.3A).

The internal surface of the lamina is smooth. Above and behind, it is slightly concave and covered by mucosa. The thyroepiglottic ligament, the paired vestibular and vocal ligaments, the thyroarytenoid, thyroepiglottic and vocalis muscles, and the stalk of the epiglottis are all attached to the inner surface of the cartilage, in the angle between the laminae The true vocal folds lie 6-9 mm below the median thyroid notch. The superior border of each lamina is concave posteriorly and convex anteriorly, dropping sharply to form the thyroid notch; the thyrohyoid membrane is attached along the superior border (see Figs 35.1, 35.2). The inferior border of each lamina is concave posteriorly and nearly straight anteriorly; the two parts are separated by the inferior thyroid tubercle. Anteriorly, the thyroid cartilage is connected to the cricoid cartilage by the median (anterior) cricothyroid ligament, which is the thickened medial portion of the conus elasticus.

The anterior border of each thyroid lamina fuses with its partner at an angle of approximately $90^{\circ}$ in men and approximately $120^{\circ}$ in women. The shallower angle in men is associated with the larger laryngeal prominence, the greater length of the vocal cords, and the resultant deeper pitch of the voice. The posterior border is thick and rounded, and receives fibres of stylopharyngeus and palatopharyngeus. The superior cornu, which is long and narrow, curves upwards, backwards and medially, and ends in a conical apex to which the lateral thyrohyoid ligament is attached. The inferior cornu is short and thick, and curves down and slightly anteromedially. On the anteromedial surface of its lower end there is a small oval facet for articulation with the side of the cricoid cartilage; this facet is variable and is only sometimes well defined.

During infancy, some older authors describe a narrow, rhomboidal, flexible strip, the intrathyroid cartilage, lying between the two thyroid laminae and joined to them by fibrous tissue. The significance of this structure is not clear.

## CRICOID CARTILAGE

The cricoid cartilage is attached below to the trachea, and articulates with the thyroid cartilage and the two arytenoid cartilages by synovial joints. It forms a complete ring around the airway, the only laryngeal cartilage to do so (see Fig. 35.3B). It is smaller, but thicker and stronger, than the thyroid cartilage, and has a narrow curved anterior arch and a broad, flatter posterior lamina.

## Cricoid arch

The cricoid arch is vertically narrow in front ( $5-7 \mathrm{~mm}$ in height) and widens posteriorly towards the lamina. Cricothyroid is attached to the external aspect of its front and sides, and cricopharyngeus (part of the inferior pharyngeal constrictor) is attached behind cricothyroid. The arch is palpable below the laryngeal prominence, from which it is separated by a depression containing the conus elasticus. The inferior border of the cartilage is nearly horizontal and is circular in outline, whereas the upper border is more elliptical.

## Cricoid lamina

The cricoid lamina is approximately quadrilateral in outline, and $2-3 \mathrm{~cm}$ in vertical dimension. It bears a posterior median vertical ridge that creates posterior concavities on either side. The two fasciculi of the longitudinal layer of oesophageal muscle fibres (muscularis externa) are attached by a tendon to the upper part of the ridge. Posterior cricoarytenoid attaches to a shallow depression on either side of the ridge.

A discernible circular synovial facet, facing posterolaterally, sometimes marks the junction of the lamina and arch; it indicates the site where the cricoid articulates with the inferior thyroid cornu. The inferior border of the cricoid is horizontal, and joined to the first tracheal cartilage by the cricotracheal ligament (see Fig. 35.1). The superior border runs obliquely up and back, and gives attachment anteriorly to the thick median cricothyroid ligament, and laterally to the conus elasticus (see Fig. 35.1) and lateral cricoarytenoid. The posterosuperior aspect of the lamina presents a shallow median notch, on each side of which is a smooth, oval, convex facet, directed upwards and laterally, for articulation with the base of an arytenoid cartilage.

The internal surface of the cricoid cartilage is smooth and lined by mucosa.

## Subglottic stenosis

Congenital malformation of the cricoid cartilage may result in severe narrowing of the subglottic airway and respiratory obstruction, which, in severe cases, is present from birth. It is the third most common congenital disorder of the larynx. The cause is unknown. Acquired subglottic stenosis is more common and is the result of trauma and scarring following prolonged endotracheal intubation for the purposes of ventilation of premature babies (Walner et al 2009).

## ARYTENOID CARTILAGE

The paired arytenoid cartilages articulate with the lateral parts of the superior border of the cricoid lamina (see Figs 35.2-35.3C, E). Each is pyramidal and has three surfaces, two processes, a base and an apex. The posterior surface, which is triangular, smooth and concave, is covered by transverse arytenoid. The anterolateral surface is convex and rough, and bears, near the apex of the cartilage, an elevation from which a crest curves back, down and then forwards to the vocal process. The lower part of this arcuate crest separates two depressions (foveae). The upper is triangular (fovea triangularis), and the vestibular ligament is attached to it. The lower is oblong (fovea oblonga), and vocalis and lateral cricoarytenoid are attached to it. The medial surface is narrow, smooth and flat, and is covered by mucosa; its lower edge forms the lateral boundary of the intercartilaginous part of the rima glottidis. The base is concave, with a smooth surface for articulation with the lateral part of the upper border of the cricoid lamina. Its round, prominent lateral angle, or muscular process, projects backwards and laterally; it gives attachment to posterior cricoarytenoid behind and lateral cricoarytenoid in front. The vocal ligament is attached to its pointed anterior angle (vocal process), which projects horizontally forwards. The apex curves backwards and medially, and articulates with the corniculate cartilage.

## CORNICULATE CARTILAGES

The corniculate cartilages are two conical nodules of elastic cartilage that articulate with the apices of the arytenoid cartilages, prolonging them posteromedially (see Figs 35.3E, 35.8). They lie in the posterior parts of the aryepiglottic mucosal folds, and are sometimes fused with the arytenoid cartilages.

## CUNEIFORM CARTILAGES

The cuneiform cartilages are two small, elongated, club-like nodules of elastic cartilage, one in each aryepiglottic fold anterosuperior to the corniculate cartilages, and are visible as whitish elevations through the mucosa (see Fig. 35.8).

## TRITIATE CARTILAGES (CARTILAGO TRITICEA)

The tritiate cartilages are two small nodules of elastic cartilage, situated one on either side above the larynx within the posterior free edge of
the thyrohyoid membrane, about halfway between the superior cornu of the thyroid cartilage and the tip of the greater cornu of the hyoid bone (see Figs 35.1-35.2). Their functions are unknown, although they may serve to strengthen this connection.

Other inconstant or supernumerary cartilages may occur in the larynx. They are the small, paired sesamoid cartilages, found at the lateral edges of the arytenoid cartilages, and a single interarytenoid cartilage, enclosed by the cricopharyngeal ligament.

## CALCIFICATION OF LARYNGEAL CARTILAGES

The thyroid, cricoid and most of the arytenoid cartilages consist of hyaline cartilage and may therefore become calcified. This process normally starts at about 18 years of age. Initially, it involves the lower and posterior part of the thyroid cartilage, and subsequently spreads to involve the remaining cartilages, calcification of the arytenoid cartilage starting at its base. The degree and frequency of calcification of the thyroid and cricoid cartilages appear to be less in females. There is some evidence to suggest that a predilection for tumour invasion may be enhanced by calcification of the laryngeal cartilages (Hatley et al 1965).

The tip and upper portion of the vocal process of the arytenoid cartilage consists of non-calcifying, elastic cartilage. This may have considerable functional significance: the vocal process may bend at the elastic cartilage during adduction and abduction, and the two arytenoid cartilages will contact mainly at their 'elastic' superior portions during adduction.

## JOINTS

## CRICOTHYROID JOINT

The joints between the inferior cornua of the thyroid cartilage and the sides of the cricoid cartilage are synovial. Each is enveloped by a capsular ligament strengthened posteriorly by fibrous bands (see Figs 35.1-35.2; Fig. 35.4). Both capsule and ligaments are rich in elastin fibres. The primary movement at the joint is rotation around a transverse axis that passes transversely through both cricothyroid joints. There is some controversy as to whether the cricoid or thyroid cartilage rotates more. The effect of this rotation is to move the cricoid and thyroid cartilages relative to one another in such a way as to bring together or approximate the lamina of the thyroid cartilage and the arch of the cricoid cartilage ('closing the visor'). When the joint is in a neutral position, the ligaments are slack and the cricoid can glide, to a limited extent, in horizontal and vertical directions on the thyroid cornua. The effect of these movements is to lengthen the vocal folds, provided the arytenoid cartilages are stabilized at the cricoarytenoid joint. This may also increase vocal fold tension. For further reading, see Vilkman et al (1987), Hammer et al (2010).

## CRICOARYTENOID JOINT

The cricoarytenoid joints are a pair of synovial joints between the facets on the lateral parts of the upper border of the lamina of the cricoid
cartilage and the bases of the arytenoids (see Figs 35.2, 35.3E, 35.4). Each joint is enclosed by a capsular ligament and strengthened by a ligament that, although traditionally called the posterior cricoarytenoid ligament, is largely medial in position.

The cricoid facets are elliptical, convex and obliquely directed laterally, anteriorly and downwards. The long axes of the two facets intersect posteriorly at an angle of about $50^{\circ}$. Two movements occur at this joint. The first is rotation of the arytenoid cartilages at right angles to the long axis of the cricoid facet (dorso-medio-cranial to ventro-latero-caudal), which, because of its obliquity, causes each vocal process to swing laterally or medially, thereby increasing or decreasing the width of the rima glottidis. This movement is sometimes referred to as a rocking movement of the arytenoid cartilages. There is also a gliding movement, by which the arytenoids approach or recede from one another, the direction and slope of their articular surfaces imposing a forward and downward movement on lateral gliding. The movements of gliding and rotation are associated, i.e. medial gliding occurs with medial rotation and lateral gliding with lateral rotation, resulting in adduction or abduction of the vocal folds, respectively. When viewed from above, foreshortening can give the illusion that the arytenoid cartilages are rotating about their vertical axes, but the shape of the facets prevents such movement occurring (Selbie et al 1998). However, some authors maintain that rotatory movement about a vertical axis can occur (Liu et al 2013). The posterior cricoarytenoid ligaments limit forward movements of the arytenoid cartilages on the cricoid cartilage. It has been suggested that the 'rest' position of the cricoarytenoid ligament is a major determinant of the position of a denervated vocal cord (England et al 1996).

## ARYTENOCORNICULATE JOINTS

Synovial or cartilaginous joints link the arytenoid and corniculate cartilages.

## INNERVATION OF THE CRICOTHYROID, CRICOARYTENOID AND ARYTENOCORNICULATE JOINTS

The cricothyroid, cricoarytenoid and arytenocorniculate joints are innervated by branches of the recurrent laryngeal nerves, which arise either independently or from branches of the nerve to the laryngeal muscles. The capsules of the laryngeal joints contain numerous lamellated (Pacinian) corpuscles, Ruffini corpuscles and free nerve endings (Bradley 2000).

## SOFT TISSUES

The skeletal framework of the larynx is joined to surrounding structures by extrinsic membranes. It is also interconnected by intrinsic ligaments and fibroelastic membranes, of which the thyrohyoid and quadrangular membranes, together with the conus elasticus, are the most significant. The thyrohyoid membrane is external to the larynx, whereas the

Fig. 35.4 A, A lateral view of the cricothyroid joint. B, An anterosuperior view of the cricoarytenoid joint.

There is a significant amount of variation in the shape of the cricothyroid facet, which can vary in shape from a well-defined facet to a nearly flat surface with just a slight protuberance or, in some cases, to no obvious definable facet. The shape of the facet determines the degree of horizontal and vertical gliding possible at the joint, and thus the degree of elongation of the vocal folds in each case, which has been shown to vary between $3 \%$ and $12 \%$. It has been suggested that this variation might be one factor in determining the success of cricothyroid approximation surgery aimed at raising the pitch of the voice in male to female transsexuals (Chen et al (2012), Hammer et al (2010), Windisch et al (2010), Storck et al (2011)).
paired quadrangular membranes and conus elasticus are internal. The named ligaments are the median (anterior) cricothyroid ligament, the hyoepiglottic and thyroepiglottic ligaments, and the cricotracheal ligament.

## EXTRINSIC LIGAMENTS AND MEMBRANES

## Thyrohyoid membrane

The thyrohyoid membrane is a broad, fibroelastic layer attached below to the superior border of the thyroid cartilage lamina and the front of its superior cornua, and above to the superior margin of the body and greater cornua of the hyoid (see Figs 35.1-35.2; Fig. 35.5C). It thus ascends behind the concave posterior surface of the hyoid, separated from its body by a bursa that facilitates the ascent of the larynx during swallowing. Its medial portion is thickened, forming the median thyrohyoid ligament. The more lateral, thinner, parts are pierced by the superior laryngeal vessels and internal laryngeal nerves (see Fig. 35.1). Externally, it is in contact with thyrohyoid and omohyoid, and with the body of the hyoid bone. Its inner surface is related to the lingual surface of the epiglottis and the piriform fossae of the pharynx. The round, cord-like, elastic lateral thyrohyoid ligaments form the posterior borders of the thyrohyoid membrane, and connect the tips of the superior thyroid cornua to the posterior ends of the greater hyoid cornua. For further reading, see Bosma and Bartner (1993).

## Hyo- and thyroepiglottic ligaments

The epiglottis is attached to the hyoid bone and thyroid cartilage by the extrinsic hyoepiglottic and intrinsic thyroepiglottic ligaments, respectively (see Fig. 35.5A).

## Cricotracheal ligament

The cricotracheal ligament unites the lower border of the cricoid to the first tracheal cartilage, and is thus continuous with the perichondrium of the trachea (see Fig. 35.1).

## INTRINSIC LIGAMENTS AND MEMBRANES

The fibroelastic membrane of the larynx lies within the cartilaginous skeleton of the larynx, beneath the laryngeal mucosa (see Fig. 35.5). It forms a discontinuous sheet, separated on both sides of the larynx by a horizontal cleft between the vestibular and vocal ligaments. Its upper part, the quadrangular membrane, lies within the walls of the upper part of the laryngeal cavity, the laryngeal vestibule, and extends between the arytenoid cartilages and the sides of the epiglottis. Its lower part, the conus elasticus, lies within the walls of the lower part of the laryngeal cavity, the infraglottic cavity, and connects the thyroid, cricoid and arytenoid cartilages.

## Quadrangular membrane

Each quadrangular membrane passes from the lateral margin of the epiglottis to the apex and fovea triangularis of the ipsilateral arytenoid cartilage. It is often poorly defined, especially in its upper portion. The upper and lower borders of the membrane are free. The upper border slopes posteriorly to form the aryepiglottic ligament, which constitutes the central component of the aryepiglottic fold. Posteriorly, it passes through the fascial plane of the oesophageal suspensory ligament, and helps to form the median corniculopharyngeal ligament, which extends into the submucosa adjacent to the cricoid cartilage. This ligament may exert vertical traction on the tissues of the laryngopharynx. The cuneiform cartilages lie within the aryepiglottic folds. The lower border of the quadrangular membrane forms the vestibular ligament within the vestibular fold.

## Cricothyroid membrane and conus elasticus

The conus elasticus is that part of the fibroelastic membrane found in the lower part of the cavity of the larynx. The terminology used to describe this structure is confusing, as different terms may be used to describe apparently similar structures. Two synonyms for the conus elasticus that are commonly found in the literature are the cricovocal membrane and the cricothyroid membrane. The conus elasticus

C

Fig. 35.5 A and B, Sagittal sections of the left side of the larynx, showing the laryngeal membranes $(\mathbf{A})$ and the interior aspect $(\mathbf{B})$ of the left half of the larynx. C, The quadrangular membrane viewed from the left side. (A, With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
consists of three distinct parts: right and left lateral parts and a thickened median portion. The term conus elasticus is frequently applied to the lateral parts, while the median part is often called either the median or the anterior cricothyroid ligament.

Median (anterior) cricothyroid ligament The median or anterior cricothyroid ligament is the thickened central portion of the conus elasticus. Inferiorly, it is attached to the upper border of the midline region of the cricoid arch and it extends upwards to attach to the inferior border of the thyroid cartilage, passing on to the inner surface of the thyroid angle as far superiorly as the attachment of thyroarytenoid.

Conus elasticus The lateral parts of the conus elasticus are thinner than the median cricothyroid ligament. Inferiorly, the conus elasticus attaches to the superior cricoid arch and the cricoid lamina. Superiorly, it does not attach to the inferior border of the thyroid cartilage but extends upwards within the thyroid lamina to attach anteriorly to the inner surface of the thyroid cartilage (just below its midpoint) and posteriorly to the tip, upper surface and fovea oblonga of the arytenoid cartilage. Between these anterior and posterior attachments, the upper edges of the conus elasticus are free, thickened and aligned horizontally, forming the vocal ligaments. Each vocal ligament lies within a mucosacovered vocal fold, covered on its internal surface by the mucosal lining of the larynx, and externally by the lateral cricoarytenoid and thyroarytenoid muscles (Reidenbach 1995).

The conus elasticus derives its name from the cone or funnel shape produced by the superior and medial curving of its walls between its inferior and superior attachments that is thought to maximize the efficient flow of air towards the rima glottidis during phonation (Lenneberg 1967).

## LARYNGEAL CAVITY

The laryngeal cavity extends from the laryngeal inlet opening into the pharynx down to the lower border of the cricoid cartilage, where it continues into the trachea (see Fig. 35.5; Fig. 35.6). The walls of the cavity are formed of the fibroelastic membranes described above and lined with mucous membrane that folds over the free edges of these membranes within the larynx. On either side, the continuity of the fibroelastic membrane is interrupted between the upper vestibular and lower true vocal folds.

The folds project into the lumen of the cavity and divide it into upper and lower parts, separated by a middle portion between the two sets of folds that leads into the laryngeal ventricle. The upper folds are the vestibular (ventricular or false vocal) folds; the median aperture between them is the rima vestibuli. The lower pair are the (true) vocal folds (or vocal cords), and the fissure between them is the rima glottidis or glottis. The true vocal folds are the primary source of phonation, whereas the vestibular folds normally do not contribute directly to

Fig. 35.6 A coronal section through the larynx and the cranial end of the trachea, posterior aspect.

sound production. The supraglottis is a clinical term sometimes used in tumour staging; it refers to all those parts of the larynx that lie above the glottis and thus comprises the laryngeal inlet (formed of the laryngeal surface of the epiglottis and arytenoid cartilages, and the laryngeal aspects of the aryepiglottic folds), the laryngeal vestibule and the vestibular folds. Other terms that are used clinically in tumour staging are the glottis, defined as the anterior and inferior surfaces of the true vocal folds and the anterior and posterior commissures; and the subglottis, defined as the region below the glottis that extends to the inferior border of the cricoid cartilage.

## MICROSTRUCTURE OF THE LARYNX

The laryngeal mucosa is continuous with that of the pharynx above and the trachea below. It lines the entire inner surface of the larynx, including the ventricle and saccule, and is thickened over the vestibular folds, where it is the chief component. Over the vocal folds, it is thinner and is firmly attached to the underlying vocal ligaments. It is loosely adherent to the anterior surface of the epiglottis but firmly attached to its anterior surface and the floor of the valleculae. On the aryepiglottic folds, it is reinforced by a considerable amount of fibrous connective tissue, and it adheres closely to the laryngeal surfaces of the cuneiform and arytenoid cartilages.

The laryngeal epithelium is mainly a ciliated, pseudostratified respiratory epithelium (see Fig. 2.2D) where it covers the inner aspects of the larynx, including the lower part of the posterior, laryngeal surface of the epiglottis, and it provides a mucociliary clearance mechanism shared with most of the respiratory tract. The vocal folds, however, are covered by non-keratinized, stratified squamous epithelium where they contact each other; this important variation protects the tissue from the effects of the considerable mechanical stresses that act on the surfaces of the vocal folds. The exterior surfaces of the larynx, which merge with the laryngopharynx and oropharynx (including the anterior, lingual and upper, posterior surfaces of the epiglottis and the upper parts of the aryepiglottic folds), are subject to the abrasive effects of swallowed food, and are therefore also covered by non-keratinized, stratified squamous epithelium.

The laryngeal mucosa has numerous mucous glands, especially over the epiglottis, where they pit the cartilage, and along the margins of the aryepiglottic folds anterior to the arytenoid cartilages, where they are known as the arytenoid glands. Many large glands in the saccules of the larynx secrete periodically over the vocal folds during phonation. The free edges of these folds are devoid of glands, and their stratified epithelium is vulnerable to drying and requires the secretions of neighbouring glands; hoarseness as a result of excessive speaking is due to partial temporary failure of this secretion. The epithelial surfaces are ridged and this may help retain the lubricating secretions over the surfaces of the edges of the folds. Poorly lubricated folds offer increased resistance to airflow, which means that higher subglottal pressures are needed to initiate phonation. Taste buds, like those in the tongue, are present on the posterior epiglottic surface and aryepiglottic folds, and less often in other laryngeal regions. Laryngeal stretch-, touch- and pressure-sensitive mechanoreceptors provide perceptual and proprioceptive afferent information for a variety of essential functions, including airway protection, breathing, deglutition, speech and voice (Hammer and Krueger 2014).

## UPPER PART

The upper part of the laryngeal cavity consists of the laryngeal inlet (aditus), the aryepiglottic fold and the laryngeal vestibule.

## Laryngeal inlet (aditus)

The upper part of the laryngeal cavity is entered by the laryngeal inlet (aditus laryngis), an approximately triangular aperture between the larynx and pharynx. This faces backwards and somewhat upwards because the anterior wall of the larynx is much longer than the posterior (and slopes downwards and forwards in its upper part because of the oblique inclination of the epiglottis). The inlet is bounded anteriorly by the upper edge of the epiglottis, posteriorly by the transverse mucosal fold between the two arytenoids (posterior commissure), and on each side by the edge of a mucosal ridge, the aryepiglottic fold, that runs between the side of the epiglottis and the apex of the arytenoid cartilage. The midline groove between the two corniculate tubercles is termed the interarytenoid notch.

## Aryepiglottic fold

The aryepiglottic fold contains ligamentous and muscular fibres. The ligamentous fibres represent the free upper border of the quadrangular membrane (see Fig. 35.5). The muscle fibres are continuations of the oblique arytenoids. The posterior part of the aryepiglottic fold contains two oval swellings, one above and in front, the other behind and below, that mark the positions of the underlying cuneiform and corniculate cartilages, respectively. They are separated by a shallow vertical furrow that is continuous below with the opening of the laryngeal ventricle.

## Laryngeal vestibule

The laryngeal vestibule is the region between the laryngeal inlet and vestibular folds. It is wide above, narrow below, and higher anteriorly than posteriorly. The anterior wall is formed by the posterior surface of the epiglottis, the lower part of which (epiglottic tubercle) bulges backwards a little. The lateral walls, higher in front and shallow behind, are formed by the medial surfaces of the aryepiglottic folds. The posterior wall consists of the interarytenoid mucosa above the ventricular folds.

## MIDDLE PART

The middle part of the laryngeal cavity is the smallest, and extends from the rima vestibuli above to the rima glottidis below. On each side it contains the vestibular folds, the ventricle and the saccule of the larynx.

## Vestibular folds and ligaments

The narrow vestibular ligament represents the thickened lower border of the quadrangular membrane (see Fig. 35.5C). It is fixed in front to the thyroid angle below the epiglottic cartilage and behind to the anterolateral surface of the arytenoid cartilage above its vocal process. With its covering of mucosa, it is termed the vestibular (ventricular or false vocal) fold (see Figs 35.5B-35.6). The presence of a loose vascular mucosa lends the vestibular folds a pink appearance in vivo, as they lie above and lateral to the vocal cords. Muscle fibres can be observed within the vestibular folds, though they are variable in extent between individuals. Their function is disputed, with some authors suggesting that, when present, they produce an adductive (or medializing) and downward movement on the vestibular folds (Reidenbach 1991, Moon and Alipour 2013).

## Ventricle of the larynx

The laryngeal ventricle (also known as the laryngeal sinus) is a slit between the vestibular folds above and the true vocal folds below (see Figs 35.5-35.6). On each side, it extends from a narrow opening in the wall of the middle part of the laryngeal cavity into a fusiform recess that extends upwards into the laryngeal wall, lateral to the vestibular fold, and opens anteriorly into the saccule.

## Saccule of the larynx

The saccule is a pouch of variable size that ascends forwards from the anterior end of the ventricle, between the vestibular fold and thyroid cartilage (see Fig. 35.6), and occasionally reaches the upper border of the cartilage or even beyond, when it protrudes through the thyrohyoid membrane. It is conical and curves slightly backwards; between 60 and 70 mucous glands, sited in the submucosa, open on to its luminal surface. The orifice of the saccule is guarded by a delicate fold of mucosa, the ventriculosaccular fold.

The saccule has a fibrous capsule that is continuous below with the vestibular ligament. It is covered medially by a few muscular fasciculi from the apex of the arytenoid cartilage that pass forwards between the saccule and vestibular mucosa into the aryepiglottic fold; laterally, it is separated from the thyroid cartilage by the thyroepiglottic muscle. The latter compresses the saccule, expressing its secretion on to the vocal cords, which lack glands, to lubricate and protect them against desiccation and infection.

## Laryngoceles and saccular cysts

## Vocal folds (cords) and ligaments

The vocal folds are concerned with sound production. The free thickened upper edge of the conus elasticus forms the vocal ligament (see (Fig. 35.5C). It stretches back on either side from the midlevel of the thyroid angle to the vocal processes of the arytenoids. When covered by mucosa, it is termed the vocal fold or vocal cord (cord is the preferred clinical term) (see Figs 35.5B-35.6). The vocal folds lie on either side of a fissure, the rima glottidis, and form the anterolateral three-fifths of its edges. The posterior two-fifths of the edges of the rima glottidis are formed by the vocal processes of the arytenoid cartilages (to which the vocal folds are attached).

Each vocal fold consists of five layers, namely: mucosal epithelium, lamina propria (three layers) and a muscular layer (fibres of thyroarytenoid and vocalis) (Fig. 35.7). The mucosa overlying the vocal ligament is thin and attached to the underlying lamina propria by a basement membrane. It lies directly on the ligament, and so the vocal fold appears pearly white in vivo. At birth, the lamina propria consists of a single layer of cells. It becomes a bilaminar structure by 2 months of age and three layers become established by 7 years of age (Hartnick 2005). The lamina propria is composed of three layers. The most superficial consists of loose collagen and elastic fibres and is only loosely attached to the underlying vocal ligament, an arrangement that produces a potential space (Reinke's space) that extends along the length of the free margin of the vocal ligament and a little way on to the superior surface of the cord; oedema fluid readily collects here in disease. The intermediate layer consists of elastic fibres, and the deep layer is formed of collagen fibres; these two layers collectively form the vocal ligament. The appearance of differential fibres - namely, elastin and collagen - is noted at 13 years of age (Hartnick 2005). Fibres of thyroarytenoid and vocalis form the fifth layer of the vocal folds; they shorten, relax and aid adduction of the vocal folds (see p. 596).

The site where the vocal folds meet anteriorly, the anterior commissure, is the region where fibres of the vocal ligament pass through the thyroid cartilage to blend with the overlying perichondrium. The point at which the vocal ligaments attach to the thyroid cartilage is known as Broyles ligament; it contains blood vessels and lymphatics, and therefore represents a potential route for the escape of malignant tumours from the larynx. This is a very significant anatomical escape pathway for primary tumours arising on the vocal cord.

Located at the anterior and posterior end of each vocal ligament are the maculae flavae. These form conspicuous mucosal bulges visible on endoscopic examination of the larynx through the mucosa as whitish yellow masses. The vocal folds are connected to thyroid cartilage anteriorly via the anterior maculae flavae and the anterior commissure tendon, and posteriorly via the posterior maculae flavae. The maculae flavae themselves are described as being formed of dense masses of stellate cells with a morphology markedly different from that of fibroblasts surrounded by a dense extracellular matrix. The function of the maculae flavae remains unclear but it has been suggested that they play a critical role in the growth, development and metabolism of the extracellular matrix of the vocal folds (Awd Allah et al 2009, Fayoux et al 2004, Sato et al 2010a, 2010b).

## Laryngeal carcinoma

Squamous cell carcinoma is by far the most common laryngeal neoplasm. The pattern of spread is largely determined by anatomical features at the site of origin and this, in turn, influences its management and potential outcomes (Welsh et al 1989, Kirchner and Carter 1987).

## Reinke's oedema

The mucous membrane is loosely attached throughout the larynx. It can accommodate considerable swelling, which may compromise the airway in acute infections. At the edge of the true vocal folds, the mucosal covering is tightly bound to the underlying ligament so that oedema fluid does not pass between the upper and lower compartments of the vocal cord mucosa. Any tissue swelling above the vocal cord exaggerates the potential space deep to the mucosa (Reinke's space), causing accumulation of extracellular fluid and flabby swelling of the vocal cords (Reinke's oedema). The oedema can persist because there is very poor lymphatic drainage from the edges of the vocal folds (Liu et al 2006). Vocal abuse may initiate such changes, but the condition is nearly always confined to smokers.

## Vocal cord nodules

Vocal fold nodules are chronic lesions of the vocal folds and develop most commonly as the result of persistent overuse of the voice, which has caused an increase in vocal fold tension and a more forceful adduction. They normally develop at the point of maximum contact of the

Laryngoceles and saccular cysts are air- or fluid-filled enlargements of the saccule. A laryngocele is a herniation of the saccular mucosa. The aetiology is uncertain; repeated, sustained, high transglottal pressures (such as in trumpet playing) may be a possible cause of acquired symptoms, and some cases may be the result of congenital enlargement of the saccule. Growth of a laryngocele is constrained by the surrounding tissues, and so it expands upwards into the paraglottic space anterior to the piriform fossa, and superiorly to expand the aryepiglottic fold and reach the vallecula (internal laryngocele). It can extend to the thyrohyoid membrane, which it may pierce to form an external laryngocele, and where it may be palpable in the neck. Symptoms include hoarseness, stridor and dysphagia. The laryngeal saccule may also become pathologically enlarged as a result of obstruction of the ventricular aditus by inflammation, scarring, or compression by a tumour; an expanding, mucus-filled cyst forms as the glandular secretions accumulate. These fluid-filled saccular cysts can expand in a similar direction to a laryngocele and may also pierce the thyrohyoid membrane. In addition to hoarseness and stridor, acute respiratory obstruction may occur, especially in the young, if the contents of the cyst become infected.

There are alternative descriptions of the soft tissues of the vocal folds. Some authors describe only two layers, namely: the body (the deep layer of the lamina propria and the muscle) and the cover (the mucosa and superficial and intermediate layers of the lamina propria). Others divide the soft tissues of the vocal folds into three layers: the mucosal layer (the mucosa and the superficial layer of the lamina propria), the vocal ligament (the intermediate and deep layers of the lamina propria) and the muscle layer (Titze 1994).

Supraglottic tumours arising from the laryngeal surface of the epiglottis have a tendency to spread through the perforations in the epiglottic cartilage and into the pre-epiglottic space, through which branches of the internal laryngeal nerve pass. It is likely that the neural deficit this may cause accounts for the most common presenting symptom: a feeling of something in the throat and discomfort when swallowing. In some, this space becomes filled with tumour and can even infiltrate the hyoid bone. Inferior spread into the paraglottic space is more common and may extend as far as the subglottis or even beyond the larynx. Spread in this space medializes the vocal cord; this can be seen on careful laryngoscopy when assessing the tumour stage and may be confirmed by scans. Lateral spread into the piriform sinus is also a feature of tumours arising lower down in the supraglottis on the vestibular folds. Deeper invasion infiltrates the thyroarytenoid muscle and eventually the thyroid and arytenoid cartilages.

Ventricular tumours often obstruct mucus outflow from the saccule to cause a saccular cyst or mucocele. Further infiltration of the paraglottic space and transglottic spread ultimately fixes the vocal cord through muscle invasion and, more rarely, direct involvement of the cricoarytenoid joint or infiltration of the recurrent laryngeal nerve. Fixation of the vocal cord is a good indicator of a tumour within the paraglottic space and this is reflected in the TNM staging system as an adverse sign.

Glottic tumours tend to spread by local growth in the first instance, when they may be contained in Reinke's space for some time. The paucity of lymphatics in the vocal cord slows tumour progression, allowing time for the patient to present to a clinician with a relatively small tumour load that will only have caused a chronic husky voice. This anatomical feature also accounts for the relative lack of nodal metastases associated with small glottic tumours. The proximity of anterior cord tumours to the thyroid cartilages, separated only by a thin layer of connective tissue, predisposes to cartilage invasion; spread of tumour via Broyles ligament to the outside of the larynx changes the tumour stage from a T1 lesion to a T4 lesion, with both therapeutic and survival implications. More posterior cord tumours tend to invade the vocalis muscle and fix it.

Subglottic tumours usually spread circumferentially and, by doing so, impair the airway.

Fig. 35.7 A, A coronal view of the laryngeal cavity, showing the distribution of the mucous membrane in the laryngeal cavity. B, The structure of the true vocal folds at low power, $\times 40$, stained with Movat's pentachrome stain. C, The true vocal folds at high power, $\times 100$; Movat's pentachrome stain. The non-keratinized squamous epithelium is shown forming a mucosal layer over the superficial part of the lamina propria, along with the three layers of the lamina propria, with thyroarytenoid and vocalis lying deep to the deep layer of the lamina propria. At higher magnification, the deeper yellow staining of the collagen in the deep layer of the lamina propria compared to the superficial layer indicates a greater degree of cross-linking. vocal folds, i.e. at the junction of the anterior third and the posterior two-thirds of the vocal ligament. Excessive trauma at this point, e.g. when singing with poor technique or forcing the voice, initially produces subepithelial haemorrhage or bruising; in time, this results in pathological changes such as subepithelial scarring ('singer's nodes' or 'clergyman's nodes'). Nodules increase vocal fold mass and affect vocal fold closure; the persistent posterior glottal opening causes hoarseness, a breathy voice, reduced vocal intensity and an inability to produce higher frequencies of vibration. These changes can cause a cycle in which increasing vocal effort is required by way of compensation, and this exacerbates the problem (Aronson and Bless 2009).

## Rima glottidis

The rima glottidis or glottis is the fissure between the vocal cords anteriorly and the arytenoid cartilages posteriorly (Fig. 35.8). It is bounded behind by the mucosa that passes between the arytenoid cartilages at
the level of the vocal cords. The glottis is customarily divided into two regions: an anterior intermembranous part, which makes up about three-fifths of its anteroposterior length and is formed by the underlying vocal ligament; and a posterior intercartilaginous part, formed by the vocal processes of the arytenoid cartilages. It is the narrowest part of the larynx, having an average sagittal diameter in adult males of 23 mm , and in adult females of 17 mm ; its width and shape vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation.

## LOWER PART

The lower part of the laryngeal cavity, the infraglottic cavity (also known as the subglottic cavity), extends from the vocal cords to the lower border of the cricoid. In transverse section, it is elliptical above and wider and circular below, and is continuous with the trachea. Its walls are lined by respiratory mucosa, and are supported by the cricothyroid ligament above and the cricoid cartilage below (Reidenbach 1998). The walls of this part of the laryngeal cavity are said to be exponentially curved, a feature that may serve to accelerate the airflow towards the glottis with the minimum loss of energy (Lenneberg 1967).

## LARYNGOSCOPIC EXAMINATION

The laryngeal inlet, the structures around it, and the cavity of the larynx can all be inspected using fibreoptic endoscopy, through either the mouth or nasopharynx. The epiglottis is seen foreshortened but its tubercle is visible. From the epiglottic margins, the aryepiglottic folds can be traced posteromedially and the cuneiform and corniculate elevations recognized. The pink vestibular folds and pearly white vocal cords are visible, and, when the rima glottidis is wide open, the anterior arch of the cricoid cartilage, the tracheal mucosa and cartilages may be seen (see Fig. 35.8). The piriform fossae can also be inspected.

## LARYNGEAL OBSTRUCTION AND TRAUMA

The mucosa of the upper larynx is highly sensitive and contact with foreign bodies excites immediate coughing. Large foreign bodies may
obstruct the laryngeal inlet or rima glottidis and suffocation may ensue. Smaller articles may enter the trachea or bronchi, or lodge in the laryngeal ventricle and cause reflex closure of the glottis with subsequent suffocation. Inflammation of the upper larynx, e.g. secondary to infection or the effects of smoke inhalation, may swell the mucosa by effusion of fluid into the loose submucous tissue (oedema of the supraglottis). The effusion neither involves nor extends below the vocal cords because the mucosa here is bound directly to the vocal ligaments and there is no submucous tissue. Laryngotomy below the vocal cords through the cricothyroid ligament, or tracheotomy below the cricoid cartilage, may be necessary to restore a free airway

The consequences of trauma to the larynx resulting from either blunt or penetrating injuries may lead to any or all of the following: oedema, haematoma, fracture, dislocations or paralysis. Trauma at the level of the rima glottidis may result in thyroid cartilage fracture and displacement of the fragments into the vocal folds posteriorly with consequent oedema. Suicidal wounds are usually made through the thyrohyoid membrane, damaging the epiglottis, superior thyroid vessels, external and internal carotid arteries, and internal jugular veins. Less frequently, these wounds are inflicted above the hyoid, so that the lingual muscles and lingual and facial vessels are damaged. Caustic substances swallowed accidentally or during a suicide attempt, the ingestion of hot liquids and the inspiration of hot gases may all result in serious laryngeal damage. Radiotherapy as part of the treatment for neck cancer can cause radiation burns within the larynx (Myer 2004).

## THE PAEDIATRIC LARYNX

The paediatric larynx differs markedly from its adult counterpart in size, position, consistency and shape. Although it is about one-third adult size, it is proportionately larger; the lumen is short and funnel-shaped, and disproportionately narrower. The infant larynx lies higher in the neck than the adult larynx (see Fig. 34.11). At rest, the upper border of the infant epiglottis is at the level of the second or third cervical vertebra; when the larynx is elevated, it reaches the level of the first cervical vertebra. This high position enables an infant to use its nasal airway to breathe while suckling. It also means that the larynx is protected somewhat by the jaw. The epiglottis is X-shaped, with a furled petiole, and the laryngeal cartilages are softer and more pliable than in the adult larynx (which may predispose to airway collapse in inspiration, leading to the clinical picture of laryngomalacia). The thyroid cartilage is shorter and broader, and lies closer to the hyoid bone in the neonate, which means that the thyrohyoid ligament is relatively short. Neither the superior notch nor the laryngeal prominence is as marked as it is in the adult. The cricoid cartilage is the same shape as in the adult. Calcification of the cricoid cartilage has been noted as early as 7 years of age (Strauss 2000). The arytenoid cartilages are larger in proportion to the larynx as a whole and so are more prominent; the aryepiglottic folds are disproportionally large. The vocal cords are $4-4.5 \mathrm{~mm}$ long, which is relatively shorter than either in childhood or in the adult, and consequently the proportion of the rima glottidis that is intramembranous is smaller in the neonate. The ventricle of the larynx is small, whereas the saccule of the larynx is often considerably larger than it is in adult life. The time at which the infant larynx assumes adult characteristics varies in the literature from 5 to 12 years; some adults retain a funnelshaped larynx (Wheeler et al 2009). Further discussion is beyond the scope of this book; the interested reader should consult Wheeler et al (2009) and Holzki et al (2010).

The mucosa of the vestibule is more loosely attached than it is in the adult larynx and it exhibits multiple submucosal glands. Inflammation of the vestibule will therefore rapidly result in gross oedema. The mucosa is also lax in the infraglottic cavity and swelling here rapidly causes severe respiratory obstruction because of the disproportionally narrower lumen ( 3.5 mm in diameter in neonates). The neonatal infraglottic cavity extends posteriorly as well as inferiorly, which is an important consideration when passing an endotracheal tube (Litman et al 2003). The infraglottic airway rapidly increases in size during the first two years of life (Eckel et al 1999). By about the third year, sexual differences become apparent: the larynx is larger in boys, although the angle between the thyroid laminae is more pronounced in girls. At puberty, these changes increase and there is greater enlargement of the male larynx.

Congenital anomalies of the larynx include aplasia and hypoplasia of the epiglottis, high-rising epiglottis, bifid epiglottis, saccular cysts, vocal cord palsy, laryngeal atresia, laryngocele, laryngo-tracheooesophageal cleft and laryngeal web. Laryngo-tracheo-oesophageal cleft is due to failure of fusion of the posterior cricoid lamina and abnormal development of the tracheo-oesophageal septum, resulting in a pos-
terior sagittal communication between the larynx and pharynx. For further reading, see Adewale (2009), Hudgins et al (1997), Pracy (1983) and Sapienza et al (2004).

## PARALUMENAL SPACES

A number of potential spaces lie between the laryngeal cartilages and the ligaments and membranes that support them. The three main spaces are the pre-epiglottic, the paraglottic and the subglottic spaces. Their precise definition, and the extent to which they communicate with one another, remain controversial. They are not closed compartments and so their existence does not preclude the spread of tumours. An awareness of the anatomy of these spaces, and the potential pathways of tumour spread from them, have significantly influenced the surgical approach to disease in this region (Welsh et al 1983).

## PRE-EPIGLOTTIC SPACE

Its name implies that the pre-epiglottic space (Fig. 35.9) lies anterior to the epiglottis. The upper part of this space also extends beyond the lateral margins of the epiglottis, an arrangement that gives the space the form of a horseshoe and has led to the suggestion that periepiglottic space would be a more appropriate term for this region (Reidenbach 1996a). The space is primarily filled with adipose tissue and does not appear to contain any lymph nodes.

The upper boundary is formed by the weak hyoepiglottic membrane, strengthened medially as the median hyoepiglottic ligament; the anterior boundary is the thyrohyoid membrane, strengthened medially as the median thyrohyoid ligament; and the lower boundary is the thyroepiglottic ligament, continuous laterally with the quadrangular membrane behind. The greater cornu of the hyoid bone forms its upper lateral border. Inferolaterally, the pre-epiglottic space is in continuity with the paraglottic space, from where it is often invaded by the laryngeal saccule. It is also in continuity with the mucosa of the laryngeal surface of the epiglottis via multiple perforations in the cartilage of the epiglottis (Reidenbach 1996a).

## PARAGLOTTIC SPACE

The paraglottic space (see Fig. 35.9) is a region of adipose tissue that contains the internal laryngeal nerve, the laryngeal ventricle, and all or part of the laryngeal saccule. It is bounded laterally by the thyroid cartilage and thyrohyoid membrane, superomedially by the quadrangular membrane, inferomedially by the conus elasticus, and posteriorly by the piriform fossa. The lower border of the thyroid cartilage is inferior, and the paraglottic space is continuous inferiorly with the space between the cricoid and thyroid cartilages. Anteroinferiorly, there are deficiencies in the paramedian gap at the side of the median cricothyroid ligament, and posteroinferiorly, adipose tissue extends towards the cricothyroid joint. Superiorly, the paraglottic space is usually continuous with the pre-epiglottic space, although the two spaces may be separated by a fibrous septum. There is disagreement between authors as to the precise boundaries between these two spaces. Some authorities exclude thyroarytenoid from the paraglottic space and include it within the preepiglottic space, forming its inferior border posterolaterally (Reidenbach 1996b).

## SUBGLOTTIC SPACE

The subglottic space is bounded laterally by the conus elasticus, medially by the mucosa of the infraglottic cavity, and above by the undersurface of Broyles ligament in the midline. It is continuous below with the inner surface of the cricoid cartilage and its mucosa (Reidenbach 1998)

## MUSCLES

The muscles of the larynx may be divided into extrinsic and intrinsic groups. The extrinsic muscles connect the larynx to neighbouring structures and are responsible for moving it vertically during phonation and swallowing. They include the infrahyoid strap muscles, thyrohyoid, sternothyroid and sternohyoid, and the inferior constrictor muscle of the pharynx. Two of the three elevator muscles of the pharynx, stylopharyngeus and palatopharyngeus, are also connected directly to the

Fig. 35.9 A contrast-enhanced axial computed tomogram of the neck of a 42-year-old male showing the paraglottic and pre-epiglottic spaces. (Courtesy of Dr Ivan Zammit.)
thyroid cartilage, mainly to the posterior aspect of the thyroid laminae and cornua.

The role of the extrinsic muscles during respiration appears to be variable; the larynx has been seen to rise, descend or barely move during inspiration. The extrinsic muscles can affect the pitch and the quality of the voice by raising or lowering the larynx, and geniohyoid elevates and anteriorly displaces the larynx, particularly during deglutition.

Elevation of the larynx decreases the length and calibre of the laryngopharynx and thus shortens the vocal tract overall. This tends to raise both the formant frequencies as well as the fundamental frequency and may be one way by which an increase in pitch is achieved, though a change in pitch is not an inevitable consequence of this movement. The raising of the larynx may also be accompanied by forward or backward movement of the tongue because of the attachment of the tongue to the hyoid bone. These movements may facilitate alveolar or velar articulations, respectively.

The larynx is lowered by contraction of the infrahyoid muscles. This increases the length of the laryngopharynx, tending to lower both the formant frequencies and the fundamental frequency, though, again, a pitch change is not inevitable. Another effect of lowering the larynx will be to decrease supraglottal pressure and this will facilitate the articulation of voiced stops and fricatives (to a lesser extent). Voice quality can also be varied by the height of the larynx and this is an important factor contributing to the variations in quality of voice between different speakers.

The intrinsic muscles are the cricothyroid, posterior and lateral cricoarytenoid, transverse and oblique arytenoid, aryepiglotticus, thyroarytenoid and its subsidiary part, vocalis, and thyroepiglotticus; all are confined to the larynx in their attachments, and all but the transverse arytenoid are paired (Fig. 35.10). Whereas most of the intrinsic muscles lie internally, under cover of the thyroid cartilage or the mucosa, the cricothyroids appear on the outer aspect of the larynx.

The intrinsic laryngeal muscles may be placed in three groups according to their main actions. The posterior and lateral cricoarytenoids and oblique and transverse arytenoids vary the degree of abduction and adduction of the vocal folds and thus the dimensions and the degree of opening of the rima glottidis. The cricothyroids, posterior cricoarytenoids, thyroarytenoids and vocalis regulate the length and tension of the vocal folds. In reality, the obliquity of the cricoarytenoid facets means that some overlap in function between these two muscle groups is inevitable. Thus, alterations in the dimensions of the rima glottidis will produce small changes in vocal fold length, and shortening the vocal folds will also result in a degree of adduction. The third group of muscles is the oblique arytenoids, aryepiglottic and thyroepiglottic muscles, which modify the laryngeal inlet. Bilateral pairs of muscles usually act in concert with each other.

Neuromuscular spindles have been found in all human laryngeal muscles, the maximum number being found in the transverse arytenoid (Blitzer et al 2009). The control of phonation requires very considerable neuromuscular coordination, and effective proprioception would appear to be essential to this capacity. The mass of muscle related to adduction far outweighs that related to abduction. In this context, it is of interest to note that histological examination of normal larynges revealed evidence of some degenerative changes in posterior cricoarytenoid, the single muscle associated with abduction, but none in the remaining muscles (Guindi et al 1981).

Anatomical variations in the anatomy of the laryngeal muscles

Available with the Gray's Anatomy e-book

## INTRINSIC MUSCLES

## Oblique arytenoid and aryepiglotticus

The oblique arytenoids lie superficial to the transverse arytenoid and are sometimes considered to be part of it. They cross each other obliquely at the back of the larynx, each extending from the back of the muscular process of one arytenoid cartilage to the apex of the opposite one (see Fig. 35.10D). Some fibres continue laterally round the arytenoid apex into the aryepiglottic fold, forming the aryepiglottic muscle (aryepiglotticus).

Vascular supply Oblique arytenoid receives its blood supply from the laryngeal branches of the superior and inferior thyroid arteries.
IInnervation Oblique arytenoid is innervated by the recurrent laryngeal nerve.

Actions The oblique arytenoids and aryepiglottic muscles act as a sphincter of the laryngeal inlet by adducting the aryepiglottic folds and approximating the arytenoid cartilages to the tubercle of the epiglottis. Their poor development limits their capacity to act as a sphincter of the inlet. The oblique interarytenoids are weak adductors of the vocal folds, and may be more effective in this action than the transverse interarytenoids because of the superior mechanical advantage.

## Transverse (inter)arytenoid

Transverse arytenoid is a single, unpaired muscle deep to the oblique interarytenoids (see Fig. 35.10C). It bridges the gap at the back of the larynx between the two arytenoid cartilages and fills their concave posterior surfaces. It is attached to the back of the muscular process and adjacent lateral border of both arytenoids.

Vascular supply Transverse arytenoid receives its blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation Transverse arytenoid is innervated by the recurrent laryngeal nerves. It also receives branches from the internal laryngeal nerve, although there is debate as to whether these branches contain any distinct motor input. The nerves form a dense, but highly variable, plexus.

Actions Transverse arytenoid pulls the arytenoid cartilages towards each other, closing the posterior, intercartilaginous, part of the rima glottidis (termed adductive tensing by phoneticians) (see Fig. 35.10C). During a whisper, the muscle is relaxed while lateral cricoarytenoid contracts, allowing air to escape during phonation. This action is accomplished by drawing the arytenoids upwards to slide along the sloping shoulders of the cricoid lamina, without rotation.

## Posterior cricoarytenoid

Posterior cricoarytenoid arises from the posterior surface of the cricoid lamina (see Fig. 35.10A). Its fibres ascend laterally and converge to insert on the upper and posterior surfaces of the muscular process of the ipsilateral arytenoid cartilage. The highest fibres run almost horizontally, the middle run obliquely, and the lowest are almost vertical; some reach the anterolateral surface of the arytenoid cartilage. An additional strip of muscle, ceratocricoid, is occasionally seen in relation to the lower border of posterior cricoarytenoid, arising from the cricoid cartilage and inserting on to the posterior aspect of the inferior cornu of the thyroid cartilage.

Vascular supply Posterior cricoarytenoid receives its blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation Posterior cricoarytenoid is innervated by the recurrent laryngeal branch of the vagus.

Actions The posterior cricoarytenoids are the only laryngeal muscles that open the glottis. They rotate the arytenoid cartilages laterally around an axis that passes through the long axis of the facets of the cricoarytenoid joints, producing separation of the vocal processes and the attached vocal cords (see Fig. 35.10A). They also pull the arytenoids backwards, assisting the cricothyroids to lengthen the vocal cords. The most lateral fibres draw the arytenoid cartilages laterally, and so the rima glottidis becomes triangular when the posterior cricoarytenoid muscles contract. The posterior cricoarytenoids are active in the production of unvoiced sounds.

## Lateral cricoarytenoid

Lateral cricoarytenoid is attached anteriorly to the upper border of the cricoid arch. It ascends obliquely backwards to be attached to the front of the muscular process of the ipsilateral arytenoid cartilage (see Fig. 35.10B).

Vascular supply Lateral cricoarytenoid receives its blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation Lateral cricoarytenoid is innervated by 1-6 branches of the anterior terminal division of the recurrent laryngeal nerve, with the most frequent pattern consisting of 3 branches. In the majority of cases, these branches arise over the muscle itself.

Actions Lateral cricoarytenoid rotates the arytenoid cartilage in a direction opposite to that of posterior cricoarytenoid, and so closes the

Numerous variations in the anatomy of the intrinsic muscles have been described in the literature. The more frequently found ones are described in the main text. A particularly comprehensive source documenting these variations was published in 1875 by Fürbringer. Later authors have studied many of these variations but estimates of their frequency often vary significantly between the various studies; the functional significance of many of these variations is not clear.

Fig. 35.10 The intrinsic muscles of the larynx in posterior or lateral views, with their actions shown alongside in a superior view. The arrows indicate the direction of movement of the cartilage in each case.
rima glottidis (see Fig. 35.10B). As it does so, it brings the tips of the vocal processes together, closing the ligamentous part of the rima glottidis, an action known as medial compression. The action of lateral cricoarytenoid in adducting the vocal folds is therefore distinct and complementary to that of the oblique and transverse arytenoid muscles. Contraction of lateral cricoarytenoid also results in shortening and relaxing of the vocal folds.

## Cricothyroid

Cricothyroid is attached anteriorly to the external aspect of the arch of the cricoid cartilage (see Fig. 35.10F). Its fibres pass backwards and diverge into two groups: a lower 'oblique' part, which slants backwards and laterally to the anterior border of the inferior cornu of the thyroid; and a superior 'straight' part, which ascends more steeply backwards to the posterior part of the lower border of the thyroid lamina. The medial borders of the paired cricothyroids are separated anteriorly by a triangular gap occupied by the median cricothyroid ligament.

Vascular supply Cricothyroid is supplied by the cricothyroid artery, a branch of the superior thyroid artery, which crosses high on the cricothyroid ligament to communicate with its contralateral fellow.

Innervation Unlike the other intrinsic muscles of the larynx, cricothyroid is innervated by the external branch of the superior laryngeal nerve, and not by the recurrent laryngeal nerve.

Actions Cricothyroid lengthens and affects the tension in the vocal folds. It does this by shortening the space between the inferior border of the thyroid cartilage and the cricoid cartilage, an action that increases the distance between the tip of the vocal process of the arytenoid cartilage and the posterior surface of the lamina of the thyroid cartilage. Rotation occurs at the cricothyroid joint (see above). At the same time, the posterior part of cricothyroid pulls the thyroid cartilage forwards, a gliding action that also lengthens the vocal folds. Some authors consider that cricothyroid has a slight adductive action in moving the vocal folds to a more paramedian position as they are lengthened and thinned (Mu and Sanders 2009, Wadie et al 2013). Others have attributed the relative sparing of abduction in lesions of the recurrent laryngeal nerve to a weak abductive action of cricothyroid. These contradictory views are currently unresolved.

## Thyroarytenoid and vocalis

Thyroarytenoid is a broad, thin muscle, lying lateral to the vocal fold, conus elasticus, laryngeal ventricle and saccule (see Fig. 35.10E). It is attached anteriorly to the lower half of the angle of the thyroid cartilage, and to the cricothyroid ligament. Its fibres pass backwards, laterally and upwards to the anterolateral surface of the arytenoid cartilage. The lower and deeper fibres form a band that, in coronal section, appears as a triangular bundle attached to the lateral surface of the vocal process and to the fovea oblonga on the anterolateral surface of the arytenoid cartilage. This bundle, the vocalis muscle, is viewed by some authors as simply a deeper part of the thyroarytenoid and by others as a distinct and separate muscle. The vocalis is parallel with, and just lateral to, the vocal ligament. It is said to be thicker behind than in front, because many deeper fibres start from the vocal ligament and do not extend to the thyroid cartilage. (An alternative view is that all its fibres loop and intertwine as they pass from the thyroid to the arytenoid cartilage.) A few fibres extend along the wall of the ventricle from the lateral margin of the arytenoid cartilage to the side of the epiglottis. Superior thyroarytenoid, an inconstant small muscle, lies on the lateral surface of the main mass of thyroarytenoid; when present, it extends obliquely from the thyroid angle to the muscular process of the arytenoid cartilage.

Vascular supply Thyroarytenoid receives its arterial blood supply from the laryngeal branches of the superior and inferior thyroid arteries.

Innervation All parts of thyroarytenoid are supplied by the recurrent laryngeal nerve. It also receives a communicating branch from the external laryngeal nerve, although it is not clear whether such branches carry motor or sensory fibres.

Actions The thyroarytenoids draw the arytenoid cartilages towards the thyroid cartilage, thereby shortening and relaxing the vocal ligaments. At the same time, they rotate the arytenoids medially in opposition to the action of posterior cricoarytenoid to approximate the vocal folds and so aid closure of the rima glottidis. Relaxation of the posterior parts

Fig. 35.11 An anterior view of the blood supply and innervation of the larynx. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
of the vocal ligaments by the vocalis muscles, combined with tension in the anterior parts of the ligaments, is responsible for raising the pitch of the voice. Vocalis can change the timbre of the voice by affecting the mass of the vocal cords.

## Thyroepiglotticus

Many of the fibres of thyroarytenoid are prolonged into the aryepiglottic fold, where some terminate, and others continue to the epiglottic margin as thyroepiglotticus. The thyroepiglotticus muscles can widen the inlet of the larynx by their action on the aryepiglottic folds.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The blood supply of the larynx is derived mainly from the superior and inferior laryngeal arteries (Fig. 35.11). Rich anastomoses exist between the corresponding contralateral laryngeal arteries and between the ipsilateral laryngeal arteries. The superior laryngeal arteries supply the greater part of the tissues of the larynx, from the epiglottis down to the level of the vocal cords, including the majority of the laryngeal musculature. The inferior laryngeal artery supplies the region around cricothyroid, while its posterior laryngeal branch supplies the tissue around posterior cricoarytenoid (Trotoux et al 1986).

## ARTERIES AND VEINS

## Superior laryngeal artery

The superior laryngeal artery is normally derived from the superior thyroid artery, a branch of the external carotid artery, as this artery
passes down towards the upper pole of the thyroid gland (see Fig. 29.14). Sometimes, however, it arises directly from the external carotid artery between the origins of the superior thyroid and lingual arteries or, less commonly, from the common carotid artery or carotid bifurcation (Vazquez et al 2009). The superior laryngeal artery runs down towards the larynx, with the internal branch of the superior laryngeal nerve lying above it. It enters the larynx by penetrating the thyrohyoid membrane and divides into a number of branches that supply the larynx from the tip of the epiglottis down to the inferior margin of thyroarytenoid. It anastomoses with its contralateral fellow and with the inferior laryngeal branch of the inferior thyroid artery.

## Cricothyroid artery

The cricothyroid artery arises from the superior thyroid artery and may contribute to the supply of the larynx. It follows a variable course, either superficial or deep to sternothyroid. If superficial, it may be accompanied by branches of the ansa cervicalis, and if deep, it may be related to the external laryngeal nerve. It can anastomose with the artery of the opposite side and with the laryngeal arteries.

## Inferior laryngeal artery

The inferior laryngeal artery is smaller than the superior laryngeal artery. It is a branch of the inferior thyroid artery, which arises from the thyrocervical trunk of the subclavian artery (see Fig. 29.17). It ascends on the trachea with the recurrent laryngeal nerve, enters the larynx at the lower border of the inferior constrictor, just behind the cricothyroid articulation, and supplies the laryngeal muscles and mucosa. The inferior laryngeal artery anastomoses with its contralateral fellow and with the superior laryngeal branch of the superior thyroid artery.

A posterior laryngeal artery of variable size has been described as a regular feature that arises as an internal branch of the inferior thyroid artery.

## Superior and inferior laryngeal veins

Venous return from the larynx occurs via superior and inferior laryngeal veins, which run parallel to the laryngeal arteries and are tributaries of the superior and inferior thyroid veins, respectively. The superior thyroid vein drains into the internal jugular vein, and the inferior thyroid vein usually drains into the left brachiocephalic vein.

## LYMPHATIC DRAINAGE

The vocal folds, with their firmly bound mucosa and paucity of lymphatics at their edges, provide a clear demarcation between the upper and lower areas of the larynx. Above the vocal folds, the rich network of lymph vessels draining the supraglottic part of the larynx accompany the superior laryngeal artery, pierce the thyrohyoid membrane, and end in the upper deep cervical lymph nodes, often bilaterally. The supraglottic lymphatics also communicate with those at the base of the tongue. Below the vocal fold, some of the lymph vessels of the infraglottic cavity pass through the conus elasticus to reach the prelaryngeal (Delphian) and/or pretracheal and paratracheal lymph nodes, while others accompany the inferior laryngeal artery and join the lower deep cervical nodes (Welsh et al 1983, Werner et al 2003).

## Nodal spread of laryngeal tumours

The upper deep cervical lymph nodes act as pathways for the spread of malignant tumours of the supraglottic larynx. Up to $40 \%$ of these tumours will have undergone such spread at the time of clinical presentation. As stated previously, the glottis is very poorly endowed with lymphatic vessels; some $95 \%$ of malignant tumours confined to the glottis will present only with a change in voice or airway obstruction, but will not show signs of spread to adjacent lymph nodes at presentation. Tumours of the subglottic larynx will often spread to the paratracheal lymph node chain prior to clinical presentation. The presenting symptoms are usually voice change and airway obstruction rather than a mass in the neck. The paratracheal lymph nodes occupy a deep-seated position in the root of the neck and so their enlargement may remain occult. They must be looked for carefully at surgery and included in any radiation field.

Fig. 35.12 A posterior view of the laryngeal innervation.

## INNERVATION

The larynx is innervated by the internal and external branches of the superior laryngeal nerve, the recurrent laryngeal nerve and sympathetic nerves (see Fig. 35.11; Fig. 35.12). Conventionally, the internal laryngeal nerve is described as sensory, the external laryngeal nerve as motor, and the recurrent laryngeal nerve as mixed. The internal laryngeal nerve is sensory down to the vocal cords, the recurrent laryngeal nerve is sensory below the vocal cords, and there is overlap between the territories innervated by the two nerves at the vocal cords themselves. All the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerve except for cricothyroid, which is supplied by the external laryngeal nerve. A number of anastomoses between the internal, external and recurrent laryngeal nerves have been described, with varying estimates of their incidence. Chronologically, the oldest recorded is that between the recurrent laryngeal nerve and the internal laryngeal branch of the superior laryngeal nerve (Galen's anastomosis). The majority of these anastomoses are found on the posterior surface of the larynx, forming what has been described as a laryngeal plexus to parallel the pharyngeal plexus. Their precise nature and function are unclear, but since some are thought to convey motor fibres, it is reasonable to assume that functions commonly ascribed to the three laryngeal nerves may be more complex than the conventional descriptions imply, which may have potential clinical implications (Furlan et al 2002, Sato and Shimada 1995, Sanders et al 1993, Naidu et al 2014).

The detailed course of the vagus in the neck is described on page 466.

## Superior laryngeal nerve

The superior laryngeal nerve arises from the middle of the inferior vagal ganglion. It receives one or more communications from the superior cervical sympathetic ganglion; most frequently, the connection is with
the external laryngeal nerve. The sympathetic communication contributes to the innervation of the carotid body (Monfared et al 2002) and the thyroid gland (Sun and Chang 1991). Though the superior laryngeal nerve usually lies on the medial side of the internal carotid artery, it may be found on the lateral side of the artery. The superior laryngeal nerve divides into two branches: a smaller, external and a larger, internal branch, approximately 1.5 cm below the ganglion. Rarely, both branches may arise from the ganglion.

## Internal laryngeal nerve

The internal laryngeal nerve passes forwards approximately 7 mm before piercing the thyrohyoid membrane, usually at a higher level than the superior thyroid artery (Durham and Harrison 1962). It splits into superior, middle and inferior branches on entering the larynx. The superior branch supplies the mucosa of the piriform fossa. The large middle branch is distributed to the mucosa of the ventricle, specifically the quadrangular membrane, and therefore probably conveys the afferent component of the cough reflex. The inferior ramus is mainly distributed to the mucosa of the ventricle and subglottic cavity. On the medial wall of the piriform fossa, descending branches give twigs to the interarytenoid muscle and share a number of communicating branches with the recurrent laryngeal nerve (Sanders and Mu 1998).

## External laryngeal nerve

The external laryngeal nerve continues downwards and forwards on the lateral surface of the inferior constrictor, to which it contributes some small branches. Indeed, the nerve is sometimes located within the fibres of the constrictor muscle. It passes beneath the attachment of sternothyroid to the oblique line of the thyroid cartilage and supplies cricothyroid. A communicating nerve continues from the posterior surface of cricothyroid, crosses the piriform fossa and enters thyroarytenoid, where it anastomoses with branches from the recurrent laryngeal nerve. It has been suggested that these communicating branches may provide both additional motor components to thyroarytenoid and sensory fibres to the mucosa in the region of the subglottis. An anastomosis between the external and internal laryngeal nerves has also been described in some cases. (For further reading, see Kochilas et al (2008).)

The close relationship of the external laryngeal nerve to the superior thyroid artery puts the nerve at potential risk when the artery is clamped during thyroid lobectomy, particularly when it is close to the artery (in approximately $20 \%$ of cases), or where, instead of crossing the superior thyroid vessels approximately 1 cm or more above the superior pole of the gland, it actually passes below this point (in some 20\% of cases) (Cernea et al 1992, Kierner et al 1998). The external laryngeal nerve is also at risk in parathyroidectomy, carotid endarterectomy and anterior cervical spine procedures.

## Recurrent laryngeal nerve

The recurrent laryngeal nerve enters the larynx by passing either deep to (usually) or between (sometimes) the fibres of cricopharyngeus at its attachment to the lateral aspect of the cricoid cartilage. It supplies cricopharyngeus as it passes. At this point, the nerve is in intimate proximity to the posteromedial aspect of the thyroid gland. The main trunk divides into two or more branches, usually below the lower border of the inferior constrictor, although branching may occur higher up. The anterior branch is mainly motor and is sometimes called the inferior laryngeal nerve (although this term is best avoided to prevent any confusion with a former synonym for the recurrent laryngeal nerve), while the posterior branch is mainly sensory. The anterior branch of the recurrent laryngeal nerve ascends posterior to the cricothyroid joint and its ligament, and is usually covered by fibres of posterior cricoarytenoid at this point. It bends over the joint, continuing forwards over the lateral cricoarytenoid muscle before terminating within thyroarytenoid.

The anterior branch of the recurrent laryngeal nerve first innervates posterior cricoarytenoid by one or more branches, then innervates interarytenoid and lateral cricoarytenoid, and terminates in thyroarytenoid, which it also supplies (see also Maranillo et al 2005).

The recurrent laryngeal nerve forms several anastomoses with the superior laryngeal nerves (see Fig. 35.12). The posterior branch of the recurrent laryngeal nerve ascends deep to posterior cricoarytenoid to join the descending branch of the internal laryngeal nerve. The ansa Galeni, lying on the interarytenoid muscles, forms a direct connection between the recurrent and internal laryngeal nerves (see Fig. 35.12). There is also a complex anastomosis within and over the posterior surface of the interarytenoid muscles, and, less frequently, anastomoses
on the cricoid lamina and thyroarytenoid that form connections with the internal laryngeal nerve (Furlan et al 2002, Sanudo et al 1999).

The recurrent laryngeal nerve does not always lie in a protected position in the tracheo-oesophageal groove but may be slightly anterior to it (more often on the right), and it may be markedly lateral to the trachea at the level of the lower part of the thyroid gland. The upper part of the nerve has a close but variable relationship to the inferior thyroid artery. On the right, it is as often anterior to, or posterior to, or intermingled with, the terminal branches of the artery. On the left, the nerve is usually posterior to the artery, though occasionally it lies anterior to it. The stated incidences of these relationships vary between different authors. The recurrent laryngeal nerve may supply extralaryngeal branches to the larynx that arise before it passes behind the inferior thyroid cornu (Bowden 1955).

External to its capsule, the thyroid gland is covered by the visceral layer of deep cervical fascia which splits into two layers at the posterior border of the gland. The anterior layer covers the entire medial surface of each lobe. At, or just above, the isthmus, this layer is conspicuously thickened to form the lateral ligament of the thyroid gland, which attaches the gland to the trachea and the lower part of the cricoid cartilage. The posterior layer passes behind the oesophagus and pharynx, and is attached to the prevertebral fascia. A compartment is thus formed on each side of the midline, lateral to the trachea and oesophagus; it contains fat, the recurrent laryngeal nerve and terminal parts of the inferior thyroid artery. The nerve may be lateral or medial to the lateral ligament of the thyroid gland, and sometimes may be embedded in it.

A very rare anomaly that is of relevance to laryngeal pathology and surgery is the so-called 'non-recurrent' laryngeal nerve, where the right recurrent laryngeal nerve arises directly from the vagus nerve trunk high up in the neck and enters the larynx close to the inferior pole of the thyroid gland. Only the right side is affected, and it is always associated with an abnormal origin of the right subclavian artery from the aortic arch on the left side. If unrecognized, a non-recurrent laryngeal nerve may be susceptible to injury during surgery. It may also potentially be compressed by small tumours of the thyroid gland (Friedman et al 1986).

## Lesions of the vagus nerve and recurrent laryngeal nerve paralysis

The consequences of vagal nerve lesions are complex, reflecting the long course of the nerve and the possible involvement of three of its branches, namely: the pharyngeal, superior laryngeal and recurrent laryngeal nerves. Collectively, these nerves innervate muscles of the larynx, soft palate and pharynx; injury may therefore have deleterious effects on phonation and/or soft palate movements and/or swallowing. A lesion of the vagus above the level at which the pharyngeal branch is given off will affect both the superior and recurrent laryngeal nerves. This causes immobility of the vocal folds on the affected side and imparts a breathy voice with lack of pitch and limited loudness. The affected cord is paralysed and lies in the so-called 'cadaveric' position halfway between abduction and adduction. If the lesion is unilateral, the voice is weak and hoarse, but if it is bilateral, phonation is almost absent, the vocal pitch cannot be altered, and the cough is weak and ineffective. There will also be a degree of hypernasality because of the effects on movements of the soft palate caused by paralysis of levator veli palatini. Unilateral palsies impact very significantly on the quality of life of the patient because of impaired vocalization and a tendency to aspirate. Bilateral palsies are extremely serious and a tracheostomy is required to protect the airway. In some, a tracheal diversion procedure may become necessary.

A lesion affecting the superior laryngeal nerve may be unilateral or bilateral. Complete section is most likely during the ligation of the vessels forming the vascular pedicle of the thyroid gland during thyroid lobectomy. Unilateral lesions may result in the vocal folds appearing relatively normal and the effect on voice is barely noticeable and is often overlooked. A more detailed examination may detect some shortening of the vocal folds on the affected side with asymmetric tilt of the epiglottis and the anterior larynx canted towards the unaffected side. The result is a mildly hoarse voice with loss of pitch control. Bilateral superior laryngeal nerve lesions result in shortening of both vocal folds, the overhanging of the epiglottis over the folds and reduced tilt between the thyroid and cricoid cartilage. Effects on the voice are correspondingly greater, with reduced loudness and pitch but variable breathiness.

Damage to the internal laryngeal nerve causes loss of mechanoreceptive and proprioceptive sensation from the larynx. Unilateral loss produces a feeling that something is stuck in the throat, whereas bilateral loss will result in aspiration and can cause dysphagia, with a risk of choking.

Unilateral complete palsy of the recurrent laryngeal nerve is more common on the left side, presumably because the nerve is longer on this side. There is isolated paralysis of all the laryngeal muscles on the affected side except cricothyroid, which is innervated by the external laryngeal nerve. The patient may be asymptomatic or have a hoarse, breathy voice and there will be diminished ability to manipulate pitch. The hoarseness may be permanent or may become less severe with time as the contralateral cord develops the ability to hyperadduct and appose the paralysed cord and thus close the glottis during phonation and coughing, although this is seldom enough to restore full voice quality There may be aspiration of food and drink. Bilateral lesions of the recurrent laryngeal nerve result in both vocal cords being paralysed and taking up a paramedian position. Phonation can be nearly normal because the vocal folds lie so close to the midline, but there will be audible stridor and a very compromised airway.

Clinically, the position of the vocal cord in the acute phase after section of the recurrent laryngeal nerve is very variable. Though stridor is more common after bilateral lesions and sometimes only audible to the educated ear, the cords may be sufficiently abducted so that there is little problem with airway obstruction at rest, although the voice is always weaker in this situation. The cords are slightly more widely separated in chronic lesions, which renders the voice weaker but with a less precarious airway. Atrophy and fibrosis of paraglottic muscles probably affect the position of paralysed vocal cords in chronic lesions to a greater degree than variations in the strength of the apposing adductor and abductor muscle groups.

For many years, conventional wisdom held that movements of abduction were affected to a greater degree than those of adduction when the recurrent laryngeal nerve was partially damaged (Semon's law). This effect was thought to reflect the internal segregation within the recurrent laryngeal nerve of axons supplying the laryngeal abductor muscles; the idea was later undermined by the demonstration that axons destined for particular laryngeal muscles are randomly distributed within the nerve. The weak abductive action of cricothyroid that is said to occur on lengthening the vocal folds has been proposed as an explanation for the relative sparing of abduction in these lesions but is difficult to reconcile with the alternative view that cricothyroid may be a slight adductor of the vocal folds (Mu and Sanders 2009, Wadie et al 2013). It is likely that predicting the effect of partial lesions of the recurrent laryngeal nerve is complicated by the variable patterns of anastomosis that occur between the laryngeal nerves. For further reading, see Aronson and Bless (2009) and Blitzer et al (2009).

## Autonomic innervation

Parasympathetic secretomotor fibres run with both the superior and the recurrent laryngeal nerves to mucous glands throughout the larynx Postganglionic sympathetic fibres run to the larynx with its blood supply; they originate in the superior and middle cervical ganglia. A variable number of paraganglia are located on the internal laryngeal and recurrent laryngeal nerves. Histochemical evidence suggests that one population of the neurones in these ganglia have a parasympathetic function whilst a second population may secrete dopamine (Maranillo et al 2008, Ibanez et al 2010).

## ANATOMY OF SPEECH

The principal biological function of the larynx is to act as a sphincter controlling the entry of foreign bodies into the airways and to regulate airflow during ventilation. Thus, the larynx is opened widely during ventilation and is closed tightly during swallowing. The larynx can also close tightly during exertion, effort closure, to regulate thoracic and abdominal pressure during activities such as defecation or parturition, or to fix the thorax to increase mechanical advantage when using the arms to lift objects. The importance of the latter activity should not be underestimated; one of the many problems reported by patients who have undergone a laryngectomy is a loss of power in their arms when trying to lift heavy objects.

The larynx is much more than a simple valve that opens and closes. In addition to its sphincteric functions, its location means that it is perfectly placed to act as a sound source, or voice, that forms the basis of nearly all sounds in human speech. The musculoskeletal structure of the larynx is under exquisite neuromuscular control, allowing it to modify the expiratory stream to produce highly complex patterns of sound of varying loudness, frequency and duration. The ability to execute these complex movements depends largely on specific areas of the cerebral hemispheres that are involved in the motor aspects of
language, such as speech and writing, and sensory manifestations of language, including reading and understanding the spoken word. Central control of voice production involves two parallel pathways: a limbic pathway responsible for the control of innate non-verbal and emotional vocalizations, and a larynx-specific motor cortical pathway responsible for regulating the motor control necessary for voluntary voice production. For further reading, see Clark et al (2007), Kaplan (1971), Laver (1980), Atkinson and McHanwell (2002), Titze (1994), Zemlin (1998).

## OVERVIEW OF SPEECH PRODUCTION

All speech requires an input of energy. For all sounds in Western European languages, and most sounds in other languages, this energy takes the form of a pulmonary expiration. This continuous airflow is converted into a vibration within the larynx by a mechanism called phonation, in which the vocal folds vibrate periodically, interrupting the column of air as it leaves the lungs and converting it into a series of discrete puffs of air. Speech sounds that are produced by vocal fold vibration in this way are said to be voiced. Speech sounds that are produced without vocal fold vibration are termed unvoiced sounds.

The larynx is an inadequate sound source; the laryngeal 'buzz' that is produced by phonation is very quiet and cannot be varied sufficiently to produce the complex range of sounds that is human speech. Amplification and modification of the sound occur in the supralaryngeal vocal tract, which may be considered as a 17 cm long tube, narrow at the larynx and broadening out proximally as it passes through the pharynx, and oral and nasal cavities. This tube acts as a passive amplifier of the sound. (The analogy here is of a megaphone; cupping the hands round the lips lengthens the vocal tract and increases the volume of speech.) The supralaryngeal vocal tract modifies the basic vibration of the larynx by altering its geometry, length and calibre; it provides a series of resonators that can dampen or amplify certain sound frequencies and can transiently interrupt the exhaled air flow and modify it to produce speech. This process is known as articulation. The range of sounds that the human vocal tract is capable of producing is very wide, although any one human language will employ a subset of these sounds to convey meaning.

## MUSCULAR CONTROL OF THE AIRSTREAM

Normal vegetative ventilation involves rhythmic movements of the thoracic cage that are produced by intercostal muscles and the diaphragm and by a number of accessory muscles in the neck, arm and abdomen that have one attachment to some part of the thoracic cage. The thorax is capable of responding mechanically to widely varying demands for oxygen. From a tidal volume at rest of 500 ml and a respiratory rate of 12 per minute, ventilation can increase in fit individuals during vigorous exercise to tidal volumes of 4.5 litres and respiratory rates of 20-25 per minute.

Normal ventilatory patterns are considerably modified during speech, reflecting the special demands that speech places on ventilation. The main source of energy for the production of speech sounds is a pulmonary expiration, although other mechanisms are possible. In order for speech to be produced, sufficient pressure has to be generated beneath the vocal folds. This subglottal pressure (the difference between the air pressures above and below the vocal folds) has to be sustained above a minimum level throughout an utterance. It sets the vocal folds into vibration if the sound is to be voiced or generates airflow for an unvoiced sound. The minimum subglottal pressure needed for speech production is $7 \mathrm{cmH}_{2} \mathrm{O}$, and this increases when loud sounds are produced or when sounds are stressed.

The need to generate sufficient sustained pressure means that speech ventilation is markedly non-rhythmical. At the onset of an utterance, inspiration is typically 1.5 litres, which is deeper than for normal quiet ventilation, ensuring that sufficient air is taken in to maintain adequate subglottal pressure for the duration of the utterance. Inspiration is also quicker, 0.5 seconds rather than $2-3$ seconds. Expiration is much longer than normal, perhaps lasting up to 30 seconds, reflecting the fact that the vocal tract is more constricted at the larynx to ensure that pauses for further inspirations are made at suitable points in an utterance. At the end of the first inspiration during running speech, lung volumes do not fully return to resting levels. Conversational speech normally takes place at a higher range of lung capacities than operate in normal quiet ventilation.

The non-rhythmical pattern during speech requires greater inspiratory effort, and for most people it involves a greater use of the
diaphragm, usually in combination with the abdominal muscles that are attached to the lower ribs (they stabilize the costal attachments of the diaphragm and increase the effectiveness of its action). The main differences, however, are seen in expiration. Speech takes place at higher lung volumes, which means that greater recoil forces are stored in the elastic tissues of the lungs and the ribcage. The generation of subglottal pressure is the product of these elastic recoil forces and the muscular forces generated by the expiratory muscles. At the onset of an utterance, unrestrained recoil forces would generate excessive subglottal pressures that would be wasteful of air, and hence energy, and would affect the loudness of speech. Conversely, towards the end of an utterance, as recoil forces decline, subglottal pressure would fall without additional muscular exertion. Therefore, early in an utterance, inspiratory muscles, particularly the external intercostals and parasternal parts of the internal intercostals, continue to contract, relaxing slowly to counteract the effects of excessive passive elastic recoil. As the recoil forces decline below the point where they can maintain the minimum subglottal pressure needed for phonation, expiratory muscles contract to maintain subglottal pressure as lung air volume nears its resting expiratory level. The main muscles involved are the costal parts of the internal intercostals and the subcostal and transversus thoracis muscles. Their actions are aided by contraction of the anterior abdominal muscles to compress the abdomen. Accessory muscles such as latissimus dorsi may also come into play, but normally these accessory muscles are only active at the end of a very long or loud utterance, or in patients whose ventilatory function is compromised.

Though subglottal pressure tends to remain fairly constant during an utterance, it rises when sounds are stressed, and falls during the production of unvoiced sounds when the larynx is less constricted. At these times, compensatory mechanisms are required to ensure that pressure is maintained; the precise mechanisms have yet to be elucidated but the internal intercostal muscles have been implicated. The anterior abdominal muscles are also active in singing and shouting, and in attempts to speak without the pause necessary for inspiration. Contrary to popular belief, the diaphragm plays little part in the regulation of expiratory force. Unlike the intercostal muscles, the diaphragmatic musculature is sparsely supplied with muscle spindles, and therefore control of the diaphragm is poorly regulated; minute changes can be effected more successfully using the intercostal and anterior abdominal muscles.

Though the expiratory airflow from the lungs is the source of energy for most speech sounds, other sources of airflow are also used. The larynx can be used to generate airflow. The sound /p/ is produced by closing the larynx and then raising it with the lips closed, using the larynx like a piston. Opening the lips then releases a puff of air. This is called an ejective and is an example of egressive glottalic airflow. Ingressive glottalic airflow is also possible, though less effective; examples are not found in English but do occur in some African and native American languages. A third kind of airflow is velaric, in which the back of the tongue is raised against a lowered soft palate and the vocal tract is closed anterior to that point, either at the lips or with the tongue against the hard palate. This produces a click and is rare. A non-linguistic example in English is the sound made in encouraging a horse. Ingressive pulmonary airflow, such as is found in a groan or a gasp, is theoretically possible, but none of the world's languages employ this as a source of airflow.

After removal of the larynx, e.g. following laryngeal cancer, patients can be taught to swallow air, store it in a segment of the oesophagus and then use it as the energy source to produce egressive oesophageal airflow (oesophageal speech). Speech in these circumstances tends to have a belching quality and may be badly phrased. Laryngectomy patients always produce phrases that are shorter than normal, and so prostheses incorporating valves and surgical shunts are often inserted to provide a larger egressive airstream by diverting air from the respiratory tract into the oesophagus.

## PHONATION

The default position of the rima glottidis is open, to maintain patency of the airway during respiration. In quiet respiration, the anterior intermembranous part of the rima glottidis is triangular when viewed from above. Its apex is anterior and its base posterior, and it is represented by an imaginary line approximately 8 mm long connecting the anterior ends of the arytenoid vocal processes. The intercartilaginous part between the medial surfaces of the arytenoids is rectangular, as the two vocal processes lie parallel to each other. During forced respiration, the rima glottidis is widened and the vocal cords are fully abducted to increase the airway. The arytenoid cartilages rotate laterally, and this
moves their vocal processes apart, and converts the rima glottidis into a diamond shape in which both intermembranous and intercartilaginous parts are triangular. The greatest width of the rima glottidis is at the point of the attachments of the vocal cords to the vocal processes.

During speech, the true vocal folds vibrate to act as a source of sound for subsequent speech. There have been a number of theories to explain the mechanism that produces this vibration but these are now only of historic interest. The aerodynamic-myoelastic theory is generally accepted as the mechanism underlying vocal fold vibration, although it does not account for all aspects of phonation.

At the onset of an utterance, during an expiration, the true vocal folds are adducted: the lateral cricoarytenoids and interarytenoids bring together both the intermembranous and intercartilaginous parts of the glottis, actions that either close the glottis completely or reduce the space between the vocal folds to a linear chink. The mucous membrane covering the interarytenoid muscles, the interarytenoid fold, intrudes into the larynx when these muscles adduct the arytenoids, and so aids closure of the intercartilaginous part of the rima glottidis. The vocal cords are also tensed, an essential prerequisite for vibration. These actions cause a build-up of subglottal pressure that continues until a point is reached when the muscular force of adduction is no longer sufficient to resist the rising pressure, and the vocal folds are forced open a little, releasing air into the supralaryngeal vocal tract. The subglottal pressure falls when the subglottic and supraglottic cavities become continuous and the vocal folds begin to close. Two mechanisms bring about closure. If adductive tension is sustained, then the vocal folds will close. In addition, rapid closure is aided by a physical process, the Bernoulli effect. The forcing of air from a region of high to low pressure through a narrow space causes an increase in the kinetic energy of the molecules at the edge of the space. The effect of this is to lower pressure in the space between the folds at the level of the folds themselves, and this negative pressure simply sucks the folds together because they are mobile. This causes a rise once more in the subglottal pressure and the cycle is repeated. The effect is to cause the release of a series of puffs of air into the supralaryngeal vocal tract at a frequency of many times per second, which is perceived as a sound of a particular frequency (Figs 35.13-35.14).

The source of energy for the vibration does not come from the larynx itself. The vocal folds do not behave like the prongs of a tuning fork; their predominant motion is in the horizontal plane at right angles to the movement of the air column, and there is little vertical movement. The energy is derived from the motion of the air generated by the muscular and recoil forces in the thorax, and the larynx is simply chopping that column into a series of segments.

The aerodynamic-myoelastic theory does not explain how vocal fold vibration is sustained; nor does it account for the very obvious mucoundulatory component of vocal fold vibration that is visible when the larynx is viewed stroboscopically. Without further input of energy, the vibration of the vocal folds as described above would not be sustained but would be damped and gradually diminish. For vibration to continue there has to be additional energy input. The analogy here is with a child on a swing. For the motion to continue, either the parent has to push the child at an appropriate point in the cycle, or the child has to sustain the motion for themselves by swinging their legs at the crucial point in the swing cycle. In the case of phonation, the source of this additional energy is unclear. It may come from the inertia of the air column itself, i.e. once the vocal folds close, the air column will continue moving upwards because inertia creates a negative pressure above

Fig. 35.13 A video montage of the normal phonatory cycle, obtained using a rigid fibreoptic endoscope with stroboscopic illumination. (Courtesy of Professor Paul Carding.)

Fig. 35.14 The position of the vocal folds during a cycle of vocal fold vibration (phonatory cycle). A, Superior view. B, Coronal view.
the folds. Alternatively, the energy could come from the manner in which the folds open and close. As the subglottal pressure rises, the lower portion of the fold opens first and the upper edge of the fold is last to open, and when the subglottal pressure falls, the folds close from the bottom edge. It has been suggested that this non-uniform closure creates different shapes within the glottis that may result in differing negative pressures at different phases of the cycle. It also produces a vertical wave-like motion in the folds, termed the muco-undulatory component. The analogy here is with a flag blowing in the wind, and it reflects the differing stiffnesses of the various layers of the vocal folds described above. This vertical component will impart a negligible amount of energy to the air column, but it is likely to impart harmonics to the basic laryngeal vibration.

The sound that results from the process of phonation has three characteristics: a frequency that is perceived as pitch, an intensity that is perceived as loudness, and a timbre perceived as voice quality.

The fundamental frequency of the human voice is determined by the resting length of the vocal cords and varies with age and sex. The frequency range of human speech is from 60 to 500 Hz , with an average of approximately 120 Hz in males, 200 Hz in females and 270 Hz in children. The mechanism of frequency alteration is not entirely clear. An increase in subglottal pressure will cause the frequency of phonation to rise. During an utterance, however, subglottal pressure appears to remain fairly constant, which suggests that the mechanism of frequency alteration resides in intrinsic changes within the vocal folds. Variations in frequency (pitch changes) during an utterance are determined by the complex interrelationships between length, tension and thickness of the vocal cords; one of these variables cannot be altered without affecting the other two parameters to some extent. Gross changes to the vocal cords demonstrate the effects of these variables. Inflamed and swollen vocal cords are much thicker than normal and result in a hoarse voice. At puberty, growth of the thyroid cartilage in males lengthens the vocal cords and lowers the fundamental frequency, and the voice 'breaks' as a result. During panic, the vocal cords may be tensed, which means that the cry for help is a high-pitched squeak.

Pitch is increased by lengthening the vocal folds, as may be confirmed during direct endoscopic examination of the larynx. At first sight this may seem counterintuitive but, as the vocal cords are lengthened,
there will be a consequent thinning and change in tension. Although an analogy is often drawn between the vocal cords and vibrating strings, a better analogy is that of a rubber band: if a rubber band is lengthened, the tension will increase but the thickness will decrease. The vocal cords may be lengthened by up to $50 \%$ of their resting length. It is likely that the initial pitch setting is achieved by action of the cricothyroids, and that fine adjustments can then be made using the vocales. Paralysis of both cricothyroids, which is usually associated with loss of the neurones that are distributed via the superior laryngeal nerve (as a result of damage to the vagal nuclei in brainstem stroke), results in permanent hoarseness and inability to vary the pitch of the voice. It is important to remember that, once the vocal cords are set in motion, they will deviate from their original setting as they vibrate. Auditory feedback of the sounds produced is used to make minute compensatory adjustments to length, tension and thickness in order to maintain a constant pitch.

Any lengthening of the vocal cords tends to thin them. The thickness can be increased by the vocalis part of thyroarytenoid: as vocalis shortens, it will relax the vocal cords and at the same time increase their thickness. Changes in the tension of the vocal cords are produced by the same muscles that change their length, namely: cricothyroid, posterior cricoarytenoid and vocalis, probably acting isometrically.

The mechanism by which loudness is increased is the subject of less debate. Loud sounds are produced by increasing subglottal pressure. This is achieved, in turn, by changing the opening quotient of the glottis (the ratio of the time spent in the open phase of the cycle to the total cycle time). In normal speech, this ratio is usually around 0.5 , but in very loud speech it can fall to 0.3 .

Timbre or voice quality refers to the harsh or mellow quality of the voice. At high volume, the voice tends to be harsher, especially in untrained voices; higher-frequency components predominate because higher subglottal pressures are needed to sustain the increased volume. This can be overcome to an extent by increasing the airflow rather than the pressure.

A fundamental distinction in speech needs to be made between voiced and unvoiced sounds; nearly all languages make this distinction. Voicing has been described above. In unvoiced sounds, the vocal folds are not vibrating and will usually be opened under the action of
posterior cricoarytenoid. The energy from the airstream is then used by other parts of the vocal tract to generate sound, normally by constricting or stopping the airflow. Phonation is not an all-or-nothing process, however, but is subject to considerable modification and adjustment. In modal voice, i.e. speaking using habitual pitch, forces acting on the vocal folds are moderate, pressures are sustained, and air is conserved. However, phonation can occur when the vocal folds are more open than usual, resulting in breathy phonation with more air escaping per phonatory cycle than usual. Some languages in South Asia exploit the difference between breathy and non-breathy sounds, whereas in spoken English, a breathy voice is simply recognized as a feature of some speakers. At the other end of the spectrum is vocal creak, in which the vocal folds are more closed than normal. Different speakers will habitually employ different laryngeal settings that contribute to their particular voiced quality. In whispering, the intramembranous part of the glottis is closed but the intercartilaginous part remains open, which produces a characteristic Y-shaped glottis and a greater loss of air at each phonatory cycle.

The main function of the larynx is to act as a sound source, but it can also function in speech as an airstream generator and as an articulator.

## ARTICULATION

The sound produced by the phonation is not a pure tone because several harmonics at multiples of the fundamental frequency are also generated. Harmonics give a note of a particular frequency its defining characteristics. An ' A ' played on an oboe or violin is immediately recognizable because of the different harmonics generated by the design of the instrument. The harmonic spectra of individual voices differ and will also vary depending upon the mode of phonation adopted. In the human vocal tract, the fundamental frequency and its harmonics are transmitted to the column of air that extends from the vocal cords to the exterior, mainly through the mouth. Part of the airstream can also be diverted through the nasal cavities when the soft palate is depressed to allow air into the nasopharynx. The supralaryngeal vocal tract acts as a selective resonator whose length, shape and volume can be varied by the actions of the muscles of the pharynx, soft palate, fauces, tongue, cheeks and lips; the relative positions of the upper and lower teeth, which are determined by the degree of opening and protrusion or retraction of the mandible; and alterations in the tension of the walls of the column, especially in the pharynx. Thus, the fundamental frequency (pitch) and harmonics produced by the passage of air through the glottis are modified by changes in the supralaryngeal vocal tract.

Harmonics may be amplified, or dampened. The fundamental frequency and its associated harmonics may also be raised or lowered by appropriate elevation or depression, respectively, of the hyoid bone and the larynx as a unit by the selective actions of the extrinsic laryngeal muscles. Effectively, these movements shorten or lengthen the resonating column, and to some extent also alter the geometry of the walls of the air passages. Analysis of the human voice shows that it has a very similar pattern of harmonics for all fundamental frequencies, determined by the vocal tract acting as a selective filter and resonator. This maintains a constant quality of voice without which intelligibility would be lost (recorded speech played back without its harmonics is completely unintelligible). Each human voice is unique; it has been suggested that the unique frequency spectrum of each individual voice could be used for personal identification.

During articulation, the egressive airstream is given a rapidly changing specific quality by the articulatory organs, the lips, oral cavity, tongue, teeth, palate, pharynx and nasal cavity. The discipline of phonetics primarily deals with the way in which speech sounds are produced, and consequently with the analysis of the mode of production of speech sounds by the vocal apparatus. In order to analyse the way in which the articulators are used in different speech sounds, words are broken down into units called phonemes, which are defined as the minimal sequential contrastive units used in any language.

The human vocal tract can produce many more phonemes than are employed in any one language. Not all languages have the same phonemes, and within the same language, the phonemes can vary in different parts of the same country and in other countries where that language is also spoken. Reproducing phonemes that are not used in native speech is difficult because such phonemes require unfamiliar positioning of the speech organs. A native speaker of any language can quickly recognize the origins of anyone attempting to use their language as a second language. The second-language speaker will usually speak it with an accent characteristic of their own first language because they are using the familiar configurations of their vocal tract for each phoneme instead of the correct positioning.

## PRODUCTION OF VOWELS

All vowel sounds require phonation by vibration of the vocal cords. Each vowel sound has its own characteristic higher harmonics (frequency spectrum) that exhibit peaks of energy at certain frequencies. These energy peaks are always higher multiples of the fundamental frequencies and are called formants. Formants are the result of the combined effects of phonation, selective resonance of the vocal tract, and the properties of the head as a radiator of sound. The sounds of the different vowels are determined by the shape and size of the mouth, and the positions of the tongue and lips are the most important variables. The tongue may be placed high or low (close and open vowels), or further forwards or back (front and back vowels), and the lips may be rounded or spread.

## PRODUCTION OF CONSONANTS

The production of consonants always involves some degree of constriction of the vocal tract. There are many more consonants than vowels, and, in general, consonants cannot be combined to produce syllables. The classification of consonants is complex and beyond the remit of this book; what follows is a summary (for fuller details, a textbook of phonetics should be consulted).

Consonants may be classified on the basis of where the constriction occurs, termed the place of articulation; the degree or extent of constriction, termed the manner of articulation; the shape of the constriction, termed the stricture; and whether or not there is vibration of the vocal folds, when consonants are described as voiced or unvoiced, respectively.

Consonants may also be classified as labial, dental, alveolar, velar, uvular, pharyngeal or glottic, depending on whether the point of maximum constriction occurs at the level of the lips, teeth, bony ridge behind the teeth, palate, uvula, pharynx or glottis, respectively (Fig. 35.15). Different parts of the tongue can be used in combination with the above places of articulation. Phoneticians divide the tongue into the tip, anterior edge, the front part of the dorsum, the centre and back parts of the remaining dorsum, and a most posterior part (the root). These divisions bear no obvious relationship to the anatomical

Fig. 35.15 A sagittal view of the left side of the head, showing the supralaryngeal vocal tract, the articulators and places of articulation. The red broken line indicates the tongue position during retroflexion (10).
landmarks on the tongue, but they are useful in describing the part of the dorsum of the tongue that contacts other areas of the mouth. Similarly, the manner of articulation can vary from a complete closure to a slight narrowing. An actual closure of the vocal tract is called a stop. A narrowing that is sufficient to produce turbulence of the air in the vocal tract, and which is perceived as a rustling sound, is termed a fricative. Approximants involve a degree of closure insufficient to produce turbulence but with closure greater than that for a vowel. Nasals involve a stoppage in the oral cavity with the soft palate lowered to allow airflow through the nose, and, unlike stops, they can be sustained. Stricture describes the shape of the constriction, e.g. a lateral consonant involves depression of the sides of the tongue, while a grooved consonant is produced by grooving the dorsum of the tongue. Consonants can be produced with the vocal folds vibrating, when they are termed voiced, or without vocal fold vibration, in which case they are termed unvoiced.

The best way to illustrate these classificatory systems in operation is by contrasting the production of different consonant pairs in which only one or two parameters have been changed. The /p/ of peat, the /b/ of beat and the $/ \mathrm{m} /$ of meat are all bilabial stops, meaning that they are produced by bringing together the lips. The $/ \mathrm{b} /$ and the $/ \mathrm{m} /$ are voiced but the $/ \mathrm{p} /$ is not. The contrast between the $/ \mathrm{b} /$ and the $/ \mathrm{p} /$ is in the differing way in which the airstreams are produced. The /b/ is produced with an egressive pulmonary airflow, while the / $\mathrm{p} /$ is produced with the glottis closed - hence is unvoiced - and the glottis is then raised using the larynx as a piston to compress the air in the supralaryngeal vocal tract prior to the stop being released. The $/ \mathrm{m} /$ differs from the other two stops in being a nasal in which the soft palate is lowered to allow air to escape through the nasal cavity; unlike the other two stops, it can be sustained as in a sound of approval. Bilabial stops can be contrasted with the labiodental fricatives /f/ of feet and the /v/ of veal, both of which are produced by retracting the lower lip beneath
the upper teeth. Neither involves a complete closure but both produce a significant constriction of the vocal tract with audible turbulence: the $/ f /$ is unvoiced, while the $/ \mathrm{v} /$ is voiced. The sh sound $\left(/ \int /\right)$ in ship is also a fricative involving a grooving of the tongue and is associated with significant audible turbulence; it may be contrasted with the lateral approximant / $\mathrm{l} / \mathrm{in}$ law, in which the sides of the tongue are lowered. In this case, it is the nature of the stricture that is different and the degree of closure, e.g. in the case of the approximant $/ 1 /$, closure is insufficient to produce turbulence. The sh sound in ship can be compared to the $/ \mathrm{k} /$ in keen, where the position of the tongue is different: in $/ \mathrm{k} /$ the tongue blade contacts the soft palate, while in sh the tongue tip or the blade contact the postalveolar region. The most dramatic example of the difference between voiced and unvoiced sounds may be appreciated if the $/ \mathrm{s}$ / sound in sip is compared with the $/ \mathrm{z} /$ in zip. If the larynx is loosely palpated while making a sustained unvoiced 'ssssss' sound, no vibration is felt, but if the 'ssssss' is commuted into a prolonged voiced 'zzzzzz', then vibration in the larynx should be readily detectable. The position of the tongue and other articulators is exactly the same for both $/ \mathrm{s} /$ and $/ \mathrm{z} /$; the difference between them is the presence or absence of phonation.

## Development of the head and neck

Head development is distinct from that of the trunk, utilizing regionspecific genes, signalling mechanisms and morphogenetic processes. This chapter will provide a description of head and neck development based primarily on data from studies on human embryos. Since this information is necessarily purely descriptive, it will be supplemented by observations from lineage and genetic studies in mouse embryos, where the results are likely to be valid for all mammals, including humans. The description of human development is derived from the following sources, which incorporate primary data by the authors, as well as references to older primary source material: Patten (1968), Hamilton et al (1962), O'Rahilly and Müller (1987, 2001), Hinrichsen (1990), Steding (2009). References to experimental studies in the mouse are provided in the text.

Evolution of the vertebrate head was made possible by the origin of a novel cell population, the neural crest. Neural crest cells have the potential to form connective and skeletal tissues in the head, and they make major contributions to the skull. In mammalian embryos, cranial neural crest cells emigrate from the edges of the still-open cranial neural folds, unlike trunk neural crest cells and the cranial crest of other vertebrates, which begin migration only after neural tube closure. Figure 36.1 shows stylized views of human embryos at an early stage of neural crest migration (Fig. 36.1A) and at the end of the crest migration (Fig. 36.1B). It is important to note that these views do not show the neural crest cells themselves; they can be seen at the same developmental stages in mouse embryos in Figure 36.2.

In the mouse, a lineage marker has enabled neural crest cells to be traced from the stage at which they leave the neural epithelium through to their final locations in mature tissues. These studies show three separate populations of neural crest cells migrating from the cranial neural folds; all these give rise to both neuronal and non-neuronal progeny (Jiang et al 2002; see Fig. 36.2). The first of these populations (trigeminal) originates from the diencephalic region of the forebrain, the midbrain, and prorhombomere A of the hindbrain, which subsequently divides to form the first two rhombomeres (see Figs 36.2A-B; see also Fig. 17.2). Those neural crest cells with a neuronal fate contribute to
the trigeminal ganglion. The non-neuronal cells migrate extensively to surround the telencephalon and part of the diencephalon, forming the frontonasal mesenchymal populations; they also migrate lateral to the rhombencephalon to form the mesenchyme of the maxillary and mandibular regions of the first arch (see Fig. 36.2C-D). The second (hyoid) population gives rise to the otic ganglion and then migrates from prorhombomere B (which forms rhombomeres 3 and 4), into the second pharyngeal arch. The third (vagal) population has a more extensive origin, from the neural folds caudal to the otocyst, i.e. prorhombomere C. These cells will contribute to the ganglia of the glossopharyngeal and vagal nerves, with the non-neuronal vagal crest cells migrating into pharyngeal arches 3,4 and 6 , some of them continuing into the heart to contribute to the division of the cardiac outflow tract (Jiang et al 2000). The neural crest also gives rise to the parasympathetic ganglia and parasympathetic postganglionic nerves in the head and neck. For a full account of the neuronal contribution of neural crest cells, see Chapter 17. In human embryos, histological methods have revealed equivalent cranial neural crest cell origins and migration routes to those of the mouse ( $\mathrm{O}^{\prime}$ Rahilly and Müller 2007).

Caudal to the segmented region of the cranial neural tube, neural crest cells from the occipital region (prorhombomere D/rhombomere 8) migrate with occipital myoblasts to form the hypoglossal cord, eventually differentiating to form the connective tissue (neural crest) and musculature (myoblasts) of the tongue. No sensory ganglia are formed from the occipital neural crest in human embryos. The origin of the rhombomeres and brain regions in human embryos is shown in Figures 17.2 and 17.12.

Ectodermal placodes appear as patches of columnar or pseudostratified epithelium within the otherwise squamous epithelium of the surface ectoderm. Three pairs of placodes contribute to sense organs, forming the olfactory epithelium, the lens and the otocyst, undergoing morphogenesis to form a pit and then (for the lens and otic pits) a closed cyst (vesicle). Epipharyngeal placodes are situated within the dorsal ectoderm of pharyngeal arches 2,3 and 4; some of their cells

A, A sagittal section of a stage 10 embryo, in which neural tube closure has begun in the future occipito-cervical region. B, A lateral view of a stage 12 embryo; the occipitalcervical boundary between somites 4 and 5 is indicated by an arrow (see also Fig. 17.2).

Fig. 36.2 Mouse embryo heads during the period of cranial neural crest cell migration. A-B, Scanning electron micrographs (A, dorsal view; B, median section) of embryos near the start (4 somite pairs) and end (18 somite pairs, interior view) of the period of neural crest cell migration. At the 4 -somite stage, the neural folds are convex and the hindbrain is divided into prorhombomeres $\mathrm{A}, \mathrm{B}$ and C by the preotic (arrow) and otic (arrowhead) sulci; at the 18 -somite stage, the neural tube is closed and the hindbrain is divided into seven rhombomeres (numbered) and the unsegmented occipital region (oc). Rathke's pouch is indicated by a small arrow on B. C-D, Lateral views of embryos at the 5 - and 23 -somite stage, respectively, carrying a permanent marker for neural crest cells and the neural epithelium from which the trigeminal crest cells originate (blue stain). Trigeminal neural crest cells ( nc ) migrate as a veil-like mass beneath the surface ectoderm, originating as a continuous group from prorhombomere A, the midbrain and the caudal diencephalic region (d) of the forebrain, into the frontonasal region (fn) and the first arch (white lines indicate the level of the migrating edge). After migration, frontonasal neural crest cells (fn) cover the telencephalon and rostral diencephalon, surrounding the eye (e); maxillary ( mx ) and mandibular ( md ) neural crest populates the first pharyngeal arch; the trigeminal ganglion primordium (V) is also present. Hyoid neural crest cells from prorhombomere B have populated the hyoid arch and the primordium of ganglion VII/VIII, rostral to the otocyst (ot); vagal crest cells from prorhombomere C are migrating into arches 3 and 4, and starting to form the primordia of the glossopharyngeal and vagal ganglia, caudal to the otocyst. Other abbreviations: d, diencephalon; hn, Hensen's node; ht, heart; mb, midbrain; $p$, pharynx; $r 1$, rhombomere 1 of the hindbrain; $t$, telencephalon. (A and B, With permission from Morriss-Kay GM, Wilkie AOMW 2005 Growth of the normal skull vault and its alteration in craniosynostosis. $J$ Anat 207:637-53. C and D, With permission from Jiang X, Iseki S, Maxson RE et al 2002 Tissue origins and interactions in the mammalian skull vault. Dev Biol 241:106-16.)
undergo epithelial to mesenchymal transformation, joining the underlying neural crest cell condensations to form sensory neuroblasts in the cranial sensory ganglia V, VII, IX and X. Some cells from the otocyst and an adjacent placode similarly delaminate to contribute to the ganglion of cranial nerve VIII (see Fig. 17.18).

The epithelial to mesenchymal transformation of some cells from ectodermal placodes contributes a third component to the cranial mesenchyme. It is important to note that the term mesenchyme simply
describes a loose cellular organization with a rich extracellular matrix, in contrast to the sheets of simple epithelial tissue that form the outer ectodermal and inner endodermal layers of early embryos. Prior to the migration of neural crest cells from the edges of the cranial neural folds to their final destinations, the only mesenchyme in the embryonic head is 'primary mesenchyme', i.e. mesenchymal cells formed by epithelialmesenchymal transformation in the primitive streak. There is no lateral plate mesenchyme in the head; all of the cranial mesenchyme is paraxial. Cranial mesenchyme derived from placodal, primary mesenchymal and neural crest sources has specific distributions and specific derivatives, and is not interchangeable.

The first transverse division to form in the early embryonic brain is the preotic sulcus (see Figs 36.1A, 36.2A), which defines the boundary between prorhombomeres A and B. This early division is of major functional and organizational significance, since it separates the regions of origin of the skeletogenic neural crest populations that make a major contribution to the skull from those that form skeletal structures in the neck (hyoid bone and larynx). During cranial neurulation, the prorhombomeres undergo subdivision so that, by the time the brain region of the neural tube closes, seven rhombomeres can be clearly distinguished; the occipital region (adjacent to the four occipital somites) remains unsegmented (see Fig. 36.2B). (By analogy with the segmented rhombencephalon, it is also referred to as prorhombomere $\mathrm{D} /$ rhombomere 8.) The segmental organization of the embryonic head caudal to prorhombomere A is related to the expression of evolutionarily conserved HOX genes (written Hox in the mouse) that have their rostral boundaries at specific rhombomere divisions; they are also expressed in the corresponding neural crest cells (reviewed by Santagati and Rijli 2003; see also Fig. 17.16). Genetic experiments in the mouse and other vertebrates have shown that skeletal patterning of the first pharyngeal arch depends on the absence of Hox gene expression in the neural crest cells migrating into it; skeletal patterning of the second arch depends on the expression of Hoxa2. Investigation of Hox gene expression in arches 3-6 has not revealed clear skeletal patterning functions.

## EMBRYONIC PHARYNX AND PHARYNGEAL ARCHES

The most cranial portion of the foregut, the embryonic pharynx, is the scaffolding around which the face, palate and anterior neck structures are built. The development of this region from neural crest, paraxial mesenchyme, surface ectoderm and foregut endoderm involves spatiotemporal coordination of cell movement, tissue growth and tissue interactions. As successive populations of neural crest cells migrate around the pharynx at progressively more caudal levels, five pairs of pharyngeal arches are formed (numbered 1,2,3, 4 and 6 for comparative anatomy reasons). This process is complete by stages $14-15$ ( 5 weeks). Pharyngeal clefts (grooves) separate the arches externally; they are matched internally by internal depressions, the pharyngeal pouches. Pharyngeal arches are also known as branchial arches because of their evolutionary origin supporting the gills in the earliest vertebrates. Many of the changes seen during development of the mammalian pharynx reflect the functional evolutionary origins of this region. Since the term 'branchial' means 'of the gills', the term 'pharyngeal arch' will be used in the following account of human embryology.

Each pharyngeal arch consists of an epithelial covering, ectoderm externally and endoderm internally, filled with mesenchyme that is mainly of neural crest origin, with a contribution from primitive streakderived mesenchyme (paraxial mesenchyme) (Fig. 36.3B; Table 36.1). The neural crest cells of each arch form a skeletal element and associated connective tissue; they also give rise to the walls of an aortic arch blood vessel, which is lined with endothelium derived from angiogenic mesoderm. Paraxial mesenchyme also forms the muscle associated with each pharyngeal arch. In mouse embryos, a cell lineage marker for mesoderm has shown that, by embryonic day 10.5 (equivalent to human stage 13 , or about 32 days), mesoderm-derived mesenchymal cells have contributed both angiogenic and myogenic cells to the pharyngeal arches (Yoshida et al 2008). Motor and sensory innervation derives from arch-specific cranial nerves. For an overview of the organization of these tissues in the pharynx, see Figure 12.4; for their fate, see Table 36.1 and Figures 36.5-36.7. Since the organization of the embryonic pharynx and related structures is similar in all vertebrate embryos, this phase has been termed 'pharyngula'.

The first pharyngeal arch, unlike the other arches, possesses dorsal and ventral processes, and appears C-shaped in lateral view. It is also termed the 'mandibular arch'; however, this is not entirely appropriate because its proximal (dorsal) end also contributes to maxillofacial and palatopharyngeal structures and to the middle ear. The second

Fig. 36.3 Pharyngeal arch development. A, A scanning electron micrograph of a human embryo (stage 14/15), showing the right lateral aspect of the pharyngeal arches; auricular hillocks are visible on arch two. B, The pharyngeal region (stage 15) viewed from the dorsal aspect. The whole left side and part of the right side of the endodermal roof of the pharynx has been removed to show the grooves in its lateral walls and floor, and the nerves, arteries and cartilages of the arches. The position of the right otocyst is shown as a clear oval. (A, Courtesy of Prof G Steding, Georg-August-University of Göttingen, Göttingen, Germany.)

Table 36.1 Derivatives of the pharyngeal arches

| Arch number | Arch name | Embryonic cartilage | Cartilage derivative | Muscle | Nerve | Artery |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | Mandibular | Quadrate Meckel's | Incus <br> Malleus <br> Anterior ligament of malleus Spine of sphenoid Sphenomandibular ligament Genial tubercle of mandible | Tensor tympani <br> Muscles of mastication <br> Mylohyoid <br> Anterior belly of digastric <br> Tensor veli palatini | Trigeminal (V) Mandibular division | First aortic arch artery [transitory] |
| 2 | Hyoid | Reichert's | Stapes <br> Styloid process of temporal bone <br> Stylohyoid ligament <br> Lesser horn and upper part of body of hyoid bone | Stapedius <br> Stylohyoid <br> Facial muscles, incl. <br> Buccinator <br> Platysma <br> Posterior belly digastric | Facial (VII) | Stapedial artery [transitory] |
| 3 | Third |  | Greater horn and lower part of body of hyoid bone | Stylopharyngeus | Glossopharyngeal (IX) | Common carotid artery, first part of internal carotid artery |
| 4 | Fourth |  | Thyroid cartilage Corniculate cartilage Cuneiform cartilage | Pharyngeal and extrinsic laryngeal muscles, levator veli palatini | Vagus ( X ) Pharyngeal branch | Proximal part of subclavian artery on the right Arch of aorta between origins of left common carotid and left subclavian arteries |
| 6 | Sixth |  | Arytenoid cartilages | Intrinsic laryngeal muscles | Vagus (X) Recurrent laryngeal branch | Part between the pulmonary trunk and dorsal aorta becomes ductus arteriosus on left, disappears on right |

pharyngeal arch is termed the hyoid arch because of its contribution to the hyoid bone (and to other parts of the hyomandibular apparatus in fishes). The third, fourth and sixth arches are not named.

The mandibular arches, first seen at stage 10, grow ventromedially in the floor of the pharynx to meet in the median plane, forming the ventral border of the early mouth above the cardiac (pericardial) prominence. The maxillary processes are not clearly visible as surface structures until stage 13; their enlargement coincides with the proliferation of the frontonasal mesenchyme to form the nasal swellings. The hyoid arches appear at stage 11, the third arches at stage 12 and the fourth arches by stage 13. The sixth arch can only be identified by the arrangement of the arch arteries and nerves, and by a slight projection on the pharyngeal aspect. The floor of the pharynx is formed mainly by ventral apposition of the arches. The inferior border of the second arch grows over the lower arches and encloses an ectodermal depression termed the cervical sinus (Figs 36.3A, 36.4).

## SKELETAL ELEMENTS OF THE PHARYNGEAL ARCHES

The skeletal and connective tissue elements of arches 1-3 are formed by condensation of neural crest-derived mesenchyme, which subsequently chondrifies in part or all of its length. Where chondrogenesis
is complete (first and second arch cartilages), the element extends dorsally until it comes into contact with the skull base lateral to the hindbrain (Fig. 36.5). An arch cartilage may remain as cartilage, undergo endochondral ossification or become ligamentous, or a combination of these (Fig. 36.6).

The first arch cartilage, Meckel's cartilage, forms the embryonic lower jaw skeleton. After the mandible forms by intramembranous ossification of the neural crest-derived mesenchyme lateral to it, Meckel's cartilage degenerates but its sheath persists as the anterior malleolar and sphenomandibular ligaments. At its proximal end, endochondral ossification forms two of the middle ear bones, the incus and malleus. These are homologous with the quadrate and articular bones of reptiles, and the joint between them is evolutionarily derived from the reptilian jaw articulation. In reptiles, the quadrate forms from the caudal end of the palatopterygoquadrate cartilage; the mammalian evolutionary derivatives of the palatopterygoquadrate are thought to include part of the greater wing of the sphenoid bone and the roots of its pterygoid plates, in addition to the incus. The portion of Meckel's cartilage that extends from the mental foramen almost to the site of the future mandibular symphysis probably becomes ossified and incorporated into the intramembranous mandibular bone; the remainder of the cartilage is ultimately absorbed.

The second arch cartilage, Reichert's cartilage, extends from the proximity of the otic capsule dorsally to the median plane ventrally. It

ossifies to form the upper part of the body and lesser cornua of the hyoid bone distally, and the styloid process proximally; between these two bones, it becomes ligamentous to form the stylohyoid ligament. It also gives rise to the most ancient of the three auditory ossicles, the stapes (homologous with the rod-shaped columella auris of reptiles and birds). The cartilages of the third, fourth and sixth arches form only anterior neck skeletal structures: the lower part of the body and greater cornua of the hyoid bone (third arch), and the laryngeal cartilages. Neural crest cells also give rise to ligaments, tendons and connective tissue in these arches. However, in contrast to the NC-derived cartilages

Fig. 36.6 Derivatives of the pharyngeal arch cartilages in a 4-5-month fetus.
of arches 1-3, the laryngeal cartilages associated with arches 4 and 6 (thyroid, cricoid and arytenoid) are mesodermal in origin.

## MUSCLES OF THE PHARYNGEAL ARCHES

The striated muscle of each arch (sometimes termed branchiomeric muscle) is derived from the cranial paraxial mesenchyme. Rostral to the occipital region, the paraxial mesenchyme of the head is unsegmented, and the suggestion that a segmental pattern of seven cranial somitomeres exists is not generally accepted today. In the occipital region of the head, epithelialization takes place to form four pairs of somites;
these are similar to those of the trunk, except that the first pair is rather poorly defined. Myoblasts migrate from the paraxial mesenchyme to sites of future muscle differentiation and form pre-muscle condensations prior to the development of any skeletal elements. The pattern of primary myotube alignment for any one muscle is specified by the surrounding neural crest-derived mesenchyme and is not related to the source of the myoblasts. The rate and pattern of muscle maturation are closely associated with the development of the skeletal elements but remain unattached until an appropriate time. Table 36.1 and Fig. 36.7 indicate the muscle masses of each arch, their innervation and their derivatives in the adult.

The muscle mass of the mandibular part of the first arch forms tensor tympani, tensor veli palatini, mylohyoid, anterior belly of digastric, and the masticatory muscles (see Fig. 36.7 and Table 36.1). Tensor tympani retains its connection with the skeletal element of the arch through its attachments to the malleus, and tensor veli palatini remains attached
to the base of the medial pterygoid process, which may be derived from the dorsal cartilage of the first arch. All of these muscles are supplied by the mandibular nerve, the mixed nerve of the first arch. The maxillary division of the trigeminal nerve has no motor component, suggesting that no muscles are derived from maxillary mesenchyme.

The muscles of the second arch migrate widely but retain their original nerve supply from the facial nerve; migration is facilitated by the early obliteration of part of the first pharyngeal cleft and pouch. Stapedius, stylohyoid and posterior belly of digastric remain attached to the hyoid skeleton but the facial musculature, platysma, auricular muscles and epicranius all lose connection with it.

The muscle masses from the third and fourth arches are adapted to form the musculature of the pharynx, larynx and soft palate. Stylopharyngeus is a third arch muscle, cricothyroid develops in the fourth arch, and the other laryngeal muscles are derived from the sixth arch. The precise origin of the remaining palatal muscles and the pharyngeal

Fig. 36.7 The muscular derivatives of the prechordal mesenchyme, unsegmented paraxial mesenchyme and rostral somites.
constrictors is uncertain. Palatoglossus, a muscle of the palate, is innervated by the vagus via the pharyngeal plexus and may derive from the lower arches.

## NERVES OF THE PHARYNGEAL ARCHES

The nerves associated with each arch arise from the adjacent hindbrain (see Fig. 36.7; see also Figs 12.4, 17.18). They are cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), X (vagal) and XI (accessory). The motor nerves extend from the basal plate of the hindbrain to innervate the striated muscle of the arches; they are termed special branchial (visceral) efferent nerves because they innervate branchiomeric (pharyngeal) musculature. Sensory nerves extend peripherally and centrally from cranial ganglia that are formed partly from neural crest and partly from cells that delaminate from epipharyngeal placodes; they convey general and special somatic afferent axons. Each arch is innervated by a mixed nerve, but the nerves of the first three arches also have a purely sensory branch that innervates the arch rostral to its 'own' arch; this sensory nerve is called the pretrematic branch because it extends rostral to the cleft or trema between the two arches (see Figs 36.3, 36.7). Hence, the nerves to the mandibular arch include the mandibular division of the trigeminal nerve, which is mixed, and the chorda tympani and greater petrosal nerves, purely sensory pretrematic branches of the facial nerve. The maxillary branch of the trigeminal and the tympanic branch of the glossopharyngeal are also considered to be pretrematic nerves. The ophthalmic branch of the trigeminal nerve, which supplies the frontonasal area, is not an arch nerve; in fishes, its ganglion is separate from the first arch nerve ganglion.

The vagus nerve supplies the fourth and sixth arches (see Fig. 36.7). The recurrent laryngeal branch initially loops under the sixth arch artery on both sides, but the asymmetric changes to the vascular system affect the symmetry of this nerve. On the right, when the sixth aortic arch lateral to the right pulmonary artery degenerates, the recurrent laryngeal nerve loops under the fourth arch-derived subclavian artery; on the left, it loops round the ductus arteriosus, (which is retained as the ligamentum arteriosum in the adult). Further details of cranial nerve development and composition are provided in Chapter 17.

## BLOOD VESSELS OF THE PHARYNGEAL ARCHES

The aortic arches initially develop by vasculogenesis, soon after neural crest cells have invaded the early pharyngeal arches. Mesoderm-derived angiogenic mesenchyme forms the endothelial lining of the vessels, and neural crest contributes to the outer layers of the walls (Jiang et al 2000, Yoshida et al 2008). The first aortic arch artery is part of the original vascular circuit that links the aortic sac of the heart to the paired dorsal aortae, blood returning to the heart via the allantoic, vitelline and common cardinal veins (see Fig. 13.1C). As the heart descends relative to the forebrain and other rostral structures, the aortic sac (ventral aortic root) gives rise to paired aortic arches at successively more caudal levels, each of which passes laterally on each side of the pharynx to join the dorsal aortae. The dorsal aortae are not invested by neural crest cells, and nor are the more distal (cranial) parts of the carotid arteries, which form by angiogenesis. The whole complement of aortic arches never coexists - the first aortic arch degenerates through remodelling of the cranial arteries before the sixth is formed.

When the first and second aortic arch arteries begin to regress, the supply to the corresponding pharyngeal arches is derived from a transient ventral pharyngeal artery, which terminates by dividing into mandibular and maxillary branches. The second aortic arch artery also degenerates, remaining only as the stem of the stapedial artery. The early vessel anastomoses with the ventral pharyngeal artery, passing, as it does, through the mesenchyme of the stapedial cartilage, which condenses around it, forming the foramen of the stapes. At this stage, the stapedial artery possesses three branches - mandibular, maxillary and supraorbital - which follow the divisions of the trigeminal nerve (Fig 36.8). The mandibular and maxillary branches diverge from a common stem.

Further development of the third, fourth and sixth aortic arches (Fig. 36.9) produces the main arteries to the head and the great vessels arising from the heart. The common carotid arises from an elongation of the aortic sac, and the third arch artery becomes the proximal part of the internal carotid artery. The external carotid artery arises as a sprout from the common carotid; it incorporates the stem of the ventral pharyngeal artery, and its maxillary branch communicates with the common trunk of origin of the maxillary and mandibular branches of the stapedial artery and annexes these vessels. The proximal part of the

Fig. 36.8 The arterial system of the head at stage 17 (approximately 40 days).
common trunk persists as the root of the middle meningeal artery. More distally, the meningeal artery is derived from the proximal part of the supraorbital artery. The maxillary branch becomes the infraorbital artery and the mandibular branch forms the inferior alveolar artery. When the definitive ophthalmic artery differentiates as a branch from the terminal part of the internal carotid artery, it communicates with the supraorbital branch of the stapedial artery, which distally becomes the lacrimal artery. The latter retains an anastomotic connection with the middle meningeal artery. The dorsal stem of the original second arch artery remains as one or more caroticotympanic branches of the internal carotid artery.

The fourth aortic arch on the right forms the proximal part of the right subclavian artery, whereas the corresponding vessel on the left constitutes the arch of the definitive aorta between the origins of the left common carotid and left subclavian arteries.

The sixth aortic arch is associated with the developing lung buds. Initially, each bud is supplied by a capillary plexus from the aortic sac; as the sixth aortic arch develops, it becomes the channel for blood from the aortic sac to the developing lung buds as well as to the corresponding dorsal aorta, the latter being the main channel. Soon after formation of the sixth aortic arch, the outflow tract of the heart is divided by an influx of neural crest cells, which form the spiral aorticopulmonary septum (Jiang et al 2000); this separates the aortic sac into the pulmonary trunk and ascending aorta. The part of the sixth aortic arch between the pulmonary trunk and the dorsal aorta becomes the main vascular channel on the left, and is defined as the ductus arteriosus when the equivalent vessel on the right side is lost. The right dorsal aorta caudal to the right subclavian artery also degenerates, leaving the left dorsal aorta as the definitive descending aorta (Fig. 36.9B). The ductus arteriosus remains the main channel for blood to pass from the right ventricle to the descending aorta until the lungs and their associated blood vessels expand at birth. After birth, the ductus arteriosus is functionally closed by contraction of the circular muscle of the tunica media (p. 922), leaving a ligamentous remnant, the ligamentum arteriosum (Fig. 36.9C).

## PHARYNGEAL ECTODERM AND CLEFTS

Surface ectoderm lines the roof of the embryonic pharynx up to and including Rathke's pouch (see Figs 17.13-17.14). It also completely covers the first arch, including the lateral walls and floor of the pharynx, unlike the more caudal arches, which are lined with pharyngeal endoderm. The external surface ectoderm of the first arch ultimately produces the keratinized stratified squamous epithelium of the epidermis, including hair follicles, sweat and sebaceous glands, and the specialized epithelium of the vermilion of the lip. Within the oral cavity, first arch ectoderm forms the mucous membranes of the internal surface of the lips and cheeks, the palate, the anterior part of the tongue, the epithelial components of the salivary and mucous glands, and the enamel organs

compressed (see Fig. 36.18A). Laterally, the endoderm of the pouches approaches the ectoderm of the pharyngeal clefts to form thin closing membranes (see Fig. 36.4). The approximating ectoderm and endoderm between the first cleft and pouch form the outer and inner surfaces of the tympanic membrane. The ventral end of the first pouch is obliterated, but its dorsal end persists and expands as the head enlarges. This, together with the adjoining lateral part of the pharynx, possibly with a contribution from the dorsal part of the second pharyngeal pouch, constitutes the tubotympanic recess. The recess forms the middle ear cavity, the pharyngotympanic tube and their extensions. Expansion of the middle ear cavity around the ear ossicles occurs late during fetal life, by breakdown of the mesenchyme around the ossicles so that the cavity comes to surround them, except at their attachments to the tympanic membrane and fenestra ovalis (fenestra vestibuli, oval window).

The ectoderm of the pharyngeal clefts and the endoderm of the pouches become increasingly separated by mesenchyme. The blind recesses of the second, third and fourth pouches are prolonged dorsally and ventrally as angular, wing-like diverticula (see Fig. 36.18); the pouch endoderm thickens and evaginates into localized neural crestderived mesenchymal condensations. Further development of the second, third and fourth pouches is summarized in Figure 36.18 and described in the associated text.

Rarely, failure of normal modification of the pharyngeal clefts and pouches may lead to the formation of fistulae, external or internal sinuses, and cysts (see Commentary 2.2). Lateral cervical cysts are now considered to be lymphoepithelial in origin.

## FACE, NASAL CAVITIES AND PALATE, ORAL CAVITY AND TONGUE

## FACE

By stage 12, migration of the most rostral neural crest cell population is complete and the sequence of morphogenetic changes that will form the face begins (Fig. 36.10). Neural crest cells have populated the mandibular arch and its maxillary extension, and formed the frontonasal mesenchyme that covers the telencephalon and caudal diencephalon (see Fig. 36.2D). They also contribute to the primordium of the trigeminal nerve, whose first fibres begin to extend at stage 13. The three divisions of the trigeminal nerve will provide sensory innervation to the frontonasal, maxillary and mandibular parts of the face.

Localized mesenchymal proliferation results in the formation of four paired processes: the medial and lateral nasal, maxillary and mandibular processes. The lateral and medial nasal processes surround the nasal placodes, causing them to sink deep to the surface, forming the nasal pits. The two medial nasal processes approach each other to form the nasal septum between them and extend downwards to form the premaxillary component of the upper lip and jaw and the primary palate. Concomitant with formation of the nasal processes, proliferation of the maxillary mesenchyme forms the maxillary processes. These make contact with the medial and lateral nasal processes at stages 16-17 (see Fig. 36.10E). Fusion of the maxillary processes with the medial nasal processes unites the premaxillary and maxillary parts of the upper jaw and lip; failure of this process on one or both sides causes unilateral or bilateral cleft lip (see Fig. 36.17). Superiorly, this fusion closes the cleft at the lower edge of the nasal pits, completing the future nostrils. Fusion of the maxillary with the lateral nasal processes is a much simpler process and rarely gives rise to abnormality. At stage 16, the epithelium of the groove between these fusing processes thickens to form the lacrimal lamina, the primordium of the lacrimal system. At stage 19, it separates from the surface ectoderm, forming the lacrimal cord beneath the surface. The cord becomes canalized to form the nasolacrimal duct in the tenth week (de la Cuadra-Blanco et al 2006). The original site of the lacrimal lamina marks the lateral division between frontonasal and maxillary contributions to the face, the territories whose sensory nerve supply is from the ophthalmic and maxillary divisions of the trigeminal nerve, respectively (Fig. 36.11).

At the start of facial development, the stomodeal opening extends across the whole width of the embryonic head. A wide mouth is maintained until differential growth brings the eyes and the lateral parts of the maxillary-mandibular structures from the sides to the front of the face (stage 18 to stage $23,7-8$ weeks). Although differential growth makes the mouth opening proportionately smaller, progressive fusion of the lateral regions of the maxillary and mandibular processes also makes an important contribution to decreasing the width of the mouth and to forming the cheeks. Differences in mouth width within the human population are mainly due to variation in the extent of maxil-
lomandibular fusion. The period from 7 to 8 weeks is the final period of major morphogenetic change in facial development. In addition to formation of the mouth and cheeks, it is marked by further narrowing of the nasal region and philtrum, and ascent of the ears. By stage 20, the face is recognizably human, although differential growth will continue to bring about changes in proportion and relative position of the features.

The contribution made by the frontonasal process to surface epithelial derivatives extends from the skin of the forehead, over the supraorbital and glabellar regions, including the upper eyelid and conjunctiva, to the external aspect of the nose and philtrum of the upper lip. During later development, the maxillary nerve invades the skin of the philtrum and nasal alae, so that the trigeminal nerve distribution does not completely coincide with the tissue origins (compare Figs 36.10 F and 36.11).

## NASAL CAVITIES AND PALATE

After formation of the nasal pits, the original olfactory placodal cells lie deep within the pit, adjacent to the underlying telencephalon. They differentiate into olfactory neuroblasts, supporting (sustentacular) cells and stem cells. Neurites begin to extend from the olfactory neuroblasts, reaching the olfactory region of the telencephalon by stage 16 (sixth week). The earliest pioneer neurites cross a mesenchyme-filled gap between the placode and the brain. The remaining placodal cells differentiate into columnar supporting cells, rounded basal cells and, by invagination, the duct-lining and secretory acinar cells of the glands of Bowman. Basal infiltration by lymphocytes is a relatively late event.

Once the nasal cavities have formed, the roof of the oral cavity is regarded as the primitive palate (not to be confused with the primary palate, which forms from the most rostral part of the primitive palate). Each nasal cavity has an arcuate shape, extending upwards over the primary palate to the differentiating olfactory epithelium and then down again towards the oral cavity, from which it is separated by an epithelial choanal membrane (see Fig. 17.13). Towards the end of stage 18, the choanal membranes degenerate to form internal openings, the choanae, lateral to the primary palate; the nasal cavities are now a duct from the external environment to the oral cavity. Within the nasal cavity, the ectodermal lining and subjacent mesenchyme differentiate to form the mucous membrane of the nasal vestibule, conchae and paranasal sinuses, and the olfactory epithelium.

At stage 17, the internal aspect of each maxillary process begins to bulge into the oral cavity as a palatal process; the palatal processes are the primordia of the secondary palate (Fig. 36.12). The tongue is well developed by this stage, and its domed form fills the space between the nascent palatal shelves laterally and the primitive palate above. The mandible is still short, relative to the maxillary region, and does not extend as far as the primary palate. Further growth of Meckel's cartilages brings the mandibular region and tongue forwards, extending to a position below the primary palate. At the same time, the (secondary) palatal processes continue to grow, projecting vertically downwards on either side of the tongue. At stage 23 (56-57 days), the tongue descends and the palatal shelves rotate, bringing the shelves to a horizontal position above the tongue (Fig. 36.12B). The rapidity of the process of shelf elevation is caused, at least in part, by swelling of the palatal mesenchyme due to accumulation and hydration of hyaluronan in the extracellular matrix (Ferguson 1991). This occurs during a period of continuous growth in head height but almost no growth in head width. This latter factor is important because, if palatal shelf elevation is delayed so that it occurs during a period of growth in facial width, the unfused processes may be unable to make contact in the midline, resulting in a cleft palate (see Fig. 36.17). Other factors affecting palatal closure include the growth in length of Meckel's cartilages and the change in position of the maxillae relative to the anterior cranial base; both of these have the effect of lifting the head and upper jaw away from the mandible during weeks 9 and 10, facilitating withdrawal of the tongue from between the palatal shelves and hence creating space for their elevation. Mouth opening, tongue protrusion and hiccup movements have also been noted at this time, and it may be that these movements and their associated pressure changes assist palatal shelf elevation. Generally, palatal shelf elevation occurs slightly later in female embryos than in males.

Midline fusion of the two palatal shelves involves adherence and breakdown (by apoptosis) of the apposed epithelial surfaces. They also fuse with the posterior border of the primary palate, except over a small median area, where a nasopalatine canal maintains connection between the nasal and oral cavities for some time and marks the future position of the incisive fossa. During the period of palatal shelf development, a

median downgrowth from the primitive palate forms the definitive nasal septum; it is supported by cartilage. The fusing medial edges of the elevated palatal shelves also fuse with the free edge of the nasal septum, forming separate right and left nasal cavities above the secondary palate. The original positions of the choanae are now covered by the palatal shelves so that the nasal cavities extend from the nostrils to the free (caudal) edge of the palate at the nasopharynx. Bone forms by both intramembranous ossification within the palatal mesenchyme to form the hard palate, except near its caudal border, and by endochondral ossification of the cartilaginous nasal septum. At this time, the free edge of the palatal shelves lies directly below the former position of the attachment of the adenohypophysial (Rathke's) pouch to the roof of the oral cavity. Caudal to the hard palate, its free edges grow to form the soft palate and uvula, which extend into the oropharynx. Myogenic mesenchyme from the first (tensor palati only) and third pharyngeal arches migrates into the soft palate and around the caudal margins of the pharyngotympanic tube. Separation of the definitive nasal and oral
cavities is now complete. A number of elevations appear on the lateral wall of each nasal cavity: the superior, middle and inferior conchae (Fig. 36.12B,C).

Within the nasal septum, on either side of the septal cartilage, a pair of small diverticula, the vomeronasal organs, form at stage 18 ( 6 weeks). From 12 to 19 weeks, the vomeronasal organ has an olfactory epithelium-like appearance, and luteinizing hormone-releasing hormone (LHRH)-immunoreactive cells are present in nerve fascicles extending from it to the olfactory bulb (Boehm et al 1994). In many species, the vomeronasal organ has a pheromonal communication function; however, although most adult humans have a vomeronasal organ, its olfactory-type structure and LHRH immunoreactivity are lost during later fetal life and a pheromonal function in adults has not been established (Ch. 33 e-book only).

Bilateral dorsal expansions of the first, second and, possibly, third pharyngeal pouches form the tubotympanic recesses, which will become the tympanic cavities and pharyngotympanic tubes. A number of focal
proliferations of nasopharyngeal endoderm become invaded by lymphoid tissue.

## ORAL CAVITY

In the fifth week (stage 12), the oropharyngeal membrane breaks down so that communication is established between the ectoderm-lined stomodeum and the endoderm-lined part of the pharynx, creating a continuous cranial foregut cavity. Formation of the hard and soft palates separates the cranial foregut into the nasal cavity and nasopharynx above and the definitive oral cavity below. The oral cavity is demarcated from the oropharynx posteriorly by the oropharyngeal isthmus, formed by the free edge of the soft palate and uvula above, and the palatoglossal arch laterally.

## Tongue

Because the mandibular arch grows more rapidly than the others, it makes the greatest contribution to the pharyngeal floor. By stage 14 ( 5 weeks), three swellings are apparent: a small median elevation, the tuberculum impar or median tongue bud; and paired lateral lingual swellings distally (Fig. 36.13A). These three swellings fuse to form the anterior two-thirds of the tongue (Fig. 36.13B), and a small median diverticulum, the foramen caecum (thyroid diverticulum), forms immediately caudal to the median tongue bud (Fig. 36.13B,C; see Fig. 36.18 A ). A sulcus forms along the ventral and lateral margins of this elevation and deepens, internal to the future dental lamina, to form the linguogingival sulcus (groove) (see Fig. 36.13C). Caudal to the median tongue bud, a small swelling, the copula, forms in the floor of the second arch. The hypobranchial (hypopharyngeal) eminence forms in the floor of the third arch; it grows over the second arch (which does not contribute to the tongue) and fuses with the anterior tongue rudiment along a V-shaped line, the sulcus terminalis, at stage 17 (sixth week). Another transverse groove separates the developing tongue from the caudal (fourth arch) swelling, which forms the epiglottis.

Fig. 36.12 Development of the palate. A-C, Developmental progression over weeks 7-8; ventral views (top row) and coronal sections (bottom row).

In general, the composite character of the mucous membrane of the tongue is reflected in its sensory innervation. The anterior, oral, part is innervated by the lingual branch of the mandibular nerve, and by the chorda tympani of the facial nerve. The posterior, pharyngeal, part of the tongue is innervated by the glossopharyngeal nerve, which is the nerve of the third arch; this nerve also invades the tissue immediately distal to the sulcus limitans, including innervation of the vallate papillae. The vallate papillae appear within the mucous membrane at around 10 weeks and increase in number until the end of the second trimester. The root of the tongue, near the epiglottis, is innervated by the vagus. The motor innervation is from the hypoglossal nerves, which extend around and under the pharynx together with myogenic cells migrating from the occipital myotomes during stages 14 and 15.

Tongue development is essentially complete by stage 23. At birth, the tongue is short and broad, and its entire surface lies within the oral cavity (see Fig. 14.7). The posterior third of the tongue descends as the hyoid bone and larynx descend during the first postnatal year, and by the fourth or fifth year, it forms part of the anterior wall of the oropharynx.

## Salivary glands

The salivary glands arise bilaterally as the result of epithelialmesenchymal interactions between the ectodermal epithelial lining of the oral cavity and the subjacent neural crest-derived mesenchyme. The parotid gland can be recognized at stage $15(8 \mathrm{~mm})$ as an elongated furrow running dorsally from the angle of the mouth between the mandibular and maxillary prominences. The groove, which is converted into a tube, loses its connection with the epithelium of the oral cavity, except at its ventral end, and grows dorsally into the soft tissue of the cheek. The tube persists as the parotid duct. After fusion of the lateral parts of the maxillary and mandibular prominences, the parotid duct opens on the inside of the cheek at some distance from the angle of the mouth. As the gland develops, its branches interweave with the branches of the facial nerve. In the neonate, the parotid gland is rounded and lies between masseter and the ear. During infancy and early childhood, the growing gland extends to cover the parotid duct. Its secretions remain entirely serous.

The submandibular and sublingual glands form as solid diverticula that undergo branching morphogenesis, the whole tree-like structure later acquiring a lumen. The blind ends of the branches form acini, whose cells differentiate to form serous cells initially, and mucussecreting cells postnatally. The submandibular gland is identifiable at stage 18 as an epithelial diverticulum into the mesenchyme from the floor of the caudal part of the linguogingival sulcus. It increases rapidly in size and branches several times. At first, the connection of the submandibular gland with the floor of the mouth lies at the side of the tongue, but as the edges of the linguogingival sulcus come together,
from behind forwards, they enclose the elongating duct. The orifice of the submandibular duct is thus located progressively more distally until it is below the tip of the tongue, close to the median plane. The sublingual gland arises at stage 20 as a number of small epithelial thickenings within and lateral to the linguogingival sulcus. Each thickening canalizes separately, so multiple sublingual ducts open on the summit of the sublingual fold, while others join the submandibular duct.

The minor salivary glands, which are distributed throughout the wall of the oral cavity, except for the gingiva and hard palate, form in a similar manner to the major glands but undergo very little branching and remain within the submucosa.

## Lymphoid tissues

Tonsils form at several sites around the oro- and nasopharynx, where focal proliferations of endoderm become invaded by lymphoid tissue. The endodermal epithelial lining grows into the surrounding mesenchyme as a number of solid buds, which are excavated by degeneration and shedding of their central cells, forming tonsillar fossae and crypts. Lymphoid cells accumulate around the crypts at about the fifth month and become grouped as lymphoid follicles; T- and B-cell regions can be identified. The palatine tonsils develop from the ventral parts of the second pharyngeal pouches (see Fig. 36.4C). A slit-like intratonsillar cleft extends into the upper part of the tonsil and is possibly a remnant of the second pharyngeal pouch. Lymphoid tissue similar to that of the palatine tonsils is found in the first pouch (tubal tonsils), the surface of the posterior part of the tongue (lingual tonsils), and in the dorsal pharyngeal wall (adenoid or pharyngeal tonsil).

## Teeth and gums

Demarcation of the lips begins after fusion of the facial primordia at stage 18, during the period of secondary palatal development. Two parallel epithelial thickenings, an outer labiogingival lamina and an inner dental lamina, form around the interior border of the mouth in both upper and lower jaws (see Figs 36.13C, 36.15). The linguogingival sulcus is formed as an indentation between the dental lamina and the tongue. At stage 22, each labiogingival lamina indents the underlying mesenchyme to form a shallow groove that deepens to form the labiogingival sulcus between the lips and gums. The lining of the oral cavity between the vestibular epithelium of the upper and lower jaws forms the inner aspect of the cheeks. The dental lamina gives rise to the epithelial component of the teeth.

Tooth formation involves a sequence of epithelial-mesenchymal interactions along the dental lamina (Fig. 36.14). These interactions are controlled by a large number of genetic factors, and the extracellular

Fig. 36.14 A summary of the epithelial-mesenchymal interactions during tooth development.

Fig. 36.15 The lip, gums and teeth after 24 weeks. A, Oral view. B, The right half of the lower jaw viewed from below; the midline is upper right.
matrix (particularly of the basement membranes) is of major importance (Thesleff 2000, Fukumoto and Yamada 2005). In 25 mm embryos, 10 localized thickenings of the upper and lower dental laminae initiate formation of the dental epithelial components of the tooth primordia (see Fig. 36.14). They expand into dental sacs surrounded by vascular mesenchyme. The epithelium proliferates and indents to form an enamel organ, which, by 10 weeks, forms a cap over a mesenchymal condensation, the dental papilla; collectively, this unit constitutes a tooth bud or germ. The enamel organ becomes bell-shaped and differentiates into two layers, the internal and external enamel epithelia; these are separated by a glycosaminoglycan-rich extracellular matrix, the stellate reticulum. The cells of the internal epithelium differentiate into ameloblasts, and the underlying layer of mesenchymal cells differentiates into odontoblasts. The odontoblasts produce and secrete dentine, which influences the ameloblasts to form enamel; this is laid down in successive layers and, after mineralization, is the hardest tissue in the body. Enamel and dentine production from the bell-shaped tooth germ both begin at 24 weeks (Fig. 36.15). The dental papilla mesenchyme below the odontoblast layer forms the pulp, which becomes vascularized and innervated. Experimental studies in mice (which have only incisors and molars) have revealed that regional differences in signalling pathways within the maxillary and mandibular mesenchymes govern the type of tooth produced (Tummers and Thesleff 2009). Fibronectin is present in the basement membrane of the internal enamel epithelium during the bell phase. It assists attachment of the pre-odontoblasts and is essential for their differentiation; it becomes progressively more abundant during the later fetal period. Collagen I is the major supportive extracellular scaffold in the maturing dental papilla and stellate reticulum.

At birth, each quadrant of the jaws has five deciduous tooth germs and the germs of the first five permanent teeth. Permanent teeth develop in accessional positions from the lingual aspects of the deciduous tooth germs and, for the 12 permanent molar teeth, from posterior extensions of the dental laminae on each side of both jaws. Mineralization begins in both deciduous and permanent teeth before birth. The deciduous teeth have well-developed crowns by full term, and eruption through the gingiva (gum) usually begins with the lower incisors between 3 and 6 months after birth. After eruption, the gingiva remains attached to the neck of each tooth by the upper part of the periodontal ligament, whose major part attaches the tooth root to the bone of the tooth socket.

## The oral cavity after birth

In the neonate, the oral cavity is only potential when the mouth is closed, but three spaces are formed during suckling. The median space between the tongue and hard palate, which is occupied by the nipple, bifurcates posteriorly to produce channels on each side of the soft palate and epiglottis. The larynx is elevated so that its opening is directed into the nasopharynx, i.e. above the level of the channels, and milk passes on either side of it to the pharynx and oesophagus. This anatomical arrangement enables the infant to breathe while suckling (see Figs 34.11, 34.12A). The hard palate is only slightly arched and its mucous membrane is corrugated by five or six irregular transverse folds (rugae), which assist with gripping the nipple. Two lateral spaces, the lateral arcuate cavities, are formed between the tongue and cheeks; the upper and lower gums situated within these spaces do not touch during suckling. Each cheek is supported by a mass of subcutaneous fat, the suctorial pad, which lies between buccinator and masseter.

## ANOMALIES OF FACIAL DEVELOPMENT

## Malformations involving the neural crest

Congenital malformations of the face may be initiated early, mainly related to abnormal migration, proliferation and/or apoptosis of neural crest cells, or later, during the morphogenetic phase of facial development. Craniofrontonasal syndrome is characterized by a broad forehead and hypertelorism, premature fusion of one or both coronal sutures, a central nasal groove, and sometimes cleft lip and palate; there are also extracranial features. It is caused by deletions of the gene EFNB1, which is known to play essential roles in boundary formation between tissues, including those between neural crest and adjacent non-crest cells (Twigg et al 2004). Mandibulofacial dysostosis (Treacher Collins syndrome) is characterized by incomplete orbits, reduced jaws and auditory ossicles (hence conductive deafness), abnormal external ears and fistulae or cysts, suggesting involvement of the first and second arch components of the cranial neural crest. It is caused by haploinsufficiency of the gene TCOF1. Hemifacial microsomia (Goldenhaar's syndrome) affects only one side of the face and comprises a small mandible (sometimes with absence of the temporomandibular joint), malformed or absent ears with accessory ear tags, and facial clefts. Experimental evidence in animals suggests that it is due to haemorrhage of the stapedial artery, which may have a genetic basis. Deficient growth of the mandible (micrognathia) is usually associated with other defects. In Pierre Robin sequence (Fig. 36.16), the small size of the mandible obstructs descent of the tongue, resulting in a U-shaped cleft palate; a conotruncal septum defect is present in one-quarter of cases, suggesting possible involvement of the cardiac neural crest. Further details and references for facial malformations may be found in Morriss-Kay and Wilkie (2005) and Hennekam et al (2010).

## Clefts of the face and palate

Cleft lip occurs when one or both medial nasal processes fail to fuse with the corresponding maxillary process(es). The severity of clefting varies from a small notch in the upper lip to a double cleft extending into both nostrils (Fig. 36.17). In a unilateral cleft lip, the nasal septum deviates to the non-cleft side. This is because the muscles on the medial side of the cleft (transverse muscles of the nose and orbicularis oris) are not inserted into either the muscles of the contralateral side or the tissues around the nasal septum (Fig. 36.17B). The three functional groups of superficial facial muscles - nasolabial (transverse nasalis, levator labii superioris and levator labii superioris alaeque nasi), bilabial (orbicularis oris) and labiomental (depressor anguli oris) - are all displaced inferiorly. A further consequence is the underdevelopment of the incisor-bearing part of the maxilla. These abnormalities, in turn, influence the mucocutaneous tissues, which results in the displacement of the skin of the nostril to the upper part of the lip, retraction of the labial skin and abnormalities of the soft tissues on either side of the mucocutaneous junction.

A narrow or incomplete cleft of the hard palate is likely to be due to a growth defect in the palatal shelves and/or a delay in shelf elevation, and/or to failure of fusion of the apposed palatal shelves. Broader clefts (Fig. 36.17D,E), in which the tongue lies between the still-vertical shelves, are caused by a greater developmental delay that may be associated with abnormality of other structures in the face and elsewhere in the body. In the mildest forms of cleft palate, only the soft palate, and sometimes just the uvula, is cleft (Fig. 36.17F). A submucous cleft, which may be detected as a median V-shaped notch of the soft palate, can cause speech difficulties. Very rarely, muscle hypoplasia, particularly of the musculus uvulae, causes palatopharyngeal incompetence.

Cleft lip with or without cleft palate ( $\mathrm{CL} / \mathrm{P}$ ) is multigenic or multifactorial in origin, i.e. it has both genetic and environmental components (Gorlin et al 2001). CL/P has a frequency of 0.5-3.6/1000 live births, with a $2: 1$ male to female ratio. Isolated cleft palate is genetically unrelated to CL/P, and has a frequency of $0.4 / 1000$; it is more common in females. Clefts of the face are rare ( $1 / 50,000-1 / 175,000$ births); they are mainly caused by pressure from amniotic bands rather than from dysmorphogenesis, although a morphogenetic component cannot be ruled out when the cleft is along a line of fusion, e.g. maxillarymandibular. Median cleft lip (true hare lip) is also rare, since this is not a line of morphogenetic fusion. Median grooving of the nose occurs
with hypertelorism in various frontonasal dysplasias, suggesting a developmentally early broadening of the median region of the face.

## FORMATION OF THE NECK

By the time the facial swellings have merged to form a recognizably human face (stage 20, 7 weeks), Meckel's cartilage has grown sufficiently to project outwards as a potential chin but the face is still orientated towards, and close to, the cardiac prominence (see Fig. 36.5). Formation of the posterior part of the neck is, by this time, well advanced, with cartilaginous cervical vertebrae, muscles, nerves and blood vessels. The anterior neck forms gradually, as relatively rapid growth of the anterior structures, including the trachea, oesophagus, common carotid arteries and jugular veins, takes place. As the extending neck lifts the head to a forward-facing orientation, the angle between the spinal cord and brainstem increases. Other contributory changes include growth of the first pharyngeal arch at a more rapid rate than the others, so that Meckel's cartilage and the developing membrane bone of the mandible project further forwards, while the hyoid bone primordium remains small, defining the future angle between the anterior neck and lower jaw. Myoblasts derived from paraxial mesenchyme invade the second pharyngeal arch as it forms and by this stage are present in the superficial connective tissue beneath the anterior neck skin; these spread out from the underside of the chin to the upper thorax and differentiate to form the platysma (this is the main human remnant of the panniculus carnosus, the muscle that is present throughout the skin of many mammals).

The interface between cranial nerve-innervated pharyngeal arch muscles and spinal nerve-innervated trunk muscles occurs at the lower neck and the upper parts of the pectoral girdle. Both the proximal and distal connections of the trapezius muscle, at the nuchal line of the occipital bone and the attachment to the spine of the scapula, are formed from post-otic neural crest cells (Matsuoka et al 2005). The neural crest generates areas of endochondral ossification in the cervical vertebral column and scapula associated with trapezius attachment. This observation has promoted the conception of a 'muscle scaffold model' of development to replace the older 'ossification model', to explain the types of ossification seen associated with the accessory nerve-innervated trapezius and sternocleidomastoid muscles. It is suggested that defects in the fate choices of neural crest cells could explain
a number of syndromes that have pharyngeal, laryngeal, occipital, cervical and shoulder dysmorphologies and co-occurrence of swallowing problems; related syndromes include Klippel-Feil, Sprengel's deformity and cleidocranial dysplasia (Matsuoka et al 2005) (see p. 794).

## GLANDS OF THE NECK

Further development of the pharyngeal floor and the second to fourth pharyngeal pouches gives rise to glands that are ultimately disposed in the neck and anterior mediastinum, namely: the paired thyroid and parathyroid glands and the thymus.

## Thyroid gland

The thyroid gland is a midline derivative of the pharynx. It is first identifiable in embryos of approximately 20 somites as a median thickening of endoderm lying in the floor of the pharynx between the first and second pharyngeal pouches and immediately dorsal to the aortic sac The foramen caecum is the site of a median diverticulum that appears early in the fifth week in the furrow immediately caudal to the median tongue bud (see Fig. 36.13B, C; Fig. 36.18). It extends caudally as the thyroglossal duct, passing ventral to the primordium of the hyoid bone. The tip of the duct bifurcates and the tissue mass subsequently divides to form the isthmus and lateral lobes of the thyroid gland. The endoderm-derived epithelial tissue is invested by vagal neural crest mesenchyme, which gives rise to the connective tissue capsule and interlobular septa, and perifollicular mesenchyme, which carries the neurovascular and lymphatic supply to the gland. The gland has three stages of development. Stage 1 ( $10-18$ weeks) is characterized by active folliculogenesis and gradual accumulation of colloid; the thyroid tissue
is able to concentrate iodine and synthesize thyroxine. Stage 2 (19-29 weeks) is quiescent, with little change in the epithelium/colloid ratio and follicular size. Stage 3 (after 29 weeks) is characterized by a gradual increase in the epithelium/colloid ratio and a decrease in follicular size (Bocian-Sobkowska et al 1997). The parafollicular or C cells of the thyroid gland are derived from the ultimobranchial body, a small diverticulum of the fourth pharyngeal pouch. The thyroid gland is relatively large in the neonate (see Fig. 14.6A), where it has a long, narrow isthmus connecting lobes that do not yet contact the upper part of the trachea. It usually attains half the adult size by 2 years of age.

Failure of downgrowth of all or part of the thyroid gland from the pharyngeal floor results in ectopic thyroid tissue within the tongue (lingual thyroid), lying between the foramen caecum and the epiglottis. Occasionally, parts of the midline thyroglossal duct persist and may occur in lingual, suprahyoid, retrohyoid or infrahyoid positions; they may form aberrant masses of thyroid tissue, cysts, fistulae or sinuses, usually in the midline. Nodules of glandular tissue may also be found laterally, posterior to sternocleidomastoid.

## Parathyroid glands

The parathyroid glands develop from interactions between the third and fourth pharyngeal pouch endoderm and local cranial (vagal) neural crest mesenchyme. The third pharyngeal pouch has dorsal and ventral sites of proliferation (Fig. 36.18B). The epithelium on the dorsal aspect of the pouch and in the region of its duct-like connection with the cavity of the pharynx becomes differentiated as the primordium of the inferior parathyroid glands (parathyroid III). Although the connection between the pouches and the pharynx is soon lost, the connection between the dorsal parathyroids and the ventral thymic rudiments of the third pharyngeal pouch persists for some time and both move caudally. The

Fig. 36.18 A, The ventral aspect of the endoderm of the pharynx, showing the pharyngeal pouches. The areas of contact of the pharyngeal endoderm with the surface ectoderm are shown as flattened surfaces. Note that the colours of the pharyngeal pouches and the median thyroid diverticulum are retained in B, C and D. B, Ventral and dorsal diverticuli of the third and fourth pharyngeal pouches and midline thyroid gland at 6 weeks. C, The thymus, thyroid and parathyroid glands at 7 weeks. D, The thymus, thyroid and parathyroid glands at $7 \frac{1}{2}$ weeks. (Redrawn with permission from Hamilton WJ , Boyd JD, Mossman HW 1962 Human Embryology: Prenatal Development of Form and Function. Cambridge: W Heffer \& Sons.)
superior parathyroid glands (parathyroid IV) develop from the dorsal recess of the fourth pharyngeal pouches. They make contact with, and appear to be anchored by, the lateral lobes of the thyroid gland and thus remain cranial to the descended parathyroid III glands. Vagal neural crest mesenchyme provides the connective tissue elements, and invading angiogenic mesenchyme gives rise to fenestrated capillaries and lymphatics. In the neonate, the parathyroid glands are as variable in size and position as they are in the adult. They double in size between birth and puberty. Parathyroid hormone is produced from the twelfth week of development.

## Thymus

The thymus gland is formed from the ventral part of the third pharyngeal pouch on each side (see Fig. 36.18). It cannot be recognized prior to the differentiation of the inferior parathyroid glands at stage 16 but, thereafter, it is represented by two elongated diverticula that soon become solid cellular masses and grow caudally into the surrounding vagal neural crest mesenchyme. Ventral to the aortic sac, the two thymic rudiments meet but do not fuse, and they are subsequently united by connective tissue only. The thymus gland becomes located in the anterior mediastinum of the thorax once the neck is fully developed and the heart has descended. The connection with the third pouch is soon lost, but the stalk may persist for some time as a solid, cellular cord.

As the thymus proliferates and descends, the local neural crestderived mesenchyme controls the pattern and development of the gland. Defective development of the vagal neural crest, which affects the heart and peripheral neural ganglia, also results in thymic deficiencies, as seen in DiGeorge syndrome and Pierre Robin sequence. Neural crest mesenchyme forms connective tissue septa, which produce the lobulated architecture of the gland. Angiogenic mesenchyme, including lymphoid stem cells, invades this local mesenchyme, and by 10 weeks, over $95 \%$ of the cells in the gland belong to the T-cell lineage, with a few erythroblasts and B lymphocytes. Hassall's corpuscles are also present. By 12 weeks, the mesenchymal septa, blood vessels and nerves have reached the newly differentiating medulla, which allows the entry of macrophage lineage precursors. Macrophages and interdigitating cells are first seen at 14 weeks. Granulopoiesis occurs in the perivascular spaces. By 17 weeks, the thymus appears fully differentiated, and after this time, it produces the main type of thymocyte that is present throughout life (designated TdT ${ }^{+}$).

## Caudal pharyngeal complex

The most caudal endodermal evaginations of the pharynx are the fourth pharyngeal pouch and the ultimobranchial body, a small diverticulum medial to the main pouch. Collectively, these diverticula are termed the caudal pharyngeal complex (see Fig. 36.18), and they are connected to the pharynx via the pharyngobranchial duct. They are surrounded by vagal neural crest and by the tissues of the developing thyroid gland. The cells of the ultimobranchial body become incorporated into the lateral thyroid lobes, and give rise to the calcitonin-secreting ' C ' or parafollicular cells of the thyroid gland.

## PHARYNX, LARYNX, OESOPHAGUS AND TRACHEA

The larynx forms at the cranial end of the laryngotracheal groove, caudal to the epiglottis (see Figs 36.5-36.6, 36.13). The thyroid cartilage develops from the ventral ends of the cartilages of the fourth, or fourth and sixth, pharyngeal arches. The cartilage appears as two lateral plates, each chondrified from two centres and united in the mid-ventral line by a fibrous membrane, within which an additional centre of chondrification develops. The cricoid cartilage arises from two cartilaginous centres, which soon unite ventrally, gradually extend, and ultimately fuse on the dorsal surface of the tube as the cricoid lamina. It has the appearance of a modified tracheal cartilage. Paired arytenoid swellings appear within the ventral tissue of the sixth arches from stage 14, one on each side of the cranial end of the laryngotracheal groove. As they enlarge, they approximate to each other and to the caudal part of the hypobranchial eminence, where the epiglottis develops. The opening into the larynx, at first a simple slit, is converted into a T-shaped cleft by the enlargement of the arytenoid swellings. The vertical limb of the T lies between the two swellings, and its horizontal limb lies between them and the epiglottis. The arytenoid swellings differentiate into the arytenoid and corniculate cartilages (Fig. 36.6), and the ridges that join them to the epiglottis become the definitive aryepiglottic folds, within which the cuneiform cartilages differentiate from the
epiglottis. Two linear ridges in the ventral wall of the pharynx extend ventrally from the sixth arches to the median laryngotracheal groove, from which the lower part of the larynx, the trachea, bronchi and lungs develop (Ch. 52).

The laryngotracheal groove forms at stage 12 as a ventral endodermal outgrowth from the floor of the caudal part of the pharynx into the mesenchyme surrounding the sinus venosus and inflow tract of the heart (see Figs 52.1C, 60.3). This initiates the separation of the respiratory and alimentary tubes. The groove remains at a constant level during the embryonic period, and the trachea lengthens distally as its bifurcation point descends. The splanchnopleuric mesenchyme that surrounds the developing trachea and oesophagus induces the different histogenic pathways of the two tubes. By stage 17, the mesenchyme around the trachea is beginning to condense at regular intervals and undergo chondrogenesis to form C-shaped cartilages, whereas that around the oesophagus has a wide submucosal zone and muscular coats. The respiratory diverticulum becomes surrounded by angiogenic mesenchyme that connects to the developing sixth aortic arch artery (see above).

For details of early development of the trachea, see page 926; for early development of the oesophagus, see page 1048.

In the neonate, the pharynx is one-third of the relative length seen in the adult. The nasopharynx is a narrow tube that curves gradually to join the oropharynx without any sharp junctional demarcation. An oblique angle is formed at this junction by 5 years of age, and in the adult, the nasopharynx and oropharynx join at almost a right angle. The oesophagus in the newborn begins and ends one to two vertebrae higher than in the adult, extending from between the fourth and sixth cervical vertebrae to the level of the ninth thoracic vertebra. The narrowest constriction is at its junction with the pharynx, where the inferior pharyngeal constrictor functions to constrict the lumen; in this region, it may be traumatized with instruments or catheters.

The neonatal hyoid bone and larynx are relatively high in the neck, and the trachea is relatively small in relation to the larynx (see Fig. 14.6B); both descend during infancy. The walls of the trachea are relatively thick and the tracheal cartilages are relatively closer together than in the adult. The trachea commences at the upper border of the sixth cervical vertebra, a relationship that is conserved with growth, and it bifurcates at the level of the third or fourth thoracic vertebra.

## BLOOD VESSELS IN THE NECK

With elongation of the neck and the appearance of the major conducting vessels from the aortic arch arteries, longitudinal anastomoses in the cervical region link intersegmental arteries and their branches, and direct blood flow to the developing brain in the vertebral arteries in parallel with the internal carotid arteries (see Figs 36.8-36.9).

The primary blood vessels of the head and neck consist of a closemeshed capillary plexus drained on each side by the precardinal vein, which is, at first, continuous cranially with a transitory primordial hindbrain channel that lies on the neural tube medial to the cranial nerve roots (see Figs 13.1-13.2). This is soon replaced by the primary head vein, which runs caudally from the medial side of the trigeminal ganglion, lateral to the facial and vestibulocochlear nerves and the otocyst, then medial to the vagus nerve, to become continuous with the precardinal vein. A lateral anastomosis subsequently brings it lateral to the vagus nerve.

The ventral pharyngeal vein drains the mandibular and hyoid arches into the common cardinal vein (see Fig. 17.36A). As the neck elongates, its termination is transferred to the cranial part of the precardinal vein, which later becomes the internal jugular vein (see Fig. 17.36B). The ventral pharyngeal vein receives tributaries from the face and tongue, and becomes the linguofacial vein. As the face develops, the primitive maxillary vein extends its drainage into the territories of supply of the ophthalmic and mandibular divisions of the trigeminal nerve, including the pterygoid and temporal muscles, and it anastomoses with the linguofacial vein over the lower jaw. This anastomosis becomes the facial vein; it receives blood from the retromandibular vein from the temporal region, and drains through the linguofacial vein into the internal jugular. The stem of the linguofacial vein is now the lower part of the facial vein, whilst the dwindling connection of the facial with the primitive maxillary becomes the deep facial vein. The external jugular vein develops from a tributary of the cephalic vein from the tissues of the neck; it anastomoses secondarily with the anterior facial vein. At this stage, the cephalic vein forms a venous ring around the clavicle, by which it is connected with the caudal part of the precardinal vein. The deep segment of the venous ring forms the subclavian vein and receives the definitive external jugular vein. The superficial segment of the venous ring dwindles, but may persist in adult life. The deep
aspects of the maxillomandibular facial prominences, the retrogingival oral cavity, the pharyngeal walls and their lymphoid and endocrine derivatives, and the cervicothoracic oesophagus thus all have drainage channels that connect with the precardinal complex. Laryngeal and tracheobronchial veins also drain to the precardinal complex, whilst the capillary plexuses, developed in the (splanchnopleuric) walls of the fine terminal respiratory passages and alveoli, converge on pulmonary veins of increasing calibre, finally making secondary connections with the left atrium of the heart, and may be grouped with the vitelline systems.

## SKULL

The skull has two major functional and anatomical components: the neurocranium and the viscerocranium. The neurocranium is composed of the calvaria and basicranium; it surrounds and protects the brain and the special sense organs of olfaction, vision, hearing and balance. The viscerocranium, which includes the squamous part of the temporal bone, forms the skeleton of the face, palate and pharynx, and mediates the functions of feeding, breathing and facial expression; it also protects the tongue and forms the middle ear and the bony external acoustic meatus. The most rostral neural crest cell population makes a major contribution to the skull, forming the whole viscerocranium and the rostral part of the neurocranium (Fig. 36.19). The boundary between neural crest and cranial mesoderm lies between the frontal and parietal bones (coronal suture) of the calvaria; the skull base is formed by neural crest rostral to the tip of the notochord, and is sclerotome-derived (i.e. from paraxial mesenchyme) in the notochordal region (McBratneyOwen et al 2008). The tip of the notochord lies immediately caudal to the hypophysial fossa (Fig. 36.20A). Broadly speaking, the bones of the skull base are formed by endochondral ossification (chondrocranium), whereas those of the calvaria and face ossify directly from mesenchymal condensations, i.e. by intramembranous ossification. Several bones are of compound structure with respect to their tissue origins and/or type of ossification: the occipital, temporal and sphenoid bones, and the mandible. The following account is based largely on descriptive studies on human embryos and fetuses (O'Rahilly and Müller 1987, 2001, 2007), with some details of cell lineage based on investigations in the mouse

## CHONDROCRANIUM

The first cranial skeletal structures to differentiate are the cartilages of the skull base, sensory capsules, viscerocranium and occiput (see Figs $36.5,36.20 B$ ). Development of the pharyngeal arch-related cartilages of the viscerocranium and ear ossicles has been described in the section on the pharynx. Before any mesenchyme condenses to initiate the formation of cranial cartilage, the major cranial nerves and blood vessels are already in place; hence, the foramina of the skull are specified before

Fig. 36.19 The newborn skull, showing the tissue origins of the bones (based on combined mouse and human data). The darker green represents the sites of fontanelles.
the bones are formed. The adenohypophysial (Rathke's) pouch is still connected to the roof of the oral cavity as the skull base cartilage forms (dashed lines in Fig. 36.20A; see also Fig. 17.14), but already lies adjacent to the diencephalon-derived neurohypophysis to form the downwardly projecting pituitary gland (hypophysis) at the base of the caudal diencephalon.

The notochordal sheath is rich in sulphated glycosaminoglycans, which play a role in inducing condensation and chondrification of the occipital sclerotome-derived mesenchyme around it.

The structures referred to in the following account are illustrated in Figure 36.20B, which shows the cartilaginous skull base of a 40 mm (9-week) embryo. The central regions of all four occipital sclerotomes contribute to the parachordal cartilage, which surrounds the notochord and extends as a flat plate on either side of it by the end of the seventh week, forming the basioccipital component of the occipital bone (see Fig. 44.13). Laterally, the exoccipital components (derived from sclerotomes 3 and 4) chondrify soon afterwards; they extend around the hindbrain to form the occipital arch, which is developmentally equivalent to the neural arch components of vertebrae. Roots of the hypoglossal nerve run between the parachordal and exoccipital cartilages, so that when the exoccipital and parachordal components fuse, they leave foramina for these nerve roots (see Fig. 44.12). The supraoccipital part of the occipital cartilage extends dorsally from the exoccipital cartilage to complete the foramen magnum. After formation of the exoccipital cartilages, differentiation also extends further rostrally in the medial part of the skull base, with formation of the hypophysial polar cartilages on either side of the hypophysial stalk; they unite in the median plane to form the primordium of the postsphenoid, cradling the hypophysis and retaining a perforation for the hypophysial stalk until the third month. This part of the basisphenoid cartilage will form the sella turcica with its hypophysial fossa. The presphenoid cartilages, rostral to it, form the jugum of the sphenoid body. This is the last part of the medial part of the skull base to differentiate as cartilage, bridging the gap between the postsphenoid and the cartilaginous nasal capsule.

At stage 17, mesenchyme begins to condense and later to chondrify around the nasal pits, forming the outer part of the nasal capsule and the nasal septum; the roof of each nasal capsule is completed slightly later, when cartilage differentiates around the olfactory nerve bundles to form the cribriform plates of the ethmoid bone. During the third month, cartilaginous conchae form. The whole nasal capsule is well developed by the end of the third month, and consists of a common median septal part, sometimes initially termed the interorbitonasal septum or mesethmoid, and the outer ectethmoid. The conchae ossify during the fifth month; the superior and middle conchae form part of the ethmoid bone, and the inferior pair become separate elements. Each lateral part of the nasal capsule becomes ossified as the orbital plate and ethmoidal labyrinth, whose spaces ('cells') communicate with the nasal cavity and become filled with air after birth (see p. 566). Part of the capsule remains cartilaginous as the septal and alar cartilages of the nose, and part is replaced by the intramembranous vomer and nasal bones.

Orbital cartilages surround the eye but do not undergo ossification in their entirety. The most rostral of them becomes continuous with the presphenoid cartilage by differentiation of a cartilaginous bridge that forms the caudal boundary of the optic foramen, enclosing the optic nerve; this later ossifies to form the lesser wing of the sphenoid bone (orbitosphenoid). The greater wing of the sphenoid (alisphenoid) has both intramembranous and endochondral components; the endochondral part initially differentiates as a cartilage surrounding the mandibular branch of the trigeminal nerve, forming the foramen ovale. This condensation extends medially to join the rostral edge of the hypophysial (polar) cartilage on each side. It also extends rostrally to surround the maxillary branch of the trigeminal nerve, forming the foramen rotundum. Lastly, it extends laterally to join the intramembranous part of the bone, which replaces the caudal part of the orbital cartilage. The greater and lesser wings of the sphenoid are separated by the oculomotor, trochlear and abducens nerves and by the first (ophthalmic) division of the trigeminal nerve.

The otic capsule differentiates from a mesenchymal condensation around the otocyst, after its morphogenesis to form the cochlea and semicircular canals. Differentiation of cartilage begins laterally, at the same time as the hypophysial cartilages are first detectable; it is complete by stage 20. Chondrogenesis around the point of exit of the vestibulocochlear nerve creates the internal acoustic meatus. Chondrogenesis of mesenchyme around the carotid arteries joins each hypophysial cartilage to the otic capsule, forming the carotid canals. A gap occupied by the jugular vein and the glossopharyngeal, vagus and accessory nerves remains between each otic capsule and the parachordal cartilage; this is the jugular foramen. Chondrogenesis of the mesenchyme

between the separate cartilages completes formation of the cartilaginous skull base and sensory capsules, which together form a continuous framework around the pre-existing blood vessels and cranial nerves by 9 weeks ( 40 mm ) (see Fig. 36.20B,C).

The process of endochondral ossification in the skull is essentially the same as that of the long bones, except that each ossification centre is equivalent to a primary centre, and follows a specific programme of growth and patterning. Growth takes place within the cartilage between adjacent ossification centres; these joints are termed synchondroses. The first ossification centres to appear are those of the lesser and greater wings of the sphenoid, at 8 and 9 weeks, respectively. A single basisphenoid ossification centre appears at 11 weeks; three presphenoid and four postsphenoid ossification centres appear at 16 weeks. Bone replaces
most of the cartilage until only the major synchondroses remain; these enable the endochondral skull base and sensory capsules to continue growing until they reach their final size at puberty or earlier. At birth, unossified chondrocranium persists in the alae, lateral nasal cartilage and septum of the nose, the sphenoethmoidal junction, the sphenooccipital and sphenopetrous junctions, the apex of the petrous temporal bone (foramen lacerum), and between ossification centres of the sphenoid and occipital bones. As indicated above, parts of the chondrocranium do not ossify, but are replaced by adjacent intramembranous bone, e.g. the greater wing of the sphenoid (alisphenoid). In general, endochondral ossification centres form later than intramembranous ossification sites, which first appear during the seventh and eighth weeks.

## CALVARIA

The bones of the calvaria (roof and lateral walls of the neurocranium) are formed entirely by intramembranous ossification. They are also described as dermal bones, since they are considered to be the evolutionary descendants of dermal plates formed as a protective cover for the brain in fishes. In humans, as in all mammals, the major part of the calvaria is formed by paired frontal and parietal bones and the unpaired interparietal (membranous part of the occipital bone). The squamous part of the temporal bones and the alisphenoids contribute to the lateral walls. Lineage data from mouse studies indicate that the frontal and squamous temporal bones are of neural crest origin and the parietals are of mesodermal origin; the interparietal is mixed (Jiang et al 2002). The coronal suture thus forms at the neural crest-mesoderm interface, as does the sagittal suture, due to a small tongue of neural crest tissue lying between the two developing bones. These tissue interfaces are significant for initiating the molecular signalling system that governs growth of the calvaria. Growth at the borders of adjacent bone, i.e. in the sutures, is the major mechanism of calvarial growth. A sequence of events that maintains a balance between cell proliferation and osteogenic differentiation is mediated by an intercellular signalling system that includes the transcription factor TWIST and ligand-receptor interactions between fibroblast growth factors (FGFs) and their receptors (FGFRs). Mutations in the genes encoding these proteins cause premature fusion of the cranial sutures (craniosynostosis), which results in deficient growth in the plane perpendicular to the suture (Fig. 36.21; Morriss-Kay and Wilkie 2005, Johnson and Wilkie 2011). In addition to the expansion-related growth that takes place in the sutures, appositional growth, in which bone is laid down on, and resorbed from, the bone surfaces, plays an important role in remodelling the calvarial bones to maintain a degree of curvature that matches the curved surface of the growing brain. Appositional growth can also provide some compensatory expansion of the skull in craniosynostosis (see Fig. 36.21).

The frontal and parietal bones are initiated as basolateral mesenchymal primordial, which extend upwards between the dermal connective tissue and the mesenchymal dura mater. They do not, as previously thought, differentiate within the mesenchyme of an 'ectomeninx' that surrounds the brain. As the frontal and then the parietal primordia extend upwards, the differentiating osteoblasts secrete osteoid, which then undergoes mineralization. Only the mineralized parts of the bones are detected in alizarin-stained specimens and X-rays. Clear frontal bone primordia are detectable in the superciliary arch region of alizarinstained human embryos by the eighth week. As they become mineralized above this level, the parietal bone primordia can also be seen. The
two bones appear to be separated by a wide gap at the coronal suture; in fact, this gap only shows the separation of the mineralized parts of the bone - the unmineralized edge of the parietal bone actually overlaps the caudal edge of the frontal bone. After the upgrowth phase, mineralization takes place centrifugally from the central points of the frontal and parietal bones, which, by this time, form convex plates over the curvature of the underlying brain (see Fig. 36.20D).

During vaginal birth, the overlap of the frontal and parietal bones enables them to slide over each other. During the neonatal period, when the baby cries and intracranial pressure rises, the overlapping bones slide apart, increasing the fronto-occipital diameter of the skull. Growth at the coronal suture provides the major increase in the frontooccipital plane of the calvaria. Premature synostosis of the coronal sutures restricts growth in this plane, causing brachycephaly; unilateral coronal synostosis leads to plagiocephaly, in which one side of the skull fails to grow in the fronto-occipital plane. Uni- and bilateral coronal synostosis comprises $20-25 \%$ of all forms of craniosynostosis.

The metopic and sagittal sutures are formed when the upwardly extending frontal and parietal bones (respectively) reach the vertex of the skull and abut in the median plane. Growth in these sutures increases the breadth of the skull. Premature fusion results in the formation of a narrow, elongated skull. Sagittal synostosis is the most common form of craniosynostosis (40-55\%).

The interparietal bone (supranuchal squamous portion of the occipital bone) forms from two ossification centres that appear in the eighth week. These are considered to be homologous with the paired postparietal bones of reptiles. The fact that they unite to form a single bone in mammals may be due to the interpolation of a small area of neural crest that migrates from the hindbrain after neural tube closure (Jiang et al 2002). Two further ossification centres develop laterally at 12 weeks. There is, at first, a wide gap occupied by cartilage between the interparietal and parietal bones, which disappears as the membrane bones grow towards each other, forming the lambdoid suture when they abut. The lambdoid suture contributes growth to the caudal border of the parietal bones and to the upper part of the occipital bone. Synostosis of this suture is relatively rare (fewer than $5 \%$ of craniosynostosis cases) and has a less severe effect on overall skull growth than coronal and median fusions. Between the interparietal bone and the foramen magnum, the calvaria is completed by endochondral ossification of the supraoccipital component of the occipital bone.

In addition to the sutures that are formed where two membrane bones abut, fontanelles are formed where three or four bones meet. In the median plane, these are the anterior fontanelle, at the junction of the metopic and sagittal sutures, and the posterior fontanelle, at the junction of the sagittal and lambdoid sutures. The anterolateral

Fig. 36.21 Craniosynostosis. A-B, Line drawings of frontal and lateral views of sagittal synostosis. C-D, Three-dimensional computed tomography (3D-CT) scans. Premature fusion of the sagittal suture has restricted growth in breadth of the skull but there is compensatory growth in the frontooccipital plane. E-F, Line drawings of frontal and lateral views of bicoronal synostosis. G-H, 3D-CT scans. Premature fusion of both coronal sutures has restricted growth in the fronto-occipital plane but there is compensatory growth in breadth. The pairs of CT scans are not from the same patients as those indicated in the line drawings; the endotracheal tube has been digitally removed from $D$. (CT scans courtesy of $P$ Anslow.)
fontanelle lies between the frontal, parietal, greater wing of the sphenoid and squamous temporal bones; its site after closure is called the pterion. The posterolateral fontanelle lies between the parietal, petrous temporal, exoccipital and basioccipital bones; after closure, its site is called the asterion. The size of the fontanelles at birth, and the timing of their closure, are highly variable. Delayed growth of the skull bones causes ossification defects, including cranium bifidum and parietal foramina, for which several genetic defects have been identified. Cleidocranial dysplasia is a defect of ossification affecting the intramembranous part of the clavicle as well as the calvaria; it is caused by haploinsufficiency of the bone master gene RUNX2.

## MEMBRANE BONES OF THE FACE AND VISCEROCRANIUM

The face and viscerocranium are formed from neural crest-derived membrane bones. The facial skeleton includes, from forehead to chin: the frontal bones, the orbital bones (frontal, lacrimal and zygomatic), the nasal bones and the vomer, the maxilla and the mandible. The maxilla and mandible form from first arch mesenchyme, as do the medial pterygoid plates of the sphenoid bone, the palatine and the tympanic bones.

During migration, the trigeminal neural crest cells divide into a frontonasal population that migrates superior to the eye and comes to surround the telencephalon and part of the diencephalon, a mandibular population that migrates into the first pharyngeal arch, and a maxillary population that forms the maxillary swelling (see Fig. 36.2). The frontal, lacrimal, nasal bones, the vomer and the premaxillary (incisor tooth-bearing) part of the maxilla are derived from the frontonasal mesenchyme; the maxilla and zygoma are derived from the maxillary mesenchyme; and the mandible and tympanic bone are derived from the mandibular mesenchyme. The mandible is the first membrane bone to begin ossification; its single ossification centre appears in the seventh week. The maxilla and premaxilla have primary ossification centres by 7 weeks, and three further ossification centres (orbitonasal, nasopalatine and zygomatic) form in the maxillary mesenchyme at 8 weeks; these components fuse to form a single bone, in contrast to some mammals, in which the incisor-bearing premaxillary part remains separate. In the neonatal skull, the suture between the primary (premaxilla-derived) and secondary parts of the palate is still patent. By 8 weeks, ossification centres for most of the facial and viscerocranial bones are present, except for the tympanic ring, for which four ossification centres appear at 12 weeks. They fuse to form the sickle-shaped bone that supports the tympanic membrane (see Fig. 36.6). There is as much anteroposterior as vertical growth in the first 5 years of life. After the age of 5 years, there is more vertical growth. During the first 5 years of life, there is a steady increase in maxillary volume; maxillary growth rate accelerates during the time that the permanent dentition is developing and erupting (Langford et al 2003).

The mandible is a developmentally complex bone. Although the body of the bone is formed by intramembranous ossification, the coronoid region and condyle are formed by endochondral ossification in cartilage that develops after formation of the membrane bone. These secondary ossification centres form at 10-14 weeks. Distal cartilage forms two further secondary ossification centres, the mental ossicles, at 7 months. This complex system enables the mandible to grow at both proximal and distal ends, analogous to a long bone.

Growth of the face occurs in the sutures between the membrane bones in a similar manner to that of the calvarial sutures but, during
the fetal period, the amount of growth is proportionately less than that of the calvaria, reflecting the dominant influence of brain growth in the latter.

## ANTENATAL ULTRASOUND IMAGING OF THE HEAD AND NECK

The fetal head appears oval on transthalamic and transventricular planes, symmetrical and broader posteriorly (see Fig. 14.4). Biparietal diameter and head circumference are routinely measured. The size of the cisterna magna can be estimated to note hypoplasia of the posterior fossa of the skull. Increased thickness of the nuchal tissues at the back of the neck, measured from the outer edge of the occipital bone to the outer skin edge, is part of screening for Down's syndrome (Nafziger and Vilensky 2014). Nuchal translucency is increased in a number of trisomies and in fetuses with congenital heart defects (Chen 2010). The causes of this are complex and include an increase in hyaluronic acid in the extracellular matrix in the nuchal skin folds, aberrant jugular lymphatic flow and disturbed venous-lymphatic differentiation leading to local oedema (de Mooij et al 2010).

Prenatal diagnosis of asymmetrical craniodystosis and of craniofacial syndrome has been reported. Facial clefting can be identified, although demonstration of isolated cleft palate is difficult (Twining 2007). Abnormalities of the fetal neck are uncommon.

## POSTNATAL GROWTH OF THE SKULL

Postnatal growth of the skull is characterized by changing proportions of its components. Growth of the brain continues to be extremely rapid in the first 2 years. The metopic suture fuses during the first year, by which time the rapid phase of increase in breadth of the forehead is complete; further growth and remodelling of the frontal bones is mediated by appositional growth. The sagittal suture continues as an active growth centre until puberty, when growth of the brain is complete. In addition to continuing growth of the frontal and parietal bones, the squamous temporal bone increases in size so that it contributes a greater proportion of the calvaria in the adult than in the neonate (Fig. 36.22). The inner ear and the petrous temporal bone around it grow very little after birth, so the increasing breadth of the skull draws the petrous temporal bone out laterally, creating the bony external acoustic meatus. The tympanic ring (with the tympanic membrane) lies at the surface of the meatus in the neonatal skull; it remains at the proximal end of the deepening canal. Use of sternocleidomastoid to lift the head results in formation of the mastoid process of the temporal bone, which develops air-filled spaces (mastoid air cells) that are continuous with the middle ear cavity. The paranasal sinuses begin to form in late fetal life as diverticula from the nasal cavity that gradually invade the maxilla, frontal, ethmoid and sphenoid bones. At birth, small ethmoidal and maxillary sinuses are present, but the frontal sinus is nothing more than an out-pouching from the nasal cavity, and there is no pneumatization of the sphenoid bone (p. 566). Thickening of the skull bones is accompanied by increasing size of the sinuses, and by a change in form of the sutures, from straight to wavy lines and, finally, to the complex interdigitations seen in the adult. After growth ceases, the skull sutures contain inert connective tissue and some cartilage; in old age, some of them are completely replaced by bone (natural synostosis).

Fig. 36.22 During postnatal growth of the skull, the viscerocranium increases in size relative to the neurocranium. This diagram shows that, with the height of the cranial vault expressed as similar in newborn and adult skulls (lines $\mathrm{a} \leftrightarrow \mathrm{b}$ ), the facial skeleton increases particularly rapidly during childhood and puberty.

## External and middle ear

By convention, the ear is subdivided into three parts: the external, middle and inner ear. It is largely, but not entirely, contained within the temporal bone. The ears not only receive, modulate, conduct, amplify and discriminately analyse the complex pressure waves that are sound, but also contain the end organs of balance.

## TEMPORAL BONE

Each temporal bone consists of four components: the squamous, petromastoid and tympanic parts and the styloid process (Fig. 37.1). The squamous part has a shallow mandibular fossa associated with the temporomandibular joint (Ch. 32). The petromastoid part is relatively large; its petrous portion houses the auditory apparatus and is formed of compact bone. In contrast, the mastoid process is trabecular and variably pneumatized. The tympanic part has the form of a thin and incomplete ring whose ends are fused with the squamous part. The styloid process gives attachment to the styloid group of muscles. The temporal bone contains two canals. The external acoustic meatus (external auditory canal), visible on the lateral surface, conveys sound waves to the tympanic membrane and the internal acoustic meatus (internal auditory canal), evident on the medial surface, through which the facial and vestibulocochlear nerves pass.

## Squamous part

The squamous part lies anterosuperiorly, and is thin and partly translucent. Its external temporal surface is smooth, slightly convex, and forms part of the temporal fossa, to which temporalis muscle is attached. Above the external acoustic meatus, it is grooved vertically by the middle temporal artery. The supramastoid crest curves backwards and upwards across its posterior part and gives attachment to the temporal fascia. The junction between the squamous and mastoid parts is approximately 1.5 cm below this crest, and traces of the squamomastoid suture may persist. The suprameatal triangle, a depression marking the position of the mastoid antrum (which is medial to the triangle at a depth of approximately 1.25 cm ), lies between the anterior end of the supramastoid crest and the posterosuperior quadrant of the external acoustic meatus. The triangle usually contains a small suprameatal spine anteriorly.

The internal cerebral surface of the squamous part is concave and contains depressions that correspond to convolutions of the temporal lobe of the cerebral hemisphere. This surface is grooved by the middle meningeal vessels. Its lower border is fused to the anterior region of the petrous part but traces of a petrosquamosal suture often appear in adult bones. The superior border is thin and bevelled internally; it overlaps the inferior border of the parietal bone at the squamosal suture. Posteriorly, it forms an angle with the mastoid element. The anteroinferior border, thin above and thick below, meets the greater wing of the sphenoid bone; it is bevelled internally above, and bevelled externally below.

The squamous part has a zygomatic process and a mandibular fossa.

## Zygomatic process

The zygomatic process juts forwards from the lower region of the squamous part. Its triangular posterior aspect has a broad base that is directed laterally, presenting superior and inferior surfaces. The zygomatic process then twists anteromedially, so that its surfaces become medial and lateral.

The superior surface of the posterior part is concave. The inferior surface is bounded by anterior and posterior roots, converging into the anterior part of the process. The tubercle of the zygomatic root gives attachment to the lateral temporomandibular ligament at the junction of the roots. The posterior root is prolonged forwards above the external acoustic meatus, its upper border continuing into the supramastoid crest. Very rarely, the squamous part is perforated above the posterior
root by a squamosal foramen, which transmits the petrosquamous sinus. The anterior root juts almost horizontally from the squamous part. Its inferior surface, with an anteroposterior convexity, forms a short semi-cylindrical articular tubercle and comes into contact with the articular disc of the temporomandibular joint. The tubercle forms the anterior limit of the mandibular fossa.

The anterior part of the zygomatic process is thin and flat, and the temporal fascia is attached to its superior border. The inferior border is short and arched, and gives origin to some fibres of masseter. The lateral surface is convex. The medial surface is concave and provides further attachment for part of masseter. The anterior end is deeply serrated and slopes obliquely posteroinferiorly to articulate with the temporal process of the zygomatic bone, forming the zygomatic arch. Anterior to the articular tubercle, a small triangular area forms part of the roof of the infratemporal fossa; it is continuous behind with the anterior root and in front with the infratemporal crest of the greater wing of the sphenoid.

## Mandibular fossa

The mandibular fossa is limited in front by the articular eminence of the zygomatic process. It presents an anterior articular area, formed by the squamous part, and a posterior non-articular area, formed by the tympanic element. The articular surface is smooth, oval and concave, and contacts the articular disc of the temporomandibular joint. Unlike most other synovial joints, it is lined by fibrous tissue rather than hyaline cartilage, reflecting its intramembranous development. The non-articular area sometimes contains part of the parotid gland. A small, conical postglenoid tubercle separates the articular surface laterally from the tympanic plate.

Posteriorly, the mandibular fossa is separated from the tympanic part by the squamotympanic fissure. Rarely, a postglenoid foramen exists anterior to the external acoustic meatus in the line of fusion of the squamous and tympanic parts. When present, it replaces the squamosal foramen noted above and transmits the petrosquamous sinus. Medially, a projection from the petrous part of the temporal bone (tegmen tympani) comes to lie within the squamotympanic fissure, further dividing it into petrotympanic and petrosquamous fissures. The petrotympanic fissure leads into the tympanic cavity and contains an anterior malleolar ligament and the anterior tympanic branch of the maxillary artery. The anterior opening of the anterior canaliculus for the chorda tympani nerve lies at the medial end of the fissure.

## Petromastoid part

The petromastoid part of the temporal bone, although morphologically one element, is more conveniently described as two parts, namely: mastoid and petrous parts.

## Mastoid part

The mastoid part is the posterior region of the temporal bone and has an outer surface roughened by the attachments of the occipital belly of occipitofrontalis and auricularis posterior. A mastoid foramen, of variable size and position, and traversed by a vein from the sigmoid sinus and a small dural branch of the occipital artery, frequently lies near its posterior border. The foramen may be in the occipital or occipitotemporal suture; it may sometimes be parasutural or may be absent.

The mastoid part projects down as the conical mastoid process and is larger in adult males. Sternocleidomastoid, splenius capitis and longissimus capitis are all attached to its lateral surface, and the posterior belly of digastric is attached to a deep mastoid notch on its medial aspect. The occipital artery runs in a shallow occipital groove that lies medial to the mastoid notch. The internal surface of the mastoid process bears a deep, curved sigmoid sulcus for the sigmoid venous sinus; the sulcus is separated from the underlying innermost mastoid air cells by a thin lamina of bone.

A

Fig. 37.1 The left temporal bone. A, Lateral aspect. B, Medial aspect. C, Inferior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The superior border of the mastoid part is thick and serrated for articulation with the mastoid angle of the parietal bone. The posterior border is also serrated and articulates with the inferior border of the occipital bone between its lateral angle and jugular process. The mastoid element is fused with the descending process of the squamous part; below, it appears in the posterior wall of the tympanic cavity.

## Petrous part

The petrous part is a mass of bone that is wedged between the sphenoid and occipital bones in the cranial base; it contains the labyrinth. It is inclined superiorly and anteromedially, and has a base, apex, three surfaces (anterior, posterior and inferior) and three borders (superior, posterior and anterior).

The base would correspond to the part that lies on the base of the skull and is separated from the squamous part by a suture. However, this suture disappears soon after birth. The subsequent development of the mastoid processes means that the precise boundaries of the base are no longer identifiable.

The apex, blunt and irregular, is angled between the posterior border of the greater wing of the sphenoid and the basilar part of the occipital bone. It contains the anterior opening of the carotid canal and limits the foramen lacerum posterolaterally.

The anterior surface contributes to the floor of the middle cranial fossa (Ch. 28) and is continuous with the cerebral surface of the squamous part (although the petrosquamosal suture often persists late in life). The whole surface is adapted to the inferior temporal gyrus Behind the apex is a trigeminal impression for the trigeminal ganglion. Bone anterolateral to this impression roofs the anterior part of the carotid canal but is often deficient. A ridge separates the trigeminal impression from another hollow behind, which partly roofs the internal acoustic meatus and cochlea. This, in turn, is limited behind by the arcuate eminence, which is raised by the superior (anterior) semicircular canal but is not necessarily directly over it. Laterally, the anterior surface roofs the vestibule and, partly, the facial canal. Between the squamous part laterally and the arcuate eminence and the hollows just described medially, the anterior surface is formed by the tegmen tympani, a thin plate of bone that forms the roof of the mastoid antrum, and extends forwards above the tympanic cavity and the canal for tensor tympani. The lateral margin of the tegmen tympani meets the squamous part at the petrosquamosal suture, turning down in front as the lateral wall of the canal for tensor tympani and the osseous part of the pharyngotympanic tube; its lower edge is in the squamotympanic fissure. Anteriorly, the tegmen bears a narrow groove related to the greater petrosal nerve (which passes posterolaterally to enter the bone by a hiatus anterior to the arcuate eminence). The groove passes forwards to the foramen lacerum. A smaller and similar hiatus and groove may be found more laterally; they are related to the lesser petrosal nerve (which runs to the foramen ovale). The posterior slope of the arcuate eminence overlies the posterior and lateral semicircular canals. Lateral to the eminence, the posterior part of the tegmen tympani roofs the mastoid antrum.

The posterior surface contributes to the anterior part of the posterior cranial fossa and is continuous with the internal surface of the mastoid part. The opening of the internal acoustic meatus lies near its centre. A small slit leading to the vestibular aqueduct lies behind the opening of the meatus, almost hidden by a thin plate of bone. This contains the saccus and ductus endolymphaticus, together with a small artery and vein. The terminal half of the saccus endolymphaticus protrudes through the slit between the periosteum and dura mater. The subarcuate fossa lies above these openings.

The irregular inferior surface is part of the exterior of the cranial base. Near the apex of the petrous part, a quadrilateral area is partly associated with the attachment of levator veli palatini and the cartilaginous pharyngotympanic tube, and partly connected to the basilar part of the occipital bone by dense fibrocartilage. Behind this region is the large, circular opening of the carotid canal, and behind the opening of the canal is the jugular fossa, which is of variable depth and size, and contains the superior jugular bulb. The inferior ganglion of the glossopharyngeal nerve lies in a triangular depression anteromedial to the jugular fossa (below the internal acoustic meatus). At its apex is a small opening into the cochlear canaliculus, occupied by the perilymphatic duct (a tube of dura mater) and a vein draining from the cochlea to the internal jugular vein. A canaliculus for the tympanic nerve from the glossopharyngeal nerve lies on the ridge between the carotid canal and the jugular fossa. The mastoid canaliculus for the auricular branch of the vagus nerve is laterally positioned in the jugular fossa. Behind the jugular fossa, the rough quadrilateral jugular surface is covered by cartilage that joins it to the jugular process of the occipital bone.

The superior border, the longest, is grooved by the superior petrosal sinus. The attached margin of the tentorium cerebelli is fixed to the edges of the groove except at its medial end, where it is crossed by the roots of the trigeminal nerve. The posterior border, intermediate in length, bears a sulcus medially, which forms, together with the occipital bone, a gutter for the inferior petrosal sinus. Behind this, the jugular fossa contributes (together with the occipital bone) to the jugular foramen and is notched by the glossopharyngeal nerve. Bone on either or both sides of the jugular notch may meet the occipital bone and divide the jugular foramen into two or three parts. The anterior border is joined laterally to the squamous part of the temporal bone at the petrosquamosal suture; medially, it articulates with the greater wing of the sphenoid bone.

Two canals exist at the junction of the petrous and squamous parts, one above the other, separated by a thin osseous plate and both leading to the tympanic cavity; the upper canal contains tensor tympani, while the lower canal is the pharyngotympanic tube.

## Tympanic part

The tympanic part of the temporal bone is a curved plate below the squamous part and anterior to the mastoid process. Internally, it fuses with the petrous part and appears between this and the squamous part, where it is inferolateral to the auditory orifice. Behind, it fuses with the squamous part and mastoid process, and is the anterior limit of the tympanomastoid fissure. Its concave posterior surface forms the anterior wall, floor and part of the posterior wall of the external acoustic meatus. The tympanic membrane is attached to a narrow tympanic sulcus on its medial surface. The quadrilateral concave anterior surface is the posterior wall of the mandibular fossa and may contact the parotid gland. Its rough lateral border forms most of the margin of the osseous part of the external acoustic meatus and is continuous with its cartilaginous part. Laterally, the upper border is fused with the back of the postglenoid tubercle; medially, it forms the posterior edge of the petrotympanic fissure. The inferior border is sharp and splits laterally to form, at its root, the sheath of the styloid process (vaginal process). Centrally, the tympanic part is thin and is often perforated. The stylomastoid foramen lies between the styloid and mastoid processes; it represents the external end of the facial canal, contains part of the aponeurosis of the posterior belly of digastric, and transmits the facial nerve and stylomastoid artery.

## Styloid process

The styloid process is slender and pointed, and projects anteroinferiorly from the inferior aspect of the temporal bone. Its length varies, ranging from a few millimetres to an average of 2.5 cm . Often almost straight, it can show a curvature, an anteromedial concavity being most common. Its proximal part (tympanohyal) is ensheathed by the tympanic plate, especially anterolaterally, while muscles and ligaments are attached to its distal part (stylohyal). In vivo, its relationships are important. The styloid process is covered laterally by the parotid gland; the facial nerve crosses its base; the external carotid artery crosses its tip, embedded in the parotid; and medially, the process is separated from the beginning of the internal jugular vein by the attachment of stylopharyngeus.

## External acoustic meatus

The temporal bone contains the bony (osseous) part of the external acoustic meatus.

## Ossification

The four temporal components ossify independently (Fig. 37.2). The squamous part is ossified in a sheet of condensed mesenchyme from a single centre near the zygomatic roots, which appears in the seventh or eighth week in utero. The petromastoid part has several centres that appear in the cartilaginous otic capsule during the fifth month; as many as 14 have been described. These centres vary in order of appearance. Several are small and inconstant, soon fusing with others. The otic capsule is almost fully ossified by the end of the sixth month. The tympanic part is also ossified in mesenchyme from a centre identifiable about the third month; at birth, it is an incomplete tympanic ring, deficient above, its concavity grooved by a tympanic sulcus for the tympanic membrane. The malleolar sulcus for the anterior malleolar process, chorda tympani and anterior tympanic artery inclines obliquely downwards and forwards across the medial aspect of the anterior part

Fig. 37.2 The left temporal bone at birth. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
of the ring. The styloid process develops from two centres at the cranial end of cartilage in the second visceral or hyoid arch; a proximal centre for the tympanohyal appears before birth, and another, for the distal stylohyal, appears after birth. The tympanic ring unites with the squamous part shortly before birth, and the petromastoid fuses with it and the tympanohyal during the first year. The stylohyal does not unite with the rest of the process until after puberty and may never do so.

Once ossified, the tympanic cavity, mastoid antrum and the posterior end of the pharyngotympanic tube become surrounded by bone. The petrous part forms the roof, floor and medial wall of the cavity, while the squamous and tympanic parts, together with the tympanic membrane, form its lateral wall. At birth, the middle and inner ears are adult size, and the tympanic cavity, mastoid antrum, tympanic membrane and auditory ossicles are all almost adult size. The anterior process does not join the malleus until 6 months later. The internal acoustic meatus is approximately 6 mm in horizontal diameter, 4 mm in vertical diameter and 7 mm in length at birth, and the adult diameters are 7.7 mm and 11 mm , respectively.

After birth and apart from general growth, the tympanic ring extends posterolaterally to become cylindrical, growing into a fibrocartilaginous tympanic plate, which forms the adjacent part of the external acoustic meatus at this stage. This growth is not equal but is rapid in the anterior and posterior regions, which meet and blend. Thus, for a time, an opening (foramen of Huschke) exists in the floor; it usually closes at about the fifth year but is sometimes permanent. The external acoustic meatus is relatively as long in children as it is in adults, but the canal is fibrocartilaginous, whereas its medial two-thirds are osseous in adults. Surgical access to the tympanic cavity is via the mastoid antrum, and in children it is necessary to remove only a thin scale of bone in the suprameatal triangle to reach the antrum. The tympanic plate ensheathes the styloid process by posterior extension, and extends medially over the petrous bone to the carotid canal.

Initially, the mandibular fossa is shallow, facing more laterally, but it then deepens and ultimately faces downwards. Posteroinferiorly, the squamous part grows down behind the tympanic ring to form the lateral wall of the mastoid antrum. The mastoid part is at first flat, so that the stylomastoid foramen and rudimentary styloid process are immediately behind the tympanic ring. The mastoid part becomes invaded by air cells, especially at puberty. The lateral mastoid region grows downwards and forwards to form the mastoid process, which means that the styloid process and stylomastoid foramen become inferior. Descent of the foramen lengthens the facial canal. The mastoid process is not perceptible until late in the second year; consequently, the facial nerve is relatively superficial and susceptible to damage during surgical exploration during this period. The subarcuate fossa gradually fills and is almost obliterated.

In the neonate, the petrous and squamous parts of the temporal bone are usually partially separated by the petrosquamous fissure, which opens directly into the mastoid antrum of the middle ear. Rarely, the fissure closes in infants during the first year but it sometimes remains unclosed up to the age of 19 years; it is a route for the spread of infection from the middle ear to the meninges. There is a bimodal growth pattern in the lateral surface dimensions of the temporal bone in children; marked increases in dimension occur from birth to the age of 4 years but little growth is seen between the ages of 4 and 20 years (Simms and Neely 1989). The neonatal internal acoustic meatus is about half the length of its adult counterpart. Its opening from the

Fig. 37.3 The lateral surface of the left auricle. Key: 1, helix; 2, crus of helix; 3, auricular tubercle; 4 antihelix; 5 , crura of antihelix; 6, triangular fossa; 7, scaphoid fossa; 8, concha of auricle; 9 , external acoustic meatus; 10, tragus; 11, antitragus; 12, intertragic notch; 13, lobule of auricle. (With permission from Berkovitz BKB, Moxham BJ 2002 Head and Neck Anatomy. London: Martin Dunitz.)
middle ear cavity is as large as it is in the adult but the pharyngeal opening in the nasal part of the pharynx is relatively smaller. The course of the pharyngotympanic tube is horizontal in the newborn, whereas in the adult it passes from the middle ear downwards, forwards and medially.

## EXTERNAL EAR

The external ear consists of the auricle, or pinna, and the external acoustic meatus. The auricle projects to a variable and individual degree from the side of the head. It collects sound waves and conducts them along the external acoustic meatus inwards towards the ear drum, the tympanic membrane. The auricle thus acts as the first element of a series of stimulus modifiers in the auditory apparatus.

## AURICLE (PINNA)

The lateral surface of the auricle is irregularly concave, faces slightly forwards, and displays numerous eminences and depressions (Fig. 37.3). It has a prominent curved rim, the helix. This usually bears a small tubercle posterosuperiorly, Darwin's tubercle, which is quite pronounced around the sixth month of intrauterine life. The antihelix is a curved prominence, parallel and anterior to the posterior part of the helix; it divides above into two crura, which flank a depressed triangular fossa. The curved depression between the helix and antihelix is the scaphoid fossa. The antihelix encircles the deep, capacious concha of the auricle, which is incompletely divided by the crus or anterior end of the helix. The conchal area above this, the cymba conchae, overlies the suprameatal triangle of the temporal bone, which can be felt through it, and which overlies the mastoid antrum. The tragus is a small curved flap below the crus of the helix and in front of the concha; it projects posteriorly, partly overlapping the meatal orifice. The antitragus is a small tubercle opposite the tragus and is separated from it by the intertragic incisure or notch. Below it is the lobule, composed of fibrous and adipose tissues. It is soft, unlike the majority of the auricle, which is supported by elastic cartilage and is firm. The cranial surface of the auricle presents elevations that correspond to the depressions on its lateral surface and after which they are named (e.g. eminentia conchae, eminentia fossae triangularis).

At birth, most of the linear dimensions of the auricle are approximately three-quarters of their adult size; the length and height of the tragus are less than half of their adult size. Width dimensions mature between the ages of 5 and 11 years; length dimensions mature between 12 and 16 years (Purkait 2013).

## Common congenital anomalies

Developmental anomalies of the branchial arches may produce a grossly misshapen or microtic auricle, sometimes with associated anomalies of the middle ear and significant hearing loss. Deformity of the pinna may be the result of hereditary factors, exposure to teratogens
or unusual intrauterine positioning. A number of common anomalies have been recognized; they carry descriptive names or eponyms (Porter and Tan 2005) (Table 37.1).

## Skin

The skin of the auricle continues into the external acoustic meatus to cover the outer surface of the tympanic membrane. It is thin, has no dermal papillae, and is closely adherent to the cartilaginous and osseous parts of the canal; inflammation of the canal skin is very painful because of this attachment to the underlying structures. The thick subcutaneous tissue of the cartilaginous part of the meatus contains numerous ceruminous glands that secrete wax, or cerumen. Their coiled tubular structure resembles that of sweat glands. The secretory cells are columnar when active but cuboidal when quiescent; they are covered externally by myoepithelial cells. Ducts open either on to the epithelial surface or into the nearby sebaceous gland of a hair follicle. Cerumen prevents the maceration of meatal skin by trapped water. Antibacterial properties have been attributed to cerumen but the evidence for this is lacking (Campos et al 2000, Pata et al 2003).

Two types of wax - wet and dry - are recognized. They are genetically determined. Dry wax is common in East Asians, while the wet type is more common in other ethnic groups (Yoshiura et al 2006). Overproduction, accumulation or impaction of wax may completely occlude the meatus. This may hinder sound from reaching the tympanic membrane and so restrict its natural vibration. Although ceruminous glands and hair follicles are largely limited to the cartilaginous meatus, a few small glands and fine hairs are also present in the roof of the lateral part of the bony meatus. The warm, humid environment of the relatively enclosed meatal air aids the mechanical responses of the tympanic membrane.

## Cartilaginous framework

The auricle is a single thin plate of elastic fibrocartilage covered by skin, its surface moulded by eminences and depressions (Fig. 37.4). It is connected to the surrounding parts by ligaments and muscles, and is continuous with the cartilage of the external acoustic meatus. There

Fig. 37.4 The auricular cartilages of the left ear. A, Lateral surface
B, Medial surface.
is no cartilage in the lobule or between the tragus and the crus of the helix, where the gap is filled by dense fibrous tissue. Anteriorly, where the helix curves upwards, there is a small cartilaginous projection: the spine of the helix. Its other extremity is prolonged inferiorly as the tail of the helix and it is separated from the antihelix by the fissura antitragohelicina (antitragohelicine fissure). The cranial aspect of the cartilage bears the eminentia conchae and eminentia scaphae, which correspond to the depressions on the lateral surface. The two eminences are separated by a transverse furrow, the sulcus antihelicis transversus, which corresponds to the inferior crus of the antihelix on the lateral surface. The eminentia conchae is crossed by an oblique ridge, the ponticulus, for the attachment of auricularis posterior. There are two fissures in the auricular cartilage, one behind the crus of the helix and another in the tragus.

## Ligaments

Anterior and posterior extrinsic ligaments connect the auricle with the temporal bone. The anterior ligament extends from the tragus and the spine of the helix to the root of the zygomatic process of the temporal bone. The posterior ligament passes from the posterior surface of the concha to the lateral surface of the mastoid process. Two main intrinsic ligaments connect individual auricular cartilages: a strong fibrous band passes from the tragus to the helix, thereby completing the meatus anteriorly and forming part of the boundary of the concha; and another band passes between the antihelix and the tail of the helix. Less prominent bands exist on the cranial aspect of the auricle.

## Auricular muscles

Extrinsic auricular muscles connect the auricle to the skull and scalp, and move the auricle as a whole. Intrinsic auricular muscles connect the different parts of the auricle.

## Extrinsic muscles

The extrinsic auricular muscles are the auriculares anterior, superior and posterior (Fig. 37.5B). The smallest of the three is auricularis anterior, a thin fan of pale fibres that arise from the lateral edge of the epicranial aponeurosis and converge to attach to the spine of the helix. The largest of the three, auricularis superior, is also thin and fan-shaped, and converges from the epicranial aponeurosis via a thin, flat tendon to attach to the upper part of the cranial surface of the auricle. The auricularis posterior consists of two or three fleshy fasciculi that arise by short aponeurotic fibres from the mastoid part of the temporal bone and insert into the ponticulus on the eminentia conchae.

Vascular supply The arterial supply of the extrinsic auricular muscles is derived mainly from the posterior auricular artery.

Innervation Auriculares anterior and superior are supplied by temporal branches of the facial nerve, and auricularis posterior is supplied by the posterior auricular branch of the facial nerve.

Actions In humans, these muscles have very little obvious effect. Despite the paucity of auricular movement, auditory stimuli may evoke patterned responses from these small muscles and electromyography can detect the 'crossed acoustic response' that can be used to determine auditory threshold levels and brainstem latencies, which is elicited by this means in investigative clinical neurotology.

## Intrinsic muscles

The intrinsic auricular muscles are helicis major and minor, tragicus, antitragicus, transversus auriculae and obliquus auriculae (Fig. 37.5A). Helicis major is a narrow vertical band on the anterior margin of the helix, passing from its spine to its anterior border, where the helix is about to curve back. Helicis minor is an oblique fasciculus covering the crus of the helix. Tragicus is a short, flattened, vertical band on the lateral aspect of the tragus. Antitragicus passes from the outer part of the antitragus to the tail of the helix and the antihelix. Transversus auriculae, located on the cranial aspect of the auricle, consists of scattered fibres - partly tendinous, partly muscular, which extend between the eminentia conchae and the eminentia scaphae. Obliquus auriculae, also located on the cranial aspect of the auricle, consists of a few fibres that extend from the upper and posterior parts of the eminentia conchae to the eminentia scaphae.

Vascular supply The intrinsic auricular muscles are supplied by branches of the posterior auricular and superficial temporal arteries.

Fig. 37.5 Extrinsic and intrinsic auricular muscles of the left ear. Auricularis anterior is not illustrated. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Innervation The intrinsic auricular muscles on the lateral aspect of the auricle are innervated by the temporal branches of the facial nerve, and those on the cranial aspect of the auricle are innervated by the posterior auricular branch of the facial nerve.

Actions The intrinsic muscles modify auricular shape minimally, if at all, in most human ears: helicis major can draw the auricle forwards and upwards. Rare individuals can modify the shape and position of their external ears.

## Vascular supply and lymphatic drainage

Arteries The posterior auricular branch of the external carotid artery is the dominant blood supply (Imanishi et al 1997). It supplies three or four branches to the cranial surface of the auricle; twigs from these arteries reach the lateral surface - some through fissures in the cartilage, others round the margin of the helix. The posterior auricular artery ascends between the parotid gland and the styloid process to the groove between the auricular cartilage and mastoid process. The superior auricular artery has a constant course and connects the superior temporal artery and the posterior auricular arterial network; this branch can provide a reliable vascular pedicle for retro-auricular flaps (Moschella et al 2003). The auricle is also supplied by anterior auricular branches of the superficial temporal artery, which are distributed to its lateral surface, and by a branch from the occipital artery.

Veins Auricular veins correspond to the arteries of the auricle. Arteriovenous anastomoses are numerous in the skin of the auricle and are thought to be important in the regulation of core temperature.

Lymphatic drainage The posterior aspect of the pinna drains to nodes at the mastoid tip. The tragus and upper part of the pinna drain
into pre-auricular nodes, while the remainder of the pinna drains to upper deep cervical lymph nodes.

## Innervation

The sensory innervation of the auricle is complex and not fully determined. This is perhaps because the external ear represents an area where skin originally derived from a branchial region meets skin originally derived from a postbranchial region. The sensory nerves involved are the great auricular nerve, which supplies most of the cranial surface and the posterior part of the lateral surface (helix, antihelix, lobule); the lesser occipital nerve, which supplies the upper part of the cranial surface; the auricular branch of the vagus, which supplies the concavity of the concha and posterior part of the eminentia; the auriculotemporal nerve, which supplies the tragus, crus of the helix and the adjacent part of the helix; and the facial nerve, which, together with the auricular branch of the vagus, probably supplies small areas on both aspects of the auricle, in the depression of the concha and over its eminence. The details of the cutaneous innervation derived from the facial nerve require further clarification. It is possible that, as the auricular branch of the vagus traverses the temporal bone and crosses the facial canal, approximately 4 mm above the stylomastoid foramen, it contributes an ascending branch to the facial nerve and that, in this way, fibres of the vagus are carried via the facial nerve to the pinna.

## EXTERNAL ACOUSTIC MEATUS

The external acoustic meatus extends from the concha to the tympanic membrane; it is approximately 2.5 cm from the floor of the concha and approximately 4 cm from the tragus. It has two structurally different parts: its lateral third is cartilaginous and its medial two-thirds is osseous (Figs 37.6-37.8). It forms an S-shaped curve, directed at first medially, anteriorly and slightly up (pars externa), then posteromedially and up (pars media), and lastly anteromedially and slightly down (pars interna). It is oval in section; its greatest diameter is obliquely inclined posteroinferiorly at the external orifice but is nearly horizontal at its medial end. There are two constrictions: one near the medial end of the cartilaginous part, and the other, the isthmus, in the osseous part about 2 cm from the bottom of the concha. The tympanic membrane, which closes its medial end, is obliquely set, which means that the floor and the anterior wall of the meatus are longer than its roof and posterior wall.

The lateral, cartilaginous part is approximately 8 mm long. It is continuous with the auricular cartilage and attached by fibrous tissue to the circumference of the osseous part. The meatal cartilage is deficient posterosuperiorly, and the gap is occupied by a sheet of collagen. Two or three deep fissures (of Santorini) exist in its anterior part. Tumours of the external acoustic meatus escape the confines of the canal through these fissures and spread into the adjacent soft tissues; the extent of these fissures, which are subject to individual variation, must influence outcomes.

The osseous part is approximately 16 mm long and is narrower than the cartilaginous part. In sagittal section, it is oval or elliptical, and it is directed anteromedially and slightly downwards, with a slight posterosuperior convexity. Its medial end is smaller than the lateral end and it terminates obliquely. The anterior wall projects medially approximately 4 mm beyond the posterior and is marked, except above, by a narrow tympanic sulcus or anulus, to which the perimeter of the tympanic membrane is attached. Its lateral end is dilated and mostly rough for the attachment of the meatal cartilage. The anterior, inferior, and most of the posterior parts of the osseous meatus are formed by the tympanic plate of the temporal bone, which in the fetus is only a tympanic ring. The posterosuperior region is formed by the squamous part of the temporal bone. The outer wall of the meatus is bounded above by the posterior zygomatic root, below which there may be a suprameatal spine.

Relations of the meatus The condylar process of the mandible lies anterior to the meatus and is partially separated from the cartilaginous part by a small portion of the parotid gland. A blow on the chin may cause the condyle to break into the meatus. The middle cranial fossa lies above the osseous meatus and the mastoid air cells are posterior to it, separated from the meatus only by a thin layer of bone. Its deepest part is situated below the epitympanic recess and is anteroinferior to the mastoid antrum; the lamina of bone that separates it from the antrum is only $1-2 \mathrm{~mm}$ thick and provides the 'transmeatal approach' of aural surgery.

Vasculature and lymphatic drainage The arterial supply of the external acoustic meatus is derived from the posterior auricular artery, the deep auricular branch of the maxillary artery and the auricular branches of the superficial temporal artery. Associated veins drain into the external jugular and maxillary veins and the pterygoid plexus. The lymphatics drain into those associated with the pinna.
Innervation The sensory innervation of the external acoustic meatus is derived from the auriculotemporal branch of the mandibular nerve (see Fig. 32.23), which supplies the anterior and superior walls, and the auricular branch of the vagus, which supplies the posterior and inferior walls. The facial nerve may also contribute via its communication with the vagus nerve.

## EXTERNAL SURGICAL APPROACHES TO THE MIDDLE EAR

Surgical access to the middle ear can be achieved by a number of methods. Provided the external acoustic meatus is wide enough, the tympanic membrane can be elevated by incising the skin of the bony meatus circumferentially, leaving a vascular pedicle superiorly. The canal skin is then elevated from the underlying bone until the fibrous anulus of the tympanic membrane is visualized. This can then be elevated from the tympanic groove and the middle ear mucosa can be incised to allow the tympanic membrane to be reflected forwards and upwards. This per-meatal approach is called a tympanotomy and is used

Fig. 37.7 The left auditory apparatus as if viewed through a semi-transparent temporal bone. Note the first genu in the facial nerve at the site of the geniculate ganglion.

Fig. 37.8 A bone-windowed, coronal computed tomography (CT) scan of the external ear canal and middle ear showing the curvature of the floor and roof, and the obliquity of the tympanic membrane (arrow) at the medial end of the external acoustic meatus. (Courtesy of Dr Steven Connor.)
for stapedectomy, ossiculoplasty, myringoplasty and the removal of small middle-ear tumours.

If the external acoustic meatus is too narrow to allow adequate visualization of the middle ear, or if access is required to the mastoid aditus and antrum, it is necessary to displace the superficial soft tissues. There are two main external approaches to the middle ear: the endaural approach and the postauricular approach.

The endaural approach involves making an incision in the notch between the tragus and the helix. This is carried down to expose the lower margin of temporalis muscle and the bone of the external acoustic meatus. The cartilaginous meatus is separated from the bony meatus and reflected laterally as a conchomeatal flap. The bony meatus can then be widened by drilling away bone (canalplasty). This gives more space to manipulate the delicate structures of the middle ear, as well as improving subsequent visualization of the tympanic membrane when the incision has healed.

The postauricular approach involves making an incision approximately 1 cm behind the postauricular skin crease and deepening the incision to the periosteum of the mastoid process, dividing the posterior auricular muscles on the way. Grafts can be harvested from the temporalis fascia. The periosteum is incised and elevated to expose the bony external acoustic meatus from behind. The skin over the junction of the bony and cartilaginous meatus is incised to allow the cartilage of the auricle and meatus to be swung forwards on its blood supply and so expose the bony meatus and mastoid process. Access can then be gained by drilling and elevating a tympanomeatal skin flap, as described for the endaural approach.

Temporalis fascia is the most popular tissue used as a free graft for repair of the tympanic membrane because it is easily obtainable. In recent years, tragal perichondrium has become a popular alternative; it has the additional advantage that the cartilage can also be harvested and used to reinforce the repair.

More extensive resections of the temporal bone are undertaken using extended pre- or postauricular incisions into the temporal region and neck. The blood supply of the pinna is sufficient to maintain viability despite significant elevation and undermining.

## MIDDLE EAR

The middle ear is an irregular, laterally compressed space in the petrous part of the temporal bone. It is lined with mucous membrane and filled with air, which reaches it from the nasopharynx via the pharyngotympanic tube (see Figs 37.6-37.7; Fig. 37.9). The middle ear contains three small bones - the malleus, incus and stapes, collectively called the auditory ossicles - which form an articulated chain connecting the lateral and medial walls of the cavity, and which transmit the vibrations of the tympanic membrane across the cavity to the cochlea.

The essential function of the middle ear is to transfer energy efficiently from relatively weak vibrations in the elastic, compressible air in the external acoustic meatus to the incompressible fluid around the delicate receptors in the cochlea. Mechanical coupling between the two systems must match their resistance to deformation or 'flow', i.e. their impedance, as closely as possible. Aerial waves of low amplitude and low force per unit area arrive at the tympanic membrane, which has

Continued online

15-20 times the area of the stapedial footplate that contacts the perilymph in the inner ear; the force per unit area generated by the footplate is increased by a similar amount, while the amplitude of vibration is almost unchanged.

Protective mechanisms incorporated into the design of the middle ear include the presence of the pharyngotympanic tube (to equalize pressure on both sides of the delicate tympanic membrane); the shape of the articulations between the ossicles; and the reflex contractions of stapedius and tensor tympani in response to sounds of fairly high intensity (preventing damage caused by sudden or excessive excursions of the ossicles).

The space within the middle ear can be subdivided into three parts. These are the mesotympanum or tympanic cavity proper, which is opposite the tympanic membrane; the epitympanum or attic, which is above the level of the membrane, and contains the head of the malleus and the body and short process of the incus; and the hypotympanum, which is in the floor of the cavity between the jugular bulb and the lower margin of the tympanic membrane. The vertical and anteroposterior diameters of the mesotympanum and hypotympanum are each approximately 15 mm ; the transverse diameter is 6 mm superiorly and 4 mm inferiorly, narrowing to 2 mm opposite the umbo. The cavity is
bounded laterally by the tympanic membrane and medially by the lateral wall of the internal ear, the promontory. It communicates posteriorly with the mastoid antrum and the mastoid air cells, and anteriorly with the nasopharynx via the pharyngotympanic tube (see Figs 37.6-37.7).

The tympanic cavity and mastoid antrum, auditory ossicles and structures of the internal ear are all almost fully developed at birth and subsequently alter little; almost all of the volume changes are due to expansion of the epitympanic space (Osborn et al 2011). In the fetus, the cavity contains a gelatinous tissue that has practically disappeared by birth, when it is filled by a fluid that is absorbed when air enters via the pharyngotympanic tube. The tympanic cavity is a common site of infection in childhood.

## BOUNDARIES OF THE TYMPANIC CAVITY

The tympanic cavity has a roof, a floor and lateral, medial, posterior and anterior walls.

## Roof

A thin plate of compact bone, the tegmen tympani, separates the cranial and tympanic cavities, and forms much of the anterior surface of the petrous temporal bone. It is prolonged posteriorly as the roof of the mastoid antrum and anteriorly it covers the canal for tensor tympani. In youth, the unossified petrosquamosal suture may allow the spread of infection from the tympanic cavity to the meninges. In adults, veins from the tympanic cavity traverse this suture to reach the superior petrosal or petrosquamous sinus and thus may also transmit infection to these structures through a process of thrombophlebitis.

Longitudinal fractures of the middle cranial fossa almost always involve the tympanic roof, accompanied by dislocation of the ossicular chain, rupture of the tympanic membrane, or a fractured roof of the osseous external acoustic meatus, which can be seen as a notch on otoscopy. Such injuries usually cause bleeding from the ear, with escape of cerebrospinal fluid if the dura mater has been torn (CSF otorrhoea).

## Floor

The floor of the tympanic cavity is a narrow, thin, convex plate of bone that separates the cavity from the superior bulb of the internal jugular vein. The bone may be patchily deficient, in which case the tympanic cavity and the vein are separated only by mucous membrane and fibrous tissue. Alternatively, the floor is sometimes thick and may contain some accessory mastoid air cells. A small aperture for the tympanic branch of the glossopharyngeal nerve lies near the medial wall.

## Lateral wall

The lateral wall consists mainly of the tympanic membrane but also contains the ring of bone to which the membrane is attached (see Fig. 37.15 A ). The lateral epitympanic bony wall is wedge-shaped in section and its sharp inferior portion is known as the outer attic wall or scutum. This part is easily eroded or blunted by cholesteatoma, a feature easily detected on computed tomography (CT) scans (see Fig. 37.8). There is a deficiency or notch in the upper part of this ring, close to which are the small openings of the anterior and posterior canaliculi for the chorda tympani and the petrotympanic fissure. The posterior canaliculus for the chorda tympani is situated in the angle between the posterior and lateral walls of the tympanic cavity just behind the tympanic membrane, at a variable position approximately level with the upper end of the handle of the malleus. This variable position or entrance into the tympanic cavity should be kept in mind when mobilizing the chorda tympani in stapes surgery. It may not reflect inferiorly to the extent desired and can be easily damaged in the process. Within the mastoid, the chorda tympani passes into a minute canal that descends in front of the facial canal and ends in it about 6 mm above the stylomastoid foramen. This canal and the chorda tympani should not be mistaken for the main trunk of the facial nerve when skeletonizing the Fallopian canal during surgery. The canaliculus transmits the chorda tympani and a branch of the stylomastoid artery to the tympanic cavity. The chorda tympani leaves the tympanic cavity through the anterior canaliculus, which opens at the medial end of the petrotympanic fissure.

The petrotympanic fissure is a mere slit approximately 2 mm in length, which opens just above and in front of the ring of bone to which

Fig. 37.10 An auroscopic view of the left tympanic membrane. Note that a bright cone of light is seen in the anteroinferior quadrant of the membrane when it is illuminated. (Courtesy of Mr Simon A Hickey.)
the tympanic membrane is attached. It contains the anterior process and anterior ligament of the malleus, and transmits the anterior tympanic branch of the maxillary artery to the tympanic cavity.

## Tympanic membrane

The tympanic membrane separates the tympanic cavity from the external acoustic meatus (Fig. 37.10; see Figs 37.6, 37.15). It is thin, semitransparent and almost oval, though somewhat broader above than below. It lies obliquely, at an angle of approximately $55^{\circ}$ with the meatal floor in adults. Its longest, anteroinferior diameter is $9-10 \mathrm{~mm}$, and its shortest is $8-9 \mathrm{~mm}$. Most of its circumference is a thickened fibrocartilaginous ring or anulus, which is attached to the tympanic sulcus at the medial end of the meatus. The anulus contains radially orientated smooth muscle cells in several locations that possibly play a role in controlling blood flow or maintaining tension (Henson et al 2005). The sulcus is deficient superiorly, i.e. it is notched. Two bands, the anterior and posterior malleolar folds, pass from the ends of this notch to the lateral process of the malleus. The small triangular part of the membrane, the pars flaccida, lies above these folds and is lax and thin. The major part of the tympanic membrane, the pars tensa, is taut. The handle of the malleus is firmly attached to the internal surface of the tympanic membrane as far as its centre, which projects towards the tympanic cavity. The inner surface of the membrane is thus convex and the point of greatest convexity is termed the umbo. Although the membrane as a whole is convex on its inner surface, its radiating fibres are curved with their concavities directed inwards.

## Microstructure

Histologically, the tympanic membrane is composed of an outer cuticular layer, an intermediate fibrous layer and an inner mucous layer.

The cuticular stratum is continuous with the thin skin of the meatus. It is keratinized, stratified squamous in type, devoid of dermal papillae and hairless. Its subepithelial tissue is vascularized and may develop a few peripheral papillae. Ultrastructurally, it is typically 10 cells thick and has two zones: a superficial layer of non-nucleated squames, and a deep zone that resembles the epidermal prickle cell layer (stratum spinosum). There are numerous desmosomes between cells, the deepest of which lie on a continuous basal lamina, but lack epithelial pegs and hemidesmosomes. The cells of this stratum have a propensity for lateral migration and differentiation not shared with any other stratified squamous epithelia in the body.

The fibrous stratum consists of an external layer of radiating fibres that diverge from the handle of the malleus, and a deep layer of circular fibres, which are plentiful peripherally but sparse and scattered cen-
trally. Ultrastructurally, the filaments are 10 nm in diameter and are linked at 25 nm intervals. They have a distinctive amino acid composition, and may consist of a protein peculiar to the tympanic membrane. Small groups of collagen fibrils appear at 11 weeks in utero, interspersed with small bundles of elastin microfibrils. Older specimens contain more typically cross-banded collagen fibrils and an amorphous elastin component. The fibrous stratum is replaced by loose connective tissue in the pars flaccida.

The mucous stratum is a part of the mucosa of the tympanic cavity and is thickest near the upper part of the membrane. It consists of a single layer of very flat cells, with overlapping interdigitating boundaries and desmosomes and tight junctions between adjacent cells. The cytoplasm contains only a few organelles; the luminal surfaces of these apparently metabolically inert cells have a few irregular microvilli and are covered by an amorphous electron-dense material. There are no ciliated columnar cells.

## Innervation

The tympanic membrane is mainly innervated by the auriculotemporal nerve and appears to perceive only pain. There is a minor, inconstant and overlapping sensory supply from the facial, glossopharyngeal and vagus nerves.

The auricular branch of the vagus arises from the superior vagal ganglion and is joined soon after by a ramus from the inferior ganglion of the glossopharyngeal nerve. It passes behind the internal jugular vein and enters the mastoid canaliculus on the lateral wall of the jugular fossa. It traverses the temporal bone and crosses the facial canal about 4 mm above the stylomastoid foramen. At this point, it supplies an ascending branch to the facial nerve. Fibres of the nervus intermedius may pass to the auricular branch of the vagus here, which may explain the cutaneous vesiculation that sometimes accompanies geniculate herpes. The auricular branch then traverses the tympanomastoid fissure and divides into two rami. One ramus joins the posterior auricular nerve and the other is distributed to the skin of part of the cranial surface of the auricle, the posterior wall and floor of the external acoustic meatus, and to the adjoining part of the outer surface of the tympanic membrane. The auricular branch therefore contains somatic afferent nerve fibres, which probably terminate in the spinal trigeminal nucleus. Stimulation of the vagus nerve, e.g. in syringing the ear, can cause a reflex bradycardic reaction on heart rate. From a practical point of view, the tympanic membrane can be anaesthetized for minor procedures like myringotomy by the application of topical anaesthetic agents. For more complicated surgical procedures, e.g. tympanoplasty, it is possible to provide sufficient anaesthesia by local infiltration at the level of the bony and cartilaginous external acoustic meatus.

## Otitis media

It is assumed that acute otitis media usually arises as a result of ascending infection from the nasopharynx via the pharyngotympanic tube to the middle ear cleft. From there, it may extend to the mastoid aditus and antrum. Swelling secondary to the infection may result in the closure of both exits from the middle ear, i.e. the pharyngotympanic tube and the aditus, with subsequent accumulation of pus under pressure, which causes lateral bulging and inflammation of the tympanic membrane. The latter may burst, releasing mucopurulent discharge into the external acoustic meatus, which results in a release of the pressure in the middle ear and a diminution in the levels of pain. After a brief period, the discharge dries up and, for the most part, the resultant perforation of the tympanic membrane heals. Normal ventilation and drainage of mucus from the middle ear are restored once the swelling and function of the pharyngotympanic tube resolve. On occasion, the process will fail to produce a perforation of the tympanic membrane and the inflammatory exudates will not drain. The immune defence system sterilizes the exudates of organisms, resulting in a sterile mucoid effusion, otitis media with effusion or glue ear (see below). The effusion may cause protracted deafness because its relatively incompressible nature prevents free vibration of the tympanic membrane (Bluestone and Klein 2002).

## Myringoplasty

Persistent perforation of the tympanic membrane caused by infection or trauma leads to hearing impairment and predisposes to continuing infection as a result of contamination with organisms from the external acoustic meatus. This condition is known as chronic suppurative otitis media of the tubotympanic type. Myringoplasty is a surgical procedure that uses a connective tissue scaffold or graft to support healing of the perforation. The most common technique involves the elevation of the tympanic anulus and the placement of a piece of fibrous connective tissue, e.g. part of the fibrous deep fascia that invests the lateral surface of temporalis or the perichondrium of the tragal cartilage, on to the

B

undersurface of the tympanic membrane to close the perforation. The healed edges of the perforation are stripped of epithelium to encourage healing and scar formation. The fibrous tissue supports the healing tympanic membrane and may, in part, be incorporated into the repair. Once the perforation is healed, the vibratory function of the tympanic membrane is usually restored to normal.

## Medial wall

The medial wall of the tympanic cavity is also the lateral boundary of the internal ear. Its features are the promontory, fenestra vestibuli (fenestra ovalis, oval window), fenestra cochleae (fenestra rotunda, round window) and the facial prominence (Fig. 37.11).

The promontory is a rounded prominence furrowed by small grooves that lodge the nerves of the tympanic plexus. It lies over the lateral projection of the basal turn of the cochlea. A minute spicule of bone frequently connects the promontory to the pyramidal eminence of the posterior wall. The apex of the cochlea lies near the medial wall of the tympanic cavity, anterior to the promontory. A depression behind the promontory is known as the sinus tympani.

The fenestra vestibuli is a kidney-shaped opening situated above and behind the promontory, and leading from the tympanic cavity to the vestibule of the inner ear. Its long diameter is horizontal and its convex border is directed upwards. It is occupied by the base of the stapes, the footplate; the circumference of the footplate is attached to the margin of the fenestra by an anular ligament.

The fenestra cochleae is situated below and a little behind the fenestra vestibuli, from which it is separated by a posterior extension of the promontory, called the subiculum. Occasionally, another ridge

Fig. 37.11 The medial wall of the left tympanic cavity, anterolateral aspect. A, The lateral wall and adjacent parts of the anterior and superior walls have been removed; the facial canal and carotid canal have been opened. B, A section along the axis of the petrous part of the temporal bone. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
of bone, the ponticulus, leaves the promontory above the subiculum and runs to the pyramid on the posterior wall of the cavity. The fenestra cochleae lies completely under the overhanging edge of the promontory in a deep hollow or niche, and is placed very obliquely. In dried specimens, it opens anterosuperiorly from the tympanic cavity into the scala tympani of the cochlea, but in life it is closed by the secondary tympanic membrane. This is somewhat concave towards the tympanic cavity and convex towards the cochlea, and is bent so that its posterosuperior third forms an angle with its anteroinferior two-thirds. The membrane is composed of an external layer derived from the tympanic mucosa; an internal layer, derived from the cochlear lining membrane; and an intermediate, fibrous layer.

The prominence of the facial nerve canal indicates the position of the upper part of the bony facial canal (Fallopian canal), which contains the facial nerve. The canal crosses the medial tympanic wall from the cochleariform process anteriorly, runs just above the fenestra vestibuli, and then curves down into the posterior wall of the cavity. Its lateral wall may be partly deficient.

## Posterior wall

The posterior wall of the tympanic cavity is wider above than below. Its main features are the aditus to the mastoid antrum, the pyramid and the fossa incudis (see Fig. 37.11).

The aditus to the mastoid antrum is a large irregular aperture that leads back from the epitympanic recess into the upper part of the mastoid antrum. A rounded eminence on the medial wall of the aditus, above and behind the prominence of the facial nerve canal, corresponds to the position of the lateral semicircular canal.

The pyramidal eminence is situated just behind the fenestra vestibuli and in front of the vertical part of the facial nerve canal. It is hollow and contains the stapedius muscle. Its summit projects towards the fenestra vestibuli and is pierced by a small aperture that transits the tendon of stapedius. The cavity in the pyramidal eminence is prolonged down and back in front of the facial nerve canal; it communicates with the canal by an aperture through which a small branch of the facial nerve passes to stapedius.

The fossa incudis is a small depression in the lower and posterior part of the epitympanic recess. It contains the short process of the incus, which is fixed to the fossa by ligamentous fibres.

## Mastoid antrum

The mastoid antrum is an air sinus in the petrous part of the temporal bone. Its topographical relations are of considerable surgical importance. The aditus to the mastoid antrum, which leads back from the epitympanic recess, opens in the upper part of its anterior wall. The lateral semicircular canal lies medial to the aditus. The descending part of the facial nerve canal is anteroinferior. The medial wall is related to the posterior semicircular canal. The sigmoid sinus lies some distance posteriorly; the distance can be extremely variable and is dependent on the degree of pneumatization of the mastoid. The roof is formed by the tegmen tympani, and so the antrum lies below the middle cranial fossa and the temporal lobe of the brain. The floor has several openings that communicate with the mastoid air cells. The lateral wall, which offers the usual surgical approach to the cavity, is formed by the postmeatal process of the squamous part of the temporal bone. This is only 2 mm thick at birth but increases at an average rate of 1 mm a year, attaining a final thickness of $12-15 \mathrm{~mm}$. In adults, the lateral wall of the antrum corresponds to the suprameatal triangle (Macewen's triangle) on the outer surface of the skull. This is palpable through the cymba conchae. The superior side of the triangle, the supramastoid crest, is level with the floor of the middle cranial fossa; the anteroinferior side, which forms the posterosuperior margin of the external acoustic meatus, indicates approximately the position of the descending part of the facial nerve canal; and the posterior side, formed by a posterior vertical tangent to the posterior margin of the external acoustic meatus, is anterior to the sigmoid sinus.

The adult capacity of the mastoid antrum is variable, but on average is 1 ml , with a general diameter of 10 mm . Unlike the other air sinuses in the skull, it is present at birth, and indeed is then almost adult in size, although it is at a higher level relative to the external acoustic meatus than it is in adults. In the very young, the thinness of the lateral antral wall and the absence or underdevelopment of the mastoid process mean that the stylomastoid foramen and emerging facial nerve are very superficially situated.

## Mastoid air cells

Though the mastoid antrum is well developed at birth, the mastoid air cells are merely minute antral diverticula at this stage. As the mastoid develops in the second year, the air cells gradually extend into it and by the fourth year they are well formed, although their greatest growth occurs at puberty. They vary considerably in number, form and size. Usually, they interconnect and are lined by a mucosa with squamous non-ciliated epithelium, continuous with that in the mastoid antrum and tympanic cavity. They may fill the mastoid process, even to its tip, and some may be separated from the sigmoid sinus and posterior cranial fossa only by extremely thin bone, which is occasionally deficient (see Fig. 37.11). Some may lie superficial to, or even behind, the sigmoid sinus, and others may be present in the posterior wall of the descending part of the facial nerve canal. Those in the squamous part of the temporal bone may be separated from deeper cells in the petrous part by a plate of bone in the line of the squamomastoid suture (Körner's septum). Sometimes, they extend only minimally into the mastoid process, in which case the process consists largely of dense bone or trabecular bone containing bone marrow. Varieties of the mastoid process are recognized. The three types most commonly described are pneumatized (with many air cells); sclerotic or diploic (with few or no air cells); and mixed (contain both air cells and bone marrow).

The mastoid process may sometimes have no air cells at all. Alternatively, air cells may extend beyond the mastoid process into the squamous part of the temporal bone above the supramastoid crest; into the posterior root of the zygomatic process of the temporal bone; into the osseous roof of the external acoustic meatus just below the middle cranial fossa; or into the floor of the tympanic cavity very close to the superior jugular bulb. Rarely, a few may excavate the jugular process of the occipital bone. An important group may extend medially into the petrous part of the temporal bone, even to its apex, and are related to the pharyngotympanic tube, carotid canal, labyrinth and abducens
nerve. Some investigators maintain that these are not continuous with the mastoid cells but grow independently from the tympanic cavity. All of these extensions of the mastoid air cells are pathologically important since infection may spread to the structures around them. (For further reading on the mastoid air cells and other pneumatized regions of the temporal bone, see Allam (1969).)

Innervation The mastoid air cells are innervated by a meningeal branch of the mandibular division of the trigeminal nerve.

## Mastoiditis

Mastoiditis is a potentially dangerous, life-threatening condition that develops as a result of the spread of bacterial infection from the tympanic cavity via the aditus to the mastoid antrum and associated mastoid air cells. Occasionally, the infection may spread through the tegmen tympani to the dura mater of the middle cranial fossae, to cause meningitis or a temporal lobe abscess. Similar spread may be seen into the posterior cranial fossa and cerebellum.

Infection may spread laterally through the cortical bone of the lateral aspect of the mastoid process to form a subperiosteal postauricular abscess (Bezold's abscess), or through the cortical bone of the tip of the mastoid process to the attachment of the posterior belly of digastric and sternocleidomastoid, which stimulates painful muscular contraction and torticollis.

## Anterior wall

The inferior, larger area of the anterior wall of the tympanic cavity is narrowed by the approximation of the medial and lateral walls of the cavity (see Fig. 37.6). It is a thin lamina and forms the posterior wall of the carotid canal. It is perforated by the superior and inferior caroticotympanic nerves and the tympanic branch or branches of the internal carotid. The canals for tensor tympani and the osseous part of the pharyngotympanic tube open above it, the canal for tensor tympani being superior to that for the pharyngotympanic tube. Both canals incline downwards and anteromedially, to open in the angle between the squamous and petrous parts of the temporal bone, and are separated by a thin, osseous septum. The canal for tensor tympani and the bony septum runs posterolaterally on the medial tympanic wall, and ends immediately above the fenestra vestibuli. Here, the posterior end of the septum is curved laterally to form a pulley, the processus cochleariformis (cochleariform process), which is a surgical landmark for the identification of the geniculate ganglion of the facial nerve. The tendon of tensor tympani turns laterally over the pulley before attaching to the upper part of the handle of the malleus.

## Pharyngotympanic tube blockage in children

The pharyngotympanic tube serves to ventilate the middle ear, exchanging nasopharyngeal air with the air in the middle ear, which has been altered in its composition via transmucosal gas exchange with the haemoglobin in the blood vessels of the mucosa. The tube also carries mucus from the middle ear cleft to the nasopharynx as a result of ciliary transport.

In children, the pharyngotympanic tube is relatively narrow. It is prone to obstruction when the mucosa swells in response to infection or allergic challenge; obstruction results in a relative vacuum being created in the middle ear secondary to transmucosal gas exchange, and this in turn promotes mucosal secretion and the formation of a middle ear effusion. Because of the collapsibility of the pharyngotympanic tube, the vacuum thus created can overcome the distending effect of the muscles of the tube and 'lock' the tube shut. The resultant persistent middle ear effusion, otitis media with effusion (glue ear), can cause hearing loss by splinting the tympanic membrane and impeding its vibration. It can also provide an ideal environment for the proliferation of bacteria, with the result that an acute otitis media may develop (see above). It is possible to relieve the vacuum and unlock the tube, and then remove the effusion by myringotomy, i.e. by surgically creating a hole in the tympanic membrane. This hole will generally heal rapidly and it is common practice to insert a flanged ventilation tube (a grommet or tympanostomy tube) to keep the hole open. Migration of the outer squamous layer of the tympanic membrane eventually displaces the tube and the myringotomy heals.

## AUDITORY OSSICLES

A chain of three mobile ossicles - the malleus, incus and stapes transfers sound waves across the tympanic cavity from the tympanic

membrane to the fenestra vestibuli. The malleus is attached to the tympanic membrane, and the base (footplate) of the stapes is attached to the rim of the fenestra vestibuli. The incus is suspended between them and articulates with both bones.

## Malleus

The malleus is the largest of the ossicles and is shaped somewhat like a mallet (Fig. 37.12). It is $8-9 \mathrm{~mm}$ long and has a head, neck, handle (manubrium) and anterior and lateral processes. The head is the large upper end of the bone and is situated in the epitympanic recess. It is ovoid in shape, articulates posteriorly with the incus, and is covered elsewhere by mucosa. The cartilaginous articular facet for the incus is narrowed near its middle and consists of a larger upper part and a smaller lower part, orientated almost at right angles to each other. Opposite the constriction, the lower margin of the facet projects in the form of a process, the spur of the malleus. The neck is the narrowed part below the head, and inferior to this is an enlargement from which the anterior and lateral processes project.

The handle of the malleus is connected by its lateral margin to the tympanic membrane (see Figs 37.6, 37.10, 37.15A). It is directed downwards, medially and backwards. It decreases in size towards its free end, which is curved slightly forwards and is flattened transversely. Near the upper end of its medial surface there is a slight projection to which the tendon of tensor tympani is attached. The anterior process is a delicate bony spicule, directed forwards from the enlargement below the neck, and connected to the petrotympanic fissure by ligamentous fibres. In fetal life, it is the longest process of the malleus and is continuous in front with Meckel's cartilage. The lateral process is a conical projection from the root of the handle of the malleus. It is directed laterally, and is attached to the upper part of the tympanic membrane and, via the anterior and posterior malleolar folds, to the sides of the notch in the upper part of the tympanic sulcus.

## Ossification

The cartilaginous precursor of the malleus originates as part of the dorsal end of Meckel's cartilage. With the exception of its anterior process, the malleus ossifies from a single endochondral centre that appears near the future neck of the bone in the fourth month in utero. The anterior process ossifies separately in dense connective tissue and joins the rest of the bone at about the sixth month in utero.

## Incus

The incus is shaped less like an anvil, from which it is named, than a premolar tooth with its two diverging roots. It has a body and two processes (see Fig. 37.12). The body is somewhat cubical but laterally compressed. On its anterior surface, it has a saddle-shaped facet for articulation with the head of the malleus. The long process, rather more than half the length of the handle of the malleus, descends almost vertically, behind and parallel to the handle. Its lower end bends medially and ends in a rounded lenticular process, the medial surface of which is covered with cartilage and articulates with the head of the stapes. The short process, somewhat conical, projects backwards and is attached by ligamentous fibres to the fossa incudis in the lower and posterior part of the epitympanic recess. The presence of a single nutrient vessel within the long process of the incus and the absence of any collateral circulation render this segment of the bone susceptible to aseptic necrosis following middle ear infections.

## Ossification

The incus has a cartilaginous precursor continuous with the dorsal extremity of Meckel's cartilage. Ossification often spreads from a single centre in the upper part of its long process in the fourth fetal month; the lenticular process may have a separate centre.

## Stapes

The stapes is also known as the stirrup. It has a head, neck, two limbs (processes or crura) and a base (footplate) (see Fig. 37.12). The head (caput) is directed laterally and has a small cartilaginous facet for articulation with the lenticular process of the incus. The neck is the constricted part supporting the head, and the tendon of stapedius is attached to its posterior surface. The processes diverge from the neck and are connected at their ends by a flattened oval plate, the base, which forms the footplate of the stapes. The footplate is attached to the margin of the fenestra vestibuli by a ring of fibres (the anular ligament). The anterior process is shorter, thinner and less curved than the posterior.

## Ossification

The stapes is preformed in the perforated dorsal moiety of the hyoid arch cartilage of the fetus. Ossification starts from a single endochondral centre, which appears in the base in the fourth month in utero and then gradually spreads through the limbs of the stapes to reach the head.

At birth, the auditory ossicles have achieved their full adult size and configuration. They increase in density during the first years of life as marrow cavities are replaced with endosteal bone and fine trabeculae (Isaacson 2014).

## Ossicular ligaments

The ossicles are connected to the tympanic walls by ligaments (see Fig. $37.6 B$ ): three for the malleus and one each for the incus and stapes. Some are mere mucosal folds that carry blood vessels and nerves to and from the ossicles and their articulations, and others contain a central, strong band of collagen fibres.

The anterior ligament of the malleus stretches from the neck of the malleus, just above the anterior process, to the anterior wall of the tympanic cavity near the petrotympanic fissure. Some of its collagen fibres traverse this fissure to reach the spine of the sphenoid, and others continue into the sphenomandibular ligament. The latter, like the anterior malleolar ligament, is derived from the perichondrial sheath of Meckel's cartilage. The anterior malleolar ligament may contain muscle fibres, called laxator tympani or musculus externus mallei. The lateral ligament of the malleus is a triangular band that stretches from the posterior part of the border of the tympanic incisure to the head of the malleus. The superior ligament of the malleus connects the head of the malleus to the roof of the epitympanic recess.

The posterior ligament of the incus connects the end of its short process to the fossa incudis. The superior ligament of the incus is little more than a mucosal fold passing from the body of the incus to the roof of the epitympanic recess.

The vestibular surface and rim of the stapedial base are covered with hyaline cartilage. The cartilage encircling the base is attached to the margin of the fenestra vestibuli by a ring of elastic fibres, the anular ligament of the base of the stapes. The posterior part of this ligament is much narrower than the anterior part; it acts as a kind of hinge on which the stapedial base moves when stapedius contracts and during acoustic oscillation.

## Ossicular articulations

The ossicular articulations are typical synovial joints. The incudomalleolar joint is saddle-shaped and the incudostapedial joint is a ball and socket articulation. The articular surfaces are covered with articular cartilage, and each joint is enveloped by a capsule rich in elastic tissue and lined by synovial membrane. Versican, fibronectin, elastin and hyaluronan have been co-localized in the attachments of tensor tympani and stapedius to the malleus and stapes, respectively, and in the anular ligament of the incudostapedial joint in histological sections of adult middle ears (Kawase et al 2012). Co-localization between elastic fibres and hyaluronan in middle ear entheses looks to be a postnatal maturational event, possibly an adaptation to acoustic oscillation producing multidirectional mechanical stress (Takanashi et al 2013).

## Movements of the auditory ossicles

The handle of the malleus faithfully follows all movements of the tympanic membrane. The malleus and incus rotate together around an axis that runs from the short process and posterior ligament of the incus to the anterior ligament of the malleus. When the tympanic membrane and handle of the malleus move inwards (medially), the long process of the incus moves in the same direction and pushes the stapedial footplate towards the labyrinth and the perilymph contained within the labyrinth. The movement of the perilymph causes a compensatory outward bulging of the secondary tympanic membrane. These events are reversed when the tympanic membrane moves outwards. If the movement of the tympanic membrane is considerable, however, the incus does not follow the full outward excursion of the malleus and merely glides on it at the incudomalleolar joint, so preventing a dislocation of the footplate of the stapes from the fenestra vestibuli. When the handle of the malleus is carried medially, the spur at the lower margin of the head of the malleus locks the incudomalleolar joint, and this necessitates an inward movement of the long process of the incus. The joint is unlocked again when the handle of the malleus is carried outwards. The three bones together act as a bent lever so that the stapedial footplate does not move in the fenestra vestibuli like a piston, but rocks on a fulcrum at its anteroinferior border, where the anular ligament is thick. The rocking movement around a vertical axis, which is like a swinging door, is said to happen only at moderate intensities of sound. With loud, low-pitched sounds, the axis becomes horizontal, and the upper and lower margins of the stapedial footplate oscillate in opposite directions around this central axis, thus preventing excessive displacement of the perilymph.

## Otosclerosis, stapedectomy and stapedotomy

Otosclerosis is a localized disease of the bone derived from the embryonic otic capsule in which lamellar bone is replaced by woven bone of greater thickness and vascularity. It may develop spontaneously but is often seen in pedigrees; the inherited form is associated with mutations of the RELN gene. The position of the focus of new bone formation determines its effect on the function of the ear. When new bone develops around the footplate of the stapes, it may fix the footplate to the margin of the fenestra vestibuli and prevent it from moving. This impedes the passage of vibrations of the tympanic membrane passing through the ossicular chain to the inner ear, producing a conductive hearing loss. Otosclerosis affecting other parts of the otic capsule is thought to cause a sensorineural element to the overall hearing loss.

Stapedectomy is a surgical procedure designed to bypass the fixation of the stapes footplate caused by otosclerosis or congenital fixation. The tympanic membrane is temporarily elevated for access to the middle ear and, under microscopic control, the incudostapedial joint is disarticulated. The limbs of the stapes and stapedius are then both divided and the superstructure of the stapes removed. A small hole (stapedotomy) is then made in the fixed footplate of the stapes using a microdrill, reamer or laser to expose the fluids of the inner ear. A small graft of connective tissue is used to seal the hole with a flexible membrane. A piston, usually made of Teflon or titanium incorporating a wire made of stainless steel, platinum or titanium, is crimped on to the long process of the incus and placed in the perforation in the stapes footplate. The tympanic membrane is then returned. The connection between the tympanic membrane and the inner ear is thus reconstituted and hearing restored.

## MUSCLES

There are two intratympanic muscles: tensor tympani and stapedius (Anderson 1976).

## Tensor tympani

Tensor tympani is a long, slender muscle that occupies the bony canal above the osseous part of the pharyngotympanic tube, from which it is separated by a thin bony septum (see Fig. 37.6). It arises from the cartilaginous part of the pharyngotympanic tube and the adjoining region of the greater wing of the sphenoid, as well as from its own canal. It passes back within its canal, and ends in a slim tendon which bends laterally round the pulley-like processus cochleariformis and attaches to the handle of the malleus, near its root (see Fig. 37.14).

Vascular supply Tensor tympani receives its arterial blood supply from the superior tympanic branch of the middle meningeal artery.

Innervation Tensor tympani is innervated by a branch of the nerve to medial pterygoid (a ramus of the mandibular division of the trigeminal nerve), which traverses the otic ganglion without interruption to reach the muscle.

Actions Tensor tympani draws the handle of the malleus medially, and so tenses the tympanic membrane and helps to damp sound vibrations; its action also pushes the base of the stapes more tightly into the fenestra vestibuli.

## Stapedius

Stapedius arises from the wall of a conical cavity in the pyramidal eminence on the posterior wall of the tympanic cavity, and from its continuation anterior to the descending part of the facial nerve canal. Its minute tendon emerges from the orifice at the apex of the pyramid and passes forwards to attach to the posterior surface of the neck of the stapes. The muscle is of an asymmetric bipennate form. It contains numerous small motor units, each of only 6-9 muscle fibres; a few neuromuscular spindles exist near the myotendinous junction.

Vascular supply Stapedius receives its arterial blood supply from branches of the posterior auricular, anterior tympanic and middle meningeal arteries.

Innervation Stapedius is supplied by a branch of the facial nerve that is given off in the facial canal.

Actions Stapedius helps to damp down excessive sound vibrations. It opposes the action of tensor tympani (which pushes the stapes more tightly into the fenestra vestibuli). Paralysis of stapedius results in hyperacusis.

Stapedial and tensor tympani reflexes When noises are loud, and immediately before speaking, a reflex contraction of stapedius and tensor tympani takes place that helps damp down the movement of the ossicular chain before vibrations reach the internal ear. The afferent pathways involve the auditory component of cranial nerve VIII, and higher centres prior to speech. The efferent pathway involves the facial nerve (stapedius) and the mandibular nerve (tensor tympani).

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

A number of arteries supply the walls and contents of the tympanic cavity. The deep auricular, anterior tympanic and stylomastoid arteries are larger than the others.

The deep auricular branch of the first part of the maxillary artery often arises with the anterior tympanic artery. It ascends in the parotid gland behind the temporomandibular joint, pierces the cartilaginous or bony wall of the external acoustic meatus and supplies its cuticular lining, the exterior of the tympanic membrane and the temporomandibular joint.

The anterior tympanic branch of the first part of the maxillary artery ascends behind the temporomandibular joint and enters the tympanic cavity through the petrotympanic fissure. It ramifies on the interior of the tympanic membrane, and forms a vascular circle around it with the posterior tympanic branch of the stylomastoid artery. It also anastomoses with twigs of the artery of the pterygoid canal and caroticotympanic branches of the internal carotid artery in the mucosa of the tympanic cavity.

The stylomastoid branch of the occipital or posterior auricular arteries supplies the posterior part of the tympanic cavity and mastoid air cells. It also enters the stylomastoid foramen to supply the facial nerve and semicircular canals. In the young, its posterior tympanic branch forms a circular anastomosis with the anterior tympanic artery.

The smaller arteries supplying the tympanic cavity include the petrosal branch of the middle meningeal artery, which enters through the hiatus for the greater petrosal nerve; the superior tympanic branch of the middle meningeal artery, which traverses the canal for tensor tympani; an inferior tympanic branch from the ascending pharyngeal artery, which traverses the tympanic canaliculus together with the tympanic branch of the glossopharyngeal nerve, to supply the medial wall of the tympanic cavity; a branch from the artery of the pterygoid canal, which accompanies the pharyngotympanic tube; and a tympanic branch or branches from the internal carotid artery, which is given off in the carotid canal and perforates the thin anterior wall of the tympanic cavity.

The mastoid air cells and dura mater are also supplied by a mastoid branch from the occipital artery. It is small in size and sometimes absent. When present, it enters the cranial cavity via the mastoid foramen near the occipitomastoid suture.

In early fetal life, a stapedial artery traverses the stapes.
The veins from the tympanic cavity terminate in the pterygoid venous plexus and the superior petrosal sinus. A small group of veins runs medially from the mucosa of the mastoid antrum through the arch formed by the superior (anterior) semicircular canal, and emerges on to the posterior surface of the petrous temporal bone at the subarcuate fossa. These veins drain into the superior petrosal sinus and are the remains of the large subarcuate veins of childhood. They represent a potential route for the spread of infection from the mastoid antrum to the meninges.

Lymphatic vessels of the tympanic and antral mucosae drain to the parotid or upper deep cervical lymph nodes. Vessels draining the tympanic end of the pharyngotympanic tube probably end in the deep cervical nodes.

## INNERVATION

The tympanic cavity contains the tympanic plexus and the facial nerve. Branches from the plexus and the facial nerve supply structures within the tympanic cavity but also leave the cavity to supply structures on the face.

## Tympanic plexus

The nerves that constitute the tympanic plexus ramify on the surface of the promontory on the medial wall of the tympanic cavity. They are derived from the tympanic branch of the glossopharyngeal nerve and the caroticotympanic nerves (Fig. 37.13). The former arises from the

Fig. 37.13 The intracranial branches of the facial and glossopharyngeal nerves and the connections of the tympanic plexus and the otic ganglion. The course of the taste fibres from the mucous membrane of the palate and from the anterior presulcal part of the tongue is represented by the blue lines.
inferior ganglion of the glossopharyngeal nerve, and reaches the tympanic cavity via the tympanic canaliculus for the tympanic nerve. The superior and inferior caroticotympanic nerves are postganglionic sympathetic fibres that are derived from the carotid sympathetic plexus and traverse the wall of the carotid canal to join the plexus.

The tympanic plexus supplies branches to the mucosa of the tympanic cavity, pharyngotympanic tube and mastoid air cells. It sends a branch to the greater petrosal nerve via an opening anterior to the fenestra vestibuli. The lesser petrosal nerve, which may be regarded as the continuation of the tympanic branch of the glossopharyngeal nerve, traverses the tympanic plexus. It occupies a small canal below that for the tensor tympani. It runs past, and receives a connecting branch from, the geniculate ganglion of the facial nerve. The lesser petrosal nerve emerges from the anterior surface of the temporal bone via a small opening lateral to the hiatus for the greater petrosal nerve and then traverses either the foramen ovale or the sphenopetrosal fissure or the innominate canal (of Arnold) to join the otic ganglion. Postganglionic secretomotor fibres leave this ganglion in the auriculotemporal nerve to supply the parotid gland. In former times, the operation of tympanic neurectomy was undertaken to reduce salivation in patients who drooled and to diminish facial sweating in those with Frey's syndrome following parotidectomy; less invasive and more effective procedures are employed nowadays.

## Facial nerve

The facial nerve consists of intracranial (cisternal), intratemporal and extratemporal portions. The intratemporal portion is further divided into meatal, labyrinthine, tympanic (horizontal) and mastoid (vertical) segments (Fig. 37.14). The cisternal portion emerges from the ventrolateral aspect of the caudal border of the pons. The meatal portion enters the porus acusticus of the internal auditory meatus accompanied by the nervus intermedius, the vestibulocochlear nerve and the labyrinthine vessels (see Fig. 37.7). In this part of its course, the nerve lacks a fibrous sheath or endoneurium and is surrounded by a thin layer of arachnoid. The motor root, which supplies the muscles of the face, and the nervus intermedius, which contains sensory fibres concerned with the perception of taste and parasympathetic (secretomotor) fibres to various glands, are still separate components; they usually merge within the meatus. The labyrinthine segment runs from the fundus of the internal acoustic meatus to the geniculate ganglion, where the nerve makes the first bend or genu (see Figs 37.7, 37.13). The labyrinthine segment is the shortest and narrowest part of the facial nerve; it lacks anastomosing arterial cascades, which renders it susceptible to vascular compression. The tympanic part initially curves around the oval window niche, then lies just anterior and inferior to the lateral semicircular canal and bends again at the second genu to become the vertical or mastoid part. The mastoid part is the longest of the petrous segments and runs from the pyramidal process to the stylomastoid foramen. The tympanic and mastoid segments of the facial nerve are supplied by the facial arch, formed by the petrosal branch of the middle meningeal artery and the stylomastoid branch of the posterior auricular artery. The extratemporal course of the facial nerve is described on page 502.

The branches that arise from the facial nerve within the temporal bone can be divided into those that come from the geniculate ganglion and those that arise within the facial canal.

The main branch from the geniculate ganglion is the greater (superficial) petrosal nerve, a branch of the nervus intermedius. The greater petrosal nerve passes anteriorly, receives a branch from the tympanic plexus and traverses a hiatus on the anterior surface of the petrous part of the temporal bone. It enters the middle cranial fossa, runs forwards in a groove on the bone above the lesser petrosal nerve, and then passes beneath the trigeminal ganglion to reach the foramen lacerum. Here it is joined by the deep petrosal nerve from the internal carotid sympathetic plexus, to become the nerve of the pterygoid canal (Vidian nerve). The greater petrosal nerve contains parasympathetic fibres destined for the pterygopalatine ganglion, and taste fibres from the palate. The geniculate ganglion also communicates with the lesser petrosal nerve.

The nerve to stapedius arises from the facial nerve in the facial nerve canal behind the pyramidal eminence of the posterior wall of the tympanic cavity and passes forwards through a small canal to reach the muscle.

The chorda tympani (see Fig. 37.13; Fig. 37.15) leaves the facial nerve some 6 mm above the stylomastoid foramen and runs anterosuperiorly in a canal to enter the tympanic cavity via the posterior canaliculus. It then curves anteriorly in the substance of the tympanic membrane between its mucous and fibrous layers (see Fig. 37.15A), and

Fig. 37.14 The anatomy of the infratemporal portion of the facial nerve and associated middle ear structures. The nerve is vulnerable to injury at several sites. Perigeniculate region: nerve compression and ischaemia are most likely to occur in the narrow meatal and labyrinthine segments, which are the vascular watershed areas of branches of the external carotid artery and the posterior circulation; the first genu is tethered by the greater petrosal nerve, increasing susceptibility to shearing injuries; and the geniculate ganglion is susceptible to injury during surgical dissection in the supratubal recess of the anterior epitympanum. Tympanic segment: the nerve is most frequently dehiscent above the oval window; the distal tympanic segment and the second genu are both susceptible to injury in cholesteatoma surgery as a result of pathological dehiscence or distorted anatomy and failure to identify important surgical landmarks. Mastoid segment: the facial nerve is positioned lateral to the tympanic anulus and just distal to the stylomastoid foramen in the lower portion of its vertical course and is therefore susceptible to injury during surgery involving the external acoustic meatus. (Redrawn from Francis HW 2010 Anatomy of the temporal bone, external ear, and middle ear. In: Flint PW, Haughey BH, Lund VJ, et al (eds) Cummings Otolaryngology: Head \& Neck Surgery, 5th ed. Mosby. Ch 127, 1821-1830.)
crosses medial to the upper part of the handle of the malleus to the anterior wall of the tympanic cavity, where it enters the anterior canaliculus. It exits the skull at the petrotympanic fissure, and its further course is described on page 552. The chorda tympani contains parasympathetic fibres that supply the submandibular and sublingual salivary glands via the submandibular ganglion and taste fibres from the anterior two-thirds of the tongue.

## Dehiscences of the facial nerve canal

The facial nerve may be somewhat variable in its anatomical course through the temporal bone (Proctor and Nager 1982). It may split into two or three strands, starting at the geniculate ganglion, and then make its way across the promontory to the stylomastoid foramen, or pass a few millimetres posteriorly to its second genu, before it turns inferiorly posterior to the fossa incudis, a position where it is particularly vulnerable during surgical exploration of the mastoid antrum. The more proximal the division into strands, the more bizarre is the subsequent course. More distal bifurcations pass either side of the fenestra vestibuli. It may be dehiscent, particularly in its second part, when it occasionally overhangs the stapes, or run inferior to the stapedial superstructure, a position that renders it vulnerable during surgery to the stapes (Barnes et al 2001). The motor fibres to the face may be carried through the chorda tympani, which is then enlarged. When this is the case, the distal facial nerve dwindles to a fibrous strand in a narrowed stylomastoid foramen. In chronic bone disease in the tympanic cavity, the facial nerve may be exposed in its canal. Inflammation may lead to facial paralysis of the infranuclear or lower motor neurone type.

## Bell's palsy

Bell's palsy is the eponym given to an idiopathic lower motor neurone facial palsy. It may be complete or partial, and is characterized by a
flaccid paralysis of the ipsilateral muscles of facial expression; decreased lacrimation in the ipsilateral eye (which is controlled by neurones in the greater petrosal nerve); and hyperacusis or decreased tolerance of loud noises in the ipsilateral ear as a result of paralysis of stapedius. Its cause remains the subject of speculation. Magnetic resonance imaging studies suggest that there are inflammatory changes in labyrinthine and perigeniculate segments of the facial nerve. In the vast majority of cases, spontaneous full recovery takes place after a few weeks.

## TYMPANIC MUCOSA

The mucosa of the tympanic cavity is pale, thin and slightly vascular. It is continuous with that of the pharynx, via the pharyngotympanic tube, and covers the ossicles, muscles and nerves in the cavity to form the inner layer of the tympanic membrane and the outer layer of the secondary tympanic membrane. It also spreads into the mastoid antrum and air cells. The middle ear mucosa is a mucus-secreting respiratory mucosa bearing cilia on its surface. The precise distribution of the mucociliary epithelium varies in normal middle ears, being more widespread in the young. Three distinct mucociliary pathways have been identified - epitympanic, promontorial and hypotympanic - the latter being the largest. Each of these pathways coalesces at the tympanic orifice of the pharyngotympanic tube (Gleeson et al 1991).

The mucosa forms several vascular folds that extend from the tympanic walls to the ossicles: one descends from the roof of the cavity to the head of the malleus and the upper margin of the body of the incus, and a second surrounds the stapedius. Other folds invest the chorda tympani nerve and tensor tympani. The folds separate off saccular recesses that give the interior of the tympanic cavity a somewhat honeycombed appearance; these mucosal folds have been described in greater detail by Proctor (1964). Of note, the superior recess of the

tympanic membrane, Prussak's space, lies between the neck of the malleus and the pars flaccida, bounded by the lateral malleolar fold. This space can play an important role in the retention of keratin and subsequent development of cholesteatoma.

## Cholesteatoma

Cholesteatoma is the name given to keratinizing squamous epithelium within the middle ear. There is debate as to how such epithelium comes to be in the middle ear. Theories include development from embryological cell rests, metaplasia from inflamed mucoperiosteum, and aberrant migration of squamous epithelium either through a perforation in the tympanic membrane (usually in the pars flaccida or posterosuperior pars tensa) or within an area of tympanic membrane atelectasis where the tympanic membrane becomes adherent to the medial wall of the tympanic cavity. It is likely that all of these processes may be implicated at some time. A feature of cholesteatoma that remains poorly understood is its ability to erode bone, by activating osteoclasts, thus allowing the epithelium to proliferate and invade, destroying the temporal bone
and carrying infection to the soft tissues. Cholesteatoma can therefore cause deafness through damage to the ossicles and inner ear; problems with balance through damage to the vestibule and semicircular canals; facial palsy through ischaemia and necrosis of the facial nerve; and intracranial sepsis. Treatment involves microsurgical dissection of the invading sac of epithelium with, wherever possible, preservation of the delicate structures just listed.

## Inner ear

The inner ear contains the organ of hearing and the organs of balance. All are located within the labyrinth, a series of interlinked cavities in the petrous temporal bone containing interconnected membranous sacs and ducts. All spaces within the labyrinth are filled with fluid. The different sacs contain sensory epithelia consisting of supporting cells and mechanosensory cells, the hair cells that underlie acoustico-lateralis sensory systems in all vertebrates. In humans, there are six such mechanosensory epithelia: the organ of Corti within the cochlea (the hearing organ); the utricle and saccule (static balance organs); and the cristae of the semicircular canals (dynamic balance organs). Whilst sharing the same basic structure, hair cells and the accessory systems that surround them show specific adaptations to each of the different sensory modalities.

The disarticulated temporal bone is described in detail in Chapter 37. The internal acoustic meatus (internal auditory canal) and bony and membranous labyrinths are described here.

## OSSEOUS (BONY) LABYRINTH

The bony labyrinth consists of the vestibule (sacculus and utriculus/ saccule and utricle), semicircular canals and cochlea, which are all cavities lined by periosteum and which contain the membranous labyrinth (Fig. 38.1). The bone is denser and harder than that of the other parts of the petrous bone, and it is therefore possible, particularly in young skulls, to dissect the bony labyrinth out from the petrous temporal bone.

The osseous and membranous labyrinths are filled with fluid (Fig. 38.2). The gap between the internal wall of the osseous labyrinth and the external surface of the membranous labyrinth is filled with perilymph, a clear fluid with an ionic composition similar to that of other extracellular fluids, i.e. low in potassium ions and high in sodium and calcium. The membranous labyrinth contains endolymph, a fluid with an ionic composition more like that of cytosol, i.e. high in potassium ions and low in sodium and calcium. Moreover, the endolymphatic compartment has an electrical potential that is approximately 80 mV more positive than the perilymphatic compartment (the endolymphatic potential). These differences in ionic composition and potential, maintained by homeostatic tissues in the walls of the labyrinth, are essential to maximize the sensitivity of the mechanosensory hair cells that convert the vibrations set up in the inner ear fluids by head or sound movements into electrical signals that are transmitted via the vestibulocochlear nerve to the vestibular and cochlear nuclei, respectively, in the brainstem.

## VESTIBULE

The vestibule is the central part of the bony labyrinth and lies medial to the tympanic cavity, posterior to the cochlea and anterior to the semicircular canals (see Fig. 38.1). It is somewhat ovoid in shape but flattened transversely, and (on average) measures 5 mm from front to back and vertically, and 3 mm across. In its lateral wall is the opening of the oval window (fenestra vestibuli), into which the base of the stapes inserts, and to which the base of the stapes is attached by an anular ligament. Anteriorly, on the medial wall, is a small spherical recess that contains the saccule; it is perforated by several minute holes, the macula cribrosa media, which transmit fine branches of the vestibular nerve to the saccule. Behind the recess is an oblique vestibular crest, the anterior end of which forms the vestibular pyramid. This crest divides below to enclose a small depression, the cochlear recess, which is perforated by vestibulocochlear fascicles as they pass to the vestibular end of the cochlear duct. Posterosuperior to the vestibular crest, in the roof and medial wall of the vestibule, is the elliptical recess (see Fig. 38.1B), which contains the utricle. The pyramid and adjoining part of

Fig. 38.1 The left bony labyrinth. A, Lateral aspect. B, Interior. C, The membranous labyrinth (blue) projected on to the bony labyrinth.

Fig. 38.2 A transverse section through the left posterior semicircular canal and duct.
the elliptical recess are perforated by a number of holes, the macula cribrosa superior; those in the former transmit nerves to the utricle and those in the latter transmit nerves to the ampullae of the anterior and lateral semicircular canals (see Fig. 38.1B). The region of the pyramid and elliptical recess corresponds to the superior vestibular area in the internal acoustic meatus (see Fig. 38.3). The vestibular aqueduct opens below the elliptical recess. It reaches the posterior surface of the petrous bone and contains one or more small veins and part of the membranous labyrinth, the endolymphatic duct (see Fig. 38.1C). In the posterior part of the vestibule are the five openings of the semicircular canals; in its anterior wall is an elliptical opening that leads into the scala vestibuli of the cochlea.

## SEMICIRCULAR CANALS

The three semicircular canals - anterior (superior), posterior and lateral (horizontal) - are located posterosuperior to the vestibule (see Fig. 38.1). They are compressed from side to side and each forms approximately two-thirds of a circle. They are unequal in length but similar in diameter along their lengths, except where they bear a terminal swelling, an ampulla, which is almost twice the diameter of the canal.

The anterior semicircular canal is $15-20 \mathrm{~mm}$ long. It is vertical in orientation and lies transverse to the long axis of the petrous temporal bone under the anterior surface of its arcuate eminence. The eminence may not accurately coincide with this semicircular canal but may instead be adapted to the occipitotemporal sulcus on the inferior surface of the temporal lobe of the brain. The ampulla at the anterior end of the canal opens into the upper and lateral part of the vestibule. Its other end unites with the upper end of the posterior canal to form the crus commune (common limb), which is 4 mm long, and opens into the medial part of the vestibule.

The posterior semicircular canal is also vertical but curves backwards almost parallel with the posterior surface of the petrous bone. It is $18-22 \mathrm{~mm}$ long and its ampulla opens low in the vestibule, below the cochlear recess where the macula cribrosa inferior transmits nerves to it. Its upper end joins the crus commune.

The lateral canal is $12-15 \mathrm{~mm}$ long and its arch runs horizontally backwards and laterally. Its anterior ampulla opens into the upper and lateral angle of the vestibule, above the oval window and just below the ampulla of the anterior canal; its posterior end opens below the opening of the crus commune.

The two lateral semicircular canals of the two ears are often described as being in the same plane and the anterior canal of one side as being almost parallel with the opposite posterior canal. However, measurements of the angular relations of the planes of the semicircular osseous
canals in 10 human skulls led Blanks et al (1975) to suggest that the planes of the three ipsilateral canals are not completely perpendicular to each other. The angles were measured as: lateral/anterior $111.76 \pm 7.55^{\circ}$, anterior/posterior $86.16 \pm 4.72^{\circ}$, posterior/lateral $95.75 \pm 4.66^{\circ}$. The planes of similarly orientated canals of the two sides also showed some departure from being parallel: left anterior/right posterior $24.50 \pm 7.19^{\circ}$, left posterior/right anterior $23.73 \pm 6.71^{\circ}$, left lateral/right lateral $19.82 \pm 14.93^{\circ}$. The same observers (Curthoys et al 1977) also measured the dimensions of the canals. The mean radii of the osseous canals were found to be as follows: lateral 3.25 mm , anterior 3.74 mm , posterior 3.79 mm . The diameters of the osseous canals are 1 mm (minor axis) and 1.4 mm (major axis). The membranous ducts within them are much smaller, but are also elliptical in transverse section, and have major and minor axes of 0.23 and 0.46 mm (see Fig. 38.2). Representative means for ampullary dimensions are as follows: length 1.94 mm , height 1.55 mm . Phylogenetic studies suggest that the arc sizes of the semicircular canals in humans and other primates may be functionally linked to sensory control of body movements. The angulation and dimensions of the canals may be related to locomotor behaviour and possibly to agility, or more specifically to the frequency spectra of natural head movements (see review by Spoor and Zonneveld (1998)).

## COCHLEA

The cochlea (from the Greek cochlos for snail) is the most anterior part of the labyrinth, lying in front of the vestibule (see Figs 38.1 and 38.9A). It is 5 mm from base to apex, and 9 mm across its base. Its apex, or cupula, points towards the anterosuperior area of the medial wall of the tympanic cavity (see Fig. 38.9A). Its base faces the bottom of the internal acoustic meatus and is perforated by numerous apertures for the cochlear nerve. The cochlea has a conical central bony core, the modiolus, and a spiral canal runs around it. A delicate osseous spiral lamina (or ledge) projects from the modiolus, partially dividing the canal (see Fig. 38.9B). Within this bony spiral lies the membranous cochlear duct, attached to the modiolus at one edge and to the outer cochlear wall by its other edge. There are therefore three longitudinal channels within the cochlea. The middle canal (the cochlear duct or scala media) is blind and ends at the apex of the cochlea; its flanking channels communicate with each other at the modiolar apex at a narrow slit, the helicotrema (see Fig. 38.1C). Two elastic membranes form the upper and lower bounds of the scala media. One is Reissner's membrane, the thin vestibular membrane that separates the scala media from the scala vestibuli. The other is the basilar membrane, which forms the partition between the scala media and the scala tympani. The organ of Corti, the sensory epithelium of hearing, sits on the inner surface of the basilar membrane. At the base of the scala vestibuli is the oval window (fenestra vestibuli), which leads on to the vestibular cavity but is sealed by the footplate of the stapes. The scala tympani is separated from the tympanic cavity by the secondary tympanic membrane at the round window (fenestra cochleae). The central cochlear core, the modiolus, has a broad base near the lateral end of the internal acoustic meatus, where it corresponds to the spiral tract (tractus spiralis foraminosus). There are several openings in this area for the fascicles of the cochlear nerve: those for the first $1 \frac{1}{2}$ turns run through the small holes of the spiral tract, and those for the apical turn run through the hole that forms the centre of the tract. Canals from the spiral tract go through the modiolus and open in a spiral sequence into the base of the osseous spiral lamina. Here the small canals enlarge and fuse to form Rosenthal's canal, a spiral canal in the modiolus that follows the course of the osseous spiral lamina and contains the spiral ganglion (see Fig. 38.9B). The main tract continues through the centre of the modiolus to the cochlear apex.

The osseous cochlear canal spirals for about $23 / 4$ turns around the modiolus and is 35 mm long. At its first turn, the canal bulges towards the tympanic cavity, where it underlies the promontory. At the base of the cochlea, the canal is 3 mm in diameter but it becomes progressively reduced in diameter as it spirals apically to end at the cupula. In addition to the round and oval windows, which are the two main openings at its base, the canal has a third, smaller opening for the cochlear aqueduct or canaliculus. The latter is a minute funnel-shaped canal that runs to the inferior surface of the petrous temporal bone; it transmits a small vein to the inferior petrosal sinus (see p. 437) and connects the subarachnoid space to the scala tympani.

The osseous or primary spiral lamina is a ledge that projects from the modiolus into the osseous canal like the thread of a screw (see Fig. 38.9B). It is attached to the inner edge of the basilar membrane and ends in a hook-shaped hamulus at the cochlear apex, partly bounding
the helicotrema (see Fig. 38.1C). From Rosenthal's canal, many tiny canals, the habenula perforata, radiate through the osseous lamina to its rim, where they each carry a fascicle of the cochlear nerve through the foramen nervosum to the organ of Corti. A secondary spiral lamina projects inwards from the outer cochlear wall towards the osseous spiral lamina and is attached to the outer edge of the basilar membrane. It is most prominent in the lower part of the first turn; the gap between the two laminae increases progressively towards the cochlear apex, which means that the basilar membrane is wider at the apex of the cochlea than at the base.

## MICROSTRUCTURE OF THE BONY LABYRINTH

The wall of the bony labyrinth is lined by fibroblast-like perilymphatic cells and extracellular matrix fibres (see Fig. 38.2). The morphology of the cells varies in different parts of the labyrinth. Where the perilymphatic space is narrow, as in the cochlear aqueduct, the cells are reticular or stellate in form; they give off sheet-like cytoplasmic extensions that cross the extracellular space. Where the space is wider, as in the scalae vestibuli and tympani of the cochlea and much of the vestibule, the perilymphatic cells on the periosteum and the external surface of the membranous labyrinth are extremely flat and resemble a squamous epithelium. Elsewhere, on parts of the perilymphatic surface of the basilar membrane, the cells are cuboidal.

Recent evidence suggests that micropores or canaliculi (canaliculi perforantes) (0.2-23.0 $\mu \mathrm{m}$ diameter) are more widely distributed within the bony surfaces lining the perilymphatic space than was previously suspected; they are numerous in the peripheral and modiolar portions of the osseous spiral lamina and the floor of the scala tympani, but sparse in the osseous wall of the scala vestibuli. The proposal that these canaliculi normally provide an extensive fluid communication channel between the scala tympani and the spiral canal of the cochlea could have implications not only for novel drug-based cochlear therapies delivered via the scala tympani and the delivery of stem cells or appropriate cell lines into the deafened cochlea, but also for the design of implanted perimodiolar electrode arrays (Shepherd and Colreavy 2004). (For further reading about the changes in the inner ear that are induced by implanted cochlear electrodes, both acute and long-term, see Keifer et al (2006).)

## Composition of inner ear fluids

Perilymph resembles cerebrospinal fluid in ionic composition, particularly in the scala tympani. Its composition differs a little between the two cochlear scalae: concentrations of potassium, glucose, amino acids and proteins are greater in the scala vestibuli. This has led to the suggestion that perilymph in the scala vestibuli is derived from plasma via the endothelial boundary of the cochlear blood vessels, whereas the perilymph in the scala tympani contains some cerebrospinal fluid derived from the subarachnoid spaces via the cochlear canaliculus. However, the lack of significant bulk flow suggests that perilymph homeostasis is predominantly locally regulated. Perilymph contains approximately $5 \mathrm{mM} \mathrm{K}, 150 \mathrm{mM} \mathrm{Na}, 120 \mathrm{mM} \mathrm{Cl}^{-}$and $1.5 \mathrm{mM} \mathrm{Ca}^{2+}$.

The membranous labyrinth is filled with endolymph, a fluid produced by the marginal cells of the stria vascularis and the dark cells of the vestibule (see review by Wangemann and Schacht (1996)) (see Fig. $38.2 B$ ). Whatever their relative contributions, endolymph probably circulates in the labyrinth; it enters the endolymphatic sac, where it is transferred into the adjacent vascular plexus via the specialized epithelium of the sac. Pinocytotic removal of fluid may also occur in other labyrinthine regions.

Endolymph contains greater $\mathrm{K}^{+}(150 \mathrm{mM})$ and $\mathrm{Cl}^{-}(130 \mathrm{mM})$ concentrations and lower $\mathrm{Na}^{+}(2 \mathrm{mM})$ and $\mathrm{Ca}^{2+}(20 \mu \mathrm{M})$ concentrations than perilymph. The high potassium concentration is important for the function of the mechanosensory hair cells and is maintained by the actions of the lateral wall, which contains two tissues, namely: the spiral ligament and the stria vascularis. Together, these tissues promote the recirculation of potassium from perilymph back to endolymph by uptake via potassium channels and gap junctional communication. Gap junctions are formed from connexins; their importance to this process is emphasized by the fact that mutations in connexins are significant causes of hearing loss (Duman and Tekin 2013). The vestibular regions may not have an endolymphatic potential, as their lateral wall structure is simplified compared to that of the cochlea, although the difference in potassium concentration between endolymph and perilymph remains important.

Fig. 38.3 The fundus of the left internal acoustic meatus, exposed by a section through the petrous part of the left temporal bone nearly parallel to the line of its superior border.

## INTERNAL ACOUSTIC MEATUS

The internal acoustic meatus (internal acoustic/auditory canal) is separated from the internal ear at its lateral fundus by a vertical plate divided unequally by a transverse (falciform) crest (Fig. 38.3). Five nerves facial, nervus intermedius, cochlear, superior and inferior vestibular pass through openings in the vertical plate, above and below the transverse crest. The facial and superior vestibular nerves enter canals that are superior to the crest. The facial nerve is anterior to the superior vestibular nerve, from which it is separated at the lateral end of the meatus by a vertical ridge of bone (Bill's bar). The nervus intermedius lies between the facial motor root and the superior vestibular nerve, to which it may be adherent. The superior vestibular area contains openings for nerves to the utricle and anterior and lateral semicircular ducts. Below the crest, an anterior cochlear area contains a spiral of small holes, the tractus spiralis foraminosus, which encircles the central cochlear canal. Behind this, the inferior vestibular area contains openings for saccular nerves, and most posteroinferiorly, a single hole (foramen singulare) admits the nerve to the posterior semicircular duct. It has been suggested that vascular loops in the internal acoustic meatus (from the anterior inferior cerebellar artery) might generate pulsatile tinnitus.

## MEMBRANOUS LABYRINTH

The membranous labyrinth is separated from the periosteum by a space that contains perilymph and a web-like network of fine blood vessels (see Figs 38.1C, 38.2). It can be divided into two major regions: the vestibular apparatus and the cochlear duct.

## VESTIBULAR APPARATUS

The vestibular apparatus consists of three membranous semicircular canals that communicate with the utricle, a membranous sac leading into a smaller chamber, the saccule, via the utriculosaccular duct. This Y-shaped duct has a side branch to the endolymphatic duct, which passes to the endolymphatic sac, a small but functionally important expansion situated under the dura of the petrous temporal bone. From the saccule, a narrow canal, the ductus reuniens, leads to the base of the cochlear duct. These various ducts and sacs form a closed system of intercommunicating channels. Endolymph is resorbed into the cerebrospinal fluid from the endolymphatic sac, which therefore provides the site for the drainage of endolymph for the entire membranous labyrinth.

The terminal fibres of the vestibular nerve are connected to the five specialized sensory epithelia (two maculae and three cristae) in the walls of the membranous labyrinth. Maculae are flat plaques of sensory hair cells surrounded by supporting cells, and are found in the utricle and saccule. The cristae (crests) are ridges bearing sensory hair cells and supporting cells. They are found in the walls of the ampullae near the utricular openings of the three semicircular canals, one for each canal.

## Utricle

The utricle is the larger of the two major vestibular sacs. It is an irregular, oblong, dilated sac that occupies the posterosuperior region of the vestibule (see Fig. 38.1C), and contacts the elliptical recess (where it is a blind-ended pouch) and the area inferior to it.

The macula of the utricle (or utriculus) is a specialized neurosensory epithelium lining the membranous wall, and is the largest of the vestibular sensory areas (Fig. 38.4). It is triangular or heart-shaped in surface view and lies horizontally with its long axis orientated anteroposteriorly and its sharp angle pointing posteriorly (Fig. 38.5). It is flat except at the anterior edge, where it is gently folded in on itself, and it measures 2.8 mm long by 2.2 mm wide. The mature form of the macula is reached early in development, but in the adult a bulge is often present on the anterolateral border; there is sometimes an indentation at the anteromedial border. The epithelial surface is covered by the otolithic membrane (statoconial membrane), a gelatinous structure in which many small crystals, the otoconia (otoliths, statoliths), are embedded. A curved ridge, the 'snowdrift line', runs along the length of the otolithic membrane. It corresponds to a narrow crescent of underlying sensory epithelium termed the striola, 0.13 mm wide. The density of sensory hair cells in this strip of epithelium is $20 \%$ less than in the rest of the macula. The striola is convex laterally and runs from the medial aspect of the anterior margin in a posterior direction towards, but not reaching, the posterior pole. The part of the macula medial to the striola is called the pars interna and is slightly larger than the pars externa, which is lateral to it. The significance of this area is that the sensory cells are functionally and anatomically polarized with respect to the

Fig. 38.4 A section of the utricular macula from a guinea pig, showing the relative positions of the hair cells and supporting cell nuclei. Semi-thin resin section, toluidine blue stain. (The inner ear is extremely vulnerable to hypoxia and situated in one of the hardest bones in the body, which means that well-fixed human tissue is rarely obtained for histology. Guinea pigs are one of the most frequently used animal models of human hearing and their inner ear ultrastructure is very similar.) (Courtesy of RM Walsh, DN Furness and CM Hackney, The Institute of Science and Technology in Medicine, School of Life Sciences, Keele University.)
midline of the striola (see Fig. 38.5). The macula in each utricle is approximately horizontal when the head is in its normal position. Linear acceleration of the head in any horizontal plane will result in the otolithic membrane lagging behind the movement of the membranous labyrinth as a result of the inertia produced by its mass. The membrane thus maximally stimulates one group of hair cells by deflecting their bundles towards the striola whilst inhibiting others by deflecting their bundles away from it. Hence each horizontal movement of the head will produce a specific pattern of firing in utricular afferent nerve fibres.

## Saccule

The saccule (or sacculus) is a slightly elongated, globular sac lying in the spherical recess near the opening of the scala vestibuli of the cochlea (see Fig. 38.1C). The saccular macula is an almost elliptical structure, 2.6 mm long and 1.2 mm at its widest point. Its long axis is orientated anteroposteriorly but, in contrast to the utricular macula, the saccular macula lies in a vertical plane on the wall of the saccule. Its elliptical shape is very slightly distorted by a small anterosuperior bulge. Like the utricular macula, it is covered by an otolithic (statoconial) membrane and possesses a striola similar to that of the utricle, 0.13 mm wide, which extends along its long axis as an S-shaped strip about which the sensory cells are functionally and anatomically polarized (see Fig. 38.5). The part of the macula above the striola is termed the pars interna, and that below it, the pars externa. The operation of the saccule is similar to that of the utricle. However, because of its vertical orientation, the saccule is particularly sensitive to linear acceleration of the head in the vertical plane and is, therefore, a major gravitational sensor when the head is in an upright position. It is also particularly sensitive to movement along the anteroposterior axis.

## Semicircular canals

The lateral, anterior and posterior semicircular ducts follow the course of their osseous canals. Throughout most of their length they are securely attached, by much of their circumference, to the osseous walls. They are approximately one-quarter of the diameter of their osseous canals (see Fig. 38.2). The medial ends of the anterior and posterior canals fuse to form a single common duct, the crus commune, before entering the utricle. The lateral end of each canal is dilated to form an ampulla, within the ampulla of the osseous canal. The short segment of duct between the ampullae and utricle is the crus ampullaris.

Fig. 38.5 A, The morphological organization of the saccular and utricular maculae and the relationship of their hair cells to the otolithic membrane. The utricular macula has been tilted in the plane of the page to emphasize that it lies horizontally, whereas the saccular macula lies vertically when the head is in an upright position. Note the different shapes of the maculae, the position of the striola as indicated by a curved line in each case, and the different orientations of their stereociliary bundles. The arrows indicate the excitatory direction of deflection. B, A scanning electron micrograph of a fracture of a utricular macula (guinea pig) showing a type I hair cell (left) and a type II hair cell (right). C, The differing innervation patterns of the two types of hair cell. (B, Courtesy of DN Furness, The Institute of Science and Technology in Medicine, School of Life Sciences, Keele University.)

Fig. 38.6 A section of an ampullary crest.

The membranous wall of each ampulla contains a transverse elevation (septum transversum), on the central region of which is a saddleshaped sensory ridge, the ampullary crest, containing hair cells and supporting cells. It is broadly concave on its free edge along most of its length and has a concave gutter (planum semilunatum) at either end between the ridge and the duct wall. Sectioned across the ridge, the crests of the lateral and anterior semicircular canals have smoothly rounded corners; the posterior crest is more angular. A vertical plate of gelatinous extracellular material, the cupula, is attached along the free edge of the crest (Fig. 38.6). It projects far into the lumen of the ampulla so that it is readily deflected by movements of endolymph derived from head rotations within the duct, by means of which stimuli are delivered to the sensory hair cells. The three semicircular canals thus detect angular accelerations during tilting or turning movements of the head in all three different planes of three-dimensional space.

## Microstructure of the vestibular system

The maculae and crests detect the orientation of the head with respect to gravity and changes in head movement by means of the mechanosensitive hair cells. These hair cells are in synaptic contact with afferent and efferent endings of the vestibular nerve on their basolateral aspect. The entire epithelium lies on a bed of thick, fibrous connective tissue containing myelinated vestibular nerve fibres and blood vessels. The axons lose their myelin sheaths as they perforate the basal lamina of the sensory epithelium. There are two types of sensory hair cell in the vestibular system, type I and type II (see Figs 38.5, 38.8).

Type I vestibular sensory cells measure $25 \mu \mathrm{~m}$ in length, with a free surface of $6-7 \mu \mathrm{~m}$ in diameter. The basal part of the cell does not reach the basal lamina of the epithelium. Each cell is typically bottle-shaped, with a narrow neck and a rather broad, rounded basal portion containing the nucleus (see Fig. 38.5). The apical surface is characterized by 30-50 stereocilia (large, regularly arranged, modified microvilli about $0.25 \mu \mathrm{~m}$ across) and a single kinocilium (with the typical ' $9+2^{\prime}$ arrangement of microtubules characteristic of true cilia). The kinocilium is considerably longer than the stereocilia, and may attain $40 \mu \mathrm{~m}$, whereas the stereocilia are of graded lengths. They are characteristically arranged in regular rows behind the kinocilium in descending order of height, the longest being next to the kinocilium (Fig. 38.7). The kinocilium emerges basally from a typical basal body, with a centriole immediately beneath it.

Fig. 38.7 A scanning electron micrograph of a stereociliary bundle from the utricle (guinea pig). The stereocilia are arranged in rows of increasing height
towards the tallest element, the kinocilium. Deflection in the direction of the kinocilium results in depolarization of the hair cell. The inset shows a tip link connecting a short stereocilium tip to the tall stereocilium side behind. (Courtesy of DN Furness, The Institute of Science and Technology in Medicine, School of Life Sciences, Keele University.)

Close to the inner surface of their basal two-thirds, every cell contains numerous synaptic ribbons with associated synaptic vesicles. The postsynaptic surface of an afferent nerve ending encloses the greater part of the sensory cell body in the form of a cup (chalice or calyx). Efferent nerve fibres make synapses with the external surface of the calyx, rather than directly with the sensory cell.

The kinocilium confers structural polarity on the bundle, which relates to functional polarity. The stereocilia and kinocilium are all interconnected by fine extracellular filaments of various types, called cross links. One in particular, the tip link, connects the shorter stereocilia in each row with adjacent stereocilia in the taller row next to it (see Fig. 38.7). The tip link is common to all types of hair cell and is thought to play a central role in transduction; mutations in the proteins that comprise the tip link are significant in Usher syndrome, which is characterized by auditory and visual abnormalities. Deflection of the bundle towards the kinocilium results in depolarization of the hair cell and increases the rate of neurotransmitter release from its base. Deflection away from the kinocilium hyperpolarizes the hair cell and reduces the release of neurotransmitter. How deflections produce these responses will be considered in more detail later.

There is much greater variation in the sizes of type II sensory cells (see Fig. 38.5B,C; Fig. 38.8). Some are up to $45 \mu \mathrm{~m}$ long and almost span the entire thickness of the sensory epithelium, whereas others are shorter than type I cells. They are mostly cylindrical, but otherwise resemble type I cells in their contents and the presence of an apical kinocilium and stereocilia. However, their kinocilia and stereocilia tend to be shorter and less variable in length. The most striking difference between type I and II cells is their efferent nerve terminals: type II cells receive several efferent nerve boutons containing a mixture of small clear and dense-core vesicles around their bases, and afferent endings are small expansions rather than chalices.

Polarization allows the hair cells to have specific orientations that optimize their function within each sensory organ. In the maculae, they are arranged symmetrically on either side of the striola. In the utricle, the kinocilia are positioned on the side of the sensory cell nearest to the striola so that the excitatory direction is towards the midline. In the saccule, the structural and functional polarity is the opposite, i.e. away from it. In the ampullary crests, the cells are orientated with their rows of stereocilia at right angles to the long axis of the semicircular duct. In the lateral crest, the kinocilia are on the side towards the utricle, whereas in the anterior and posterior crests they are away from it. These different arrangements are important functionally because any given acceleration

Fig. 38.8 Human vestibular hair cells (transmission electron micrographs). A, Type I cell (VR) bearing an apical group of stereocilia (ST) seen in a vertical section through the macula. Note that the hair cell is bottle-shaped, and that much of it is enclosed in the calyceal ending (C) of an afferent nerve terminal. Other abbreviations: SC, supporting cells. B, Human type II vestibular hair cell. A bouton-type afferent nerve terminal is in contact with the basal part. (Courtesy of H Felix, M Gleeson and L-G Johnsson, ENT Department, University of Zurich and GKT School of Medicine, London.)
of the head maximally depolarizes one group of hair cells and maximally inhibits a complementary set, thus providing a unique representation of the magnitude and orientation of any movement (for further details, see Furness (2002)).

The type I and II sensory cells are set within a matrix of supporting cells that reach from the base of the epithelium to its surface and form rosettes round the sensory cells, as seen in surface view. Although their form is irregular, they can easily be recognized by the position of their nuclei, which tend to lie below the level of sensory cell nuclei and just above the basal lamina (see Fig. 38.4). The apices of the supporting cells are attached by tight junctions to neighbouring supporting cells and to the hair cells to produce the reticular lamina, a composite layer that forms a plate that is relatively impermeable to cations other than via the mechanosensitive transduction channels of the hair cells.

The otolithic membrane is a layer of extracellular material divided into two strata. The external layer is composed of otoliths or otoconia, which are barrel-shaped crystals of calcium carbonate with angular ends, up to $30 \mu \mathrm{~m}$ long, and heterogeneous in distribution. They are attached to a more basal gelatinous layer into which the stereocilia and kinocilia of the sensory cells are inserted (see Fig. 38.5). The gelatinous material consists largely of glycosaminoglycans associated with fibrous protein.

## Epley's manœuvre

Benign paroxysmal positional vertigo is a condition in which a sensation of rotation with associated nystagmus is induced by adopting a particular position (with the abnormal ear dependent). It is believed that calcium carbonate crystals from the otoliths become freed from the otolithic membrane and, in certain positions, drop into the ampulla of the posterior semicircular canal, possibly becoming adherent to the cupula and rendering it gravity-sensitive. In certain positions, the alignment of the axis of the posterior semicircular canal with gravity results in the displacement of the cupula and the activation of the vestibuloocular reflex, leading to compensatory nystagmoid eye movements in response to apparent head movements.

Epley's canalith repositioning procedure relies on the adoption of a series of body postures designed to allow the aberrant crystals (or canaliths) to float out of the posterior semicircular canal and to stick to the wall of the vestibule. Cure rates in excess of $80 \%$ have been recorded and the procedures have largely superseded surgical procedures designed to denervate the ampulla of the posterior semicircular canal (singular neurectomy) or obliterate the canal completely.

## Endolymphatic duct and sac

The endolymphatic duct runs in the osseous vestibular aqueduct and becomes dilated distally to form the endolymphatic sac. This is a structure of variable size, which may extend through an aperture on the posterior surface of the petrous bone to end between the two layers of the dura on the posterior surface of the petrous temporal bone near the sigmoid sinus (see Fig. 38.1C). The surface cells throughout the entire endolymphatic duct resemble those lining the non-specialized parts of the membranous labyrinth and consist of squamous or low cuboidal
epithelium. The epithelial lining and subepithelial connective tissue become more complex where the duct dilates to form the endolymphatic sac. An intermediate or rugose segment and a distal sac can be distinguished. In the intermediate segment, the epithelium consists of light and dark cylindrical cells. Light cells are regular in form and have numerous long surface microvilli with endocytic invaginations between them and large clear vesicles in their apical region. In contrast, dark cells are wedge-shaped and have a narrow base, few apical microvilli and dense, fibrillar cytoplasm.

The endolymphatic sac has important roles in the maintenance of vestibular function. Endolymph produced elsewhere in the labyrinth is absorbed in this region, probably mainly by the light cells. Damage to the sac, or blockage of its connection to the rest of the labyrinth, causes endolymph to accumulate; this produces hydrops, which affects both vestibular and cochlear function. The epithelium is also permeable to leukocytes, including macrophages, which can remove cellular debris from the endolymph, and to various cells of the immune system that contribute antibodies to this fluid.

## COCHLEAR DUCT

The cochlear duct is a spiral tube that runs within the bony cochlea (see Figs 38.1C, Fig. 38.9). The osseous spiral lamina projects for part of the distance between the modiolus and the outer wall of the cochlea and is attached to the inner edge of the basilar membrane. Above it is a thickened ridge of endosteum called the spiral limbus. The endosteum of the outer wall is thickened to form a spiral cochlear ligament that projects inwards as a triangular basilar crest attached to the outer rim of the basilar membrane. Immediately above this is a concavity, the external spiral sulcus (sulcus spiralis externus), above which the thick, highly vascular periosteum projects as a spiral prominence. Above the prominence is a specialized, thick epithelial layer, the stria vascularis. A second, thinner vestibular membrane, Reissner's membrane, extends from the spiral limbus to the outer wall of the cochlea, where it is attached above the stria. Reissner's membrane consists of two layers of squamous epithelial cells separated by a basal lamina. The side facing the scala vestibuli bears flattened perilymphatic cells, with tight junctions between them, creating a diffusion barrier. The endolymphatic side is lined by squamous epithelial cells with many microvilli; these are also joined by tight junctions and are involved in ion transport. The canal thus enclosed between the scala tympani and the scala vestibuli is the cochlear duct (see Fig. 38.9B). It is triangular in cross-section throughout the length of the cochlea. The closed upper end, the lagena, is attached to the cupula. The lower end of the duct turns medially, narrowing into the ductus reuniens, and connects with the saccule (see Fig. 38.1C).

The organ of Corti, the sensory epithelium of the cochlea, sits on the basilar membrane. The apices of the sensory hair cells and the supporting cells it contains are joined by tight junctions to form the reticular lamina. The diffusion barriers that line the cochlear duct ensure that the apices of the sensory hair cells are bathed in endolymph, whereas their lateral and basal regions are bathed in perilymph.

Fig. 38.9 The cochlea. A, A horizontal section through the left temporal bone showing the position of the cochlea with respect to the tympanic cavity. $\mathbf{B}$, A section through the second turn of the cochlea seen in $\mathbf{A}$. The modiolus is to the left. $\mathbf{C}$, The structure of the cochlear organ of Corti and stria vascularis, showing the arrangement of the various types of cell and their overall innervation. The organization of the inner and outer hair cells and their synaptic connections are also depicted. $\mathbf{A}$ and $\mathbf{B}$ are drawn from histological sections.

The stria vascularis lies on the outer wall of the cochlear duct, above the spiral eminence (see Fig. 38.9B and C). It has a special stratified epithelium containing a dense intraepithelial capillary plexus and three cell types: superficial marginal, dark or chromophil cells; intermediate light, or chromophobe cells; and basal cells. The endolymphatic surface consists only of the apices of marginal cells. The intermediate and basal cells lie deeper within the stria and send cytoplasmic processes towards the surface, between the deeper parts of the marginal cells. The long
descending cytoplasmic processes of the marginal dark cells and the ascending processes of the intermediate and basal cells envelop the intraepithelial capillaries. The stria vascularis is involved in ion transport and helps to produce the unusual ionic composition of endolymph. It is the source of the large positive endocochlear electrical potential, maintenance of which is directly dependent on adequate oxygenation of the epithelial cells, provided by the intraepithelial capillary plexus.

The spiral ligament is lateral to the stria vascularis. It is composed of thick collagenous fibres interspersed with fibrocytic cells of several different types, and root cells that send large processes into the ligament from the region of the basilar crest. The fibrocytes and the root cells express connexins and have gap junctional systems (Jagger et al 2010) that allow transcellular transport of ions, although the two types of cell are not directly coupled. It is thought that potassium recycling from perilymph to endolymph is mediated partly through these gap junctional networks emanating from the Deiters' cells underlying the sensory hair cells. Late-onset hearing loss (DFN3) is thought to be the result of fibrocyte degeneration (Minowa et al 1999).

The osseous spiral lamina consists of two plates of bone between which are canals for the cochlear nerve fibres. On the upper plate, the periosteum is thickened to form the spiral limbus (limbus laminae spiralis) (see Fig. 38.9B). It ends externally in the internal spiral sulcus, which in section is shaped like a C. Its upper part, the overhanging limbic edge, is the vestibular labium, and the lower tapering part is the tympanic labium, which is perforated by small holes (the habenula perforata) for branches of the cochlear nerve. The upper surface of the vestibular labium is crossed at right angles by furrows, separated by numerous elevations - the auditory teeth (dentes acustici). The limbus is covered by a layer that appears superficially to be squamous epithelium; however, only the cells over the 'teeth' are flat, and those in the furrows are flask-shaped interdental cells. The epithelium is continuous with the epithelium in the internal spiral sulcus and on the inferior surface of Reissner's membrane. During development, the interdental cells secrete some of the material that forms the tectorial membrane. The limbus contains fibrocytic cells interspersed with extracellular matrix.

## Basilar membrane

The basilar membrane stretches from the tympanic lip of the osseous spiral lamina to the basilar crest of the spiral ligament (see Fig. 38.9B and C). It consists of two zones. The thin zona arcuata stretches from the spiral limbus to the bases of the outer pillar cells and supports the organ of Corti. It is composed of compact bundles of small ( $8-10 \mathrm{~nm}$ diameter) collagenous filaments, mainly radial in orientation. The outer, thicker zona pectinata starts beneath the bases of the outer pillar cells and is attached to the crista basilaris. The basilar membrane is trilaminar in the zona pectinata, but the upper and lower layers fuse at its attachment to the crista basilaris. The length of the basilar membrane is 35 mm ; its width increases from 0.21 mm basally to 0.36 mm at its apex, accompanied by corresponding narrowing of the osseous spiral lamina and a decrease in the thickness of the basilar crest. The lower or tympanic surface of the basilar membrane is covered by a layer of vascular connective tissue and elongated perilymphatic cells. One vessel, the spiral vessel (vas spirale), is larger; it lies immediately below the tunnel of Corti.

## Organ of Corti

The organ of Corti consists of a series of epithelial structures that lie on the zona arcuata of the basilar membrane (see Fig. 38.9B and C). The more central of these structures are two rows of cells: the internal (inner) and external (outer) pillar cells. The bases of the pillar cells are expanded, and rest contiguously on the basilar membrane, but their rod-like cell bodies are widely separated. The two rows incline towards each other and come into contact again at the heads of the pillars, enclosing between them and the basilar membrane the tunnel of Corti, which has a triangular cross-section (see Fig. 38.9C). Internal to the inner pillar cells is a single row of inner hair cells. External to the outer pillar cells are three or four rows of outer hair cells. The bases of the outer hair cells are cupped by supporting cells called outer phalangeal (Deiters') cells, except for a gap where cochlear axons synapse with them. The apical ends of the hair cells and apical processes of the supporting cells form a regular mosaic called the reticular lamina, which is covered by the tectorial membrane, a gel-like structure projecting from the spiral limbus. The reticular lamina is impervious to ions and thus maintains the electrochemical gradient between the fluids surrounding the apices and the basolateral membranes of the sensory hair cells. A narrow gap separates the tectorial membrane from the reticular lamina except where the apical stereocilia of the outer hair cells project to make contact with it.

In addition to the tunnel of Corti, other intercommunicating spaces, the spaces of Nuel, surround the outer hair cells. This entire intercommunicating complex of spaces of Nuel and tunnel of Corti is filled with perilymph, which diffuses through the matrix of the basilar membrane. The fluid in these spaces is also sometimes called the cortilymph; it is possible that minor alterations in perilymphatic composition occur within it because it is exposed to the activities of synaptic endings and specialized excitable cells.

Each pillar cell has a base or crus, an elongated scapus (rod) and an upper end or caput (head) (see Fig. 38.9C); each crus and caput are in contact, but the scapi are separated by the tunnel of Corti. Electron microscopy shows many microtubules, 30 nm in diameter, arranged in linked parallel bundles of 2000 or more in the scapus, originating in the crus and diverging above the scapus to terminate in the head region. The nucleus is situated in the foot-like expansion resting on the basal lamina.

There are almost 6000 inner pillar cells. Their bases rest on the basilar membrane near the tympanic lip of the internal spiral sulcus, and their bodies form an angle of approximately $60^{\circ}$ with the basilar membrane. Their heads resemble the proximal end of the ulna, with deep concavities for the heads of the outer pillar cells, which they overhang to form the top of the tunnel of Corti. There are almost 4000 outer pillar cells. They are longer and more oblique than the inner pillar cells, and form an angle of approximately $40^{\circ}$ with the basilar membrane. Their heads fit into the concavities on the heads of the inner pillar cells and project externally between the first row of outer hair cells as thin processes that contact the processes of the Deiters' cells. The distances between the bases of the inner and outer pillar cells increase from the cochlear base to its apex, whereas the angles they make with the basilar membrane diminish.

Cochlear hair cells are the sensory transducers of the cochlea; collectively, they detect the amplitude and frequency of the sound waves that enter the cochlea. All cochlear hair cells have a common pattern of organization. They are elongated cells with a group of modified apical microvilli or stereocilia (which contain parallel arrays of actin filaments), similar to those of vestibular hair cells, and a group of synaptic contacts with cochlear nerve fibres at their rounded bases (Fig. 38.10). The inner hair cells form a single row along the inner edge of

Fig. 38.10 Scanning electron micrographs of the surface of the organ of Corti (guinea pig). A, The reticular lamina. Three rows of V-shaped stereociliary bundles can be seen protruding from the apices of the outer hair cells. They are separated from the single row of inner hair cells (which have relatively linear stereociliary bundles) by the apices of the inner pillar cells. B, The stereociliary bundle of one outer hair cell, showing three rows of stereocilia increasing in height; deflection of the stereocilia in the direction of the tallest row results in depolarization of the hair cell. Microvilli can be seen on the surface of Deiters' cells (front right). The inset shows a tip link connecting a short stereocilium tip to the side of the tall stereocilium behind. (Courtesy of DN Furness, The Institute of Science and Technology in Medicine, School of Life Sciences, Keele University.)
inner pillar cells (and the spiral tunnel), whereas the outer hair cells are arranged in three or, in some regions of the human cochlea, in four or even five rows, interspersed with supporting cells (see Fig. 38.10A). These two groups have distinctive roles in sound reception; the differences in their detailed structure reflect this functional divergence. There are 3500 inner hair cells and 12,000 outer hair cells. The two sets of hair cells lean towards each other apically at about the same angles as the neighbouring inner and outer pillar cells. The geometric arrangement of these cells is very precise, and this pattern is closely related to the sensory performance of the cochlea.

The inner hair cells are pear-shaped and slightly curved; the narrower end is directed towards the surface of the organ of Corti and the wider basal end is positioned some distance above the inner end of the basilar membrane (see Fig. 38.9C). The inner hair cells are surrounded by inner border cells and by inner phalangeal cells, which are attached externally to the heads of the inner pillar cells. The flat apical surface of each inner hair cell is elliptical when viewed from above, its long axis directed in the direction of the row of hair cells (see Fig. 38.10A). The breadth of the apex exceeds that of the inner pillar cells so that each inner hair cell is related to more than one inner pillar cell. The apex bears 50-60 stereocilia, arranged in several ranks of progressively ascending height, the tallest on the strial side. The tips of the shorter rows are connected diagonally to the sides of the adjacent taller stereocilia by thin filaments called tip links; each stereocilium is also connected to all its neighbours by a variety of lateral links. The height of a stereociliary row varies along the length of the cochlea, being tallest at the apex and shortest at its base. The stereociliary bases insert into a transverse lamina of dense fibrillar material, the cuticular plate, which lies immediately beneath the apical surface of each inner hair cell. The cuticular plate includes a small aperture containing a basal body. During development, a kinocilium containing microtubules is anchored here, a condition that persists in vestibular hair cells.

At its base, each inner hair cell forms 10 or more synaptic contacts with afferent endings, each being marked by a presynaptic structure similar to the ribbon synapses of the retina. Occasionally, an efferent synapse makes direct contact with a hair cell base but these are usually presynaptic to the terminal expansions of afferent endings, rather than to the hair cell itself.

Outer hair cells are long cylindrical cells that are nearly twice as tall as the inner hair cells (see Figs 38.9C, 38.10A). There is a gradation of length: the outermost row is longest in any one cochlear region, and those of the cochlear apex are taller than those of the base. They are surrounded by the apical or phalangeal processes of the Deiters' cells or, on the internal side of the inner row, by the heads of the outer pillar cells. The stereocilia, which may number up to 100 per cell, are arranged in three rows of graded heights; the tallest is on the outer side. The rows are arranged in the form of a V or W , depending on cochlear region, the points of the angles directed externally. The stereocilia are also graded in height according to cochlear region; those of the cochlear base are shortest. Like those of inner hair cells, the stereocilia possess tip links (see Fig. 38.10B) and other filamentous connections with their neighbours, and are inserted at their narrow bases into a cuticular plate. The tallest stereocilia are embedded in shallow impressions on the underside of the tectorial membrane.

The rounded nucleus is positioned near the base of the cell. Below the nucleus are a few ribbon-like synapses associated with afferent endings of the cochlear nerve. The latter are fewer in number and smaller than the cluster of efferent boutons that contact the base of the cell. The neurotransmitter at the afferent synapse in both inner and outer hair cells is glutamate whereas that of the efferent endings is acetylcholine, although other neurotransmitters or neuromodulators have been demonstrated.

Cochlear hair cells respond with phenomenal speed and sensitivity to sound vibrations that cause submicron deflections of their stereociliary hair bundles. Outer hair cells not only detect these vibrations but also generate force to increase auditory sensitivity and frequency discrimination. (See Fettiplace and Hackney (2006) for further details about the sensory and motor functions of auditory hair cells.)

Deiters' or phalangeal cells lie between the rows of outer hair cells. Their expanded bases lie on the basilar membrane and their apical ends partially envelop the bases of the outer hair cells (see Fig. 38.9C; Fig. 38.11). Each has a finger-like (phalangeal) process that extends diagonally upwards between the hair cells to the reticular membrane, where it forms a plate-like expansion that fills the gaps between hair cell apices.

Five or six rows of columnar supporting cells or external limiting cells, such as Hensen's cells and Claudius' cells, lie external to the Deiters' cells (see Fig. 38.9C).

Fig. 38.11 A scanning electron micrograph of a portion of the organ of Corti (guinea pig), dissected to expose the outer row of outer hair cells and their attendant Deiters' cells with narrow phalangeal processes. The stereociliary bundles of two rows of outer hair cells are visible above the reticular lamina. (Courtesy of DN Furness, The Institute of Science and Technology in Medicine, School of Life Sciences, Keele University.)

The apices of the hair cells and supporting cells that form the reticular lamina are linked by tight junctions, adherens junctions and desmosomes. This arrangement is significant for two reasons. The reticular lamina creates a highly impermeable barrier to the passage of ions other than via the mechanotransducer channels in the stereociliary membranes. It also forms a rigid support between the apices of the hair cells, coupling them mechanically to the movements of the underlying basilar membrane, which causes lateral shearing movements between the stereocilia and the overlying tectorial membrane. If there is hair cell loss as a result of trauma such as excessive noise or ototoxic drugs, the supporting cells expand rapidly to fill the gap, disturbing the regular pattern of the reticular lamina (phalangeal scars) but restoring its function.

## Hair cell mechanotransduction

Mechanotransduction is central to both hearing and balance, and is a phenomenon that is shared by all the sensory hair cells of vestibular and auditory epithelia. The basic mechanism is the same in all of the different types of hair cell and is dependent on common features of the hair bundle: specifically, the 'staircase' array of stereocilia and the tip links connecting the tips of shorter and adjacent taller stereocilia. Deflections of the bundle in an excitatory (depolarizing) direction cause tension in the tip link, which acts to open non-specific cationic mechanoelectrical transduction channels. These then allow influx of potassium and calcium ions, depolarizing the cell and leading to calcium influx through basolateral voltage-gated calcium channels, which causes release of neurotransmitter. The hair cells also have basolateral potassium channels that allow efflux of potassium into perilymph. The tip link that is central to this process consists of two molecules of cadherin 23 and two molecules of protocadherin 15, forming a strong twisted strand (Hackney and Furness 2013). The importance of this structure is emphasized by the fact that mutations in these cadherins underlie deafblindness conditions (Usher syndrome).

The sensitivity of mechanotransduction is greatly increased by the combination of the hair-cell membrane potential $(-70 \mathrm{mV})$ and the endolymphatic potential $(+80 \mathrm{mV})$, producing an overall driving potential of up to 150 mV . It is therefore vital to maintain a high potassium concentration, despite its depletion from endolymph during detection of acoustic or balance stimuli.

## Tectorial membrane

The tectorial membrane overlies the sulcus spiralis internus and organ of Corti, and is a stiff, gelatinous plate (see Fig. 38.9B and C). It contains collagen types II, V and IX, interspersed with glycoproteins (tectorins), which contribute approximately half of the total protein.

In transverse section, the tectorial membrane has a characteristic shape. The underside is nearly flat and the upper surface is convex, and it is thin on the modiolar side where it is attached to the vestibular labium of the spiral limbus. Its outer part forms a thickened ridge, overhanging the edge of the reticular lamina. The lower surface is relatively smooth, except where the stereocilia of the outer hair cells are
embedded in the membrane, leaving a pattern of W - or V -shaped indentations: an S-shaped ridge called Hensen's stripe, which projects towards the stereocilia of the inner hair cells. The interdental cells of the spiral limbus are believed to secrete the membrane.

## VASCULAR SUPPLY

## ARTERIES

The inner ear is principally supplied by the labyrinthine artery. The stylomastoid branch of either the occipital artery or the posterior auricular artery (see Fig. 29.8) also supplies the semicircular canals.

## Labyrinthine artery

The labyrinthine artery arises from the basilar artery (see Fig. 19.2), or sometimes from the anterior inferior cerebellar artery. It divides at the bottom of the internal acoustic meatus into cochlear and vestibular branches. The cochlear branch divides into 12-14 twigs, which traverse the canals in the modiolus and are distributed as a capillary plexus to the spiral lamina, basilar membrane, stria vascularis and other cochlear structures. Vestibular arterial branches supply the utricle, saccule and semicircular ducts.

## VEINS

Descriptions of the venous drainage of the inner ear are often conflicting, presumably reflecting both normal variation and the existence of connections between the veins that provide the potential for collateral circulation. Veins draining the vestibule and semicircular canals accompany the arteries. They pass towards the utricle to form the vein of the vestibular aqueduct, which empties into either the sigmoid or inferior petrosal sinus. The vein of the cochlear aqueduct (inferior cochlear vein) usually drains into either the inferior petrosal sinus or the superior bulb of the internal jugular vein. It is formed by the union of the common modiolar and vestibulocochlear veins and provides almost all of the venous outflow of the cochlea (Wright and Roland 2013). The common modiolar vein is formed by the union of the anterior and posterior spiral veins near the basal cochlear turn; the vestibulocochlear vein is formed by the confluence of the anterior and posterior vestibular veins and the vein of the round window. When present, a labyrinthine vein drains the apical and middle cochlear coils into either the posterior part of the superior petrosal sinus or the transverse sinus or the inferior petrosal sinus.

For details of the microvasculature of the cochlea of humans and other mammals, see Axelsson (1988).

## INNERVATION

## VESTIBULOCOCHLEAR NERVE

The vestibulocochlear nerve emerges from the cerebellopontine angle (see Figs 21.4, 21.5). It courses through the posterior cranial fossa in close association with the facial nerve, nervus intermedius and labyrinthine vessels. Together with these structures, it enters the petrous temporal bone via the porus acusticus of the internal acoustic meatus, and divides into an anterior trunk, the cochlear nerve, and a posterior trunk, the vestibular nerve (Fig. 38.12A; see Fig. 37.7). Both contain the centrally directed axons of bipolar neurones, together with a smaller number of efferent fibres that arise from brainstem neurones and terminate on cochlear and vestibular sensory cells. In humans, the intratemporal portion of the vestibulocochlear nerve consists of two histologically distinct portions: a central glial zone adjacent to the brainstem, and a peripheral or non-glial zone (Bridger and Farkashidy 1980). In the glial zone, the axons are supported by central neuroglia, whereas in the nonglial zone they are ensheathed by Schwann cells. The non-glial zone sometimes extends into the cerebellopontine angle medial to the internal acoustic meatus in human vestibulocochlear nerves. During development, a gap of several weeks has been reported between the onset of Schwann cell myelination distally and glial myelination proximally; it has been suggested that the gap may coincide with the time of the final maturation of the organ of Corti. (For further details about the development of the human cochlear nerve, see Ray et al (2005).)

In audiological practice, it is important to distinguish between intratemporal and intracranial lesions. However, this surgical distinc-

Fig. 38.12 The vestibulocochlear nerve (human). A, A transverse section. The cochlear nerve (the comma-shaped profile on the left) abuts the inferior division of the vestibular nerve (right). The singular nerve is a separate fascicle between the superior and inferior divisions of the vestibular nerve. B, A portion of a vestibular ganglion, showing neuronal perikarya, myelinated axons and small blood vessels. tion does not correlate with the precise anatomical description of peripheral and central portions of the auditory and vestibular systems. Clinically, the term 'peripheral auditory lesion' is used to describe lesions peripheral to the spiral ganglion, and the term 'peripheral vestibular disturbance' includes lesions of the vestibular ganglion and the entire vestibular nerve.

## Vestibular nerve

The cell bodies of the bipolar neurones that contribute to the vestibular nerve lie in the vestibular ganglion, which is situated in the trunk of the nerve within the lateral end of the internal acoustic meatus (Fig. 38.12B). Their peripheral processes innervate the maculae of the utricle and saccule and the ampullary crests of the semicircular canals (see below). Their axons travel to the central nervous system in the vestibular nerve, which enters the brainstem at the cerebellopontine angle and terminates in the vestibular nuclear complex (see p. 319). Neurones in this complex project to motor nuclei in the brainstem and upper spinal cord, and to the cerebellum and thalamus. Thalamic efferent projections pass to a cortical vestibular area that is probably located near the intraparietal sulcus in area 2 of the primary somatosensory cortex.

## Vestibular (Scarpa's) ganglion

The cell bodies of the neurones in the vestibular ganglion vary considerably in size: their circumferences range from 45 to $160 \mu \mathrm{~m}$ (Felix et al 1987). No topographically ordered distribution relating to size has been found. The cell bodies are notable for their abundant granular endoplasmic reticulum, which in places forms Nissl bodies, and prominent Golgi complexes. They are covered by a thin layer of satellite cells and are often arranged in pairs, closely abutting each other so that only a thin layer of endoneurium separates the adjacent coverings of satellite cells. This arrangement has led to speculation that ganglion cells may
affect each other directly by electrotonic spread (ephaptic transmission: see Felix et al (1987)).

Two distinct sympathetic components have been identified in the vestibular ganglion: a perivascular adrenergic system derived from the stellate ganglion, and a blood vessel-independent system derived from the superior cervical ganglion.

## Intratemporal vestibular nerve

The peripheral processes of the vestibular ganglion cells are aggregated into definable nerves, each with a specific distribution. The main nerve divides at and within the ganglion into superior and inferior divisions, which are connected by an isthmus. The superior division, the larger of the two, passes through the small holes in the superior vestibular area at the fundus of the internal acoustic meatus (see Fig. 38.3) and supplies the ampullary crests of the lateral and anterior semicircular canals via the lateral and anterior ampullary nerves, respectively. A secondary branch of the lateral ampullary nerve supplies the macula of the utricle; however, the greater part of the utricular macula is innervated by the utricular nerve, which is a separate branch of the superior division. Another branch of the superior division, supplies part of the saccule.

The inferior division of the vestibular nerve passes through small holes in the inferior vestibular area (see Fig. 38.3) to supply the remainder of the saccule and the posterior ampullary crest via saccular and singular branches, respectively; the latter passes through the foramen singulare. Occasionally, a very small supplementary or accessory branch innervates the posterior crest; it is probably a vestigial remnant of the crista neglecta, an additional area of sensory epithelium found in some other mammals but seldom in humans.

Afferent and efferent cochlear fibres are also present in the inferior division of the vestibular nerve, but leave at the anastomosis of Oort to join the main cochlear nerve (see review by Warr (1992)). Another anastomosis, the vestibulofacial anastomosis, is situated more centrally between the facial and vestibular nerves, and is the point at which fibres originating in the intermediate nerve pass from the vestibular nerve to the main trunk of the facial nerve.

There are approximately 20,000 fibres in the vestibular nerve, of which 12,000 travel in the superior division and 8000 travel in the inferior division. The distribution of fibre diameters is bimodal, with peaks at $4 \mu \mathrm{~m}$ and $6.5 \mu \mathrm{~m}$. The smaller fibres go mainly to the type II hair cells and the larger fibres tend to supply the type I hair cells. In addition to the afferents, efferent and autonomic fibres have been identified. Efferent fibres synapse exclusively with the afferent calyceal terminals around type I cells and usually with the afferent boutons on type II cells, although a few are in direct contact with the cell bodies of type II cells. The autonomic fibres do not contact vestibular sensory cells but terminate beneath the sensory epithelia.

## Anatomy of balance and posture

The vestibular labyrinths on each side of the head are arranged symmetrically with respect to each other. Vestibular sensory pathways are concerned with perception of the position of the head in space and movement of the head; they also establish important connections for reflex movements that govern the equilibrium of the body and the fixity of gaze.

The vestibular system consists of two otolithic organs - the utricle and the saccule - and three semicircular canals. The otolithic organs detect linear acceleration due to gravitational pull (gravito-inertial acceleration) and the direction of other linear accelerations such as the up-and-down movements of the head that occur in running. They also respond when the head is tilted relative to gravity: so-called pitch (forward and backward tilting) and roll (side-to-side tilting) movements. The semicircular canals detect angular accelerations resulting from rotations of the head or body.

The stereocilia in the apical hair bundles of the mechanosensitive hair cells in each of these organs are embedded in an overlying accessory gel-like structure, the otolithic membrane (in the utricle and the saccule) and the cupula (in the semicircular canals). Their apical surfaces are bathed in endolymph; tight junctional complexes between the apices of the hair cells and their adjacent supporting cells separate the endolymph from the perilymph that bathes their basolateral surfaces. As noted earlier, deflection of the stereocilia (caused by displacements of their overlying accessory membranes by fluid movements in the membranous labyrinth) produces either an increased or a decreased rate of opening of the mechanotransduction channels at their tips, depending on whether they are deflected towards or away from the tallest row, respectively. The change in the membrane potential of the receptor cell is signalled to the brain as a change in the firing frequency
of the vestibular nerve afferents (either an increase or a decrease of the basal resting discharge, depending on the direction of stimulation). The signals are compared centrally with visual and somatosensory signals, which also signal the position of the head in space (for a more detailed account, see Furness (2002)).

## Semicircular canals

Angular acceleration and deceleration of the head cause a counterflow of endolymph in the semicircular canals, which deflects the cupula of each crista and bends the stereociliary/kinociliary bundles. When a steady velocity of head movement is reached, the endolymph rapidly adopts the same velocity as the surrounding structures because of friction with the canal walls, so that the cupula and receptor cells return to their resting state. The three semicircular canals are orientated approximately at right angles to each other, which means that all possible directions of acceleration can be detected. Directional sensitivity to head movement is coded by opposing receptor signals: the left and right semicircular canals of each functional pair (e.g. the left and right anterior canals) respond oppositely to any movement of the head that affects them (Fig. 38.13). Some vestibular neurones receive a bilateral input from vestibular receptors, which means that they can compare the discharge rates of right and left canal afferents, a mechanism that increases the sensitivity of the system.

## Maculae

In the maculae, the weight of the otoconial crystals creates a gravitational pull on the otoconial membrane and thus on the stereociliary bundles of the sensory cells that are inserted into its base. Because of this, they are able to detect the static orientation of the head with respect to gravity. They also detect shifts in position according to the extent to which the stereocilia are deflected. The two maculae are set at right angles to each other, and the cells of both are orientated functionally in opposite directions across their striolar boundaries. Movement causes depolarization of the hair cells on one side of the striola and hyperpolarization of cells on the other side; because the striola is curved, small groups of hair cells on the macular epithelium each respond to a specific direction of head tilt or linear acceleration (Fig. 38.14). Moreover, because the otoconia have a collective inertia/ momentum, linear acceleration and deceleration along the anteroposterior axis can be detected by the lag or overshoot of the otoconial membrane with respect to the epithelial surface, and so the saccular macula is able to signal these changes of velocity.

The macular receptors can also be stimulated by low-frequency sound, which sets up vibratory movements in the otoconial membrane, although this appears to require relatively high sound levels. Efferent synapses on the afferent endings of the type I sensory cells and on the bases of type II cells receive inputs from the brainstem that appear to be inhibitory. They serve to reduce the activity of the afferent fibres either indirectly, in the case of the type I cells, or directly, for the type II cells.

## Visual reflexes

The vestibular system plays a major role in the control of visual reflexes, which allow the fixation of gaze on an object in spite of movements of the head, and require the coordinated movements of the eye, neck and upper trunk. Constant adjustments of the visual axes are achieved chiefly through the medial longitudinal fasciculus, which connects the vestibular nuclear complex with neurones in the oculomotor, trochlear and abducens nuclei and with upper spinal motor neurones (Fig. 38.15; see Fig. 41.12), and also by the vestibulospinal tracts. See page 347 and Fig. 22.24 for further information about the vestibulo-ocular reflex.

Abnormal activity of the vestibular input or central connections has various effects on these reflexes, e.g. the production of nystagmus. This can be elicited by the caloric test, a clinical test of vestibular function, by syringing the external acoustic meatus with water above or below body temperature, a procedure that appears to stimulate the cristae of the lateral semicircular canal directly. Spontaneous high activity in the afferent fibres of the vestibular nerve is seen in Ménière's disease, in which those affected experience a range of disturbances, including the sensation of dizziness and nausea, the latter reflecting the vestibular input to the vagal reflex pathway.

## Cochlear nerve

## Intratemporal cochlear nerve

The cochlear nerve connects the organ of Corti to the cochlear nuclei and related nuclei of the brainstem. The cochlear nerve lies inferior to the facial nerve throughout the internal acoustic meatus (see above). It

Fig. 38.13 The response of the lateral semicircular canals to head rotation in the horizontal plane. The firing rates of afferents from the left and right lateral canals are equivalent at rest (A). However, when the head is turned to the right (B) or to the left (C), receptor depolarization and afferent fibre excitation occurs on the side to which the head turns; there is inhibition on the contralateral side.
becomes intimately associated with the superior and inferior divisions of the vestibular nerve, which are situated in the posterior compartment of the canal, and leaves the internal acoustic meatus in a common fascicle (see Fig. 38.12A).

There are 30-40,000 nerve fibres in the human cochlear nerve (for review, see Nadol (1988)). Their fibre diameter distribution is unimodal, and ranges from 1 to $11 \mu \mathrm{~m}$, with a peak at $4-5 \mu \mathrm{~m}$. Functionally, the nerve contains both afferent and efferent somatic fibres, together
with adrenergic postganglionic sympathetic fibres from the cervical sympathetic system.

## Afferent cochlear innervation

The afferent fibres are myelinated axons with bipolar cell bodies that lie in the spiral ganglion in the modiolus (see Fig. 38.9B; Fig. 38.16). There are two types of ganglion cell: most (90-95\%) are large type I cells, while the remainder are smaller type II cells (see review by Nadol (1988)). Type I cells contain a prominent spherical nucleus, abundant ribosomes and many mitochondria; in many mammals (although possibly not in humans), they are surrounded by myelin sheaths. In contrast, type II cells are smaller and always unmyelinated, and have a lobulated nucleus. The cytoplasm of type II cells is enriched with neurofilaments but has fewer mitochondria and ribosomes than type I cells.

Basilar fibres Basilar fibres are the peripheral processes of type II ganglion cells and are afferent to the outer hair cells. They take an independent spiral course, turning towards the cochlear apex near the bases of the inner hair cells. They run for a distance of about five pillar cells before turning radially again and crossing the floor of the tunnel of Corti, often diagonally, to form part of the outer spiral bundle.

Outer spiral bundles The afferent fibres of the bundles of the outer spiral group course towards the basal part of the cochlea, continually branching off en route to supply several outer hair cells. The outer spiral bundles also contain efferent fibres (see below).

## Efferent cochlear fibres

The efferent nerve fibres in the cochlear nerve are derived from the olivocochlear system (see reviews by Warr (1992), Guinan (1996)). Within the modiolus, the efferent fibres form the intraganglionic spiral bundle, which may be one or more discrete groups of fibres situated at the periphery of the spiral ganglion (Fig. 38.17). There are two main groups of olivocochlear efferents: lateral and medial. The lateral efferents come from small neurones in and near the lateral superior olivary nucleus and arise mainly, but not exclusively, ipsilaterally. They are organized into inner spiral fibres that run in the inner spiral bundle before terminating on the afferent axons that supply the inner hair cells. The medial efferents originate from larger neurones in the vicinity of the medial superior olivary nucleus, and the majority arise contralaterally. They are myelinated and cross the tunnel of Corti to synapse with the outer hair cells mainly by direct contact with their bases, although a few synapse with the afferent terminals. The efferent innervation of the outer hair cells decreases along the organ of Corti from cochlear base to apex, and from the first (inner) row to the third. The efferents use acetylcholine, $\gamma$-aminobutyric acid (GABA) or both as their neurotransmitter. They may also contain other neurotransmitters and neuromodulators.

Activity of the medial efferents inhibits cochlear responses to sound; the strength of the activity grows slowly with increasing sound level. They are believed to modulate the micromechanics of the cochlea by altering the mechanical responses of the outer hair cells, thus changing their contribution to frequency selectivity and sensitivity. The lateral efferents related to the inner hair cells also respond to sound. They make contacts most commonly with the inner radial afferent fibres rather than the inner hair cell base (see Fig. 38.9C) and appear to modify transmission through the afferents. The cholinergic fibres may excite the radial fibres, while those containing GABA may inhibit them, although their role is less well understood than that of the medial efferents (see review by Guinan (1996)).

## Autonomic cochlear innervation

Autonomic nerve endings appear to be entirely sympathetic. Two adrenergic systems have been described within the cochlea: a perivascular plexus derived from the stellate ganglion and a blood vessel-independent system derived from the superior cervical ganglion. Both systems travel with the afferent and efferent cochlear fibres and seem to be restricted to regions away from the organ of Corti. The sympathetic nervous system may cause primary and secondary effects in the cochlea by remotely altering the metabolism of various cell types and by influencing the blood vessels and nerve fibres with which it makes contact.

## Anatomy of hearing

Sound waves entering the external ear are converted into electrical signals in the cochlear nerve by the peripheral auditory system (Fig. 38.18). The axons in the cochlear nerve constitute the auditory component of the vestibulocochlear nerve and terminate in the dorsal

Fig. 38.14 Head tilt is encoded by a macular map of directional space. These diagrams depict the responses of the utricular maculae to head tilt. Firing rates in the vestibular afferents that innervate receptors on either side of the striola (red and green lines) are equivalent when the head is upright (A). When the head is tilted to the right (B) or to the left (C), the stereocilia are deflected by displaced otoconia; hair cells on the upward slope side of the striola increase their firing rate, while those on the downward slope decrease their firing rate.
and ventral cochlear nuclei (see p. 319); onward connections make up the ascending (central) auditory pathway.

## Peripheral auditory system

Vibrations in the air column in the external acoustic meatus cause a comparable set of vibrations in the tympanic membrane and auditory ossicles. The chain of ossicles acts as a lever that increases the force per unit area at the round window by 1.2 times while the reduction in size of the round window compared with the tympanic membrane increases the force per unit area of the oscillating surface a further 17 times. This overcomes the inertia of the cochlear fluids and produces in them pressure waves that are conducted almost instantaneously to all parts of the basilar membrane. The latter varies continuously in width, mass and stiffness from the basal to the apical end of the cochlea. Each part of the basilar membrane vibrates, but only the region tuned to a specific frequency will respond maximally to a pure tone entering the ear. A wave of mechanical motion, the travelling wave, is propagated along the basilar membrane to the position where it responds maximally and then dies away again. With increasing frequency, the locus of maximum amplitude moves progressively from the apical to the basal end of the cochlea. The pattern of vibrations in the basilar membrane thus varies with the intensity and frequency of the acoustic waves reaching the perilymph. Because of the arrangement of the hair cells on the basilar membrane, these oscillations generate a largely transverse shearing force between the outer hair cells and the overlying tectorial membrane (in which the apices of the hair cell stereocilia are embedded). This movement depends on the mechanical properties of the entire organ of Corti, including its cytoskeleton, which stiffens this structure. The inner hair cell stereocilia, which probably do not touch the tectorial membrane, although they come very close to it, are likely to be stimulated by local movements of the endolymph. Displacement of the stereociliary bundle of a hair cell activates mechanoelectrical transduc-
tion channels near the tips of its stereocilia, and this allows potassium and calcium ions from the endolymph to enter the hair cell (see earlier and overview by Fettiplace and Hackney (2006)). This induces a depolarizing receptor potential and the release of neurotransmitter on to the cochlear afferents at the base of the cell. In this way, a specific group of auditory axons is activated at the position of maximal basilar membrane vibration.

The mechanical behaviour of the basilar membrane is responsible for a broad discrimination between different frequencies (passive tuning; see overview by Ashmore (2002)), but fine frequency discrimination in the cochlea appears to be related to physiological differences between the hair cells. Individual tuning of hair cells may result from differences in shape, stereociliary length, or possibly variations in the molecular composition of sensory membranes, and may have a role in cochlear amplification (active tuning).

The activity of the outer hair cells appears to play an important part in regulating inner hair-cell sensitivity at specific frequencies. Outer hair cells can change length when stimulated electrically at frequencies of many thousands of cycles per second. The rapidity of these changes in length indicates a novel type of motile mechanism, which is believed to depend on conformational changes in prestin, a protein that displays piezoelectricity and is located in the plasma membrane of the cells (Fettiplace and Hackney 2006, Hudspeth 2014) (Fig. 38.19). When the membrane potential of the outer hair cells changes, they generate forces along their axes. When the mechanoelectrical transduction channels open, they are thought to oppose the viscous forces that tend to damp down the vibration of the cochlear partition, and adjust the mechanics of the organ of Corti on a cycle-bycycle basis. Alternatively, they may alter the mechanics of the partition more slowly under the influence of the efferent pathway. At a particular frequency, an increase in the intensity of stimulus is signalled by an increase in the rate of discharge in individual cochlear axons. At greater

Fig. 38.17 A simplified view of the innervation of the organ of Corti. Note the contrast between the convergent afferent innervation of the inner hair cells (approximately 10 fibres to each cell) and the divergent supply of the outer hair cells (1 afferent fibre to 10 cells).

Fig. 38.18 The principal activities of the peripheral auditory apparatus. For clarity, the cochlea is depicted as though it had been uncoiled, but it is normally coiled as in the inset. Different sound frequencies differentially excite different regions of the cochlea, the specific locations being given in kHz from 0.1 to 20 kHz in humans. Note that the frequency map is logarithmic, so that each decade occupies an equivalent distance on the basilar membrane. The components are drawn roughly to scale for the human ear, in which the cochlea is 35 mm in length. The points of maximal stimulation of the basilar membrane by high-frequency and low-frequency vibrations, together with their transmission pathways through the external and middle ear, are also indicated.
intensities, it is signalled by the number of activated cochlear axons (recruitment)

The respective roles of the two groups of hair cells have been much debated, particularly since differences in their innervation and physiological behaviour have become apparent. Because of their rich afferent supply, inner hair cells are believed to be the major source of auditory signals in the cochlear nerve. Some evidence for this view is based on the finding that animals treated with antibiotics that are specifically toxic to outer hair cells are still able to hear, but their sensitivity and frequency discrimination is impaired

Some electrical responses of the cochlea can be recorded with extracellular electrodes. The most significant is the endolymphatic potential, a steady potential recordable between the cochlear duct and the scala tympani, which is caused by the different ionic compositions of their fluids. As the resting potential of hair cells is approximately 70 mV (negative inside) and the endolymphatic potential is positive in the cochlear duct, the total transmembrane potential across the apices of hair cells is 150 mV . This is a greater resting potential than is found anywhere else in the body, and provides the driving force for mechanotransduction and for the cochlear amplifier.

Under stimulation by sound, a rapid oscillatory cochlear microphonic potential can be recorded. It matches the frequency of the stimulus and movements of the basilar membrane precisely, and appears to depend on fluctuations in the conductance of hair cell membranes, probably of the outer hair cells. At the same time, an extracellular summating potential develops, a steady direct current shift related to the (intracellular) receptor potentials of the hair cells. Cochlear nerve fibres then begin to respond with action potentials that are also recordable from the cochlea. Intracellular recording of auditory responses from inner hair cells has confirmed that these cells resemble other
receptors; their steady receptor potentials are related in size to the amplitude of the acoustic stimulus. At the same time, afferent axons are stimulated by synaptic action at the bases of the inner hair cells. They fire more rapidly as the vibration of the basilar membrane increases in amplitude, up to a threshold that depends on the sensitivity of the specific nerve fibre involved. Each inner hair cell is contacted by axons with response thresholds that range from 0 decibels sound pressure level (dBSPL), the approximate threshold of human hearing, to those that respond to intensities in excess of 100 dBSPL ; the loudest sound tolerable is around 120 dBSPL. Each axon responds most sensitively to the frequency represented by its particular cochlear location, its characteristic frequency (see Fig. 38.18).

## Central auditory pathway

The primary afferents of the auditory pathway arise from cell bodies in the spiral ganglion of the cochlea. The axons travel in the vestibulocochlear nerve, which enters the brainstem at the cerebellopontine angle. Afferent fibres bifurcate, and terminate in the dorsal and ventral cochlear nuclei (Fig. 38.20, see p. 319). The dorsal cochlear nucleus projects via the dorsal acoustic stria to the contralateral inferior colliculus. The ventral cochlear nucleus projects via the trapezoid body or the intermediate acoustic stria to relay centres in either the superior olivary complex, the nuclei of the lateral lemniscus, or the inferior colliculus. The superior olivary complex is dominated by the medial superior olivary nucleus, which receives direct input from the ventral cochlear nucleus on both sides, and is involved in localization of sound by measuring the time difference between afferent impulses arriving from the two ears.

The inferior colliculus consists of a central nucleus and two cortical areas. The dorsal cortex lies dorsomedially, and the external cortex lies

Fig. 38.19 The putative motors of outer hair cells. Outer hair cells can generate force, mechanically boosting sound-induced vibrations of the hair bundle and augmenting frequency tuning. Two mechanisms have been advanced to explain this cochlear amplifier: the somatic motor and the hair bundle motor. A, In the resting state, $\mathrm{Cl}^{-}$ions are bound to prestin molecules in the lateral membrane of the hair cell. When force is applied to the hair bundle, the cell is depolarized, the $\mathrm{Cl}^{-}$ions dissociate and the prestin changes conformation, reducing its area in the plane of the membrane and shortening the hair cell body (the somatic motor). Adaptation of mechanoelectrical transduction (MET) channels, which are activated by bending of the stereocilia at their tapered base, also causes the hair bundle to produce extra force in the direction of the stimulus (the hair bundle motor). The amplitudes of the hair bundle movements have been exaggerated to illustrate the concept. B, The effects of the somatic motor (blue arrows) on the organ of Corti mechanics, which leads to downward motion of the reticular lamina (the upper surface of the organ of Corti) and a negative deflection of the hair bundle. This is a negative feedback pathway, as a positive deflection of the hair bundle causes outer hair cell depolarization, cell contraction and opposing motion of the bundle (see Fettiplace and Hackney (2006)).

Fig. 38.20 The main features of the human ascending auditory pathway. A, A series of sections showing that ipsilateral and commissural connections occur at most levels in this system. The major connections are shown by the thicker arrows; thinner arrows denote less heavy projections. B, The main stations of the auditory pathway.
ventromedially. Secondary and tertiary fibres ascend in the lateral lemniscus. They converge in the central nucleus, which projects to the ventral division of the medial geniculate body of the thalamus. The external cortex receives both auditory and somatosensory input. It projects to the medial division of the medial geniculate body and, together with the central nucleus, also projects to olivocochlear cells in the superior olivary complex and to cells in the cochlear nuclei. The dorsal cortex receives input from the auditory cortex and projects to the dorsal division of the medial geniculate body. Connections also run from the nucleus of the lateral lemniscus to the deep part of the superior colliculus, to coordinate auditory and visual responses.

The ascending auditory pathway crosses the midline at several points both below and at the level of the inferior colliculus. However, the input to the central nucleus of the inferior colliculus and higher centres has a clear contralateral dominance; during the initial stages of cortical auditory processing, both hemispheres respond most strongly to the contralateral ear. The medial geniculate body is connected reciprocally to the primary auditory cortex, which lies in the posterior half of the superior temporal gyrus and also dives into the lateral sulcus as the transverse temporal gyri (Heschl's gyri). Secondary areas of the auditory cortex are located in an adjacent belt region, and other regions of auditory association cortex have been described in a parabelt region beyond the secondary cortex.

The corpus callosum, particularly the posterior third of the body, contains auditory interhemispheric fibres that originate from the primary and second auditory cortices. Asymmetries of minicolumn number in primary and association auditory regions have been correlated with axonal fibre numbers in the subregions of the corpus callosum through which they project (Chance et al 2006).

The presence of tonotopic gradients in the primary auditory cortex is well established in animals and in humans. Hemispheric differences for frequency selectivity (i.e. the ability of the cochlea to separate the acoustic frequencies along its length like an acoustic prism) and tonotopic organization have been reported, e.g. the right hemisphere appears to be most responsive to acoustic sound features such as pitch, whereas the left hemisphere seems to be more involved in processing temporal dynamics such as the phonological aspects of speech. Morphological asymmetries favouring the left hemisphere in the planum temporale and Heschl's gyri have been correlated with left hemispheric dominance for language functions but a direct link between structure and function has not been clearly established; studies often show relative rather than absolute differences in hemispheric specialization for particular attributes.

The transformation of the physical characteristics of sound into 'auditory objects' is thought to occur in the transition from primary to secondary auditory cortex. (For a critical perspective on auditory objects, see Griffiths and Warren (2004).)

## Deafness

Hearing impairment is the most common disabling sensory defect in humans. Two causes of deafness are usually distinguished: conductive hearing loss and sensorineural hearing loss.

Conductive hearing loss may result from trauma to the external or middle ears, blockage of the external acoustic meatus, or disruption of the tympanic membrane (e.g. by intense sounds or extreme pressure changes). It may also result from acute or chronic infection associated with a perforation of the tympanic membrane, as in acute otitis media. The ossicular chain may be disrupted by trauma, avascular necrosis of the long process of the incus following a middle ear infection or cholesteatoma. The most common cause of a conductive hearing loss is a middle ear effusion (glue ear), in which fluid that has replaced the normally air-filled middle ear impedes the movements of the tympanic membrane. Other less common causes include tympanosclerosis, in which calcium plaques are formed in the tympanic membrane and middle ear mucosa that stiffen the tympanic membrane and limit the mobility of the ossicular chain. Similarly, new bone laid down around the oval window and footplate of the stapes, otosclerosis, impedes stapes mobility and imparts a conductive hearing loss.

Sensorineural hearing loss is the most prevalent form of hearing impairment. It refers commonly to loss or damage of the sensory hair cells or their innervation, but can also result from lateral wall degeneration and loss of the endolymphatic potential. The hair cells are particularly vulnerable to mechanical trauma produced by high-intensity noise and to changes in their physiological environment caused by infection or hypoxia. These can lead to rapid degenerative processes that result in hair cell loss, often by apoptosis, and produce either hearing loss or vestibular dysfunction. These changes can be induced by drugs such as the aminoglycoside antibiotics, some diuretics and certain anticancer drugs. A decrease in cochlear sensitivity, presbyacusis, almost invariably occurs with age; hair cells at the high frequency end of the cochlea tend to be lost first. At least $60 \%$ of hearing loss may have a genetic basis, a significant proportion may be non-syndromic, and most of these genes are inherited in an autosomal recessive mode (see Ch. 39).

Ménière's disease is a distressing disorder of the inner ear characterized by episodes of hearing loss, tinnitus and vertigo. Histological examination of an affected ear reveals endolymphatic hydrops (swelling of the endolymphatic spaces), suggesting poor drainage of the endolymph via the endolymphatic sac.

A review of inner ear fluids (perilymph and endolymph), how they are produced and their possible functional significance.

The inner ear may be approached surgically in a number ways. Many drugs, e.g. gentamicin and steroids, are now injected through the intact tympanic membrane, where they diffuse through the round window membrane to access the inner ear. The promontory that overlies the basal turn of the cochlea and the oval window may be opened through a tympanotomy (per-meatal elevation of the tympanic membrane). The semicircular canals are generally accessed by a transmastoid approach. In days gone by, such an approach would be used to fenestrate the lateral canal in the management of otosclerosis. The advent of stapes prostheses and stapedectomy rendered this operation obsolete. However, the transmastoid approach is the workhorse for much middle and inner ear surgery because it gives a wide exposure of all the vital structures. For patients with profound hearing loss, enlarging the mastoid aditus inferiorly (posterior tympanotomy) to produce a triangle bounded above by the fossa of incus, superficially by the chorda tympani and deeply by the descending portion of the facial nerve, gives access to the round window so that it can be instrumented and a multichannel cochlear electrode inserted into the scala tympani of the cochlea so that it lies against the spiral lamina and can stimulate the adjacent fibres of the cochlear nerve. This is then connected to the cochlear implant device, which is housed in an extension of the mastoid cavity. Posterior canal obliteration for cupulolithiasis not responsive to Epley's manœuuve is also undertaken through the mastoid. The endolymphatic sac may be approached by elevating the cortical bone of the anterolateral wall of the posterior cranial fossa, anterior to the sigmoid venous sinus and posterior to the posterior semicircular canal (below a line extended from the axis of the lateral semicircular canal). Decompression of the sac or a shunt procedure is favoured by some for the management of Ménière's disease. Superior canal dehiscences, as seen in Minor's syndrome, are repaired either through the mastoid or by using a middle fossa approach. In patients with intractable Ménière's disease, the whole of the labyrinth can be removed through the mastoid. Vestibular nerve section and the removal of vestibular schwannomas are generally undertaken through retrosigmoid, retrolabyrinthine, translabyrinthine or middle fossa approaches. The choice of approach is dictated or influenced by the size of the tumour, desire or need to preserve hearing, and the surgeon's choice. In recent years, the development of auditory brainstem implants has brought hope to those with profound hearing loss associated with neurofibromatosis type 2 or cochlear nerve aplasia. These devices are similar to a cochlear implant but the electrodes are placed directly into the cochlear nucleus within the brainstem through a retrosigmoid approach.

## CHAPTER <br> 39

## Development of the ear

## INNER EAR

The production of a precisely positioned and functionally well-tuned inner ear depends on genetic patterning and a cascade of transcription signals expressed by numerous tissues, including the developing inner ear and its surrounding periotic mesenchyme, the adjacent hindbrain, neural crest and notochord (Ohyama et al 2010, Sienknecht 2013).

The first signs of inner ear development are visible shortly after those associated with the developing eyes. Two patches of ectodermal thickening, the otic placodes, appear lateral to the hindbrain at stage 9. Each placode invaginates as an otic pit, adjacent to rhombomeres 5 and 6 of the hindbrain and dorsal to the second pharyngeal cleft. During stage 12, the pit is pinched off from the surface ectoderm to form a simple, hollow epithelial sac, the otic vesicle (otocyst or auditory vesicle) (Fig. 39.1).

Regions of the vesicle differentiate into prosensory domains, which give rise to the membranous labyrinth and the vestibulocochlear (statoacoustic) ganglia of the eighth cranial nerve. The first morphological evidence of this differentiation is visible during stage 14 (approximately 33 days), when the otic vesicle loses its initial piriform shape. A tubular diverticulum, the endolymphatic appendage, develops from its dorsomedial rim. The remainder of the vesicle, the utriculosaccular chamber, differentiates into an expanded pars superior and a narrower pars
inferior. The endolymphatic appendage elongates and its tip expands into an endolymphatic sac that is connected to the pars superior by a narrow endolymphatic duct.

Two plate-like diverticula, one vertical and one horizontal, emerge from the dorsal part of the pars superior. The epithelia in the centre of each outgrowth coalesce to form a fusion plate; the central part of this plate is eventually resorbed, leaving the anlagen of the semicircular canals. The vertical plate gives rise to the anterior and posterior semicircular canals, which share a common crural attachment to the utriculosaccular chamber, and the horizontal plate gives rise to the lateral semicircular canal. A small expansion, the ampulla, forms at one end of each semicircular canal.

The central part of the utriculosaccular chamber, which now represents the membranous vestibule, becomes divided into a small ventral saccule and a larger dorsal utricle, mainly by horizontal infolding extending from the lateral wall of the chamber towards the opening of the endolymphatic duct. In this way, communication between the utricle and saccule is restricted to a narrow utriculosaccular duct. The latter becomes acutely bent on itself; its apex is continuous with the endolymphatic duct. While this is happening, the membranous labyrinth rotates so that its long axis, which was originally vertical, becomes more or less horizontal.

The ventral tip of the pars inferior begins to elongate. A medially directed evagination, the cochlear anlagen, is evident in the ventral part

Fig. 39.1 A-F, The stages in the development of the membranous labyrinth from the otocyst, at the embryonic stages and aspects indicated. Note the relationship of the vestibular (orange) and cochlear (yellow) parts of the vestibulocochlear nerve.
of the utriculosaccular chamber in a $7-9 \mathrm{~mm}$ (approximately 35 days) embryo. The proximal region of this cochlear duct continues to increase in length and its distal region becomes progressively more coiled. When the duct has achieved its final length and spiral configuration, its proximal part becomes constricted, forming the ductus reuniens by which the saccule remains connected to the cochlea. The cochlea is initially patterned into several prosensory domains. The central domain will give rise to the organ of Corti. Molecular signals regulating the induction and differentiation of the organ of Corti are complex (Kelly and Chen 2009). Relatively little is known about the mechanisms establishing sensory and non-sensory territories in the cochlear duct; there is evidence that bone morphogenetic protein (BMP) signalling is required (Ohyama et al 2010).

Cells derived from the otocyst differentiate into the bipolar neurones that populate the vestibular and cochlear ganglia; sustentacular cells (Wan et al 2013); the unique endolymph-producing epithelia of the stria vascularis; the absorbing epithelia of the endolymphatic sac; the general epithelial lining of the membranous labyrinth; and specialized cells in the six sensory patches of the inner ear (crista ampullaris of the three semicircular canals, maculae of the utricle and saccule, organ of Corti in the cochlea). Each of the sensory patches consists of mechanosensory hair cells and non-sensory supporting cells arranged into mosaic patterns that are essential for normal hearing and balance. The only cells in the mature inner ear that are not of otocyst origin are melanocytes in the stria vascularis, which are derived from the neural crest.

The very different morphologies of the mature cristae, maculae and organ of Corti reflect the differential expression of multiple genes during their development and maturation. The formation of the utricle and saccule occurs during a time that coincides with the initiation of hair cell planar polarity. It is important to note that the development of core planar cell polarity in the orientation of stereocilia in the mechanosensory hair cells of the mammalian inner ear is the subject of an extensive and conflicting literature (Deans 2013, Ezan and Montcouquiol 2013).

At the same time as these changes are taking place, mesenchymal cells surrounding the developing membranous labyrinth chondrify to form an encasing cartilaginous otic capsule. Between 16 and 23 weeks, the otic capsule ossifies to form all of the bony labyrinth of the internal ear within the petrous temporal bone, except the modiolus and osseous spiral lamina, which ossify directly from connective tissue. The cartilaginous capsule is initially incomplete and the cochlear, vestibular and facial ganglia are temporarily exposed in the gap between its canalicular and cochlear parts. They subsequently become covered by an outgrowth of cartilage, in which the facial nerve becomes enclosed.

Vacuoles filled with perilymph develop in the embryonic connective tissue between the cartilaginous capsule and the epithelial wall of the membranous labyrinth. The rudiment of the periotic cistern or vestibular perilymphatic space can be seen in the reticulum between the saccule and fenestra vestibuli in an 11-14 mm (approximately 42 days) embryo. The cochlear scalae (scala vestibuli and scala tympani) develop by fusion of these spaces; the mechanism is uncertain (Kim et al 2011). The two scalae gradually extend along each side of the cochlear duct; a communication, the helicotrema, opens between them when they reach the tip of the coiled duct.

The rudiment of the eighth cranial nerve appears in the $4-6 \mathrm{~mm}$ embryo as the vestibulocochlear (statoacoustic) ganglion that lies between the otocyst and the hindbrain and is initially temporarily fused with the ganglion of the facial nerve. Neuroblasts, whose fate is already specified in the ectoderm of the otic placode, delaminate from the anteroventral region of the otic vesicle, proliferate and migrate to the site of the presumptive ganglion, where they coalesce. They differentiate into mature bipolar sensory neurones and become segregated into vestibular and spiral ganglia, each associated with the corresponding division of the eighth cranial nerve. These neurones are unusual because they are exclusively placodal in origin, unlike neurones in most cranial ganglia (which have a dual placodal and neural crest origin), and many of their somata become enveloped in thin myelin sheaths. Their peripheral processes collectively provide the afferent innervation of the labyrinthine hair cells, relaying balance and auditory information. Tantalizing evidence about the transcriptional networks that encode the positioning of sensory hair cells and spiral ganglion neurones along a frequency (tonotopic) gradient within the developing cochlea, and which ensure that the two cell types make appropriate functional connections, is appearing in animal models (Appler and Goodrich 2011, Appler et al 2013, Coate and Kelley 2013). The olivocochlear bundle, an outgrowth of axons from neurones in the superior olivary complexes in the pons, accompanies the axons of the developing eighth cranial nerve; these axons provide the inner ear with an efferent innervation,
mainly to the outer hair cells in the organ of Corti, where they are associated with modulation of hearing. In utero, the fetus receives sound by bone conduction; interaural sound differences are not established until birth, whether preterm or term.

## MIDDLE EAR (TYMPANIC CAVITY AND PHARYNGOTYMPANIC (AUDITORY) TUBE)

All the components of the outer and middle ears develop from the first and second pharyngeal arches. The pharyngotympanic tube and tympanic cavity are lateral extensions of the early pharynx (see Fig. 36.4). They become visible in a $4-6 \mathrm{~mm}$ embryo as a hollow, the tubotympanic recess, lying between the first and second pharyngeal arches, with a floor that consists of the second arch and its limiting pouches. The forward growth of the third pharyngeal arch causes the proximal part of the recess to remain narrow, forming the pharyngotympanic tube region, and also excludes the inner part of the second arch from this portion of the floor. The more lateral part of the recess eventually comes in contact with the first pharyngeal cleft and widens and develops into the tympanic cavity; its floor later forms the lateral wall of the tympanic cavity up to approximately the level at which the chorda tympani branches off from the facial nerve. The lateral wall of the tympanic cavity contains first and second arch elements. The first arch territory is limited to that part in front of the anterior process of the malleus, and the second arch forms the outer wall behind this and also turns on to the posterior wall to include the tympanohyal region.

The tubotympanic recess at first lies inferolateral to the cartilaginous otic capsule; this spatial relationship alters as the capsule enlarges and the tympanic cavity becomes anterolateral. A cartilaginous process grows from the lateral part of the capsule to form the tegmen tympani (Rodríguez-Vázquez et al 2011). The process curves caudally to form the lateral wall of the pharyngotympanic tube, incorporating the tympanic cavity and the proximal part of the pharyngotympanic tube into the petrous region of the temporal bone. The mastoid antrum appears as a dorsal expansion of the tympanic cavity during the sixth to seventh months (some sources place this as a later phenomenon). Exactly how middle ear cavitation occurs is poorly understood (Sienknecht 2013); it seems to involve cavitation of a neural crest mass (Thompson and Tucker 2013).

The middle ear ossicles are of neural crest origin, i.e. crest cells that have migrated from rhombomeres 1-4 into the mesenchyme of the first and second pharyngeal arches. The malleus develops from the dorsal end of the ventral mandibular (Meckel's) cartilage of the first arch. The incus develops from the dorsal cartilage of the first arch, which is probably homologous to the quadrate bone of birds and reptiles. The origin of the stapes in humans remains controversial. It is thought to be derived mainly from an anlage situated in the cranial end of the cartilage of the second pharyngeal arch, initially as a ring (anulus stapes) that encircles the small stapedial artery (Rodríguez-Vázquez 2005). The ossicles remain embedded in the mesenchymal roof of the tympanic cavity until the eighth month of gestation, when the mesenchyme is resorbed. As this happens, the ossicles become suspended within the developing tympanic cavity, initially by transient endodermal mesenteries and ultimately by supporting ligaments. They become covered by the mucosa of the middle ear as the tympanic cavity fills with air after birth. Further postnatal developmental changes contribute to the functional maturation of the middle ear.

Two anlagen of each stapedius muscle appear close to the stapedial artery and facial nerve in second arch mesenchyme in $13-17 \mathrm{~mm}$ embryos. Tensor tympani starts to appear near the extremity of the tubotympanic recess at almost the same time in first arch mesenchyme. The pyramidal eminence is formed within a condensation of mesenchyme around the belly of stapedius (Rodríguez-Vázquez 2009). The pharyngeal membrane separating the tympanic cavity from the external acoustic meatus develops into the tympanic membrane.

## EXTERNAL EAR

The external acoustic meatus develops from the dorsal end of the first pharyngeal (hyomandibular) cleft (see Fig. 36.4). Close to its dorsal extremity, this groove extends inwards as a funnel-shaped primary meatus, from which the entire cartilaginous part of the meatus, and a small area of its roof, are developed. A solid epidermal plug extends inwards from the tube along the floor of the tubotympanic recess. The cells in the centre of the plug subsequently degenerate to produce the inner part of the meatus (secondary meatus). The epidermal stratum of
the tympanic membrane is formed from the deepest ectodermal cells of the epidermal plug; the fibrous stratum is formed from the mesenchyme between the meatal plate and the endodermal floor of the tubotympanic recess. The osseous part of the external acoustic meatus develops postnatally from the tympanic ring of the squamous part of the temporal bone; the cartilaginous part develops much earlier and independently of the osseous part (Ikari et al 2013).

The development of the auricle is initiated by the appearance of six tissue elevations, the auricular hillocks, which form round the margins of the dorsal portion of the first pharyngeal cleft. Of the six, three are on the caudal edge of the first pharyngeal (mandibular) arch and three on the cranial edge of the second pharyngeal (hyoid) arch (see Fig. 36.3A). The hillocks appear from stage 15 ; before then, only the most ventral hillock on the mandibular arch, which subsequently forms the tragus, can be identified. The rest of the auricle is formed in the mesenchyme of the hyoid arch, which extends forwards round the dorsal end of the remains of the first pharyngeal cleft, forming a keel-like elevation that is the forerunner of the helix. The contribution made by the mandibular arch to the auricle is greatest at the end of the second month; thereafter, this contribution becomes relatively reduced as growth continues and, eventually, the area of skin supplied by the mandibular nerve extends little above the tragus. The lobule is the last part of the auricle to develop.

Common congenital anomalies of the auricle are described in Chapter 37.

## HEREDITARY DEAFNESS

Prelingual deafness is the most common congenital anomaly, affecting 2-6/1000 newborns: at least two-thirds of cases reported in the developed world are due to genetic factors, classified as non-syndromic (typically sensorineural and accounting for approximately $70 \%$ of cases) and syndromic (which may be sensorineural, conductive or mixed and accounts for approximately $30 \%$ of cases). A number of molecules likely to be mediators of genetic hearing loss have been identified, including TGFB1, BMP4, ERK1/2 and many GPCR genes (Stamatiou and Stankovic 2013). The range of affected chromosomes and the specific genes involved in sensorineural deafness is given by Hildebrand et al (2010). The structural abnormalities resulting from absent or aberrant gene expression during the development of the ear include labyrinthine dysplasias (e.g. a reduction in the number of cochlear turns or an enlargement of the endolymphatic duct); disorganization of the patterns of stereocilia in sensory hair cells and loss of cytoskeletal components in these cells; and defects in $\mathrm{K}^{+}$recycling across gap junctions between activated hair cells.

## Development of the eye

The development of the eye involves a series of inductive interactions between neighbouring tissues in the embryonic head. These are the neurectoderm of the forebrain (which forms the sensory retina and accessory pigmented structures), the surface ectoderm (which forms the lens and the corneal epithelium) and the intervening neural crest mesenchyme (which contributes to the fibrous coats of the eye and to tissues of the anterior segment of the eye). A broad anterior domain of neurectoderm, characterized by the activation of several homeoboxcontaining transcriptional regulators, including PAX6, RX, SIX3 and OTX2, develops the potential to form optic vesicles. Subsequent interactions between mesenchyme and neurectoderm, involving expression of the secreted protein sonic hedgehog $(S H H)$ at the midline, subdivides this eye-field region into bilateral domains at the future sites of the eyes (Chow and Lang 2001). Loss of SHH function causes holoprosencephaly and a range of malformations that can include cyclopia, due to incomplete separation of the prosencephalon (Dubourg et al 2004).

In three-dimensional culture of murine embryonic stem cells supplemented with the correct growth factors and Matrigel ${ }^{\circledR}$ (to promote basement membrane formation), but in the absence of surface ectoderm or lens epithelium, an epithelial vesicle develops and undergoes dynamic shape change to form a two-layered optic cup (Eiraku and Sasai 2012). The tissue so formed demonstrated interkinetic nuclear migration and a fully stratified architecture similar to that of postnatal eyes, including appropriate synapses. Similar results, i.e. production of retinal architecture and retinal pigment epithelial cells, have been reported using human embryonic stem cells (Nakano et al 2012, Zhu et al 2013).

The parallel process of lens determination appears to depend on a brief period of inductive influence that spreads through the surface ectoderm from the rostral neural plate and elicits a lens-forming area of the head. Reciprocal interactions that are necessary for the complete development of both tissues take place as the optic vesicle forms and contacts the potential lens ectoderm (Saha et al 1992, Nakano et al 2012, Fuhrmann 2010). The vascular tissue of the developing eye forms by local angiogenesis or vasculogenesis of angiogenic mesenchyme (Hughes et al 2000). (Accounts of the development of the eye are given in O'Rahilly $(1966,1983)$.)

## EMBRYONIC COMPONENTS OF THE EYE

The first morphological sign of eye development is a thickening of the diencephalic neural folds at 29 days post ovulation, when the embryo has seven to eight somites. This optic primordium (eye field) extends on both sides of the neural plate and crosses the midline at the primordium chiasmatis. A slight transverse indentation, the optic sulcus, appears in the inner surface of the optic primordium on each side of the brain. During the period when the rostral neuropore closes, at about 30 days (stage 11), the walls of the neuromere diencephalon 1 (see Fig. 17.2) begin to evaginate at the optic sulcus, projecting laterally towards the surface ectoderm; by 32 days, the optic vesicles are formed. Failure of the specification and development of the optic vesicle is associated with mutation of several transcriptional regulator genes expressed in the eye field and leads to anophthalmia (absence of the eye) (Graw 2003). Each optic vesicle is surrounded by a sheath of mesenchymal cells derived from the head mesenchyme and neural crest; its lumen is continuous with that of diencephalon 1 . By 31 days, regional differentiation is apparent in each of the source tissues of the eye. The optic vesicle is visibly differentiated into its three primary parts: at the junction with the diencephalon, a thick-walled region marks the future optic stalk; laterally, the tissue that will become the sensory (neural) retina forms a flat disc of thickened epithelium in close contact with the surface ectoderm; and the thin-walled part that lies between these regions will later form the pigmented layer of the retina (retinal
pigmented epithelium). The area of surface ectoderm that is closely apposed to the distal optic vesicle thickens to form the lens placode, and the mesenchymal sheath of the vesicle begins to show signs of angiogenesis. Between 33 and 35 days post ovulation, the lens placode and optic vesicle undergo coordinated morphogenesis. The lens placode invaginates, forming a pit that pinches off from the surface ectoderm to form the lens vesicle (Fig. 40.1). The surface ectoderm reforms a continuous layer that will become the corneal epithelium. The lateral part of the optic vesicle invaginates to form a cup; the inner layer (facing the lens vesicle) will become the sensory (neural) retina, and the outer layer, influenced by signals from the surrounding extraocular mesenchyme, becomes the retinal pigmented epithelium. As a result of these folding movements, what were the apical (luminal) surfaces of the two layers of the cup now face one another across a much-reduced lumen, the intraretinal space. The pigmented layer becomes attached to the mesenchymal sheath, but the junction between the pigmented and sensory layers is less firm and is the site of pathological detachment of the retina. The two layers are continuous at the lip of the cup (Fig. 40.2). The narrow part of the optic vesicle between the base of the cup and the brain forms the optic stalk. As well as the invagination of the lateral part of the optic vesicle, the ventral surface of the vesicle and distal part of the stalk similarly invaginate, forming a wide groove, the choroid (optic) fissure, through which mesenchyme and the hyaloid artery extend. These infoldings involve differential growth and cell movement, and high levels of proliferation in the inner neuroepithelial layer.

As growth proceeds, the fissure closes and the artery is included in the distal part of the stalk. The fusion process is characterized by apoptosis at the margins of the fissure. Failure of the optic fissure to close is a rare anomaly that is accompanied by a corresponding deficiency in the choroid and iris (congenital coloboma) and is often associated with microphthalmia (small eyes). Reduced growth of the optic cup caused by mutation of the homeobox gene CHX10, important for specification and growth of the neural retina, is one known cause of microphthalmia (Graw 2003). Anophthalmia, microphthalmia and coloboma are also associated with mutation of the SOX2 gene.

## DIFFERENTIATION OF THE FUNCTIONAL COMPONENTS OF THE EYE

The developments just described bring the embryonic components of the eye into the spatial relationships necessary for the passage, focusing and sensing of light. The next phase of development involves further patterning and phenotypic differentiation in order to develop the specialized structures of the adult organ.

The optic cup becomes patterned, from the base to the rim, into regions with distinct functions. Several secreted factors, including bone morphogenetic proteins (BMP), retinoic acid and SHH, and transcriptional regulators, including PAX6 and PAX2, are important for specifying each region (Chow and Lang 2001, Sinn and Wittbrodt 2013). The outer layer of the optic cup remains as a thin layer of cells, which begin to acquire pigmented melanosomes and form the pigmented epithelium of the retina at around 36 days. In a parallel process, which begins before invagination, the cells of the inner layer of the cup proliferate to form a thick pseudostratified neuroepithelium, the future neural retina, over the base and sides of the cup. The peripheral region around the lip of the cup extends, and is further differentiated into the components of the prospective iris at the rim, and the ciliary body a little further back, adjacent to the neural retina (see Fig. 40.2). The development of this pattern is reflected in regional differences in the expression of various genes that encode transcriptional regulators and which are therefore likely to play key roles in controlling and coordinating

Fig. 40.1 Development and morphogenesis of the optic cup. A-D Scanning electron micrographs of early eye development, $\mathbf{A}$ and $\mathbf{C}$ showing external view, $\mathbf{B}$ and $\mathbf{D}$ showing longitudinal sections through the eye. $\mathbf{B}$ and $\mathbf{E}$ show the early invagination of the lens placode and the modification of the optic vesicle to an optic cup. $\mathbf{F}$ and $\mathbf{D}$ show the formation of the lens vesicle and the two layers of the retina (nervous and pigmented). $\mathbf{G}$ and $\mathbf{H}$ show three dimensional images of the outer aspect of the optic cup. G. Early formation of the choroid fissure along the side of the optic cup and optic stalk; the layers of the retina are shown. H The fused choroid fissure; the position of the lens within the optic cup is shown in dotted outline. (A, B, C, D Courtesy of Kathleen Sulik PhD, Professor, University of North Carolina.)

Fig. 40.2 Sections through the developing eyes of human embryos. A, Equivalent to 8 mm crown-rump length (CRL); stage 16. The thick nervous and the thinner pigmented layers of the developing retina and the lens are shown. The two layers of the embryonic optic cup are separated by the intraretinal space. B, Equivalent to 13.2 mm CRL; stage 17. The surface ectoderm anterior to the lens forms the corneal epithelium, whereas the corneal stroma and endothelium will differentiate from the invading mesenchyme (of neural crest and mesodermal origin). C, Equivalent to 40 mm CRL. The development of the anterior aqueous chamber is apparent with choroidal extensions and iris visible. The eyelids have developed and are fused; the extent of the conjunctival fornices can be seen. D, Anterior growth of the peripheral retina, pigmented layer of the retina and mesenchymal proliferation at the anterior part of the retina will give rise to the ciliary body and iris. The surface ectoderm anterior to the lens forms the corneal epithelium, whereas the corneal stroma and endothelium will differentiate from invading mesenchyme (of neural crest and mesodermal origin). E, Details of the developing uveal tract. Note the development of the anterior and posterior aqueous chambers, separated by the iris, and the attachment of the lens to the ciliary body.
development. Distinct sets of genes are expressed prior to and during overt cell-type differentiation. For example, PAX6 is expressed in the prospective ciliary and iris regions of the optic cup; individuals heterozygous for mutations in PAX6 lack an iris (aniridia), which suggests a causal role for this gene in the development of the iris. The genes expressed in the eye are also often active at a variety of other specific sites in the embryo, which may, in part, account for the co-involvement of the eye and other organs in syndromes that result from single genetic lesions, e.g. PAX2 mutation causes coloboma and kidney defects, reflecting the sites of expression of the gene (Graw 2003).

## Developing neural retina

The developing neural retina consists of an outer nuclear zone, which contains dividing neuroepithelial retinal progenitor cells, and an inner marginal zone, which is initially devoid of nuclei. At around 37 days, the cells of the nuclear zone invade the marginal zone, and by stage 18 ( 44 days), the nervous stratum of the retina consists of inner and outer neuroblastic layers. Cell lineage analyses have shown that seven retinal cell types are all derived from a common multipotential retinal progenitor cell. Different types of retinal cells are born (cease dividing) in a conserved sequence during development: ganglion cells, amacrine cells, cone photoreceptors and horizontal cells develop early, whereas bipolar cells, rod photoreceptors and Müller glial cells develop later (Cepko et al 1996). Newly born cells migrate from the apical (ventricular) surface to the appropriate cell layer in the developing retina, establishing its characteristic laminar structure. The developing ganglion cell layer first separates from the neuroblastic layers by formation of the inner plexiform layer. The inner nuclear layer, containing developing amacrine, horizontal, bipolar and Müller glial cells, then separates from the outer nuclear layer, containing the developing rod and cone photoreceptors by formation of the outer plexiform layer. Mature retinal neurones first appear in the central part of the retina. By the eighth month, all the named layers of the retina can be identified. However, the photoreceptor cells continue to differentiate after birth, generating an array of increasing resolution and sensitivity; the macula does not reach maturity until 15-45 months after birth (Hendrickson and Yuodelis 1984).

The divergent differentiation of the pigmented and sensory layers of the retina from the initially bipotential neuroepithelium of the optic vesicle involves activation of region-specific regulatory genes, e.g. CHX10 in the presumptive neural retina and MITF in the presumptive pigmented epithelium (Bharti et al 2006). Patterning by gene expression is an important aspect of establishing regional identity of the optic cup and the subsequent maturation of these respective tissues. Soluble factors from the retina elicit the polarized distribution of plasma membrane proteins and the formation of tight junctions in the pigmented epithelium. Neural retinal differentiation is mediated by several growth factors, including fibroblast growth factors, SHH and retinoic acid. Basic helix-loop-helix proneural transcriptional regulatory genes also play a central role in regulating retinal cell fate. However, the pigmented epithelium initially retains the potential to become neural retina and will do so if the embryonic retina is wounded, demonstrating the plasticity of the early commitment to pigment epithelium or neural retinal fate.

The retinal vasculature forms by the aggregation of spindle-shaped cells (mesenchymal cells) that emanate from the optic disc by week 15 and form vascular cords, consistent with vessel formation by vasculogenesis, which give rise to the inner plexus of the retina. Vessel formation in the temporal and peripheral retina occurs by angiogenesis. New vessel segments sprout from pre-existing vessels and grow tangentially by angiogenesis into the neuroepithelium (Hughes et al 2000).

## Optic nerve

The optic nerve develops from the optic stalk. The centre of the optic cup, where the optic fissure is deepest, will later form the optic disc, where the neural retina is continuous with the corresponding invaginated cell layer of the optic stalk; the developing axons of the ganglion cells, therefore, pass directly into the wall of the stalk and convert it into the optic nerve. Myelination of the axons within the optic nerve begins shortly before birth but the process is not completed until some time later. The optic chiasma is formed by the meeting and partial decussation of the axons within the two optic nerves in the ventral part of the lamina terminalis (at the junction of the telencephalon with the diencephalon in the floor of the third ventricle). Beyond the chiasma, the axons continue as the optic tracts, and pass principally to the lateral geniculate bodies and to the superior tectum of the midbrain.

## Ciliary body

The ciliary body is a compound structure. Its epithelial components are derived from the region of the inner layer of the retina, between the iris and the neural retina, and the adjacent outer layer of pigmented epithelium. The cells here differentiate in close association with the surrounding mesenchyme to form highly vascularized folds that secrete aqueous fluid into the globe of the eye.

The inner surface of the ciliary body forms the site of attachment of the lens. The outer layer is associated with smooth muscle derived from mesenchymal cells in the choroid that lie between the anterior scleral condensation and the pigmented ciliary epithelium (p. 691).

## Iris

The iris develops from the tip of the optic cup, where the two neuroepithelial layers remain thin and are associated with vascularized, muscular connective tissue. The muscles of the sphincter and dilator pupillae are unusual in that they are of neurectodermal origin, and develop as a result of further growth and differentiation of the two layers of the optic cup. Mesenchymal cells, largely composed of neural crest cells that have migrated anterior to the lens, form the collagen-rich iris stroma; they overlay the pigmented epithelium of the iris, which is continuous with the ciliary body and neural retina, and is of neurectodermal origin. The mature colour of the iris develops after birth and is dependent on the relative contributions made by the pigmented epithelium on the posterior surface of the iris and the neural crest-derived melanocytes in the mesenchymal stroma of the iris. If only epithelial pigment is present, the eye appears blue, whereas if there is an additional contribution from the melanocytes, the eye appears brown. Aniridia, the absence of the iris, is commonly caused by heterozygous mutations of PAX6.

## Lens

The lens develops from the lens vesicle (see Figs 40.1F, 40.2A). Initially, this is a ball of actively proliferating epithelium, but by stage 16, there is a discernible difference between the thin anterior (i.e. outwardfacing) epithelium and the thickened posterior epithelium. Cells of the posterior wall lengthen and fill the vesicle (see Fig. 40.2B,C), reducing the original cavity to a slit by about 44 days. The posterior cells become filled with a very high concentration of proteins (crystallins), which render them transparent; they also become densely packed within the lens as primary lens fibres. Cells at the equatorial region of the lens elongate and contribute secondary lens fibres to the body of the lens in a process that continues into adult life, sustained by continued proliferation of cells in the anterior epithelium (p. 697). The polarity and growth of the lens appear to depend on the differential distribution of soluble factors that promote either cell division or lens fibre differentiation, and are present in the anterior chamber and vitreous humour, respectively. Congenital cataracts can be associated with mutations in genes that encode structural lens proteins, particularly crystallin proteins, as well as genes that encode transcriptional regulatory factors expressed specifically in the lens, such as MAF and PITX3, which are needed for normal lens development and which also influence normal growth of the globe of the eye (Graw 2003, Graw 2010).

The developing lens is surrounded by a vascular mesenchymal condensation, the vascular capsule, the anterior part of which is named the pupillary membrane. The posterior part of the capsule is supplied by branches from the hyaloid artery, and the anterior part is supplied by branches from the anterior ciliary arteries. During the fourth month, the hyaloid artery gives off retinal branches. By the sixth month, all of the vessels have atrophied, except the hyaloid artery, which becomes occluded during the eighth month of intrauterine life, although its proximal part persists in the adult as the central artery of the retina. Atrophy of the hyaloid vasculature and of the pupillary membrane appears to be an active process of programmed tissue remodelling that is macrophage-dependent; visual impairment occurs in persistent hyperplastic primary vitreous, a condition in which normal regression of the hyaloid vasculature fails to occur. The hyaloid canal, which carries the vessels through the vitreous, persists after the vessels have become occluded. In the neonate, it extends more or less horizontally from the optic disc to the posterior aspect of the lens, but when the adult eye is examined with a slit-lamp, it can be seen to follow an undulating course, sagging downwards as it passes forwards to the lens. With the loss of its blood vessels, the vascular capsule disappears and the lens becomes dependent for its nutrition on diffusion via the aqueous and
vitreous humours. The lens remains enclosed in the lens capsule, a thickened basal lamina derived from the lens epithelium. Sometimes, the pupillary membrane persists at birth, giving rise to congenital atresia of the pupil.

## Vitreous body

The vitreous body develops between the lens and the optic cup as a transparent, avascular gel of extracellular substance. The precise derivation of the vitreous remains controversial. The lens rudiment and the optic vesicle are, at first, in contact, but they draw apart after closure of the lens vesicle and formation of the optic cup, and remain connected by a network of delicate cytoplasmic processes. This network, derived partly from cells of the lens and partly from those of the retina, is the primitive vitreous body. At first, these cytoplasmic processes are connected to the whole of the neuroretinal area of the cup but, later, they become limited to the ciliary region, where, by a process of condensation, they form the basis of the suspensory ligaments of the ciliary zonule. The vascular mesenchyme, which enters the cup through the choroidal fissure and around the equator of the lens, associates locally with this reticular tissue and thus contributes to the formation of the vitreous body.

## Anterior segment

Mesenchymal cells of neural crest origin migrate anteriorly around the optic cup and between the surface ectoderm and the lens to contribute to the development of anterior segment structures, including the ciliary body, the iris, the cornea and the iridocorneal angle tissues (see Fig. 40.2C-E) (Gould et al 2004). The anterior chamber initially appears as a cleft in this mesenchymal tissue. The mesenchyme superficial to the cleft forms the stroma (substantia propria) and endothelium of the cornea, and that deep to the cleft forms the stroma of the iris and the pupillary membrane. Tangentially, this early cleft extends as far as the iridocorneal angle, where communications are established with the scleral venous sinus (canal of Schlemm). Mesenchymal cells of neural crest origin lying at the angle of the anterior chamber differentiate to form a specialized meshwork of trabecular beams (collagen fibrils covered by cells); the open spaces of the meshwork become open to the anterior chamber as the beams develop. The canal of Schlemm develops deep to the trabecular meshwork and is derived from mesodermal mesenchyme. Initially a vascular structure lined by endothelial cells, the canal acts as an aqueous sinus from the fifth month of gestation (McMenamin 1989). The forward-growing optic cup rim differentiates into the ciliary epithelium and the iris; the posterior chamber is formed between the iris, the lens capsule, the zonular suspensory fibres and the ciliary processes. The ciliary processes produce the aqueous humour that flows through the pupil and is drained in the iridocorneal angle, mainly by the trabecular meshwork and the canal of Schlemm. In this way, the walls of the anterior and posterior segment chambers furnish both the sites of production, and the channels for circulation and reabsorption, of the aqueous humour (p. 687). The FOXC1 and PITX2 transcriptional regulatory genes are expressed in the neural crest cells migrating into the presumptive anterior segment, and regulate differentiation of the anterior segment tissues. Anterior segment dysgenesis, involving malformation of the iris, cornea and angle, occurs when these genes are mutated (e.g. Axenfeld-Rieger syndrome) and is often associated with raised intraocular pressure and glaucoma (Gould et al 2004).

## Cornea

The cornea is induced in front of the anterior chamber by the lens and optic cup. The corneal epithelium is formed from surface ectoderm. The primordial corneal endothelium lining the front of the anterior chamber is formed from mesenchymal cells derived from the neural crest (see Fig. 40.2C,D,E). Mesenchymal cells migrate between these layers and differentiate to form specialized fibroblasts (keratocytes) that secrete the extracellular matrix of the corneal stroma. A regular array of collagen fibres (lamellae) is established between these two layers and serves to reduce scattering of light entering the eye. The most anterior region of the stroma (Bowman's layer) develops as an acellular zone packed with collagen fibrils that confer strength on the layer. From the third month, the endothelium is organized as a monolayer of cells and develops a strong, laminated basal lamina (Descemet's membrane) adjacent to the stroma. The endothelium maintains corneal transparency by regulating the water content of the stroma (p. 689).

## Choroid and sclera

The choroid and sclera differentiate as inner vascular and outer fibrous layers, respectively, from the neural crest mesenchyme that surrounds the optic cup; the choroid is continuous with the leptomeningeal internal sheath of the optic nerve, and the sclera is continuous with the outer dural sheath of the optic nerve. The blood vessels of the choroid develop from the fifteenth week and include the vasculature of the ciliary body.

## DIFFERENTIATION OF STRUCTURES AROUND THE EYE

## Extraocular muscles

Development of the extrinsic ocular muscles is complex, involving coordinated juxtaposition of specific muscle precursors, cranial motor nerve outgrowth and neural crest mesenchyme. During gastrulation, when the earliest cells are migrating through the primitive node to form the prechordal plate and notochordal process, they transitorily express myogenic markers. In stages 9 and 10 a population of prechordal mesenchyme cells migrate laterally from the lateral edge of the prechordal plate toward the unsegemental paraxial mesenchyme each side of the notochord. After neurulation is complete, bilateral premandibular, intermediate and caudal cavities develop adjacent to the neural tube. The walls of these 'head cavities' are lined by flat or cylindrical cells that do not exhibit the characteristics of a germinal epithelium; they were previously termed preotic somites.

As the oculomotor nerve grows towards the developing eye, at the level of the premandibular head cavity, the prechordal mesenchyme becomes apparent as a condensation of premuscle cells at its ventrolateral side. This later subdivides into the blastema of superior, inferior, medial and lateral recti and inferior oblique. Similar events occur in the intermediate head cavity which is associated with the trochlear nerve and premuscle cells forming superior oblique, and the caudal head cavity (abducens nerve and lateral rectus) (see Figs 12.4 and 35.7).

The early myogenic properties of the prechordal mesenchyme have been demonstrated experimentally; if transplanted into limb buds, the cells are able to develop into muscle tissue (Wachtler and Jacob 1986), however, the timing of expression of myosin heavy chain isoforms is different from that of limb myoblasts. Myotube formation starts later and progresses at a slower pace than in the limb, and coexpression of $\mathrm{MyHCI} / 1^{\text {st }}$ and $\mathrm{MyHCI} / 2^{\text {nd }}$ are both seen from the earliest stages of development in contrast to only $\mathrm{MyHCI} / 1^{\text {st }}$ in the limb. These early myoblasts retain their distinct differences from other skeletal muscles as they mature: they are smaller and loosely arranged, and belong to very small motor units (Porter and Baker 1996, Pedrosa-Domellöf et al 2000). Their final attachment to the eye is specified by neural crest formation of the sclera, extraocular muscle tendons and the orbit. In cases of anophthalmia the relative location and structure of extraocular muscles can be identified (Pedrosa-Domellöf et al 2000, Bohnsack et al 2011).

## Eyelids

The eyelids are formed as small cutaneous folds of surface ectoderm with a core of neural crest mesenchyme (see Fig. 40.2D). During the middle of the third month, their edges come together and unite over the cornea to enclose the conjunctival sac; they usually remain united until about the end of the sixth month. When the eyelids open, the conjunctiva lining their inner surfaces and covering the scleral region of the eye fuses with the corneal epithelium. Transforming growth factor alpha (TGF- $\alpha$ ) and several other growth factors regulate the mesenchyme-epithelium interactions and cell migration that are required for eyelid formation; keratinization is thought to play an important role in lid separation. The eyelashes and lid glands, i.e. sebaceous glands associated with the eyelashes and tarsal (Meibomian) glands, develop from ectoderm, as do the lacrimal and accessory lacrimal glands. Orbicularis oculi, which closes the eyelids, develops on each side from skeletal myoblasts from the second pharyngeal arch that invade the eyelids. The muscles that widen the palpebral fissure develop within the orbit from mesenchymal cells; the superior and inferior tarsal muscles are smooth muscle, whereas levator palpebrae superioris is striated muscle that is attached to each upper eyelid by a tendon derived from the neural crest (Plock et al 2005). (For a detailed timetable for upper eyelid development in staged human embryos and fetuses, see Byun et al (2011).)

## Lacrimal apparatus

The ectodermal epithelium of the superior conjunctival fornix proliferates and gives rise to a series of tubular buds that form the alveoli and ducts of the lacrimal gland. The buds are arranged in two groups: one forms the gland proper and the other forms its palpebral process (de la Cuadra-Blanco et al 2003). The lacrimal sac and nasolacrimal duct are derived from ectoderm in the nasomaxillary groove (between the lateral nasal process and the maxillary process of the developing face) (see Fig. 36.11). The ectoderm thickens to form a solid cord of cells, the nasolacrimal ridge, which subsequently sinks into the mesenchyme and becomes canalized during the third month to form the nasolacrimal duct. The lacrimal canaliculi arise from the cranial extremity of the cord as buds that establish openings (puncta lacrimalia) on the margins of the lids. The inferior canaliculus isolates a small part of the lower eyelid to form the lacrimal caruncle and plica semilunaris.

## Neonatal and infant eye

Low-birth-weight and preterm infants are at risk of developing retinopathy of prematurity, a proliferative retinopathy (Kashani et al 2014,

Hartnett et al 2014). At full term, the eye is $65 \%$ of its adult size. It grows rapidly for the first year, slightly slower until 3 years and then more slowly until puberty. There is proportionately less growth of anterior, compared to posterior, structures and the globe of the eye becomes more spherical. The neonatal lens is more spherical than that of the adult, which helps to compensate for the relative shortness of the eye. The visual acuity of neonates is estimated to be 20/400 and can reach $20 / 30-20 / 20$ by $2-3$ years of age; there is a general trend for infants to be far-sighted (Olitsky et al 2011). The visual pathways, lateral geniculate body and occipital visual cortex are patterned postnatally by exposure to visual stimuli. Visual loss with no structural anomaly of the eye, amblyopia, is caused by abnormal visual stimulation during infancy and early childhood (up to 6-7years of age) (Ruiz de Zárate and Tejedor 2007). Neonatal extraocular muscle coordination is usually achieved by 3-6 months of age and persistent deviation of an eye requires evaluation. Preterm infants have reduced reflex and tear secretion, and tears may not be present with crying until more than 3 months of age (Olitsky et al 2011).

## Orbit and accessory visual apparatus

## BONY ORBIT

The bony orbits are skeletal cavities located on either side of the root of the nose that serve as sockets for the eyes and associated tissues. The walls of each orbit protect the eye from injury, provide points of attachment for six extraocular muscles that allow the accurate positioning of the visual axis, and determine the spatial relationship between the two eyes, which is essential for both binocular vision and conjugate eye movements.

By convention, each cavity is considered to approximate to a quadrilateral pyramid with its base at the orbital opening, narrowing to its apex along a posteromedially directed axis. Each orbit has a roof, floor and medial and lateral walls. The medial walls lie approximately 25 mm apart in adults and are nearly parallel. The angle between the medial and lateral walls is about $45^{\circ}$. The compromise between protection and ensuring a good field of view dictates that each eyeball is located anteriorly within the orbit. The eyeball thus occupies only one-fifth of the volume of the orbit (Fig. 41.1); the remainder of the cavity is filled with extraocular muscles, vessels and nerves that are contained within and supported by orbital fat and connective tissue. In brief, the orbit transmits the optic, oculomotor, trochlear and abducens nerves, and branches of the ophthalmic and maxillary divisions of the trigeminal nerve, the ciliary parasympathetic ganglion and the ophthalmic vessels. It also contains the nasolacrimal apparatus that mediates tear drainage into the nasal cavity.

Fig. 41.1 A, A T2-weighted axial magnetic resonance imaging (MRI) scan through the mid-orbit. B, Note optic nerve in its entirety. (Courtesy of Dr Timothy Beale FRCR, Royal National Throat Nose and Ear Hospital, London.)

There is a strong correlation between the pattern of orbital growth and eyeball growth. Orbital growth is most rapid during the first 12-24 months of life and most parameters reach $86-96 \%$ of adult values by the age of 8 years (Escaravage and Dutton 2013). Orbital volumes are larger in boys than in girls throughout childhood (Bentley et al 2002).

## Roof

The roof of the orbit is formed principally by the thin orbital plate of the frontal bone (Fig. 41.2). It is gently concave on its orbital aspect, which separates the orbital contents and the brain in the anterior cranial fossa. Anteromedially, it contains the frontal sinus and displays a small trochlear fovea, sometimes surmounted by a small spine, where the cartilaginous trochlea (pulley) for superior oblique is attached. Anterolaterally, there is a shallow fossa that houses the orbital part of the lacrimal gland. The roof slopes down significantly towards the apex, joining the lesser wing of the sphenoid, which completes the roof. The optic canal lies between the roots of the lesser wing and is bounded medially by the body of the sphenoid.

## Medial wall

The medial wall of the orbit is formed principally by the orbital plate (lamina papyracea) of the ethmoid bone (see Fig. 41.2). This paperthin, rectangular plate covers the middle and posterior ethmoidal air cells, providing a route by which infection can spread into the orbit. The ethmoid articulates with the medial edge of the orbital plate of the frontal bone at a suture that is interrupted by anterior and posterior ethmoidal foramina. Posteriorly, it articulates with the body of the sphenoid, which forms the medial wall of the orbit to its apex. The lacrimal bone lies anterior to the ethmoid; it contains a fossa for the nasolacrimal sac that is limited in front by the anterior lacrimal crest on the frontal process of the maxilla and behind by the posterior lacrimal crest of the lacrimal bone (to which the lacrimal part of orbicularis oculi and lacrimal fascia are attached). A descending process of the lacrimal bone at the lower end of the posterior lacrimal crest contributes to the formation of the upper part of the nasolacrimal canal, which is completed by the maxilla (Fig. 41.3). During development, the medial wall of the orbit doubles in length, with disproportionate enlargement of its anterior half. Growth is rapid during the first 6 years of life and gradual between 7 years and adulthood (Isaacson and Monge 2003).

## Floor

The floor of the orbit is mostly formed by the orbital plate of the maxilla, which articulates with the zygomatic bone anterolaterally and the small triangular orbital process of the palatine bone posteromedially (see Fig. 41.3). The floor is thin and largely roofs the maxillary sinus. Not quite horizontal, it ascends a little laterally. Anteriorly, it curves into the lateral wall, and posteriorly, it is separated from the lateral wall by the inferior orbital fissure, which connects the orbit posteriorly to the pterygopalatine fossa, and more anteriorly to the infratemporal fossa. The medial lip is notched by the infraorbital groove. The latter passes forwards and sinks into the floor to become the infraorbital canal, which opens on the face at the infraorbital foramen; the infraorbital groove, canal and foramen contain the infraorbital nerve and vessels. Proportionally more pure orbital fractures involve the floor, particularly in the region of the infraorbital groove (Burm et al 1999). The classic 'blowout fracture' leaves the orbital rim intact and typically entraps soft tissue structures, leading to diplopia, impaired ocular motility and enophthalmos; infraorbital nerve involvement leads to ipsilateral sensory disturbance of the skin of the midface.

Fig. 41.2 An anterior view of the left orbit indicating the bones forming the walls (A) and the principal apertures (B). Fig. 41.3 A horizontal section through the floor of the left orbit and the adjacent ethmoidal and sphenoidal sinuses, viewed from above.

## Lateral wall

The lateral wall of the orbit is formed by the orbital surface of the greater wing of the sphenoid posteriorly and the frontal process of the zygomatic bone anteriorly; the bones meet at the sphenozygomatic suture. The zygomatic surface contains the openings of minute canals for the zygomaticofacial and zygomaticotemporal nerves, the former near the junction of the floor and lateral wall, and the latter at a slightly higher level, sometimes near the suture. The orbital tubercle, to which the lateral palpebral ligament, the check ligament of lateral rectus and the aponeurosis of levator palpebrae are all attached, lies just inside the midpoint of the lateral orbital margin. The lateral wall is the thickest wall of the orbit, especially posteriorly, where it separates the orbit from the middle cranial fossa. Anteriorly, the lateral wall separates the orbit and the infratemporal fossa. The lateral wall and roof are continuous anteriorly but are separated posteriorly by the superior orbital fissure, which lies between the greater wing (below) and lesser wing (above) of the sphenoid, and communicates with the middle cranial fossa. The fissure tapers laterally but widens at its medial end, its long axis descending posteromedially. Where the fissure begins to widen, its inferolateral edge shows a projection, often a spine, for the lateral attachment of the common tendinous ring (see Fig. 41.4). An infraorbital sulcus, which runs from the superolateral end of the superior orbital fissure towards
the orbital floor, is sometimes associated with an anastomosis between the middle meningeal and infraorbital arteries.

## ORBITAL FISSURES AND FORAMINA

## Optic canal

The lesser wing of the sphenoid is connected to the body of the sphenoid by a thin, flat anterior root and a thick, triangular posterior root. The optic canal lies between these (see Fig. 41.2) and connects the orbit to the middle cranial fossa, transmitting the optic nerve and its meningeal sheaths, and the ophthalmic artery. The common tendinous ring, which gives origin to the four recti, is attached to the bone near the superior, medial and lower margins of the orbital opening of the canal (see Fig. 41.4). The diameter of the cranial opening of the optic canal increases significantly during the fetal period and childhood into adulthood.

## Superior orbital fissure

The superior orbital fissure is the gap between the greater and lesser wings of the sphenoid, bounded medially by the body of the sphenoid, and closed at its anterior extremity by the frontal bone (see Fig. 41.2). It connects the cranial cavity with the orbit and transmits the oculomotor, trochlear and abducens nerves, branches of the ophthalmic nerve and the ophthalmic veins (see Fig. 41.4).

## Inferior orbital fissure

The inferior orbital fissure is bounded above by the greater wing of the sphenoid, below by the maxilla and the orbital process of the palatine bone, and laterally by the zygomatic bone (see Fig. 41.2). The maxilla and sphenoid often meet at the anterior end of the fissure, excluding the zygomatic bone. The inferior orbital fissure connects the orbit with the pterygopalatine and infratemporal fossae and transmits the infraorbital and zygomatic branches of the maxillary nerve and accompanying vessels (see Fig. 41.4), orbital rami from the pterygopalatine ganglion and a connection between the inferior ophthalmic vein and pterygoid venous plexus. A small maxillary depression may mark the attachment of inferior oblique anteromedially, lateral to the lacrimal hamulus.

## Ethmoidal foramina

The anterior and posterior ethmoidal foramina usually lie in the frontoethmoidal suture (see Fig. 41.2). The posterior foramen may be absent, and occasionally there is a middle ethmoidal foramen. The foramina open into canals that transmit their vessels and nerves into the ethmoidal sinuses, anterior cranial fossa and nasal cavity.

## COMMON TENDINOUS RING

The common tendinous ring is a fibrous ring that surrounds the optic canal and part of the superior orbital fissure at the apex of the orbit, and gives origin to the four recti (Fig. 41.4). The optic nerve and ophthalmic artery enter the orbit via the optic canal, and so lie within the common tendinous ring. The superior and inferior divisions of the oculomotor nerve, the nasociliary branch of the ophthalmic nerve, and the abducens nerve also enter the orbit within the common tendinous ring, but they do so via the superior orbital fissure (see Fig. 41.15). The trochlear nerve and the frontal and lacrimal branches of the ophthalmic

Fig. 41.4 The common tendinous ring: muscle origins have been superimposed. The relative positions of the nerves and vessels that enter the orbital cavity by passing through the superior orbital fissure or optic canal are shown. Note that the attachments of levator palpebrae superioris and superior oblique lie external to the common tendinous ring but are attached to it. The ophthalmic veins frequently pass through the ring. The recurrent meningeal artery (a branch of the ophthalmic artery) is often conducted from the orbit to the cranial cavity through its own foramen. Abbreviations: III, oculomotor nerve; IV, trochlear nerve;
VI, abducens nerve.
nerve all enter the orbit through the superior orbital fissure but lie outside the common tendinous ring. Structures that enter the orbit through the inferior orbital fissure lie outside the common tendinous ring. The close anatomical relationship of the optic nerve and other cranial nerves at the orbital apex means that lesions in this region may lead to a combination of visual loss from optic neuropathy and ophthalmoplegia from multiple cranial nerve involvement (Yeh and Foroozan 2004)

## ORBITAL CONNECTIVE TISSUE AND FAT

The orbit contains a complex arrangement of connective tissue that forms a supporting framework for the eyeball and also influences ocular rotations and compartmentalizes orbital fat (Fig. 41.5). Certain regions have anatomical and clinical significance, including the orbital septum, fascial sheath of the eye, 'check' ligaments, suspensory ligament and periosteum. The notion that orbital connective tissues function as extraocular muscle pulleys and influence ocular motility has recently gained widespread acceptance (Demer 2002, Miller 2007).

## ORBITAL SEPTUM

The orbital septum is a weak membranous sheet, attached to the orbital rim where it becomes continuous with the periosteum (see Fig. 41.5). It extends into each eyelid and blends with the tarsal plates and, in the upper eyelid, with the superficial lamella of levator palpebrae superioris. The orbital septum is thickest laterally, where it lies in front of the lateral palpebral ligament. It passes behind the medial palpebral ligament and nasolacrimal sac, but in front of the pulley of superior oblique. The septum is pierced above by levator palpebrae superioris and below by a fibrous extension from the sheaths of inferior rectus and inferior oblique. The lacrimal, supratrochlear, infratrochlear and supraorbital nerves and vessels pass through the septum from the orbit en route to the face and scalp. Clinically, the septum is an important anatomical reference to differentiate pre- and postseptal (orbital) cellulitis.

## FASCIAL SHEATH OF THE EYEBALL

A thin fascial sheath, the fascia bulbi (Tenon's capsule), envelops the eyeball from the optic nerve to the corneoscleral junction, separating it from the orbital fat and forming a socket for the eyeball (see Fig. 41.5; Fig. 41.6). The ocular aspect of the sheath is loosely attached to the sclera by delicate bands of episcleral connective tissue. Posteriorly, it is traversed by ciliary vessels and nerves. It fuses with the sclera and with the sheath of the optic nerve where the latter enters the eyeball; attachment to the sclera is strongest in this position and again anteriorly, just behind the corneoscleral junction at the limbus. Injection of local anaesthetics via a cannula into the space between the fascia bulbi and

Fig. 41.5 The contents of the orbit, sagittal section.

Fig. 41.6 A, The orbital fascia, sagittal section. B, The orbital fascia, horizontal section.
the sclera (sub-Tenon's anaesthesia) has become a popular technique for many ophthalmic surgical procedures (Davison et al 2007).

The fascia bulbi is perforated by the tendons of the extraocular muscles and is reflected on to each as a tubular sheath, the muscular fascia. The sheath of superior oblique reaches the fibrous pulley (trochlea) associated with the muscle. The sheaths of the four recti are very thick anteriorly but are reduced posteriorly to a delicate perimysium. Just before they blend with the fascia bulbi, the thick sheaths of adjacent recti become confluent and form a fascial ring.

Expansions from the muscular fascia are important for the attachments they make. Those from the medial and lateral recti are triangular and strong, and are attached to the lacrimal and zygomatic bones, respectively; since they may limit the actions of the two recti, they are termed the medial and lateral check ligaments (see Fig. 41.6). Other extraocular muscles have less substantial check ligaments, and the capacity of any of them actually to limit movement has been questioned.

The sheath of inferior rectus is thickened on its underside and blends with the sheath of inferior oblique. These two, in turn, are continuous with the fascial ring noted earlier and therefore with the sheaths of the medial and lateral recti. Since the latter are attached to the orbital walls by check ligaments, a continuous fascial band, the suspensory ligament of the eye, is slung like a hammock below the eye, providing sufficient support such that, even when the maxilla (forming the floor of the orbit) is removed, the eye will retain its position.

The thickened fused sheath of inferior rectus and inferior oblique also has an anterior expansion into the lower eyelid, where, augmented

Fig. 41.7 A coronal section through the left orbit (viewed from in front), cut through a plane passing 5 mm behind the posterior pole of the globe. Abbreviations: atc, adipose tissue compartments; eb, ethmoid bone; fn, frontal nerve; frb, frontal bone; ir, inferior rectus; Ips, levator palpebrae superioris; Ir, lateral rectus; m, maxilla (bone); mr, medial rectus; ncn, nasociliary nerve; opn, optic nerve; som, superior oblique; sov, superior ophthalmic vein; sr, superior rectus. (With permission from Koornneef $L$ 1977 The architecture of the musculo-fibrous apparatus in the human orbit. Acta Morphol Neerl Scand 15:35-64.)
by some fibres of orbicularis oculi, it attaches to the inferior tarsus as the inferior tarsal muscle; contraction of inferior rectus in downward gaze therefore also draws the lid downward. The sheath of levator palpebrae superioris is also thickened anteriorly, and just behind the aponeurosis it fuses inferiorly with the sheath of superior rectus. It extends forwards between the two muscles and attaches to the upper fornix of the conjunctiva.

Other extensions of the fascia bulbi pass medially and laterally, and attach to the orbital walls, forming the transverse ligament of the eye. This structure is of uncertain significance, but presumably plays a part in drawing the fornix upwards in gaze elevation and may act as a fulcrum for levator movements. Other numerous finer fasciae form radial septa that extend from the fascia bulbi and the muscle sheaths to the periosteum of the orbit, and so provide compartments for orbital fat. They also prevent the gross displacement of orbital fat, which could interfere with the accurate positioning of the two eyes that is essential for binocular vision.

The periosteum of the orbit is only loosely attached to bone. Behind, it is united with the dura mater surrounding the optic nerve and, in front, it is continuous with the periosteum of the orbital margin, where it gives off a stratum that contributes to the orbital septum. It also attaches to the trochlea and, as the lacrimal fascia, forms the roof and lateral wall of the fossa for the nasolacrimal sac.

## Orbital connective tissue pulleys

There is mounting evidence that challenges the traditional view that the recti are attached only at their origin and scleral insertion. The concept that orbital connective tissue sheaths elastically coupled to the orbital walls function as pulleys was initially proposed as an explanation for the observed orbital stability of rectus muscle paths (Miller 1989). Each pulley consists of an encircling sleeve of collagen located within the fascia bulbi, near the equator of the globe. Elastic fibres and bundles of smooth muscle confer the required internal rigidity to the structure (Demer 2002). Although the original model described a passive pulley system, the current view is that fibres from the orbital surface of the muscle insert into the pulley sleeve to allow small longitudinal movements. This 'active pulley hypothesis' provides a better explanation for normal ocular kinematics (Miller 2007).

## ORBITAL FAT

The spaces between the main structures of the orbit are occupied by fat, particularly in the region between the optic nerve and the surrounding cone of muscles (see Fig. 41.5; Fig. 41.7). Fat also lies between the muscles and periosteum, and is limited anteriorly by the orbital septum. Collectively, the fat helps to stabilize the position of the eyeball and also acts as a socket within which the eye can rotate. Conditions
resulting in an increased overall volume of orbital fat with associated swelling of the extraocular muscles, e.g. hyperthyroidism (Graves' disease), may lead to forward protrusion of the eyeball (exophthalmos).

## EXTRAOCULAR MUSCLES

There are seven skeletal extraocular (extrinsic) muscles associated with the eye. Levator palpebrae superioris is an elevator of the upper eyelid, and the other six, i.e. four recti (superior, inferior, medial and lateral) and two obliques (superior and inferior), are capable of moving the eye in almost any direction. Complete congenital absence of the extraocular muscles, thought to represent a severe form of congenital fibrosis syndrome, has been described (Brady et al 1992). Rarely, humans have deep orbital bands consistent with supernumerary extraocular muscles (Khitri and Demer 2010).

## LEVATOR PALPEBRAE SUPERIORIS

Levator palpebrae superioris is a thin, triangular muscle that arises from the inferior aspect of the lesser wing of the sphenoid, above and in front of the optic canal, and separated from it by the attachment of superior rectus (see Fig. 41.4). It has a short narrow tendon at its posterior attachment and broadens gradually, then more sharply as it passes anteriorly above the eyeball. The muscle ends in front in a wide aponeurosis Some of its tendinous fibres pass straight into the upper eyelid to attach to the anterior surface of the tarsus, while the rest radiate and pierce orbicularis oculi to pass to the skin of the upper eyelid. A thin lamina of smooth muscle, the superior tarsal muscle, passes from the underside of levator palpebrae superioris to the upper margin of the superior tarsus (see Fig. 41.20).

The connective tissue sheaths of the adjoining surfaces of levator palpebrae superioris and superior rectus are fused (see Fig. 41.5). Where the two muscles separate to reach their anterior attachments, the fascia between them forms a thick mass to which the superior conjunctival fornix is attached; this is usually described as an additional attachment of levator palpebrae superioris. Traced laterally, the aponeurosis of the levator passes between the orbital and palpebral parts of the lacrimal gland to attach to the orbital tubercle of the zygomatic bone. Traced medially, it loses its tendinous nature as it passes closely over the reflected tendon of superior oblique, and continues on to the medial palpebral ligament as loose strands of connective tissue.

Vascular supply Levator palpebrae superioris receives its arterial supply both directly from the ophthalmic artery and indirectly from its supraorbital branch.

Innervation Levator palpebrae superioris is innervated by a branch of the superior division of the oculomotor nerve that enters the inferior surface of the muscle. Sympathetic fibres to the smooth muscle component of levator palpebrae superioris (superior tarsal muscle) are derived from the plexus surrounding the internal carotid artery; these nerve fibres may join the oculomotor nerve in the cavernous sinus and pass forwards in its superior branch.

Actions Levator palpebrae superioris elevates the upper eyelid. During this process, the lateral and medial parts of its aponeurosis are stretched and thus limit its action; the elevation is also checked by the orbital septum. Elevation of the eyelid is opposed by the palpebral part of orbicularis oculi. Levator palpebrae superioris is linked to superior rectus by a check ligament; thus the upper eyelid elevates when the gaze of the eye is directed upwards.

The position of the eyelids depends on reciprocal tone in orbicularis oculi and levator palpebrae superioris, and on the degree of ocular protrusion. In the opened position, the upper eyelid covers the upper part of the cornea, while the lower lid lies just below its lower margin. The eyes are closed by movements of both lids, produced by the contraction of the palpebral part of orbicularis oculi and relaxation of levator palpebrae superioris. In looking upwards, the levator contracts and the upper lid follows the ocular movement. At the same time, the eyebrows are also usually raised by the frontal parts of occipitofrontalis to diminish their overhang. The lower lid lags behind ocular movement, so that more sclera is exposed below the cornea and the lid is bulged a little by the lower part of the elevated eye. When the eye is depressed, both lids move; the upper retains its normal relation to the eyeball and still covers about a quarter of the cornea, whereas the lower lid is depressed because the extension of the thickened fascia of inferior rectus and inferior oblique pull on its tarsus as the former contracts.

The palpebral apertures are widened in states of fear or excitement by contraction of the superior and inferior tarsal muscles as a result of increased sympathetic activity. Lesions of the sympathetic supply result in drooping of the upper eyelid (ptosis), as seen in Horner's syndrome.

## THE RECTI

The four recti are approximately strap-shaped; each has a thickened middle part that thins gradually to a tendon (Figs 41.8-41.9). They are attached posteriorly to a common tendinous ring that encircles the superior, medial and inferior margins of the optic canal, continues laterally across the inferior and medial parts of the superior orbital fissure, and is attached to a tubercle or spine on the margin of the greater wing of the sphenoid (see Fig. 41.4). The tendinous ring is closely adherent to the dural sheath of the optic nerve medially and to the surrounding periosteum. Inferior rectus, part of medial rectus and the lower fibres of lateral rectus are all attached to the lower part of the ring, whereas superior rectus, part of medial rectus and the upper fibres of lateral rectus are all attached to the upper part. A second small tendinous slip of lateral rectus is attached to the orbital surface of the greater wing of the sphenoid, lateral to the common tendinous ring.

Fig. 41.8 The extraocular muscles viewed from above.

Fig. 41.9 The muscles of the left orbit, lateral view.

Each rectus muscle passes forwards, in the position implied by its name, to be attached anteriorly by a tendinous expansion into the sclera, posterior to the margin of the cornea. However, before their scleral attachment, the recti make functionally important connections within orbital connective tissue that influence muscle action.

## Superior rectus

Superior rectus is slightly larger than the other recti. It arises from the upper part of the common tendinous ring, above and lateral to the optic canal. Some fibres also arise from the dural sheath of the optic nerve. The fibres pass forwards and laterally (at an angle of approximately $25^{\circ}$ to the median plane of the eye in the primary position) to insert into the upper part of the sclera, approximately 8 mm from the limbus (see Fig. 41.8). The insertion is slightly oblique, the medial margin more anterior than the lateral margin.

Vascular supply Superior rectus receives its arterial supply both directly from the ophthalmic artery and indirectly from its supraorbital branch.

Innervation Superior rectus is innervated by the superior division of the oculomotor nerve that enters the inferior surface of the muscle.

Actions Superior rectus moves the eye so that the cornea is directed upwards (elevation) and medially (adduction). To obtain upward movement alone, the muscle must function with inferior oblique. Superior rectus also causes intorsion of the eye (i.e. medial rotation). Because a check ligament extends from superior rectus to levator palpebrae superioris, elevation of the eye also results in elevation of the upper eyelid. For more detailed discussion of its actions, see page 672.

## Inferior rectus

Inferior rectus arises from the common tendinous ring, below the optic canal. It runs along the orbital floor in a similar direction to superior rectus (i.e. forwards and laterally) and inserts obliquely into the sclera below the cornea, approximately 6.5 mm from the limbus (see Fig. 41.9).

Vascular supply Inferior rectus receives its arterial supply from the ophthalmic artery and from the infraorbital branch of the maxillary artery.

Innervation Inferior rectus is innervated by a branch of the inferior division of the oculomotor nerve that enters the superior surface of the muscle.

Actions The principal activity of inferior rectus is to move the eye so that it is directed downwards (depression). It also causes the eye to deviate medially and extorts the eye (i.e. produces lateral rotation). To obtain downward movement alone, inferior rectus must function with superior oblique. A fibrous extension from inferior rectus to the inferior tarsal plate of the eyelid causes the lower eyelid to be depressed when the muscle contracts. For more detailed discussion of its actions, see page 672.

## Medial rectus

Medial rectus is slightly shorter than the other recti but is the strongest of the group. It arises from the medial part of the common tendinous ring, and also from the dural sheath of the optic nerve, passing horizontally forwards along the medial wall of the orbit, below superior oblique (see Figs 41.8, 41.9). It inserts into the medial surface of the sclera, approximately 5.5 mm from the limbus and slightly anterior to the other recti.

Vascular supply Medial rectus receives its arterial supply from the ophthalmic artery.

Innervation Medial rectus is innervated by a branch from the inferior division of the oculomotor nerve that enters the lateral surface of the muscle.

Actions Medial rectus moves the eye so that it is directed medially (adducted). The two medial recti acting together are responsible for convergence of the eyes. For more detailed discussion of its actions, see page 672 .

## Lateral rectus

Lateral rectus arises principally from the lateral part of the common tendinous ring and bridges the superior orbital fissure (see Fig. 41.4); some fibres also arise from a spine on the greater wing of the sphenoid.

The muscle passes horizontally forwards along the lateral wall of the orbit to insert into the lateral surface of the sclera, approximately 7 mm from the limbus (see Fig. 41.8).

Vascular supply Lateral rectus receives its arterial supply from the ophthalmic artery directly and/or from its lacrimal branch.

Innervation Lateral rectus is innervated by the abducens nerve by branches that enter the medial surface of the muscle.

Actions Lateral rectus moves the eye so that it is directed laterally (abducted). For more detailed discussion of its actions, see page 672.

## THE OBLIQUES

## Superior oblique

Superior oblique is a fusiform muscle that arises from the body of the sphenoid superomedial to the optic canal and the tendinous attachment of the superior rectus (see Fig. 41.4). It runs forwards to end in a round tendon that passes through a fibrocartilaginous loop, the trochlea, attached to the trochlear fossa of the frontal bone (see Fig. 41.8). Tendon and trochlea are separated by a delicate synovial sheath. The tendon subsequently descends posterolaterally and inferior to superior rectus, and is attached to the sclera in the superolateral part of the posterior quadrant behind the equator, between the superior and lateral recti.

Vascular supply Superior oblique receives its arterial supply directly from the ophthalmic artery and indirectly from its supraorbital branch.

Innervation Superior oblique is innervated by the trochlear nerve, which enters the superior surface of the muscle.

Actions Superior oblique is inserted into the posterior part of the eyeball; when it contracts, the back of the eyeball is elevated, and the front of the eyeball is depressed (particularly in the adducted position). Superior oblique also moves the eye laterally (abducted) and intorts the eyeball. For more detailed discussion of its actions, see page 672 .

## Inferior oblique

Inferior oblique is a thin, narrow muscle that lies near the anterior margin of the floor of the orbit. It arises from the orbital surface of the maxilla lateral to the nasolacrimal fossa and ascends posterolaterally, at first between inferior rectus and the orbital floor, and then between the eyeball and lateral rectus. It is inserted into the lateral part of the sclera behind the equator of the eyeball, in the inferolateral part of the posterior quadrant between the inferior and lateral recti, near, but slightly posterior to, the attachment of superior oblique (see Fig. 41.9). The muscle broadens and thins, and, in contrast to the other extraocular muscles, its tendon is barely discernible at its scleral attachment.

Vascular supply Inferior oblique receives its arterial supply from the ophthalmic artery and from the infraorbital branch of the maxillary artery.

Innervation Inferior oblique is innervated by a branch of the inferior division of the oculomotor nerve that enters the orbital surface of the muscle.

Actions Inferior oblique is inserted into the posterior part of the eyeball; when it contracts, the back of the eyeball is depressed and the front of the eyeball is elevated (particularly in the adducted position). The muscle moves the eye laterally (abduction) and also causes extorsion. For more detailed discussion of its actions, see below.

## MINOR MUSCLES OF THE EYELIDS

Several smooth muscles are associated with the orbit, although they are not directly attached to the eyeball. Orbitalis, the orbital muscle of Müller, lies at the back of the orbit and spans the infraorbital fissure. Its functions are uncertain but its contraction may possibly produce a slight forward protrusion of the eyeball. The superior and inferior tarsal muscles are small muscle laminae inserted into the upper and lower eyelids, and are described in more detail with the tarsal plates. All three minor muscles receive a sympathetic innervation from the superior cervical ganglion via the internal carotid plexus.

## MOVEMENTS OF THE EYES

Movements of the eyes involve rotations around a centre of rotation within the globe. For practical purposes, this can be considered to lie 13.5 mm behind the corneal apex. Normal eye movements are binocular. Movements of the eyes in the same direction are termed versions, whilst those in opposite directions are termed vergences. Eye movements are often accompanied by corresponding movements of the eyelids, particularly in upgaze, where the activity of levator palpebrae superioris is closely coupled to that of superior rectus. The following section describes the ocular motor system in terms of the actions of individual extraocular muscles, the diversity of eye movements and their neural control.

## Actions of the extraocular muscles

Levator palpebrae superioris elevates the upper lid, and its antagonist is the palpebral part of orbicularis oculi. The degree of elevation, which, apart from blinking, is maintained for long periods during waking hours, is a compromise between ensuring an adequate exposure of the cornea and controlling the amount of incident light. In bright sunshine, the latter can be reduced by lowering the upper lid, so limiting glare. The role of the superior tarsal muscle is less clear. Its tonus is related to sympathetic activity, and since ptosis is a consequence of impairment of its sympathetic nerve supply, it may function as an accessory elevator of the upper eyelid.

Six extraocular muscles rotate the eyeball in directions that depend on the geometrical relation between their bony and global attachments (Fig. 41.10), which are altered by the ocular movements themselves. For convenience, each muscle will be considered in isolation, but it must be appreciated that any movement of the eyeball alters the tension and/or length in all six muscles. It is useful to consider the four recti and two obliques as separate groups (remembering always that they act in concert) because they form more obvious groupings as antagonists or synergists. The extrinsic ocular muscles collectively position the eyeball in the orbital cavity and prevent its anteroposterior movements, other than a slight retraction during blinks, because the recti exert a posterior traction while the obliques pull the eyeball to some degree anteriorly. They may be assisted by various 'check ligaments' (see above). A simplified description of the actions of the extraocular muscles is summarized in Figure 41.11.

Of the four recti, the medial and lateral exert comparatively straightforward forces on the eyeball. Being approximately horizontal, when the visual axis is in its primary position, i.e. directed to the horizon, they rotate the eye medially (adduction) or laterally (abduction) about an imaginary vertical axis. They are antagonists. The visual axis can be swept through a horizontal arc by reciprocal adjustment of their lengths. When, as is usual, both eyes are involved, the medial and lateral recti of each eye either can adjust both visual axes in a conjugate movement from point to point at infinity (their axes remaining parallel), or they can converge or diverge the axes to or from nearer or more distant objects of attention in the visual field.

The medial and lateral recti do not rotate the eye around its horizontal axis and so cannot elevate or depress the visual axes as gaze is transferred from nearer to more distant objects or the reverse. This movement requires the superior and inferior recti (aided by the two oblique muscles). It is important to remember that the orbital axis does not correspond with the visual axis in its primary position but diverges from it at an angle of approximately $23^{\circ}$ (see Fig. 41.10A) (the value varies between individuals, and depends on the angle between the orbital axes and the median plane). Thus, the simple rotation caused by an isolated superior rectus, analysed with reference to the three hypothetical ocular axes, appears more complex, being primarily elevation (horizontal axis), and secondarily a less powerful medial rotation (vertical axis) and slight intorsion (anteroposterior axis) in which the midpoint of the upper rim of the cornea (often referred to as ' 12 $o^{\prime}$ clock') is rotated medially. These actions, compounded as a single, simple rotation, are easily appreciated when it is seen that the direction of traction of superior rectus runs in a posteromedial direction from its attachment in front, which is anterior to the equator and superior to the cornea, to its bony attachment near the orbital apex (see Fig. 41.10). Inferior rectus pulls in a similar direction to superior rectus but rotates the visual axis downwards about the horizontal axis. It rotates the eye medially on a vertical axis but its action around the anteroposterior axis extorts the eye, i.e. rotates it so that the corneal ' 12 o'clock' point turns laterally. The combined, equal contractions of the superior and inferior recti therefore rotate the eyeball medially, since their effects around the horizontal and anteroposterior axes are opposed. In binocular move-
ments, they assist the medial recti in converging the visual axes, and by reciprocal adjustment can elevate or depress the visual axes. As the eyeball is rotated laterally, the lines of traction of the superior and inferior recti approach the plane of the anteroposterior ocular axis (see Fig. 41.10), and so their rotational effects about this and the vertical ocular axis diminish. In abduction to approximately $23^{\circ}$, they become almost purely an elevator and depressor, respectively, of the visual axis.

Superior oblique acts on the eye from the trochlea and, since the attachment of inferior oblique is, for practical purposes, vertically below this, both muscles approach the eyeball at the same angle, being attached in approximately similar positions in the superior and inferior posterolateral ocular quadrants (see Fig. 41.10). Superior oblique elevates the posterior aspect of the eyeball, and inferior oblique depresses it, which means that the former rotates the visual axis downwards and the latter rotates it upwards, and both movements occur around the horizontal axis. When the eye is in the primary position, the obliquity of both muscles means that they pull in a direction posterior to the vertical axis and both therefore rotate the eye laterally around this axis. With regard to the anteroposterior axis, in isolation, superior oblique intorts the eye and inferior oblique extorts it. Like the superior and inferior recti, therefore, the two obliques have a common turning movement around the vertical axis but are opposed forces in respect of the other two. Acting in concert, they could therefore assist the lateral rectus in abducting the visual axis, as in divergence of the eyes in transferring attention from near to far. Again, like the superior and inferior recti, the directions of traction of the oblique muscles also vary with ocular position, such that they become more nearly a pure elevator and a depressor as the eye is adducted.

Ocular rotations are, for the most part, under voluntary control, whereas torsional movements cannot be initiated at will. When the head is tilted in a frontal plane, reflex torsions occur. Any small lapse in the concerted adjustment of both eyes produces diplopia.

## Movements that shift or stabilize gaze

The role of eye movements is to bring the image of objects of visual interest on to the fovea of the retina and to hold the image steady in order to achieve the highest level of visual acuity. Several types of eye movement are required to ensure that these conditions are met. Moreover, the movements of both eyes must be near perfectly matched to achieve the benefits of binocularity. Both voluntary and reflex movements are involved and may be so classified. Alternatively, they may be grouped into those movements that shift gaze as visual interest changes, and those that stabilize gaze by maintaining a steady image on the retina. They have distinct characteristics, and are generated by different neural mechanisms in response to different stimuli, but share a common final motor pathway. Movements that shift or stabilize gaze include saccades, vergence, pursuit and vestibular-generated reflexes (Leigh and Zee 2006).

Saccadic activity is almost omnipresent in human vision. Thus, both visual axes are endlessly and rapidly transferred to new points of interest in any part of the visual field. Binocular gaze is frequently made to travel routes of the most variable complexity in examining objects of interest in the field, and both visual axes must be maintained with sufficient accuracy to avoid diplopia. In so-called 'fixation' of a focus of attention, whether uniocular or binocular, the visual axis is not 'fixed' in a perfectly steady manner but undergoes minute, but measurable, flicking (of a few minutes or even seconds of arc) across the true line of fixation. These microsaccades are rapid and surprisingly complex. When interest changes to another feature of the visual scene, the eyes execute a fast or saccadic movement to take up fixation. If the required rotation is small, the saccade is accurate, whereas small supplementary corrective saccades are needed if the shift is substantial. Saccades may also occur in response to other, i.e. non-visual, exteroceptive stimuli (e.g. auditory, tactile or centrally evoked). They may be volitional or reflex. As an example of the latter, in reading a line of print, the eyes make three or four jerky saccades rather than following the line smoothly; the line is usefully imaged only when the eye is stationary, which means that little of the line is seen by the centre of the fovea. In general, reaction times and movements are measured in microseconds, amplitude varies from seconds of arc to many degrees, with an accuracy of $0.2^{\circ}$ or better, and the velocity of a large saccade may reach $500^{\circ} \mathrm{sec}^{-1}$. The speed of saccades is assured by an initial, slightly excessive, contraction of the appropriate muscles to overcome orbital viscous resistance. The necessary deceleration when the target is fixated is largely dependent on the elasticity of the extraocular muscles and orbital soft tissues, and not on antagonistic muscular activity.

Fig. 41.10 The geometrical basis of ocular movements. A, The relationship between the orbital and ocular axes, with the eyes in the primary position, where the visual axes are parallel. B and $\mathbf{C}$, The ocular globe in anterior and posterior views to show conventional geometry. $\mathbf{D}$, The orbits from above, showing the medial and lateral recti and the superior rectus (left) and the inferior rectus (right), indicating turning moments primarily around the vertical axis. E, The superior (left) and inferior (right) oblique muscles showing turning moments primarily around the vertical and also anteroposterior axes. F, A lateral view to show the actions of the superior and inferior recti around the horizontal axis. G, A lateral view to show the action of the superior and inferior oblique muscles around the anteroposterior axis. $\mathbf{H}$, An anterior view to show the medial rotational movement of the superior and inferior recti around the vertical axis. Conventionally, the 12 o'clock position indicated is said to be intorted (superior rectus) or extorted (inferior rectus), as indicated by the small arrows on the cornea. I, An anterior view to show the torsional effects of the superior oblique (intorsion) and inferior oblique (extorsion) around the anteroposterior axis, as indicated by the small arrows on the cornea.

Fig. 41.11 A simplified summary of the actions of the extraocular muscles. Clockwise and anticlockwise curved arrows represent intorsion and extorsion, respectively.

Vergence is a relatively slow movement permitting maintenance of single binocular vision of close objects. The eyes converge towards the midline between the two eyes to achieve imagery of the object on both foveas. The view of the object at the two eyes is not quite the same and the disparity is used to assess depth. In addition, the pupils constrict and the eyes accommodate to achieve sharp, focused images. These three activities constitute the near reflex.

Pursuit eye movements are used to track a moving object of visual interest, maintaining the image approximately on the fovea. They are usually preceded by a saccade to capture the image but, unlike saccades, they are slow and motivated by vision. If the angular shift required to track the moving object is large or the object is moving swiftly, the initial saccade is frequently inaccurate and one or more small corrective saccades are made before tracking begins. Because the stimulus is visual, the pursuit system response is subject to a relatively long latency (approximately 100 msec ); the limitation in performance this imposes may be offset by a predictive capacity when object movement follows a regular pattern, and the eye movements adjust in anticipation to speed and direction.

The vestibular apparatus induces a variety of reflex eye movements to compensate for the potentially disruptive effects on vision caused by head and body movement (Ch. 38). Receptors in the semicircular canals respond to active or passive rotational (angular) accelerations of the head. When the body makes substantial rotational movements, a vestibulo-ocular reflex generates a cycle of responses involving both the shifting and stabilizing of gaze. Body rotation is matched by counterrotation of the eyes so that gaze direction is unaltered and clear vision is maintained. Physical constraint limits the rotation to $30^{\circ}$ or less and is followed by a rapid saccadic movement of the eyes to another object in the visual scene and the cycle is repeated. Vision is therefore clear throughout most of the cycle while the image is stationary, but at the cost of no useful vision during the brief periods of the saccades. The reflex is efficient and rapid; this speed could not be generated by the visual system, which is slow relative to the short latency of vestibular receptors.

Other reflexes generated by the vestibular system, which induce compensatory eye movements to stabilize gaze, are activated during brief head movements. When the head is sharply rotated in any direction, the eyeball rotates by an equal amount in the opposite direction in response to the stimulation of semicircular canal cristae (angular acceleration), and gaze is undisturbed. Brief rotational movements are commonly combined with translational movements (linear acceleration) that are monitored by otolith organs. For example, a linear displacement occurs in walking as the head bobs vertically with each stride, and a rotational displacement occurs as the head rolls, invoking otolith and canal responses, respectively, to stabilize the retinal image. Vestibular disease incurring the loss of the rapid, fine compensatory eye
movements in locomotion destabilizes the retinal image, blurs vision and may render locomotion intolerable

The otoliths also respond to the pull of gravity, generating static vestibulo-ocular reflexes associated with head tilt. When static otolith orientation is changed, e.g. when the head is tilted upwards or downwards, the eyes counter-rotate to maintain fixation of the horizontal meridian. Lateral tilt towards a shoulder generates a torsional counterrotation of the eyes, a movement that cannot be made voluntarily. The torsional tilt reflex, equal and opposite in direction by the two eyes, is fully compensatory over $40^{\circ}$ or so in afoveate animals, but in humans it is vestigial; it is fractionally compensatory and varies in extent between individuals. Because the foveal image is unaffected by torsional movements, the subject is unaware of any visual penalty.

The optokinetic response is another visually mediated reflex that stabilizes retinal imagery when a visual scene is rotated about a stationary subject. As the scene changes, the eyes follow and hold the retinal image steady until the eyes shift rapidly in the opposite direction to another area of the visual scene. The full field of vision, rather than small objects within it, is the stimulus, and the alternating slow and fast phases of movement that are generated describe optokinetic nystagmus. This reflex functions in collaboration with the rotational vestibulo-ocular reflex. In sustained rotations of the body, the vestibuloocular reflex fades because of the mechanical arrangements of the semicircular canals. In darkness, the reflex, which is initially compensatory, loses velocity, and after approximately 45 seconds the eyeballs become stationary. With a visual input, the reflex is sustained by the optokinetic response. Because the reflex is already initiated, the relative delay of visual input is overcome. The integration of the two systems is served by an accessory visual system projection to the vestibular nuclei via the inferior olive and cerebellum. The usual method of evoking optokinetic nystagmus in the laboratory or clinic is to present a horizontally moving pattern of vertical black-on-white stripes while the head of the subject is held stationary.

## Neural control of gaze

Although the detailed anatomical substrates for the different types of eye movement differ, they share common neural circuitry that lies mainly in the pons and midbrain, for horizontal and vertical gaze movements, respectively (Fig. 41.12). The common element for all types of horizontal gaze movements is the abducens nucleus. It contains motor neurones that innervate the ipsilateral lateral rectus and interneurones that project via the medial longitudinal fasciculus to the contralateral oculomotor nucleus, which controls medial rectus. A lesion of the abducens nucleus leads to a total loss of ipsilateral horizontal conjugate gaze. A lesion of the medial longitudinal fasciculus produces slowed or absent adduction of the ipsilateral eye, usually associated with jerky movements (nystagmus) of the abducting eye, a syndrome called internuclear ophthalmoplegia (Leigh and Zee 2006). The gaze motor command involves specialized areas of the reticular formation of the brainstem, which receive a variety of supranuclear inputs. The main region for the generation of horizontal saccades is the paramedian pontine reticular formation, located on each side of the midline in the central paramedian part of the tegmentum, and extending from the pontomedullary junction to the pontopeduncular junction. Each paramedian pontine reticular formation contains excitatory neurones (referred to as 'burst' cells) that discharge at high frequencies just prior to and during ipsilateral saccades. Excitatory burst cells make monosynaptic connections with the ipsilateral abducens nucleus. Pause neurones, located in a midline caudal pontine nucleus, called the nucleus raphe interpositus, discharge tonically during fixation but stop firing immediately prior to a saccade. They appear to exert an inhibitory influence on the burst neurones and act as a switch to change from fixation to saccadic mode (Ramat et al 2007).

The tonic activity of neurones in the nucleus prepositus hypoglossi and medial vestibular nucleus is thought to provide an eye position signal to maintain the eccentric position of the eye against the viscoelastic forces in the orbit. These forces tend to move the eyeball back to looking straight ahead, i.e. the primary position, after a saccade. Vestibular nuclei and the perihypoglossal complex project directly to the abducens nuclei. These projections probably also carry smooth pursuit signals, via the cerebellum.

The final common pathway for vertical gaze movements is formed by the oculomotor and trochlear nuclei. The rostral interstitial nucleus of the medial longitudinal fasciculus contains excitatory burst neurones that discharge in relation to up-and-down vertical saccadic movements and project to motor neurones involved in vertical gaze. The rostral interstitial nucleus of the medial longitudinal fasciculus projects

through the posterior commissure to its equivalent on the other side of the mesencephalon, as well as directly to the ipsilateral oculomotor and trochlear nuclei (see Fig. 41.12). Neurones in and around the interstitial nucleus of Cajal, which lies slightly caudal to the rostral interstitial nucleus of the medial longitudinal fasciculus, provide signals for vertical gaze holding. Vertical gaze palsies can affect upgaze, downgaze or both. Lesions within the posterior commissure predominantly give rise to disturbances in upgaze, associated with other signs of dorsal midbrain syndrome, e.g. pupillary abnormalities (light-near dissociation). Discrete lesions placed more ventrally in the region of the rostral interstitial nucleus of the medial longitudinal fasciculus may cause mixed up-and-down, or mainly downgaze disturbances (Leigh and Zee 2006).

The cerebellum plays an important role in the control of eye movements (p. 347, see Fig. 22.24). The vestibulocerebellum (flocculus and nodule) is involved in gaze holding, smooth pursuit and the vestibuloocular reflex. The dorsal vermis and fastigial nucleus play a major role in programming accurate saccades and smooth pursuit.

The cerebral hemispheres are extremely important for the programming and coordination of both saccadic and pursuit conjugate eye movements (Ch. 25). There appear to be four main cortical areas in the cerebral hemispheres involved in the generation of saccades. These are the frontal eye field, which is located at the intersection of the superior precentral sulcus with the superior frontal sulcus (Brodmann area 8) (Amiez and Petrides 2009); the supplementary eye field, which lies in the dorsomedial frontal cortex (Brodmann area 6); the dorsolateral prefrontal cortex, which lies anterior to the frontal eye field in the second frontal gyrus (Brodmann area 46); and a posterior eye field, which lies in the parietal lobe in the medial wall of the posterior half of the intraparietal sulcus, including parts of the supramarginal and angular gyri (Brodmann areas 39 and 40), and the adjacent lateral intraparietal sulcus (Müri et al 1996). These areas all appear to be interconnected and to send projections to the superior colliculus and the brainstem areas controlling saccades.

Two parallel pathways are involved in the cortical generation of saccades. An anterior system originates in the frontal eye field and projects, both directly and via the superior colliculus, to the brainstem saccadic generators. This pathway also passes indirectly via the basal ganglia to the superior colliculus. Projections from the frontal cortex influence cells in the pars reticularis of the substantia nigra, via a relay in the caudate nucleus. An inhibitory pathway from the pars reticulata projects directly to the superior colliculus. This may be a gating circuit related
to voluntary saccades, especially of the memory-guided type. A posterior pathway originates in the posterior eye field and passes to the brainstem saccadic generators via the superior colliculus. This pathway is important for triggering visually guided saccades.

The smooth pursuit system has developed relatively independently of the saccadic oculomotor system to maintain foveation of a moving target, although there are inevitable interconnections between the two. The first task is to identify and code the velocity and direction of a moving target. This is carried out in the extrastriate visual area known as the middle temporal visual area (also called visual area V5), which contains neurones sensitive to visual target motion. In humans, this lies immediately posterior to the ascending limb of the inferior temporal sulcus at the occipitotemporal border. The middle temporal visual area sends this motion signal to the medial superior temporal visual area, thought to lie superior and a little anterior to the middle temporal visual area within the inferior parietal lobe; damage to this area results in an impairment of smooth pursuit of targets moving towards the damaged hemisphere.

Both the medial superior temporal visual area and the frontal eye field send direct projections to a group of nuclei that lie in the basal part of the pons. In monkeys, the dorsolateral and lateral groups of pontine nuclei receive direct cortical inputs related to smooth pursuit. Lesions of similarly located nuclei in humans result in abnormal pursuit. These nuclei transfer the pursuit signal bilaterally to the posterior vermis, contralateral flocculus and fastigial nuclei of the cerebellum. The pursuit signal ultimately passes from the cerebellum to the brainstem, specifically to the medial vestibular nucleus and nucleus propositus hypoglossi, and thence to the paramedian pontine reticular formation and possibly directly to the ocular motor nuclei. This circuitry therefore involves a double decussation: firstly, at the level of the midpons (pontocerebellar neurones), and secondly, in the lower pons (vestibulo-abducens neurones).

The vestibulo-ocular reflex maintains coordination of vision during movement of the head and results in a compensatory conjugate eye movement that is equal but opposite to the movement of the head. This essentially three-neurone arc consists of primary vestibular neurones that project to the vestibular nuclei, secondary neurones that project from these nuclei directly to the abducens and oculomotor nuclei, and tertiary neurones that innervate the extraocular muscles. Vestibular neurones responding to head rotation also respond to optokinetic stimuli, which means that the neural substrate is likely to include both the visual and vestibular systems.

Fig. 41.13 The orbital distribution of the ophthalmic artery. Abbreviations: lpca, long posterior ciliary artery; m, muscular arteries; p, pial arteries; spca, short posterior ciliary arteries.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES

The main vessel supplying orbital structures is the ophthalmic artery (Fig. 41.13). Its terminal branches anastomose on the face and scalp with those of the facial, maxillary and superficial temporal arteries, thereby establishing connections between the external and internal carotid arteries. The infraorbital branch of the maxillary artery, and possibly the recurrent meningeal artery, also supply orbital structures.

## Ophthalmic artery

The ophthalmic artery leaves the internal carotid artery as it exits the cavernous sinus medial to the anterior clinoid process. It enters the orbit by the optic canal, inferolateral to the optic nerve and continues forwards for a short distance before turning medially by crossing (almost always) over or (sometimes) under the optic nerve (see Fig. 41.13). The main trunk of the artery continues along the medial wall of the orbit between the superior oblique and lateral rectus, and divides into supratrochlear (frontal) and dorsal nasal branches at the medial end of the upper eyelid. Although the order of branches from the ophthalmic artery is quite variable, a number may be identified consistently, including the central retinal artery, lacrimal artery, muscular branches, ciliary arteries, supraorbital artery, anterior and posterior ethmoidal arteries, meningeal branch, medial palpebral arteries, supratrochlear artery and dorsal nasal artery (Hayreh and Dass 1962). Many of the branches of the ophthalmic artery accompany sensory nerves of the same name and have a similar distribution. Variations in the origin and course of the ophthalmic artery have been described (Huynh-Le et al 2005). The artery may arise within, near or significantly distal to the upper dural ring, and the point of penetration of the dura lining the optic canal may be posterior, below or anterior to the falciform ligament. The ophthalmic artery may also arise from the clinoid or intracavernous segment of the carotid artery. In the latter case, the ophthalmic artery may pass through either the superior orbital fissure or the optic canal.

## Central retinal artery

The small central artery of the retina is the first branch of the ophthalmic artery. It begins below the optic nerve and, for a short distance, lies in the dural sheath of the nerve. It enters the inferomedial surface of the nerve $6.4-15.2 \mathrm{~mm}$ behind the eye, and runs to the retina (accompanying the central retinal vein) along its axis. The further distribution of the central retinal artery is described on page 704.

## Muscular branches

Muscular branches frequently spring from a common trunk to form superior and inferior groups, most of which accompany branches of the oculomotor nerve. The inferior branch contains most of the anterior ciliary arteries. Other muscular vessels branch from the lacrimal and supraorbital arteries or from the trunk of the ophthalmic artery.

## Ciliary arteries

The ciliary arteries are distributed in long and short posterior, and in anterior groups (see Fig. 41.13). Long posterior ciliary arteries, usually two, pierce the sclera near the optic nerve, pass anteriorly along the horizontal meridian and join the major arterial circle of the iris (see Fig. 42.8). About seven short posterior ciliary arteries pass close to the optic nerve to reach the eyeball, where they divide into 15-20 branches. They pierce the sclera around the optic nerve to supply the choroid, and anastomose with twigs of the central retinal artery at the optic disc (see Fig. 42.30). Anterior ciliary arteries arise from muscular branches of the ophthalmic artery. They reach the eyeball on the tendons of the recti, form a circumcorneal subconjunctival vascular zone, and pierce the sclera near the sclerocorneal junction to end in the major arterial circle of the iris.

## Lacrimal artery

The lacrimal artery is a large branch that usually leaves the ophthalmic artery near its exit from the optic canal (see Fig. 41.13), although it occasionally arises before the ophthalmic artery enters the orbit. It accompanies the lacrimal nerve along the upper border of lateral rectus, supplies and traverses the lacrimal gland, and ends in the eyelids and conjunctiva as the lateral palpebral arteries. The latter run medially in the upper and lower lids and anastomose with the medial palpebral arteries. The lacrimal artery gives off one or two zygomatic branches. One reaches the temporal fossa via the zygomaticotemporal foramen and anastomoses with the deep temporal arteries. The other reaches the cheek by the zygomaticofacial foramen and anastomoses with transverse facial and zygomatico-orbital arteries. A recurrent meningeal branch, usually small, passes back via the lateral part of the superior orbital fissure to anastomose with a middle meningeal branch. This branch is sometimes large and replaces the lacrimal artery, in which case it becomes a more significant contributor to the orbital blood supply.

## Supraorbital artery

The supraorbital artery leaves the ophthalmic artery where it crosses the optic nerve (see Fig. 41.13), and ascends medial to superior rectus and levator palpebrae superioris. It accompanies the supraorbital nerve between the periosteum and levator palpebrae superioris, passes through the supraorbital foramen or notch, and divides into superficial and deep branches. These supply the skin, muscles and frontal periosteum, and anastomose with the supratrochlear artery and with the frontal branch of the superficial temporal artery and its contralateral fellow (see Fig. 30.20). The supraorbital artery supplies superior rectus and levator palpebrae superioris, and sends a branch across the trochlea to the medial canthus. It often sends a branch to the diploë of the frontal bone at the supraorbital margin, and may also supply the mucoperiosteum in the frontal sinus.

## Posterior ethmoidal artery

The posterior ethmoidal artery runs through the posterior ethmoidal canal and supplies the posterior ethmoidal air sinuses. Entering the cranium, it gives off a meningeal branch to the dura mater, and nasal branches that descend into the nasal cavity via the cribriform plate and anastomose with branches of the sphenopalatine artery (see Fig. 33.9).

## Anterior ethmoidal artery

The anterior ethmoidal artery passes with its accompanying nerve through the anterior ethmoidal canal to supply the ethmoidal and frontal air sinuses. Entering the cranium, it gives off a meningeal branch to the dura mater, and nasal branches that descend into the nasal cavity with the anterior ethmoidal nerve (see Fig. 33.9). It runs in a groove on the deep surface of the nasal bone to supply the lateral nasal wall and septum. A terminal branch appears on the nose between the nasal bone and the upper nasal cartilage (see Fig. 33.9).

## Meningeal branch

A meningeal branch, usually small, passes back through the superior orbital fissure to the middle cranial fossa, where it anastomoses with the middle and accessory meningeal arteries. It is sometimes large, in which case it becomes a major contributor to the orbital blood supply.

## Medial palpebral arteries

Above the trochlea, two medial palpebral arteries branch separately from the ophthalmic artery and join the lateral palpebral arteries to complete the arcades of the upper and lower eyelids.

## Supratrochlear artery

The supratrochlear artery is a terminal branch of the ophthalmic artery. It leaves the orbit superomedially with the supratrochlear nerve, ascends on the forehead to supply the skin, muscles and pericranium, and anastomoses with the supraorbital artery and with its contralateral fellow.

## Dorsal nasal artery

The dorsal nasal artery is the other terminal branch of the ophthalmic artery and emerges from the orbit between the trochlea and medial palpebral ligament. It gives a branch to the upper part of the nasolacrimal sac and then divides into two branches. One branch joins the terminal part of the facial artery, and the other runs along the dorsum of the nose, supplies its outer surface and anastomoses with its contralateral fellow and the lateral nasal branch of the facial artery.

## Infraorbital branch of the maxillary artery

The infraorbital branch of the maxillary artery enters the orbit through the inferior orbital fissure (see Fig. 32.20). Accompanying the infraorbital nerve, it passes along the infraorbital groove of the maxilla in the floor of the orbit before entering the infraorbital canal, and comes out on to the face through the infraorbital foramen. While in the infraorbital groove, it gives off branches that supply inferior rectus and inferior oblique, the nasolacrimal sac and, occasionally, the lacrimal gland.

## VEINS

The orbit is drained by the superior and inferior ophthalmic veins and the infraorbital vein (Fig. 41.14). The veins of the eyeball mainly drain into the vortex veins; the retinal veins drain into the central retinal vein.

## Superior and inferior ophthalmic veins

The superior and inferior ophthalmic veins link the facial and intracranial veins, and are devoid of valves. The superior ophthalmic vein forms posteromedial to the upper eyelid from two tributaries that connect anteriorly with the facial and supraorbital veins. It runs with the ophthalmic artery, lying between the optic nerve and superior rectus, and receives the corresponding tributaries, the two superior vortex veins of the eyeball, and the central vein of the retina. The central retinal vein sometimes drains directly into the cavernous sinus, although it still gives a communicating branch to the superior ophthalmic vein. The

Fig. 41.14 The principal veins of the orbit.
superior ophthalmic vein may also receive the inferior ophthalmic vein. It traverses the superior orbital fissure, usually above the common tendinous ring of the recti, and ends in the cavernous sinus.

The inferior ophthalmic vein begins in a network near the anterior region of the orbital floor and medial wall. It runs backwards on inferior rectus and across the inferior orbital fissure, and then either joins the superior ophthalmic vein or passes through the superior orbital fissure, within or below the common tendinous ring, to drain directly into the cavernous sinus. The inferior ophthalmic vein receives tributaries from inferior rectus and inferior oblique, the nasolacrimal sac, the eyelids and the two inferior vortex veins of the eyeball. It communicates with the pterygoid venous plexus by a branch that passes through the inferior orbital fissure, and may also communicate with the facial vein across the inferior margin of the orbit.

## Infraorbital vein

The infraorbital vein runs with the infraorbital nerve and artery in the floor of the orbit, and passes backwards through the inferior orbital fissure into the pterygoid venous plexus. It drains structures in the floor of the orbit and communicates with the inferior ophthalmic vein; it may also communicate with the facial vein on the face.

## LYMPHATIC DRAINAGE

Lymphatic vessels other than those draining the conjunctiva have not been identified.

## INNERVATION

Somatic and autonomic motor and somatic sensory nerves are found in the orbit (Figs 41.15-41.17). The oculomotor, trochlear and abducens nerves supply the extraocular muscles. Parasympathetic fibres from the oculomotor nerve supply sphincter pupillae and the ciliary muscle (ciliaris) via the ciliary ganglion, and those from the facial nerve innervate the lacrimal gland and choroid via the pterygopalatine ganglion. Sympathetic fibres supply dilator pupillae. Both sympathetic and parasympathetic nerves supply the arteries. The sensory nerves within the orbit are the optic, ophthalmic and maxillary nerves (the maxillary nerve and most of the ophthalmic branches only pass through the orbit en route to supply the face and jaws).

## Oculomotor nerve

The oculomotor nerve is the third cranial nerve (see Fig. 41.15). It innervates levator palpebrae superioris and four of the extraocular muscles (superior, inferior and medial rectus and inferior oblique), and also conveys parasympathetic fibres that relay in the ciliary ganglion. The nerve emerges at the midbrain, on the medial side of the crus of the cerebral peduncle, and passes along the lateral dural wall of the cavernous sinus, dividing into superior and inferior divisions that run beneath the trochlear and ophthalmic nerves. The two divisions enter the orbit through the superior orbital fissure, within the common

Fig. 41.15 The left orbit viewed from in front, showing motor and sensory nerves and the origins of the extraocular muscles. Note that in this figure the trochlear nerve is shown inserting on the inferior aspect of the superior oblique, whereas it more commonly inserts on the superior surface of the muscle. (With permission from Dutton JJ 1994 Atlas of Clinical and Surgical Orbital Anatomy. Philadelphia: Saunders.)
tendinous ring of the recti, separated by the nasociliary branch of the ophthalmic nerve.

The superior division of the oculomotor nerve passes above the optic nerve to enter the inferior (ocular) surface of superior rectus. It supplies this muscle and gives off a branch that runs to innervate levator palpebrae superioris. The inferior division of the oculomotor nerve divides into medial, central and lateral branches. The medial branch passes beneath the optic nerve to enter the lateral (ocular) surface of medial rectus; the central branch runs downwards and forwards to enter the superior (ocular) surface of inferior rectus; the lateral branch travels forwards on the lateral side of inferior rectus to enter the orbital surface of inferior oblique and also communicates with the ciliary ganglion to distribute parasympathetic fibres to sphincter pupillae and the ciliary muscle.

## Trochlear nerve

The trochlear nerve is the fourth cranial nerve and innervates superior oblique exclusively. It is the only cranial nerve to emerge from the dorsal surface of the brainstem, passing from the midbrain on to the lateral surface of the crus of the cerebral peduncle. It runs through the lateral dural wall of the cavernous sinus and then crosses the oculomotor nerve to enter the orbit through the superior orbital fissure, outside the common tendinous ring, above levator palpebrae superioris and medial to the frontal and lacrimal nerves (see Fig. 41.16). The trochlear nerve travels a short distance to enter the superior (orbital) surface of superior oblique.

Fig. 41.16 The nerves of the left orbit, superior aspect.

## Abducens nerve

The abducens nerve is the sixth cranial nerve and exclusively innervates lateral rectus. It emerges from the brainstem between the pons and the medulla oblongata, and usually runs through the inferior venous compartment of the petroclival venous confluence in a bow-shaped canal, Dorello's canal. It then bends sharply across the upper border of the petrous part of the temporal bone to enter the cavernous sinus, where it lies lateral to the internal carotid artery (unlike the oculomotor, trochlear, ophthalmic and maxillary nerves, which merely invaginate the lateral dural wall of the sinus). The abducens nerve enters the orbit through the superior orbital fissure, within the common tendinous ring, at first below, and then between, the two divisions of the oculomotor nerve and lateral to the nasociliary nerve (see Fig. 41.15). It passes forwards to enter the medial (ocular) surface of lateral rectus.

## Optic nerve

The optic nerve is the second cranial nerve. It arises from the optic chiasma on the floor of the diencephalon and enters the orbit through the optic canal, accompanied by the ophthalmic artery. It changes its shape from being flattened at the chiasma to rounded as it passes through the optic canal. In the orbit, the optic nerve passes forwards, laterally and downwards, and pierces the sclera at the lamina cribrosa, slightly medial to the posterior pole. It has a somewhat tortuous course within the orbit to allow for movements of the eyeball, and is surrounded by extensions of the three layers of the meninges.

The optic nerve has important relationships with other orbital structures (see Fig. 41.4). As it leaves the optic canal, it lies superomedial to the ophthalmic artery, and is separated from lateral rectus by the oculomotor, nasociliary and abducens nerves, and sometimes by the ophthalmic veins. It is closely related to the origins of the four recti, whereas more anteriorly, where the muscles diverge, it is separated from them by a substantial amount of orbital fat. Just beyond the optic canal, the ophthalmic artery and the nasociliary nerve cross the optic nerve to reach the medial wall of the orbit. The central artery of the retina enters the substance of the optic nerve about halfway along its length. Near the back of the eyeball, the optic nerve becomes surrounded by the long and short ciliary nerves and vessels.

## Ophthalmic nerve

The ophthalmic division of the trigeminal nerve arises from the trigeminal ganglion in the middle cranial fossa. It passes forwards along the lateral dural wall of the cavernous sinus, giving off three main branches - the lacrimal, frontal and nasociliary nerves - just before it reaches the superior orbital fissure (see Figs 41.16-41.17). These branches subsequently travel through the orbit to supply targets that are primarily in the upper part of the face (see Fig. 30.22).

## Lacrimal nerve

The lacrimal nerve enters the orbit through the superior orbital fissure, outside the common tendinous ring and lateral to the frontal and trochlear nerves. It passes forwards along the lateral wall of the orbit on the superior border of lateral rectus, and travels through the lacrimal

Fig. 41.17 The nerves of the left orbit and the ciliary ganglion, lateral aspect.
gland and the orbital septum to supply the conjunctiva and skin covering the lateral part of the upper eyelid. The nerve also communicates with the zygomatic branch of the maxillary nerve, which may carry some postganglionic parasympathetic fibres from the pterygopalatine ganglion to the lacrimal gland (see orbital branches from pterygopalatine ganglion, below).

## Frontal nerve

The frontal nerve is the largest branch of the ophthalmic nerve. It enters the orbit through the superior orbital fissure outside the common tendinous ring, and lies between the lacrimal nerve laterally and the trochlear nerve medially. It passes forwards towards the rim of the orbit on levator palpebrae superioris; about halfway along this course, it divides into the supraorbital and supratrochlear nerves.

## Supraorbital nerve

The supraorbital nerve, the larger of the two terminal branches of the frontal nerve, continues forwards along levator palpebrae superioris until it leaves the orbit through the supraorbital notch or foramen. It emerges on to the forehead and supplies the mucous membrane that lines the frontal sinus, the conjunctiva and skin covering the upper eyelid, and the skin over the forehead and scalp. The postganglionic sympathetic fibres that innervate the sweat glands of the supraorbital area probably travel in the supraorbital nerve, having entered the ophthalmic nerve via its communication with the abducens nerve within the cavernous sinus.

## Supratrochlear nerve

The supratrochlear nerve runs medially above the trochlea for the tendon of superior oblique. It gives a descending branch to the infratrochlear nerve and ascends on to the forehead through the frontal notch to supply the conjunctiva and skin covering the upper eyelid and the forehead.

## Nasociliary nerve

The nasociliary nerve is intermediate in size between the frontal and lacrimal nerves, and is more deeply placed in the orbit, which it enters through the common tendinous ring, lying between the two rami of the oculomotor nerve. It crosses the optic nerve with the ophthalmic artery and runs obliquely below superior rectus and superior oblique to reach the medial orbital wall, where it gives off the anterior and posterior ethmoidal nerves. The nasociliary nerve also has long ciliary and infratrochlear branches and a connection with the ciliary ganglion.

## Anterior ethmoidal nerve

The anterior ethmoidal nerve passes through the anterior ethmoidal foramen and canal, and enters the cranial cavity. It runs forwards in a groove on the upper surface of the cribriform plate beneath the dura mater, and descends through a slit lateral to the crista galli into the nasal cavity, where it occupies a groove on the internal surface of the nasal bone and gives off the medial and lateral internal nasal branches. For a description of the subsequent distribution of the anterior ethmoidal nerve, see page 564 .

## Posterior ethmoidal nerve

The posterior ethmoidal nerve leaves the orbit by the posterior ethmoidal foramen and supplies the ethmoidal and sphenoidal sinuses.

## Infratrochlear nerve

The infratrochlear nerve leaves the orbit below the trochlea and supplies the skin of the eyelids, the conjunctiva, lacrimal sac, lacrimal caruncle and the side of the nose above the medial canthus.

## Long ciliary nerves

Two or three long ciliary nerves branch from the nasociliary nerve as it crosses the optic nerve. They accompany the short ciliary nerves, pierce the sclera near the attachment of the optic nerve, and run forwards between the sclera and choroid. They supply the ciliary body, iris and cornea, and contain postganglionic sympathetic fibres for the dilator pupillae from neurones in the superior cervical ganglion. An alternative pathway for the supply of the dilator pupillae is via the sympathetic root associated with the ciliary ganglion (Fig. 41.18).

## Ramus communicans to the ciliary ganglion

The ramus communicans to the ciliary ganglion usually branches from the nasociliary nerve as the latter enters the orbit lateral to the optic

Fig. 41.18 The ciliary ganglion, with its roots and branches of distribution. Key: red, sympathetic fibres; green, parasympathetic fibres; blue, sensory fibres. Alternative pathways are given for the sympathetic fibres.
nerve. It is sometimes joined by a filament from the internal carotid sympathetic plexus or from the superior ramus of the oculomotor nerve as it enters the posterosuperior angle of the ganglion.

## Maxillary nerve

Most of the branches of the maxillary division of the trigeminal nerve arise in the pterygopalatine fossa. They include the zygomatic and infraorbital nerves, which pass into the orbit through the inferior orbital fissure (see Figs 32.30, 41.17).

## Zygomatic nerve

The zygomatic nerve lies close to the base of the lateral wall of the orbit. It divides soon after entering the orbit into two branches, the zygomaticotemporal and the zygomaticofacial nerves, which run within the orbit for only a short distance before passing on to the face through the lateral wall of the orbit. Either they may enter separate canals within the zygomatic bone or the zygomatic nerve itself may enter the bone before dividing. For a description of the distribution of the zygomaticotemporal and zygomaticofacial nerves on the face, see page 502.

## Infraorbital nerve

The infraorbital nerve initially lies in the infraorbital groove on the floor of the orbit (see Fig. 32.30B). As it approaches the rim of the orbit, it runs into the infraorbital canal, through which it passes to emerge on to the face at the infraorbital foramen. It supplies the skin of the lower eyelid and possibly the conjunctiva. For a description of the subsequent distribution of the infraorbital nerve on the face, see page 502.

## Ciliary ganglion

The ciliary ganglion is a parasympathetic ganglion concerned with the innervation of certain intraocular muscles. It is a small, flat, reddishgrey swelling, 1-2 mm in diameter, connected to the nasociliary nerve, and located near the apex of the orbit in loose fat approximately 1 cm in front of the medial end of the superior orbital fissure. It lies between the optic nerve and lateral rectus, usually lateral to the ophthalmic artery. Its neurones, which are multipolar, are larger than those found in typical autonomic ganglia; a very small number of more typical neurones are also present.

Its connections or roots (motor, sensory and sympathetic) enter or leave the ganglion posteriorly (see Fig. 41.18). Eight to ten delicate filaments, termed the short ciliary nerves, emerge anteriorly from the ganglion, arranged in two or three bundles, the lower being larger. They run forwards sinuously with the ciliary arteries, above and below the optic nerve, and divide into 15-20 branches that pierce the sclera around the optic nerve and run in small grooves on the internal scleral surface. They convey parasympathetic, sympathetic and sensory fibres between the eyeball and the ciliary ganglion; only the parasympathetic fibres synapse in the ganglion.

The parasympathetic root, derived from the branch of the oculomotor nerve to the inferior oblique, consists of preganglionic fibres from the Edinger-Westphal nucleus, which relay in the ganglion. Postganglionic fibres travel in the short ciliary nerves to the sphincter pupillae and ciliary muscle. More than $95 \%$ of these fibres supply the ciliary muscle, which is much the larger muscle in volume.

The sympathetic root contains fibres from the plexus around the internal carotid artery within the cavernous sinus. These postganglionic fibres, derived from the superior cervical ganglion, form a fine branch that enters the orbit through the superior orbital fissure inside the common tendinous ring. The fibres may pass directly to the ganglion, or may join the nasociliary nerve and travel to the ganglion in its sensory root; either way, they traverse the ganglion without synapsing
to emerge into the short ciliary nerves. They are distributed to the blood vessels of the eyeball. Sympathetic fibres innervating dilator pupillae may sometimes travel via the short ciliary nerves (rather than the more usual route via the ophthalmic, nasociliary and long ciliary nerves).

The sensory fibres that pass through the ciliary ganglion are derived from the nasociliary nerve. They enter the short ciliary nerves and carry sensation from the cornea, the ciliary body and the iris.

## Orbital branches of the pterygopalatine ganglion

Several rami orbitales arise dorsally from the pterygopalatine ganglion and enter the orbit through the inferior orbital fissure. Branches leave the orbit through the posterior ethmoidal air sinus. There is strong experimental evidence from studies of animals, including monkeys, that postganglionic parasympathetic branches pass directly to the lacrimal gland, ophthalmic artery and choroid.

## EYELIDS, CONJUNCTIVA AND LACRIMAL SYSTEM

The exposed ocular surface is protected by retractable eyelids and by a tear film produced mainly by the lacrimal gland, with contributions from glands within the eyelid and conjunctiva (a transparent mucous membrane that covers the inner surface of the eyelid and the exposed surface of the sclera) (see Fig. 42.1).

## EYELIDS

The eyelids (palpebrae) are two folds of modified skin that cover the anterior surface of the eye (Fig. 41.19). By their reflex closure, achieved by contraction of orbicularis oculi, they protect the eye from injury and shield the eyes from excessive light. Periodic blinking maintains a thin film of tears over the cornea that prevents desiccation; movement of the eyelids during blinking helps ensure the even distribution of the tear film and facilitates tear outflow through the nasolacrimal drainage system.

The upper eyelid is larger and more mobile than the lower eyelid and contains an elevator muscle, levator palpebrae superioris (see above). A transverse opening, the palpebral fissure, lies between the free margins of the lids, which join at their extremities (termed the medial and lateral canthus). The lateral canthus is relatively featureless. The medial canthus is approximately 2 mm lower than the lateral canthus; this distance is increased in some Asiatic groups. It is separated from the eyeball by a small triangular space, the lacrimal lake (lacus lacrimalis), in which a small, reddish body called the lacrimal caruncle is situated. The caruncle represents an area of modified skin containing some fine hairs and is mounted on the plica semilunaris, a fold of conjunctiva that is believed by some to be a vestige of the nictitating membrane of other animals.

A small elevation, the lacrimal papilla, is located on each palpebral margin approximately one-sixth of the way along from the medial canthus of the eye. There is a small aperture, the punctum lacrimale, in the centre of the papilla that forms the opening to the lacrimal drainage system. The margin of the eyelid lateral to the lacrimal papilla bears

Fig. 41.19 The eyelids and anterior aspect of the eyeball. Key: 1, pupil; 2, plica semilunaris; 3 , lacrimal caruncle; 4 , medial canthus; 5 , conjunctiva; 6 , upper eyelid; 7, eyelashes; 8, lateral canthus; 9, lid margin; 10, iris; 11, lower eyelid. (With permission from Berkovitz BKB, Moxham BJ 2002 Head and Neck Anatomy. London: Martin Dunitz.)
the eyelashes and is termed the ciliary part of the eyelid. The margin medial to the papilla lacks eyelashes and forms the lacrimal part of the eyelid.

When looking straight ahead, the upper eyelid overlaps the upper part of the cornea by $2-3 \mathrm{~mm}$, whereas the lower lid margin lies just below the corneoscleral junction (limbus). When the eyelids are closed, the upper lid moves down to cover the whole of the cornea. Malposition of the lower eyelid is common, particularly in the elderly. Ectropion describes the rolling out of the lower eyelid so that it is no longer in contact with the cornea, leading to epiphora (watering). Entropion describes the inversion of the eyelid with corresponding inturning of the eyelashes (trichiasis), which contact the cornea and cause irritation.

Each eyelid margin is $2-3 \mathrm{~mm}$ thick from front to back. The anterior two-thirds is skin and the posterior third is conjunctival mucosa. A narrow 'grey line' lies anterior to the mucocutaneous junction. This corresponds to the location of the ciliary (marginal) part of orbicularis oculi and is an important surgical landmark, since an incision at this point allows the eyelid to be split into anterior and posterior lamellae along a relatively bloodless plane. The eyelashes lie in front of the grey line, and the circular openings of the tarsal glands (Meibomian glands) lie behind it. The tarsal glands are often visible through the palpebral conjunctiva, when the eyelids are everted, as a series of parallel, faint yellow lines arranged perpendicular to the lid margins.

Eyelashes are short, thick, curved hairs, arranged in double or triple rows. The upper lashes, which are longer and more numerous, curve upwards, while those in the lower lid curve down, so that upper and lower lashes do not interlace when the lids are closed.

The eyelids pass to adjacent facial skin without obvious demarcation, although their limits are clearly defined in pathological conditions such as oedema. Various skin folds or furrows are of topographical interest. A prominent superior palpebral furrow or fold lies approximately opposite the upper margin of the tarsal plate and is deeply recessed when the lids are open. Asians have a skin flap, the epicanthus, which begins laterally in the superior palpebral fold and progresses medially to cover the medial canthus. Infant Caucasians frequently have a transient epicanthus, which sometimes persists in the adult. A less prominent inferior palpebral furrow occupies a similar position in the skin of the lower lid and deepens on downward gaze. A nasojugal furrow extends obliquely from the medial lower margin of the bony orbit to the cheek, and a malar furrow may be seen laterally along the inferior orbital rim in middle age, but only infrequently and faintly in the young.

## Structure

From its anterior surface inwards, each eyelid consists of skin, subcutaneous connective tissue, fibres of the palpebral part of orbicularis oculi (see Fig. 30.18A), submuscular connective tissue, the tarsal plate (tarsus) with its tarsal glands and orbital septum, and palpebral conjunctiva (Fig. 41.20). The upper lid also contains the aponeurosis of levator palpebrae superioris.

The skin is extremely thin and is continuous at the palpebral margins with the conjunctiva. The subcutaneous connective tissue is very delicate, seldom contains any adipose tissue, and lacks elastic fibres.

The palpebral part of orbicularis oculi is subdivided anatomically into ciliary, pretarsal and preseptal parts. The palpebral fibre bundles are thin and pale, and lie parallel with the palpebral margins. Deep to them is the submuscular connective tissue, a loose fibrous layer that is continuous in the upper lid with the subaponeurotic layer of the scalp; effusions of blood or pus at this level can therefore pass down from the scalp into the upper eyelid. The main nerves lie in the submuscular layer, which means that local anaesthetics should be injected deep to orbicularis oculi.

## Tarsal plates

The two tarsal plates (Fig. 41.21A) are thin, elongated, crescent-shaped plates of firm, dense fibrous tissue approximately 2.5 cm long. There is one in each eyelid to provide support and determine eyelid form. Each is convex and conforms to the configuration of the anterior surface of the eye. The free ciliary border is straight and adjacent to the eyelash follicles. The orbital border is convex and attached to the orbital septum. The superior tarsus, the larger of the two, is semi-oval, approximately 10 mm in height centrally. Its inferior edge is parallel to, and approximately 2 mm from, the lid margin. The smaller inferior tarsus is narrower and approximately 4 mm in vertical height.

The tarsal plates are connected to the margins of the orbit by the orbital septum and by the medial and lateral palpebral (canthal) ligaments (see Fig. 41.21A). The medial palpebral ligament passes from the medial ends of the two tarsal plates to the anterior lacrimal crest and

The palpebral fissure undergoes complex changes during infancy （Paiva et al 2001）．At birth，the upper eyelid is at its lowest position and the margin of the lower eyelid is close to the centre of the pupil． Between the ages of 3 and 6 months，the upper eyelid reaches its maximum height and then declines in a linear fashion．The distance between the centre of the pupil and the margin of the lower eyelid increases linearly until the age of 18 months，when it stabilizes in posi－ tion．The most common pattern of the lower eyelid crease is a single crease at birth and a double crease by the age of about 3 years．Ageing mainly affects the size of the horizontal eyelid fissure，which lengthens by about $10 \%$ between the ages of 12 and 25 ，and shortens by almost the same amount between middle age and old age．The peak level of growth in the horizontal dimension of the palpebral fissure is reached between the ages of 17 and 19 years，in the vertical dimension between 10 and 13 years，and in the intercanthal distance between 14 and 16 years in Asian children（Park et al 2008）．

Fig. 41.20 The upper eyelid and anterior segment of the eye, sagittal section.

Fig. 41.21 A, The tarsal plates and their attachments. B, The anterior insertion of levator palpebrae superioris.
the frontal process of the maxilla. It splits at its insertion into the tarsal plates to surround the lacrimal canaliculi, and lies in front of the nasolacrimal sac and the orbital septum. The lateral palpebral ligament is relatively poorly developed. It passes from the lateral ends of the tarsal plates to a small tubercle on the zygomatic bone within the orbital margin and is more deeply situated than the medial palpebral ligament. It lies beneath the orbital septum and the lateral palpebral raphe of orbicularis oculi.

The deepest fibres of the aponeurosis of levator palpebrae superioris are attached to the anterior surface of the superior tarsus. The superior and inferior tarsal plates are also associated with a thin lamina of smooth muscle forming the superior and inferior tarsal muscles, respectively. Opposite the equator of the eye, the superior tarsal muscle passes from the inferior face of levator palpebrae superioris to a fibrous extension that projects to the upper margin of the superior tarsus (see Fig. 41.20). The muscle is innervated by the sympathetic nervous system and, on contraction, elevates the eyelid. Although it may be regarded as supplementing the action of the levator muscle, its full role is not clear. The mild ptosis that is a characteristic feature of Horner's syndrome is the result of an interruption to the sympathetic supply to the superior tarsal muscle. A corresponding but less prominent inferior tarsal muscle in the lower eyelid unites the inferior border, and possibly also the anterior surface, of the inferior tarsus to the capsulopalpebral fascia, which is the anterior expansion of the fused fascial sheath of inferior rectus and inferior oblique. Contraction of inferior rectus during downward gaze
therefore also pulls the lower lid downwards. The lower lid is capable of depressing by $4-5 \mathrm{~mm}$, although it is not equipped with a striated muscle counterpart to the levator of the upper lid.

## Palpebral glands

Tarsal (Meibomian) glands are modified sebaceous glands embedded in the tarsi. They are yellow and arranged in approximately 25 parallel rows perpendicular to the eyelid margin in the upper lid, and slightly fewer in the lower lid. They occupy the full tarsal height and are therefore longer centrally where the tarsi are higher. Each gland consists of a straight tube with many lateral secretory diverticula, and opens by a minute orifice on the free palpebral margin. It is enclosed by a basement membrane, and is lined at its orifice by stratified epithelium and elsewhere by a single layer of polyhedral cells. The sebaceous secretion of the tarsal glands spreads over the margins of the eyelids, and so an oily layer is drawn over the tear film as the palpebral fissure opens after a blink, reducing evaporation and contributing to tear film stability. The presence of the oily, hydrophobic secretions of tarsal glands along the margins of the eyelids also inhibits the spillage of tears on to the face. Obstruction of the tarsal gland ducts by lipid and cellular debris may result in lipogranulomatous inflammation and the clinical manifestations of an internal hordeolum or chalazion.

Small sebaceous glands (of Zeis) and sweat glands (of Moll) are associated with the eyelashes (see Fig. 41.20) and are prone to infection, producing an external hordeolum (stye).

## Vascular supply and lymphatic drainage

The arterial supply to the eyelids is derived principally from the medial and lateral palpebral branches of the ophthalmic artery. Their branches course laterally along the tarsal edges to form superior and inferior arcades (two in the upper eyelid and one in the lower). The eyelids are also supplied by branches of the infraorbital, facial, transverse facial and superficial temporal arteries.

The veins that drain the eyelids are larger and more numerous than the arteries; they pass either superficially to veins on the face and forehead, or deeply to the ophthalmic veins within the orbit.

The lymph vessels that drain the eyelids and conjunctiva commence in a superficial plexus beneath the skin, and in a deep plexus in front of and behind the tarsi. These plexuses communicate with one another, and medial and lateral sets of vessels arise from them. The lateral lymph vessels drain the whole thickness of the lateral part of the upper and lower lids, and pass laterally from the lateral canthus to end in the superficial and deep parotid lymph nodes. The lymph vessels of the medial set drain the skin over the medial part of the upper eyelid, the whole thickness of the medial half of the lower lid, and the caruncle; they follow the course of the facial vein to end in the submandibular group of lymph nodes.

## Innervation

The sensory innervation of the eyelids comes from both the ophthalmic and maxillary divisions of the trigeminal nerve. The upper eyelid is supplied mainly by the supraorbital branch of the frontal nerve. Additional contributions come from the lacrimal nerve, the supratrochlear branch of the frontal nerve, and the infratrochlear branch of the nasociliary nerve. The nerve supply to the lower eyelid is derived principally from the infraorbital branch of the maxillary nerve, with small contributions from the lacrimal and infratrochlear nerves.

## CONJUNCTIVA

The conjunctiva is a thin, transparent mucous membrane that extends from the eyelid margins anteriorly, providing a lining to the lids, before turning sharply on itself to form the fornices; from here, it is reflected on to the globe to cover the sclera up to its junction with the cornea. The conjunctiva thus forms a sac that opens anteriorly through the palpebral fissure (Fig. 41.22). At the free palpebral margins, the conjunctiva is continuous with the skin of the eyelids, the lining epithelium of the ducts of the tarsal glands, and with the lacrimal canaliculi and lacrimal sac (see below). The continuity between the conjunctiva and the nasolacrimal duct and nasal mucosa is important in the spread of infection.

Fig. 41.22 The regions of the conjunctiva, sagittal section.

Conjunctival goblet cells contribute the mucin component of the preocular tear film and play a central role in the defence of the ocular surface against microbial infection. The conjunctiva is conventionally divided into five regions: marginal, tarsal, orbital, bulbar and limbal (see Fig. 41.22). The marginal, tarsal and orbital regions are collectively referred to as the palpebral conjunctiva.

The marginal zone extends from a line immediately posterior to the openings of the tarsal glands and passes around the eyelid margin to continue on the inner surface of the lid as far as the subtarsal groove (a shallow sulcus that marks the marginal border of the tarsus). The tarsal conjunctiva is highly vascular and is firmly attached to the underlying tarsal plate. The orbital zone extends as far as the fornices, which mark the line of reflection of the conjunctiva from the lids on to the eyeball. The conjunctiva is more loosely attached to underlying tissues over the orbital zone and so folds readily. Elevations of the conjunctival surface in the form of papillae and lymphoid follicles (part of the mucosa-associated lymphoid tissue, MALT) are commonly observed in this region (Knop and Knop 2002).

Ducts of the lacrimal gland open into the lateral part of the superior fornix. The bulbar conjunctiva is loosely connected to the eyeball over the exposed sclera, is thin and transparent, and readily permits the visualization of conjunctival and episcleral blood vessels. The loose attachment of the conjunctiva to the fascial sheath of the globe (Tenon's capsule) in this region means that the conjunctiva is freely movable here; as the bulbar conjunctiva approaches the cornea, its surface becomes smoother and its attachment to the sclera increases. The limbal conjunctiva extends approximately $1-1.5 \mathrm{~mm}$ around the cornea and contains a dense network of capillaries.

## Structure

The conjunctiva is composed of an epithelial layer and an underlying fibrous layer or substantia propria. The form of the epithelium and thickness of the substantia propria vary with location. At the margin of the lids, the epithelium is non-keratinized stratified squamous and 10-12 cells thick. The epithelium of the tarsal conjunctiva thins to two or three layers and consists of columnar and flat surface cells. Near the fornices, the cells are taller, and a trilaminar conjunctival epithelium covers much of the bulbar conjunctiva. It thickens closer to the corneoscleral junction and then changes to stratified squamous epithelium typical of the cornea. A proportion of limbal conjunctival epithelial cells serve as stem cells for the corneal epithelium; this region of the conjunctiva is therefore essential for maintaining corneal integrity.

Mucous-secreting goblet cells are scattered within the conjunctival epithelium. They show a marked regional variation in density, being most frequent in conjunctival regions normally covered by the eyelids, and reduced in number within exposed interpalpebral locations (Doughty 2012).

The substantia propria, or fibrous layer, is thickest at the fornix and thinnest over the tarsi where conjunctival attachment is firmest. With the exception of the tarsal conjunctiva, the substantia propria adjacent to the epithelium is mainly loose. It merges with the fibrous fascia bulbi and episclera in the limbal and bulbar regions, and is loosely attached to the sheaths of the recti. At the fornix, it is continuous with orbital fascial tissues and has loose attachments to the overlying tendon of levator palpebrae superioris and the superior tarsal muscle fascia superiorly, an arrangement that provides support for the fornix during eyeball rotation.

## Vascular supply and lymphatic drainage

The arteries of the palpebral conjunctiva are derived from the vascular arcades of the eyelids. Many of the small vessels of the eyelid drain to the conjunctival veins, which, in turn, pass back to the orbital and facial veins. The substantia propria of the tarsal and orbital conjunctiva is richly vascular. A dense capillary network is arranged in a single subepithelial lamina, a distribution that meets the requirement of the cornea during sleep, when oxygen is available to the cornea only through this vascular system. The bulbar conjunctiva receives blood from the palpebral arcades and from the anterior ciliary arteries that reach the conjunctiva on the orbital surface of the recti. The veins drain by the same route and join the ophthalmic veins.

Lymphatics drain into pre-auricular and submandibular lymph nodes.

## Innervation

The conjunctiva is innervated by sensory nerves from the same ophthalmic and maxillary branches of the trigeminal nerve that serve the eyelid. Autonomic nerve fibres are abundant in the conjunctiva, particularly in bulbar and limbal regions, and are probably vasomotor in function.

## LACRIMAL SYSTEM

The lacrimal system consists of structures responsible for the production of tears (principally, the main lacrimal gland with a contribution from accessory lacrimal glands) and the lacrimal drainage pathway that collects the tear fluid and conveys it into the nasal cavity (paired lacrimal canaliculi, lacrimal sac and nasolacrimal duct) (Fig. 41.23).

The total tear volume is approximately $7 \mu \mathrm{l}$. It is distributed within the precorneal tear film $(1-2 \mu \mathrm{l})$, and along the upper and lower marginal tear strips (5-6 $\mu \mathrm{l}$ ), which are wedge-shaped menisci that run along the posterior border of the lid margins and join together at the canthi.

## Lacrimal gland

The lacrimal gland is the primary producer of the aqueous component of the tear layer. Its secretion is a watery fluid with an electrolyte content similar to that of plasma and containing several proteins that play key

Fig. 41.23 A representation of tear dynamics on the ocular surface. Tears are produced by the lacrimal gland and flow within the upper and lower meniscus. Tears drain sequentially through the puncta, canaliculi, lacrimal sac and nasolacrimal duct.
roles in protecting the ocular surface from microbial infection (e.g. lysozyme, lactoferrin, immunoglobulin A (IgA)) and also maintaining ocular surface epithelial integrity.

The lacrimal gland consists of orbital and palpebral parts that are continuous posterolaterally around the concave lateral edge of the aponeurosis of levator palpebrae superioris. The orbital part, about the size and shape of an almond, lodges in a shallow fossa on the medial aspect of the zygomatic process of the frontal bone, just within the orbital margin. It lies above levator palpebrae superioris and, laterally, above lateral rectus. Its lower surface is connected to the sheath of levator palpebrae superioris and its upper surface is connected to the orbital periosteum. Its anterior border is in contact with the orbital septum and its posterior border attached to the orbital fat. The palpebral part, about one-third the size of the orbital part, is subdivided into two or three lobules and extends below the aponeurosis of levator palpebrae superioris into the lateral part of the upper lid, where it is attached to the superior conjunctival fornix. It is visible through the conjunctiva when the lid is everted. The lacrimal gland may be congenitally absent (Keith and Boldt 1986).

The main ducts of the lacrimal gland, up to 12 in number, discharge into the conjunctival sac at the superior lateral fornix. Those from the orbital part penetrate the aponeurosis of levator palpebrae superioris to join those from the palpebral part. Excision of the palpebral part is therefore functionally equivalent to total removal of the gland (Maitchouk et al 2000).

Many small accessory lacrimal glands (glands of Krause and Wolfring) occur in or near the fornix. They are more numerous in the upper eyelid, and their presence may explain why the ocular surface does not dry up after extirpation of the main lacrimal gland.

## Microstructure

The lacrimal gland is lobulated and tubulo-acinar in form. Its secretory units are acini similar to those found in the salivary glands (Fig. 41.24) (Ruskell 1975). Acini consist of secretory cells that discharge their product into a central lumen continuous with an intercalated duct formed from a single layer of epithelial cells that lack secretory granules. Myoepithelial cells extend processes around the perimeter of acini and ducts; their contraction imparts a mechanical force on the acini and ducts, which promotes the expulsion of tears from the gland. The interstices of the gland are composed of loose connective tissue that contains numerous immune cells, mainly B-lymphocytes and plasma cells (particularly IgA-secreting cells).

Fig. 41.24 The organization of the secretory units in the lacrimal gland.

## Vascular supply

The lacrimal gland receives its arterial blood supply from the lacrimal branch of the ophthalmic artery. It may also receive blood from the infraorbital artery. Venous drainage is into the superior ophthalmic vein.

## Innervation

The lacrimal gland is innervated by secretomotor postganglionic parasympathetic fibres from the pterygopalatine ganglion (Ch. 32). They reach the gland either via zygomatic and lacrimal branches of the maxillary nerve, or by passing directly from the ganglion (Ruskell 2004). Sympathetic fibres that issue from the superior cervical ganglion also supply the lacrimal gland. These fibres may be involved in the regulation of blood flow and the modulation of gland secretion (Dartt 2009).

## Lacrimation reflex

The lacrimation reflex is stimulated by irritation of the conjunctiva and cornea, which elicits a large increase in tear volume (Situ and Simpson 2010). The afferent limb of the reflex involves branches of the ophthalmic nerve, with an additional contribution from the infraorbital nerve if the conjunctiva of the lower eyelid is involved. Impulses enter the brain and spread by interneurones to activate parasympathetic neurones in the superior salivatory nucleus and sympathetic neurones in the upper thoracic spinal cord. The efferent pathway to the lacrimal gland involves the greater petrosal nerve, which carries preganglionic parasympathetic secretomotor fibres, and the deep petrosal nerve, which conveys postganglionic sympathetic fibres; the parasympathetic fibres relay in the pterygopalatine ganglion, and the sympathetic fibres pass through the ganglion without synapsing.

Lacrimation may also occur in response to emotional triggers without any irritation of ocular structures, when it may be accompanied by alterations in the mimetic facial muscles, vocalizations and sobbing (Gračanin et al 2014).

## Preocular tear film

The tear film is a complex fluid that covers the exposed parts of the ocular surface framed by the eyelid margins. Classically, the tear film has been regarded as a trilaminar structure, with a superficial lipid layer (secreted by the Meibomian glands) that overlies an aqueous phase (derived from the main and accessory lacrimal glands) and an inner mucinous layer (produced mainly by conjunctival goblet cells) (Fig. 41.25). The tear film performs a number of important functions. By smoothing out irregularities of the corneal epithelium, it creates an even surface of good optical quality that is reformed with each blink. The air-tear interface forms the principal refractive surface of the optical system of the eye. Since the cornea is avascular, it is dependent on the tear film for its oxygen provision. When the eye is open, the tear film is in a state of equilibrium with the oxygen in the atmosphere, and gaseous exchange takes place across the tear-epithelial interface. The constant turnover of the tear film also provides a mechanism for the removal of metabolic waste products. Tears play a major role in the defence of the eye against microbial colonization; the washing action of the tear fluid reduces the likelihood of microbial adhesion to the ocular surface, and the tears contain a host of protective antimicrobial proteins.

## Lacrimal drainage pathway

There is a constant turnover of tears; production is matched by elimination. Some tears are lost by evaporation or absorption across the conjunctiva, but the majority are eliminated via the nasolacrimal drainage system (see Fig. 41.23). Tears collect at the medial canthal angle, where they drain into the puncta of the upper and lower lids, which are directed towards the surface of the eye to receive tear fluid. From each punctum, tears drain into lacrimal canaliculi. There is one canaliculus, approximately 10 mm long, in each lid. Each canaliculus first passes vertically from its punctum for about 2 mm and widens to form an ampulla, before passing medially towards the lacrimal sac. The superior canaliculus is smaller and shorter than the inferior. The canaliculi almost always unite to form a common canaliculus before reaching the lacrimal sac. Congenital absence of the lacrimal puncta, as well as supernumerary lacrimal puncta and canaliculi, have been described (Satchi and McNab 2010).

Fig. 41.25 Orbital glands that contribute the various components of the preocular tear film. The aqueous component (consisting primarily of proteins, ions and water) is produced by the main and accessory lacrimal glands. Tarsal glands in the eyelids produce the lipid layer of the tear film, and the mucous component is derived from conjunctival goblet cells.

The mucosa lining the canaliculi has a non-keratinized stratified squamous epithelium lying on a basement membrane, outside which is a lamina propria rich in elastic fibres (the canaliculi are therefore easily dilated when probed). Striated muscle fibres of orbicularis oculi interweave on each side of the canaliculus in a manner suggesting a sphincter-like spiralling, and supporting the claim that lumen size is regulated on blinking, possibly facilitating tear drainage.

The lacrimal sac is the closed upper end of the nasolacrimal duct. It is approximately 12 mm long and lies in a fossa in the lacrimal bone in the anterior part of the medial wall of the orbit (see Fig. 41.2). The sac is bounded in front by the anterior lacrimal crest of the maxilla and behind by the posterior lacrimal crest of the lacrimal bone. Its closed upper end is laterally flattened, its lower part is rounded and merges into the duct, and the lacrimal canaliculi open into its lateral wall near its upper end.

A layer of lacrimal fascia, continuous with the orbital periosteum, passes between the lacrimal crest of the maxilla and the lacrimal bone. It forms a roof and lateral wall to the lacrimal fossa and separates the lacrimal sac from the medial palpebral ligament in front and the lacrimal part of orbicularis oculi behind. A plexus of minute veins lies between the fascia and the sac. The upper half of the lacrimal fossa is related medially to the anterior ethmoidal sinuses, and the lower half to the anterior part of the middle meatus. The lacrimal sac has a fibroelastic wall and is lined internally by mucosa that is continuous with the conjunctiva through the lacrimal canaliculi, and with the nasal mucosa through the nasolacrimal duct (Paulsen 2003).

The nasolacrimal duct is approximately 18 mm long, and descends from the lacrimal sac to open anteriorly in the inferior meatus of the nose at an expanded orifice. A fold of mucosa (plica lacrimalis) forms an imperfect valve just above its opening (ostium lacrimalis). The duct runs down an osseous canal formed by the maxilla, lacrimal bone and inferior nasal concha. It is narrowest in the middle and is directed downwards, backwards and a little laterally. The mucosa of the lacrimal sac and the nasolacrimal duct has a bilaminar columnar epithelium, which is ciliated in places. A rich plexus of veins forms erectile tissue around the duct; engorgement of these veins may obstruct the duct.

## CHAPTER 42

The outer surface of the eye is composed of parts of two spheres with different radii. The anterior segment, part of the smaller sphere, is formed by the transparent cornea and accounts for approximately 7\% of the ocular surface. The posterior segment of the eyeball is part of the larger sphere formed by the opaque sclera (Fig. 42.1).

Internal to the sclera is a vascular, pigmented layer consisting of three continuous parts that collectively make up the uveal tract: a thin
choroid lying posteriorly, a thicker ciliary body and an anterior iris that is displaced from the outer coat and terminates at the pupillary aperture. The internal surface of the choroid is covered by the photosensory retina, which terminates anteriorly at the ora serrata; the latter also marks the junction between the ciliary body and choroid. The vasculature of the choroid supplies nutrients to the avascular outer retina.

Fig. 42.1 The left eye and part of the lower eyelid in horizontal section, viewed from above. Parts have been cut away to show internal structures.

The ocular lens is located immediately behind the iris and is suspended from the ciliary body via zonular fibres (see Fig. 42.1). Smooth muscles within the ciliary body regulate the tension exerted on the elastic lens and hence determine its shape, thereby adjusting the focus of the eye in the process of accommodation. The iris, which does not allow the transmission of light due to a heavily pigmented posterior surface, also contains smooth muscle, allowing it to regulate the size of the pupillary aperture.

The iris and lens separate the eye into three chambers. The largest, the vitreous chamber, is filled with the gel-like vitreous humour, and lies posterior to the lens, comprising about two-thirds of the volume of the eye (see Fig. 42.1). The spaces between the lens and iris, and the iris and cornea, are, respectively, the posterior and anterior chambers of the eye. Both are filled with aqueous humour, which is produced by the epithelium of the ciliary body, travels through the pupil, circulates in the anterior chamber and is drained principally through the canal of Schlemm at the iridocorneal filtration angle. Aqueous humour provides metabolic support to the avascular lens and cornea.

The sole purpose of the eyes and their associated structures within the bony orbit is to form a good image on a healthy retina. The photoreceptors of the retina transduce the optical radiation into neurobiological activity and other cells within the retina then begin to process the output of the photoreceptors. The retinal signal is transferred via the optic nerve, along the visual pathway (see Fig. 42.32) to various regions within the brain, where further processing results in visual perception.

## OUTER COAT

The fibrous outer coat of the eye consists of the opaque posterior sclera and the transparent anterior cornea. Together they form a semi-elastic protective capsule enclosing the eye, which, when made turgid by intraocular pressure, determines the optical geometry of the eye and ensures its shape is not distorted when it moves. The sclera also provides attachments for the extraocular muscles, and its smooth external surface rotates easily on the adjacent tissues of the orbit when these muscles contract (Ch. 41). The opacity of the sclera helps ensure that only light that enters the eye through the pupil reaches the retina. The cornea, on the other hand, not only admits light but also its covering tear film is the major refractive surface of the eye.

## SCLERA

The sclera accounts for approximately $93 \%$ of the outer coat of the eye. Anteriorly, it is continuous with the cornea at the corneoscleral junction (see Fig. 42.1). It is punctured by a number of foramina containing nerves and blood vessels, most notably the optic foramen, which lies 3 mm medial to the midline and 1 mm below the horizontal, and houses the optic nerve. Smaller openings contain anterior ciliary arteries that penetrate anteriorly, vortex veins that cross the sclera equatorially, and the long and short ciliary nerves and arteries that enter posteriorly. There is considerable individual variation in scleral dimensions. The sclera is thickest at the posterior pole (approximately 1 mm ) and decreases anteriorly, reaching a minimum equatorially at about half this thickness. It also thins approaching the optic nerve. The sclera is thinner when the eye is elongated in myopia.

The external surface of the sclera is covered by a delicate episcleral lamina of loose fibrovascular tissue, which contains sparse blood vessels and is in contact with the inner surface of the fascial sheath of the eyeball. Anteriorly, the external scleral surface is covered by conjunctiva, which is reflected on to it from the posterior surfaces of the eyelids. The scleral internal surface adjacent to the choroid is attached to it by a delicate fibrous layer, the suprachoroid lamina, which contains numerous fibroblasts and melanocytes. Anteriorly, the inner sclera is attached to the ciliary body by the lamina supraciliaris. Posteriorly, the sclera is pierced by the optic nerve. Here, the outer half of the sclera turns back to become continuous with the dura mater, while the inner half is modified to form a perforated plate, the lamina cribrosa sclerae. The optic nerve fascicles pass through these minute orifices, while the central retinal artery and vein pass through a larger, central aperture. The lamina cribrosa sclerae is the weakest part of the sclera and bulges outwards (a cupped disc) when intraocular pressure is raised chronically, as in glaucoma.

Like the cornea, the scleral stroma is composed mainly of densely packed collagen embedded in a matrix of proteoglycans, which are mixed with occasional elastic fibres and fibroblasts. However, in contrast to the cornea, scleral collagen fibrils show a large variation in diameter and spacing, and the lamellae branch and interlace extensively. This arrangement of fibres results in increased light scatter, which is responsible for the opaque, dull-white appearance of the sclera, and also imparts a high tensile strength to the sclera to resist the pull of the extraocular muscles and contain the intraocular pressure. Collagen fibre bundles are arranged circumferentially around the optic disc and the orifices of the lamina cribrosa. The fibres of the tendons of the recti intersect scleral fibres at right angles at their attachments, and then interlace deeper in the sclera. Collagen fibres of the scleral spur are orientated in a circular fashion, and there is an increased incidence of elastic fibres here (Figs 42.2-42.3A). Although the sclera acts as a conduit for blood vessels, scleral vessels are few and mainly disposed in the episcleral lamina, especially close to the limbus. Its nerve supply is surprisingly rich, accounting for the intense pain associated with scleral inflammation (Watson and Young 2004).

Scleral development is under active regulation to ensure an eye of the correct axial length to produce a focused image (Wallman and Winawer 2004).

## Filtration angle and aqueous drainage

Aqueous humour is produced by the ciliary epithelium; it passes through the pupil and circulates within the anterior chamber, supplying the avascular cornea and lens with nutrients and removing metabolic waste products. It drains from the eye mainly through the trabecular meshwork into the canal of Schlemm at the iridocorneal (filtration) angle (see Figs 42.2-42.3), formed between the posterior aspect of the corneoscleral limbus and the periphery of the iris. Differences in drainage angle morphology most probably underlie ethnic variations in the prevalence of primary angle closure glaucoma (Wang et al 2012).

The trabecular meshwork is continuous anteriorly with Descemet's membrane and the endothelium of the cornea. Aqueous humour filters from the anterior chamber through interconnected spaces among loose trabecular fibres, most of which are attached to the anterior, external aspect of the scleral spur. Of the remainder, most are continuous with longitudinal fibres of the ciliary muscle, some of which attach to the

Fig. 42.2 A meridional section through the anterior eye, highlighting the ciliary body and drainage apparatus.

Fig. 42.3 A, A schematic representation of the tissues bordering the anterior chamber angle. The trabecular meshwork is an anulus of tissue spanning the angle; its meshes are shown in transverse section opposite the canal of Schlemm and partly attached to the scleral spur. A single iris process bridges the angle, connecting the trabecular meshwork to the anterior tissues of the iris. B, An optical coherence tomography (OCT) in vivo image of the anterior segment of a 60 -year-old Caucasian female taken in dim room light. (B, Courtesy of Mr Gus Gazzard, Consultant Ophthalmic Surgeon, Moorfields Eye Hospital, London.)

Fig. 42.4 Tissues of the filtration angle in section. The approximate borders of the limbal region are indicated by the solid lines. Aqueous humour drains from the anterior chamber at T through the trabecular meshwork into the canal of Schlemm; from here, it flows through collector channels, either to the intrascleral venous plexus, where it mixes with blood from the ciliary venous plexus, or directly to the surface tissues of the eye as an aqueous vein. The aqueous vein is shown joining an episcleral vein at the surface to form a laminated vessel.
Aqueous and blood drain posteriorly in episcleral veins, which, in turn, join anterior ciliary veins.
posterior internal aspect of the scleral spur. The trabecular meshwork provides sufficient resistance to aqueous humour outflow to generate an intraocular pressure of approximately 15 mmHg . It also acts as a filter and has the capacity to phagocytose particulate matter, although overloading may contribute to the pathogenesis of various forms of obstructive secondary glaucoma (p. 697).

The canal of Schlemm (sinus venosus sclerae) is an anular endothelial canal located near the internal surface of the sclera close to the limbus. In section, the canal appears as an oval cleft, with an outer wall that grooves the sclera. Posteriorly, the cleft extends as far as a rim of scleral tissue, the scleral spur, which, in section, forms a triangle with its apex directed forwards (see Figs 42.2-42.3A). The canal of Schlemm may be double or multiple in part of its course, and its walls are constructed of a continuous single thin endothelial layer. Passage of aqueous humour to the canal probably occurs via giant pinocytotic vacuoles and associated transcellular pores, which form on the inner face of the endothelium and discharge into the canal at the outer face. Aqueous humour passes through a plexus of fine intrascleral vessels that connect the canal of Schlemm with episcleral veins (Fig. 42.4). Normally, the canal does not contain blood; pressure gradients prevent the reflux of blood, even though the channels between the canal and veins have no valves. However, in venous congestion, blood may enter the canal; the continuous endothelial outer wall of the canal prevents further reflux.

An alternative route for aqueous outflow, the uveoscleral pathway, has been described (Fautsch and Johnson 2006, Goel et al 2010). Estimates of aqueous drained by this route in humans vary from under $5 \%$
to as much as much as $54 \%$ (Alm and Nilsson 2009), and decrease with age. Since there is no epithelial barrier between the anterior chamber and the ciliary body, aqueous humour is able to enter the loose connective tissue in front of the ciliary muscle and pass between the muscle fibres into the supraciliary and suprachoroidal spaces, where, potentially, it can be absorbed by vessels that drain the uvea. Clinically, aqueous outflow via this route can be increased by topical prostaglandin analogues, which are first-line therapy for the treatment of open angle glaucoma.

## CORNEA

The avascular cornea is the anterior transparent part of the outer coat. Convex anteriorly, it projects from the sclera as a dome-shaped elevation with an area of $1.1 \mathrm{~cm}^{2}$, forming approximately $7 \%$ of the external tunic area. Since it is more curved (average radius, $\mathrm{r}=7.8 \mathrm{~mm}$ ) than the sclera ( $\mathrm{r}=11.5 \mathrm{~mm}$ ), a slight sulcus sclerae marks the corneoscleral junction (limbus). The high corneal curvature of the neonate cornea decreases to reach adult levels within a relatively short space of time (Friling et al 2004).

The cornea is approximately $670 \mu \mathrm{~m}$ thick close to the corneoscleral junction, and $520 \mu \mathrm{~m}$ at its centre. At the nasal and temporal limbus, the transition from cornea to sclera occurs in a line that is approximately perpendicular to the cornea; this transition occurs more obliquely superiorly and inferiorly, with the sclera overlapping the cornea to a greater extent anteriorly. Consequently, when viewed from

in front, the corneal perimeter is slightly elliptical, as its horizontal diameter ( 11.7 mm ) is a little greater than its vertical ( 10.6 mm ). Its posterior perimeter is circular (diameter 11.7 mm ).

Since the cornea carries most of the optical power of the eye, changes to its shape can have a significant impact on the refractive state of the eye (p. 699). This has been used to advantage in a number of techniques for correcting refractive error such as laser refractive surgery.

Microscopically, the cornea consists of five layers: corneal epithelium, anterior limiting lamina (Bowman's layer), substantia propria (stroma), posterior limiting lamina (Descemet's membrane) and endothelium, arranged anteroposteriorly (Fig. 42.5).

## Corneal epithelium

The corneal epithelium accounts for approximately $10 \%$ of the corneal thickness $(50 \mu \mathrm{~m})$. It usually consists of 5-6 layers of cells (Fig. 42.5B) that protect the ocular surface from mechanical abrasion, form a permeability barrier (to small molecules, water and ions) and prevent the entry of pathogens. The deepest cells are columnar with flat bases, rounded apices and large round or oval nuclei. Outside these are $2-3$ layers of polyhedral (often wing-shaped) cells. In the more superficial layers, the cells become progressively flatter and present a smooth, optically perfect surface. Scanning electron microscopy of surface cells reveals extensive finger-like and ridge-like projections (microvilli and microplicae). A complex network of tight junctions links the superficial cells, consistent with their barrier function.

## Anterior limiting lamina (Bowman's layer)

The anterior limiting lamina lies behind the corneal epithelium. It contains a dense mass of collagen fibrils set in a matrix similar to that of the substantia propria. The lamina is $12 \mu \mathrm{~m}$ thick, is readily distinguishable from the substantia propria because it does not contain fibroblasts, and appears amorphous by light microscopy (see Fig. 42.5B).

## Substantia propria (stroma)

The substantia propria is approximately $500 \mu \mathrm{~m}$ thick and forms the bulk of the cornea. It is a compact and transparent layer, composed of 200-250 sequential lamellae, each made up of fine parallel collagen fibrils mainly of type I collagen. Flat dendritic interconnecting fibroblasts (keratocytes) form a coarse mesh between the lamellae. Alternate lamellae are typically orientated at large angles to each other (Fig. 42.6). X-ray diffraction studies indicate that they run along two preferred directions - superior-inferior and nasal-temporal - to account for the additional tensile stress exerted by the recti along these meridians (Boote et al 2005). Each lamella is approximately $2 \mu \mathrm{~m}$ thick and of variable width ( $10-250 \mu \mathrm{~m}$ or, rarely, more). In the central cornea, fibrils within the lamellae have a similar diameter of approximately 31 nm . This increases slightly with age and approaching the limbus. The small size of the fibrils (much smaller than the wavelength of light), along with the regularity of their spacing (maintained by collagenproteoglycan interactions) and the careful control of corneal hydration,

Fig. 42.6 An electron micrograph of the stroma of the human cornea, showing the geometric precision of the alternation in direction of adjacent layers of fibres. (Courtesy of John Marshall, St Thomas' Hospital, London.)
are the principal factors that determine stromal transparency. Light scattered by the collagen fibrils is eliminated by destructive interference in all directions other than forwards.

## Posterior limiting lamina (Descemet's layer)

The posterior limiting lamina covers the substantia propria posteriorly. It is thin and apparently homogeneous, and is regarded as the basement membrane of the endothelium (see Fig. 42.5C). Some $4 \mu \mathrm{~m}$ thick at birth, it may increase to $12 \mu \mathrm{~m}$ by the eighth decade.

## Endothelium

The endothelium covers the posterior surface of the cornea and consists of a single layer of squamous cells (see Fig. 42.5C) with prominent interdigitations between adjacent cells, which are also connected by tight and gap junctions. When viewed en face, the endothelium appears as a mosaic of polygonal (typically hexagonal) cells. As these cells have a limited capacity for mitosis, in response to pathology, trauma, age and prolonged contact lens wear, the endothelial mosaic becomes less regular, and shows a greater variation in cell size (pleomorphism) and shape (polymegathism), as cells spread to fill gaps caused by cell loss. The numerous mitochondria and prominent rough endoplasmic reticulum within these cells reflects their high metabolic activity. Thus, for example, active pumping mechanisms largely control the degree of corneal hydration.

Fig. 42.7 Drawing of a histological section through the choroid close to the posterior pole.

## Corneal innervation

The cornea is innervated by numerous branches of the ophthalmic nerve, which either form an anular plexus around the periphery of the cornea, or pass directly from the sclera and enter the corneal stroma radially as $70-80$ small groups of fibres. On entering the cornea, the few myelinated nerves lose their myelin sheaths and ramify throughout the anterior corneal stroma in a delicate reticulum, their terminal filaments forming an intricate subepithelial plexus. Axon bundles from this plexus cross the anterior limiting membrane and form a sub-basal plexus from which individual beaded axons pass to more superficial epithelial layers, eventually terminating as free nerve endings. Corneal nerves provide the afferent arm of the blink and lacrimation reflexes (Ch. 41) and may also have a neurotrophic function (Müller et al 2003).

## CORNEOSCLERAL JUNCTION (LIMBUS)

The limbus marks the transitional zone between the cornea and sclera (see Fig. 42.3B). Here, the corneal epithelium merges with the epithelium of the conjunctiva, which thickens (up to 12 cells). Bowman's layer terminates and the corneal stromal collagen loses its regularity. As the cornea contains neither blood nor lymphatic vessels, the capillaries of the conjunctiva and episclera end in loops near the limbus. Internally, Descemet's membrane disperses into the fibres of trabecular meshwork and the corneal endothelium is continuous with that covering the trabeculae. The limbus forms a convenient surface landmark for ocular surgery and intravitreal injection. A position 4 mm posterior to the limbus, for example, indicates the pars plana of the ciliary body (orbiculus ciliaris) in adults, through which safe surgical access to the posterior segment of the eye can be achieved.

The corneal epithelium does not possess stem cells and its replacement depends on the centripetal migration of cells from the edges of the cornea. These cells are the progeny of mitotic limbal stem cells located within radially orientated epithelial ingrowths (palisades of Vogt).

## UVEA

The vascular tunic of the eye consists of the choroid, ciliary body and iris, which collectively form a continuous structure: the uvea (see Fig. 42.1). The choroid covers the internal scleral surface and extends forwards to the ora serrata. The ciliary body continues forwards from the choroid to the circumference of the iris, which is a circular diaphragm behind the cornea and in front of the lens, forming an almost central aperture, the pupil.

## CHOROID

The choroid is a thin, highly vascular, pigmented layer that lines almost five-sixths of the eye posteriorly. Its mean thickness, measured by optical coherence tomography (OCT), is approximately $230 \mu \mathrm{~m}$ (Arora
et al 2012) and is greatest behind the macula. These dimensions are influenced by several factors, including age (Park and Oh 2013), axial length, central corneal thickness and time of day, and vary in pathological conditions such as angle closure.

The choroid is pierced by the optic nerve where it is firmly adherent to the sclera. Elsewhere, its external surface is only loosely connected to the sclera by the suprachoroid layer (lamina fusca). Internally, it is attached to the retinal pigment epithelium, and at the optic disc is continuous with the pia-arachnoid tissues around the optic nerve.

Four layers can be identified in transverse section (Fig. 42.7; see also Fig. 42.22): suprachoroid, vascular stroma, choriocapillaris and lamina vitrea (Bruch's membrane).

## Suprachoroid

The suprachoroid covers the external surface of the choroid; it is approximately $30 \mu \mathrm{~m}$ thick and composed of delicate non-vascular lamellae, each one a network of fine collagen and elastic fibres, fibroblasts and melanocytes. Ciliary nerves and long posterior ciliary arteries pass forwards to the anterior uvea in this layer.

## Vessel layer (stroma)

Internal to the suprachoroid lies a layer composed mainly of arteries and veins, but also some loose connective tissue containing scattered pigment cells. These melanocytes limit the passage of light through the sclera to the retina. More importantly, like the retinal pigment epithelium, they also absorb light traversing the retina that is not absorbed by the photoreceptors, so preventing internal reflection.

The blood supply of the choroid, as well as the rest of the uvea, is summarized in Figure 42.8. Short posterior ciliary arteries enter the eye through the sclera near the optic disc and supply the posterior choroid. These vessels branch and gradually decrease in size as they approach the retinal border. The choroidal stroma can be divided into layers based on the change in the calibre of these vessels: an outer layer of larger vessels (Haller's layer) and an inner layer of smaller vessels (Sattler's layer), which eventually give rise to the choriocapillaris (see Fig. 42.7). Long posterior ciliary arteries and recurrent branches of anterior ciliary arteries supply the anterior part of the choriocapillaris.

Veins within the choroid converge spirally on to four, or very occasionally more, principal vortex veins. These pierce the sclera behind the equator to reach tributaries of the ophthalmic veins.

The vessels of the choroid have a rich autonomic vasomotor supply.
The blood flow through the choroid is high, a feature probably associated with an intraocular pressure of $15-20 \mathrm{mmHg}$, which means that a venous pressure above 20 mmHg is required to maintain circulation. The choroidal perfusion rate exceeds that required to supply nutrients and may serve to cool the retina during exposure to bright light.

## Choriocapillaris

The choriocapillaris provides nutrients to the avascular outer five layers of the retina and is composed of large (up to $20 \mu \mathrm{~m}$ thick), densely

Fig. 42.8 The vasculature of the uveal tract. The long posterior ciliary arteries, one of which is visible (A), branch at the ora serrata (b) and feed the capillaries of the anterior part of the choroid. Short posterior ciliary arteries (C) divide rapidly to form the posterior part of the choriocapillaris. Anterior ciliary arteries ( D ) send recurrent branches to the choriocapillaris (e) and anterior rami to the major arterial circle ( f ). Branches from the circle extend into the iris ( g ) and to the limbus. Branches of the short posterior ciliary arteries (C) form an anastomotic circle (of Zinn) (h) round the optic disc, and twigs from this (i) join an arterial network on the optic nerve. The vortex veins (J) are formed by the junctions (k) of suprachoroidal tributaries (I). Smaller tributaries are also shown ( $m, n$ ). The veins draining the scleral venous sinus ( 0 ) join anterior ciliary veins and vorticose tributaries. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)
packed, freely anastomosing, fenestrated capillaries. While pericytes occur mainly on the scleral surface, most fenestrations face the retina. The permeability of choriocapillaris is exceptionally high, even compared to other structures invested with fenestrated capillaries.

## Lamina vitrea (Bruch's membrane)

The lamina vitrea lies between the choriocapillaris and the retinal pigment epithelium, from both of which it is derived. Under the light microscope, it appears as a homogeneous layer, $2-4 \mu \mathrm{~m}$ in diameter and consists largely of a central elastic fibre mesh, although some authors include flanking internal and external layers of collagen and the basal laminae of the choriocapillaris and retinal pigment epithelium in this structure. Its function is thought to be related to the passage of fluid and solutes from the choroidal capillaries to the retina. In advancing years, extracellular deposits may accumulate in this membrane (drüsen), which impairs the exchange of gases, nutrients and metabolites between the choroidal blood and the outer layers of the retina, potentially contributing to degenerative disease in the photoreceptor layer of the neural retina.

## CILIARY BODY

The ciliary body serves to anchor the lens via suspensory ligaments, and by the contraction of its smooth muscle changes the refractive power of the lens (accommodation). Its anterior internal surface is also the source of aqueous humour, while posteriorly its inner surface is contiguous with the vitreous humour and secretes several of its components. The anterior ciliary arteries and the long posterior ciliary arteries meet in the ciliary body, and the major nerves to all the anterior tissues of the eyeball pass through it.

Externally, the ciliary body may be represented by a line that extends from approximately 1.5 mm posterior to the limbus of the cornea (corresponding also to the scleral spur) to a line $7.5-8 \mathrm{~mm}$ posterior to this on the temporal side, and $6.5-7 \mathrm{~mm}$ on the nasal side. The ciliary body is thus slightly eccentric. It projects posteriorly from the scleral spur, which is its attachment, with a meridional width varying from 5.5 to 6.5 mm . Internally, it exhibits a posteriorly crenated or scalloped periphery, the ora serrata, where it is continuous with the choroid and retina (Figs 42.9-42.10). Anteriorly, it is confluent with the periphery of the iris, and externally, it bounds the iridocorneal angle of the anterior chamber.

In cross-section, the ciliary body is composed of four layers (from internal to external): a double layer of epithelial cells, the stroma, ciliary muscle and a supraciliary layer (see Fig. 42.2).

Meridionally, the ciliary body can be divided into two parts (see Figs $42.2,42.10$ ). Anteriorly, the ridged pars plicata (corona ciliaris) surrounds the base of the iris and accounts for about one-third of the ciliary body. Posteriorly, the relatively smooth and thin pars plana (orbiculus ciliaris) lies adjacent to the ora serrata, and forms a convenient access point for instruments during vitreoretinal surgery and for intraocular injection. The whole ciliary body is covered by a double epithelium, in which the inner layer is unpigmented, while the outer layer contains melanin. At the ora serrata, the retinal pigment epithelium is continuous with the outer pigmented epithelium of the pars plana, while the neural retina is replaced by inner unpigmented ciliary epithelium (see Fig. 42.24). Anteriorly, this double epithelium continues over the pars plicata until it merges with the double epithelium on the posterior surface of the iris (where the inner layer of cells also accumulates melanin). The anterior pars plicata is ridged meridionally by $70-80$ ciliary processes radiating from the base of the iris (see Figs 42.9-42.10). In the young eye, these process are approximately parallelsided structures, but in the adult, their flanks become less regular and appear thicker. A minor ridge, or ciliary plica, lies in the valley between

Fig. 42.9 The ciliary region seen from the ocular interior. Above is the periphery of the lens, attached by the fibres of the zonule (suspensory ligament) to the processes of the pars plicata (corona ciliaris) of the ciliary body (a). The pars plana ciliaris (orbiculus ciliaris) (b) has a scalloped boundary, the ora serrata (c), which separates it from the retina (d). Flanking the 'dentate bays' (e) of the ora serrata are the dentate processes (f), with which linear ridges or striae (g) are continuous; the striae extend forwards between the main ciliary processes, providing an attachment for the longer zonular fibres. The posterior aspect of the iris shows radial ( h ) and circumferential (i) sulci. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)

Fig. 42.10 The posterior aspect of the anterior half of the eye, showing the termination of the neural retina at the ora serrata and the ciliary body. The lens has retained sufficient transparency to reveal the iris border; the crenated perimeter of the lens is due to tension imposed by the attached suspensory ligaments (unseen).
most of the processes. The crests of the processes are less pigmented, giving them the appearance of white (or light) striae, from which the name ciliary is derived. The suspensory ligaments attached to the lens extend into the valleys between the ciliary processes and pass beyond them to fuse with the basal lamina of the superficial epithelial layer of pars plana. Their sites of attachment are marked by striae that pass back from the valleys of the pars plicata, across the pars plana, almost as far as the apices of the dentate processes of the ora serrata (see Fig. 42.9).

## Ciliary epithelium

The ciliary epithelium is bilaminar, consisting of two layers of epithelial cells that are derived embryonically from the two layers of the optic cup. The superficial layer consists of columnar cells over the pars plana, and cuboidal cells over the ciliary processes of the pars plicata; it becomes irregular and more flattened between the processes. These cells contain little or no pigment. The outer layer of the ciliary epithelium, in contrast, contains cuboidal cells that are loaded with melanin. Normally, the two layers are firmly united but fluid may separate them pathologically. The pigment layer is attached to the stroma of the ciliary body by its basal lamina, which continues back into the basal lamina of the choroid. As a consequence of the invagination of the optic cup during development, a basal lamina covers the free surface of the bilayer, which is continuous with the internal limiting membrane of the retina.

The ciliary epithelium is responsible for the secretion of aqueous humour, while the outer pigmented epithelium additionally

Fig. 42.11 The ciliary muscle and its components. The meridional or longitudinal (1), radial or oblique (2), and circular or sphincteric (3) layers of muscle fibres are displayed by successive removal towards the ocular interior. The cornea and sclera have been removed, leaving the canal of Schlemm (a), collecting venules (b), scleral spur (c) and trabecular meshwork (d). The meridional fibres (1) often display acutely angled junctions (d) and terminate in epichoroidal stars (e). The radial fibres meet at obtuse angles (f) and similar junctions, at even wider angles (g), occur in the circular ciliary muscle. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)
contributes to the eye's 'black box effect', like the retinal pigment epithelium, choroidal pigment and posterior iris epithelium, absorbing stray light to enhance image quality.

## Ciliary stroma

The ciliary stroma is composed largely of loose bundles of collagen, which form a considerable mass between the ciliary muscle and overlying processes, and extend into both of them. It also contains numerous larger branches of the ciliary vessels. A dense reticulum of large (up to $35 \mu \mathrm{~m}$ in diameter) fenestrated capillaries is concentrated in the ciliary processes, facilitating the passage of substances from the blood plasma during aqueous production. Anteriorly, near the periphery of the iris, the major arterial circle (see Fig. 42.8) is formed by anastomosis between the anterior ciliary arteries and long posterior ciliary arteries, branches of the ophthalmic artery (see Fig. 41.13). Ciliary veins, also draining the iris, pass posteriorly to join the vortex veins of the choroid.

## Ciliary muscle

Ciliary muscle is composed of smooth muscle cells, most of which are attached to the scleral spur and arranged in three different orientations. The outermost fibres are meridional or longitudinal, and pass posteriorly into the stroma of the choroid. The innermost fibres swerve acutely from the spur to run circumferentially as a sphincter near the periphery of the lens. Obliquely interconnecting radial fibres run between these two muscular strata, frequently forming an interweaving lattice (see Fig. 42.2; Fig. 42.11).

## Accommodation reflex

At rest, distant objects are focused on the retina in an emmetropic eye. In order to focus closer objects, the dioptric power of the eye has to be increased, which is achieved by increasing the curvature of the lens. At rest, the lens is under tension from the zonular ligaments and hence flattened. On accommodation, the ciliary muscle contracts, moving the ciliary body forwards and inwards towards the optic axis. All parts of the muscle act in concert and tension on the zonular ligaments is relaxed. As the lens is covered by an elastic capsule, once tension on it is released, it assumes a more convex shape suitable for focusing closer objects. The radius of curvature of the anterior lens surface changes most during accommodation. This classic view of accommodation, first proposed in principal by Helmholtz nearly 100 years ago, remains generally accepted, although details of the roles of various ocular structures continue to be debated (Charman 2008).

Information from the retina passing to the visual cortex does not constitute the afferent limb of a simple reflex in the usual sense of the term, but permits the visual areas to assess the clarity of objects in the visual field. Cortical efferent information passes to the pretectal area and thence to the Edinger-Westphal nucleus, which contains preganglionic parasympathetic neurones whose axons travel in the oculomotor nerve and synapse in the ciliary ganglion within the orbit (Fig. 42.12). Postganglionic fibres (short ciliary nerves) innervate the ciliary muscle, causing it to contract. There is also a sparse sympathetic innervation of ciliary muscle, which has a very limited capacity to relax the muscle.

Accommodation is usually accompanied by constriction of the pupil brought about by contraction of the sphincter pupillae, and convergent eye movements caused by contraction of the medial, superior and

Fig. 42.12 The neural pathways of the pupillary light reflex (left) and the accommodation reflex (right). (From Oxford Textbook of Functional Anatomy, Vol 3 Head and Neck, MacKinnon P, Morris J (eds) 1990. With permission of Oxford University Press.)

border layer blends with the trabecular connective tissue of the iridocorneal angle; at the pupillary rim, it meets the epithelium of the posterior surface of the iris.

The colour of the iris is a product of the combined effect of reflection/ absorption by the iridial connective tissue and the concentration of pigment in the anterior border layer and, to a lesser extent, in the iris stroma. The distribution of pigment is often irregular, which produces a flecked appearance. When pigment is largely absent, other than in the posterior epithelial layers (the condition at birth), the colour is light blue.

## Stroma

The stroma of the iris is formed of fibroblasts, melanocytes and a loose collagenous matrix but no elastic tissue. The intercellular spaces appear to communicate freely with the anterior chamber. A few large, heavily pigmented 'clump cells' may be present; these are phagocytes and contain lysosomes and ingested melanosomes. The stroma contains regional vessels and nerves. An aggregation of smooth muscle cells near the pupillary rim forms an anular contractile sphincter pupillae (see below).

## Epithelial layers

The epithelial surface covering the iris posteriorly is a continuation of the bilaminar epithelium of the ciliary body and is formed from the two layers of the optic cup. The pupil, through which this epithelium curves for a short distance on to the anterior surface as the pigment ruff, corresponds to the opening of the optic cup.

The layer of epithelial cells nearest the stroma is, somewhat confusingly, termed the anterior epithelium, although it lies posterior to the stroma. Its cells are pigmented, as are those of the corresponding layer in the ciliary epithelium. They give rise to the dilator pupillae (see below). Vitreal to this stratum is a layer of heavily pigmented cells, the posterior epithelium, which is continuous with the inner nonpigmented layer of the ciliary epithelium. As is readily apparent from in vivo scans, the pupillary region of the iris rests on the front surface of the lens (see Fig. 42.3B). Its posterior surface therefore bears numerous radial ridges that facilitate the movement of aqueous humour from the posterior to the anterior chamber. Adjacent epithelial cells are extensively joined by various junctions that ensure the layer can
inferior recti (all innervated by the oculomotor nerve). This is the 'near triad' that may become disrupted in various diseases.

## Supraciliary layer

The thin supraciliary layer separates the sclera from the ciliary muscle and is largely composed of collagen fibres derived from the two layers it divides. It also forms an alternative 'unconventional' route (other than the canal of Schlemm) for the drainage of aqueous humour.

## IRIS

The iris is an adjustable diaphragm around a central aperture (slightly medial to true centre), the pupil. It lies between the cornea and lens, and is immersed in aqueous fluid (see Fig. 42.1), partially dividing the anterior segment into an anterior chamber, enclosed by the cornea and iris, and a posterior chamber, situated between the iris and the lens anterior to the vitreous. The efficacy of the iris as a light stop is mainly due to a densely pigmented posterior double epithelium. The pupillary aperture is adjusted by the action of two muscles, dilator and sphincter pupillae.

Seen from the front, the iris is divided into a large ciliary zone adjacent to the ciliary body and a smaller, inner, pupillary zone (Fig. 42.13). The two regions join at the collarette. The anterior surface of the iris often contains large depressions (crypts of Fuchs), and at the pupillary margin, the posterior pigmented epithelium is visible as the pupillary ruff.

In transverse section, several subdivisions of the iris are evident (Fig. 42.14). From anterior to posterior, they are an anterior border layer, the stroma (which contains the sphincter pupillae), and two pigmented epithelial layers, the most anterior of which contains the dilator pupillae. It is thinnest at its root (approximately $200 \mu \mathrm{~m}$ ), where the ciliary body is attached, and thickest at the collarette.

## Anterior border layer

The anterior surface of the iris is not a distinct epithelium but a modified layer of the iris stroma, formed mainly by an increased number of fibroblasts that constitute a network on the anterior surface with a layer of underlying melanocytes. At the periphery of the iris, the anterior

Fig. 42.13 A composite view of the surfaces and internal strata of the iris. In a clockwise direction from above, the pupillary $(A)$ and ciliary $(B)$ zones are shown in successive segments. The first (brown iris) shows the anterior border layer and the openings of crypts (c). In the second segment (blue iris), the layer is much less prominent and the trabeculae of the stroma are more visible. The third segment shows the iridial vessels, including the major arterial circle (e) and the incomplete minor arterial circle (f). The fourth segment shows the muscle stratum, including the sphincter ( g ) and dilator ( h ) of the pupil. The everted 'pupillary ruff' of the epithelium on the posterior aspect of the iris (d) appears in all segments. The final segment, folded over for pictorial purposes, depicts this aspect of the iris, showing radial folds ( i and j ) and the adjoining ciliary processes (k). (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)
withstand the excursions of the iris during changes in pupillary size (Fig. 42.15)

## Iris muscles

## Sphincter pupillae

The sphincter pupillae is a flat anulus of smooth muscle approximately $750 \mu \mathrm{~m}$ wide and $150 \mu \mathrm{~m}$ thick. Its densely packed, fusiform muscle cells are often arranged in small bundles, as in the ciliary muscle, and pass circumferentially around the pupil (see Fig. 42.13). Collagenous connective tissue lies in front of and behind the muscle fibres. It is very dense posteriorly, where it binds the sphincter to the pupillary end of the dilator muscle, and is attached to the epithelial layer at the pupil margin. Small axons, mostly non-myelinated, ramify in the connective tissue between bundles.

Fig. 42.14 A meridional section of an iris. The posterior surface is lined with a double epithelium ( $\mathrm{E}, \mathrm{E}^{\prime}$ ); the arrow points to the processes of the anterior layer of the epithelium forming the dilator pupillae muscle. The iris is in a contracted state, as shown by the thickened epithelium opposite the dilator muscle and thinning opposite the sphincter, and by the shortness of the pupillary zone. Abbreviations: A, anterior border layer; C, collarette; CM, ciliary muscle; CP, ciliary processes; I, major iridic circle; P , pupillary region of the iris; PF, folds in anterior surface towards the root; R, pupillary ruff; RT, root; S, sphincter pupillae muscle; ST, stroma.

## Dilator pupillae

The dilator (dilatator) pupillae forms a thin layer that lies immediately anterior to the epithelium of the posterior surface of the iris. Its 'fibres' are the muscular processes of the anterior layer of this epithelium, whose cells are therefore myoepithelial. Myofilaments are present throughout these cells but are more abundant in their fusiform basal muscular processes, which are approximately $4 \mu \mathrm{~m}$ thick, $7 \mu \mathrm{~m}$ wide and $60 \mu \mathrm{~m}$ in length. They form a layer 3-5 elements thick through most of the iris, from its periphery to the outer perimeter of the sphincter, which it slightly overlaps. Here the dilator thins out and sends spurs to blend with the sphincter. Unlike the apical parts of the myoepithelial cells, these have a basal lamina and are joined by gap junctions like those between the sphincteric muscle cells. Small, unmyelinated axons pass between, and terminate on, their muscular processes (see Fig. 42.15).

## Innervation of muscles of the iris

The iris is innervated mainly by the long and short ciliary nerves. Short ciliary nerves, which contain parasympathetic, postganglionic, myelinated axons derived from the ciliary ganglion (see Figs 41.17, 42.12), innervate the sphincter pupillae, losing their myelin well before entering the muscle. The dilator is supplied with sympathetic, nonmyelinated, postganglionic fibres from the superior cervical ganglion; their routes are less well established. Some go via the ciliary ganglion and reach the eye in the short ciliary nerves, whereas other fibres may travel in the long ciliary nerves, which are branches of the nasociliary nerve. An additional small fraction of nerve endings in the dilator and sphincter muscles have been identified as parasympathetic and sympathetic, respectively, in experimental animal studies, including those on primates. Although ganglion cells have been noted in the iris, the majority of axons are probably postganglionic. They form a plexus around the periphery of the iris, from which fibres extend to innervate the two muscles, the vessels and the anterior border layer; some fibres may be afferent and others are vasomotor.

Fig. 42.15 Posterior structures of the iris. The dilator pupillae is shown in transverse section on the right and in longitudinal section on the left (the arrow shows a rarer deeper nerve terminal).

## Pupillary light reflex

Pupillary diameter varies from around 2 mm when fully constricted (miosis) in bright light to at least 8 mm when dilated in darkness (mydriasis), and has an even wider range under the influence of drugs. The resulting variation in pupil area (maximally a factor of 16) will obviously affect the amount of light impinging on the retina. However, compared to the total range of illumination within which humans can maintain some degree of vision (approximately 10 log units), this effect, though important, is small. Most mechanisms for dark/light adaptation are retinal, and neural or biochemical in nature. Enhancing visual acuity by restricting light to the centre of the lens, and thereby decreasing the amount of spherical aberration, is at least as important a function of pupillary constriction.

If only one eye is illuminated, the pupil of that eye constricts (direct response), as does the pupil of the contralateral, unilluminated, eye (consensual response). While change in pupillary diameter is usually considered a reflex response to changes in light level, the pupil also constricts on viewing near objects (as part of the near triad; p. 693) and in response to painful stimuli; it can also be influenced to some degree by more complex cortical factors.

In pupillary constriction, light acting on both traditional retinal photoreceptors (rods and cones) and on intrinsically photosensitive retinal ganglion cells gives rise to activity in retinal ganglion cells. This activity is conducted along the optic nerve, through the optic chiasma and along the optic tract. Although the majority of tract fibres end in the lateral geniculate nucleus of the thalamus, a small number leave the optic tract before it reaches the thalamus, at the superior brachium, and synapse in the olivary pretectal nucleus. The information is relayed from the pretectal nucleus by short neurones that synapse bilaterally on preganglionic parasympathetic neurones in the Edinger-Westphal nucleus (in the oculomotor nerve complex in the rostral midbrain) Efferent impulses pass along parasympathetic fibres carried by the oculomotor nerve to the orbit, where they synapse in the ciliary ganglion. Postganglionic fibres travel in the short ciliary nerves to the sphincter pupillae, which reduces the size of the pupil when it contracts (see Fig. 42.12).

Pupillary dilation is brought about by lessening the parasympathetic drive to the sphincter (see above) and by sympathetic activation of the dilator. Sympathetic preganglionic fibres arise from neurones in the lateral column of the first and second thoracic segments, and pass via the sympathetic trunk to the superior cervical ganglion. Postganglionic neurones travel up the neck next to the internal carotid artery as the internal carotid nerve; at the level of the cavernous sinus, the nerve breaks up to form an interweaving network of fibres, the carotid plexus,
around the carotid artery. Some of the axons from the plexus form the sympathetic root of the ciliary ganglion, passing through the ciliary ganglion without synapsing; mostly travelling in the short ciliary nerves, they innervate the dilator.

## Vascular supply of the iris

The iris receives its blood supply from the long posterior and anterior ciliary arteries (see Figs 41.13, 42.8). On reaching the attached margin of the iris, both long ciliary arteries divide into an upper and a lower branch. The branches anastomose with the corresponding contralateral arteries, and with the anterior ciliary arteries, to form the major arterial (iridic) circle (circulus arteriosus major) at the base of the iris (see Figs 42.13-42.14). Vessels converge from this circle towards the free margin of the iris, where they form loops and become veins. At the level of the collarette, arteries and veins anastomose to form an incomplete minor iridic circle (circulus arteriosus minor). The smaller arteries and veins are very similar in their structure and are often slightly helical, which allows them to adapt to changes in iridial shape as the pupil varies in size. All of the vessels, including the capillaries, have a non-fenestrated endothelium and a prominent, often thick, basal lamina. There is no elastic lamina in the arteries or veins, and there are few smooth muscle cells, especially in the veins. Connective tissue in the tunica media is loose, whereas the adventitia is remarkably dense and collagenous, so that it appears to form almost a separate tube.

## LENS AND HUMOURS

The cornea, aqueous humour, lens and vitreous body, often collectively termed the ocular media, serve to form an image on the retina by transmitting and refracting light. Additionally, the aqueous provides nutrients to the avascular cornea and lens, and removes their metabolic waste, as well as generating the intraocular pressure that maintains the shape of the eye.

## AQUEOUS HUMOUR

Aqueous humour is derived from the plasma within the fenestrated capillaries of the ciliary processes. The major component of aqueous, like plasma, is water and the composition of the two fluids is broadly similar, although they do differ in the concentration of some electrolytes and organic solutes. In the interests of optical clarity, the

Fig. 42.16 A sagittal section through part of the lens and related structures. The cortex is distinguished from the nucleus, which is composed of embryonic, fetal, infantile and adult parts. The capsule is drawn in blue, exaggerated in thickness 100 times, and is based on observations from a 35 -year-old.
blood-aqueous barrier also ensures a very low concentration of protein in the aqueous (generally less than $1 \%$ of the level in plasma). Inflammation of the anterior uvea can lead to a breakdown of this barrier and the presence of protein in the aqueous, resulting in light scatter that is manifest clinically as 'flare'.

The aqueous is actively secreted into the posterior chamber by the epithelium overlying the ciliary processes. It passes around the equator of the lens and flows through the pupil into the anterior chamber, where it circulates before being drained at the iridocorneal angle. Most aqueous is drained from the eye through the trabecular meshwork into the canal of Schlemm; from here, it drains into episcleral veins. However, some exits through the ciliary muscle into the supraciliary and suprachoroidal spaces (uveoscleral pathway).

Any interference with the drainage of aqueous into the canal of Schlemm increases intraocular pressure and leads to glaucoma. Glaucoma is either 'primary', or secondary to a specific anomaly or disease of the eye. Primary glaucoma can be either 'closed angle', where the filtration angle is narrowed by the proximity of the root of the iris to the cornea, or, more commonly 'open angle', where aqueous access to angle tissues is unimpeded. In the most common form of primary open angle glaucoma, pathological changes within the trabecular meshwork reduce the facility of aqueous drainage, thus raising intraocular pressure. Sustained raised pressure leads to progressive defects in the visual field, because of either direct mechanical damage to retinal ganglion cell axons (particularly at the optic nerve head), or impairment of the optic nerve head blood supply, or both.

## LENS

The lens is a transparent, encapsulated, biconvex body bathed in aqueous humour, which serves to adjust the focus of the eye. Posteriorly, it contacts the hyaloid fossa of the vitreous body. Anteriorly, it forms a ring of contact with the posterior border of the pupillary region of the iris but, further away from the axis of the lens, the gap between the lens and iris increases to form the posterior chamber of the eye (see Fig. 42.1; Fig. 42.16). The lens is encircled by the ciliary processes, and is attached to them by the zonular fibres, which issue mainly from the pars plana of the ciliary body. Collectively, the fibres form the zonule, which holds the lens in place and transmits the forces that stretch the lens.

The anterior convexity of the lens is less steep than that of the posterior surface. The central points of these surfaces are the anterior and posterior poles of the lens and a line connecting them is its axis. The marginal circumference of the lens is its equator.

At birth, the lens is colourless and transmits all wavelengths from the infra-red to the near-ultraviolet well. However, throughout life, the

Fig. 42.17 A section through the anterior layers of the lens. The thin capsule covers the single row of epithelial cells (arrow), and the lens substance is composed of regularly stacked younger fibres and more densely stained and complex older deeper fibres.
amount of short-wave radiation transmitted diminishes until, in old age, the lens takes on an amber tinge as it absorbs visible short-wave radiation, decreasing blue sensitivity in older people. In cataract, the lens gradually becomes opaque.

The dimensions of the lens are optically and clinically important, but change with age as a consequence of continuous growth. Its equatorial diameter at birth is 6.5 mm , increasing rapidly at first, then more slowly to 9.0 mm at 15 years of age, and even more gradually to reach 9.5 mm in the ninth decade. Its axial dimension increases from $3.5-4.0 \mathrm{~mm}$ at birth to $4.75-5.0 \mathrm{~mm}$ at age 95 . The lens flattens during the first decade of life (Mutti et al 1998). Average adult radii of the anterior and posterior surfaces of the lens are 10 mm and 6 mm , respectively. These reduce in later life, the anterior surface increasing most in curvature as the lens thickens, so that, in old age, the lens pushes the iris forwards slightly, predisposing the elderly eye to angle closure glaucoma.

The lens consists of three layers (Fig. 42.17). Its bulk is composed of elongated cells (lens fibres), which anteriorly, as far as the equator, are covered by a single layer of epithelial cells, and the whole is surrounded by the lens capsule. The lens is avascular and devoid of nerve fibres or other structures that might affect its transparency. Its surface forms a very effective barrier against invasion by cells or elements of the immune system, and so creates an immunologically sequestered environment. It is unique because it retains all the cells formed throughout its life.

## Lens capsule

The lens capsule is a basement membrane that covers the surface of the lens. It consists of various classes of collagen fibre (I, III and IV), as well as a range of glycosaminoglycans and glycoproteins. It is derived from the anterior lens epithelial cells and their fetal precursors, and is firmly attached to the epithelium anteriorly and to lens fibres posteriorly. The capsule is elastic, a property it owes to the arrangement of its collagen, and which is central to the process of accommodation. Capsule thickness varies with position and age. One view is that, in adults, it is thicker at the anterior pole ( $12-14 \mu \mathrm{~m}$ ) and equator than at the posterior pole, with a band of increased thickness between the pole and equator (anteriorly, 20-24 $\mu \mathrm{m}$ ) (see Fig. 42.16). Zonular fibres insert into the capsule at the equator. They are composed of thin ( $4-7 \mathrm{~nm}$ ) fibrils with hollow centres, and resemble fibrils associated with elastic connective tissue.

## Lens epithelium

The anterior surface of the lens between the outer capsule and the underlying lens fibres is covered by a layer of simple, roughly cuboidal ( $10 \mu \mathrm{~m}$ high and $13 \mu \mathrm{~m}$ wide), epithelial cells that, in surface view, are polygonal (see Fig. 42.17). These cells differentiate into lens fibres; they undergo mitosis at a germinative zone just anterior to the equator and are displaced towards the equator, where they synthesize characteristic lens fibre proteins and undergo extreme elongation. As other cells follow suit, the earlier cells come to occupy a deeper position within the lens.

## Lens fibres

The inwardly displaced epithelial cells elongate further in both an anterior and a posterior direction, becoming up to 12 mm long, depending on age and position in the lens. Fibres near the surface at the equator are nucleated; the nuclei form a short, S -shaped bow, which extends inwards from the surface. The deeper fibres lose their nuclei and most other organelles.

Variations in lens fibre structure and composition make it possible to distinguish a softer cortical zone, made up of younger fibres, and a firmer central part, representing the older nucleus. The nucleus can be further subdivided into layers representing the age at which the fibres within them were formed.

In cross-section, individual fibres are flattened hexagons measuring approximately $10 \mu \mathrm{~m}$ by $2 \mu \mathrm{~m}$. They are tightly packed, and fibres are firmly attached to their neighbours by a variety of mechanical junctions (Fig. 42.18). Lens fibres are also in contact through desmosomes and numerous gap junctions.

All lens fibres cross a plane passing through the equator and terminate on both the anterior and posterior lens surfaces at lens 'sutures' These radiate out from the poles towards the equator and represent lines of linearly registered, interlocking junctions between terminating lens fibres. In fetuses, the sutures on the anterior surface of the lens form a triradiate pattern centred on the anterior pole resembling the limbs of an upright letter Y (Fig. 42.19A). Posteriorly, the sutural configuration is similar but inverted. The sutures increase in number and complexity as a consequence of lens growth and other changes in the arrangement of lens fibres (Fig. 42.19B). Fibres that start near the central axis of the lens anteriorly terminate posteriorly on a suture near the periphery, and vice versa.

Lens fibres contain crystallins, proteins that are responsible for the transparency and refractile properties, and for much of the elasticity, of

Fig. 42.18 The mechanical junctions between lens fibres. There are no junctions immediately below the epithelium. Ball and socket junctions develop in deeper layers; these are subsequently eliminated towards the nucleus, where tongue and groove junctions gradually form. Angle joints are present at most levels.
the lens. At least three varieties coexist $-\alpha, \beta$ and $\gamma$, their relative proportions changing throughout life. They occur in very high concentrations, and form up to $60 \%$ of the lens fibre mass. Variations in their concentration in different parts of the lens give rise to regional differences in refractive index, correcting for the spherical and chromatic aberrations which might otherwise occur in a homogeneous lens.

## Ocular refraction

The cornea and humours have a refractive index close to that of water, but the tear film covering the curved corneal surface is in contact with air and therefore approximately two-thirds (approximately 40 dioptres) of the refractive power of the eye is effected here. The lens has a greater refractive index than the adjacent media, varying from 1.386 at its periphery to 1.406 at its core, and contributes the remaining approximately 20 dioptres of the power of the relaxed eye. The main value of the lens is its ability to vary its dioptric power during the process of accommodation. Accommodation allows an increase in refraction of 12 dioptres in youth but this decreases with age, being halved at 40 years and reduced to 1 dioptre or less at 60 years (presbyopia).

## Disorders of refraction

A relaxed eye is said to be emmetropic when the refracting structures are so related to its length that the retina receives a focused image of a distant object. Although the majority of eyes are emmetropic, a large

Fig. 42.19 The structure of the fetal $(\mathbf{A})$ and adult $(\mathbf{B})$ human lens, showing the major details of arrangement of the lens fibres. The anterior (a) and posterior (b) triradiate sutures are shown in the fetal lens. Fibres pass from the apex of an arm of one suture to the angle between two arms at the opposite pole, as shown in the coloured segments. Intermediate fibres show the same reciprocal behaviour. The suture pattern becomes much more complex as successive strata are added to the exterior of the growing lens, and the original arms of each triradiate suture show secondary and tertiary dichotomous branchings. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)
minority have errors of refraction or ametropia that can take three different forms. In myopia, the eye is too long for its refractive power and distant objects are focused in front of the retina when relaxed; closer objects will be in focus and, consequently, the eye is said to be 'shortsighted'. Conversely, in hyperopia (long sight), the eye is too short for its refractive power and, when it is relaxed, distant objects are focused behind the retina. In astigmatism, the refractive power of the eye is not the same in different meridians, which are approximately $90^{\circ}$ apart in regular astigmatism.

Normally, emmetropia is assured during development both by the active control of the sclera's biomechanical and biochemical properties and changes in the optical features of the eye's refractive elements, a process known as emmetropization (Wallman and Winawer 2004). A resting focal plane behind the retina results in scleral growth causing axial elongation of the globe until the focused image and the position of the retina are coincident. On the other hand, light focused in front of the retina retards scleral growth, reducing axial length. In ametropia, this process fails.

The causes of refractive errors such as myopia are both genetic and environmental. Not only have several candidate genes been identified, but also factors such as increased near work and lack of outdoor activity have all been linked to myopia (Wallman and Winawer 2004, Flitcroft 2013). This has led to a recent increase in the incidence of myopia to epidemic proportions, with a prevalence of over $80 \%$ in the adult population of some East Asian cities (Rose et al 2008). Fortunately, errors of refraction are amenable to correction using spectacle or contact lenses and by various forms of refractive surgery.

As noted above, the ability to change the power of the lens through accommodation diminishes during the fifth decade to an extent that neither the corrected ametrope nor the emmetrope is able to focus near objects clearly, and reading spectacles become necessary. Many factors could potentially cause such loss of accommodation, but it seems likely that the main cause is reduced lens elasticity with age. This is offset to a very limited extent by the reduction of the pupil aperture with age, which increases the depth of focus but at the cost of creating the further problem of requiring greater illumination.

Other errors of refraction are the concomitants of eye disease, especially those that affect the cornea. Corneal curvature, for example, may be sufficiently altered as a residual defect of past disease to cause irregular astigmatism. In keratoconus, the cornea is thinned and steepened centrally, distorting the refracting surface. A dislocated lens, caused, for example, by Marfan's syndrome, also disrupts the refractive status of the eye.

## VITREOUS HUMOUR

The vitreous body occupies about four-fifths of the eyeball. Posteriorly, it is in contact with the retina, while further forwards it abuts the ciliary body, zonule and lens. Its anterior surface is hollowed into a deep concavity, the hyaloid fossa, fitting the shape of lens (see Fig. 42.1). It is colourless, consisting of approximately $99 \%$ water, but is not entirely structureless. At its perimeter, it has a gel-like consistency (100-300 $\mu \mathrm{m}$ thick); nearer the centre, it contains a more liquid zone. Hyaluronan, in the form of long glycosaminoglycan chains, fills the whole vitreous. In addition, the peripheral gel or cortex contains a random loose network of type II collagen fibrils, which are occasionally grouped into fibres. The cortex also contains scattered cells, the hyalocytes, which possess the characteristics of mononuclear phagocytes and may contribute to the production of hyaluronan. While they are normally in a resting state, they have the capacity to be actively phagocytic in inflammatory conditions. Hyalocytes are not present in the cortex bordering the lens.

The liquid vitreous is absent at birth, appears first at 4 or 5 years, and increases to occupy half the vitreous space by the seventh decade. Vitreous liquefaction results in an increased incidence of posterior vitreous detachment and associated floaters in the elderly. The cortex is most dense at the pars plana of the ciliary body adjacent to the ora serrata, where attachment is strongest, and this is often referred to as the base of the vitreous. Apart from the vitreous base, the vitreous also has a firm (peripapillary) attachment at the edge of the optic disc. This adherence of the vitreous to the retina can result in traction on the retina if the vitreous shrinks, such as occurs in old age, resulting in macular holes or peripheral breaks, possibly leading to retinal detachment.

A narrow hyaloid canal runs from the optic nerve head to the central posterior surface of the lens (see Fig. 42.1). In the fetus, this contains the hyaloid artery, which normally disappears about 6 weeks before birth. The canal persists in adult life as a very delicate fibrous structure and is of no functional importance.

Fig. 42.20A A fundus photograph of the right eye of a 19-year-old Caucasian female. The central retinal vessels are seen emanating from the optic disc. Retinal arteries are narrower and lighter in colour, and generally are vitreal to the veins. The avascular centre of the macular region, with its associated macular pigment, can be seen temporal to the disc.

## RETINA

The retina is a thin sheet of cells, ranging from less than $100 \mu \mathrm{~m}$ at its edge to a maximum of around $300 \mu \mathrm{~m}$ at the foveal rim. It lines the inner posterior surface of the eyeball, sandwiched between the choroid externally and the vitreous body internally, and terminates anteriorly at the ora serrata (see Fig. 42.1).

When it is viewed with an ophthalmoscope to show the fundus oculi, the most prominent feature is the blood vessels emanating from and entering the optic disc (Fig. 42.20A). Centred temporal and inferior to the disc lies the 'central retina' or macula (diameter 5-6 mm), the middle of which is composed of the fovea and foveola, and easily identified with an ophthalmoscope as an avascular area with a yellow tinge (see Fig. 42.20A). The lack of blood vessels at the foveola is even more apparent in a fluorescein angiogram. The peripheral retina lies outside the central retina (Fig. 42.20B).

## MICROSTRUCTURE

The retina is composed of a variety of epithelial, neural and glial cell types, whose distribution conventionally divides it into 10 layers (Fig. 42.21). These are apparent in histological sections (Fig. 42.22), but can also be seen in vivo using optical coherence tomography, an imaging technique that uses backscattered light to visualize layers by differences in their optical scattering properties (Fig. 42.23). Embryologically, the retina is derived from the two layers of the invaginated optic vesicle. The outer layer becomes a stratum of cuboidal pigment cells that separates the choroid from the neural retina, and therefore forms the outermost layer of the retina: the retinal pigment epithelium (layer 1). The other nine strata of the retina develop from the inner layer of the optic vesicle and form the neural retina.

The outermost layer of the neural retina contains the light-sensitive parts of the photoreceptors, which convert the optical image into neural activity. From the photoreceptors, neural activity flows radially to bipolar and ganglion cells, and laterally via horizontal cells in the outer retina and amacrine cells in the inner retina. Photoreceptors synaptically contact each other and bipolar and horizontal cells in the outer plexiform layer (layer 5), while bipolar, amacrine and ganglion cells synapse in the inner plexiform layer (layer 7). The axons of ganglion cells run towards the optic disc in the nerve fibre layer (layer 9), where they leave the retina as the optic nerve, which transmits the retinal output to the visual areas of the brain where visual processing is completed. Although most neural activity flows from the

which masks fluorescence from the choroidal circulation.

Fig. 42.21 Neural cells whose cell bodies and interconnections account for the layered appearance of the retina in histological section (compare with Fig. 42.22). Also shown are the two principal types of neuroglial cell in the retina (although microglia are also present, they are not shown).

Fig. 42.22 A transverse section of the retina and choroid. The 10 layers of the retina are shown. Key: 1, pigment epithelial layer; 2, rod and cone layer; 3, external limiting membrane; 4, outer nuclear layer; 5, outer plexiform layer; 6, inner nuclear layer; 7, inner plexiform layer; 8, ganglion cell layer; 9, nerve fibre layer; 10, internal limiting membrane. Abbreviations: CC, choriocapillaris; SC, suprachoroid.
photoreceptors towards the brain, some information flow occurs in the opposite direction via centripetal fibres in the optic nerve and interplexiform cells in the retina that connect the inner and outer plexiform layers.

The classic 10-layered appearance of the retina is absent in the optic nerve head, the fovea and foveola, and the ora serrata. At the optic nerve head, the axons of the retinal ganglion cells leave the retina to form the optic nerve and all the other neural cell types are missing. At the fovea and foveola, the inner five layers of the retina are 'pushed aside'. At the ora serrata, where the retina borders the ciliary body (see Fig. 42.10), the retinal pigment epithelium merges with the outer pigmented epithelium of the ciliary body, while the neural retina borders the inner unpigmented ciliary epithelium; the retina is thinnest at this point. The normal layered arrangement of the neural retina approaching the ora serrata is frequently disrupted by cysts in older individuals (Fig. 42.24).

Fig. 42.23 A high-definition optical coherence tomography (OCT) in vivo image of the human retina. The image has approximately $2 \mu \mathrm{~m}$ axial resolution, is 8 mm long and consists of 10,000 axial scans. The image is expanded in the vertical direction to permit better visualization of retinal layers. ## Cells of the retina

## Retinal pigment epithelium

The retinal pigment epithelium is composed of approximately cuboidal cells that form a single continuous layer extending from the periphery of the optic disc to the ora serrata, where it continues as the outer ciliary epithelium. The cells are flat in radial section and hexagonal or pentagonal in surface view, and number 4-6 million in the human retina. Their cytoplasm contains numerous melanosomes. Apically (towards the rods and cones), the cells bear long ( $5-7 \mu \mathrm{~m}$ ) microvilli that contact, or project between, the outer segments of rods and cones. The tips of rod outer segments are deeply inserted into invaginations in the apical membrane of the retinal pigment epithelium. The different
embryological origins of the retinal pigment epithelium and neural retina mean that the attachments between these two layers are unsup－ ported by junctional complexes；the neural retina and retinal pigment epithelium are therefore easily parted（retinal detachment）due to trauma or disease．

Fig．42．24 The junction between the retina and ciliary body（ora serrata）． The retinal pigment epithelium is continuous with the outer，pigmented epithelium of the ciliary body，while the neural retina abuts the inner， unpigmented epithelium of the ciliary body．The layered appearance that is apparent elsewhere in the neural retina is disrupted adjacent to the ora serrata by cystic degeneration．

Retinal pigment epithelium cells play a major role in the turnover of rod and cone photoreceptive components．Their cytoplasm contains the phagocytosed tips of rods and cones undergoing lysosomal destruc－ tion．The final products of this process are lipofuscin granules，which accumulate in these cells with age．Disturbances in this phagocytic activity of the retinal pigment epithelium can lead to retinal disease （Kevany and Palczewski 2010）．

Light reaching the outer retina but missing the photoreceptors is absorbed by the retinal pigment epithelium，which，like melanin else－ where in the eye，prevents such stray light degrading image quality．The zone of tight junctions between adjacent cells also allows the epithe－ lium to function as an important blood－retinal barrier between the retina and the vascular system of the choroid．The retinal pigment epi－ thelium is required for the regeneration of bleached visual pigment and may have antioxidant properties．It also secretes a variety of growth factors necessary for the integrity of the choriocapillaris endothelium and the photoreceptors，and produces a number of immunosuppressive factors．A failure of any of the diverse functions of the retinal pigment epithelium could result in compromised retinal function and eventual blindness（Strauss 2005）．

## Rods and cones

Rods and cones are the＇image－forming＇photoreceptors of the outer retina and function at low（scotopic）and higher（photopic）light levels， respectively．Both are long，radially orientated structures with a similar organization，although details differ（Fig．42．25）．From the choroidal end inwards，the cells consist of outer and inner segments connected

Fig．42．25 The major features of a retinal rod cell（A）and a retinal cone cell（B）．The relative size of the pigment epithelial cells has been exaggerated for illustrative purposes．
by a thin connecting cilium (together making up layer 2 of the retina), a cell body containing the nucleus, and a synaptic terminal (either a more complex pedicle for cones or a simpler rod spherule) where they make synaptic connections with adjacent bipolar and horizontal cells and with other cone or rod cells within the outer plexiform layer.

The nuclei of the rods and cones form the outer nuclear layer (layer 4). The cone nuclei are relatively large and oval, and generally form a single layer that often penetrates the external limiting membrane (layer 3). They also contain less heterochromatin and thus usually stain more lightly. Rod nuclei are round and smaller, stain more darkly, and form several layers vitreal to the cone nuclei.

The external limiting is not, in fact, a membrane at all, although it appears as such in the light microscope; rather, it is a series of zonulae adherentes between photoreceptors and the glial (Müller) cells that separate them. These junctions most likely serve to anchor the photoreceptors and prevent leakage of the interphotoreceptor matrix that surrounds the photoreceptor outer and inner segments.

Rod outer segments are cylindrical and consist of around 1000 flattened, lobulated, membranous discs. These form as deep infoldings of the plasma membrane at the base of the outer segment; they 'bud off' after formation so that the discs are not attached to the plasma membrane and are free-floating within the outer segment. Cone outer segments are generally shorter and, as their name implies, often conical (especially in the peripheral retina). Cone discs do not bud off after formation and remain as infoldings of the plasma membrane.

The inner segment of both rods and cones is divided into an outer, mitochondria-rich, ellipsoid and an inner myoid that contains endoplasmic reticulum. In most of the retina, these inner segments are much wider in cones ( $5-6 \mu \mathrm{~m}$ at their widest point) than rods ( $1.5 \mu \mathrm{~m}$ ) (Fig. 42.26). In both rods and cones, proteins are manufactured within the myoid and incorporated into the newly formed discs at the base of the outer segment. In rods, as new discs are added, and old discs are pushed up the outer segment and eventually phagocytosed by the retinal pigment epithelium. Cone discs are also phagocytosed but the incorporation of new proteins within the discs is more diffuse (NguyenLegros and Hicks 2000). While all rods within the retina have a similar structure, the cones at the foveola are highly modified compared to those situated more peripherally and, in many ways, resemble rods with a longer outer segment and a thinner inner segment.

Light is absorbed by rhodopsins, visual pigments consisting of a protein, opsin, that spans the membrane of the outer segment discs, bound to a light-absorbing chromophore, retinal, which is an aldehyde of vitamin $\mathrm{A}_{1}$. Such rhodopsins have a smooth, bell-shaped absorption profile with a point of maximum absorbance $\left(\lambda_{\max }\right)$, indicating the wavelength at which they are most sensitive. Humans possess four different opsins, resulting in four spectrally distinct visual pigments: one located within the rods ( $\lambda_{\text {max }} 498 \mathrm{~nm}$ ) and three within different

Fig. 42.26 A tangential section of a human retina in the parafovea cut at the level of the inner/outer segments, showing the 'mosaic' of both the larger cones and the more numerous, but smaller, rods. Photoreceptors at the top of the image are sectioned at a level closer to the retinal pigment epithelium than receptors lower in the figure. The reduction in size of the cones at the top of the figure is explained by the conical shape of their outer segment. If the figure were continued upwards, representing sections closer to the retinal pigment epithelium, the size of the cones would continue to decrease and the amount of surrounding white space would increase. Rod outer segment diameter, however, would change little.
populations of cones absorbing maximally at the short- ( $\lambda_{\max } 420 \mathrm{~nm}$ ), middle- $\left(\lambda_{\max } 534 \mathrm{~nm}\right.$ ) and longer-wave ( $\lambda_{\max } 563 \mathrm{~nm}$ ) end of the visible spectrum. The three cone classes are sometimes referred to as the blue, green and red cones but are better classed as $\mathrm{S}, \mathrm{M}$ and L cones. The action of light is to isomerize the retinal, separating it from the opsin, a process which, via a G-protein coupled enzyme cascade and a second messenger system, results in the closure of cation channels in the receptor outer segment membrane, a hyperpolarization of the photoreceptor, and a consequent decrease in the release of the neurotransmitter glutamate from its synapses.

The human retina contains, on average, 4.6 million cones and 92 million rods, although there is significant inter-individual variation (Curcio et al 1990). Although cones populate the whole retina, their density is highest in the foveola, where approximately 7000 cones reach an average density of 199,000 cones $/ \mathrm{mm}^{2}$; this area is entirely rod-free. Going outwards from the foveola, rod numbers rise, reaching a peak density in a horizontal elliptical ring at the eccentricity of the optic disc, before declining once more towards the periphery. Cone density is $40-45 \%$ higher in the nasal compared to the temporal retina, and slightly higher inferiorly than superiorly.

The number of $S$ cones in all human retinae is similar, making up less than $10 \%$ of all cones (Curcio et al 1991, Hofer et al 2005). The distribution of $S$ cones is relatively even throughout the retina, although they are absent from the central fovea. The relative proportions of $L$ and $M$ cones shows a much greater degree of variation between individuals, the $\mathrm{L}: \mathrm{M}$ cone ratio varying from close to unity to over 10 . The distribution of $L$ and $M$ cones is more irregular than that of $S$ cones, and appears random with some indication of clumping (Bowmaker et al 2003, Hofer et al 2005).

The high packing density of cones at the foveola, achieved by decreasing inner segment size, ensures maximal resolution, while the presence of more than one spectral cone type allows colour vision. S cones probably contribute little to spatial resolution because they are absent from the foveola. Rod-based vision provides high sensitivity, but with relatively low spatial discrimination and no ability to distinguish wavelengths. Although many of the functional differences between rods and cones rely on the different properties of the photoreceptors themselves, their connectivity to other retinal neurones is equally important.

## Horizontal cells

Horizontal cells are inhibitory interneurones. Their dendrites and axons extend laterally within the outer plexiform layer, making synaptic contacts with cone pedicles and rod spherules, and, via gap junctions at the tips of their dendrites, with each other. Their cell bodies lie in the outer part of the inner nuclear layer (layer 6). Three morphological types of horizontal cell can be distinguished in the human retina (Kolb et al 1992). The dendrites of HI and HIII cells contact cones, and their axons terminate on rods. Both the axons and dendrites of HII cells synapse only with cones.

## Bipolar cells

Bipolar cells are radially orientated neurones. Their dendrites synapse on photoreceptors, horizontal cells and interplexiform cells in the outer plexiform layer. Their somata are located in the inner nuclear layer, and axonal branches in the inner plexiform layer synapse with dendrites of ganglion cells or amacrine cells. Golgi staining has identified nine distinct types of bipolar cell in the human retina (Kolb et al 1992), eight of which contact cones exclusively, and the remaining type synapses only on rods.

Cone bipolars are of three major morphological types: midget, S (blue) cone and diffuse, according to their connectivity and size. Midget cone bipolar cells either invaginate the cone pedicle or synapse on its base (flat subtype). In the central retina, each midget bipolar cell contacts only a single cone (2-3 in the periphery), forming part of a one-to-one channel from cone to ganglion cell that mediates high spatial resolution. S cones form part of a short-wavelength mediating channel, while the larger diffuse cone bipolars are connected to up to 10 cones and are thought to signal luminosity rather than colour.

Cone bipolar cells can also be of two physiological types, according to their response to the light-induced decrease in glutamate release from the photoreceptors to which they are synaptically connected. If illumination of the photoreceptors with a point of light causes a depolarization of the connected bipolar cell, it is said to be an 'ON' bipolar, contacting the cone by 'sign-inverting' synapses with metabotropic receptors. However, if cones are connected to an 'OFF' bipolar cell via 'sign-conserving' synapses with ionotropic receptors, illumination of the photoreceptor will result in hyperpolarization of the bipolar cell. Illumination of a concentric area of surrounding photoreceptors causes the opposite response in bipolar cells to illumination within their
dendritic field. This inhibition is mediated via horizontal cells and gives rise to the antagonistic centre-surround type receptive field that is characteristic of all levels of the visual system up to and including the occipital cortex.

The single morphological type of rod bipolar cell contacts 30-35 rods in the central retina, increasing to $40-45$ rods in the periphery. Such convergence serves to increase the absolute sensitivity of the rod system. All rod bipolar cells are 'ON-centre' and do not contact ganglion cells directly, but synapse with a class of amacrine cell (AII), which then contacts cone bipolar cells.

The inner plexiform layer can be divided into two main layers: an outer layer containing the synaptic endings of 'OFF' cone bipolar cells, and an inner layer of 'ON' cone and rod bipolar cell synapses.

## Amacrine cells

Most amacrine cells lack typical axons and, consequently, their dendrites make both incoming and outgoing synapses. Each neurone has a cell body either in the inner nuclear layer near its boundary with the inner plexiform layer, or on the outer aspect of the ganglion cell layer, when it is known as a displaced amacrine cell. The processes of amacrine cells make a variety of synaptic contacts in the inner plexiform layer with bipolar and ganglion cells, as well as with other amacrine cells.

The various classes of amacrine cell serve a number of important functions. AII cells play an essential role in the rod pathway (see above). Other cells appear to be important modulators of photoreceptive signals, and serve to adjust or maintain relative colour and luminosity inputs under changing light conditions. They are probably also responsible for some of the complex forms of image analysis known to occur within the retina, such as directional movement detection. Up to 24 different morphological types are recognized in humans (Kolb et al 1992); coupled to their neurochemical complexity, this makes them perhaps the most diverse neural cell type in the body.

## Interplexiform cells

Interplexiform cells, often regarded as a subclass of amacrine cells, generally have cell bodies in the inner nuclear layer. They are postsynaptic to cells in the inner retina, and send signals against the general direction of information flow in the retina, synapsing with bipolar, horizontal and photoreceptor cells in the outer plexiform layer. Although their function is uncertain, it is likely that, through the release of $\gamma$-aminobutyric acid (GABA) and dopamine, they adjust some aspect of retinal function such as sensitivity.

## Ganglion cells

The human retina contains $0.7-1.5$ million ganglion cells, the output neurones of the retina (Curcio and Allen 1990). Their dendrites synapse with processes of bipolar and amacrine cells in the inner plexiform
layer. Ganglion cell bodies, together with displaced amacrine cells, form the ganglion cell layer of the retina (layer 8). Throughout most of the retina, they form a single layer; they become progressively more numerous near the macula, where they are ranked in up to 10 rows, reaching a peak density of up to $38,000 / \mathrm{mm}^{2}$ in a horizontally orientated elliptical ring $0.4-2.0 \mathrm{~mm}$ from the foveal centre. Their number diminishes again towards the fovea, from which they are almost totally excluded.

Up to 15 ganglion cell types have been identified in the mammalian retina based on morphology, physiology, and target area in the brain, each of them presumably functionally distinct. For example, some project to different regions of the lateral geniculate nucleus and form three parallel visual pathways involved in conscious visual perception, namely: the magnocellular and parvocellular systems and a pathway carrying the $S$ cone signal (Wässle 2004). Midget ganglion cells (P cells) contact only single midget bipolar cells in the central retina, which, in turn, connect to single cones, giving each cone a 'private line' out of the retina and ensuring optimal acuity. The large dendritic field of parasol cells ( M cells) is consistent with a role in motion detection. Parasol and midget ganglion cells together make up around $80 \%$ of human retinal ganglion cells. The remaining cells (approximately 200,000) project to the superior colliculus of the midbrain, the thalamic pulvinar, the pretectum and the accessory optic system, and contribute to various subconscious visual reflexes such as the pupillary and accommodation responses (see Fig. 42.12). In addition, a population of around 3000 large, intrinsically light-sensitive ganglion cells form a network composed of extensive overlapping dendrites (Dacey et al 2005). Such 'inner retinal photoreceptors' contain a retinal-based visual pigment (melanopsin; $\lambda_{\max } 479 \mathrm{~nm}$ ), which resembles an invertebrate-type visual pigment in many of its characteristics. These light-sensitive ganglion cells are part of a pathway parallel to the rod- and cone-mediated 'image-forming' system that monitors overall levels of illumination. This 'non-imaging' pathway is the major route by which the eye influences circadian rhythms via the suprachiasmatic nucleus; it also contributes to light-evoked pupillary constriction via projections to the olivary pretectal nucleus. Although the axons of some of these photosensitive ganglion cells also project to the lateral geniculate nucleus, their wider contribution to conscious visual perception remains incompletely understood.

Ganglion cell axons, which form the nerve fibre layer on the inner surface of the retina, run parallel to the surface of the retina, and converge on the optic nerve head where they leave the eye as the optic nerve. Fibres from the medial (nasal) retina approach the disc in a simple radial pattern (Fig. 42.27), whereas axons from the lateral (temporal) retina take an arcuate route as they avoid the fovea. Axons from the macula form a papillomacular fasciculus that passes almost straight to the disc. The thickness of the nerve fibre layer increases dramatically near the optic disc as fibres from the peripheral retina traverse more central areas. Towards the edge of the disc, the other retinal layers thin,

Fig. 42.27 Directions of axons (dashed lines) and blood vessels of the nerve fibre layer of the retina of the right eye. Axons pass radially on the nasal side of the optic disc, whereas fibres on the temporal side avoid crossing the fovea by arching around it. Some of the fibres from the fovea and central region pass straight to the optic disc and others arch above and below the horizontal; together, these form the papillomacular bundle. A raphe is formed by the central fibres temporal to the fovea. Venules are shown crossing in front of arteries; the reverse relationship is probably the more common pattern. All vessels issue from the disc on the right of the figure; the larger temporal branches tend to arch around the central region of the retina and do not approach the fovea. The peripheral retina and most of the nasal retina are not shown.
and, at the disc, all neural elements of the retina other than ganglion cell axons are excluded.

Axons of ganglion cells are surrounded by the processes of radial glial cells and retinal astrocytes, and are almost always unmyelinated within the retina, which is an optical advantage because myelin is refractile. Although a few small myelinated axons may occur, myelination does not generally start until axons enter the optic disc to become the optic nerve.

## Retinal glial cells

There are three types of retinal glial cells: radial Müller cells, astrocytes and microglia. Müller cells form the predominant glial element of the retina; retinal astrocytes are largely confined to the ganglion cell and nerve fibre layers; and microglial cells are scattered throughout the neural part of the retina in small numbers.

Müller cells span almost the entire thickness of the neural retina, ensheathing and separating the various neural cells except at synaptic sites. They constitute much of the total retinal volume, and almost totally fill the extracellular space between neural elements. Their nuclei lie within the inner nuclear layer, and from this region each cell body extends a single thick fibre that runs radially outwards, giving off complex lateral lamellae that branch among the processes of the outer plexiform layer. Apically, each central process terminates at the external limiting membrane, from which microvilli project for a short distance into the space between the rod and cone inner segments (fibre baskets) (see Fig. 42.25). On the inner surface of the retina, the main Müller cell process expands into a terminal foot plate that contacts those of neighbouring glial cells and forms part of the internal limiting membrane (see below).

The functions of Müller cells are numerous (Reichenbach and Bringmann 2013). Like astrocytes, Müller cells contact blood vessels, especially capillaries of the inner nuclear layer, and their basal laminae fuse with those of perivascular cells or vascular endothelia, contributing to the formation of the blood-retinal barrier. They also maintain the stability of the retinal extracellular environment by, for example, regulation of $\mathrm{K}^{+}$levels, uptake of neurotransmitter, removal of debris, storage of glycogen, providing neuroprotective support to the photoreceptors and mechanical support to the whole neural retina. Recently, it has been shown that they are also involved in the regeneration of cone visual pigments, that some are a source of stem cells and that they may even act as light guides, conveying light from the inner retina to the photoreceptors and overcoming some of the optical disadvantages of an 'inverted' retina.

The cell bodies of retinal astrocytes lie within the nerve fibre layer and their processes branch to form sheaths around ganglion cell axons. The close association between astrocytes and blood vessels in the inner retina suggests that they contribute to the blood-retinal barrier. Retinal microglia are scattered mostly within the inner plexiform layer. Their radiating branched processes spread mainly parallel to the retinal plane, giving them a star-like appearance when viewed microscopically from the surface of the retina. They can act as phagocytes, and their number increases in the injured retina.

The inner border of the retina is formed by the internal limiting membrane (layer 10), which consists of collagen fibres and proteoglycans from the vitreous, a basement membrane (which is continuous with the basal lamina of the ciliary epithelium), and the plasma membrane of expanded Müller cell terminal foot plates. It is $0.5-2 \mu \mathrm{~m}$ thick in the posterior retina and thickens with age. The internal limiting membrane is involved in fluid exchange between the vitreous and the retina, and, perhaps through the latter, with the choroid. It also has various other functions, including anchorage of retinal glial cells, and inhibition of cell migration into the vitreous body.

## Modifications of the central retina

The central retina, clinically referred to as the macula, is composed of four concentric areas, which, starting with the innermost, are: the foveola ( 0.35 mm diameter, equivalent of an angular subtense at the nodal point of around $1.25^{\circ}$ ), the fovea $\left(1.5 \mathrm{~mm}, 5.2^{\circ}\right)$, the parafovea $\left(2.5 \mathrm{~mm}, 8.6^{\circ}\right)$ and the vaguely defined perifovea ( $5-6 \mathrm{~mm}, 20^{\circ}$ ). The foveola, which contains no rods or $S$ cones, is centred about 3 mm temporal and 1 mm inferior to the optic disc (see Fig. 42.20A). In the foveola and surrounding fovea, all the inner layers of the neural retina beyond the outer nuclear layer have been displaced peripherally, resulting in a retinal thickness around half of that elsewhere in the retina (see Fig. 42.23; Fig. 42.28). This foveal pit is created by the cone 'axons', known here as Henle fibres, running almost parallel to the retinal surface before connecting to postreceptoral retinal neurones outside the

Fig. 42.28 A section through the fovea centralis. (With permission from Young B, Heath JW 2000 Wheater's Functional Histology. Edinburgh: Churchill Livingstone.)
fovea. The Henle fibres contain two xanthophyll carotenoid pigments (lutein and zeaxanthin), which create an elliptical yellowish area (approximately 2 mm horizontally and 1 mm vertically): the macula lutea. Macular pigment density varies by more than an order of magnitude between individuals, is influenced by several environmental factors, including diet, and is negligible in the central foveola. Low levels of macular pigment are likely to be associated with retinal pathologies such as age-related macular degeneration (Beatty et al 2008).

The absence of the inner retinal layers, including blood vessels (see Fig. 42.20A), reduces light scatter, which, along with the increased packing density of cones in the foveola and their lack of convergence with ganglion cells, ensures that visual resolution is highest in this part of the retina. Acuity may be further enhanced by the macular pigment, which, apart from having antioxidant properties and removing potentially harmful short-wave radiation, will absorb those wavelengths most prone to chromatic aberration and Rayleigh scatter.

## VASCULAR SUPPLY

The retina has a dual arterial supply and both parts are necessary to maintain retinal function. The outer five layers of the retina are avascular and rely on an indirect supply from the choroidal capillaries. The inner retina receives a direct blood supply through capillaries connected to branches of the central retinal artery and vein. Only the inner retinal circulation is described here.

The central retinal artery enters the optic nerve as a branch of the ophthalmic artery $6.4-15.2 \mathrm{~mm}$ behind the eyeball (Kocabiyik et al 2005), and travels within the optic nerve to its head, where it passes through the lamina cribrosa. At this level, the central artery divides into equal superior and inferior branches, which, after a few millimetres, divide into superior and inferior nasal, and superior and inferior temporal, branches, each supplying a 'quadrant' of the retina (see Fig. 42.27). Although similar retinal veins unite to form the central retinal vein, the courses of the arteries and veins do not correspond exactly. These vessels mainly run within the nerve fibre and ganglion cell layers of the retina, accounting for their clarity when seen through an ophthalmoscope (see Fig. 42.20A). Arteries often cross veins, usually lying superficial to them; in severe hypertension, the arteries may press on the veins and cause visible dilations distal to these crossings. The vitreal location of arteries, their lighter, bright red colouration and smaller diameter in comparison to veins allow the two vessel types to be distinguished ophthalmoscopically.

From the four major arteries within the inner retina, dichotomous branches run from the posterior pole to the periphery, supplying the whole retina (Zhang 1994). Arteries and veins ramify in the nerve fibre layer, near the internal limiting membrane, and arterioles pass deeper into the retina to supply capillary beds. Venules return from these beds to larger superficial veins that converge towards the disc to form the central retinal vein.

Retinal capillary networks can occur in three different layers, the number of layers depending on location (Zhang 1994). Radial peripapillary capillaries are the most superficial of the capillary networks
and lie within the inner nerve fibre layer. A layer of inner capillaries runs within the nerve fibre and ganglion cell layers, while an outer capillary layer is located in the inner plexiform and inner nuclear layers (Fig. 42.29). Approaching the fovea, capillaries are restricted to two layers, and terminal capillaries eventually join to form a single-layered macular capillary ring, producing a capillary-free zone 450-500 $\mu \mathrm{m}$ in diameter at the fovea. This avascular region is clearly visible in a fluorescein angiogram (Fig. 42.20B). Capillaries become less numerous in the peripheral retina and are absent from a zone approximately 1.5 mm wide adjoining the ora serrata.

The territories of the arteries that supply a particular quadrant do not overlap, nor do the branches within a quadrant anastomose with each other; consequently, a blockage in a retinal artery causes loss of vision in the corresponding part of the visual field. The only exception to this end-arterial pattern is in the vicinity of the optic disc. Here, the posterior ciliary arteries enter the eye near the disc (Fig. 42.30), and their rami not only supply the adjacent choroid, but also form an anastomotic circle in the sclera around the head of the optic nerve. Branches from this ring join the pial arteries of the nerve, and small cilioretinal arteries from any arteries in this region may enter the eye and contribute to the retinal vasculature, possibly resulting in the preservation of visual function following central retinal artery occlusion. Similarly, small retinociliary veins may sometimes also be present.

The structure of retinal blood vessels resembles that of vessels elsewhere, except that the internal elastic lamina is absent from the arteries, and muscle cells may appear in their adventitia. Capillaries are nonfenestrated and endothelial cells are joined by complex tight junctions, fulfilling the requirements of a functional blood-retinal barrier. Within the optic nerve, the central artery is innervated by both branches of the autonomic nervous system; this innervation does not extend to the vessels in the retina. The cholinergic parasympathetic supply is derived mainly from the pterygopalatine ganglion and is vasodilatory (Ch. 32).

Fig. 42.29 A tangential section of the retina at the level of the inner nuclear layer, highlighting the dense network of capillaries.

The adrenergic postganglionic sympathetic supply originates in the superior cervical ganglion and travels via a plexus around the internal carotid and ophthalmic arteries; it is unclear whether it elicits vasoconstriction or dilation (Bergua et al 2013).

## RETINOPETAL INNERVATION OF THE RETINA

The human retina receives input from the brain via retinopetal axons within the optic nerve. Although there are only a small number of these (usually less than 10 ), they branch extensively within the retina. They emerge at the optic disc, course through the nerve fibre layer, and give off orthogonal branches that ramify in the inner plexiform layer (Repérant et al 2006). One set of such axons arises from perikarya in the posterior hypothalamus and uses histamine as a neurotransmitter, while other, serotoninergic, fibres arise from cell bodies in the dorsal raphe. These neurones are not specialized for vision; they project to many other targets in the central nervous system besides the retina, forming components of an ascending arousal system (Gastinger et al 2006). Histamine is released during the day in the inner plexiform layer, but it activates receptors located on cone pedicles, horizontal cell perikarya and ON bipolar cell dendrites via volume transmission. Histamine decreases the absolute sensitivity of the retina to light and, possibly, modulates retinal blood flow (Vila et al 2012).

## OPTIC NERVE HEAD

The axons of more than a million retinal ganglion cells converge the optic nerve head and leave the eye by penetrating the sclera to form the optic nerve. The optic nerve head represents that part of the optic nerve lying within the bulb of the eye. Since all retinal neural elements, apart from ganglion cell axons, are absent from this region, it is insensitive to light and forms the 'blind spot'.

Histologically, the optic nerve head can be divided into three zones (Fig. 42.31): the prelaminar (the anterior part terminating at the vitreous), laminar (formed by the lamina cribrosa) and postlaminar (continuous with the retrobulbar optic nerve). The surface view of the optic nerve head, usually seen with an ophthalmoscope, is referred to as the optic disc (Fig. 42.20).

## Prelaminar zone

The inner surface of the optic nerve head is covered by an astroglial membrane (of Elschnig) that is continuous with the internal limiting membrane of the retina. At the centre of the disc, the layer of astrocytes thickens into a central meniscus (of Kuhnt). Retinal ganglion cells turn into the optic nerve head accompanied by astrocytes, which gradually increase in number posteriorly, eventually forming a sieve-like structure, the glial lamina cribrosa, through which the nerve fibres pass as separate fasciculi. At the perimeter of the optic nerve head, a collar of astrocytes several cells thick (the intermediary tissue of Kuhnt) separates the optic nerve from the terminating outer layers of the retina. This layer continues posteriorly and forms a barrier between the optic nerve head and the choroid (the border tissue of Jacoby).

Fig. 42.30 Vessels of the optic nerve head. The dotted areas represent the principal glial membranes. Arteries are represented on the right and veins on the left.

Fig. 42.31 The optic nerve head, showing the distribution of collagenous tissue (grey) and neuroglial nuclei (solid blue circles). Key: 1a, retinal internal limiting membrane; 1b, inner limiting membrane of Elschnig; 2, central meniscus of Kuhnt; 3, spur of collagenous tissue separating the anterior lamina cribrosa (6) from the choroid; 4, border tissue of Jacoby; 5, intermediary tissue of Kuhnt; 7, posterior lamina cribrosa. Abbreviations: Ar, arachnoid mater; Du, dura mater; GI.C, astrocytes and oligodendrocytes among the fibres in their fascicles; GI.M, astroglial membrane; Pia, pia mater; Sep, connective tissue septa from pia mater. The dotted lines represent the borders of the lamina cribrosa. (With permission from Anderson DR, Hoyt W 1969 Ultrastructure of intraorbital portion of human and monkey optic nerve. Arch Ophthalmol 82:506-30.)

## Laminar zone

The lamina cribrosa is composed of discrete trabeculae of collagenous and elastic connective tissue, which extend from the sclera to form a meshwork through which the optic nerve fascicles and central retinal vessels pass. Each trabecula has a lining of astrocytes that are continuous with those of the glial lamina cribrosa.

## Postlaminar zone

The optic nerve thickens in the postlaminar zone as its axons become myelinated. The reflected sclera, and the dura mater with which it is continuous, invest the nerve together with the other two meningeal sheaths, the arachnoid and pia mater. Fine fibrous septa penetrate the optic nerve from the pia mater, dividing it into 300-400 fascicles, giving pial blood vessels access to the nerve.

## Optic disc

As it is visible by ophthalmoscopy (see Fig. 42.20A), the disc is a region of great clinical importance. Oedema of the disc (papilloedema) may be the first sign of raised intracranial pressure, which is transmitted into the subarachnoid space around the optic nerve. The disc is also sensitive to the raised intraocular pressure that occurs in glaucoma and shows characteristic structural changes due to retinal ganglion cell loss.

The optic disc is superomedial to the posterior pole of the eye, and so lies away from the visual axis. It is round or oval, and usually approximately 1.6 mm in transverse diameter and 1.8 mm in vertical diameter; its appearance is very variable. In light-skinned subjects, the
general retinal hue is a bright terracotta-red, with which the pale pink of the disc contrasts sharply; its central part is usually even paler and may be light grey. These differences are due in part to the degree of vascularization of the two regions, which is much less at the optic disc, and also to the total absence of choroidal or retinal pigment cells. In subjects with strongly melanized skins, both retina and disc are darker. The optic disc rarely projects sufficiently to justify the term papilla, although it is usually a little elevated on its lateral side, where the papillomacular nerve fibres turn into the optic nerve (see Fig. 42.27). There is usually a slight depression where the retinal vessels traverse its centre.

## Vascular supply

The blood supply to the three regions of the optic nerve head differs (see Fig. 42.30). The prelaminar region is supplied mainly by branches of the central retinal artery. Branches from the short posterior ciliary arteries form an often incomplete circle within the sclera around the optic nerve head (circle of Zinn/Haller); centripetal branches from this structure supply the laminar region of the optic nerve head. The short posterior ciliary arteries may also give off centripetal branches directly to supply the lamina, and branches that pass anteriorly to augment the prelaminar blood supply. In the postlaminar region, arteries from the prepapillary choroid and circle of Zinn pass retrogradely as pial vessels, providing centripetal branches that supply the optic nerve. More posteriorly, the optic nerve receives pial arterioles directly from the posterior ciliary arteries. The central retinal artery may also contribute some centrifugal branches in this region.

The central retinal vein drains the optic nerve head at all levels; other drainage pathways are minor.

Fig. 42.32 A simplification of the visual pathway, showing the spatial arrangement of neurones and their fibres in relation to the quadrants of the retinae and visual fields. The proportions at various levels are not exactly to scale. In particular, the macula is exaggerated in size in the visual fields and retinae. In each quadrant of the visual field, and in the parts of the visual pathway subserving it, two shades of each respective colour are used; the paler shade denotes the peripheral field and the darker shade denotes the macular part of the quadrant. From the lateral geniculate nucleus onwards, these two shades are both made more saturated to denote intermixture of neurones from both retinae, the palest shade being reserved for parts of the visual pathway concerned with monocular vision.

## VISUAL PATHWAY

The visual pathway includes the interneurones of the retina, retinal ganglion cells whose axons project via the optic nerve, chiasma, and optic tract to the lateral geniculate nucleus and neurones within the lateral geniculate nucleus that project via the optic radiation to the primary visual cortex (Fig. 42.32). It is important to remember that visual space is optically inverted by the crystalline lens when relating the spatial location of neurones within the visual pathway to corresponding visual field locations.

Retinal ganglion cell axons, on entering the optic nerve, initially maintain their relative retinal positions, with axons from the fovea forming a lateral wedge. Such retinotopic mapping is largely maintained within the optic nerve, although nearer the chiasma the foveal axons take a position in the centre of the optic nerve while temporal fibres occupy their previous lateral location.

At the chiasma, a substantial rearrangement of axons occurs. Most axons arising from the nasal half of a line bisecting the fovea within each retina cross in the chiasma to enter the contralateral optic tract. Fibres from the temporal hemi-retinas do not generally cross in the chiasma. Classically, the axons within the optic tract were thought to maintain their topographic order and each tract was assumed to be a single representation of the contralateral hemifield. However, it is now clear that axons are mainly organized in functional groupings, larger superficial axons representing the magnocellular pathway and deeper axons originating from midget ganglion cells and forming the parvocellular pathway. This arrangement is chronotopic, the deeper axons
developing earlier during axogenesis than the more superficial ones (Reese 1993).

The lateral geniculate nucleus contains cells arranged in six laminae (see Fig. 23.6). Each layer receives input from either crossed or uncrossed projections from the retina. The contralateral nasal retina projects to laminae 1, 4 and 6 , whereas the ipsilateral temporal retina projects to layers 2, 3 and 5. Layers 1 and 2 contain magnocellular cells; the remaining layers are parvocellular. Unlike in the optic tract, there is a point-to-point retinotopic arrangement between corresponding points in each hemi-retina so that the contralateral visual field is mapped within each lateral geniculate nucleus.

Axons from the lateral geniculate nucleus run in the retrolenticular part of the internal capsule and form the optic radiation. This curves dorsomedially to the primary visual cortex, located around and within the depths of the calcarine sulcus in the occipital lobe (also known as the striate cortex, Brodmann area 17, or V1 (see Fig. 25.19). The visual cortex also has a strict retinotopic organization. Fibres representing the lower half of the visual field sweep superiorly to reach the visual cortex above the calcarine sulcus, while those representing the upper half of the visual field curve inferiorly into the temporal lobe (Meyer's loop) before reaching the visual cortex below the calcarine sulcus. The periphery of the retina is represented anteriorly within the visual cortex, and the macula is represented towards the posterior pole, occupying a disproportionately large area that reflects the high number of foveal retinal ganglion cells that subserve the enhanced acuity of this region.

The primary visual cortex is connected to prestriate and other cortical regions where further processing of visual stimuli occurs.

Almost all of the retinal ganglion cell axons (90\%) terminate on neurones in the lateral geniculate nucleus. Extrageniculate axons (10\%) leave the optic tract before the lateral geniculate nucleus; they may leave the optic chiasma dorsally and project to the suprachiasmatic nucleus of the hypothalamus, while others branch off the optic tract at the superior brachium and project to the superior colliculus, pretectal areas and inferior pulvinar.

## VISUAL FIELD DEFECTS

The basis for clinical assessment of damage to the visual pathway is an understanding of the retinotopic projections within the pathway. Moreover, plotting visual field loss frequently reveals the approximate location of the causative lesion and sometimes its nature. Since retinal lesions can be visualized with an ophthalmoscope, field testing might appear to be redundant for such defects, but visual field measurement is still helpful in assessing the extent of the damage and may be the key factor in confirming a diagnosis. Field defects in glaucoma, for example, that occur as a consequence of damage to the nerve fibre bundles at the optic nerve head, may be detectable ophthalmoscopically, but confirmation of the diagnosis frequently depends on field assessment. Early defects consist of one or more areas of paracentral focal field loss, progressing to arcuate scotomas. The shape of the defect corresponds to the anatomical arrangement of ganglion cell axons.

As far as the location of lesions central to the retina is concerned, deficits in the vision of one eye are usually attributable to optic nerve lesions. Lesions of the optic chiasma, involving crossing nerve fibres, produce a bilateral field loss, as exemplified by a pituitary adenoma. The tumour expands upwards from the pituitary fossa, compressing the inferior midline of the chiasma, and eventually produces bitemporal hemianopia, starting with an early loss in the upper temporal quadrants (bitemporal quadrantanopia).

Since the optic tract contains contralateral nasal and ipsilateral temporal retinal projections, damage to it will cause a homonymous contralateral visual field loss. Although complete disruption of the tract results in contralateral hemianopia, the incomplete spatial segregation of axons within the tract, described above, makes the field losses following smaller lesions harder to interpret. They do, however, show substantial incongruity (dissimilar defects in the fields of the two eyes) and often specific functional deficits, consistent with the partial segregation of functionally distinct axons from the two half-retinas (Reese 1993). Incongruity is most marked in defects of the optic tract, less obvious in optic radiation defects, and usually absent in cortically induced field defects, thus providing an additional clue in assessing location of the cause.

Lesions of the optic radiations are usually unilateral, and commonly vascular in origin. Field defects therefore develop abruptly, in contrast to the slow progression of defects associated with tumours, and the resulting hemifield loss follows the general rule that visual field defects central to the chiasma are on the opposite side to the lesion. Little or no incongruity is seen in visual cortical lesions, but they commonly display the phenomenon of macular sparing, the central $5-10^{\circ}$ field being retained in an otherwise hemianopic defect.

# Surgery of the skull base 

Juan C Fernandez-Miranda

Accessing the skull base for removal of complex lesions is a formidable challenge. Accurate knowledge of the intricate osseous, dural and neurovascular anatomy is mandatory to perform a successful cranial base operation and restore or preserve normal structure and function (Rhoton 2007). Lesions involving the base of the skull are most commonly tumours, which are classified based on their origin: meningiomas (from meninges), adenomas (from pituitary gland cells), schwannomas (from nerve sheath cells), chondrosarcomas (from cartilage cells), chordomas (from notochordal remnant cells), esthesioneuroblastomas (from olfactory cells), and others.

Surgical approaches to the skull base can be divided, based on the location of the targeted lesion, into three broad categories: anterior, middle and posterior skull base approaches. Certain lesions may involve more than one cranial fossa, and therefore the cranial base approach for that particular lesion will have to be either extended or complemented with another approach. As a general principle, skull base approaches are designed to minimize trauma to neural tissues and at the same time maximize access to the target lesion, following the rule of 'maximal bone removal for minimal brain manipulation'. They comprise several sequential steps: tailored skin incision; dissection of muscular and fascial planes; completion of craniotomy, osteotomies, and drilling of osseous structures as needed; extradural approach to the target lesion, when feasible, to avoid unnecessary brain retraction and facilitate early devascularization of the lesion; intradural approach, if needed, with microsurgical dissection of arachnoid cisterns, preservation of neurovascular structures, and lesion removal; meticulous haemostasis; dural closure (primary or using grafts or patches); osseous reconstruction; and fascial, muscular and skin re-approximation.

## Approaches to the anterior cranial base

The anterior cranial fossa is formed by the frontal, ethmoid and sphenoid bones, and supports the frontal lobes of the cerebral hemispheres (see Figs 16.5, 28.2). There are two main transcranial approaches to this region: anterior (or bifrontal transbasal) and anterolateral (or frontolateral). The bifrontal transbasal approach consists of a bifrontal craniotomy and provides direct access to the cribriform plate region and planum sphenoidale bilaterally; the approach can be augmented with orbital osteotomies that provide a more basal trajectory and hence minimize brain retraction, and it can also include nasal bone and medial orbital wall osteotomies to enhance access the sinonasal cavity, sphenoid sinus and clival region (Feiz-Erfan et al 2008).

The frontolateral approach entails an ipsilateral craniotomy that provides access to the anterior skull base, anterior clinoid process, optic canal and basal cisterns from a lateral to medial trajectory. It can be augmented with an orbital osteotomy to facilitate a more inferior to superior trajectory for lesions that expand in the vertical axis (Jane et al 1982, Delashaw et al 1993).

## Approaches to the middle cranial fossa

The middle cranial fossa is formed by the sphenoid and temporal bones, and supports the temporal lobes of the cerebral hemispheres (see Figs 16.5, 28.2). Lesions that are exclusively located in this fossa can be accessed with a temporal craniotomy, which can be supplemented with zygomatic osteotomies to improve the inferior to superior working corridor or to facilitate access to the infratemporal fossa by further mobilization of the temporalis muscle. Lesions, however, often occupy anterior and middle cranial fossas, for which a frontotemporal or pterional craniotomy with optional orbitozygomatic osteotomies is typically required. This craniotomy allows for an extradural middle fossa approach, which consists of peeling away the meningeal layer of dura of the middle fossa to expose the superior orbital fissure, lateral wall of the cavernous sinus, $\mathrm{V}_{2}, \mathrm{~V}_{3}$, Meckel's cave and anterior petrous apex
(Alaywan and Sindou 1990). This middle fossa approach can also be used to open the roof of the internal acoustic canal, and can be extended to the posterior fossa by drilling out the petrous apex that forms the posteromedial triangle of the middle fossa (Kawase et al 1985).

## Approaches to the posterior cranial fossa

The posterior cranial fossa is formed by the sphenoid, temporal and occipital bones, and contains the cerebellum, pons and medulla oblongata (see Figs 16.5, 28.2). The suboccipital approach is a posterior midline approach that consists of removing part of the occipital squama and posterior arch of foramen magnum to provide access to bilateral cerebellar hemispheres and the posterior cervicomedullary junction. The retrosigmoid craniectomy is a posterolateral approach that entails completion of a bony window located just behind the sigmoid sinus and just inferior to the transverse sinus; it provides access to the cerebellopontine angle, as typically required for vestibular schwanommas and for microvascular decompression for treatment of trigeminal neuralgia or hemifacial spasm. Both suboccipital and retrosigmoid approaches can be augmented with full removal of the posterior arch of the foramen magnum, including part of the occipital condyle. This modification is called the far lateral transcondylar approach, and is used to obtain a better trajectory into the ventral aspect of the lower clival region and cervicomedullary junction (Wen et al 1997). The mastoid bone can also be drilled in front of the sigmoid sinus to complete a presigmoid approach, which provides access to the labyrinthine, middle ear cavity, facial nerve canal and jugular foramen; opening of the presigmoid dura will directly expose the cerebellopontine angle, providing a more direct route into the ventral aspect of the posterior fossa and clival region (presigmoid retrolabyrinthine approach), while additional drilling of the labyrinthine will facilitate opening of the internal acoustic canal (presigmoid translabyrinthine approach). Large lesions extending from the posterior to the middle fossa, typically petroclival meningiomas, can be removed using a combined presigmoid approach and temporal craniotomy with transection of the tentorium (presigmoid transtentorial approach) (Gross et al 2012).

The implementation of many of the skull base approaches detailed here has evolved in recent decades, facilitated by the introduction of modern technology (surgical microscope, microinstrumentation, highspeed drill) and the pioneer efforts of surgical innovators. The latest of all innovations in skull base surgery has been the introduction of the endoscopic endonasal approach, which uses the nostrils as natural corridors to access the ventral aspect of the skull base. The trans-sphenoidal route, described more than a century ago to access the sella turcica, can now be greatly expanded thanks to the development of endoscopic visualization and specifically designed instrumentation. Accessing the skull base from the endonasal route is ideal for lesions located in the midline skull base because it facilitates a direct approach to the target without any external incision, craniotomy or manipulation of the brain (Kassam et al 2005a, Kassam et al 2005b). The endoscopic endonasal approach has become an excellent alternative choice for tumours such as large pituitary adenomas (Paluzzi et al 2014, Koutourousiou et al 2013a), craniopharyngiomas (Koutourousiou et al 2013b, FernandezMiranda et al 2012), midline anterior and posterior skull base meningiomas (Koutourousiou et al 2014, Fernandez-Miranda et al 2014a), chordomas and chondrosarcomas (Fernandez-Miranda et al 2014b, Koutourousiou et al 2012), given their favourable anatomical location. The main disadvantage of the endonasal approach in comparison to the open approaches is the more difficult skull base reconstruction, currently solved largely with the use of pedicled vascularized flaps harvested locally from the nasal septum.

As a result, contemporary skull base surgery selectively uses and occasionally combines transcranial and endonasal approaches to the anterior, middle and posterior skull base for effective treatment.

# The role of three-dimensional imaging in facial anatomical assessment 

Vikram Sharma, Bruce Richard

'What is a face, really? Its own photo? Its make-up? Or is it a face as painted by such or such painter? ... Doesn't everyone look at himself in his own particular way? Deformations simply do not exist.'

Pablo Picasso
(1881-1973)
The face is central to human social interaction and it has been shown that symmetrical or 'average' faces are perceived as more attractive (Baudouin and Tiberghien 2004). Even a minor visual difference can result in a reduced level of perceived attractiveness in general society and is associated with several negative factors concerning appearance, symmetry and facial expression. This, in turn, adversely affects the quality of life of a person and has been shown to trouble patients with cleft lip and palate - the most common craniofacial deformity, which is present in 1 in 700 live births (Mossey et al 2009). This can cause emotional distress in childhood and adolescence due to teasing from peers, and subsequent unhappiness with facial appearance into adulthood, despite optimal surgical correction (Marcusson 2001).

Embryologically, all tissues of the head and face of vertebrates are derived from the three primary germ layers (endoderm, mesoderm, ectoderm) and a fourth layer, the neural crest. This was originally described by Wilhelm His in 1868 as the intermediate cord or 'cord in between' the neural plate and non-neural ectoderm, in studies on chick embryos (His 1868). Through migration and proliferation of neural crest cells in the branchial arches at the fourth week of gestation, five facial primordia develop around the primitive mouth or stomatodeum. They include: a single frontonasal prominence (forming forehead, middle of the nose, philtrum and primary palate) and paired mandibular and maxillary prominences (lower jaw, middle and lower face, lateral border of lips and secondary palate) (Baynam et al 2013). The proportions and position of various facial features continue to develop slowly from week eight until birth, with the rapidly enlarging brain causing the ears to rise, the eyes to move medially and the forehead to become more apparent.

While human facial anatomy can be thought of as largely similar, with features such as eyes, nose and mouth approximately in the same location, there are enough minor differences in proportions, size and position both between and within different ethnicities to make us all unique individuals. When considering more local features such as inner and outer canthi, columella or philtrum, there can be considerable differences in addition to the effects of congenital malformations or acquired deformities due to trauma and surgical repair. The human face is a complex three-dimensional (3D) structure and capturing an image in its entirety with true-to-life precision is likely to be challenging for both human and machine. A systematic review of methods of facial aesthetic assessment in a specific patient population and a rating system for outcome comparison have been described previously (Sharma et al 2012).

Traditionally, direct facial measurements have been taken using manual anthropometry utilizing rulers, tape measures and callipers, as pioneered by Leslie Farkas, the father of modern craniofacial anthropometry (Farkas 1994). Although low-cost and straightforward, this method requires a high degree of cooperation from the subject and is very labour-intensive if used to assess hundreds of individuals to obtain representative normative data. Digital photography, by contrast, provides a rapid and permanent image that can be rapidly processed and archived on to computer databases. Drawbacks of using a twodimensional (2D) modality to derive accurate facial measurements include differential positioning of subjects despite a standardization protocol and perspective projection distortion, where a 3D object is unavoidably misrepresented by an attempted projection on to a 2D plane.

Capturing a face in three dimensions is mainly achieved by laser scanning or stereo photogrammetric devices that can capture many thousands of points in an instant. The former method, however, can
take up to 20 seconds for image acquisition and is reliant on the subject keeping absolutely still to prevent motion artefact, such as ridges, on the captured image (Bush and Antonyshyn 1996). Three-dimensional photogrammetry is a software-driven approach utilizing multiple digital cameras set at different angles to acquire the facial image rapidly, in little over a millisecond. Time-of-flight technology, which measures the time taken for emitted light from an illumination unit to reach an object and travel back to a detector, has been used by a range of scanners to make very precise measurements of distance. This technology uses either optical shutter technology or modulated light of various wavelengths to create a 3D image of the actual face and head (Zhang and Lu 2013). It allows human faces to be recognized and tracked in real time in a manner that is both rapid and efficient from a computational standpoint. Furthermore, it is not affected by differences in facial orientation, illumination or features that might obscure part of the face (Meers and Ward 2009). The nasal tip is the optimal facial landmark to use, as it is easily detected by an observer, has a central position on the face and is not usually obscured by hair or spectacles (Gorodnichy 2002). Furthermore, it has certain geometric and illumination characteristics from which spherical intersection profiles are utilized to obtain a 'faceprint' that is then normalized. However, there are currently no clinical validation studies for facial assessment using time-of-flight 3D cameras.

Gross anatomical landmarks on the face are captured by a series of relatively simple measurements. Delineation of finer features that will allow a detailed surface-based analysis of facial shape, however, requires a significantly larger number of densely arranged surface points corresponding to quasi-landmarks. Tens of thousands of these points can be derived from as few as 22 facial landmarks. A technique known as thinplate spline warping will then pull these points on the surface of the face together, similar to a thin sheet of rubber, into a precise alignment. The number of landmarks chosen is a balance, as too few will cause the face scan to be registered poorly and too many will result in significant noise that causes the placement of soft-tissue landmarks on a virtual image to be inaccurate (Hammond et al 2004).

A further advantage of digital anthropometry is that it obviates the need for a general anaesthetic in a young, uncooperative patient and/ or exposure to a high-dose of ionizing radiation as would be the case if using either computed tomography or computed axial tomography (CT/CAT scanning). CAT is not the best modality for evaluation of soft tissue structures, and current protocols tend to be focused on the brain, with facial imaging omitted or distorted by an endotracheal tube (Littlefield et al 2004). Examples of a widely used, commercially available, 3D surface imaging modality and system based on active stereo photogrammetry are shown in Figure 4.2.1 and Video 4.2.1.

Three-dimensional facial imaging has significant potential for accurately capturing the human face in health and disease. Current research aims to validate protocols that hopefully will translate into routine clinical practice. The FaceBase Consortium from the National Institute of Dental and Craniofacial Research (National Institutes of Health, USA) is utilizing 3D active stereo photogrammetry in concert with highthroughput DNA sequencing of thousands of individuals to map accurately how normal facial features are influenced by genetic determinants (Hochheiser et al 2011). This will be further aided by its Ontology of Craniofacial Development and Malformation project, which aims to gather wide-ranging, specifically annotated data from multiple sources, ranging from the level of genes to gross anatomical structures and clinical images, to unravel causal mechanisms of craniofacial deformity (Brinkley et al 2013).

Genome-wide association studies (GWAS) describe case-control studies where single nucleotide polymorphisms (SNPs), the most common form of genetic variation in the genome, are compared between affected and non-affected individuals for a particular disease. Two independent GWAS projects have implicated the gene PAX3 (paired box 3 ) in craniofacial development and facial morphology (particularly

Fig. 4.2.1 An example of a commercially available three-dimensional active stereo photogrammetry device (3dMD) in use at a national imaging research project ('Meln3D') at the London Science Museum, UK (2012). (Courtesy of Ms Kelly Duncan (3dMD).)
the positioning of the nasion) in stratified European populations. This gene encodes a transcription factor expressed by neural crest cells, important in vertebrate facial patterning. Mutations of PAX3 are associated with Waardenburg syndrome, typified by telecanthus, a broad and high nasal root, deafness and pigmentation abnormalities of the hair, skin and eyes (Waardenburg 1951). Paternoster et al (2012) used 3D laser scanning to identify 22 landmarks in over 3000 individuals genotyped for nearly 300,000 SNPs and found an association between rs7559271 (located in an intronic region of PAX3) and nasion position.

Later, in a second and importantly independent GWAS, Liu et al (2012) identified five genetic loci (all at $p<5 \times 10^{-8}$ significance threshold) that are associated with face morphology, but with a small effect size. Again, SNPs associated with PAX3 were found to influence the position of the nasion. A candidate gene found at a second locus, TP63 (transformation related protein 63), is associated with orofacial clefting both in humans with heterozygous mutations and in null mice. Phenotyping in this study was performed using 3D magnetic resonance imaging (MRI) of nine facial landmarks of the upper face and midface but missed features of the lower face - a drawback easily obviated by the use of 3D stereo photogrammetry.

A GWAS of patients with cleft lip, with or without cleft palate, undertaken in 825 European and 1038 Asian ancestry case-parent trios, identified SNPs associated with two novel genes (MAFB - v-Maf avian musculoaponeurotic fibrosarcoma oncogene homolog B1 - and ABCA4 - ATP-binding cassette, sub-family A (ABC1), member 4), a known gene (IRF6 - interferon regulatory factor 6 , mutations of which cause Van der Woude's syndrome) and a known region (8q24, associated with non-syndromic cleft lip/palate) (Beaty et al 2010). Expression studies in mice using in situ hybridization of MAFB showed strong staining in the epithelium around palatal shelves and medial fusing palatal edges, as well as the oral epithelium, implicating a role for this gene in normal lip and palate development (see Ch. 36).

Characterizing a normal individual face as accurately as possible may facilitate genotype-phenotype correlation of diseases with specific facial features. It should also highlight more discrete facial characteristics that might be present as part of a craniofacial syndrome, but not immediately apparent to all but the most experienced dysmorphologist. Coordinated research efforts that combine molecular biology with advanced facial imaging will no doubt improve the accuracy of clinical diagnosis and lead to stratified medical practice that is better tailored to patient care.

## Acknowledgement

The authors wish to express their appreciation to Ms Kelly Duncan (3dMD) for the kind provision of images and video for this article.

## Anatomy of facial ageing

Bryan C Mendelson, Chin-Ho Wong

## Overview

The human face undergoes dramatic changes of appearance with ageing; these changes are so consistent and predictable that they reveal a person's age. In youth, the surface of the face is a continuous smooth structure on which only the major features - the eyes, nose and mouth - are identified. However, the surface changes with the ageing process and progressively reveals the internal structure. Ageing is not uniform across the face because the various functional regions age differently. Facial ageing takes place essentially around the eyes and mouth and over the neck.

Most ageing is seen on the anterior face, the face proper, where the specific facial features are located. The lateral aspect of the face is quite distinct from the anterior face, both functionally and structurally. The soft tissues on the lateral face change less because they are not actively involved with the underlying structures (temporalis, masseter, arch of zygoma and parotid gland), whose only function is mastication.

Ageing happens at all tissue levels; whether these changes develop primarily at one or more levels and lead to secondary changes at the other levels is not known, but their appearance is concurrent.

## Soft tissue organization of the face

Ageing of the face, and the extent of the changes involved, are consequences of its unique functions. These require mobility of the soft tissues that is not found elsewhere in the body and that necessitates major structural adaptations. In most regions of the face, there are conflicting structural requirements for mobility over support (fixation). Ultimately, the requirements for movement determine the need for areas of reduced fixation that contribute so much to the changes that we recognize as ageing.

The facial skeleton provides a foundation to which the overlying soft tissues are variably attached (Furnas 1989, Stuzin et al 1992). Having a strong facial skeleton is the single most important determinant in 'ageing well', meaning at a slower rate than average. The multiple bones of the facial skeleton have diverse embryonic origins; the most significant in ageing are the odontogenic bones (maxilla and mandible). The skeleton protects the receptor organs of the central nervous system, i.e. visual, olfactory and auditory receptors, in a series of cavities that are 'open' to the exterior, together with the expansile, mobile, oral cavity. With the exception of the ear, all the cavities are located on the front of the face and their presence contributes to ageing of the mid-cheek.

Musculoskeletal movement in the face is initiated only from the temporomandibular joint; the two major skeletal masticatory muscles (temporalis and masseter) are located beneath the deep fascia of the lateral face. The soft tissues overlying the lower third of the face are significantly impacted by this skeletal movement, as well as by the extensive movement of the subjacent neck.

The facial soft tissues have considerable capacity for movement. Active movement, a unique feature of facial anatomy, arises on the anterior face, primarily in relation to the orbital and oral cavities, as a result of the contraction of the sphincter muscles embedded in the soft tissues overlying the cavities. Movement around the orbit is modified by the forehead and glabellar musculature and by the orbital part of orbicularis oculi. The lip elevator and depressor muscles add to the lip movement around the oral sphincter. Movement on the lateral face is passive only, secondary to major tissue displacements extending from the anterior face, or to movement of the underlying mandible or neck.

The concentric layered structure of the face allows movement to take place. The driver of movement is the separate layer of superficial muscles, the so-called 'muscles of facial expression' (Ch. 30). These muscles are intimately attached to the overlying soft tissues and skin,
which they are programmed to move, and have minimal attachment to the underlying skeleton. A discontinuous glide plane layer beneath the muscle layer consists of spaces that allow movement of the overlying soft tissues.

The soft tissues of the face are stabilized in position by an extensive fibrous support system that is unique to the facial structure (Furnas 1989, Stuzin et al 1992). The system takes its fixation from attachment to the underlying skeleton and provides strong direct support to the dermis via its layered arrangement. Overlying the cavities, the support system is necessarily modified by the absence of bone for ligamentous fixation, which means that support over the orbital and oral cavities is indirect. The support of the specialized, very mobile, soft tissues that form the eyelids over the orbital cavity and the part of the cheek that overlies the extensive vestibule of the oral cavity, together with the soft tissue apertures forming the lid margins and the lips, is therefore structurally compromised. Bony rims provide the skeletal base for this indirect ligamentous attachment around the bony cavities. Focused areas of greater support, e.g. the canthal tendons, are found within the cavities. Further adaptations of the fibrous support system are necessary over the oral cavity because here the bony rim is not fixed and continuous, as it is in the orbital rim, but enlarges with jaw movement.

The combination of soft tissue movement over the orbital and oral cavities, along with the necessary reduction of ligamentous support to allow this movement, is the basis for the ageing of the soft tissue around the eye and around the mouth.

## Overview of facial ageing

The general pattern with ageing is a progressive loss of facial volume with increasing laxity and possibly expansion of the outer layers with descent. The smooth, taut surface of a full and uniformly rounded youthful face deteriorates with ageing to form a series of individual segments that are separated by surface grooves located where internal ligaments attach to the dermis, and that progress to form skin creases or wrinkles as the dermis weakens (Mendelson and Jacobson 2008).

The multiple structures of the face are interconnected at several levels. Changes in one structure will have an impact on the others and, in more advanced ageing, simultaneous changes in more than one component will produce a cumulative effect. The extent to which these changes are attributable primarily to ageing, e.g. whether laxity arises secondary to volume loss or from intrinsic weakening of ligament strength or is a combination of both effects, is not clear. The only certain primary change is a loss of anterior volume of the maxilla that is associated with the eruption of the secondary dentition.

## Details of tissue layers

## Tissue planes, sub-SMAS spaces and facial ageing

The facial soft tissues are organized in concentric tissue layers (Fig. 4.3.1). The superficial muscles are in the middle layer (layer three), although muscle is not present in all areas of the face. The layer is fibroaponeurotic where muscle is not present; hence the name, superficial musculo-aponeurotic system (SMAS) (Mitz and Peyronie 1976), (see Ch. 30). Functionally, this layer is related to the skin, via the connections of the retinacula cutis in the subcutaneous layer, rather than to the deeper structures. In an arrangement that resembles that of the structure of the scalp, the outer three layers of the face form a composite anatomical unit, whose quality of adherence varies according to the character of the SMAS in each area. The SMAS is muscular where movement happens (frontalis, orbital part of orbicularis oculi and platysma) and is also mobile, with a looser deep attachment as well as less tight subcutaneous connections; laxity develops in these areas with ageing

Fig. 4.3.1 The three-dimensional arrangement of the ligaments of the facial soft tissues. The ligaments take origin from the deep fascia and form septa-like boundaries in the temple. The main ligaments around the oral cavity extend through the superficial musculo-aponeurotic system (SMAS) and subcutaneous layers to the dermis. Key: a, zygomatic ligament; b, uppermost masseteric ligament; c, upper key masseteric ligament; d, lower key masseteric ligament; e, mandibular ligament.
(Rohrich and Pessa 2007). In contrast, the fibrous aponeurotic SMAS lacks intrinsic mobility and, as seen over the lateral face, is fixed directly to the underlying deep fascia, the parotid fascia, where it maintains a tight skin attachment (Furnas 1994).

The fourth layer, the sub-SMAS plane, is effectively a glide plane that allows movement of the composite flap independent of the deep fascia. This involves a discontinuous series of sub-SMAS spaces that are located above and lateral to the mobile oral cavity (Fig. 4.3.2) (Mendelson 2007).

The SMAS of the mid-cheek, i.e. the anterior face between the lower eye lid and lips, includes the orbital part of orbicularis oculi. It covers the large area overlying the vestibule of the oral cavity and its support is limited largely to its superolateral corner, where it is provided by the zygomatic ligament. This robust structure does not tend to weaken; however, distension of the cheek SMAS tends to develop.

The lower premasseteric space is the largest of the sub-SMAS spaces lateral to the oral cavity. It overlies the masseteric fascia above the mandibular rim, and prevents soft tissue drag from movement of the mouth that would restrict opening of the jaw. With ageing, weakness of the lower masseteric ligaments allows distension of its anterior and inferior boundaries and the roof formed by platysma, resulting in the formation of the jowl (Fig. 4.3.3) (Mendelson et al 2008). The buccal fat pad, when compact, adds to youthfully compact cheeks (see Fig. 30.18A). However, when there is weakness of the lower masseteric ligaments (normally holding platysma in close relation to the masseteric fascia), the buccal fat pad becomes more mobile, and it may descend into a more anterior location towards the corner of the mouth, adding to fullness of the labiomandibular fold.

## The facial skeleton and its ageing

The facial skeleton is not only the foundation of a person's individual appearance but also a key determinant of how that person ages, because the projection of the skeleton provides support for the overlying soft tissues. It is now known that the facial skeleton is not static and changes significantly with age. Accordingly, people who lack strong skeletal projection are prone to premature ageing because they have less 'in reserve' when ageing starts with the loss of skeletal volume and projection.

Fig. 4.3.2 Ligamentous arrangement of the lateral face. The structures of the lateral face reflect its masticatory function. From above, these structures are: temporalis fascia; arch of zygoma; masseter (largely overlain by the parotid and masseteric fasciae). The body of the zygoma separates the orbital and oral cavities. The prezygomatic space overlies the body of the zygoma, between the orbicularis retaining ligament around the orbit above and the zygomatic ligaments above the oral cavity. The platysma auricular fascia (PAF) on the surface of the parotid is a diffuse area of ligamentous fusion of the parotid capsule with the overlying superficial musculo-aponeurotic system (SMAS). The vertical line of ligaments in relation to the anterior edge of masseter provides support for the SMAS over the oral cavity. A series of premasseteric spaces overlie masseter, in the interval between the concave anterior border of the parotid gland (including its accessory lobe) and the line of masseteric ligaments. These spaces allow gliding movement of the composite soft tissues associated with the oral cavity and opening the jaw.

The most significant change is retrusion of the maxilla, which contributes directly to the loss of mid-cheek support and affects the inferior orbital rim, piriform and oral cavities, leading to 'sagging' of the soft tissues of the medial suborbital region (Fig. 4.3.4) (Pessa et al 1998, Shaw and Kahn 2007, Mendelson et al 2007).

The dimensions of the orbital aperture increase slightly but are significant in periorbital ageing. Recession of the inferolateral rim (by more than $10 \%$ ) causes the greatest alteration of orbital shape. The changes exhibit sexual dimorphism in that they are generally seen at a younger age in women (by middle age) compared to men. Thus, a small increase of transverse orbital width and aperture area happens earlier in women, and superomedial recession occurs later and to a greater extent in men (Kahn and Shaw 2008)

Soft tissue laxity of the lower face accompanies the reduction in size of the mandible. By middle age, there is a considerable reduction of the mandibular angle with shortening of the length of the mandibular body and its height; shortening of the height of the ramus occurs later (Pessa et al 2008, Shaw et al 2010).

## Retaining ligaments and ageing

A discontinuous vertical line of retaining ligaments separates the lateral face from the anterior face (see Fig. 4.3.2). The skeletal origin of the ligaments continues from the anterior end of the superior temporal line, down the lateral orbital rim to the body of the zygoma, and down the anterior border of masseter to the mandibular ligament. There is no evidence to suggest that weakening of the main ligaments, where movement is least (specifically, the stronger zygomatic ligaments on the zygoma), contributes to facial laxity, although the lower premasseteric ligaments do weaken in their effect.

The attachment of ligaments to the dermis is responsible for the cutaneous grooves that appear with ageing, e.g. the palpebromalar, nasojugal, mid-cheek and nasolabial grooves, whereas the surface bulges, e.g. the malar mound, nasolabial fold and jowl, overlie the spaces between the ligaments (Mendelson et al 2002). The part of the orbicularis retaining ligament that crosses the central inferior orbital rim is distensible and allows the orbital fat to bulge as 'fat bags' (Fig. 4.3.5), whereas shrinkage of the maxilla at the medial end of the orbital rim pulls the ligaments (tear trough ligament). Below, as the medial maxillary ligament is pulled back into the face, the depth of the nasolabial groove is increased.

Fig. 4.3.3 The origin of the jowl with ageing and the changing relations of platysma and masseter. A, In youth, platysma, which forms the roof of the lower premasseteric space, is in close and tight relation to the anterior border of masseter via the vertical line of ligaments. B, The jowl develops as a result of the developing laxity and distension of the septa-like lower masseteric ligaments. This allows enlargement of the lower premasseteric space, specifically of its anterior and lower boundaries and the adjacent roof. This ligamentous weakness allows the inferior extent of the buccal fat pad to prolapse, which contributes fullness to the labiomandibular fold above the jowl.

## Subcutaneous layer and ageing

The fat and fibrous components in the subcutaneous tissue are not uniform but arranged in discrete compartments that are delimited by septal boundaries related to the dermal extensions of the retaining ligaments (Rohrich and Pessa 2008). In youth, the boundaries between compartments are not discernible on the surface: with ageing, a series of contour changes occur in which concavities separate the convexities that reflect these compartments. Specific names have been given to certain areas of the subcutaneous layer at sites where the subcutaneous fat becomes more prominent, e.g. the malar fat pad and nasolabial fat. The changes of the subcutaneous compartments become most apparent
with advanced ageing due to a combination of their descent from fixed structures - in particular, the bony rims (superior and inferior orbital and mandibular border), as well as changes in the volume distribution within the compartments, with increasing inferior fullness (Gierloff et al 2012). These changes have been attributed to a number of causes, including selective atrophy or hypertrophy and attenuation of the retaining ligaments that allow fat redistribution within compartments. It is now believed that fat descent with ageing is less than it appears; distinct compartmentalization by the retaining ligaments holds the fat in its relative positions, and it is likely that the reduction of internal volumes deep to the subcutaneous fat accounts for the major part of the appearance of descent, especially of the mid-cheek (Lambros 2007).

Fig. 4.3.4 Changes of the facial skeleton with ageing. The most significant amount of bony change is the mid-cheek skeleton. Shrinkage of the anterior projection of the maxilla predominates, along with a reduction of the bony rim of the piriform aperture. The inferior orbital rim, where it is formed by the zygoma, becomes more rounded, whereas the medial rim, where it is formed by the maxilla, loses its thickness. The anterior surface of the mandible becomes more hollowed and prejowl hollowing appears.

Fig. 4.3.5 Linking of ageing changes through the tissue layers. A, Youthful. B, Aged. C-D, Sections taken through the mid-cheek. The changes in the bony orbital rim (inferolateral resorption and blunting of the sharply defined rim) are associated with changes of the attached septum orbitale, which undergoes attenuation and distension. The bulging retroseptal orbital fat associated with this weakening extends over the rim until constrained by the stronger orbicularis retaining ligament. The orbicularis retaining ligament is attached several millimetres outside the rim. The medial third, named the tear trough (TT) ligament, is drawn posteriorly by the reduction of anterior maxillary volume. The bony change, expressed through the ligament, accentuates the depth of the nasojugal groove. Maxillary resorption around the piriform aperture accentuates the depth of the nasolabial groove and crease as it causes the medial maxillary ligament (MML) to become similarly indrawn. In the same way, the lateral maxillary ligament (LML), between zygomaticus minor and levator labii superioris, draws the tissues deeper. By contrast the major ligaments that provide support for the soft tissues over the oral cavity (zygomatic, upper masseteric and mandibular) are essentially unchanged with ageing. The ageing weakness of the cheek soft tissues occurs within the SMAS and the thicker subcutaneous layer.

## Sequence of appearance of facial ageing

While ageing is traditionally associated with the presence of wrinkles, in reality the earliest onset of ageing probably results from a reduction of skeletal volume. Facial skeletal changes are inevitable and appear early because they are a consequence of the reshaping of the maxilla and mandible that follows the eruption of the secondary dentition. While the changes of the deeper skeleton are not immediately apparent, they contribute to a cascade of secondary changes due to the interlinking of the tissue layers. Accordingly, the deep fat, preperiosteal and buccal, also has less projection; with the reduction of tissue tone, there is an effect on the ligaments, producing early laxity and sag.

The reduction of skeletal support places strain on the ligamentous boundaries, such as the orbicularis retaining ligament and the lateral canthal tendon, and this leads to the onset of weakening and eventual lengthening, and bulging of the deeper structures they previously supported.

Dynamic expression lines develop with muscle contraction: while not present in youth, they increase with the reduction of ligamentous tissue resistance. With age, muscle contraction produces an increased amplitude of tissue displacement, e.g. movement of the eyebrows and cheeks when they are elevated from a sagged position results in the frontalis lines of the forehead and periorbital crow's feet lines, respectively. As the quality of the dermis deteriorates, the lines deepen, especially perioral wrinkles.

Small reductions of facial volume, whether of bone or fat (deeper supraperiosteal fat, as well as subcutaneous fat), contribute to loss of tone in the composite outer layers and laxity of the finer ligaments. Tissue laxity that is initially latent is revealed under the influence of gravity. It becomes apparent with the head up and is exacerbated when
leaning forwards; its visibility is decreased when recumbent. Changes to the quality of the subcutaneous layer appear with more advanced ageing. The changes described above are endogenous. Dermal changes reflect the long-term effect of environmental damage more and are exaggerated by tissue laxity.

Most clinical disorders of the back present as low back pain with or without associated lower limb pain, weakness or numbness, and so, historically, most attention has been paid to the anatomy of the lower (lumbosacral) back. In this Section, the term 'back' will include the whole of the posterior aspect of the trunk and of the neck. The whole of this region has great clinical importance but its anatomy has often been neglected. Recent understanding of the detailed topography of the bony and soft tissue elements of the lower back owes much to the work of Bogduk (2005).

The soft tissues of the back of the trunk and neck include the skin and subcutaneous fat, the underlying fascial layers and the musculature The deep, 'true' or epaxial muscles lie within compartments in their own fascial 'skeleton'. The bony framework to which the muscles and fasciae attach includes elements of the axial skeleton, i.e. the vertebral column and occiput, elements of the pectoral and pelvic girdles, and the ribs. The occiput is described below, the scapula on page 801, the ribs on page 934 and the pelvis on page 1339.

## SKIN

The skin of the back of the trunk is thick and highly protective, but has low discriminatory sensation. The superficial fascia is thick and fatty in most areas of the back. Its attachment to the deeper fascial layers is strong in the midline, especially in the neck, but becomes weaker more laterally. The skin of the back of the neck is thicker than that of the front of the neck, but thinner than that of the back of the trunk. The quantity, texture and distribution of hair vary with sex, race and the individual, though well-defined hair tracts have been delineated (Fig. 43.1).

Lines of skin tension run horizontally in the cervical and lumbosacral regions but form segments of two adjacent circles in the thoracic region (Fig. 43.2).

## CUTANEOUS INNERVATION AND DERMATOMES

The skin of the back of the neck and trunk is innervated by the dorsal (posterior primary) rami of the spinal nerves (see Fig. 45.10 and pp. 768-769, where dorsal rami are covered in detail). In the cervical and upper thoracic regions (down to T6) skin is supplied by the medial branches of these rami, while in the lower thoracic, lumbar and sacral regions it is supplied by the lateral branches. The total area supplied by these dorsal rami is shown in Figure 45.12. The spinal nerves involved include C2-C5, T2-L3, S2-S4 and Co1. The pattern of their dermatomes is shown in Figure 43.3. There is about half a segment of overlap between these cutaneous 'strips'; the strips supplied by the dorsal rami do not correspond exactly to those served by ventral rami, and differ slightly in both width and position.

## CUTANEOUS VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The skin of the back of the trunk receives its arterial blood supply mainly from musculocutaneous branches of posterior intercostal, lumbar and lateral sacral arteries (Fig. 43.4), which all accompany the cutaneous branches of their respective dorsal rami. In addition, there is a supply from the dominant vascular pedicles of the superficial (extrinsic) back muscles. The skin over the scapula is supplied by branches of the suprascapular, dorsal scapular and subscapular arteries. The skin of the back of the neck is supplied mainly from the occipital and deep cervical arteries. The superficial cervical or transverse cervical artery supplies the skin of the lower part of the back of the neck (Cormack and Lamberty 1994).

Veins drain the skin of the back of the neck into tributaries of the occipital and deep cervical veins. The skin of the back of the trunk drains into the azygos system, via tributaries of the posterior intercostal and lumbar veins.

Lymph from the skin of the back of the neck drains into occipital, lateral deep cervical and axillary nodes (Fig. 43.5). From the back of the trunk, drainage is to the posterior (subscapular) axillary nodes and to the lateral superficial inguinal nodes.

## FASCIAL LAYERS

The main fascial layers in the axial and paraxial regions of the trunk and neck are the thoracolumbar fascia, the deep cervical fascia and the prevertebral, endothoracic, retroperitoneal and posterior parts of the pelvic fasciae (the latter four layers collectively form the continuous prevertebral plane). Other important structures with fascial components are the ligamentum nuchae and the aponeurosis of erector spinae (see below).

## THORACOLUMBAR FASCIA

The thoracolumbar (lumbodorsal) fascia covers the deep muscles of the back and the trunk. Above, it passes anterior to serratus posterior superior and is continuous with the superficial lamina of the deep cervical fascia on the back of the neck. In the thoracic region, the thoracolumbar fascia provides a thin fibrous covering for the extensor muscles of the vertebral column and separates them from the muscles connecting the vertebral column to the upper extremity. Medially, it is attached to the spines of the thoracic vertebrae, and laterally to the angles of the ribs. In the lumbar region, the thoracolumbar fascia is in three layers (Fig. 43.6; see Fig. 62.1). The posterior layer is attached to the spines of the lumbar and sacral vertebrae and to the supraspinous ligaments. The middle layer is attached medially to the tips of the lumbar transverse processes and the intertransverse ligaments, below to the iliac crest, and above to the lower border of the twelfth rib and the lumbocostal ligament. The anterior layer covers quadratus lumborum and is attached medially to the anterior surfaces of the lumbar transverse processes behind the lateral part of psoas major; below, it is attached to the iliolumbar ligament and the adjoining part of the iliac crest; above, it forms the lateral arcuate ligament. The posterior and middle layers unite to form a tough raphe at the lateral margin of erector spinae, and at the lateral border of quadratus lumborum they are joined by the anterior layer to form the aponeurotic origin of transversus abdominis. At sacral levels, the posterior layer is attached to the posterior superior iliac spine and posterior iliac crest, and fuses with the underlying erector spinae aponeurosis. Bogduk (2005) describes two laminae in the posterior layer at lumbar levels, with varying orientation of the constituent collagen fibres relating to the biomechanical function of the fascia. The posterior and middle layers of the thoracolumbar fascia and the vertebral column together form an osteofascial compartment that encloses the erector spinae muscle group.

The attachments of the fascia, especially those that assure continuity with the abdominal wall musculature, putatively give it an important role in lifting, though the exact details of this role remain controversial. The fascia may also play an important role in load transfer between the trunk and the limbs: its tension is affected by the actions of latissimus dorsi, gluteus maximus and the hamstrings. Additionally, the thoracolumbar fascia contains nociceptive nerve endings that may be responsible for some forms of back pain. Other mechanisms related to the

Fig. 43.3 Dermatomes on the dorsal surface of the body. The small diagram shows the regular arrangement of dermatomes in the upper and lower limbs of the embryo. Maps of dermatome distribution are useful in clinical neurology as a guide to identify the location of pathology in patients with peripheral sensory deficits, but it is important to remember that they are approximations (see Ch. 15). (Adapted with permission from Moffat DB 1993 Lecture Notes on Anatomy, 2nd edn. Oxford: Blackwell Scientific.)
thoracolumbar fasciae that have been implicated as a possible source of back pain include tissue deformation due to injury or immobility, resulting in impaired proprioceptive signalling and possibly an increase in pain sensitivity, and increased sensitivity of the thoracolumbar fascia in conditions involving other tissues innervated by the same spinal nerve (Willard et al 2012).

## DEEP CERVICAL FASCIA

The investing layer of the deep cervical fascia forms the deep fascia of the posterior aspect of the neck (see Fig. 29.4A). It attaches in the midline to the external occipital protuberance, the ligamentum nuchae and the spine of the seventh cervical vertebra, and splits to enclose trapezius on each side. Inferiorly, the posterior part of the investing layer attaches with trapezius to the spine and acromion of the scapula.

## BONES

## OCCIPITAL BONE

The occipital bone forms much of the back and base of the cranium (Fig. 43.7). It is trapezoid and internally concave, and encloses the foramen magnum. It has four parts: basilar (basioccipital), which is the quadrilateral part in front of the foramen magnum; squamous, which is the expanded plate posterosuperior to the foramen; and two lateral (condylar or exoccipital), one on each side of the foramen magnum. The latter is anteromedian and wider behind, with an anteroposterior diameter greater than its transverse diameter.

Fig. 43.4 Areas of cutaneous arterial supply on the dorsum of the trunk. (Redrawn with permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps. Edinburgh: Churchill Livingstone.)

The occipital bone provides attachment for a number of the muscles of the neck and upper part of the back (longus capitis; recti capitis anterior, lateralis, posterior major and minor; superior oblique; semispinalis capitis; splenius capitis; occipitofrontalis; trapezius; sternocleidomastoid), and articulates with the first cervical vertebra at the atlanto-occipital joints.

## Squamous part

The squamous part is an expanded plate posterosuperior to the foramen magnum, convex externally and concave internally. On its external surface, the external occipital protuberance lies midway between its summit and the foramen magnum. On each side, two curved lines extend laterally from this protuberance. The upper one, faintly marked and often almost imperceptible, is the highest nuchal line, and the lower one is the superior nuchal line. The epicranial aponeurosis is attached to the medial part of the highest nuchal line. The median external occipital crest is often faint; it descends from the external occipital protuberance to the foramen magnum. On each side, an inferior nuchal line spreads laterally from the midpoint of the crest.

The internal surface of the squamous part is divided into four deep fossae by an irregular internal occipital protuberance and by ridged sagittal and horizontal extensions from the protuberance. The two superior fossae are triangular and adapted to the occipital poles of the cerebral hemispheres; the inferior fossae are quadrilateral and shaped to

Fig. 43.5 Cutaneous lymphatics on the dorsum of the trunk. (With permission from Romanes GJ (ed) 1964 Cunningham's Textbook of Anatomy, 10th edn. London: Oxford University Press.)
accommodate the cerebellar hemispheres. A wide groove with raised banks, the superior sagittal sulcus, ascends from the protuberance to the superior angle of the squamous part. The posterior part of the falx cerebri is attached to the margins of the sulcus. A prominent internal occipital crest descends from the protuberance and bifurcates near the foramen magnum, and provides an attachment for the falx cerebelli. The occipital sinus, sometimes double, lies in this attachment. A small vermian fossa may exist at the lower end of the internal occipital crest; when present, it is occupied by part of the inferior cerebellar vermis. On each side, a wide sulcus for the transverse sinus extends laterally from the internal occipital protuberance; the tentorium cerebelli is attached to the margins of these sulci. The right sulcus is usually larger than the left, and passes into the sulcus for the superior sagittal sinus, whereas the left usually receives the straight sinus. The position of the confluence of the sinuses is indicated by a depression on one side of the protuberance.

The position of the fetal posterior fontanelle coincides with the junction between the superior angle of the squamous part of the occipital bone and the occipital angle of the parietal bone on either side. The lateral angles of the squamous part are marked internally by the ends of the transverse sulci and project between the parietal and temporal bones. The lambdoid borders extend from superior to lateral angles and are serrated for articulation with the occipital borders of the parietal bones at the lambdoid suture. The mastoid borders extend from the lateral angles to the jugular processes, articulating with the mastoid parts of the temporal bones. A variety of sutural bones (ossicles) may occur at or near the lambda, e.g. the 'interparietal' (Inca bone or ossicle of Goethe).

Muscle attachments The occipital part of occipitofrontalis is attached to the lateral part of the highest nuchal line (see Fig. 43.7C). Trapezius attaches to the medial third of the superior nuchal line and to the external occipital protuberance. Sternocleidomastoid attaches to the lateral half of the superior nuchal line, with splenius capitis just below the lateral third of that line. Semispinalis capitis is attached to

the medial part of the area between the superior and inferior nuchal lines; obliquus capitis superior attaches to the lateral part of this area. Rectus capitis posterior major attaches to the lateral part of the inferior nuchal line and to the bone immediately below, and rectus capitis posterior minor attaches to the medial part of the inferior nuchal line and to the bone between that line and the foramen magnum.

## Basilar part

The basilar part extends anterosuperiorly from the foramen magnum. In young skulls, it presents a rough and uneven surface where it is joined to the body of the sphenoid by a growth cartilage (sphenooccipital synchondrosis). This plate has fully ossified by the twenty-fifth year, at which time the occipital and sphenoid bones are fused.

The inferior surface bears a small pharyngeal tubercle, about 1 cm in front of the foramen magnum, which gives attachment to the fibrous pharyngeal raphe. A small depression immediately anterior to the occipital condyle may occasionally be replaced by a small precondylar tubercle. The anterior atlanto-occipital membrane is attached to the anterior margin of the foramen magnum.

The superior surface has the form of a broad groove that slopes upwards and forwards from the foramen magnum, directly into the basilar part of the sphenoid; together, these bones form the clivus. The lateral margins articulate below with the petrous part of the temporal bones.

Muscle attachments Longus capitis is attached anterolateral to the pharyngeal tubercle, and rectus capitis anterior is attached to the small depression anterior to the occipital condyle (see Fig. 43.7C).

## Lateral (condylar) parts

The lateral (condylar) parts of the occipital bone flank the foramen magnum. On their inferior surfaces are occipital condyles for articulation with the superior articular facets of the atlas vertebra. The condyles are oval or reniform, their long axes converging anteromedially. The articular surfaces, wholly convex, face inferolaterally. They are occasionally constricted and a condyle may be in two parts (as may be the reciprocal surfaces of the atlas vertebra). A tubercle gives attachment to an alar ligament medial to each articular facet. The hypoglossal (anterior condylar) canal, which is situated anteriorly above each condyle,
starts internally a little above the anterolateral part of the foramen magnum and continues anterolaterally. It may be partly or wholly divided by a spicule of bone and transmits the hypoglossal nerve and a meningeal branch of the ascending pharyngeal artery. A condylar fossa, behind each condyle, fits the posterior margin of the superior facet of the atlas vertebra in full extension of the skull. Its floor is sometimes perforated by a posterior condylar canal for a sigmoid emissary vein. A quadrilateral plate, the jugular process, projects laterally from the posterior half of each condyle, and contributes the posterior part of the jugular foramen. The jugular process is indented in front by a jugular notch, which may be partly divided by a small intrajugular process projecting anterolaterally. A paramastoid process sometimes projects downwards and may even articulate with the transverse process of the atlas vertebra. Laterally, the jugular process has a rough quadrilateral or triangular area that is joined to the jugular surface of the temporal bone by cartilage; it begins to ossify at around 25 years.

An oval jugular tubercle overlies the hypoglossal canal on the superior surface of the occipital condyle. Its posterior part often bears a shallow furrow for the glossopharyngeal, vagus and accessory nerves. A deep groove containing the end of the sigmoid sinus curves anteromedially around a hook-shaped process to end at the jugular notch. The posterior condylar canal opens into the posterior cranial fossa near the medial end of the groove.

Muscle attachments Rectus capitis lateralis attaches to a roughened area on the inferior surface of the jugular process (see Fig. 43.7C).

## Ossification

Above the highest nuchal lines, the squamous part of the occipital bone is developed in a fibrous membrane and is ossified from two centres (one on each side) from about the second fetal month. This part of the occipital bone may remain separate as the interparietal bone. The remainder of the occipital bone is preformed in cartilage. Below the highest nuchal lines, the squamous part ossifies from two centres that appear in about the seventh week and soon unite. The two components of the squamous part unite in the third postnatal month but the line of their union is recognizable at birth. The remainder of the cartilage of the occipital bone is ossified from five centres: two each for the lateral parts appear during the eighth week, and one for the basilar part appears around the sixth week.

Fig. 43.8 The occipital bone of a newborn child, external surface. Parts of the chondrocranium that are still unossified are shown in blue.

At birth, the occipital bone consists of four separate parts (Fig. 43.8) - a basilar part, two lateral parts and a squamous part - all joined by cartilage and forming a ring around the foramen magnum. The squamous and lateral parts fuse together from the second year. The lateral parts fuse with the basilar part during years three and four, but fusion may be delayed until the seventh year.

## VERTEBRAL COLUMN

The vertebral column is a curved linkage of individual bones or vertebrae (Fig. 43.9). A continuous series of vertebral foramina runs through the articulated vertebrae posterior to their bodies, and collectively constitutes the vertebral canal, which transmits and protects the spinal cord and nerve roots, their coverings and vasculature (Fig. 43.10; see Fig. 45.2). A series of paired lateral intervertebral foramina transmits the spinal nerves and their associated vessels between adjacent vertebrae. The linkages between the vertebrae include cartilaginous interbody joints and paired synovial facet (zygapophysial) joints, together with a complex of ligaments and overlying muscles and fasciae. The muscles directly concerned with vertebral movements and attached to the column lie mainly posteriorly. Several large muscles producing major spinal movements lie distant from the column and without direct attachment to it, e.g. the anterolateral abdominal wall musculature. Movements of the column and the muscles concerned are described on page 745 . The column as a whole receives its vascular supply and innervation according to general anatomical principles, which are considered below.

Vertebral column morphology is influenced externally by mechanical and environmental factors and internally by genetic, metabolic and hormonal factors. These all affect its ability to react to the dynamic forces of everyday life, such as compression, traction and shear. These dynamic forces can vary in magnitude and are much influenced by occupation, locomotion and posture.

The adult vertebral column usually consists of 33 vertebral segments. Each presacral segment (except the first two cervical) is separated from its neighbour by a fibrocartilaginous intervertebral disc. The

Fig. 43.10 A sagittal magnetic resonance (MR) image of the cervical and upper thoracic (A) and lower thoracic and lumbar (B) spine.
and by transverse processes in the thoracic region (see Fig. 43.9C). Anteriorly, it is formed by the sides of vertebral bodies and intervertebral discs. The oval intervertebral foramina, behind the bodies and between the pedicles, are smallest at the cervical and upper thoracic levels, and increase progressively in size in the thoracic and upper lumbar regions. The lumbosacral (L5/S1) intervertebral foramen is the smallest of the lumbar foramina (Fig. 43.11). The foramina permit communication between the lumen of the vertebral canal and the paravertebral soft tissues (a 'paravertebral space' is sometimes described), which may be important in the spread of tumours and other pathological processes. The lateral aspects of the column have important anatomical relations, some of which vary considerably between the two sides.

## Posterior aspect

The posterior aspect of the column is formed by the posterior surfaces of the laminae and spinous processes, their associated ligaments, and the facet joints (see Fig. 43.9B). It is covered by the deep muscles of the back.

## Structural defects of the posterior bony elements

Deformity and bony deficiency may occur at several sites within the posterior elements. The laminae may be wholly or partially absent, or the spinous process alone may be affected, with no abnormalities in the overlying soft tissues (spina bifida occulta). A defect may occur in the bone that joins the superior and inferior articular processes (pars interarticularis): this condition is spondylolysis, and may be developmental or result from acute or fatigue fracture. If such defects are bilateral, the column becomes unstable at that level, and forward displacement of that part of the column above (cranial to) the defects may occur: this is spondylolisthesis (Fig. 43.12). Abnormality of the laminar bone, or degenerative changes in the facet joints, may also lead to similar displacement in the absence of pars defects. The deformity of the vertebral canal resulting from severe spondylolisthesis may lead to neural compression and subsequent damage (Fig. 43.13). Much more rarely, bony defects may occur elsewhere in the posterior elements, e.g. in the pedicles.

Detailed anatomical relations of all aspects of the vertebral column at the various levels are best appreciated by the study of horizontal (axial) sections and images (see Figs 43.47B and 43.72).

## Curvatures

## Embryonic and fetal curvatures

The embryonic body appears flexed. It has primary thoracic and pelvic curves, which are convex dorsally. Functional muscle development leads to the early appearance of secondary cervical and lumbar spinal curvatures in the sagittal plane. The cervical curvature appears at the end of the embryonic period, and reflects the development of function in the muscles responsible for head extension, an important component of the 'grasp reflex'. Radiographic examination of human fetuses aged from 8 to 23 weeks shows that the secondary cervical curvature is almost always present. Lumbar flattening has also been identified as early as the eighth week. Ultrasound investigations support the role of movement in the development of these curvatures. The early appearance of the secondary curves is probably accentuated by postnatal muscular and nervous system development at a time when the vertebral column is highly flexible and is capable of assuming almost any curvature.

## Neonatal curvatures

In the neonate, the vertebral column has no fixed curvatures. It is particularly flexible and, if dissected free from the body, it can easily be bent (flexed or extended) into a perfect half-circle. A slight sacral curvature can be seen, which develops as the sacral vertebrae ossify and fuse. The thoracic part of the column is the first to develop a relatively fixed curvature, which is concave anteriorly. An infant can usually support its head at 3 or 4 months, sit upright at around 9 months, and will commence walking between 12 and 15 months. These functional changes exert a major influence on the development of the secondary curvatures in the vertebral column and changes in the proportional size of the vertebrae, in particular in the lumbar region. The secondary lumbar curvature becomes important in maintaining the centre of gravity of the trunk over the legs when walking starts, and thus changes in body proportions exert a major influence on the subsequent shape of curvatures in the vertebral column.

## Adult curvatures

In adults, the cervical curve is a lordosis (convex forwards), and the least marked. It extends from the atlas to the second thoracic vertebra, with its apex between the fourth and fifth cervical vertebrae. Sexual dimorphism has been described in the cervical curvatures. The thoracic curve is a kyphosis (convex dorsally). It extends between the second and the eleventh and twelfth thoracic vertebrae, and its apex lies between the sixth and ninth thoracic vertebrae. This curvature is caused by the

Fig. 43.11 A sagittal MR image of the lumbar spine showing the L5-S1 intervertebral foramen (neuroforamen) and a pathologically narrowed L4-5 intervertebral foramen (arrow). This narrowing, known as lumbar foraminal stenosis, results in leg pain in an L4 sensory distribution.

Fig. 43.12 A sagittal computed tomographic (CT) image of the lumbar spine showing the left side of an isthmic spondylolisthesis resulting from bilateral fractures of the pars interarticularis (arrow).

Fig. 43.13 (A) Sagittal and (B) axial MR images of a degenerative spondylolisthesis at L4-5. This condition is accompanied by massive superior articular facet hypertrophy and subsequent critical central and lateral recess stenosis (arrowheads).
increased posterior height of the thoracic vertebral bodies. The lumbar curve is also a lordosis. It has a greater magnitude in females and extends from the twelfth thoracic vertebra to the lumbosacral angle; there is an increased convexity of the last three segments as a result of the greater anterior height of the intervertebral discs and some posterior wedging of the vertebral bodies. Its apex is at the level of the third lumbar vertebra. The pelvic curve is concave anteroinferiorly and involves the sacrum and coccygeal vertebrae. It extends from the lumbosacral junction to the apex of the coccyx.

The presence of these curvatures means that the cross-sectional profile of the trunk changes with spinal level. The anteroposterior diameter of the thorax is much greater than that of the lower abdomen. In the normal vertebral column, there are well-marked curvatures in the sagittal plane and no lateral curvatures other than in the upper thoracic region, where there is often a slight lateral curvature, convex to the right in right-handed persons, and to the left in the left-handed. Compensatory lateral curvature may also develop to cope with pelvic obliquity, such as that imposed by inequality of leg length. The sagittal curvatures are present in the cervical, thoracic, lumbar and pelvic regions (see Fig. 43.9). These curvatures have developed with rounding of the thorax and pelvis as an adaptation to bipedal gait.

## Vertebral column in the elderly

In older people, age-related changes in the structure of bone lead to broadening and loss of height of the vertebral bodies. These changes are more severe in females. The bony changes in the vertebral column are accompanied by changes in the collagen content of the discs and by decline in the activity of the spinal muscles. This leads to progressive decline in vertebral column mobility, particularly in the lumbar spine. The development of a 'dowager's hump' in the mid-thoracic region in females, caused by age-related osteoporosis, increases the thoracic kyphosis and cervical lordosis. Overall, these changes in the vertebral column lead directly to loss of total height in the individual.

As discs desiccate, there is often a straightening of the cervical spine and development of subsequent cervical kyphosis. This, coupled with narrowing of the spinal canal, can lead to increased risk of neurological damage of the cervical spinal cord, in addition to pain.

In mid-lumbar vertebrae, the width of the body increases with age. In men there is a relative decrease of posterior to anterior body height, while in both sexes anterior height decreases relative to width. Twomey et al (1983) observed a reduction in bone density of lumbar vertebral bodies with age, principally as a result of a reduction in transverse trabeculae (more marked in females as a result of postmenopausal osteoporosis), which was associated with increased diameter and increasing concavity in their juxtadiscal surfaces (end-plates).

Other changes affect the vertebral bodies. Osteophytes (bony spurs) may form from the compact cortical bone on the anterior and lateral surfaces of the bodies. Although individual variations occur, these changes appear in most individuals from 20 years onwards. They are most common on the anterior aspect of the body and never involve the ring epiphysis. Osteophytic spurs are frequently asymptomatic but may result in diminished movements within the spine.

## Vascular supply and lymphatic drainage

## Arteries

The vertebral column, its contents and its associated soft tissues all receive their arterial supply from derivatives of dorsal branches of the embryonic intersegmental somatic arteries (see Fig. 13.13). The named artery concerned depends on the level of the column. These intersegmental vessels persist in the thoracic and lumbar regions as the posterior intercostal and lumbar arteries (Figs 43.14-43.16). In the cervical and sacral regions, longitudinal anastomoses between the intersegmental vessels persist as longitudinal vessels, which themselves give spinal branches to the vertebral column. In the neck, the postcostal anastomosis becomes most of the vertebral artery, while the post-transverse anastomosis forms most of the deep cervical artery (Figs 43.17-43.19). The ascending cervical artery and the lateral sacral artery are persistent parts of the precostal anastomosis.

In the thorax and abdomen, the primitive arterial pattern is retained by the paired branches of the descending aorta, which supply the vertebral column (Fig. 43.20A; see Fig. 43.14). On each side, the main trunk of the artery (posterior intercostal or lumbar) passes around the vertebral body, giving off primary periosteal and equatorial branches to the body, and then a major dorsal branch. The latter gives off a spinal branch that enters the intervertebral foramen, before itself supplying the facet joints, the posterior surfaces of the laminae and the overlying

Fig. 43.20 The arterial supply to the vertebrae and the contents of the vertebral canal. A, The branching pattern of the lumbar segmental arteries. B, Arterial anastomoses between postcentral branches of spinal arteries within the vertebral canal.
muscles and skin. There is free anastomosis between these dorsal articular and soft tissue branches, extending over several segments (Boelderl et al 2002, Crock and Yoshizawa 1976). At cervical and sacral levels, the longitudinally running arteries described above have direct spinal branches. The spinal branches are the main arteries of supply to all bony elements of the vertebrae and to the dura and epidural tissues, and also contribute to the supply of the spinal cord and nerve roots via radicular branches. As they enter the vertebral canal, the spinal arteries divide into postcentral, prelaminar and radicular branches. The postcentral branches, which are the main nutrient arteries to the vertebral bodies and to the periphery of the intervertebral discs, anastomose beneath the posterior longitudinal ligament with their fellows above and below, as well as across the midline (Fig. 43.20B). This anastomosis also supplies the anterior epidural tissues and dura. The majority of the vertebral arch, the posterior epidural tissues and dura, and the ligamentum flavum are supplied by the prelaminar branches and their anastomotic plexus on the posterior wall of the vertebral canal. (For further reading on the arterial supply and venous drainage of the vertebral column and spinal cord, see Crock (1996) and Parke et al (2011).)

## Veins

Veins of the vertebral column form intricate plexuses along the entire column, external and internal to the vertebral canal (Fig. 43.21) (Groen

Fig. 43.14 A vertical radiograph of a section through T6 of a specimen from a 6 -year-old child injected with barium sulphate. The intercostal arteries (IA) give rise to dorsal branches (DB) that provide spinal branches to the vertebral canal and posterior branches to the arch and dorsal musculature. The posterior central branches (PCB) are well shown as they send vessels into the vertebral body. Fine anterior central and anterior laminar and posterior laminar vessels can be seen. Note the neurocentral synchondrosis. (With permission from Parke WW, Bono CM, Garfin SR 2011 Applied anatomy of the spine. In: Herkowitz HN, Garfin SR, Eismont FJ, et al (eds) Rothman-Simeone The Spine, 6th edition. Saunders, Elsevier.)

Fig. 43.15 An anteroposterior arteriogram of the lower thoracic and upper lumbar vertebrae in a 6-year-old child injected with barium sulphate. The interlocking anastomotic pattern formed by the posterior central branches (PCB) and the manner in which four branches converge over the centre of the dorsum of the body of each vertebra are well shown. The arteria radicularis magna (Arm), which forms a major contribution to the anterior spinal artery of the cord, can be seen arising at L2. (With permission from Parke WW, Bono CM, Garfin SR 2011 Applied anatomy of the spine. In: Herkowitz HN, Garfin SR, Eismont FJ, et al (eds) Rothman-Simeone The Spine, 6th edition. Saunders, Elsevier.)

Fig. 43.16 A vertical radiograph of a section through a lumbar vertebra of a 6 -year-old child injected with barium sulphate. The vascularity of the lumbar vertebra may be regarded as the archetypal pattern from which other regions evolved variations. The segmental lumbar artery gives rise to numerous anterior central branches (ACB) that penetrate the cortical bone of the body. The spinal branch (SB) sends prominent posterior central branches (PCB) to the dorsum of the body, whereas the dorsal branch (DB) supplies the anterior (ALB) and posterior (PLB) laminar branches. Neural branches (NB) follow the nerve roots to the cord. In this section, the arteria radicularis magna is seen as a neural branch on the right side. Other abbreviations: IA, intercostal arteries; IB, intercostal branches. (With permission from Parke WW, Bono CM, Garfin SR 2011 Applied anatomy of the spine. In: Herkowitz HN, Garfin SR, Eismont FJ, et al (eds) Rothman-Simeone The Spine, 6th edition. Saunders, Elsevier.)

Saunders, Elsevier.)

Fig. 43.18 A vertical radiograph of a section through the fourth cervical vertebra of a 6 -year-old child injected with barium sulphate. The deep cervical artery (DC) provides the posterior laminar branches (PLB). Vertebral arteries show numerous anastomoses with other cervical arteries and send spinal branches (SB) that form posterior central branches (PCB) of the body and anterior laminar branches of the arch. Anterior central branches (ACB) may arise independently from the vertebral arteries (VA). (With permission from Parke WW, Bono CM, Garfin SR 2011 Applied anatomy of the spine. In: Herkowitz HN, Garfin SR, Eismont FJ, et al (eds) Rothman-Simeone The Spine, 6th edition. Saunders, Elsevier.)

Fig. 43.19 An arteriogram of the cervical and upper thoracic regions of the 6 -year-old spine seen in Figures 42.16 and 42.18. The vertebral artery (VA) and deep cervical branch (DC) of the costocervical trunk (CC) supply segmental branches to each vertebra. The costocervical artery also typically supplies T1 and T2, but in this case T2 receives a high intercostal (IC) branch on the left side. (With permission from Parke WW, Bono CM, Garfin SR 2011 Applied anatomy of the spine. In: Herkowitz HN, Garfin SR, Eismont FJ, et al (eds) Rothman-Simeone The Spine, 6th edition. Saunders, Elsevier.)

Fig. 43.21 The venous drainage of the vertebral column. Note that the basivertebral vein is shown beneath (i.e. anterior to) the posterior longitudinal ligament. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
et al 2004). Both groups are devoid of valves, anastomose freely with each other, and join the intervertebral veins. Interconnections are widely established between these plexuses and longitudinal veins early in fetal life. When development is complete, the plexuses drain into the caval and azygos/ascending lumbar systems via named veins that accompany the arteries described above.

The veins also communicate with cranial dural venous sinuses and with the deep veins of the neck and pelvis. The venous complexes associated with the vertebral column can dilate considerably, and can form alternative routes of venous return in patients with major venous obstruction in the neck, chest or abdomen. The absence of valves allows pathways for the wide and sometimes paradoxical spread of malignant disease and sepsis. Pressure changes in the body cavities are transmitted through these venous plexuses and thus to the cerebrospinal fluid, though the cord itself may be protected from such congestion by valves in the small veins that drain from the cord into the internal vertebral plexus.

## External vertebral venous plexuses

The external vertebral venous plexuses are anterior and posterior. They anastomose freely, and are most developed in the cervical region. Anterior external plexuses are anterior to the vertebral bodies, communicate with basivertebral and intervertebral veins, and receive tributaries from vertebral bodies. Posterior external plexuses lie posterior to the vertebral laminae and around spines and transverse and articular processes. They anastomose with the internal plexuses and join the vertebral, posterior intercostal and lumbar veins.

## Internal vertebral venous plexuses

The internal vertebral venous plexuses are embedded in epidural fat, supported by a network of collagenous fibres (Chaynes et al 1998). These thin-walled channels receive tributaries from the bones, red bone marrow and spinal cord. (For the venous drainage of the spinal cord, see p. 770 and Fig. 45.14.) They form a denser network than the external plexuses and are arranged vertically as four interconnecting longitudinal vessels: two anterior and two posterior.

The anterior internal plexuses are large plexiform veins on the posterior surfaces of the vertebral bodies and intervertebral discs. They flank the posterior longitudinal ligament, beneath which they are connected by transverse vessels into which the large basivertebral veins open. The posterior internal plexuses, on each side in front of the vertebral arches and ligamenta flava, anastomose with the posterior external plexuses via veins that pass through and between the ligaments. The internal plexuses interconnect by venous rings near each vertebra. Around the foramen magnum, they form a dense network connecting
with vertebral veins, occipital and sigmoid sinuses, the basilar plexus, the venous plexus of the hypoglossal canal and the condylar emissary veins.

## Basivertebral veins

The basivertebral veins are paired valveless veins that drain the pars spongiosa of the vertebral bodies into the internal and external vertebral venous plexuses. In each segment, they emerge horizontally from foramina in the vertebral bodies. Posteriorly, they drain into the transverse branches of the anterior internal vertebral plexuses. Anteriorly, they drain directly into the anterior external vertebral venous plexus. The basivertebral veins enlarge in advanced age.

## Intervertebral veins

Branches of the anterior internal plexuses drain into retrocorporal veins that join the posterior internal venous plexuses to form intervertebral veins. As their name suggests, these veins accompany the spinal nerves through intervertebral foramina; they drain in craniocaudal sequence into the vertebral, posterior intercostal, lumbar and lateral sacral veins. Upper posterior intercostal veins may drain into the caval system via brachiocephalic veins, whereas the lower intercostals drain into the azygos system. Lumbar veins are joined longitudinally in front of the transverse processes by the ascending lumbar veins, in which they may terminate. Alternatively, they may proceed around the vertebral bodies to drain into the inferior vena cava. Whether the basivertebral or intervertebral veins contain effective valves is uncertain but experimental evidence strongly suggests that their blood flow can be reversed (Batson 1957). This may explain how pelvic neoplasms, e.g. carcinoma of the prostate, may metastasize in vertebral bodies: the cells spread into the internal vertebral plexuses via their connections with the pelvic veins when blood flow is temporarily reversed by raised intra-abdominal pressure or postural alterations (Pearce 2006).

## Lymphatic drainage

Little is known in detail about the lymphatic drainage of the vertebral column and its associated soft tissues. In general, deep lymphatic vessels tend to follow the arteries. The cervical vertebral column drains to deep cervical nodes, the thoracic to (posterior) intercostal nodes, and the lumbar column to lateral aortic and retro-aortic nodes. The pelvic part of the column drains to lateral sacral and internal iliac nodes.

## Innervation

The innervation of the vertebral column and its associated soft tissues has been studied in greatest detail in the lumbar region (see Fig. 43.61). The account given here relies particularly on the work of Bogduk (2005), to whose textbook on the lumbosacral spine the interested reader is referred. See also the work of Groen et al (1990).

Innervation is derived from the spinal nerves where they branch, in and just beyond the intervertebral foramina. There is an input from the sympathetic system either via grey rami communicantes or directly from thoracic sympathetic ganglia. The branches of the spinal nerve concerned are the dorsal ramus and the recurrent meningeal or sinuvertebral nerves (usually more than one at each level) (see Fig. 45.7). The dorsal ramus branches to supply the facet joints, periosteum of the posterior bony elements, overlying muscles and skin. The exact origin and branching pattern of the sinuvertebral nerves is controversial, but they may be best considered as recurrent branches of the ventral rami. They receive the sympathetic input described above, then re-enter the intervertebral foramina to supply the structures that form the walls of the vertebral canal, the dura and epidural soft tissues. Their subsequent course is described on page 767 .

## VERTEBRAE: GENERAL FEATURES

A typical vertebra has a ventral body; a dorsal vertebral (neural) arch, extended by lever-like processes; and a vertebral foramen, which is occupied in life by the spinal cord, meninges and their vessels (Fig. 43.22).

Opposed surfaces of adjacent bodies are bound together by intervertebral discs of fibrocartilage. The complete column of bodies and discs forms the strong but flexible central axis of the body and supports the full weight of the head and trunk. It also transmits even greater forces generated by muscles attached to it directly or indirectly. The foramina form a vertebral canal for the spinal cord, and between adjoining neural arches, near their junctions with vertebral bodies, intervertebral foramina transmit mixed spinal nerves, smaller recurrent nerves, and blood and lymphatic vessels.

Key: 1, bone derived from anular epiphysis; 2, vertebral body - bone derived from centrum; 3, pedicle; 4, superior articular facet; 5, transverse process; 6 , spinous process; 7, vertebral body - bone derived from neural arch; 8 , vertebral foramen; 9, costal facet; 10, lamina.

Unossified cartilaginous area
Fig. 43.23 A median sagittal section through a lumbar vertebra. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The cylindroid vertebral body varies in size, shape and proportions in different regions of the vertebral column. Its superior and inferior (discal) surfaces vary in shape from approximately flat (but not parallel) to sellar, with a raised peripheral smooth zone, formed from an 'anular' epiphysial disc, within which the surface is rough. These differences in texture reflect variations in the early structure of intervertebral discs. In the horizontal plane, the profiles of most bodies are convex anteriorly, but concave posteriorly where they complete the vertebral foramen. Most sagittal profiles are concave anteriorly but flat posteriorly. Small vascular foramina appear on the front and sides, and posteriorly there are small arterial foramina and a large irregular orifice (sometimes double) for the exit of basivertebral veins (Fig. 43.23). The adult vertebral body is not coextensive with the developmental centrum but includes parts of the neural arch posterolaterally.

Viewed anteriorly, there is a cephalocaudal increase in vertebral body width from the second cervical to the third lumbar vertebra, which is associated with an increased load-bearing function. The increase is linear in the neck but not in the thoracic and lumbar regions. There is some variation in size of the last two lumbar bodies, but thereafter width diminishes rapidly to the coccygeal apex. In the two lowest lumbar vertebrae, there is an inverse relation between the areas of the upper and lower surfaces of the bodies and the size of the pedicles and transverse processes.

On each side, the vertebral arch has a vertically narrower ventral part - the pedicle - and a broader lamina dorsally. Paired transverse, superior and inferior articular processes project from their junctions. There is a median dorsal spinous process.

Pedicles are short, thick, rounded dorsal projections from the superior part of the body at the junction of its lateral and dorsal surfaces; the concavity formed by the curved superior border of the pedicle is
shallower than the inferior one (see Fig. 43.23). When vertebrae articulate by the intervertebral disc and facet joints, these adjacent vertebral notches contribute to an intervertebral foramen. The complete perimeter of an intervertebral foramen consists of the notches, the dorsolateral aspects of parts of adjacent vertebral bodies and the intervening disc, and the capsule of the synovial facet joint (see Fig. 43.25). The laminae are directly continuous with the pedicles. They are vertically flattened and curve dorsomedially.

Lateral to the spinous processes, vertebral grooves contain the deep dorsal muscles. At cervical and lumbar levels, these grooves are shallow and mainly formed by laminae. In the thoracic region, they are deeper, broader and formed by the laminae and transverse processes. The laminae are broad for the first thoracic vertebra and narrow for the second to seventh, then broaden again from the eighth to eleventh, but become narrow thereafter down to the third lumbar vertebra.

The spinous process (vertebral spine) projects dorsally and often caudally from the junction of the laminae. Spines vary considerably in size, shape and direction. They lie approximately in the median plane and project posteriorly, although in some individuals a minor deflection of the processes to one side may be seen. The spines act as levers for muscles that control posture and active movements (flexion/ extension, lateral flexion and rotation) of the vertebral column.

The paired superior and inferior articular processes (zygapophyses) arise from the vertebral arch at the pediculolaminar junctions. The superior processes project cranially, bearing dorsal facets that may also have a lateral or medial inclination, depending on level. Inferior processes run caudally with articular facets directed ventrally, again with a medial or lateral inclination that depends on vertebral level. Articular processes of adjoining vertebrae thus contribute to the synovial zygapophysial or facet joints, and form part of the posterior boundaries of the intervertebral foramina. These joints permit limited movement between vertebrae; mobility varies considerably with vertebral level.

Transverse processes project laterally from the pediculolaminar junctions as levers for muscles and ligaments, particularly those concerned in rotation and lateral flexion. In the cervical region, the transverse processes are anterior to the articular processes, lateral to the pedicles and between the intervertebral foramina. In the thoracic region, they are posterior to the pedicles, considerably behind those of the cervical and lumbar processes. In the lumbar region, the transverse processes are anterior to the articular processes, but posterior to the intervertebral foramina. There is considerable regional variation in the structure and length of the transverse processes. In the cervical region, the transverse process of the atlas is long and broad, which allows the rotator muscles maximum mechanical advantage. Breadth varies little from the second to the sixth cervical vertebra, but increases in the seventh. In thoracic vertebrae, the first is widest, and breadth decreases to the twelfth, where the transverse elements are usually vestigial. The transverse processes become broader in the upper three lumbar vertebrae, and diminish in the fourth and fifth. The transverse process of the fifth lumbar vertebra is the most robust. It arises directly from the body and pedicle to allow for force transmission to the pelvis through the iliolumbar ligament.

The thoracic transverse processes articulate with ribs, but at other levels the mature transverse process is a composite of a 'true' transverse process and an incorporated costal element. Costal elements develop as basic parts of neural arches in mammalian embryos, but become independent only as thoracic ribs. Elsewhere, they remain less developed and fuse with the 'transverse process' of descriptive anatomy (see Fig. 44.11).

Vertebrae are internally trabecular and have an external shell of compact bone perforated by vascular foramina (see Fig. 43.23). The shell is thin on the superior and inferior body surfaces but thicker in the arch and its processes. The trabecular interior contains red bone marrow and one or two large ventrodorsal canals that contain the basivertebral veins. Pubertal adolescents have higher trabecular bone density than prepubertal children.

Sexual dimorphism in vertebrae has received little attention, but Taylor and Twomey (1984) have described radiological differences in adolescent humans and have reported that female vertebral bodies have a lower ratio of width to depth. Vertebral body diameter has also been used as a basis for sex prediction in the analysis of skeletal material (MacLaughlin and Oldale 1992).

## Vertebral canal

The vertebral canal (Fig. 43.24) extends from the foramen magnum to the sacral hiatus, and follows the vertebral curves. In the cervical and lumbar regions, which exhibit free mobility, it is large and triangular, but in the thoracic region, where movement is less, it is small and
circular. These differences are matched by variations in the diameter of the spinal cord and its enlargements. In the lumbar region, the vertebral canal decreases gradually in size between L1 and L5, with a greater relative width in the female.

For clinical purposes, it is useful to consider the vertebral canal as having three zones. These are a central zone, between the medial margins of the facet joints, and two lateral zones, beneath the facet joints and entering the intervertebral foramina. Each lateral zone, which passes into and just beyond the intervertebral foramen, can be further subdivided into subarticular (lateral recess), foraminal and extraforaminal regions (MacNab and McCulloch 1990). The lateral zone thus described forms the canal of the spinal nerve (the radicular or 'root' canal). The central zone of the canal is a little narrower than the radiological interpedicular distance if the lateral recess is considered to be part of the radicular canal rather than part of the central zone.

## Spinal stenosis

Narrowing (stenosis) of the vertebral canal may occur at single or multiple spinal levels, and mainly affects the lumbar and cervical regions. Stenosis may affect the central canal and the 'root canals' either together or separately. There is a developmental form of the condition that mainly affects the central canal but more commonly the stenosis is degenerative, and results from intervertebral disc narrowing and osteoarthritic changes in the facet joints. This latter combination is more likely to narrow the intervertebral foramen and the 'root canal', even though the sectional profile of the vertebral canal in affected lumbar vertebrae typically changes from the shape of a bell to that of a trefoil. The lumbosacral intervertebral foramen, which is normally the smallest in the region, is particularly liable to such stenosis. Severe spinal stenosis may compress the spinal cord and compromise its arterial supply. More localized 'root canal' stenosis will present with the clinical features of spinal nerve compression, but without the tension signs that characterize the stretching of nerve roots over a prolapsed disc. Ischaemia of the nerves and roots may provoke more damage than the actual physical compression of the neural tissue.

## Intervertebral foramina

Intervertebral foramina are the principal routes of entry to and exit from the vertebral canal, and are closely related to the main intervertebral articulations. (Minor routes occur between the median, often partly fused, margins of the ligamenta flava.) The same general arrangement applies throughout the vertebral column, between the axis and sacrum, although there are some quantitative and structural regional variations. Because of their construction, contents and susceptibilities to multiple disorders, the intervertebral foramina are loci of great biomechanical, functional and clinical significance. The specializations cranial to the axis and at sacral levels are described with the individual bones and articulations.

The boundaries of a generalized intervertebral foramen (Fig. 43.25) are, anteriorly, from above downwards, the posterolateral aspect of the superior vertebral body, the posterolateral aspect of the intervertebral symphysis (including the disc), and a small (variable) posterolateral part of the body of the inferior vertebra; superiorly, the compact bone of the deep arched inferior vertebral notch of the vertebra above; inferiorly, the compact bone of the shallow superior vertebral notch of the vertebra below; and posteriorly, a part of the ventral aspect of the fibrous capsule of the facet synovial joint. Cervical intervertebral foramina are distinct in having superior and inferior vertebral notches of almost equal depth, which, in accord with the direction of the

pedicles, face anterolaterally. External to them, and oriented in the same direction, is a transverse process. The thoracic and lumbar intervertebral foramina face laterally and their transverse processes are posterior. In addition, the anteroinferior boundaries of the first to tenth thoracic foramina are formed by the articulations of the head of a rib and the capsules of double synovial joints (with the demifacets on adjacent vertebrae and the intra-articular ligament between the costocapitular ridge and the intervertebral symphysis). Lumbar foramina lie between the two principal lines of vertebral attachment of psoas major. The walls of each foramen are covered throughout by fibrous tissue, which is in turn periosteal (though the presence of a true periosteum lining the vertebral canal is controversial: Newell (1999)), perichondrial, anular and capsular. The more lateral parts of the foramina may be crossed at a variable level by narrow fibrous bands, the transforaminal ligaments (for detail of these ligaments, see Bogduk (2005)). The true foramen is the foraminal region of the canal of the spinal nerve (the radicular or 'root' canal). A foramen contains a segmental mixed spinal nerve and its sheaths, from two to four recurrent meningeal (sinuvertebral) nerves, variable numbers of spinal arteries, and plexiform venous connections between the internal and external vertebral venous plexuses. These structures, particularly the nerves, may be affected by trauma or one of the many disorders that may affect tissues bordering the foramen. In particular, nerve compression and irritation may be caused by intervertebral disc prolapse, or by bony entrapment as the size of the foramen decreases (Fig. 43.26). This decrease may result from facet joint osteoarthritis, osteophyte formation, disc degeneration and degenerative spondylolisthesis, all of which may lead to lateral or foraminal spinal stenosis.

## CERVICAL VERTEBRAE

The cervical vertebrae (Figs 43.27-43.28) are the smallest of the moveable vertebrae, and are characterized by a foramen in each transverse process. The first, second and seventh have special features and will be considered separately. The third, fourth and fifth cervical are almost identical, and the sixth, while typical in its general features, has minor distinguishing features.

## Typical cervical vertebra

A typical cervical vertebra (Figs 43.29-43.30) has a small, relatively broad vertebral body. The pedicles project posterolaterally and the longer laminae posteromedially, enclosing a large, roughly triangular vertebral foramen; the vertebral canal here accommodates the cervical

enlargement of the spinal cord. The pedicles attach midway between the discal surfaces of the vertebral body, so the superior and inferior vertebral notches are of similar depth. The laminae are thin and slightly curved, with a thin superior and slightly thicker inferior border. The spinous process ('spine') is short and bifid, with two tubercles that are often unequal in size. The junction between lamina and pedicle bulges laterally between the superior and inferior articular processes to form an articular pillar ('lateral mass') on each side. The transverse process is morphologically composite around the foramen transversarium. Its dorsal and ventral bars terminate laterally as corresponding tubercles. The tubercles are connected, lateral to the foramen, by the costal (or intertubercular) lamella; these three elements represent morphologically the capitellum, tubercle and neck of a cervical costal element (see Fig. 44.11). The attachment of the dorsal bar to the pediculolaminar junction represents the morphological transverse process, and the attachment of the ventral bar to the ventral body represents the capitellar process. In all but the seventh cervical vertebra, the foramen transversarium normally transmits the vertebral artery and vein and a branch from the cervicothoracic ganglion (vertebral nerve).

The vertebral body has a convex anterior surface. The discal margin gives attachment to the anterior longitudinal ligament. The posterior surface is flat or minimally concave, and its discal margins give attachment to the posterior longitudinal ligament. The central area displays several vascular foramina, of which two are commonly relatively larger. These are the basivertebral foramina, which transmit basivertebral veins to the anterior internal vertebral plexus. The superior discal surface is saddle-shaped, formed by flange-like lips, uncinate processes, which arise from most of the lateral circumference of the upper margin of the vertebral body. Uncinate processes are rudimentary at birth and are usually found on the third to seventh cervical vertebra in the adult. The uncinate processes on the vertebra below articulate with the corresponding bevelled surfaces on the inferior aspect of the vertebra above. Whether uncovertebral joints are synovial joints has proved controversial since their description by von Luschka in 1858; the demonstration of synoviocytes in the lateral joint capsule tissue of elderly uncovertebral joints suggests that they should be regarded as synovial joints (Hartman 2014) (see Fig. 43.59). The inferior discal surface is also concave; the concavity is produced mainly by a broad projection from the anterior margin, which partly overlaps the anterior surface of the intervertebral disc. The discal surfaces of cervical vertebrae are so shaped in order to restrict both lateral and anteroposterior gliding movements during articulation. The paired ligamenta flava extend from the superior border of each lamina below to the roughened inferior half of the anterior surfaces of the lamina above. The superior part of the anterior surface of each lamina is smooth, like the immediately adjacent surfaces of the pedicles, which are usually in direct contact with the dura mater and cervical root sheaths to which they may become loosely attached. The spinous process of the sixth cervical vertebra is larger and is often not bifid.

The superior articular facets, flat and ovoid, are directed superoposteriorly, whereas the corresponding inferior facets are directed mainly anteriorly, and lie nearer the coronal plane than the superior facets. In children, facet joint angle decreases until 10 years of age and remains unchanged thereafter (Kasai et al 1996). The dorsal rami of the cervical spinal nerves curve posteriorly, close to the anterolateral aspects of the lateral masses, and may actually lie in shallow grooves, especially on the third and fourth pairs. The dorsal root ganglion of each cervical spinal nerve lies between the superior and inferior vertebral notches of adjacent vertebrae. The large anterior ramus passes posterior to the vertebral artery, which lies on the concave upper surface of the costal lamella; the concavity of the lamellae increases from the fourth to the sixth vertebra. The fourth to sixth anterior tubercles are elongated and rough for muscle attachment. The sixth, the carotid tubercle of Chassaignac, is the longest (Fig. 43.31). The carotid artery can be forcibly compressed in the groove formed by the vertebral bodies and the larger anterior tubercles, especially the sixth. The posterior tubercles are rounded and more laterally placed than the anterior, and all but the sixth are also more caudal; the sixth is at about the same level as the anterior.

Muscle attachments The ligamentum nuchae and numerous deep extensors, including semispinalis thoracis and cervicis, multifidus, spinales and interspinales, are all attached to the spinous processes. Tendinous slips of scalenus anterior, longus capitis and longus colli are attached to the fourth to sixth anterior tubercles. Splenius, longissimus and iliocostalis cervicis, levator scapulae and scalenus posterior and medius are all attached to the posterior tubercles. Shallow anterolateral depressions on the anterior surface of the body lodge the vertical parts of the longus colli.

Fig. 43.32 The first cervical vertebra (atlas), superior aspect. Key: 1, anterior tubercle; 2, anterior arch; 3, outline of dens; 4, superior articular facet, on lateral mass (bipartite facet in this specimen); 5, outline of transverse ligament; 6, groove for vertebral artery and C1 (beneath bony overhang from lateral mass here); 7, posterior arch; 8, transverse process; 9, foramen transversarium; 10, vertebral foramen; 11, posterior tubercle.

Ossification Cervical vertebrae ossify according to the standard vertebral pattern described on page 756. Incomplete segmentation ('block vertebra') is common in the cervical spine and most commonly involves the axis and third cervical vertebra. There is a general caudal to cranial gradient in the growth of ossification centres and closure of synchondroses in the atlas and axis (Karwacki and Schneider 2012).

## Atlas, C1

The atlas, the first cervical vertebra (Fig. 43.32), supports the head. It is unique in that it fails to incorporate a centrum, whose expected position is occupied by the dens, a cranial protuberance from the axis. The atlas consists of two lateral masses connected by a short anterior and a longer posterior arch. The transverse ligament retains the dens against the anterior arch.

The transverse ligament divides the vertebral canal into two compartments (Fig. 43.33). The anterior third (approximately) of the canal is occupied by the dens. The posterior compartment is occupied by the spinal cord and its coverings, and the cord itself takes up about half of this space (i.e. the cord, like the dens, occupies one-third of the canal).

The anterior arch is slightly convex anteriorly, and carries a roughened anterior tubercle to which is attached the anterior longitudinal ligament (which is cylindrical at this level). Its upper and lower borders provide attachment for the anterior atlanto-occipital membrane and diverging lateral parts of the anterior longitudinal ligament. The posterior surface of the anterior arch carries a concave, almost circular, facet for the dens.

The lateral masses are ovoid, their long axes converging anteriorly. Each bears a kidney-shaped superior articular facet for the respective occipital condyle, which is sometimes completely divided into a larger anterior and a smaller posterior part (Lang 1986). The inferior articular facet of the lateral mass is almost circular and is flat or slightly concave. It is orientated more obliquely to the transverse plane than the superior facet, and faces more medially and very slightly backwards. On the medial surface of each lateral mass is a roughened area that bears vascular foramina and a tubercle for attachment of the transverse ligament. In adults, the distance between these tubercles is shorter than the transverse ligament itself, with a mean value of approximately 16 mm .

The posterior arch forms three-fifths of the circumference of the atlantal ring. The superior surface bears a wide groove for the vertebral artery and venous plexus immediately behind, and is variably overhung by the lateral mass; the first cervical nerve intervenes. The flange-like superior border gives attachment to the posterior atlanto-occipital membrane, and the flatter inferior border to the highest pair of ligamenta flava. The posterior tubercle is a rudimentary spinous process, roughened for attachment of the ligamentum nuchae.

The transverse processes are longer than those of all cervical vertebrae except the seventh (see Fig. 43.27). They act as strong levers for the muscles that make fine adjustments to keep the head balanced. Maximum atlantal width varies from 74 to 95 mm in males and 65 to 76 mm in females, and this affords a useful criterion for assessing sex in human remains. The apex of the transverse process, which is usually broad, flat and palpable between the mastoid process and ramus of the mandible, is homologous with the posterior tubercle of typical cervical

Fig. 43.34 Ossification in the vertebral column. A, The atlas. B, The axis. C, Lumbar vertebra.
vertebrae; the remaining part of the transverse process consists of the costal lamella. A small anterior tubercle is sometimes visible on the anterior aspect of the lateral mass. The costal lamella is sometimes deficient, which leaves the foramen transversarium open anteriorly.

Muscle attachments The superior oblique parts of longus colli are attached on each side of the anterior tubercle. The anterior surface of the lateral mass gives attachment to rectus capitis anterior. Rectus capitis posterior minor is attached just lateral to the posterior tubercle. Rectus capitis lateralis is attached to the transverse process superiorly, and obliquus capitis superior is located more posteriorly. Obliquus capitis inferior is attached laterally on the apex, below which are slips of levator scapulae, splenius cervicis and scalenus medius.

Ossification The atlas is commonly ossified from three centres (Fig. 43.34). One appears in each lateral mass at about the seventh week, gradually extending into the posterior arch where they unite between the third and fourth years, usually directly but occasionally through a separate centre. At birth, the anterior arch is fibrocartilaginous, and a separate centre appears about the end of the first year. This unites with the lateral masses between the sixth and eighth years, the lines of union extending across anterior parts of the superior articular facets. Occasionally, the anterior arch is formed by the extension and ultimate union of centres in the lateral masses and sometimes from two lateral centres in the arch itself.

The central part of the posterior arch may be absent and replaced by fibrous tissue. Frequently, bony spurs arise from the anterior and posterior margins of the groove for the vertebral artery. These are sometimes referred to as ponticles; they occasionally convert the groove into a foramen, the arcuate foramen or posticus ponticus (Fig. 43.35), which may increase the risk of injury to the vertebral artery in surgical procedures involving the C 1 arch (Klimo et al 2007). More often, the foramen is incomplete superiorly. Rarely, the atlas may be wholly or partially assimilated into (fused with) the occiput.

## Axis, C2

The axis, the second cervical vertebra (Figs 43.36-43.37), acts as an axle for rotation of the atlas and head around the strong dens (odontoid process), which projects cranially from the superior surface of the body.

The dens is conical in shape with a mean length of 15 mm in adults. It may be tilted a little, up to $14^{\circ}$, posteriorly or, less often, anteriorly on the body of the axis; it may also tilt laterally up to $10^{\circ}$. The posterior surface bears a broad groove for the transverse ligament, which is covered in cartilage. The apex is pointed, and from this point arises the apical ligament. The alar ligaments are attached to the somewhat flattened posterolateral surfaces above the groove for the transverse

ligament. The anterior surface bears an ovoid articular facet for the anterior arch of the atlas, and the surface is pitted by many vascular foramina, which are most numerous near the apex.

The body consists of less compact bone than the dens. It is composite, and consists of the partly fused centra of the atlas and axis, and a rudimentary disc (synchondrosis) between them, which usually remains detectable deep within the body of the axis throughout life. Large ovoid articular facets are present on either side of the dens at the junction of the body and neural arch; they are flat or slightly convex for articulation with the masses of the atlas. The facets lie in a plane anterior to the plane of the intercentral (Luschka) articulations, with which they are, in part, homologous. The somewhat triangular, downward-projecting anterior border gives attachment to the anterior longitudinal ligament. Posteriorly, the lower border receives the posterior longitudinal ligament and the membrana tectoria.

The pedicles are stout, and the superior surface carries part of the superior articular facet, which also projects laterally and downwards on to the transverse process. The anterolateral surface is deeply grooved by the vertebral artery, running beneath the thin lateral part of the inferior surface of the superior articular facet, which can become quite thin. The inferior surface of each pedicle bears a deep, smooth inferior interver-
tebral notch, in which the large root sheath of the third cervical nerve lies. The interarticular part of the pedicle is short and lies between the relatively small inferior posterior articular process (which is located at the pediculolaminar junction and bears a small anteriorly facing facet) and the superior articular surface.

The transverse process is pointed, projects inferiorly and laterally, and arises from the pediculolaminar junction and the lateral aspect of the interarticular area of the pedicle. The rounded tip is homologous with the posterior tubercle of a typical cervical vertebrae. The foramen transversarium is directed laterally as the vertebral artery turns abruptly laterally under the superior articular facet. Small anterior tubercles may be present near the junction of the costal lamella with the body.

The laminae are thick and give attachment to the ligamenta flava.
The spinous process is large, with a bifid tip and a broad base, which is concave inferiorly. The ligamentum nuchae is attached to the apical notch.

Muscle attachments The anterior surface of the body carries a deep depression on each side for the attachment of the vertical part of longus colli. Levator scapulae, scalenus medius and splenius cervicis are all attached to the tips of the transverse processes, and the intertransverse muscles are attached to their upper and lower surfaces. The lateral surfaces of the spinous process give origin to obliquus capitis inferior, and rectus posterior major is attached a little more posteriorly. The inferior concavity of the process receives semispinalis and spinalis cervicis, multifidus more deeply, and the interspinales near the apex.

Arterial supply Small branches arise mainly from the vertebral artery at the level of the intervertebral foramen for the third cervical nerve and form paired anterior and posterior longitudinal channels, branches of which enter the dens near the base and near the apex. The anterior channel also receives numerous twigs from nearby branches of the external carotid artery via branches to longus colli and the ligaments of the apex; hence avascular necrosis does not occur after fracture of the base of the dens.

Ossification The axis is ossified from five primary and two secondary centres (see Fig. 43.34). The vertebral arch has two primary centres and the centrum one, as in a typical vertebra. The former appear at about the seventh or eighth week, and that for the centrum at about the fourth or fifth month. The dens is largely ossified from bilateral centres, appearing at about the sixth month and joining before birth to form a conical mass, deeply cleft above by cartilage. This cuneiform cartilage forms the apex of the odontoid process. A centre appears in it which shows considerable individual variation in both time of appearance and time of fusion to the rest of the dens; it most often appears between five and eight years, but sometimes even later, fusing with the main mass in about the twelfth year. The cartilage was thought to be part of the cranial sclerotomal half of the first cervical segment or pro-atlas. It has also been suggested that the apical centre for the dens is itself derived from the pro-atlas, which may also contribute to lateral atlantal masses. The dens is separated from the body by a cartilaginous disc, the circumference of which ossifies while its centre remains cartilaginous until old age; possible rudiments of adjacent epiphyses of atlas and axis may occur in the disc. A thin epiphysial plate is formed inferior to the body around puberty.

Ossification may sometimes be incomplete. Thus the apical cuneiform centre may fail to fuse with the dens, or the dens itself may fail to fuse with the body, instead forming an os odontoideum (Fig. 43.38). This is likely to result from minor trauma in early childhood causing disruption of the developing dens rather than being a congenital failure (Klimo et al 2007). Interposition of the transverse ligament may prevent union of fractures through the base of the dens (Fig. 43.39). Hypoplasia of the dens is usually accompanied by atlanto-occipital assimilation and basilar invagination. Abnormalities of the dens are common, and can result in atlanto-axial subluxation. In some skeletal dysplasias there is abnormal ossification in which the dens ossifies separately and much later than the atlantal centrum. This is probably a result of abnormal mobility in the cartilaginous anlage, and normal ossification may be restored if motion is prevented by surgical fusion.

## Seventh cervical vertebra, vertebra prominens, C7

The seventh cervical vertebra, the vertebra prominens (Fig. 43.40), has a long spinous process that is visible at the lower end of the nuchal furrow. It ends in a prominent tubercle for the attachment of the ligamentum nuchae and the muscles detailed below. The thick and

Fig．43．38 A sagittal CT scan reconstructed image demonstrating an os odontoideum（arrow）．

Fig．43．39 A sagittal CT scan reconstructed image of a type II odontoid fracture（arrow）．These fractures involve the base of the dens and have a high non－union rate．

Fig. 43.40 The seventh cervical vertebra, superior aspect. Key: 1, body; 2, superior articular facet; 3, inferior articular process; 4, spinous process; 5 , uncinate process; 6, foramen transversarium (foramina are asymmetrical in this specimen); 7, transverse process; 8, pedicle; 9 , vertebral foramen; 10, lamina.
prominent transverse processes lie behind and lateral to the foramina transversaria. The latter transmit vertebral veins but not the vertebral artery, and each is often divided by a bony spicule. The costal lamella is relatively thin and may be partly deficient. It is grooved superiorly for the anterior ramus of the seventh cervical nerve and usually carries a small and inconspicuous anterior tubercle. The posterior tubercle is prominent. The suprapleural membrane is attached to the anterior border of the transverse process.

The costal lamella of the transverse process may be separate as a cervical rib. The foramina transversaria may be asymmetrical; sometimes one is absent if the costal lamella is undeveloped.

Muscle attachments Trapezius, spinalis capitis, semispinalis thoracis, multifidus and interspinales all attach to the tubercle of the spinous process. The anterior border of the transverse process receives the attachment of scalenus minimus (pleuralis), when present. The first pair of levatores costarum is attached to the transverse processes.

Ossification Ossific centres for the costal processes appear about the sixth month and join the body and transverse processes between the fifth and sixth years; they may remain separate and grow anterolaterally as cervical ribs. Separate ossific centres may, on occasion, also occur in the costal processes of the fourth to sixth cervical vertebrae.

## THORACIC VERTEBRAE

## Thoracic vertebrae in general

All thoracic vertebral bodies display lateral costal facets and all but the lowest two or three transverse processes also have facets (Fig. 43.41). The facets articulate with the head of the rib (costocapitular facet) and its tubercle (costotubercular facet), respectively.

The body is typically a waisted cylinder (Fig. 43.42) except where the vertebral foramen encroaches, and transverse and anteroposterior dimensions are almost equal. On each side there are two costal facets (which are really demifacets): the superior and usually larger pair at the upper border are anterior to the pedicles, while the inferior pair at the lower border are anterior to the vertebral notches. The vertebral foramen (see Fig. 43.22) is small and circular, so the pedicles do not diverge as they do in cervical vertebrae; the thoracic spinal cord is smaller and more circular than the cervical cord. The laminae are short, thick and broad, and overlap from above downwards. The spinous process slants downwards. The thin and almost flat superior articular processes project from the pediculolaminar junctions and face posteriorly and a little superolaterally. The inferior processes project down from the laminae and their facets are directed forwards and a little superomedially. The large, club-like transverse processes also project from the pediculolaminar junctions. Each passes posterolaterally and bears, near its tip, anterior oval facets for articulation with the tubercle of the corresponding rib.

Fig. 43.41 The first, ninth, tenth, eleventh and twelfth thoracic vertebrae, lateral aspect.

Fig. 43.42 The fourth thoracic vertebra, lateral aspect. Key: 1, body; 2, costocapitular demifacets; 3, superior articular facet; 4, transverse process; 5, costotubercular facet; 6, pedicle; 7, inferior articular process; 8 , spinous process.

The bodies of upper thoracic vertebrae gradually change from cervical to thoracic in type, and the lower change from thoracic to lumbar. The body of the first is typically cervical, its transverse diameter being almost twice the anteroposterior; the second retains a cervical shape but its two diameters differ less. The third body is the smallest, and has a convex anterior aspect unlike the flattened first and second thoracic vertebrae. The remaining bodies increase in size and, because of its increased anteroposterior diameter, the fourth is typically 'heart-shaped'. The fifth to eighth increase their anteroposterior dimension but change little transversely. These four, in transverse section, are asymmetrical, their left sides being flattened by pressure of the thoracic aorta. The rest increase more rapidly in all measurements, so that the body of the
twelfth resembles that of a typical lumbar vertebra. These modifications may contribute to the greater range of flexion-extension seen at the cervical and lumbar ends of the thoracic vertebral column.

The anterior and posterior longitudinal ligaments are attached to the borders of the bodies. The capsular and radiate ligaments of the costovertebral joints are attached around the margins of the costal facets.

The dimensions and angles of thoracic pedicles change progressively from the upper thoracic spine distally: there is a successive caudal increase in thickness. These changing relationships have a significant bearing on the placement of pedicle screws in spinal surgery (Wood 2013). The superior vertebral notch is recognizable only in the first thoracic vertebra, whereas the inferior notch is deep in all. Ligamenta flava are attached at the upper borders and lower anterior surfaces of the laminae.

Thoracic transverse processes shorten in caudal succession. In the upper five or six vertebrae, the costal facets are concave and face anterolaterally, and at lower levels the facets are flatter and face superolaterally and slightly forwards. The costotransverse ligament is attached to the anterior surface medial to the facet; the lateral costotransverse ligament is attached to its tuberculated apex and the superior costotransverse ligament is attached to its lower border.

Thoracic spines overlap from the fifth to the eighth vertebra, whose spine is the longest and most oblique. Supraspinous and interspinous ligaments are attached to the spines.

## The first and ninth to twelfth thoracic vertebrae

The first and ninth to twelfth thoracic vertebrae display additional atypical features. The first thoracic vertebra (see Fig. 43.41) resembles a cervical vertebra in its body, both in shape and in the distinctive posterolateral 'lipping' that forms the anterior border of the superior vertebral notch. There are circular superior costal facets for articulation with the whole facet on the head of the first rib. The smaller, semilunar inferior facets articulate with a demifacet on the head of the second rib. The upper costal facet is often incomplete, in which case the first rib articulates with the seventh cervical vertebra and the intervening disc. A small, deep depression often occurs below the facet. The long, thick spine is horizontal and commonly as prominent as that of the seventh cervical vertebra. The ninth vertebra (see Fig. 43.41) often fails to articulate with the tenth ribs, in which case the inferior demifacets are absent. The tenth thoracic vertebra (see Fig. 43.41) only articulates with the tenth pair of ribs, so that superior facets only appear on the body. These are usually large and semilunar, but are oval when the tenth ribs fail to articulate with the ninth vertebra and intervening disc. The transverse process may or may not bear a facet for the tubercle of the tenth rib. The eleventh thoracic vertebra (see Fig. 43.41) articulates only with the heads of the eleventh ribs. The circular costal facets are close to the upper border of the body and extend on to the pedicles. The small transverse processes lack articular facets. The eleventh and twelfth thoracic spinous processes are triangular, with blunt apices and a horizontal lower and an oblique upper border. The twelfth thoracic vertebra (see Fig. 43.41) articulates with the heads of the twelfth ribs by circular facets somewhat below the upper border, spreading on to the pedicles. The body is large and the vertebra has some lumbar features. The transverse process is replaced by three small tubercles: the superior is largest, projects upwards and corresponds to a lumbar mammillary process, though it does not lie as close to the superior articular process; the lateral tubercle is the homologue of a transverse process; and the inferior is the homologue of a lumbar accessory process. The superior and inferior processes are surprisingly long in some specimens.

A change in orientation of articular processes from thoracic to lumbar type usually occurs at the eleventh thoracic vertebra, but sometimes at the twelfth or tenth. In the transitional vertebra the superior articular processes are thoracic, and face posterolaterally, while the inferior are transversely convex and face anterolaterally. The transitional vertebra marks the site of a sudden change of mobility from predominantly rotational to predominantly flexion-extension.

Muscle attachments Longus colli arises from the upper three thoracic vertebral bodies, lateral to the anterior longitudinal ligament, and psoas major and minor arise from the sides of the twelfth near its lower border. Upper and lower borders of the transverse processes provide attachment for the intertransverse muscles or their fibrous vestiges. The posterior surfaces of the transverse processes provide attachment for the deep dorsal muscles, and levator costae is attached posteriorly on the apex. Trapezius, rhomboid major and minor, latissimus dorsi, serratus posterior superior and inferior, and many deep dorsal muscles are attached to the spines. Rotatores attach to the posterior aspects of the laminae.

Fig. 43.43 The first lumbar vertebra, superior aspect. Key: 1, body; 2, pedicle; 3, transverse process; 4, accessory process; 5 , mammillary process; 6, spinous process; 7, vertebral foramen; 8, superior articular facet; 9, lamina; 10, inferior articular facet.

Ossification Thoracic vertebrae all ossify according to the standard vertebral pattern described on page 756 .

## LUMBAR VERTEBRAE

## Lumbar vertebrae in general

The five lumbar vertebrae are distinguished by their large size and the absence of costal facets and transverse foramina. The body is wider transversely (Fig. 43.43; see Fig. 43.47B). The vertebral foramen is triangular, larger than at thoracic levels but smaller than at cervical levels. The pedicles are short. The spinous process is almost horizontal, quadrangular and thickened along its posterior and inferior borders. The superior articular processes bear vertical concave articular facets facing posteromedially, with a rough mammillary process on their posterior borders (Fig. 43.44A). The inferior articular processes have vertical convex articular facets that face anterolaterally. The transverse processes are thin and long, except on the more substantial fifth pair. A small accessory process marks the posteroinferior aspect of the root of each transverse process. The accessory and mammillary processes are linked by a fine ligament, the mammillo-accessory ligament, which is sometimes ossified, and beneath which runs the medial branch of the dorsal primary ramus of the spinal nerve (Bogduk 2005).

Strong paired pedicles arise posterolaterally from each body near its upper border. Superior vertebral notches are shallow and the inferior ones are deep. The laminae are broad and short, but do not overlap as much as those of the thoracic vertebrae. The fifth spine is the smallest, and its apex is often rounded and down-turned. Upper lumbar superior articular processes are further apart than inferior ones, but the difference is slight in the fourth and negligible in the fifth. The articular facets are reciprocally concave (superior) and convex (inferior), which allows flexion, extension, lateral bending and some degree of rotation. There are sex differences in the angle of inclination and depth of curvature of the articular facets. The facets are sometimes asymmetrical.

Transverse processes, except the fifth, are anteroposteriorly compressed and project posterolaterally. The lower border of the fifth transverse process is angulated, and passes laterally and then superolaterally to a blunt tip; the whole process presents a greater upward inclination than the fourth. The angle on the inferior border may represent the tip of the costal element and the lateral end the tip of the true transverse process. The lumbar transverse processes increase in length from first to third and then shorten (Fig. 43.45). The fifth pair incline both upwards and posterolaterally. The costal element is incorporated in the mature transverse process.

Fig. 43.44 The lumbar spine. A, A typical lumbar vertebra, lateral aspect. B, A lateral radiograph, 24-year-old male. Key: 1, L4 transverse process; 2, L4 pedicle; 3, twelfth rib; 4, L2 superior articular facet; 5, L3 spinous process; 6, L3/4 intervertebral foramen.

On average, the adult spinal cord ends at the level of the middle third of the body of the first lumbar vertebra, which means that the first lumbar vertebral foramen usually contains the conus medullaris. The cord may terminate above or below this level (Saifuddin et al 1998) (see Fig. 43.78 and Ch. 45); lower lumbar vertebral foramina contain the cauda equina and spinal meninges (Fig. 43.46; see Fig. 43.10B) Variation occurs in the sagittal and coronal dimensions of the lumbar vertebral canal, both within and between normal populations.

The fifth lumbar vertebra (Fig. 43.47) has a massive transverse process that is continuous with the whole of the pedicle and encroaches on the body. The body is usually the largest and markedly deeper anteriorly, so contributing to the lumbosacral angle.

Segmentation anomalies (sacralization) are considered below with the sacrum. The costal element of the first lumbar vertebra may form a short lumbar rib, which articulates with the transverse process, but not usually with the body, of the vertebra.

Fig. 43.45 An anteroposterior radiograph of the lumbosacral spine in a 22-year-old male. Key: 1, L3 inferior articular process; 2, L4 superior articular process; 3, right sacroiliac joint; 4, ilium; 5, psoas lateral border; 6, L3 transverse process; 7, facet joint; 8, L4 pedicle; 9, L4 spinous process; 10, anterior sacral foramen.

Muscle and fascial attachments Upper and lower borders of lumbar bodies give attachment to the anterior and posterior longitudinal ligaments. The upper bodies (three on the right, two on the left) give attachments to the crura of the diaphragm lateral to the anterior longitudinal ligament. Posterolaterally, psoas major is attached to the upper and lower margins of all the lumbar bodies, and between them, tendinous arches carry its attachments across their concave sides (see Fig. 62.5). The posterior lamella of the thoracolumbar fascia, erectores spinae, spinales thoracis, multifidi, interspinal muscles and ligaments, and supraspinous ligaments are all attached to spinous processes. All lumbar transverse processes present a vertical ridge on the anterior surface, nearer the tip, which marks the attachment of the anterior layer of the thoracolumbar fascia, and separates the surface into medial and lateral areas for psoas major and quadratus lumborum respectively. The middle layer of the fascia is attached to the apices of the transverse processes; the medial and lateral arcuate ligaments attach to the vertical ridge on the anterior aspect of the first pair, and the iliolumbar ligament attaches to the apices of the fifth pair. Posteriorly, the transverse processes are covered by deep dorsal muscles, and fibres of longissimus thoracis are attached to them and to their accessory processes. The ventral lateral intertransverse muscles are attached to their upper and lower borders, while the dorsal attach cranially to the accessory process and caudally to the upper border of the transverse process. The mammillary process, homologous with the superior tubercle of the twelfth thoracic vertebra, gives attachment to multifidus and the medial intertransverse muscle. The latter also attaches to the accessory process, which is sometimes difficult to identify.

Ossification Lumbar vertebrae ossify according to the standard vertebral pattern described on page 756 but also have two additional centres for the mammillary processes. A pair of scale-like epiphyses usually appear on the tips of the costal elements of the fifth lumbar vertebra (see Fig. 43.34C).

## SACRUM

The sacrum is a large, triangular fusion of five vertebrae and forms the posterosuperior wall of the pelvic cavity (Ch. 80), wedged between the

Fig. 43.46 The lumbar spine. A, A midsagittal MR image. B, A sagittal MR image.
two hip (innominate) bones. Its blunted, caudal apex articulates with the coccyx and its superior, wide base with the fifth lumbar vertebra at the lumbosacral angle. It is set obliquely and curved longitudinally, the dorsal surface is convex, and the pelvic surface is concave; this ventral curvature increases pelvic capacity. Between base and apex are dorsal, pelvic and lateral surfaces and a sacral canal. In childhood, individual sacral vertebrae are connected by cartilage, and the adult bone retains many vertebral features. The sacrum consists of trabecular bone enveloped by a shell of compact bone of varying thickness.

Base The base (Fig. 43.48) is the upper surface of the first sacral vertebra, the least modified from the typical vertebral plan. The body is large and wider transversely, and its anterior projecting edge is the sacral promontory. The vertebral foramen is triangular; its pedicles are short and diverge posterolaterally. The laminae are oblique, inclining down posteromedially to meet at a spinous tubercle. The superior articular processes project cranially, with concave articular facets directed posteromedially to articulate with the inferior articular processes of the fifth lumbar vertebra. The posterior part of each process projects backwards and its lateral aspect bears a rough area homologous with a lumbar mammillary process.

The transverse process is much modified as a broad, sloping mass that projects laterally from the body, pedicle and superior articular process. It is formed by the fusion of the transverse process and the costal element to each other and to the rest of the vertebra, and forms the upper surface of the sacral lateral mass or ala.

Terminal fibres of the anterior and posterior longitudinal ligaments are attached to the ventral and dorsal surfaces of the first sacral body. Its upper laminar borders receive the lowest pair of ligamenta flava. The ala is smooth superiorly, concave medially and rough laterally, and
covered almost entirely by psoas major. The smooth area is grooved obliquely by the lumbosacral trunk. The rough area is for the lower band of the iliolumbar ligament, which lies lateral to the fifth lumbar spinal nerve and to the anterior sacroiliac ligament.

Pelvic surface The anteroinferior pelvic surface (Fig. 43.49) is vertically and transversely concave, but the second sacral body may produce a convexity. Four pairs of pelvic sacral foramina communicate with the sacral canal through intervertebral foramina, and transmit ventral rami of the upper four sacral spinal nerves. The large area between the right and left foramina, which is formed by the flat pelvic aspects of the sacral bodies, bears evidence of their fusion at four transverse ridges. The longitudinal bars between the foramina are costal elements, which fuse to the vertebrae. Lateral to the foramina, the costal elements unite. Posteriorly, they unite with the transverse processes to form the lateral part of the sacrum, which expands basally as the ala.

The first three sacral ventral rami emerge from the pelvic sacral foramina and pass anterior to piriformis. The sympathetic trunks descend in contact with bone, medial to the foramina, as do the median sacral vessels in the midline. Lateral to the foramina, lateral sacral vessels are related to bone. Ventral surfaces of the first, second and part of the third sacral bodies are covered by parietal peritoneum and crossed obliquely, left of the midline, by the attachment of the sigmoid mesocolon. The rectum is in contact with the pelvic surfaces of the third to fifth sacral vertebrae and with the bifurcation of the superior rectal artery between the rectum and third sacral vertebra.

Dorsal surface The posterosuperior aspect of the dorsal surface bears a raised, interrupted, median sacral crest with four (sometimes three) spinous tubercles, which represent fused sacral spines (Fig. 43.50).

Fig. 43.47 Lumbar vertebrae. A, The fifth lumbar vertebra, superior aspect. B, A high-resolution axial CT scan through the lumbar spine at the level of the fourth lumbar vertebra.

Fig. 43.50 The sacrum, posterior (dorsal) surface. Key: 1, superior articular facet of S1; 2, ala; 3, first dorsal sacral foramen; 4, attachments of interosseous sacroiliac ligaments; 5, lateral crest and transverse tubercles; 6, median crest and spinous processes; 7, attachment of gluteus maximus; 8, sacral hiatus; 9, cornua; 10, intermediate crest and articular tubercle (inferior articular process); 11, posterior surface of body of S1 forming anterior wall of sacral canal; 12, area of attachment of multifidus (bounded by thin line); 13, attachment of erector spinae aponeurosis (thick line).

Below the fourth (or third) tubercle there is an arched sacral hiatus in the posterior wall of the sacral canal. This hiatus is produced by the failure of the laminae of the fifth sacral vertebra to meet in the median plane, and as a result the posterior surface of the body of that vertebra is exposed on the dorsal surface of the sacrum. Flanking the median crest, the posterior surface is formed by fused laminae, and lateral to this are four pairs of dorsal sacral foramina. Like the pelvic foramina, they lead into the sacral canal through intervertebral foramina, and each transmits the dorsal ramus of a sacral spinal nerve. Medial to the foramina, and vertically below each articular process of the first sacral vertebra, is a row of four small tubercles, which collectively constitute the intermediate sacral crest. These are sometimes termed articular tubercles, and represent fused contiguous articular processes. The inferior articular processes of the fifth sacral vertebra are free and project downwards at the sides of the sacral hiatus as sacral cornua, connected to coccygeal cornua by intercornual ligaments. The interrupted roughened crest to the lateral side of the dorsal sacral foramina is the lateral sacral crest, which is formed by fused transverse processes, whose apices appear as a row of transverse tubercles.

The upper three sacral spinal dorsal rami pierce multifidus as they emerge via dorsal foramina.

Lateral surface The lateral surface (Fig. 43.51A) is a fusion of transverse processes and costal elements. It is wide above and rapidly narrows in its lower part. The broad upper part bears an auricular surface for articulation with the ilium, and the area posterior to this is rough and deeply pitted by the attachment of ligaments. The auricular surface, borne by costal elements, is like an inverted letter L. The shorter, cranial limb is restricted to the first sacral vertebra; the caudal limb descends to the middle of the third. Beyond this, the lateral surface is nonarticular and reduced in breadth. Caudally, it curves medially to the body of the fifth sacral vertebra at the inferior lateral angle, beyond which the surface becomes a thin lateral border. A variable accessory sacral articular facet sometimes occurs, posterior to the auricular surface.

The auricular surface is covered by hyaline cartilage, and formed entirely by costal elements. It shows cranial and caudal elevations and an intermediate depression, behind which a third elevation is visible in the elderly. The surface becomes more corrugated with age. The rough area behind the auricular surface shows two or three marked depressions for the attachment of strong interosseous sacroiliac ligaments. Below the auricular surface the sacrotuberous and sacrospinous ligaments are attached between gluteus maximus dorsally and coccygeus ventrally.

Apex The apex is the inferior aspect of the fifth sacral vertebral body, and bears an oval facet for articulation with the coccyx.

Sacral canal The sacral canal (Fig. 43.51B) is formed by sacral vertebral foramina, and is triangular in section (see Fig. 43.48). Its upper opening, seen on the basal surface, appears to be set obliquely. The inclination of the sacrum means that it is directed cranially in the standing position. Each lateral wall presents four intervertebral foramina, through which the canal is continuous with pelvic and dorsal sacral foramina. Its caudal opening is the sacral hiatus. The canal contains the cauda equina and the filum terminale, and the spinal meninges. Opposite the middle of the sacrum, the subarachnoid and subdural spaces close; the lower sacral spinal roots and filum terminale pierce the arachnoid and dura mater at that level. The filum terminale with its meningeal coverings emerges below the sacral hiatus and passes downwards across the dorsal surface of the fifth sacral vertebra and sacrococcygeal joint to reach the coccyx. The fifth sacral spinal nerves also emerge through the hiatus medial to the sacral cornua, and groove the lateral aspects of the fifth sacral vertebra.

Muscle attachments The pelvic surface gives attachment to piriformis in its second to fourth segments, to iliacus superolaterally, and to coccygeus inferolaterally. The dorsal surface gives attachment to the aponeurosis of erector spinae along a U-shaped area of spinous and transverse tubercles, covering multifidus, which occupies the enclosed area (see Fig. 43.50). On the lateral border below the auricular surface, gluteus maximus is attached dorsal and coccygeus is attached ventral to the sacrotuberous and sacrospinous ligaments.

Ossification The sacrum resembles typical vertebrae in the ossification of its segments (Fig. 43.52). Primary centres for the centrum and each half vertebral arch appear between the tenth and twentieth weeks. Primary centres for the costal elements of the upper three or more segments appear superolateral to the pelvic sacral foramina, between the sixth and eighth prenatal months. Each costal element unites with its
half vertebral arch between the second and fifth years, and the conjoined element so formed unites anteriorly with the centrum and posteriorly with its opposite fellow at about the eighth year. Thereafter, the upper and lower surfaces of each sacral body are covered by an epiphysial plate of hyaline cartilage, which is separated from its neighbour by the fibrocartilaginous precursor of an intervertebral disc. Laterally, successive conjoined vertebral arches and costal elements are separated by hyaline cartilage; a cartilaginous epiphysis, sometimes divided into upper and lower parts, develops on each auricular and adjacent lateral surface. Soon after puberty, the fused vertebral arches and costal elements of adjacent vertebrae begin to coalesce from below upwards. At the same time, individual epiphysial centres develop for the upper and lower surfaces of bodies, spinous tubercles, transverse tubercles and costal elements.

The costal epiphysial centres appear at the lateral extremities of the hyaline cartilages between adjacent costal elements; two anterior and two posterior centres appear in each of the intervals between the first, second and third sacral vertebrae. Ossification spreads from these into the auricular epiphysial plates. One costal epiphysial centre, placed anteriorly, occurs in each remaining interval and from them ossification spreads to the epiphysial plate covering the lower part of the lateral surface of the sacrum. Sacral bodies unite at their adjacent margins after the twentieth year, but the central and greater part of each intervertebral disc remains unossified up to or beyond middle life.

Variants The sacrum may contain six vertebrae, by development of an additional sacral element or by incorporation of the fifth lumbar or first coccygeal vertebra. Inclusion of the fifth lumbar vertebra (sacralization) is usually incomplete and limited to one side. In the most minor degree of the abnormality, a fifth lumbar transverse process is large and articulates, sometimes by a synovial joint, with the sacrum at the posterolateral angle of its base. Reduction of sacral constituents is less common but lumbarization of the first sacral vertebra does occur; it remains partially or completely separate. The bodies of the first two sacral vertebrae may remain unfused when the lateral masses are fused. The dorsal wall of the sacral canal may be variably deficient, due to imperfect development of laminae and spines. Orientation of the superior sacral articular facets displays wide variation, as does the sagittal curvature of the sacrum. Asymmetry (facet tropism) of the superior facets alters the relation between the planes of the two lumbosacral facet joints.

Sex differences in sacra Sex differences in sacra are described on page 1348.

## COCCYX

The coccyx (Fig. 43.53) is a small, triangular bone and is often asymmetrical in shape. It usually consists of four fused rudimentary vertebrae, although the number varies from three to five, and the first is sometimes separate. The bone is directed downwards and ventrally from the sacral apex; its pelvic surface is tilted upwards and forwards, its dorsum downwards and backwards. Orientation varies with mobility and between individuals.

The base or upper surface of the first coccygeal vertebral body has an oval, articular facet for the sacral apex. Posterolateral to this, two coccygeal cornua project upwards to articulate with sacral cornua; they are homologues of the pedicles and superior articular processes of other vertebrae. A rudimentary transverse process projects superolaterally from each side of the first coccygeal body and may articulate or fuse with the inferolateral sacral angle, completing the fifth sacral foramina.

The second to fourth coccygeal vertebrae diminish in size and are usually mere fused nodules. They represent rudimentary vertebral bodies, though the second may show traces of transverse processes and pedicles.

The gap between the fifth sacral body and the articulating cornua represents, on each side, an intervertebral foramen that transmits the fifth sacral spinal nerve. The dorsal ramus descends behind the rudimentary transverse process, and the ventral ramus passes anterolaterally between the transverse process and sacrum.

Muscle and ligament attachments The lateral parts of the pelvic surface, including the rudimentary transverse processes, give attachment to the levatores ani and coccygei. The anterior sacrococcygeal ligament is attached to the front of the first and sometimes second coccygeal vertebral bodies (see Fig. 80.9A). The cornua give attachment to the intercornual ligaments. The lateral sacrococcygeal ligament connects the transverse process to the inferolateral sacral angle. Gluteus maximus

is attached to the dorsal surface, and both levator ani and sphincter ani externus are attached to the tip of the bone. The median area gives attachment to the deep and superficial posterior sacrococcygeal ligaments, the superficial descending from the margins of the sacral hiatus and sometimes closing the sacral canal. The filum terminale, which is situated between the two ligaments, blends with them on the dorsum of the first coccygeal vertebra.

Ossification Each coccygeal segment is ossified from one primary centre. A centre in the first segment appears about birth and its cornua may soon ossify from separate centres. Remaining segments ossify at wide intervals up to the twentieth year or later. Segments slowly unite: union between the first and second is frequently delayed until 30 years. The coccyx often fuses with the sacrum in later decades, especially in females.

## LIGAMENTS OF THE VERTEBRAL COLUMN

## anterior Longitudinal ligament

The anterior longitudinal ligament (Fig. 43.54B) is a strong band extending along the anterior surfaces of the vertebral bodies. It is broader caudally, and thicker and narrower in thoracic than in cervical and lumbar regions, and is also relatively thicker and narrower opposite vertebral bodies than at the levels of intervertebral symphyses. It extends from the basilar part of the occipital bone to the anterior tubercle of C 1 and the front of the body of C 2 , and then continues caudally to the front of the upper sacrum. Its longitudinal fibres are strongly adherent to the intervertebral discs, hyaline cartilage end-plates and margins of

Edinburgh: Churchill Livingstone. B, With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
adjacent vertebral bodies, and are loosely attached at intermediate levels of the bodies, where the ligament fills their anterior concavities, flattening the vertebral profile. At these various levels, ligamentous fibres blend with the subjacent periosteum, perichondrium and periphery of the anulus fibrosus. The anterior longitudinal ligament has several

Fig. 43.55 The posterior longitudinal ligament in the lumbar region. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
layers. The most superficial fibres are the longest and extend over three or four vertebrae, the intermediate extend between two or three, and the deepest from one body to the next. Laterally, short fibres connect adjacent vertebrae.

## POSTERIOR LONGITUDINAL LIGAMENT

The posterior longitudinal ligament (Fig. 43.55) lies on the posterior surfaces of the vertebral bodies in the vertebral canal, attached between the body of C 2 and the sacrum, and continuous with the membrana tectoria above. Its smooth, glistening fibres, attached to intervertebral discs, hyaline cartilage end-plates and adjacent margins of vertebral bodies, are separated between attachments by basivertebral veins and the venous channels that drain them into anterior internal vertebral plexuses. At cervical and upper thoracic levels the ligament is broad and of uniform width, but in lower thoracic and lumbar regions it is denticulated, narrow over vertebral bodies and broad over discs. Its superficial fibres bridge three or four vertebrae, while deeper fibres extend between adjacent vertebrae as perivertebral ligaments, which are close to and, in adults, fused with the anulus fibrosus of the intervertebral disc. The layers of the posterior longitudinal ligament and the relationship of the ligament to associated membranes in the epidural space are fully discussed by Loughenbury et al (2006).

## LIGAMENTA FLAVA

The ligamenta flava (see Fig. 43.54B; Fig. 43.56) connect laminae of adjacent vertebrae in the vertebral canal. Their attachments extend from facet joint capsules to the point where laminae fuse to form spines Here their posterior margins meet and are partially united; the intervals between them admit veins that connect the internal and posterior external vertebral venous plexuses. Their predominant tissue is yellow elastic tissue, whose almost perpendicular fibres descend from the lower anterior surface of one lamina to the posterior surface and upper margin of the lamina below. The anterior surface of the ligaments is covered by a fine, continuous, smooth lining membrane (Newell 1999). The ligaments are thin, broad and long in the cervical region, thicker in the thoracic and thickest at lumbar levels. They arrest separation of the

Fig. 43.56 The ligamenta flava and costotransverse ligaments, ventral aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
laminae in spinal flexion, preventing abrupt limitation, and also assist restoration to an erect posture after flexion, perhaps protecting discs from injury.

The morphology and histology of the ligamentum flavum have been studied in the thoracolumbar region (Viejo-Fuertes et al 1998). On a macroscopic level, it has two layers, superficial and deep, whose fibres run in opposite directions. The superficial layer is innervated by medial branches from the dorsal roots of the spinal nerves. The deep layer is innervated by sinuvertebral nerves.

## INTERSPINOUS LIGAMENTS

Interspinous ligaments (see Fig. 43.54B) connect the facing edges of consecutive spinous processes, and extend ventrally as far as the ligamentum flavum and dorsally to the supraspinous ligament, when this ligament is present (see below). They differ structurally at thoracic, lumbar and cervical levels. The thoracic interspinous ligaments are narrow and elongated, whereas those at lumbar levels are thick and quadrilateral, and occur as closely applied pairs, the left and right ligaments being separated by a narrow or potential cleft. In the lumbar ligaments, collagen fibres run obliquely inferiorly and ventrally, and only the deepest fibres are truly ligamentous. The more dorsal fibres are derived from tendons of longissimus thoracis that dip into the interspinous space to gain attachment to the superior edge of the spinous process rather than to its tip. Distinctive interspinous ligaments are not evident at cervical levels, where they are represented by the median septum of the ligamentum nuchae as it passes between the cervical spinous processes.

## SUPRASPINOUS LIGAMENT

The supraspinous ligament (see Fig. 43.54B) is a strong, fibrous cord that connects the tips of spinous processes from C7 to L3 or L4. It is regularly deficient. The most superficial fibres extend over three or four vertebrae, the deeper span two or three, and the deepest connect adjacent spines and are continuous with the interspinous ligament. Most of the ligament is formed by the tendons of muscles with posterior midline attachments, i.e. semispinalis, longissimus, trapezius and latissimus dorsi. Only the most superficial fibres lack any connection with muscle. Below L4, the ligament is replaced by the decussating fibres of latissimus dorsi.

## INTERTRANSVERSE LIGAMENTS

Intertransverse ligaments run between adjacent transverse processes. At cervical levels, they consist of a few, irregular fibres that are largely replaced by intertransverse muscles; in the thoracic region, they are cords intimately blended with adjacent muscles; and in the lumbar
region, they are thin and membranous. For the detailed anatomy of the lumbar intertransverse ligaments, see Bogduk (2005).

## LIGAMENTOUS INSTABILITY

Damage to the ligaments controlling stability of the column may occur in the absence of evident bony pathology. This is particularly prevalent in inflammatory disease of the upper cervical spine, where rheumatoid arthritis may weaken or destroy the ligaments on which atlanto-axial stability depends (Fig. 43.57). The transverse ligament is stronger than the dens, which therefore usually fractures before the ligament ruptures. The alar ligaments are weaker, and combined head flexion and rotation may avulse one or both alar ligaments; rupture of one side results in an increase of about one-third in the range of rotation to the opposite side. Pathological softening of the transverse and adjacent ligaments or of the lateral atlanto-axial joints results in atlanto-axial subluxation, which may cause spinal cord injury. Ligamentous damage may also occur in spinal injuries (Fig. 43.58), particularly at cervical levels.

Developmental laxity of ligaments may also lead to problems with instability, especially if there is an episode of trauma; this combination is probably responsible for atlanto-axial rotational instability. Laxity of cervical spinal ligaments may be a normal variant in children and lead to diagnostic difficulties. In radiographs of the upper cervical spine in children aged less than 8, a deceptive appearance of subluxation ('pseudosubluxation') may result from a combination of ligamentous laxity and facet orientation. This usually occurs between C2 and C3 but may occasionally be seen at $\mathrm{C} 3 / 4$. Clinical and other radiological features should facilitate the correct diagnosis.

## JOINTS

All vertebrae from C2 to S1 articulate by secondary cartilaginous joints (symphyses) between their bodies, synovial joints between their articular processes, and fibrous joints between their laminae, transverse and spinous processes. In the cervical region, from C3 to C7, joints have been described between the uncinate or neurocentral processes of the inferior vertebral body and the bevelled lateral border of the superior body at each level. These small uncovertebral or neurocentral 'joints'

Fig. 43.59 A coronal CT reconstruction: note uncovertebral 'joint' (arrow).
are absent at birth, do not contain synovium, and are probably clefts in the intervertebral discs (Fig. 43.59).

## INTERVERTEBRAL JOINTS

## Joints between the vertebral bodies

Joints between vertebral bodies are symphyses. Typical vertebral bodies are united by anterior and posterior longitudinal ligaments and by fibrocartilaginous intervertebral discs between sheets of hyaline cartilage (vertebral end-plates).

Articulating surfaces: intervertebral discs The intervertebral discs are the chief bonds between the adjacent surfaces of vertebral bodies from C2 to the sacrum. Except at the sites of the uncovertebral (neurocentral) joints of Luschka, disc outlines correspond with the adjacent bodies. Their thickness varies in different regions and within individual discs. Each disc consists of an outer lamellated anulus fibrosus and an inner nucleus pulposus (see Fig. 43.54A(1)).

In cervical and lumbar regions the discs are thicker anteriorly, contributing to the anterior convexity of the vertebral column. In the thoracic region they are nearly uniform, and the anterior concavity is largely due to the vertebral bodies. Discs are thinnest in the upper thoracic region and thickest in the lumbar region. They adhere to thin layers of cartilage on the superior and inferior vertebral surfaces, the vertebral end-plates. The latter do not reach the periphery of the vertebral bodies but are encircled by ring apophyses. The end-plates contain both hyaline cartilage and fibrocartilage. The fibrocartilaginous component lies nearer to the disc and is sometimes considered not to be part of the end-plate itself. The fibrocartilaginous components of the endplates above and below the nucleus pulposus, together with the innermost lamellae of the anulus fibrosus, form a flattened sphere of collagen that surrounds and encloses the nucleus (Fig. 43.60). The overall proportion of fibrocartilage in the end-plate increases with age. While all discs are attached to the anterior and posterior longitudinal ligaments, discs in the thoracic region are additionally tied laterally, by intraarticular ligaments, to the heads of ribs articulating with adjacent vertebrae. Intervertebral discs form about one-quarter of the length of the postaxial vertebral column; cervical and lumbar regions make a greater contribution than the thoracic and are thus more pliant.

Anulus fibrosus The anulus fibrosus has a narrow outer collagenous zone and a wider inner fibrocartilaginous zone. Its lamellae, which are convex peripherally when seen in vertical section, are incomplete collars. The internal vertical concavity of the lamellae conforms to the surface profile of the nucleus pulposus. In all quadrants of the anulus, about half the lamellae are incomplete; the proportion increases in the posterolateral region. The exact nature of the interlamellar substance remains in some doubt. Posteriorly, lamellae join in a complex manner. Fibres in the rest of each lamella are parallel and run obliquely between vertebrae at about $65^{\circ}$ to the vertical (see Fig. 43.54A(2)). Fibres in successive lamellae cross each other obliquely in opposite directions, thus limiting rotation. The obliquity of fibres in deeper zones varies in different lamellae. Posterior fibres may sometimes be predominantly vertical, which possibly predisposes them to herniation.

Fig. 43.60 The structure of the vertebral end-plate: the collagen fibres of the inner two-thirds of the anulus fibrosus sweep around into the vertebral end-plate and form its fibrocartilaginous component. The peripheral fibres of the anulus are anchored into the bone of the ring apophysis. (With permission from Bogduk N 1997 Clinical Anatomy of the Lumbar Spine and Sacrum, 3rd ed. Edinburgh: Churchill Livingstone.)
 (

Fig. 43.57 Atlanto-axial instability in the setting of rheumatoid arthritis. Note the marked widening of the atlanto-dens interval seen on extension radiographs (arrow) (A), when compared with flexion (B).

Fig. 43.58 A, A sagittal CT reconstruction showing an osseous and ligamentous injury at T10-11 sustained by a 54 -year-old male after a major compression injury. B, The MR image shows gross disruption of the supraspinous and interspinous ligaments (arrow).

This standard description of the anulus may not apply at all spinal levels; a cadaveric study indicates that the anulus is usually incomplete posteriorly in adult cervical discs (Mercer and Bogduk 1999) (see Fig. 43.54A(3)).

Nucleus pulposus The nucleus pulposus is better developed in cervical and lumbar regions and lies between the centre of the disc and its posterior surface. At birth it is large, soft and gelatinous, and is composed of mucoid material. It contains a few multinucleated notochordal cells and is invaded by cells and collagen fibres from the inner zone of the adjacent anulus fibrosus. Notochordal cells disappear in the first decade, and the mucoid material is gradually replaced by fibrocartilage, derived mainly from the anulus fibrosus and the plates of hyaline cartilage adjoining the vertebral bodies. The nucleus pulposus becomes less differentiated from the remainder of the disc as age progresses, and gradually becomes less hydrated and increasingly fibrous. The type II collagen of the nucleus becomes more like the type I of the anulus as its fibril diameter increases. The quantity of aggregated proteoglycans in the nucleus decreases, while the keratan sulphate/chondroitin sulphate ratio increases. As increased cross-linking occurs between collagen and the proteoglycans, the discs lose their water-binding capacity and become stiffer and more liable to injury. Contrary to what was previously thought, it has now been shown that lumbar discs do not decrease in overall height as a part of normal ageing. The anulus gradually loses height as its radial bulge increases, but the nucleus retains height and may increase in convexity as it increasingly indents the endplate. Loss of trunk height with age results from a decrease in vertebral body height (Bogduk 2005). When the disc is not loaded, pressure in the nucleus pulposus is low at all ages.

For a review of the structure and function of the human intervertebral disc, see Adams and Dolan (2005).

Ligaments The ligaments associated with the joints between the vertebral bodies are described on pages 731-733.

Vascular supply Small offshoots of spinal branches of arteries supplying the vertebral column form an anastomosis on the outer surface of the anulus fibrosus and supply its most peripheral fibres. Normal discs are otherwise avascular and are dependent for their nutrition on diffusion from vertebral bone beneath adjacent end-plates and from the peripheral anulus. Vascular and avascular parts differ in their reaction to injury. Venous drainage is via the external and internal vertebral venous plexuses to the intervertebral veins and thence to the larger named veins that drain the vertebral column. Lymphatic drainage of the vertebral column is briefly considered above. Nothing specific is known about the lymphatic drainage of the disc.

Innervation The nerve supply of intervertebral discs has been studied in detail in the lumbar region (Fig. 43.61). The outer third of the anulus is innervated by the sinuvertebral nerves; each sinuvertebral nerve

Fig. 43.61 The nerve supply of a lumbar intervertebral disc. Branches of the grey rami communicantes and the sinuvertebral nerves are shown entering the disc and the anterior and posterior longitudinal ligaments. Branches from the sinuvertebral nerves also supply the ventral aspect of the dural sac and the dural nerve-root sleeve.
supplies both the disc at the level of its spinal nerve of origin and the disc one level above. The anterior part of the anulus is supplied by the sympathetic (preganglionic, grey ramus communicans) rather than by the mixed nerve. In damaged and degenerate discs, the nerves may penetrate more centrally into the disc substance. The sinuvertebral nerves are condensations within extensive nerve plexuses that lie on the posterior longitudinal ligament. Similar plexuses have been demonstrated anteriorly, covering the anterior longitudinal ligament, and laterally in the fetus.

Relations and 'at risk' structures Posterior, lateral and anterior relations of the intervertebral disc are important in the planning of interventional investigative and therapeutic procedures ranging from discography to open disc surgery. The posterolateral surface of the disc forms the anterior boundary of the intervertebral foramen on each side, and so is closely related to the spinal nerve and its accompanying vessels. More centrally, the disc is related posteriorly to the dura mater covering the spinal cord and the cauda equina. Anterior relations of the discs vary considerably with vertebral level, but important 'at risk' structures include the pharynx and oesophagus, the descending aorta and the inferior vena cava. Laterally, relations change with level, but the parietal pleura in the thorax, and the sympathetic trunk and psoas muscles in the lumbar region, are important examples.

Prolapsed intervertebral disc A prolapsed intervertebral disc most commonly affects the 20-55-year age group and is most often seen at the L4/5 and lumbosacral levels. It may also affect the cervical discs, particularly at $\mathrm{C} 5 / 6$ and $\mathrm{C} 6 / 7$. The thoracic discs are rarely affected. Acute tearing or chronic degeneration of the posterior lamellae of the anulus fibrosus allows deformation and herniation of the disc contents. The disc most often prolapses just lateral to the posterior longitudinal ligament and can compress one or two spinal nerves unilaterally (Fig. 43.62). Much less commonly, the prolapse is central, in the midline posteriorly. The compression of neural structures may then be bilateral, affecting the cord itself or the whole cauda equina. If the damaged anulus ruptures completely, some of the nuclear tissue may escape into the vertebral and 'root' canals. This sequestrated material may migrate within the canals and cause nerve compression at spinal levels distant from that of the disc rupture. The disc material itself may have an irritative effect on the spinal nerve.

Regarding the anatomy of the vertebral canal and intervertebral foramen in relation to disc prolapse, it is important to understand that one or both of two spinal nerves and their roots may be affected by a single prolapse, depending on the exact site of the prolapse in the horizontal plane. At the level of each disc and foramen, there are two spinal nerves (and their roots) to consider: these are the exiting nerve and the traversing nerve (Fig. 43.63) (MacNab and McCulloch 1990). The nerve usually affected at lumbar levels is the traversing nerve, which crosses the back of the disc on its way to become the exiting nerve at the level below. Thus a lumbosacral (i.e. L5/S1) disc prolapse usually compresses the S1 nerve. However, a prolapse may affect the exiting nerve at its own level. This is especially likely if the prolapse is in the extraforaminal zone of the 'root' canal, the so-called 'far lateral' prolapse. At cervical levels, because the roots and nerve leave the vertebral canal almost horizontally, the prolapse usually affects the exiting nerve. This nerve will still bear the number of the vertebra below the affected disc because cervical nerves exit the canal above the pedicle of their numerically corresponding vertebra. Neurological presentation will include signs and symptoms of spinal nerve damage at the affected level. Thus pain and sensory loss will be dermatomal in distribution. Sensory changes usually precede motor loss.

Internal disruption of a lumbar intervertebral disc is more common than disc prolapse and is now an increasingly recognized cause of back pain. Typically, the nucleus is decompressed and the inner lamellae of the anulus appear to collapse into it.

For more detail on disc pathology and its consequences, see Adams and Dolan (2005).

## Facet (zygapophysial) joints

Joints between the vertebral articular processes (zygapophyses) are synovial and have long been called zygapophysial joints by anatomists. However, in current clinical practice they are commonly called 'facet joints'. Detailed description of the anatomy of these joints is to be found in Bogduk (2005), where the author explains why the term 'facet joint' is both incorrect and essentially ambiguous, on the grounds that facets are not restricted to zygapophysial articular processes and occur, for example, in both costovertebral and costotransverse joints.

Fig. 43.62 A left posterolateral disc extrusion. A, Axial view. B, Sagittal view.

Articulating surfaces Facet joints are of the simple (cervical and thoracic) or complex (lumbar) synovial variety; the articulating surfaces are covered in hyaline cartilage and are carried on mutually adapted articular processes. The size and shape of these processes vary with spinal level and are described with the individual vertebrae.

Fibrous capsule The fibrous capsule is thin and loose and attached peripherally to the articular facets of adjacent articular processes.

Fig. 43.63 Exiting and traversing nerve roots. The upper root (open arrow) is the exiting root at this level; the lower (closed arrow) is the traversing root here, which becomes the exiting root at the level below. The dotted roots are traversing roots of the lower segment.

The capsules are longer and looser in the cervical region. According to Bogduk (2005), the anterior fibrous capsule is replaced entirely by the ligamentum flavum in the lumbar spine.

Intracapsular structures Bogduk describes two types of intra-articular structure in lumbar facet joints: namely, subcapsular fat and 'meniscoid' structures. The latter structures may be collagenous, fibroadipose or purely adipose, and project into the crevices between non-congruent articular surfaces. They resemble inclusions seen in the small joints of the hand; their function is conjectural.

Ligaments Ligaments that work in conjunction with, and modify the function of, the facet joints throughout the vertebral column are described on pages 731-733.

Synovial membrane The synovium is attached around the periphery of the articular cartilages and lines the fibrous capsule. In the lumbar region, it is reflected over the intracapsular structures described above.

Vascular supply The posterior spinal branches of the arteries that supply the vertebral column form arterial anastomoses around the facet joints. Venous drainage is via the external and internal posterior vertebral venous plexuses to the intervertebral veins and thence to the larger named veins that drain the vertebral column. Lymphatic drainage follows the principles described for the vertebral column.

Innervation The facet joints are profusely innervated by medial branches of the dorsal primary rami of the spinal nerves, which give articular branches to the joints above and below them.

Relations and 'at risk' structures Anteriorly, the capsules of the facet joints form the posterior boundaries of the intervertebral foramina. Posteriorly and laterally, the joints are related to the deep muscles of the back, some of whose fibres attach to the capsules. The joints also lie in close relation to the medial branches of the dorsal rami of the spinal nerves and to their accompanying arteries and veins. Damage to the medial branches of the dorsal rami may denervate the deep back muscles. Access to the facet joints and their related nerves may be required in the diagnosis and treatment of spinal pain.

Lumbar articular tropism In the lumbar region, asymmetrical orientation of the facet joints occurs in about one-fifth of the population. Such facet tropism does not appear to predispose to degenerative disc disease.

## CRANIOVERTEBRAL JOINTS

The articulation between the cranium and vertebral column is specialized to provide a wider range of movement than those that occur in the

Fig. 43.64 The atlanto-occipital and atlanto-axial joints, anterior aspect. On each side a small cleft has been opened between the lateral part of the upper surface of the body of the third cervical vertebra and the bevelled, inferior surface of the body of the axis.

Fig. 43.65 The atlanto-occipital and atlanto-axial joints, posterior aspect.
rest of the axial skeleton. It consists of the occipital condyles, the atlas and the axis. It functions like a universal joint that permits horizontal and vertical scanning movements of the head, and is adapted for eyehead coordination.

## Atlanto-occipital joints

The atlas articulates with the occipital bone of the skull by a pair of synovial joints. The bones are connected by articular capsules and by the anterior and posterior atlanto-occipital membranes (Figs 43.6443.65).

Articulating surfaces Each joint consists of two reciprocally curved articular surfaces, one on the occipital condyle and the other on the lateral mass of the atlas. The atlantal facets are concave and tilted medially.

Fibrous capsules The fibrous capsules surround the occipital condyles and superior atlantal articular facets. They are thicker posteriorly and laterally, where the capsule is sometimes deficient, and may communicate with the joint cavity between the dens and the transverse atlantal ligament.

Fig. 43.66 A median sagittal section through the occipital bone and first to third cervical vertebrae.

Ligaments The ligaments are the anterior and posterior atlantooccipital membranes.

Anterior atlanto-occipital membrane The anterior atlanto-occipital membrane (see Fig. 43.64; Fig. 43.66) is a broad, dense fibrous structure that connects the anterior margin of the foramen magnum to the upper border of the anterior arch of the atlas. Laterally, it blends with the joint capsule; medially, it is strengthened by a median cord, which is the anterior longitudinal ligament stretching between the basilar occipital bone and anterior atlantal tubercle.

Posterior atlanto-occipital membrane The posterior atlanto-occipital membrane (see Figs 43.65-43.66) is broad but relatively thin, and connects the posterior margin of the foramen magnum to the upper border of the posterior atlantal arch, blending laterally with the joint capsules. It arches over the grooves for the vertebral arteries, venous plexuses and first cervical nerve, and forms the 'floor' of the suboccipital triangle. The ligamentous border of this arch is sometimes ossified. The membrane is usually attached by a soft tissue 'bridge', which may contain muscle or tendon fibres, to rectus capitis posterior minor, and is firmly attached anteriorly to the spinal dura in the same area (Zumpano et al 2006). The ligaments connecting the axis and the occipital bone are functionally involved with the posterior atlantooccipital membrane.

Synovial membrane The synovial cavities of one or both joints may communicate with that of the posterior component of the median atlanto-axial joint.

Vascular supply The arterial supply of this region is derived from an anastomosis between branches of the deep cervical, occipital and vertebral arteries.

Innervation The joints are innervated by branches of the ventral primary ramus of the first cervical spinal nerves.

Factors maintaining stability Factors maintaining stability include the fibrous capsules, the atlanto-occipital membranes, the shape of the articular surfaces, the ligaments connecting the axis and the occipital bone, the ligamentum nuchae and the posterior neck muscles. The suboccipital muscles play an important proprioceptive and postural role.

Muscles producing movements The orientation and shape of the atlanto-occipital joints allow mainly for flexion-extension, which has a total range of about $15^{\circ}$. Axial rotation and lateral flexion have not been measured in living subjects, but a few degrees of motion in these directions can be produced by forceful movement in cadavers.

The following muscles produce these movements: for flexion longus capitis and rectus capitis anterior; for extension - recti capitis posteriores major and minor, obliquus capitis superior, semispinalis capitis, splenius capitis and trapezius (cervical part); for lateral flexion - rectus capitis lateralis, semispinalis capitis, splenius capitis, sternocleidomastoid and trapezius (cervical part); and for rotation - obliquus capitis superior, rectus capitis posterior minor, splenius capitis and sternocleidomastoid.

Relations and 'at risk' structures Posteriorly, the joints are closely related to the vertebral arteries as they pass from the foramina transversaria into the foramen magnum. The dorsal primary ramus of the first cervical nerve and rectus capitis posterior major lie posteromedially and rectus capitis anterior lies anteriorly.

## Atlanto-axial joints

The atlas articulates with the axis at three synovial joints. These are a pair between the lateral masses, and a median complex between the dens of the axis and the anterior arch and transverse atlantal ligament.

Articulating surfaces The articular surfaces of the joints between the lateral masses are often classified as planar. The bony articular surfaces are more complex in shape and are usually reciprocally concave in the coronal plane; the medial parts are somewhat convex in the sagittal plane (especially that of the axis). The cartilaginous articular surfaces are usually less concave. The median joint is a pivot between the dens and a ring formed by the anterior arch and transverse atlantal ligament. A vertically ovoid facet on the anterior dens articulates with a facet on the posterior aspect of the anterior atlantal arch.

Fibrous capsules The fibrous capsules for the lateral joints are attached to the articular margins and are thin and loose. Each has a posteromedial accessory ligament attached below to the axial body near the base of its dens, and above to the lateral atlantal mass near the transverse ligament. The fibrous capsule for the median joint is also relatively weak and loose, especially superiorly.

Ligaments Anteriorly, the vertebral bodies are connected by the anterior longitudinal ligament (see Figs 43.64, 43.66): here, a strong, thickened band attaches above to the lower border of the anterior tubercle of the anterior arch of the atlas and below to the front of the axial body. Posteriorly, the vertebral arches are joined by the ligamenta flava (see Figs 43.65-43.66), which are attached to the lower border of the atlantal arch above and to the upper borders of the axial laminae. At this level, these ligaments form a thin membrane, pierced laterally by the second cervical nerves.

Transverse atlantal and cruciform ligaments The transverse atlantal ligament (Fig. 43.67; see Fig. 43.33) is a broad, strong band that arches across the atlantal ring behind the dens; its length varies about a mean of 20 mm . It is attached laterally to a small but prominent tubercle on the medial side of each atlantal lateral mass, and broadens medially where it is covered anteriorly by a thin layer of articular cartilage. It consists almost entirely of collagen fibres, which, in the central part of the ligament, cross one another at an angle to form an interlacing mesh. From its upper margin a strong median longitudinal band arises that inserts into the basilar part of the occipital bone between the apical ligament of the dens and membrana tectoria, and from its inferior surface a weaker and less consistent longitudinal band passes to the posterior surface of the axis. These transverse and longitudinal components together constitute the cruciform ligament. The transverse ligament divides the ring of the atlas into unequal parts (see Figs 43.32-43.33). The posterior two-thirds surrounds the spinal cord and meninges, and the anterior third contains the dens, which the transverse ligament retains in position even when all other ligaments are divided.

Ligaments connecting axis and occipital bone Ligaments connecting the axis and the occipital bone consist of the membrana tectoria, the paired alar ligaments, the median apical ligament, and the longitudinal components of the cruciform ligament (see Figs 43.66-43.67).

Membrana tectoria Inside the vertebral canal, the membrana tectoria is a broad strong band representing the upward continuation of the posterior longitudinal ligament. Its superficial and deep laminae are both attached to the posterior surface of the axial body. The superficial lamina expands as it ascends to the upper surface of the basilar occipital bone, and attaches above the foramen magnum, where it blends with

Fig. 43.67 The posterior aspect of the atlanto-occipital and atlanto-axial joints. The posterior part of the occipital bone and the laminae of the cervical vertebrae have been removed and the atlanto-occipital joint cavities opened. (Adapted with permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
the cranial dura mater. The deep lamina consists of a strong median band that ascends to the foramen magnum, and two lateral bands that pass to, and blend with, the capsules of the atlanto-occipital joints as they reach the foramen magnum. The membrane is separated from the cruciform ligament of the atlas by a thin layer of loose areolar tissue, and sometimes by a bursa.

Alar ligaments The alar ligaments are thick cords, about 11 mm long, which pass horizontally and laterally from the longitudinally ovoid flattenings on the posterolateral aspect of the apex of the dens to the roughened areas on the medial side of the occipital condyles. In most individuals there is also an anteroinferior band, approximately 3 mm long, which inserts into the lateral mass of the atlas in front of the transverse ligament. Fibres occasionally pass from the dens to the anterior arch of the atlas. In addition, in some $10 \%$ of cases a continuous transverse band of fibres, the transverse occipital ligament, passes
between the occipital condyles immediately above the transverse ligament. The ligaments consist mainly of collagen fibres arranged in parallel. The main function of the alar ligaments is now considered to be limitation of atlanto-axial rotation, the left becoming taut on rotation to the right and vice versa. The slightly downward movement of the atlas during rotation helps permit a wider range of movement by reducing tension in the alar ligaments, and in the capsules and accessory ligaments of the lateral atlanto-occipital joint.

Apical ligament of the dens The apical ligament of the dens fans out from the apex of the dens into the anterior margin of the foramen magnum between the alar ligaments, and represents the cranial continuation of the notochord and its sheath. It is separated for most of its extent from the anterior atlanto-occipital membrane and cruciform ligament by pads of fatty tissue, though it blends with their attachments at the foramen magnum, and with the alar ligaments at the apex of the dens.

The ligamentum nuchae and the anterior longitudinal ligament also connect cervical vertebrae with the cranium.

Synovial membrane The synovial membranes of the lateral joints have no special features. The median joint has two synovial cavities that sometimes communicate. The synovial cavity of the posterior component of the median joint complex is larger, lying between the horizontally orientated ovoid facet, on the posterior surface of the dens and the cartilaginous anterior surface of the transverse ligament; communication often exists with one or both of the atlanto-occipital joint cavities.

Vascular supply The arterial supply of this region is derived from an anastomosis between branches of the deep cervical, occipital and vertebral arteries.

Innervation The joints are innervated by branches of the ventral primary ramus of the second cervical spinal nerve.

Factors maintaining stability The most important factors maintaining stability are the ligaments, of which the transverse atlantal ligament is the strongest (see Fig. 43.33). The alar ligaments are weaker. Other ligaments connecting the axis and the occipital bone, the fibrous capsules, the ligamentum nuchae and the posterior neck muscles also contribute to stability; the suboccipital muscles play an important proprioceptive and postural role.

Muscles producing movements Movement is simultaneous at all three joints and consists almost exclusively of rotation around the axis. The shape of the articular surfaces is such that, when rotation occurs, the axis ascends slightly into the atlantal ring, limiting stretch on the lateral atlanto-axial joint capsules. Rotation is limited mainly by the alar ligaments, with a minor contribution from the accessory atlanto-axial ligament. The normal range of atlanto-axial rotation is about $40^{\circ}$.

The muscles that produce atlanto-axial rotation act on the cranium, transverse processes of the atlas and spinous process of the axis. They are mainly obliquus capitis inferior, rectus capitis posterior major and splenius capitis of one side, and the contralateral sternocleidomastoid.

Relations and 'at risk' structures The most important 'at risk' relation is the spinal cord, lying posterior to the median atlanto-axial joint. Anteriorly, the atlanto-axial articulations, capsules and ligaments are separated from the buccopharyngeal fascia and superior constrictor by longus capitis and longus colli, the prevertebral fascia and the retropharyngeal (potential) space.

## Variants of craniovertebral joints

Anomalies of the craniovertebral joints are sometimes seen. Many are minor segmentation anomalies and may be incidental radiological or osteological findings. More severe anomalies may lead to craniocervical instability (Piper and Traynelis 1998).

## LUMBOSACRAL JUNCTION

Articulations between the fifth lumbar and first sacral vertebrae resemble those between other vertebrae. The bodies are united by a symphysis that includes a large intervertebral disc. The latter is deeper anteriorly at the lumbosacral angle. The synovial facet joints are separated by a wider interval than those above.

Fig. 43.68 Joints and ligaments on the posterior aspect of the left half of the pelvis and the fifth lumbar vertebra.

Articulating surfaces The reciprocally curved surfaces of the facet joints show considerable individual variation in alignment and shape. Asymmetry (facet tropism) is not unusual.

Ligaments The major ligament associated with the lumbosacral junction is the iliolumbar ligament (see Fig. 80.9A; Fig. 43.68).
lliolumbar ligament The iliolumbar ligament is attached to the tip and anteroinferior aspect of the fifth lumbar transverse process, and sometimes has a weak attachment to the fourth transverse process. It radiates laterally and is attached to the pelvis by two main bands. A lower band passes from the inferior aspect of the fifth lumbar transverse process and the body of the fifth lumbar vertebra across the anterior sacroiliac ligament to reach the posterior margin of the iliac fossa. An upper band, part of the attachment of quadratus lumborum, passes to the iliac crest anterior to the sacroiliac joint, and is continuous above with the anterior layer of the thoracolumbar fascia. The lower ligament has a more vertical component that reaches the posterior iliopectineal line; this component is a lateral relation of the L5 ventral ramus. A posterior component of the iliolumbar ligament passes behind quadratus lumborum to attach to the ilium.

In neonates and children, the iliolumbar 'ligament' is muscular; the muscle is gradually replaced by ligament up to the fifth decade of life.

Vascular supply The vascular supply of the lumbosacral junction is derived mainly from the iliolumbar and superior lateral sacral arteries.

Innervation The lumbosacral junction is innervated by branches derived from the fourth and fifth lumbar spinal nerves.

Relations and 'at risk' structures The lumbosacral disc is related anteriorly to the common iliac veins, the median sacral vessels, and the superior hypogastric plexus of nerves. The sympathetic trunks cross it anterolaterally, while the obturator nerves and lumbosacral trunks pass close laterally. The relations of the lumbosacral facet joints are similar to those of the lumbar facet joints (see above).

## SACROCOCCYGEAL JUNCTION

The sacrococcygeal joint is usually a symphysis between the sacral apex and coccygeal base, united by a thin fibrocartilaginous disc that is somewhat thicker in front and behind than laterally. Its surfaces carry
hyaline cartilage that varies from thin veils to small islands. Occasionally, the coccyx is more mobile and the joint is synovial.

Ligaments The anterior sacrococcygeal ligament consists of irregular fibres that descend on the pelvic surfaces of both sacrum and coccyx, and is attached in the same way as the anterior longitudinal ligament. The flat superior posterior sacrococcygeal ligament passes from the margin of the sacral hiatus to the dorsal coccygeal surface, roofing the lower sacral canal (see Fig. 43.68). The deep posterior sacrococcygeal ligament passes from the back of the fifth sacral vertebral body to the dorsum of the coccyx and corresponds to the posterior longitudinal ligament. On each side, the lateral sacrococcygeal ligaments connect the coccygeal transverse processes to the inferolateral sacral angles, completing foramina for the fifth sacral spinal nerves. Similarly, the intercornual ligaments connect the sacral and coccygeal cornua, and a fasciculus connects the sacral cornua to the coccygeal transverse processes.

Vascular supply The arterial supply of the sacrococcygeal junction is derived from the inferior lateral sacral and median sacral arteries.

Innervation The innervation of the sacrococcygeal junction is derived from the lower two sacral and the coccygeal nerves.

## INTERCOCCYGEAL JOINTS

In the young the intercoccygeal joints are symphyses, with thin discs of fibrocartilage between coccygeal segments. Segments are also connected by extensions of the anterior and posterior sacrococcygeal ligaments. In adult males all segments unite comparatively early, but in females union is later. In advanced age the sacrococcygeal joint becomes obliterated. Occasionally, the joint between the first and second segments is synovial. The apex of the terminal segment is connected to overlying skin by white fibrous tissue.

## MUSCLES

The musculature of the back is arranged in a series of layers, of which only the deeper are true, intrinsic, back muscles (Fig. 43.69). The true back muscles are characterized by their position and by their innervation by branches of the posterior (dorsal) rami of the spinal nerves. The true back muscles below the neck lie deep to the posterior layer of the thoracolumbar fascia. In the lumbar region, where the layers of the thoracolumbar fascia are well defined, they occupy the compartment between its posterior and middle layers.

Lying superficial to the true, intrinsic muscles are the extrinsic, 'immigrant' muscles (see Fig. 43.69). The most superficial of these run between the upper limb and the axial skeleton, and consist of trapezius, latissimus dorsi, levator scapulae and the rhomboid muscles. Beneath this layer lie the serratus posterior group, superior and inferior, which are variably developed but usually thin muscles whose function may be respiratory or possibly proprioceptive. All the extrinsic muscles are innervated by ventral rami.

Trapezius, levator scapulae, rhomboid major, rhomboid minor and latissimus dorsi are described on pages 816, 818 and 821 respectively, serratus posterior superior and inferior are described on pages 941, 942. The muscles of the posterior abdominal wall are described on page 1085.

The intrinsic muscles are also arranged in layers. The more superficial layers contain the splenius muscles in the neck and upper thorax, and the erector spinae group in the trunk as a whole. The deeper layers include the spinotransverse group, which is itself layered into semispinalis, multifidus and the rotatores, and the suboccipital muscles. Deepest of all lie the interspinal and intertransverse muscles. The latter group constitute a mixture of dorsal and ventral spinal muscles. The lumbar intertransversarii mediales, thoracic intertransversarii and medial parts of cervical posterior intertransversarii are innervated by dorsal rami, but
[C] the others are supplied by ventral rami (Commentary 5.1).

## Muscle attachments and fibre direction

Although developmentally the muscles of the back extend caudally as the vertebral column elongates, drawing their nerve supply with them, they have traditionally been described as if their fibres ran caudocranially, so that the 'origins' of the muscles lay distal to their 'insertions'.

It has been shown that in the lumbar spine it is more appropriate morphologically and biomechanically to view the muscles in the reverse direction - from above downwards (Bogduk 2005). It is reason-

Fig. 43.69 Superficial muscles of the back of the neck and trunk. On the left only the skin, superficial and deep fasciae (other than gluteofemoral) have been removed; on the right, sternocleidomastoid, trapezius, latissimus dorsi, deltoid and external oblique have been dissected away.
able to argue that this view may also be applied to the cervical and thoracic muscles, and so for uniformity in this section, all muscles have been described in this way.

## Ligamentum nuchae

The ligamentum nuchae is not a ligament of the neck, for it does not connect adjacent bones and lacks the internal structure typical of a ligament. It is a unique arrangement of tendons and fascia between the posterior muscles of the neck. It consists of a dorsal raphe and a median septal portion. The dorsal raphe lies superficially along the posterior midline of the neck. It is attached to the external occipital protruberance superiorly, and the tip of the C7 spinous process inferiorly. In its superior half it consists of the aggregated tendons of the most medial fibres of the cervical portion of trapezius. Because of their longitudinal arrangement, these tendons have been described as forming the funicular portion of the ligamentum nuchae (Mercer and Bogduk 2003). In its inferior half, the funicular portion is joined by the obliquely orientated tendons of splenius capitis and rhomboid minor. Across the midline the tendons of splenius capitis are continuous with those of rhomboid minor on the other side, and they interweave with the tendons of the reciprocal sets of muscles to produce the raphenous structure of the ligamentum nuchae. From the ventral surface of the dorsal raphe, a median fascial septum extends deeply towards the vertebral column and separates semispinalis capitis from its opposite partner. A lateral expansion of the septum extends laterally ventral to semispinalis capitis, separating it from multifidus and semispinalis cervicis. The median continuation of the septum reaches the tips of the cervical spinous processes, and extends into the cervical interspinous spaces as far as the ligamentum flavum. At upper cervical levels, the septum is attached to the external occipital crest and the posterior

Fig. 43.70 Splenius cervicis and splenius capitis.
tubercle of the atlas, and it blends with the posterior atlanto-occipital and posterior atlanto-axial membranes. Passing through these membranes, it is attached to the posterior surface of the dura mater (Dean and Mitchell 2002). Only the dorsal raphe affords attachment to muscles; no muscles arise from the median septum.

## Splenius capitis

Attachments Splenius capitis arises from the mastoid process and the rough surface on the occipital bone just below the lateral third of the superior nuchal line. Its fibres pass downwards and medially to reach the midline. The lower fibres insert into the tips of the spinous processes of the seventh cervical and upper three or four thoracic vertebrae and the intervening supraspinous ligaments. The tendons of the upper fibres interlace in the midline with those of the opposite side in the dorsal raphe of the ligamentum nuchae in the lower half of the cervical region (Fig. 43.70).

Relations Splenius capitis lies deep to trapezius and covers semispinalis capitis and longissimus capitis. The upper part of the muscle lies beneath sternocleidomastoid. Between sternocleidomastoid and trapezius it forms part of the floor of the posterior triangle of the neck, above and behind levator scapulae.

## Vascular supply See below.

Innervation Splenius capitis is innervated by lateral branches of the second and third cervical dorsal rami.

Actions Acting unilaterally, and synergistically with the contralateral sternocleidomastoid, splenius capitis rotates the head to the same side. Acting bilaterally, splenius capitis extends the head.

## Splenius cervicis

Attachments Splenius cervicis is confluent with splenius capitis, but covers more caudal regions of the neck and thoracic region (see Fig, 43.70). It arises from the transverse process of the atlas, the tip of the transverse process of the axis and the posterior tubercle of the third cervical vertebra. Its fibres pass downwards and medially, wrapping around the other posterior intrinsic neck muscles, to insert into the third to sixth thoracic spinous processes.

Relations Splenius cervicis lies deep to serratus posterior superior, the rhomboids and trapezius. It covers the upper parts of the erector spinae and the lower semispinalis muscles.

## Vascular supply See below.

Innervation Splenius cervicis is innervated by lateral branches of the lower cervical dorsal rami.

Actions Acting unilaterally, splenius cervicis rotates the upper cervical vertebra, in the same way that the splenius capitis rotates the head. Acting bilaterally, splenius cervicis extends the upper cervical spine.

Fig. 43.71 The erector spinae muscle group.

Variations The splenii may be absent or vary in their vertebral attachments. Accessory slips also occur.

## Erector spinae

Erector spinae (see Figs 43.6; Figs 43.71-43.72) is a large musculotendinous mass that differs in size and composition at different vertebral levels. It consists of fascicles that assume systematic attachments to homologous parts of the skull, the cervical, thoracic and lumbar vertebrae, the sacrum and the ilium. Individual muscles are defined by the attachments of their fascicles and the regions that they span. There are three muscles, each with three regional parts (Table 43.1)

Spinalis Spinalis thoracis is the most medial portion of erector spinae in the thoracic region. It consists of fascicles that arise from the spinous processes of the upper thoracic vertebra and insert into the spinous processes of the eleventh and twelfth thoracic and first two lumbar vertebrae. The number of fascicles and their segmental attachments vary. The fascicles are arranged in an overlapping series of increasingly longer, flat arcs. The shortest fascicles have the lowest origin and highest insertion, and the longest fascicles have the highest origin and lowest insertion. Laterally, the muscle blends intimately with longissimus thoracis and is considered by some to be a component of that muscle.

Spinalis is irregularly and poorly developed in other regions. When present, spinalis cervicis consists of paramedian fibres that arise variously from the spinous processes of the axis and the third and fourth cervical vertebrae, and insert into the lower part of the ligamentum

Fig. 43.72 An axial MRI of the lumbar spine at the level of the L4/5 intervertebral disc.

Table 43.1 Components of erector spinae and their regional parts

| Spinalis | Longissimus | Iliocostalis |

| Spinalis capitis | Longissimus thoracis | Iliocostalis lumborum |

nuchae and the spine of the seventh cervical vertebra (sometimes also to the first and second thoracic vertebrae). Spinalis capitis is represented by occasional fibres of semispinalis capitis that insert into the spines of the seventh cervical and first thoracic vertebrae instead of reaching the thoracic transverse processes.

Longissimus Longissimus is the central component of erector spinae. It assumes a series of attachments at sites that are homologous to the junction of the transverse and costal elements of the segment. These sites are represented at thoracic levels by the tip of a transverse process and the immediately adjacent posterior surface of the rib; at cervical levels by the transverse process and posterior tubercle; and at lumbar levels by the accessory process (the transverse element) and medial half of the transverse process (the costal element).

Longissimus capitis is a narrow flat band of muscle that arises from the posterior edge of the mastoid process, under cover of splenius capitis and sternocleidomastoid. It descends across the lateral surface of semispinalis capitis and inserts by a series of tendons into the transverse processes of the lower three or four cervical and upper four or so thoracic vertebrae.

Longissimus cervicis is a long thin muscle that arises by tendons from the posterior tubercles of the transverse processes of the second to sixth cervical vertebra. It descends into the thoracic region, between the tendons of longissimus capitis and longissimus thoracis, to insert by tendons into the transverse processes of the upper four or five thoracic vertebrae.

Longissimus thoracis is the largest component of erector spinae. It consists of many small fascicles that are aggregated in a particular manner to produce a very long, and in some places thick, muscle. It has lumbar and thoracic parts.

The lumbar part is formed by fleshy bundles that arise from the accessory process and the medial half or so of the posterior surface of the transverse process of each of the five lumbar vertebrae. The fascicles pass inferiorly and slightly laterally. Those from the first four lumbar vertebrae converge on to a common flat tendon that covers the lateral surface of the muscle and separates it from the lumbar fibres of iliocostalis, for which reason it is called the lumbar intermuscular aponeurosis. The aponeurosis commences in the mid-lumbar region, with a broad irregular base, and inferiorly it tapers to a truncated point that inserts into the medial surface of the ilium just dorsal to the ala of the sacrum. The fascicle from the first lumbar vertebra attaches rostrally and dorsally to the aponeurosis. Successive fascicles attach to it more ventrally and caudally. The fascicle from the fifth lumbar vertebra inserts separately, deep to the intermuscular aponeurosis, into the ventromedial aspect of the ilium and the upper fibres of the dorsal sacroiliac ligament. Medially, the lumbar fibres of longissimus are separated from the multifidus by a wide cleavage plane filled with fat and veins.

The thoracic part consists of fascicles with small, fusiform muscle bellies that have short rostral tendons and long caudal tendons. The muscle bellies are arranged in a tiered fashion across the length of the posterior thoracic wall, with the highest lying medially and the lowest lying laterally. The upper four fascicles arise from the tips of the first four thoracic transverse processes. The succeeding fascicles have bifid tendons that arise from the transverse process and the adjacent rib at each of the lower eight thoracic segments. The long caudal tendons of the thoracic fascicles of longissimus are aggregated in parallel to form a wide aponeurosis, which allows them to assume a variety of caudal insertions. The tendons of the uppermost fascicles insert into the lumbar spinous processes and their supraspinous ligament. Those from the first thoracic segment reach the L1-2 level, and those from the sixth thoracic segment reach the L5 level. The fascicles from the seventh to ninth thoracic segments reach the median sacral crest, and those from the tenth and eleventh thoracic segments attach transversely across the posterior surface of the third segment of the sacrum. The fascicle from the twelfth thoracic segment reaches the sacrum and dorsal segment of the iliac crest just below where the intermuscular aponeurosis of the lumbar fibres of longissimus inserts into the ilium. The aponeurosis covers the multifidus and the lumbar fibres of longissimus; it extends from the midline as far laterally as the dorsal edge of the lumbar intermuscular aponeurosis, with which it fuses. Within the lumbar intermus-
cular aponeurosis, the lumbar fibres of longissimus, from L1 to L5, complete the systematic progression of attachments exhibited by the thoracic fibres.

Iliocostalis Iliocostalis is the most lateral component of the erector spinae. Its fascicles are attached to sites that are homologous with the ribs.

Iliocostalis cervicis consists of slender fascicles that arise by long tendons from the posterior tubercles of the fourth, fifth and sixth cervical vertebrae. They descend over the posterior thorax to insert into the third to sixth ribs at their angles.

Iliocostalis thoracis is a narrow, fusiform muscle. The fibres arise from the back of the transverse process of the seventh cervical vertebra and the superior borders of the angles of the upper six ribs; they lie lateral to iliocostalis cervicis, and insert into the upper borders of the angles of the lower six ribs.

Iliocostalis lumborum consists of lumbar and thoracic parts. The lumbar part is formed by fleshy fascicles that arise from the tips of the first four lumbar transverse processes and the posterior surface of the middle layer of thoracolumbar fascia lateral to these tips. These fascicles descend to the ilium in a laminated fashion, such that those from higher levels cover those from lower levels. They insert into the medial end of the iliac crest and the dorsal segment of the iliac crest, with the fascicle from L4 assuming the most ventral and lateral attachment, and the fascicle from L1 assuming the most dorsal and medial attachment. The attachment to the ilium is largely by fleshy fibres but the more superficial fibres are aponeurotic. The thoracic part consists of eight or nine small fascicles that respectively arise from the lower eight or nine ribs at their angles, lateral to the iliocostalis thoracis. Each fascicle arises from its rib by a ribbon-like tendon. The tendons are longer at high levels but become progressively shorter at lower levels. The muscle bellies of the fascicles are uniform in length, and each gives rise to a caudal tendon. These tendons are aggregated to form a dorsal aponeurosis that covers the lumbar part of iliocostalis lumborum and inserts in a linear fashion into the medial end of the iliac crest and its dorsal segment. Along this line the fascicles are represented serially, such that the fascicle from the twelfth rib attaches most laterally and that from the fourth or fifth rib attaches most medial and inferiorly.

Erector spinae aponeurosis Together, the dorsal aponeuroses of the thoracic fibres of longissimus and the thoracic fibres of iliocostalis lumborum form a wide sheet of parallel tendons known as the erector spinae aponeurosis. It is attached to the lumbar spinous processes and supraspinous ligaments, the median sacral crest, the third sacral segment, the dorsal segment of the iliac crest and the medial end of the iliac crest, and covers multifidus and the lumbar fibres of both longissimus and iliocostalis. Significantly, the erector spinae aponeurosis is formed exclusively by the tendons of the thoracic fibres of longissimus thoracis and iliocostalis lumborum; it does not give rise to the lumbar fibres of these muscles, which are attached independently to the ilium. Some of the more superficial fibres of multifidus may insert into the deep surface of the erector aponeurosis over the sacrum, but otherwise the substantive insertion of multifidus is into the sacrum. A portion of the uppermost fibres of gluteus maximus arise from the dorsal surface of the inferolateral corner of the erector spinae aponeurosis. The lumbar intermuscular aponeurosis is a ventral extension of the erector spinae aponeurosis, separating the lumbar fibres of longissimus from those of iliocostalis.

Relations Erector spinae is covered in the lumbar and thoracic regions by the thoracolumbar fascia, and by serratus posterior inferior below and the rhomboids and splenii above. In the lumbar region, it lies in the compartment between the posterior and middle layers of the thoracolumbar fascia.

## Vascular supply See below.

Innervation Erector spinae is innervated by the lateral branches of the dorsal rami of the cervical, thoracic and lumbar spinal nerves. At lumbar levels, lateral branches innervate iliocostalis and intermediate branches innervate longissimus.

Actions The thoracic and lumbar components of erector spinae are powerful extensors of the vertebral column. Acting concentrically and bilaterally they can extend the thoracic and lumbar spines whereas acting unilaterally they can laterally flex the trunk. However, more commonly, erectores spinae act eccentrically.

From the upright posture, the trunk can flex forwards under the influence of gravity. This movement is initiated by flexor muscles, such
as rectus abdominis, in order to bring the centre of gravity of the trunk forwards. Thereafter, erectores spinae control the descent of the thorax under gravity. When the trunk is fully flexed, many parts of erector spinae cease to contract and become electromyographically silent. In this position, flexion is limited by passive tension in the back muscles, and tension in the thoracolumbar fascia, the posterior spinal ligaments and the intervertebral discs. Similarly, lateral flexion under gravity is controlled by the contralateral erector spinae, with input from the abdominal oblique muscles.

The function of the cervical and capital components of erector spinae has not been determined. These are small muscles with very little force capacity, and are poorly orientated to exercise extension or to control flexion of the head or cervical spine. As putative extensors they are dwarfed by semispinalis and splenius. Axial rotation of the head draws longissimus capitis around the perimeter of the cervical spine, orientating it perhaps so that it is able to restore the head to neutral from the rotated position.

## Spinotransverse group

The spinotransverse muscle group consists of muscles where the fascicles span between a spinous process and the transverse elements of vertebrae at various levels below. The muscles are grouped according to the length of their fascicles and the region that they cover (Table 43.2).

Rotatores have the deepest and shortest fascicles, and span one and two segments, whereas the fascicles of multifidus span two, three, four or five segments, and those of semispinalis span about six segments.

Rotatores Rotatores thoracis (Fig. 43.73) consist of eleven pairs of small quadrilateral muscles. The first pair lies between the first and second thoracic vertebrae, and the last between the eleventh and twelfth thoracic vertebrae. One or more may be absent from the upper or lower ends of the series. In each segment, a rotator brevis connects the lower

Table 43.2 Components of the spinotransverse group

| Rotatores | Multifidus | Semispinalis |
| :--- | :--- | :--- |
| Rotatores thoracis | Multifidus | Semispinalis cervicis |
| Rotatores cervicis |  | Semispinalis thoracis |
| Rotatores capitis |  | Semispinalis capitis |

border and lateral surface of the lamina above to the upper, posterior part of the transverse process of the vertebra immediately below; a rotator longus connects the base of the spinous process above to the transverse process two levels below. Rotatores are not obviously present at lumbar and cervical levels, where they may be represented by some of the deeper fascicles of multifidus.

Multifidus At cervical, thoracic and upper lumbar levels, multifidus lies lateral to the spinous processes and covers the laminae of the underlying vertebrae, but at lumbosacral levels it expands to cover the posterior surface of the sacrum (Fig. 43.74). At each segmental level, multifidus is formed by several fascicles that arise from the caudal edge of the lateral surface of the spinous process and from the caudal end of its tip. They radiate caudally to insert into the transverse elements of vertebrae two, three, four and five levels below (Macintosh et al 1986). These sites are represented at cervical levels by the superior articular processes, at thoracic levels by the posterior surface of each transverse process near its base, and at lumbar levels by the mammillary processes. Fascicles that extend beyond the fifth lumbar vertebra insert into the dorsal surface of the sacrum. The longest fascicles from the first and

Fig. 43.74 Multifidus. A, Cervicothoracic parts. B, Lumbosacral parts.

Fig. 43.75 The attachments of semispinalis.
second lumbar vertebrae insert into the dorsal segment of the iliac crest. From each spinous process the shortest fascicles pass inferiorly and laterally to their insertion; the longer fascicles assume a progressively steeper course and are arranged progressively more medially. The fascicles from a given segment are flanked and overlapped dorsolaterally by fascicles from successively higher segments, an arrangement that endows the intact muscle with a laminated structure.

Semispinalis The semispinalis muscles are formed by the longest fascicles of the spinotransverse group. Three divisions are defined essentially by their origins (Fig. 43.75).

Semispinalis cervicis arises from the spinous processes of the second to fifth cervical vertebrae. Its fascicles span about six segments and cover the cervical and thoracic multifidus. They insert by fleshy or tendinous fibres into the posterior surfaces of the upper five or six thoracic transverse processes. The fascicle from the axis is the largest and is composed chiefly of muscle.

Semispinalis thoracis consists of thin, fleshy fascicles that have long tendons at both ends. They arise from the lower two cervical and the upper four thoracic spinous processes, and insert into the transverse processes of the sixth to tenth thoracic vertebrae. They cover the thoracic multifidus.

Semispinalis capitis covers semispinalis cervicis. It arises from the medial part of the area between the superior and inferior nuchal lines of the occipital bone and forms a thick muscle bundle in the suboccipital region. Individual fascicles pass inferiorly, laterally and ventrally from the muscle, ending as flat tendons that insert successively into the superior articular processes of the lower four cervical vertebrae and the tips of the transverse processes of the upper six or seven thoracic vertebrae. The medial part of the muscle in the cervical region is formed by the thoracic fascicles, which are more or less distinct from the rest, and has been called biventer cervicis because it is traversed by an incomplete tendinous intersection.

Semispinalis is not formed in the lumbar region, but vestiges of its caudal tendons are represented as the mammillo-accessory ligaments of the lumbar vertebrae.

Relations At cervical, thoracic and lumbar levels, components of erector spinae lie lateral to the spinotransverse group of muscles. They
are covered at cervical levels by splenius, at thoracic levels by spinalis thoracis, and at lumbar levels by the erector spinae aponeurosis. In the neck, semispinalis capitis lies mainly deep to splenius and trapezius, but a small portion may be exposed to form the uppermost part of the floor of the posterior triangle of the neck.

## Vascular supply See below.

Innervation Rotatores, multifidus, semispinalis thoracis and semispinalis cervicis are all innervated by the medial branches of the dorsal rami of the appropriate spinal nerves. Semispinalis capitis is innervated by descending branches of the greater occipital nerve (C2) and the third cervical nerve (C3).

Actions All the spinotransverse muscles are extensors. They extend the vertebrae from which they arise, or the head in the case of semispinalis capitis. The predominantly longitudinal orientation of their fascicles precludes any substantive action as rotators. Although rotatores have been presumed to rotate the thoracic vertebrae, this action has not been validated. Axial rotation has been expressly refuted as an action of the lumbar multifidus.

## Interspinales

Interspinales are short, paired muscular fasciculi attached above and below to the apices of the spines of contiguous vertebrae, one on either side of the interspinous ligament. They are most distinct in the cervical region, where they consist of six pairs, the first between the axis and third vertebra, and the last between the seventh cervical and first thoracic vertebrae. In the thoracic region they occur between the first and second vertebrae (sometimes between the second and third), and the eleventh and twelfth vertebrae. In the lumbar region there are four pairs between the five lumbar vertebrae. A pair is occasionally found between the last thoracic and first lumbar vertebrae, and another between the fifth lumbar vertebra and the sacrum. Sometimes cervical interspinales span more than two vertebrae.

## Intertransversarii

Intertransversarii are small muscles between the transverse processes of the vertebrae. They are best developed in the cervical region, where they consist of posterior and anterior sets of muscles separated by the ventral rami of spinal nerves. Posterior intertransverse muscles are divisible into medial and lateral slips. Each medial slip, the intertransverse muscle 'proper', is often further subdivided into medial and lateral parts by the passage through it of the dorsal ramus of a spinal nerve. There are seven pairs of these muscles, the highest between the atlas and axis, and the lowest between the seventh cervical vertebra and the first thoracic vertebra; the anterior muscles between atlas and axis are often absent. In the thoracic region, intertransversarii consist of single muscles that span between the transverse processes of the last three thoracic and the first lumbar vertebrae. In the lumbar region, they again consist of two sets of muscles. One set, intertransversarii mediales, connects the accessory process of one vertebra with the mammillary process of the next. The other set, intertransversarii laterales, can be divided into ventral and dorsal parts; the ventral parts connect the transverse processes of the lumbar vertebrae, and the dorsal parts connect the accessory processes to the transverse processes of succeeding vertebrae.

Different parts of the intertransversarii in the cervical and lumbar regions are homologous with certain muscles found in the thoracic region. The homologies are determined according to whether the muscle attaches between consecutive transverse elements of the vertebrae, or between transverse and costal elements, or between consecutive costal elements. They are reinforced by the nerve supply of the muscle, and by the relationship between the muscles and certain nerves.

The medial slips of the 'proper' posterior intertransverse muscles of the neck connect consecutive transverse elements, as do the intertransversarii mediales of the lumbar region. These muscles are homologous with the thoracic intertransverse muscles and ligaments. All are supplied by dorsal rami. The lateral slips of the 'proper' posterior intertransverse muscles connect a transverse element to a costal element, as do the intertransversarii laterales dorsales. They are homologous with levatores costarum and are supplied by the ventral rami of spinal nerves. At each level, the medial branch of a dorsal ramus separates the true intertransverse muscle from levator costae or its equivalent. The anterior intertransverse muscles of the neck and lateral parts of the posterior intertransversarii connect the costal processes of consecutive vertebrae, as do the intertransversarii laterales ventrales of the lumbar region; they are homologous with the intercostal muscles and are supplied by ventral rami.

Actions of interspinales and intertransversarii The functions of interspinales and intertransversarii have not been established. They are very small muscles and are unlikely to be able to generate enough force to be prime movers of the vertebrae. However, they are richly endowed with muscle spindles; the density approaches that found in the lumbricals of the hand and in the extraocular muscles. It therefore seems reasonable to assume that the short muscles of the back may serve a proprioceptive function in controlling the position of the vertebral column and its movements.

## Vascular supply of the true back muscles

The true (intrinsic) muscles of the back receive their blood supply from: the vertebral artery; deep cervical artery; superficial and deep descending branches of the occipital artery; deep branch of the transverse cervical artery (when present); superior intercostal artery, via dorsal branches of the upper two posterior intercostal arteries; posterior intercostal arteries of the lower nine spaces via dorsal branches; dorsal branches of the subcostal arteries; dorsal branches of the lumbar arteries; dorsal branch of arteria lumbalis ima; and dorsal branches of the lateral sacral arteries.

The detailed pattern of the arterial supply of the deep muscles of the back has been described by Michel Salmon (1994). These muscles are supplied by dorsal branches of the posterior intercostal and lumbar arteries. In the thoracic and upper lumbar regions, where the components of erector spinae run in well-defined longitudinal columns, arterial trunks from these dorsal branches run in the sulci between the columns and between erector spinae and multifidus, giving off branches to supply the muscles. This vascular pattern is less regular in the lumbar region.

## Suboccipital muscles

The suboccipital muscles (Fig. 43.76) are four small muscles that connect the occipital bone, atlas and axis posteriorly. They lie inferior to the anterior part of the occipital bone, where three of the muscles form the boundaries of the suboccipital triangle: rectus capitis posterior major lies above and medially; obliquus capitis superior lies above and laterally, and obliquus capitis inferior lies below and laterally. With the head in the anatomical position, the suboccipital triangle lies almost in the horizontal plane.

Rectus capitis posterior major Rectus capitis posterior major is attached by a pointed tendon to the spine of the axis, becomes broader as it ascends, and is attached to the lateral part of the inferior nuchal line and the occipital bone immediately below it. As the muscles of the two sides pass upwards and laterally, they leave between them a triangular space in which parts of recti capitis posteriores minores are visible.

Rectus capitis posterior minor Rectus capitis posterior minor is attached by a narrow pointed tendon to the tubercle on the posterior arch of the atlas. As it ascends, it broadens before attaching to the medial part of the inferior nuchal line and to the occipital bone between the inferior nuchal line and the foramen magnum. Either muscle may be doubled longitudinally. There is usually a soft tissue attachment to the posterior atlanto-occipital membrane, which itself is firmly attached anteriorly to the spinal dura in the same area (Zumpano et al 2006).
Obliquus capitis inferior Obliquus capitis inferior, the larger of the two oblique muscles, passes laterally and slightly upwards from the lateral surface of the spine and the adjacent upper part of the lamina of the axis to the inferoposterior aspect of the transverse process of the atlas.

Obliquus capitis superior Obliquus capitis superior is attached by tendinous fibres to the upper surface of the transverse process of the atlas. It expands in width as it ascends dorsally, and is attached to the occipital bone between the superior and inferior nuchal lines, lateral to semispinalis capitis and overlapping the insertion of rectus capitis posterior major.
Relations of the suboccipital triangle Medially, the suboccipital triangle is covered by a layer of dense adipose tissue, deep to semispinalis capitis. Laterally, it lies under longissimus capitis and sometimes splenius capitis, both of which overlap obliquus capitis superior. The 'floor' of the triangle is formed by the posterior atlanto-occipital membrane and the posterior arch of the atlas. The vertebral artery and the dorsal ramus of the first cervical nerve lie in a groove on the upper surface of the posterior arch of the atlas.
Vascular supply The suboccipital muscles receive their blood supply from the vertebral artery and deep descending branches of the occipital artery.

Fig. 43.76 The suboccipital triangles, posterior view. (From Drake RL, Vogl AW, Mitchell A, et al (eds), Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2008.)

Innervation All the suboccipital muscles are supplied by the dorsal ramus of the first cervical spinal nerve.

Actions of the suboccipital muscles The suboccipital muscles are involved in extension of the head at the atlanto-occipital joints and rotation of the head and atlas on the axis. Obliquus capitis superior and the two recti are probably more important as postural muscles than as prime movers but this is difficult to confirm by direct observation. Rectus capitis posterior major extends the head and, acting with obliquus capitis inferior, rotates the face towards the ipsilateral side. Rectus capitis posterior minor extends the head. Obliquus capitis superior extends the head and laterally flexes it to the ipsilateral side.

## MOVEMENTS OF THE VERTEBRAL COLUMN

Spinal movements between individual vertebrae cannot be measured accurately by skin-surface techniques; only biplanar radiography is sufficient for this purpose. Movements of the entire lumbar spine can be measured using skin-surface techniques, but the results are of limited clinical use because there is high inter- and intra-observer variation (Pearcy et al 1984, Pearcy and Tibrewal 1984).

The intervertebral discs are the principal sites of vertebral column movement. Conversely, at most levels, the extent to which the discs may be deformed is also the limiting factor for motion. Bony deformation in the subchondral bone and articular cartilage may contribute to movement. Regional variations in mobility of the spine depend on the geometry, orientation and properties of the facet joints and related ligamentous complexes. Physiological intervertebral movements usually combine tilting (bending) and gliding (shear), so the instantaneous centre of rotation moves continually during the movement. During flexion and extension of the lumbar vertebrae, the centre of rotation usually lies near the centre of the intervertebral disc when viewed in the transverse plane, close to the superior end-plate of the vertebra below.

The oblique and ovoid articular surfaces of the facet joints ensure that spinal movements in different planes are usually 'coupled' to a certain extent. For example, lateral flexion would cause impingement of the articular surfaces on that side, leading to a posteriorly directed force on the upper vertebra that would act to rotate it about its long axis. Physiologically, coupled movements are variable. Although movements between individual vertebrae are small, their summation gives a large total range to the vertebral column in flexion, extension, lateral flexion and axial rotation. Each pair of vertebrae with its interposed disc and ligaments is termed a motion segment or functional spinal unit.

In flexion, the anterior longitudinal ligament becomes relaxed as the anterior parts of the intervertebral discs are compressed. At its limit, the posterior longitudinal ligament, ligamenta flava, interspinous and supraspinous ligaments, and the posterior fibres of the intervertebral discs are all tensed, the interlaminar intervals widen, the inferior articular processes glide on the superior processes of subjacent vertebrae, and their capsules become taut. Tension of extensor muscles is also important in limiting flexion, e.g. when carrying a load on the shoulders. Flexion is effectively absent in the thoracic region. In forward flexion of the lumbar spine, the muscles normally protect the osteoligamentous spine from injury. However, the margin of safety can be compromised during repetitive or sustained bending by a failure of the spinal reflexes. Once the muscle protection is lost, flexion injury affects first the interspinous ligaments and then the capsules of the facet joints. The ligamentum flavum has such a high content of elastin that it is always under tension, and can be stretched by $80 \%$ without damage. This ligament probably functions to provide a constant smooth lining to the vertebral canal, which is never overstretched in flexion and which never goes slack in extension.

In extension, the opposite events occur and there is compression of posterior discal fibres. Extension is limited by tension of the anterior longitudinal ligament, anterior discal fibres and impaction of spines or articular processes. It is marked in cervical and lumbar regions, and much less at thoracic levels, partly because the discs are thinner, but also because of the presence of the ribs and chest musculature. In full extension, the axis of movement passes posterior to the disc, moves forwards as the column straightens and passes into flexion, and reaches the centre of the intervertebral disc in full flexion.

In lateral flexion, which is always combined with 'coupled' axial rotation, intervertebral discs are laterally compressed and contralaterally tensed and lengthened, and motion is limited by tension of antagonist muscles and ligaments. Lateral movements occur in all parts of the column but are greatest in cervical and lumbar regions.

Axial rotation involves twisting of vertebrae relative to each other with accompanying torsional deformation of intervening discs. About $50 \%$ of cervical rotation occurs at the atlanto-axial joint. Elsewhere in the column, although movement is slight between individual vertebrae, the range summates to become considerable for the column as a whole. In the postcervical column, the effective range of rotation is greatest at the thoracolumbar junction. There is very little rotation in the remainder of the lumbar region.

In the cervical region, the upward inclination of the superior articular facets allows free flexion and extension. The latter is usually greater, and is checked above by locking of the posterior edges of the superior facets of C1 in the occipital condylar fossae, and below by slipping of the inferior processes of C 7 into grooves inferoposterior to the first thoracic superior articular processes. Flexion stops where the cervical convexity is straightened, checked by apposition of the projecting lower lips of vertebral bodies on subjacent bodies. Cervical lateral flexion and rotation are always coupled, and the superomedial inclination of the superior articular facets imparts rotation during lateral flexion.

Cervical motion can be considered to involve the upper (i.e. the atlanto-occipital and atlanto-axial complexes) and the lower cervical spine (C3-7). Two physiological movements take place at the atlantooccipital joints: those of flexion-extension and lateral flexion. The atlanto-axial joints allow flexion-extension and rotation. Some studies have suggested that maximum flexion-extension occurs between the occiput and C1; however, Frobin et al (2002) noted between $12.6^{\circ}$ and $14.5^{\circ}$ at this level, which is less than at some of the other cervical levels. Global cervical flexion ranges from $45^{\circ}$ to $58^{\circ}$, depending on the method of assessment, age and sex; older subjects and females exhibit less motion (Ordway et al 1997, Trott et al 1996). At an intersegmental level, motion increases from the second cervical level and peaks at the mid-cervical level ( $14-17^{\circ}$ recorded at $\mathrm{C} 4 / 5$ ), before reducing at the junction of the cervical and thoracic spine ( $9.8-11.5^{\circ}$ noted at C6/7) (Frobin et al 2002). Global ranges of lateral flexion range from $32^{\circ}$ to $47^{\circ}$, with a gradual reduction in range with age and sex, while rotational movements range from $63^{\circ}$ to $78^{\circ}$. Intersegmental ranges of motion vary from $4.7^{\circ}$ to $6^{\circ}$ for lateral flexion between C2 and C7, and $2-12^{\circ}$ for rotation (White and Panjabi 1990).

In the thoracic region, especially superiorly, all movements are limited, reducing interference with respiration. Lack of upward inclination of the superior articular facets prohibits much flexion, and extension is checked by contact of the inferior articular margins with the laminae and of adjacent spines. Thoracic rotation is freer, though limited by the ribs at upper levels. Its axis is in the vertebral bodies in the mid-thoracic region, and in front of them elsewhere, so that rotation involves some lateral displacement. The direction of articular facets would allow free lateral flexion but this is limited in the upper thoracic region by the resistance of the ribs and sternum. Rotation is usually combined with slight lateral flexion to the same side.

Movement in the thoracic spine is frequently regionalized to upper, mid- and lower thoracic. In the upper thoracic, flexion ranges from $7.8^{\circ}$ to $9.5^{\circ}$, increasing to $10-11.4^{\circ}$ in the mid-thoracic and $12.5^{\circ}-12.8^{\circ}$ in the lower thoracic (Willems et al 1996). Extension is more consistent, ranging from $7.1^{\circ}$ to $9.7^{\circ}$ throughout the thoracic spine. Lateral flexion is greater in the lower thoracic spine, ranging from $5.6^{\circ}$ to $6.2^{\circ}$ in the upper thoracic, $7.9^{\circ}$ to $8.1^{\circ}$ in the mid-thoracic and $11.9^{\circ}$ to $13.2^{\circ}$ in the lower thoracic. However, rotation is greatest in the mid-thoracic region, being $11.8^{\circ}-15.9^{\circ}$ in the upper thoracic, $21.5^{\circ}-25.3^{\circ}$ in the mid-thoracic, and $8.3^{\circ}-11.8^{\circ}$ in the lower thoracic.

Flexion movements are generally greater than extension or lateral flexion in the lumbar region. Axial rotation occurs about a centre of rotation in the posterior anulus, and is limited by bony contact in the facet joints after only $1-2^{\circ}$ of movement. Functional transition between thoracic and lumbar regions is usually between the eleventh and twelfth thoracic vertebrae, where the facet joints usually fit so tightly that slight compression locks them, and prevents all movements but flexion.

During flexion of the lumbar spine there is an unfolding or straightening of the lumbar lordosis. Thus in full flexion the lumbar spine assumes a straight alignment or is curved slightly forwards. Normal ranges of global lumbar flexion range from $58^{\circ}$ to $72^{\circ}$ in those under 40 years old and $40^{\circ}$ to $60^{\circ}$ in the over-forties; females exhibit a reduced range compared with males (Dvorak et al 1995, McGregor et al 1995). At an intersegmental level, the L3/4 junction and L4/5 junction exhibit the greatest mobility - approximately $12^{\circ}$ and $13^{\circ}$ respectively, while at the lowest level (L5/S1) there is only $9^{\circ}$, and at the upper lumbar levels only $8^{\circ}$ and $10^{\circ}$ respectively (Pearcey et al 1984). Movements into extension are the converse of those seen in flexion. Normal ranges of global extension range from $25^{\circ}$ to $30^{\circ}$ in those under 40 years old and $15^{\circ}$ to $20^{\circ}$ in those over forty. At an intersegmental level, L5/S1 and L1/2 exhibit the greatest mobility at approximately $5^{\circ}$, while
the remaining levels exhibit less than $5^{\circ}$ of extension. Ranges of lateral flexion and rotation in the lumbar spine are reduced compared to other regions of the spine. Global lateral flexion ranges from $20^{\circ}$ to $35^{\circ}$, and rotation ranges from $25^{\circ}$ to $40^{\circ}$; the ranges of both movements are reduced with age. Assessment of intersegmental rotation and lateral flexion has proven difficult because of the limitations of measurement techniques.

## ROLE OF MUSCULATURE

Although muscles will move the spinal column, the majority of muscular activity is involved in providing stability to maintain posture and to provide a firm platform for limb function. Hence the concept of 'core stability' in modern rehabilitation programmes, especially in sportsrelated problems.

It is important to recognize the way in which the muscles of the back work in conjunction with those of the abdominal wall, particularly the oblique and transversus muscles, and with those of the lower limbs. The erector spinae group and internal oblique and transversus abdominis are anatomically and functionally connected by the thoracolumbar fascia (which encloses the former, and into which the latter are inserted). This fascia, together with collagenous tissue within the back muscles, plays an important role in resisting forward bending of the trunk, and during manual handling. The fascia is tensioned primarily by flexing the trunk, although this tension may be enhanced slightly by the lateral pull of the abdominal muscles. It is functionally advantageous to generate tension in the fascia and muscle sheaths because the elastic strain energy stored in these stretched tissues can be used to help bring the trunk to an upright position and so reduce the metabolic cost of the movement (Adams et al 2006). The thoracolumbar fascia may also have an important function in transferring load between the trunk and the lower limbs; tension in the fascia can be increased by the actions of gluteus maximus and the hamstrings as well as by trunk flexion.

## Muscles producing vertebral movements

The spinal column is moved both directly by muscles attached to it, and indirectly by muscles attached to other bones. Gravity always plays a part: movements with gravity usually involve the eccentric contraction of antagonists. Flexion is effected by longus capitis and longus colli, scaleni, sternocleidomastoid and rectus abdominis of both sides, aided in the lumbar region by the abdominal obliques; extension by the erector spinae complex and the transversospinalis group, splenius, semispinalis capitis and trapezius of both sides, together with the suboccipital muscles; lateral flexion by ipsilateral longissimus, iliocostalis, abdominal obliques and flexors, and quadratus lumborum; and rotation by sternocleidomastoid, splenius cervicis, abdominal obliques, rotatores and multifidus.

## FACTORS INVOLVED IN STABILITY

The vertebral column is remarkable in that it combines mobility, stability and load-bearing capacity and also protects its contained neural structures, irrespective of its position. Much of the stability of the vertebral column depends on dynamic muscular control but there are also bony and ligamentous 'static' stabilizers. There is considerable variation between segments of the column in terms of stability and mobility; the most mobile levels are the least stable. The latter are those in which the ratio of intervertebral disc height to vertebral body height is highest. Stability may be compromised by damage to any of these structures.

Trauma may affect any vertebral region. Levels of specialized mobility (e.g. atlanto-axial joint) and the junctions of mobile and relatively fixed regions (e.g. cervicothoracic, thoracolumbar) are particularly vulnerable to severe structural damage, often accompanied by spinal cord and nerve injury. Injuries of the vertebral column may affect purely soft tissue (ligaments, joint capsules and muscles) or may affect bony structures (see Fig. 43.58). Pure ligamentous/capsular injuries leading to instability may be particularly difficult to diagnose in the absence of gross radiological signs. In the cervical spine, subluxation and dislocation of the facet joints commonly occur without bony injury because of the orientation of the articular facets.

Chronic infections of many types (e.g. tuberculosis) may involve the vertebrae and lead to their deformity and collapse, affect their mechanical properties and compromise their neuroprotective function. Acute infections, spreading locally or via the blood stream, may lead to the
collection of pus within the vertebral canal, causing spinal cord compression (epidural abscess).

The integrity of the vertebrae may also be affected by malignant disease, most commonly metastatic. Vertebrae have a copious blood supply throughout life, and many of the common cancers (e.g. breast, bronchus) spread via the arterial system. Cancers of the haemopoietic system (e.g. multiple myeloma) also commonly affect the vertebrae. Prostatic carcinoma has a predilection to metastasize to the vertebral column, often using the venous (Batson's plexus) rather than the arterial route (Batson 1957). Metastatic deposits may occur within the epidural space, compressing the contents of the dural sac at multiple levels.

Systemic inflammatory diseases may cause both deformity and instability of the vertebral column. Rheumatoid arthritis inflames facet joints and weakens ligaments, leading to instability, especially in the cervical spine (see Fig. 43.57). Ankylosing spondylitis and other seronegative arthritides affect joints and ligamentous attachments (entheses), leading to ectopic ossification of collagenous structures, fusion (ankylosis) of interbody and facet joints, and loss of the normal spinal curvatures. Widespread new bone formation at and around the joints of the column occurs in DISH (diffuse idiopathic skeletal hyperostosis). Such conditions would seem to increase stability of the column, at the expense of its mobility and function, but an ankylosed spine is very liable to fracture, with an associated risk of neural damage.

Full stability and load-bearing capacity both require intact vertebral bodies and intervertebral discs. Earlier views regarding the relative importance of the disc-body complex and the posterior elements have proved somewhat simplistic. Clinical observation led to the 'threecolumn concept' of spinal stability, in which the column is divided into three longitudinal parts rather than two (Denis 1983). The anterior column is formed by the anterior longitudinal ligament, the anterior half of the vertebral body and the anterior anulus fibrosus. The middle column is made up of the posterior longitudinal ligament, the posterior half of the vertebral body and pedicles, and the posterior anulus fibrosus. The posterior column consists of the neural arch and facet joints and the posterior ligamentous complex. The more columns that are affected, the worse is the instability; an injury to two columns is usually unstable.

Although regarded as the most influential system for classifying thoracolumbar spinal injuries, the concept was criticized for oversimplifying the biomechanics of injury. A more recent classification system, aided by improved computed tomographic imaging, stresses the importance of the posterior ligamentous complex in determining the stability of the injured spine in addition to the morphology of the injury (compression, translational/rotational or distraction injuries) and the neurological status of the patient (intact, nerve root injury, complete or incomplete spinal cord injury, cauda equina syndrome) (Lee et al 2005).

The elastic deformability of intervertebral discs permits tilting and axial rotation between vertebral bodies, and also helps to reduce vertical accelerations of the head. The main shock-absorbing mechanism of the column stems from the spinal curves, which increase and decrease slightly during locomotion against the restraining tension of the trunk muscles. The elastic strain energy in the stretched tendons of the muscle is responsible for shock absorption.

Both body height and spinal stability are subject to a marked diurnal variation. Body height is affected by changes from recumbency to the upright posture. These diurnal variations appear to be due to changes that occur within the cervical, thoracic and lumbar regions of the spine. Investigations using stereophotogrammetry have demonstrated that $40 \%$ of diurnal changes occur in the thoracic spine and affect the degree of kyphosis, and a further $40 \%$ in the lumbar spine, but do not affect the lordosis (Wing et al 1992). The greatest change in vertebral column length is found in adolescents and young adults. The height loss occurs within 3 hours of rising in the morning, with an overall loss of about 15 mm .

Although the curvatures within the vertebral column contribute to the changes in height, changes within the intervertebral disc contribute both to observed height loss and to variation in stability. Magnetic resonance imaging investigations reveal a dynamic movement of fluid into and out of an intervertebral disc and adjacent vertebral body over a 24 -hour period. Body position affects the movement of fluid. In the early morning, the discs are swollen with water, the intervertebral ligaments and the anulus fibrosus are taut, and the intrinsic bending stiffness and stability of the osteoligamentous spine are relatively high. After several hours of normal activity, the discs lose approximately $20 \%$ of their water and height. This change makes the ligaments slack and greatly reduces the bending stiffness of the spine, so that relatively more of the stability of the spine must then be provided by the musculature.

The diurnal expulsion of water from intervertebral discs also affects the distribution of compressive loading in the spine. As the day progresses, the hydrostatic pressure in the nucleus pulposus falls, and stress concentrations arise in the anulus fibrosus and facet joints.

All ligaments of the column, as well as the facet joint capsules, are important in the maintenance of stability. The anterior longitudinal ligament is very strong, and resists translational displacement (shear) of the vertebrae as well as extension. All the ligaments of the posterior complex resist flexion and rotation, and their integrity determines the range of movements allowed. These ligaments can support the whole column when the muscles are inactive, e.g. in quiet standing. At the limit of lumbar flexion, the column is supported mainly by the thoracolumbar fascia and by collagenous tissue within the electrically silent muscles of the back.

Movements are both determined and constrained by the shape and orientation of the facet joints, whose articular surfaces stabilize the column primarily by resisting horizontal gliding (shear) movements and axial rotation. In the most mobile regions, the joint surfaces are flatter and more horizontally placed, as will become apparent if a typical cervical facet joint is compared with a typical lumbar joint.

Certain regions of the vertebral column are further stabilized by additional extraspinal factors. The thoracic spine is stabilized by its position as an integral part of the thoracic cage and by its strong ligamentous linkages with the ribs. The sacrum is effectively a virtually fixed integral element of the bony pelvis.

The contribution to stability conferred by the musculature has been grossly underrated. The whole vertebral column is stabilized by the 'guy-rope' or staying effect of the long muscles that attach it to the girdles, the head and the appendicular skeleton. This effect is particularly marked for erector spinae, which controls global posture and movement. The small and deep muscles of the back are best able to resist shear movements between vertebrae because only they have sufficient angulation to the long axis of the vertebral column to do this effectively. The deep muscles can also fine-tune intervertebral movements.

For most back problems in clinical practice, especially chronic low back pain, enhancing muscle strength, stamina and coordination with the many other muscle groups that contribute to stability, e.g. pelvic girdle muscles, is the most appropriate and effective therapeutic avenue. Only a minority of cases benefit from surgery. Furthermore, neglecting the musculature may explain the relatively high failure rates from surgery.

Mechanical injury to the vertebral column may be produced by flexion, extension, distraction, rotation, shear or compression; movements that cause damage are commonly combined, e.g. flexion, axial rotation and compression.

## POSTURE AND ERGONOMICS

Posture is a descriptive term for the relative position of the body segments during rest or activity. The maintenance of good posture is a compromise between minimizing the load on the spine and minimizing the muscle work required.

The well-balanced erect body has a line of gravity that extends from the level of the external auditory meatus, through the dens of the axis just anterior to the body of the second thoracic vertebra, through the centre of the body of the twelfth thoracic vertebra, and through the rear of the body of the fifth lumbar vertebra to lie anterior to the sacrum. The position of the line of gravity may move anteriorly with locomotion and may vary between individuals.

The normal curvature of the cervical spine is a lordosis. However, as a result of pain, injury or poor ergonomics, this curve can become exaggerated to give a 'protruding chin' stance, i.e. hyperlordosis in the lower cervical spine.

The thoracic spine is held convex posteriorly, and this posture primarily results from the structure of the underlying vertebrae. However, this curve or kyphosis can become exaggerated to give the impression of a rounded back. Poor posture and ergonomics can lead to this exaggerated curvature but other important causes include tuberculosis, a wedge or compression fracture of a vertebral body, Scheuermann's osteochondritis, ankylosing spondylitis, osteoporosis and metastatic carcinoma.

The lumbar spine is held in a lordosis. The degree of this lordosis is determined by the lumbosacral angle and is normally $30-45^{\circ}$. The muscles responsible for this posture include erector spinae, rectus abdominus, the internal and external obliques, psoas major, iliacus, the gluteal and hamstring muscles. The lordosis can be increased (as a result of weak abdominal muscles and tight hamstring muscles), decreased,
flattened (common in people with either acute or chronic low back pain) or reversed.

A common postural deviation seen throughout the spine is scoliosis or lateral curvature of the spine. It can be structural, compensatory or protective. In structural scoliosis, the lateral curvature is associated with vertebral rotation, and both the curve and the rotation become more accentuated on forward flexion. Such a scoliosis is common in adolescent girls and its cause is unknown. It may also be secondary to an underlying disorder, e.g. muscular dystrophy, spinal muscular atrophy or spina bifida. A compensatory scoliosis occurs when the pelvis is tilted laterally, e.g. as a result of unequal leg length or of a fixed abduction or adduction deformity at the hip joint. Usually, there is no intrinsic abnormality of the spine itself and the scoliosis disappears when the pelvic tilt is corrected. A sciatic or antalgic scoliosis is a temporary deformity produced by the protective action of muscles in certain painful conditions of the spine.

Ergonomics has been defined as 'the way humans work', and it permits an appreciation of the effects of tasks and the work environment on underlying postural biomechanics. Nachemson (1975) showed that discs were loaded maximally in sitting and in lifting in a forward-leaning position, so sitting posture and lifting have received considerable ergonomic attention.

In sitting, the goal has been to determine the seat type and reclining angle associated with lowest disc pressure and the least paraspinal muscle activity. When sitting with the hips and knees flexed to $90^{\circ}$, the pelvis rotates posteriorly, flattening the lumbar lordosis and consequently increasing the load on the intervertebral discs. Thus it is now advised that, in sitting, the angle between trunk and thigh should be between $105^{\circ}$ and $135^{\circ}$, with the sacrum tilted at $16^{\circ}$ and the fourth and fifth lumbar vertebrae supported.

In lifting heavy weights, there is considerable initial compression of lumbar intervertebral discs, and large increases in thoracic and intraabdominal pressure. The compressive force acting on the spine is shared between the vertebral bodies and the neural arch. In the lumbar spine, the neural arch typically resists $20 \%$ of this force once the disc height has been reduced by diurnal fluid expulsion, and when the spine is positioned upright. However, age-related narrowing of the disc can cause more than $50 \%$ of the compressive force to be resisted by the neural arch, which may explain why osteoarthritis of the facet joints commonly follows disc degeneration.

When lifting, manual handling advisers emphasize the importance of leg lifting as opposed to back lifting. Loads should also be kept close to the body to reduce the lever arm of the load. The use of deep inspiration to raise intra-abdominal pressure while lifting has also been advised, as this is believed to offer further support to the lumbar spine. The spine is at risk when lifting is combined with twisting, lateral bending and asymmetric postures. However, heavy lifting remains one of the key work-related risk factors for the spine together with wholebody vibration, prolonged sitting, twisting and bending.

## SURFACE ANATOMY

## SKELETAL LANDMARKS

## Vertebral spines

In the midline, a median furrow runs from the external occipital protuberance above to the natal cleft below (Figs 43.77, 43.78). The furrow is most shallow in the lower cervical region and is deepest in the midlumbar zone. Inferiorly, it widens out into a flattened, triangular area, the apex of which lies at the start of the natal cleft and corresponds approximately to the spine of the third sacral vertebra. Palpation of the median furrow reveals the sagittal curves of the spine (see Fig. 43.78): the cervical curve is convex anteriorly (lordosis) and extends from the first cervical to the second thoracic vertebra; the thoracic curvature is concave anteriorly (kyphosis) and extends from the second to the twelfth thoracic vertebra; and the lumbar curvature is convex anteriorly and extends from the twelfth thoracic vertebra to the lumbosacral prominence. The external occipital protuberance is subcutaneous and is palpable on the posteroinferior aspect of the cranium when it is approached from below. The inion is the point situated on this protuberance in the median plane. The tubercle on the posterior arch of the atlas ( C 1 ) is impalpable, whereas the transverse process of C 1 is palpable as an indistinct mass through sternocleidomastoid just inferior to the apex of the mastoid process. The spinous process of C 2 is the first palpable midline feature, located several centimetres inferior to the inion. The tips of the spines of most cervical vertebrae are obscured by

Fig. 43.77A-C The surface anatomy of the back. Key: A, 1, median furrow; 2, spine of scapula; 3, trapezius (between solid black lines); 4, triangle of auscultation; 5, latissimus dorsi (between dashed black lines); 6, lumbar (Petit's) triangle; 7, posterior superior iliac spine; 8, superior part of natal cleft (approximates S3). B, 9, ligamentum nuchae; 10, spinous process of C7 (vertebra prominens); 11, spinous process of T1. C, 1, erector spinae (black line represents lateral border); 2, zone of spinal cord termination (white): ranges from the middle third of T11 to the middle third of L3; 3, mean level of spinal cord termination (red): middle third of L1 vertebral body which corresponds with the lower part of the interspinous space between T12 and L1; 4, rib 12 (dashed black line); 5, zone of supracristal plane intersection with vertebral column (blue): ranges from the L2-L3 junction to the L4-L5 junction/ interspinous space; 6 , highest point of iliac crest and supracristal plane (Tuffier's line): almost always intersects the vertebral column from L4 to the L4/5 junction; 7, posterior superior iliac spine and interspinous plane, marked by a skin indentation (dimple of Venus). Note the overlap between zone 5 and the zone of spinal cord termination.

Fig. 43.78 The surface anatomy of the back, oblique view. Key: 1, trapezius (upper fibres); 2, median furrow; 3, spine of scapula; 4 , trapezius (lower fibres overlying erector spinae); 5, triangle of auscultation; 6 , inferior angle of scapula; 7, erector spinae; 8, lumbar (Petit's) triangle; 9, posterior superior iliac spine; 10, superior part of natal cleft: approximates the spinous process of S3; C7, T7, spinous processes of vertebrae C7 and T7.
the overlying ligamentum nuchae, which forms a palpable raised midline ridge when the neck is flexed. The ligamentum nuchae terminates inferiorly at the spine of the seventh cervical vertebra (C7, vertebra prominens), which is the most superior visible projection in this region. The spine of the first thoracic vertebra (T1) is palpable immediately inferior to it and is usually more prominent than the spine of C7. Identification of the remaining thoracic spines is not easy, even in a thin subject when the trunk is fully flexed, because they overlap one another in the mid-thoracic region. In the upper and lower thoracic regions, the tips of the thoracic spines lie opposite the upper part of the vertebral body below. In the mid-thoracic region, they lie opposite the lower part of the vertebral body below. The tip of the spine of each lumbar vertebra can usually be palpated without difficulty, especially if the trunk is

Table 43.3 Vertebral spines as landmarks for the viscera

| Spine/ <br> space | Vertebral body level | Viscera |
| :---: | :---: | :---: |
| C5 | C6 | Cricoid cartilage; start of oesophagus |
| C7 | C7-T1 | Lung apex |
| T3 | Upper T4 | Aorta reaches vertebral column; medial part of scapular spine |
| T3-T4 space | T4-5 disc | Sternal plane/angle of Louis |
| T4 | Upper T5 | Tracheal bifurcation; concavity of aortic arch; azygos vein-superior vena cava junction; bifurcation of pulmonary trunk; upper border of heart |
| T7 | Upper T8 | Inferior angle of scapula; lower border of heart; inferior vena cava crosses diaphragm; central tendon of diaphragm |
| T10 | Upper T11 | Lower border of lung; cardia of stomach; upper border of kidney |
| $\begin{aligned} & \text { T12-L1 } \\ & \text { space } \end{aligned}$ | Mid L1 | Lowest level of pleura; pylorus; transpyloric plane; hilum of left kidney; origin of renal arteries and superior mesenteric artery; pancreas (neck); spinal cord termination |
| L1-L2 space | Mid L2 | Pancreas (head); duodenojejunal flexure |
| L2-L3 space | Mid L3 | Lower border of kidney |
| L3-L4 space | Mid L4 | Bifurcation of aorta |
| L4-L5 space | Mid L5 | Formation of inferior vena cava |

flexed. Each lies opposite the inferior part of its own vertebral body and the inferiorly located intervertebral disc. The interspinous spaces are represented by a palpable depression between adjacent spines.

## Spinal levels of viscera

In adults, the spinal cord terminates, on average, level with the middle third of the body of L1 (ranging from the middle third of T11 to the middle third of L3): $25 \%$ of cords end below the level of the L1/L2 intervertebral disc (Macdonald et al 1999). In children, the reported level of spinal cord termination varies according to the breadth of the age range studied. On average, the cord terminates at the lower third of the body of L1 (ranging from the lower third of T12 to the middle of L2) (Kesler et al 2007), but may terminate as low as L3 in younger children (Malas et al 2001). The palpable vertebral spines can be used as landmarks for the levels of the viscera. Some of the more important are shown in Table 43.3 (minor differences between the two sides are ignored).

## Scapular landmarks

The shape of the back in the upper thoracic region is determined largely by the scapula and the muscles attached to it. Bony scapular landmarks are most evident when the upper limbs hang by the sides (see Figs 43.77A, 43.78).

The scapula overlies the second to seventh ribs. Its superior angle is palpable through trapezius, and its inferior angle through latissimus dorsi; these angles are joined by the medial border of the scapula, which runs vertically. The scapular spine runs subcutaneously and is easily palpable from its root medially to the acromial angle and process laterally. When the upper limb is by the side, the spinous process of T3 is level with the spine of the scapula, and the T7 spinous process is level with the inferior angle.

## Posterior pelvic and sacrococcygeal bony landmarks

At the lower part of the back, the entire iliac crest can be palpated. It can be traced backwards and upwards from the anterior superior iliac spine to its highest point, and then downwards and medially to the posterior superior iliac spine, which is overlain by a dimple in the skin. For landmarking during lumbar puncture (see Fig. 45.18), a line (Tuffier's) joining the highest points of the iliac crests is used. This line crosses the vertebral column at the level either of the body of L4 or of the L4/L5 intervertebral disc in the majority of subjects (Render 1996, Walsh et al 2006, Chakraverty et al 2007) (Fig. 43.78). Greater variability occurs in neonates, females and subjects with a higher body mass index. It is important to remember that when a subject lies on their side, the median soft tissue furrow may not coincide with the median plane, especially in the lumbar region in higher body mass subjects. Careful palpation may be necessary to identify the vertebral spinous processes in this position. The spines of the sacral vertebrae are smaller and less well defined than those of the other vertebrae. Palpation places the posterior superior iliac spines along a line that ranges from the L5-S1 vertebral junction to the S2 spinous process (Kim et al 2007), whereas radiographic assessment shows the inferior margin of the posterior superior iliac spines to be almost always coincident with the second sacral spine (McGaugh et al 2007) (see Fig. 78.16). The latter serves as a useful landmark for the inferior limit of the adult dural sac. The tip of the coccyx can be felt deeply near the centre of the natal cleft. Moving the examining finger cranially enables palpation of the raised ridges of the sacral cornua on either side of the midline; they demarcate the sacral hiatus and so form the landmark for performing a caudal anaesthetic block (see Figs 45.19, 45.20).

## MUSCULOTENDINOUS LANDMARKS

In the upper and middle cervical region, a median furrow lies between the cylindrical prominences formed mainly by the semispinalis muscles, which are accentuated by neck extension against resistance. In the tho-
racic and lumbar regions, a broad elevation produced by the erector spinae muscle group extends for about one hand's breadth on either side of the median furrow and is present between the iliac crest and the twelfth rib (see Fig. 43.78). The lateral border of this elevation then crosses the ribs at their angles, passing medially as it ascends. The muscle group can be demonstrated by extending the back against resistance.

Trapezius is a flat, triangular muscle that covers the back of the neck and shoulder (see Figs 43.69 and 43.77A). The two trapezius muscles resemble a trapezium in which two of the angles correspond to the shoulders, a third to the external occipital protuberance and the fourth to the spine of the twelfth thoracic vertebra. On each side, the anterosuperior border of the muscle forms the posterior boundary of the posterior triangle of the neck; it can be seen in muscular subjects, especially during shoulder elevation against resistance or by extension and lateral flexion of the neck against resistance. The lower fibres are best seen when the subject pushes both hands against a wall with the elbows extended.

Latissimus dorsi occupies the lower half of the back. It passes from the spines of the vertebrae from T7 inferiorly, the thoracolumbar fascia and the posterior iliac crest, to the posterior axillary fold. In lean subjects, with the arm adducted against resistance, the inferolateral border can easily be traced to the iliac crest. The upper border passes horizontally from the spinous process of T7 to the inferior angle of the scapula and on to the posterior axillary fold.

The triangle of auscultation (see Figs 43.69, 43.77A) lies between the upper border of latissimus dorsi, the lower inferolateral border of trapezius and the inferomedial border of rhomboid major, although for simplicity the medial border of the scapula is often substituted for the latter muscle.

The lumbar (Petit's) triangle (see Figs 43.69, 43.77A), one of the sites of the rare primary lumbar hernia, lies inferiorly just lateral to the highest point of the iliac crest, between the inferolateral border of latissimus dorsi, the posterior free border of external oblique and the iliac crest.

## CLINICAL EXAMINATION

Clinical examination of the back of the trunk and neck best follows the order of inspection, palpation and movement. The examination will be determined by the circumstances of presentation and by the history, and may include musculoskeletal, neurological and vascular observations. Information relevant to the neurological and vascular examination of the skin and material relating to spinal movements and deeper innervation are found above. Palpation of the region involves careful assessment of the bony and musculotendinous landmarks described above, looking in particular for asymmetry, deformity and tenderness. Note that, apart from the spines, most of the bony elements of the vertebrae and almost all of the intervertebral joints are not palpable from behind. In regions of lordosis (sagittal plane curves of the spine with anterior convexity, i.e. mid-cervical and mid- and lower lumbar), parts of the vertebral column can often be palpated anteriorly with care in well-relaxed, thin subjects.

## Development of the back

Vertebrae and their alternating intervertebral discs are one of the main manifestations of body segmentation or metamerism. A chain of segments arranged in sequence allows the overall structure to bend when it is moved by the associated muscles. The original body segments, the somites, are formed by the epithelial paraxial mesoderm (Ch. 12) that is found lateral to the neural tube and notochord in the early embryo. The somites provide the embryonic cell populations for bone and muscle. The vertebrae form between the early body segments by the recombination of portions of the somites on the craniocaudal axis, and the muscles attach to adjacent vertebrae. Each vertebra develops from bilateral origins to form a midline centrum, two lateral arches bearing transverse processes that develop lateral and dorsal to the spinal cord, and a midline fused dorsal portion with a spinous process. Individual vertebrae may be distinguished by modifications of these component parts. The intervertebral discs are of dual origin; the anulus fibrosus develops from the sclerotome and the nucleus pulposus from the notochord.

## SEGMENTATION OF PARAXIAL MESODERM

Epiblast cells that ingress through the lateral aspect of the primitive node and the rostral primitive streak (see Fig. 10.3) become committed to a somitic lineage. After passing through the streak, these mesoblastic cells retain contact with both the epiblast and hypoblast basal laminae as they migrate, and for some time after reaching their destination. Their final destination is each side of the notochord, where the cell population, initially presomitic or unsegmented mesenchyme, is referred to as paraxial mesoderm when mesenchyme to epithelial transformation occurs and somites form. Somites will form from cultured presomitic mesoderm with or without the presence of neural tube tissue or primitive node tissue. As well as specifying somitic lineage, the position of ingression of the epiblast informs the specific destination of the cells. Thus, those cells that ingress through the lateral portion of Hensen's node form the medial halves of the somites, whereas those ingressing through the primitive streak approximately $200 \mu \mathrm{~m}$ caudal to the node produce the lateral halves of the somites. The two somite halves do not appear to intermingle.

Bilateral segmentation of the paraxial presomitic mesoblastic populations, which divide into discrete epithelial spheres, occurs as a sequential process along the craniocaudal axis. In avian embryos, a pair of somites is formed every 90 minutes until the full number is obtained. The molecular pathway for this synchronous segmentation has been termed the segmentation clock. It has been identified as a conserved process in vertebrates from fish to mammals, and is based on the rhythmic production of messenger RNAs (mRNAs) for the transcription of genes related to Notch, a large transmembrane receptor, and a number of other factors, including members of the Wnt and fibroblast growth factor (FGF) signalling pathways.

Intrinsically coordinated pulses of mRNA expression appear as a wave within the presomitic mesoblast as each somite forms. As new cells enter the paraxial mesoderm caudally, they begin phases of upregulation of the cycling genes, followed by downregulation of these genes. During each cycle, the most cranial presomitic mesoblast will segment and undergo mesenchyme to epithelial transformation to form the next somite.

Experimental evidence (from chick embryos) shows that newly formed paraxial mesoblast cells undergo 12 such cycles before they finally form a somite (Pourquié and Kusumi 2001). Thus, from ingression through the primitive streak to segmentation into a somite takes approximately 18 hours. As the somite number varies between vertebrate species, it is likely that the rate of somite formation also varies and may be longer in human embryos. Indeed, those vertebrates with elongated bodies and many somites form somites more rapidly relative to their developmental rate than those with shorter bodies, a finding
that supports the concept that somite number is controlled, in part, by species-specific cyclical properties of the presomitic mesoblast (Richardson et al 1998, Gomez et al 2008).

The final determination of somitic boundary formation has not yet been fully elucidated but seems to require a periodic repression of the Notch pathway genes. The caudal presomitic mesoblastic cells are thought to be maintained in an immature state by their production of

Fig. 44.1 Processes in the development of the paraxial mesenchyme in the avian embryo. Signals are indicated by open arrows; genes are italicized. Abbreviations: BMP, bone morphogenetic protein; FGF, fibroblast growth factor. (Redrawn with permission from Christ B, Huang R, Wilting J 2000 The development of the avian vertebral column. Anat Embryol 202: 179-94, Springer.)

FGF8. The cells become competent for segmentation when FGF8 levels drop below a certain threshold. They would then be in close apposition to cells that have segmented (i.e. the next cranial somite).

This area of research is moving rapidly. For an overview of vertebrate segmentation and its clinical implications, see Pourquié (2011). An overview of the processes involved in the development of the paraxial mesoblast, based on the work of Christ et al (2000), is shown in Figure 44.1.
tin and cytotactin. Processes from the somite cells pass through this basal lamina to contact the basal laminae of the neural tube and notochord. Dorsoventral patterning of the putative vertebral column is dependent on the activity of Sonic hedgehog (SHH) from the notochord/ floor plate, Wnt1 and Wnt3a from the roof plate, and Wnt6 from the overlying ectoderm.

The sclerotomal population has been subdivided in the chick, and the fates of the cells followed (Christ et al 2004) (Figs 44.4-44.6). The

## SOMITE DEVELOPMENT

Somitogenesis and somite development encompasses a process in which five main stages can be identified (Figs 44.2-44.3). A local portion of the most cranial paraxial mesoblast undergoes compaction. The compacted cells undergo a mesenchymal/epithelial transformation, resulting in an epithelial sphere of cells that surrounds free somitocoele cells. This stage marks segmentation of the paraxial mesoderm and somite formation. Shortly after the somite boundaries have been defined, there is a region-specific epithelial/mesenchymal transition of the ventral and ventromedial walls of the somite to form the mesenchymal sclerotome. As the embryo enlarges, the sclerotomal populations on each side become contiguous with the notochord and the neural tube. The rest of the dorsal lateral somitic epithelium remains as the epithelial plate of the somite, also termed the dermomyotome, a proliferative epithelium that will give rise to (nearly) all the striated muscles of the body. Formation of the epaxial myotome begins. Segmentation of the paraxial mesoblast, mesenchymal/epithelial transformation to form epithelial somites and the resultant somite developmental processes (epithelial/mesenchymal transformation to form the sclerotome) all occur in a craniocaudal progression caudal to the otic vesicle from stage 9 .

The Golgi apparatus, actin and $\alpha$-actinin are all located in the apical region of the epithelial somite cells. Cilia develop on the free surface. The cells are joined by tight junctions (a variety of cell adhesion molecule has been demonstrated in epithelial somites). The basal surface, corresponding to the outer circumference of the spherical epithelial somite, rests on a basal lamina that contains collagen, laminin, fibronec-

Fig. 44.2 A scanning electron micrograph of a lateral view of an embryo, showing the somites. The cranial somites are at the upper border and the more caudal somites are at the lower border. A change in size of the cranially more advanced somites is apparent. (Photograph by P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)

Fig. 44.3 The stages of somite development. Development occurs in a craniocaudal progression. The more cranially placed somites (at the lower right of the figure) are further developed than those caudally placed (at the upper left of the figure). The stages in somite development are given on the left of the figure; more detailed information is given on the right.

C, The dermomyotome at limb level. Hypaxial dermomyotome cells de-epithelialize from the ventrolateral edge and migrate into the limb bud. $\mathbf{D}$, The local dermis is formed later by superficial de-epithelialization of dermomyotome cells.

Fig. 44.8 The formation of vertebrae and intervertebral discs from the mesenchymal sclerotomes. Each vertebra is formed from the cranial half of one bilateral pair of sclerotomes and the caudal half of the next pair of sclerotomes.
main mass of the sclerotome is termed the central sclerotome, that portion close to the notochord is termed the ventral sclerotome, and the portions adjacent to the dermomyotome are termed dorsal sclerotome and lateral sclerotome. The central sclerotome remains close to the dermomyotome; it will give rise to the pedicles and ventral parts of the neural arches, and the proximal ribs. The ventral sclerotomal cells, which were always laterally abutting the notochord, proliferate to form an axial cell population within the extracellular matrix of the perinotochordal space, now termed the perinotochordal sheath. The dorsal sclerotomal cells develop relatively late; they invade the space between the surface ectoderm and growing neural tube, and form the dorsal part of the neural arches. The lateral sclerotomal cells give rise to distal ribs and endothelial cells of blood vessels. Generally, there is a dorsolateral expansion of the whole sclerotome rather than the medial migration of a population of sclerotomal cells (Gasser 2006); this can be seen in Figures 44.4-44.6. Sclerotomal cells also give rise to the meninges surrounding the spinal cord, local tendons and ligaments. The somitocoele
cells, which remain mesenchymal throughout somite formation, give rise to the vertebral joints, intervertebral discs and the proximal ribs (Christ et al 2004).

The dermomyotome is a proliferative epithelium that produces cells from four borders (Fig. 44.7). Proliferation at the dorsomedial edge produces cells that elongate from the cranial to the caudal edge of the dermomyotome beneath its apical surface as they move laterally. Cells similarly proliferate from the cranial and caudal edges of the dermomyotome and these cells also elongate across it. The cells that are produced from these three edges are termed the epaxial myotome, and will give rise to skeletal muscle dorsal to the vertebrae, i.e. the epaxial musculature. At limb levels, cells de-epithelialize and migrate from the ventrolateral edges of the dermomyotome into the limb bud. Cells produced from this portion of the occipital somites migrate anteriorly to give rise to the intrinsic muscles of the tongue. At interlimb levels, the hypaxial myotome will give rise to intercostal and abdominal muscles, and extend from the ventrolateral edge of the epithelial
dermomyotome into the body wall as development proceeds (Scaal and Christ 2004).

It was thought that the somite gave rise to segmental portions of the dermis of the skin, as well as bone and muscle. However, it is now clear that the somitic contribution to the skin from the epithelial plate is limited to de-epithelialization of dermomyotomal cells over the epaxial muscles alone, which is a much smaller distribution than the segmental portion of skin usually implied by the term dermatome. The concept that an embryological dermatome, derived from the somite, produces all of the dermis of the skin is therefore outdated.

The regularity of somite formation provides criteria for staging embryos. The staging scheme proposed by Ordahl (1993) will be used in the following account of relative somite development. Ordahl noted that morphogenetic events occur in successive somites at approximately the same rate. The somite most recently formed from the unsegmented mesenchyme is designated as stage I, the next most recent as stage II, and so on. When the embryo has formed an additional somite, the ages of the previously formed somites increase by one Roman numeral. According to this scheme, compaction occurs at stage 0 , epithelialization at stage I, formation of mesenchymal sclerotome cells from stage V , and myotome formation from stage VI; early migration of the ventrolateral lip of the dermomyotome and production of myotome cells are still occurring at stage X .

## DEVELOPMENT OF SCLEROTOMES

Sclerotomal populations form from the ventral half of the epithelial somite. An intrasegmental boundary (fissure or cleft, sometimes termed von Ebner's fissure), which is initially filled with extracellular matrix and a few cells, appears within the sclerotome and divides it into loosely packed cranial and densely packed caudal halves. The epithelial plate and, later, the dermomyotome span the two half-sclerotomes. The bilateral sclerotomal cell populations migrate towards the notochord and surround it to form the perinotochordal sheath. They undergo a matrix-mediated interaction with the notochord, differentiating chondrogenetically to form the cartilaginous precursor of the vertebral centrum. The perinotochordal sheath starts to express type II collagen, and this is believed to mark a chondrogenic fate, in those mesenchyme cells that contact it. Each vertebra is formed by the combination of much of the caudal half of one bilateral pair of sclerotomes with much of the cranial half of the next caudal pair of sclerotomes. Their fusion around the notochord produces the blastemal centrum of the vertebra (Figs 44.8-44.9). The mesenchyme adjoining the intrasegmental sclerotomic fissure now increases greatly in density to form a welldefined perichordal disc, which intervenes between the centra of two adjacent vertebrae and is the future anulus fibrosus of the intervertebral symphysis ('disc') (see below).

The basic pattern of a typical vertebra is initiated by this recombination of caudal and cranial sclerotome halves (Fig. 44.10), followed by differential growth and sculpturing of the sclerotomal mesenchyme that encases the notochord and neural tube. The centrum encloses the notochord and lies ventral to the neural tube. Condensation of the sclerotomal mesenchyme around the notochord and right and left neural processes can be seen in stage 15 human embryos. The neural processes curve to enclose the neural tube and extend to the dorsolateral angles of the centrum. The neural arch consists of paired bilateral pedicles (ventrolaterally) and laminae (dorsolaterally), which coalesce in the midline dorsal to the neural tube to form the spinous process. On each side, three further processes project cranially, caudally and laterally from the junction of the pedicle and laminae. The cranial and caudal projections are the blastemal articular processes (zygapophyses), which become contiguous with reciprocal processes of adjacent vertebrae; their junctional zones mark the future zygapophysial or facet joints. The lateral projections are the true vertebral transverse processes. Bilateral costal processes (ribs) grow anterolaterally from the ventral part of the pedicles (i.e. near the centrum), from the neighbouring perichordal disc, and, at most thoracic levels, with accessions from the next adjacent caudal pedicles. The costal processes expand to meet the tips of the transverse processes. The definitive vertebral body is compound, and is formed from a median centrum (derived from the cells of the perinotochordal sheath), and bilaterally from the expanded pedicle ends (derived from the migrating sclerotomal populations). These portions of the vertebral body fuse at the neurocentral synchondroses.

The segmental nature of the vertebrae is promoted by the notochord and neural floor plate, which induce the ventral elements of the vertebrae and repress dorsal structures, e.g. the spinous processes (see Fig. 17.7). Excision of the notochord in early embryos results in fusion of the centra and formation of a cartilaginous plate ventral to the neural

Fig. 44.9 The contribution of the somites to the vertebrae. Each somite induces a ventral root to grow out from the spinal cord. When the sclerotomes recombine, the cranial half of the first cervical sclerotome fuses with the occipital sclerotome above contributing to the occipital bone of the skull. The cervical nerves, beginning with C1, exit above the corresponding vertebra. Nerve C8 exits below the seventh cervical vertebra (C7), and thereafter nerves arise below their numbered vertebrae. (With permission from Larsen WJ 1997 Human Embryology, 2nd edn. Edinburgh: Churchill Livingstone.)
tube. Dorsal segmentation is influenced by the spinal ganglia; experimental removal of the ganglia results in fusion of the neural arches and the formation of a uniform cartilaginous plate dorsal to the neural tube.

## INTERVERTEBRAL DISCS

Vertebral centra are derived from caudal and cranial sclerotomal halves. An intervertebral disc is formed from the free somitocoele cells within the epithelial somite that migrate with the caudal sclerotomal cells and from notochordal cells. The sclerotomal mesenchyme that forms the

Fig. 44.10 The contribution of two adjacent somites to one vertebra and rib. The intervertebral disc and the costal head are derived from somitocoele cells from one somite, which migrate with the caudal half of the sclerotome. The proximal rib is formed from caudal and cranial somite halves with no mixing of cells; in the distal rib, there is more mixing of cranial and caudal cells as segmentation diminishes in the ventral body wall. (Redrawn with permission from Christ B, Huang R, Wilting J 2000 The development of the avian vertebral column. Anat Embryol 202: 179-94, Springer.)
centra of the vertebrae replaces the notochordal tissue that it surrounds. In contrast, the notochord expands between the developing vertebrae as localized aggregates of cells and matrix that form the nucleus pulposus of the intervertebral disc (see Fig. 44.8; Fig. 44.11). The intermediate part of each perichordal disc, which forms the anulus fibrosus, surrounds the nucleus pulposus and differentiates into an external laminated fibrous zone and an internal cuff (which lies next to the nucleus pulposus). The inner zone contributes to the growth of the outer. Near the end of the second month of embryonic life, it begins to merge with the notochordal tissue, and is ultimately converted into fibrocartilage. Genetic labelling experiments in the mouse indicate that notochordal cells act as embryonic precursors to all cells found within the nucleus pulposus of the mature intervertebral disc (McCann et al 2012).

The original sclerotomes are coextensive with the individual metameric body segments; each sclerotomic fissure, perichordal disc and maturing intervertebral disc lies opposite the centre of each fundamental body segment. It therefore follows that the discs correspond in level to (i.e. form the anterior boundary of) the intervertebral foramina and their associated mixed spinal nerves, ganglia, vessels and sheaths. Posteriorly, the foramina are bounded by the capsules of the synovial facet joints; the rims of the vertebral notches of adjacent vertebrae lie cranially and caudally. Thus, all the structures listed (and other associated ones) are often designated segmental, whereas vertebral bodies are designated intersegmental because of their mode of development.
(For further discussion of resegmentation theories, the reader is directed to Müller and O'Rahilly 1986, Huang et al 2000, Stern and Vasiliauskas 2000.)

## DEVELOPMENT OF VERTEBRAE

The initial movements of sclerotomal cells round the neural tube and the expression of type II collagen signal the blastemal stage of vertebral development (see Fig. 44.11). Chondrification begins at stage 17, initiating the cartilaginous stage. Each centrum chondrifies from one cartilage anlage. Each half of a neural arch is chondrified from a centre, starting in its base and extending dorsally into the laminae and ventrally into the pedicles, to meet, expand and blend with the centrum. By stage 23 , there are 33 or 34 cartilaginous vertebrae but the spinous processes have not yet developed, so the overall appearance is of total spina bifida occulta. Fusion of the spines does not occur until the fourth month The transverse and articular processes are chondrified in continuity with the neural arches. Intervening zones of mesenchyme that do not become cartilage mark the sites of the facet joints and the complex of costovertebral joints, within which synovial cavities later appear.

A typical vertebra is ossified from three primary centres, one in each half-vertebral arch and one in the centrum (see Fig. 43.34). Centres in arches appear at the roots of the transverse processes, and ossification spreads backwards into laminae and spines, forwards into pedicles and posterolateral parts of the body, laterally into transverse processes, and upwards and downwards into articular processes. Classically, centres in vertebral arches are said to appear first in upper cervical vertebrae in the ninth to tenth weeks, and then in successively lower vertebrae, reaching lower lumbar levels in the twelfth week. However, in a radiographic study of unsexed human fetuses (Bagnall et al 1977), a pattern was noted that differed from such a simple craniocaudal sequence. A regular cervical progression was not observed. Centres first appeared in the lower cervical/upper thoracic region, quickly followed by others in the upper cervical region. After a short interval, a third group appeared in
the lower thoracolumbar region and remaining centres then appeared, spreading regularly and rapidly in craniocaudal directions.

The major part of the vertebral body, the centrum, ossifies from a primary centre dorsal to the notochord. Centra are occasionally ossified from bilateral centres that may fail to unite. Suppression of one of these produces a cuneiform vertebra (hemivertebra), which is one cause of lateral spinal curvature (scoliosis). At birth and during the early postnatal years, the centrum is connected to each half-neural arch by a synchondrosis or neurocentral joint. In thoracic vertebrae, costal facets on the bodies are posterior to neurocentral joints.

During the first year, the arches unite first in the lumbar region and then throughout the thoracic and cervical regions. In typical upper cervical vertebrae, centra unite with arches in about the third year, but in lower lumbar vertebrae, union is not complete until the sixth year. The upper and lower surfaces of the bodies and apices of the transverse and spinous processes are cartilaginous until puberty, at which time five secondary centres appear: one in the apex of each transverse and spinous process, and two anular epiphyses (ring apophyses) for the circumferential parts of the upper and lower surfaces of the vertebral body. Costal articular facets are extensions of these anular epiphyses; they fuse with the rest of the bone at about 25 years. There are two secondary centres in bifid cervical spinous processes. Exceptions to this pattern of ossification are described in the appropriate subsections in Chapter 43.

Vertebrae are specified as to region very early in development. If a group of thoracic somites is transplanted to the cervical region, ribs will still develop. It is the sclerotome that is restricted; the myotome will produce muscle characteristic of the new location.

## Occipitocervical junction

In humans, the junction between the head and neck (occipitocervical, craniovertebral or spinomedullary junction) is placed at the boundary between the fourth and fifth somites (Müller and O'Rahilly 1994, Muller and O'Rahilly 2003, Hita-Contreras et al 2014). In avian embryos, where all embryonic stages may be obtained experimentally, the occipitocervical boundary has been determined within the fifth somite (Wilting et al 1995). The boundary can first be determined in the human at stage 12 by the observation of hypoglossal nerve rootlets (Fig. 44.12A). At stages 14 and 15, the occipitocervical junction is seen between the hypoglossal rootlets and the first spinal ganglion (Fig. 44.12B-C).

The segmental pattern present in the development of the somites can be seen rostrally in the developing skull base, where mesenchymal condensations equivalent to the centra of occipital somites 2, 3 and 4 are apparent. The first occipital somite disintegrates early and, together with somites $2-4$, forms the basiocciput. Occipital sclerotomes 3 and 4 are the most distinct at stage 14 , by which time the first three sclerotomes have fused. The hypoglossal rootlets pass through the less dense portion of occipital sclerotome 4, accompanied by the hypoglossal artery. Occipital sclerotome 4 forms an incomplete centrum axially and exoccipital elements laterally. The latter are regarded as corresponding to neural arches and form the rim of the foramen magnum. The occipital condyles develop from the cranial part of sclerotome 5, which is derived from the first cervical somite.

In the occipitocervical junctional region, the centra formed from sclerotomes 5, 6 and 7 have a different fate from those more caudally placed, whereas the lateral portions of these sclerotomes generally develop similarly to those of lower ones. In a study of occipitocervical

B Vertebral growth, postnatal development

Fig. 44.11 A-B, Vertebral development through blastemal, cartilaginous and pre- and postnatal ossificatory stages. C, The derivation of the principal morphological parts of adult vertebrae.
segmentation in human embryos, Müller and O'Rahilly designated the three complete rostral centra that develop in the atlanto-axial region X , Y and Z (Fig. 44.13; Müller and O'Rahilly 1986, Muller and O'Rahilly 2003). They noted that the height of the XYZ complex is equal to that of three centra elsewhere. X is on the level of sclerotome 5, and Y and Z are in line with sclerotome 6 and with the less dense portion of sclerotome 7. During stage 17 , a temporary intervertebral disc appears peripherally between $Y$ and $Z$. It begins to disappear in stage 21, although remains may be found in the adult. No disc develops between X and Y . The origin of the anterior arch of the atlas is unclear. It is evident at stages 21-23 at the level of X or, sometimes, between X and
Y. The posterior arch of the atlas arises from the dense area of sclerotome 5 at the level of $X$. The XYZ complex belongs to the axis, which means that the atlas does not incorporate a part of the central column (Müller and O'Rahilly 1994). The posterior arch of the axis arises from the dense area of sclerotome 6 and is at the level of $Y$ and $Z$, particularly $\mathrm{Z} . \mathrm{XYZ}$ correspond to the three parts of the median column of the axis, where X represents the tip of the dens, Y represents the base of the dens, and Z represents the centrum of the axis. The latter differs from other cervical vertebrae in that it is thicker and square-shaped.

Most defects of the atlas do not contribute to abnormal occipitocervical anomalies and are not associated with basilar invagination.

The bony elements of the occipitocervical junction may be thought of as a central pillar (basiocciput and dens of the axis) surrounded by two rings (the rim of the foramen magnum and occipital condyles superiorly, and the anterior and posterior arches of the atlas inferiorly). Bony anomalies involving this embryologically complex region may produce altered, unstable anatomical relationships that result in the compression of underlying neural and/or vascular structures and may also compromise cerebrospinal fluid dynamics (Menezes 2008, Pang and Thompson 2011, Pang and Thompson 2014). The development of the cervical spine, particularly of the upper cervical vertebrae, is closely related to the development of the basiocciput and exocciput; anomalous development will affect both regions. For example, abnormal prolapse of the dens into the foramen magnum, a condition termed basilar invagination, has been attributed variously to hypoplasia of the basiocciput (clivus), occipital condyles or atlas; deficiencies in the bony arches of the atlas with spreading of the lateral masses; and atlanto-occipital assimilation (Smith et al 2010). Malfusions of the caudal portion of occipital sclerotome 4 and the cranial portion of cervical sclerotome 1 may produce defects of the occipital condyles. The proatlas, a transient bony structure derived from the fourth occipital sclerotome, usually fuses with the three upper occipital sclerotomes to form the occipital bone and the dorsal part of the foramen magnum. Very rarely, remnants of the proatlas persist into adult life; several malformations and anomalies of the most caudal of the occipital sclerotomes have been attributed to proatlas segmentation failures (Menezes and Fenoy 2009, Muhleman et al 2012).

Chiari malformation type I (CM-I) is defined radiographically as a displacement of the cerebellar tonsils of 5 mm or more below the foramen magnum in young adults. Classic CM-I is thought to be a congenital malformation, in which the developing brain is compressed within a hypoplastic posterior fossa, forcing the cerebellar tonsils down through the foramen magnum. Patients with classic CM-I have a characteristically small posterior cranial fossa, particularly below Twining's line (a line joining the anterior tuberculum sellae and internal occipital protuberance), the foramen magnum is constricted transversely, and superior and inferior outlet areas are reduced; the suggested pathogenesis is premature stenosis of the basiexoccipital and exosupraoccipital synchondroses (Milhorat et al 2010). Tonsillar herniation is aetiologically heterogeneous and there are many causes that do not appear to be related to skull-base hypoplasia; CM-I can also occur in association with disorders that appear to be unrelated to skull-base hypoplasia and may be acquired (Tubbs et al 2007).

Fig. 44.12 Reconstructions of the occipitocervical region of human embryos. A, Stage 12: occipital somites innervated by hypoglossal fibres (small yellow circles). Three cervical somites are shown. The crest-derived ganglia of cranial nerves V, VII, VIII, IX and X are shown in green. Neural crest associated with the occipital somites is hypoglossal and perhaps accessory (also shown in green). B, Stage 14: the somites have transformed into sclerotomes and moved ventrally. The less dense cranial and dense caudal parts of the sclerotomes and occipital sclerotomes 1-4 are indicated. Hypoglossal fibres and cervical ventral rami migrate through the less dense parts of the sclerotomes. The occipital neural crest is now seen to be mostly accessory. The cervical crest is subdivided into spinal ganglia. A perinotochordal sheath can be seen extending rostrally to the termination of the notochord. C, Stage 15: the dense parts of sclerotomes 1-8 are shown. Intersegmental arteries are visible in the less dense areas of the sclerotomes, as are the spinal nerve fibres. In all diagrams, the occipitocervical junction is indicated by the red line. (After Müller F, O'Rahilly R 1994 Occipitocervical segmentation in staged human embryos. J Anat 185: 251-8. Permission from Blackwell Publishing.)

Abnormalities of the axis are usually concerned with fusion of the dens with the centrum of the second cervical sclerotomes. Using the classification of the three complete centra that develop in the atlanto-axial region as X, Y and Z (Müller and O'Rahilly 1986), failure of fusion of X with the YZ complex produces an ossiculum terminale, a dissociated apical odontoid epiphysis. Failure of fusion of the XY complex with Z at the dentocentral synchondrosis, or maintenance of the transitory intervertebral disc at this point, produces an os odontoideum, thought to be induced by excessive movement at the time of ossification of the dens (Crockard and Stevens 1995). Hypoplasia and aplasia of the X and Y centra, and aplasia of the Z centrum, will all lead to reduced size of the dens. There are widely differing views about whether this will lead to atlanto-axial instability.

For further details of the development of the human craniovertebral joints and associated ligaments, see Hita-Contreras et al (2014).

Fig. 44.13 The relationship between the centra and neural arches of the vertebrae and the related spinal ganglia and nerves. A scheme of the details of the early development of the occipitocervical region. A, The column of sclerotomes from occipital somite 1. B, A dorsal view of the developing vertebrae, with the centra in the middle and the bilateral components of the neural processes laterally. $\mathrm{X}, \mathrm{Y}$ and Z are three centra that will produce the tip of the dens of the axis $(\mathrm{X})$, the base of the dens of the axis $(Y)$ and the centrum of the axis $(Z)$. An intervertebral disc appears temporarily between Y and Z during stage 17. No disc develops between X and Y . The occipital condyles are derived from the first cervical sclerotome. (After Müller F, O'Rahilly R 1994 Occipitocervical segmentation in staged human embryos. J Anat 185: 251-8. Permission from Blackwell Publishing.)

## Third to seventh cervical vertebrae

In cervical vertebrae 3-7 (see Fig. 44.11), the transverse process is dorsomedial to the foramen transversarium. The costal process, corresponding to the head, neck and tubercle of a rib, limits the foramen ventrolaterally. The distal parts of these cervical costal processes do not normally develop; they do so occasionally in the case of the seventh cervical vertebra, and may even develop costovertebral joints. These cervical ribs may reach the sternum.

The seventh cervical vertebra is transitional in shape between cervical and thoracic vertebrae. The laminae are longer than other cervical vertebrae in the neonate and lie almost perpendicular to the basal plane; the inferior articular facets are more upright, and resemble those of thoracic vertebrae; and, in the lateral view, the superior articular facets extend transversely to the top of the transverse processes.

Anomalies of the lower cervical vertebrae are generally caused by inappropriate cervical vertebral fusion; collectively, this is termed Klippel-Feil syndrome. This term includes all congenital fusions of the cervical spine, from two segments to the entire cervical spine. Affected individuals have a low posterior hairline, short neck and limitations of head and neck movement. Scoliosis and/or kyphosis is common.

## Thoracic vertebrae

At stage 23, the neural processes of thoracic vertebrae are short, slightly bifurcated and joined by collagenous fibres. The transverse process is prominent. The three facets for articulation with the ribs at the costovertebral and costotransverse joints are present. The thoracic neurocentral and posterior synchondroses are not fused in the neonate; the posterior synchondroses close within 2-3 months of postnatal development and the neurocentral synchondroses are open until 5-6years of age.

In general, the thoracic spine develops ahead of the cervical and lumbar spine. However, towards the end of the second month, ossification begins in the cartilaginous vertebrae in a craniocaudal progression.

## Ribs

Ribs usually develop in association with the thoracic vertebrae. Occasionally, they can arise from the seventh cervical and first lumbar vertebrae.

The costal processes attain their maximum length as the ribs in the thoracic region. Each rib originates from lateral sclerotomal populations, and forms from the caudal half of one sclerotome and the cranial half of the next subjacent sclerotome (see Fig. 44.10). The head of the rib develops from somitocoele cells from one somite, which migrate with the caudal half of the sclerotome. The proximal portion of the rib forms from both caudal and cranial sclerotomal halves; there is no mixing of cells from these origins. The distal portion of the rib forms from caudal and cranial sclerotomal halves; these cells mix as the rib extends into the ventral body wall and segmentation diminishes.

The ribs arise anterolaterally from the ventral part of the pedicles, and form bilateral costal processes that expand to meet the tips of the transverse processes. As they elongate laterally and ventrally, they come to lie between the myotomic muscle plates. In the thorax (see Fig. 44.11), the costal processes grow laterally to form a series of precartilaginous ribs. The transverse processes grow laterally behind the vertebral ends of the costal processes, at first connected by mesenchyme that later becomes differentiated into the ligaments and other tissues of the costotransverse joints. The capitular costovertebral joints are similarly formed from mesenchyme between the proximal end of the costal processes and the perichordal disc, and the adjacent parts of two (sometimes one) vertebral bodies, which are derived from the neural arch. Ribs 1-7 (vertebrosternal) curve round the body wall to reach the developing sternal plates. Ribs 8-10 (vertebrochondral) are progressively more oblique and shorter, only reaching the costal cartilage of the rib above, and contributing to the costal margin. Ribs 11-12 are free (floating), and have cone-shaped terminal cartilages to which muscles become attached.

## Lumbar vertebrae

The ribs do not develop distally in lumbar vertebrae (see Fig. 44.11). Their proximal parts become the 'costal processes', while the morphologically true transverse processes may be represented by the accessory processes of the vertebrae. Occasionally, movable ribs may develop in association with the first lumbar vertebra.

Lumbar intervertebral discs are thicker than thoracic discs. By stage 23, the anulus fibrosus can be seen in the peripheral part, and internally, the notochordal cells are expanding to form the nucleus pulposus.

## Sacrum

Sacral vertebrae have lower centra and are narrower overall from side to side than their thoracic and lumbar counterparts. Each sacral vertebra is composed of a centrum and bilateral neural processes. The contribution of the costal processes to sacral development was examined by O'Rahilly et al (1990). These authors divided the neurocentral junctional area into two parts: anterolateral or alar, and posterolateral. They found the alar element in sacral vertebra 1 to be novel, since it was absent in lumbar vertebra 5. There is support for this view if the course of the dorsal rami of the spinal nerves is used to distinguish the costal elements ventrally from the transverse elements dorsally. The alar elements of the sacral vertebrae are ventral to the sacral dorsal rami, and both costal and transverse portions are posterolateral. The alar element of S1 and S2 forms the auricular surface of the sacrum. At stage 23, the cartilaginous sacral vertebrae have joined and the outline of the future bone can be recognized. Individual pedicles and laminae are very small and can be detected in S3-5.

Ossification of the vertebral column proceeds in a craniocaudal direction. After 16 weeks, it has progressed to L5. Ossification of each
additional vertebra occurs over a period of $2-3$ weeks; S2 is ossified by 22 weeks.

Very rarely, significant malformation of the sacral or lumbosacral vertebrae may develop, often in association with a maternal history of diabetes. When there is sacral agenesis, motor paralysis is profound below the affected vertebral level, whereas the sensory disturbance does not relate to the vertebral level so clearly and sensation may be present down to the knees. Bladder involvement is a consistent feature.

## SPINA BIFIDA

Spinal dysraphism is a generic term covering a wide range of developmental abnormalities of the vertebral column and spinal cord, characterized by a failure of fusion of midline structures (Sepulveda et al 2012). The spectrum of defects includes non-fusion of the entire neural tube with no vertebral arch development (craniorachischisis); nonfusion of the rostral portion of the neural tube with no calvarial or occipital development (anencephaly); and non-fusion of caudal portions of the neural tube and local failure of vertebral arch development (spina bifida) (see Fig. 17.8; Figs 44.14-44.16). Spina bifida may be obvious at birth or before (e.g. spina bifida cystica and spina bifida aperta), or not obvious at birth (spina bifida occulta). Spina bifida cystica occurs where the meninges have developed adjacent to or over the defective neural tissue. Local accumulation of cerebrospinal fluid may push a defective neural plaque or spinal cord superficial to the level of the vertebrae, so forming a meningomyelocele. Alternatively, if one or two spinous processes are absent, a meningeal sac may protrude in the midline above a formed spinal cord, producing a meningocele. In spina bifida aperta, the exposed spinal cord has no cystic covering, although it may be covered by thin membranes. Meningomyelocele occurs in thoracolumbar, lumbar or lumbosacral regions; sacral lesions are less common. The vertebral lesion usually extends cranially further than the neural lesion, showing deformities of the vertebral bodies and laminae. Vertebrae may be wedge-shaped or hemivertebrae, and ribs may be fused or absent. In spina bifida occulta, dysraphism affects primarily the vertebrae; the neural and meningeal elements are not herniated to the surface and so the underlying defects are masked by the skin. This closed form of spina bifida affects about $5 \%$ of the population. It usually occurs in the lumbosacral or sacral segments; affected individuals have bifid spinous processes often at the lumbosacral junction and some have a pigmented naevus, angioma, hirsute patch, dimple or dermal sinus on the overlying skin.

Prior to antenatal diagnosis of spina bifida by ultrasonography, most live births with spina bifida cystica had a meningomyelocele. Prenatal diagnosis of meningomyelocele and termination of affected fetuses have led to a significant decrease in the incidence of live births with this condition.

## Tethering of the cord and diastematomyelia

The greatest change of vertebral length occurs within the last 6 months of intrauterine life (Ch. 17). When there is any degree of spina bifida, the upward migration of the spinal cord, which normally occurs within the vertebral canal during growth, is limited, and the cord is said to be tethered. become apparent soon after birth, although some individuals show symptoms later in life, especially degrees of urinary dysfunction. Very rarely, tethering symptoms may be associated with abnormal development of the vertebral centra, e.g. when a midline cartilaginous or osseous spicule or a fibrous septum projects into the vertebral canal. These obstacles may split the spinal cord or intraspinal nerve roots into two columns, a condition termed diastematomyelia. Usually, patients with this condition have a cutaneous abnormality, such as a dimple, pigmented naevus or patch of hair, along their back at the level of the tethering.

## Ultrasound antenatal imaging of the back

Antenatal ultrasound assessment of the fetal spine at 18-20 weeks routinely assesses the three ossification centres of each vertebra (in the centrum and bilaterally at the lamina-pedicle junction), in the axial, coronal and sagittal planes. In the coronal plane, the posterior ossification centres have a characteristic 'railtrack' appearance; the twelfth rib is adjacent to the twelfth thoracic vertebra; the first sacral vertebra is level with the top of the iliac wing. Longitudinal scans of the fetal spine can demonstrate scoliosis and hemivertebrae.

In spina bifida, the posterior ossification centres show abnormal widening in the axial plane, forming a U or V shape; they point outwards from each other and are no longer parallel. Anomalies of the spine (spina bifida) are among the most common fetal malformations noted on antenatal ultrasound examination. The Northern Congenital Abnormality Survey reported a total prevalence at birth and termination of 17.9/10,000 between 1984 and 1996 in the UK and Ireland, in comparison to the prevalence in Europe of 11.5 cases/10,000 over the same time period. For further details, consult Weston (2014).

## DEVELOPMENT OF DERMOMYOTOMES

The dermomyotome, which forms from the dorsal half of the early somite, gives rise to all the skeletal muscle in the trunk and limbs and to the intrinsic muscles of the tongue. Muscles in the head arise from the unsegmented paraxial mesoderm rostral to the occipital somites. The dorsomedial lip (border) of the dermomyotome is an infolding of the epithelial plate of the somite and becomes a proliferative epithelial site from which mediolateral growth of the dermomyotome itself occurs. Three structures are required for myogenesis: the neural tube, the notochord/neural floor plate complex and the (early) dorsally placed ectoderm. There is a balance between levels of Shh from the notochord and Wnts from the dorsal neural tube and ectoderm, which promotes myogenesis; high levels of either alone lead to sclerotomal or non-myogenic dermomyotomal development (Scaal and Christ 2004). Myogenic determination factors, MyoD, myogenin, Myf 5 and herculin/ MRF 4, can first be detected in the medial half of the somite as early as stage II, several hours prior to the onset of myotome formation.

The mode of formation of mononucleated, postmitotic, primitive myotubes from the dermomyotome has been elucidated in the chick but not yet confirmed in mammals (Gros et al 2004) (Fig. 44.17). In this model, all four borders of the dermomyotome give rise to myotomal cells, produced in two phases. First, cells are produced from the dorsomedial dermomyotomal lip by direct ingression and bidirectional extension. Second, myotomal precursor cells are released by the caudal dermomyotomal border, followed, in turn, by the cranial dermomyotomal border, and lastly, by the ventrolateral dermomyotomal lip. Those myotomal cells arising from the dorsomedial dermomyotomal border contribute cells exclusively to the epaxial domain, while those from the ventrolateral border contribute cells exclusively to the hypaxial domain. The cells arising from the cranial and caudal borders move into both epaxial and hypaxial domains (Scaal and Christ 2004) (see Fig. 44.7). Later in development, proliferative muscle progenitor cells originating from the de-epithelializing dermomyotome contribute to fetal muscle growth (Gros et al 2005).

## EPAXIAL MUSCLE: DORSAL TRUNK MUSCLES

Epaxial muscles arise from the dorsomedial lip of the dermomyotome. Early myotome cells are postmitotic embryonic myoblasts; later in development, they fuse to form syncytia, which produce the intrinsic muscles of the back. They bridge the early segmental borders, joining vertebrae together. The epaxial muscles are innervated by the dorsal
rami of each pair of spinal nerves. At later stages, satellite cells originating from the dermomyotome enter the myotome. The mechanism of development of endo-, peri- and epimysium in relation to the epaxial muscles has not been conclusively determined.

## HYPAXIAL MUSCLE: VENTROLATERAL TRUNK MUSCLES

Two modes of production of hypaxial musculature are seen, according to axial level (see Fig. 44.7). At cervical and trunk levels, myotubes are produced by the ventrolateral edge of the dermomyotome in a manner similar to the production of epaxial muscles. As development proceeds, lateral growth of the dermomyotome means that the ventrolateral border extends ventrolaterally into the developing lateral and ventral body wall. This process has been shown to depend on the homeoboxcontaining transcription factor Pitx2 (Eng et al 2012). The somite structures that invade the somatopleure of the abdominal and thoracic walls thus consist of two layers, dermomyotome and myotome, that give rise to the muscle blastemata for the intercostal and oblique muscles, transversus abdominis and rectus abdominis. At this time, the number of somatopleural fibroblasts situated within the muscle-forming zone increases, and myotubes can be first seen. There is a subsequent ventral shift of the already separated muscle blastemata within the growing abdominal wall as they attain their definitive positions. Muscle differentiation continues and muscular connective tissue, tendons and aponeuroses develop.

At occipital and limb levels, a ventrolateral dermomyotomal lip is not formed in the same way; instead, cells undergo epithelial/ mesenchymal transformation and migrate to their destination. Myoblasts move from the occipital dermomyotomes into the developing mandibular processes to form the intrinsic muscles of the tongue, whereas those opposite the early limb buds migrate into the limbs as dorsal and ventral muscle masses that give rise to the shoulder, hip and appendicular muscles. (For a review of dermomyotomal development, see Scaal and Christ (2004).)

## OTHER STRUCTURES DERIVED FROM THE SOMITES

Dermal precursors arise from the central portion of the dermomyotome and, possibly, also from the dorsomedial dermomyotome lip (see Fig. 44.7). The cells undergo an epithelial/mesenchyme transformation from the dermomyotome and migrate to the dorsomedial subectodermal space overlying the dorsal neural tube. Their transformation seems to be controlled by factors from the neural tube. There is a sharp boundary between dermis that is somite-derived and that which is derived from the somatopleuric mesenchyme of the lateral plate (and which covers the limbs, part of the lateral and all of the ventral body wall).

Somitic cells are now considered to give rise to smooth muscle cells within and around the developing somites, and within the tunica media of the descending aorta (Wiegreffe et al 2007). All compartments of the epithelial somite, including the somitocoele cells, give rise to angioblasts. The early ventral half of the somite gives rise to the endothelium of ventrolateral blood vessels. Angioblastic cells arising from the dorsomedial dermomyotome migrate mainly into the dorsal dermis, whereas those arising from the dorsolateral part move to the ventrolateral body wall and limbs (Scaal and Christ 2004).

# Spinal cord and spinal nerves: gross anatomy 

This chapter deals with the gross anatomy of the structures that lie within the vertebral canal and their extensions through the intervertebral foramina, the spinal nerve or radicular ('root') canals. The internal organization of the spinal cord is described in Chapter 20.

The spinal cord and its blood vessels and nerve roots lie within a meningeal sheath, the theca, which occupies the central zone of the vertebral canal and extends from the foramen magnum, where it is in continuity with the meningeal coverings of the brain, to the level of the second sacral vertebra in the adult. Distal to this level, the dura extends as a fine cord, the filum terminale externum, which fuses with the posterior periosteum of the first coccygeal segment. Tubular prolongations of the dural sheath extend around the spinal roots and nerves into the lateral zones of the vertebral canal and out into the root canals, eventually fusing with the epineurium of the spinal nerves. Between the theca and the walls of the vertebral canal is the epidural (spinal extradural) space, which is loosely filled with fat, connective tissue containing small arteries and lymphatics, and an important venous plexus. Three-dimensional appreciation of the anatomy of the spinal theca and its surroundings is essential for the efficient management of spinal pain and of spinal injuries, tumours and infections. Equally significant clinically is the anatomy of the often-precarious blood supply of the spinal cord and its associated structures. The increasing application and refinement of diagnostic imaging and endoscopic procedures lend a new importance to topographical detail here.

## SPINAL CORD

The spinal cord occupies the superior two-thirds of the vertebral canal (Figs 45.1-45.2). It is continuous cranially with the medulla oblongata, just below the level of the foramen magnum, at the upper border of the atlas. It terminates caudally as the conus medullaris. During development, the vertebral column elongates more rapidly than the spinal cord, so that there is an increasing discrepancy between the anatomical level of spinal cord segments and their corresponding vertebrae (p. 252). At stage 23, the vertebral column and spinal cord are the same length and the cord ends at the last coccygeal vertebra. In later fetal life, the conus medullaris lies between the third lumbar and fifth sacral vertebrae. In premature and term neonates, it lies between the first and third lumbar vertebrae, and in children between the ages of 1 and 7 years, it lies between the twelfth thoracic and third lumbar vertebrae (Barson 1970, Vettivel 1991, Malas et al 2001, Kesler et al 2007, Suresh et al 2013). In the adult, the spinal cord terminates on average at the level of the middle third of the body of the first lumbar vertebra (Macdonald et al 1999) (see Fig. 43.79), which corresponds approximately to the transpyloric plane. However, it may end as high as the middle third of the body of the eleventh thoracic vertebra or as low as the middle third of the body of the third lumbar vertebra (Macdonald et al 1999). Its position rises slightly in vertebral flexion, and there is some correlation with the length of the trunk, especially in females. (For dimensional data, consult Barson and Sands (1977).)

The filum terminale, a filament of connective tissue approximately 20 cm long, descends from the apex of the conus medullaris. Its upper 15 cm , the filum terminale internum, is continued within extensions of the dural and arachnoid meninges and reaches the caudal border of the second sacral vertebra. Its final 5 cm , the filum terminale externum, fuses with the investing dura mater, and then descends to the dorsum of the first coccygeal vertebral segment. The filum is continuous above with the spinal pia mater. A few strands of nerve fibres, which probably represent the roots of rudimentary second and third coccygeal spinal nerves, adhere to its upper part. The central canal is continued into the filum for $5-6 \mathrm{~mm}$. A capacious part of the subarachnoid space surrounds the filum terminale internum, and is the site of election for access to the cerebrospinal fluid (CSF) via a lumbar puncture (see below).

The spinal cord varies in transverse width, gradually tapering craniocaudally, except at the levels of the enlargements. It is not cylindrical, being wider transversely at all levels, especially in the cervical segments. The cervical enlargement, the source of the large spinal nerves that supply the upper limbs, extends from the third cervical to the second thoracic segments. Its maximum circumference (approximately 38 mm ) is in the sixth cervical segment (a spinal cord segment provides the attachment of the rootlets of a pair of spinal nerves). The lumbar enlargement, the source of the large spinal nerves that supply the lower limbs, extends from the first lumbar to the third sacral segments; the equivalent vertebral levels are the ninth to twelfth thoracic vertebrae. Its greatest circumference (approximately 35 mm ) is near the lower part of the body of the twelfth thoracic vertebra, below which it rapidly dwindles into the conus medullaris.

Fissures and sulci extend along most of the external surface. A ventral (anterior) median fissure (sulcus) and a posterior median sulcus and septum almost completely separate the cord into right and left halves; they are joined by a commissural band of nervous tissue that contains a central canal (see Fig. 20.1).

The ventral median fissure extends along the whole ventral surface with an average depth of 3 mm , although it is deeper at caudal levels. It contains a reticulum of pia mater. Dorsal to it is the anterior white commissure. Perforating branches of the spinal vessels pass from the fissure to the commissure to supply the central spinal region. The posterior median sulcus is shallower, and from it a posterior median septum penetrates more than halfway into the cord, almost to the central canal. The septum varies in anteroposterior extent from 4 to 6 mm , and diminishes caudally as the canal becomes more dorsally placed and the cord contracts. The patency of the central canal diminishes with age: a postmortem study found the canal to be patent along the length of the cord in infants under 1 year of age, but occluded in most segments with increasing age after the second decade (Yasui et al 1999).

Dorsal rootlets of spinal nerves enter the cord along a posterolateral sulcus that lies from 1.5 to 2.5 mm lateral to each side of the posterior median sulcus. The white matter between the posteromedian and posterolateral sulci on each side is the dorsal (posterior) funiculus. In cervical and upper thoracic segments, a longitudinal posterointermediate sulcus marks a septum dividing each posterior funiculus into two large tracts on either side, a medial fasciculus gracilis and a lateral fasciculus cuneatus. A ventrolateral (anterolateral) funiculus lies between the posterolateral sulcus and ventral median fissure, and is subdivided into ventral (anterior) and lateral funiculi by ventral spinal rootlets that pass through its substance to issue from the surface of the cord. The ventral funiculus is medial to, and includes, the emerging ventral rootlets, whilst the lateral funiculus lies between the roots and the posterolateral sulcus. In upper cervical segments, nerve rootlets emerge through each lateral funiculus to form the accessory nerve, which ascends in the vertebral canal lateral to the spinal cord and enters the posterior cranial fossa via the foramen magnum (see Fig. 29.11).

## DORSAL AND VENTRAL ROOTS

The paired dorsal and ventral roots of the spinal nerves are continuous with the spinal cord (see Fig. 45.1F). They cross the subarachnoid space and traverse the dura mater separately, uniting in or close to their intervertebral foramina to form the (mixed) spinal nerves. Since the spinal cord is shorter than the vertebral column, the more caudal spinal roots descend for varying distances around and beyond the cord to reach their corresponding foramina. In so doing, they form a divergent sheaf of spinal nerve roots, the cauda equina, which is gathered round the filum terminale in the spinal theca, mostly distal to the apex of the cord.

Ventral spinal roots contain efferent somatic and, at some levels, preganglionic sympathetic, axons that extend from neuronal cell bodies

Fig. 45.2 The epidural and subarachnoid spaces.
in the ventral horns and intermediolateral columns, respectively. There are also afferent nerve fibres in these roots. The rootlets comprising each ventral root emerge from the anterolateral sulcus in groups over an elongated vertical elliptical area (see Fig. 45.1F). Dorsal spinal roots bear ovoid swellings, the spinal ganglia, one on each root proximal to its junction with a corresponding ventral root in an intervertebral foramen. Each root fans out into 6-8 rootlets before entering the cord in a vertical row in the posterolateral sulcus. Dorsal roots are usually said to contain only afferent axons (both somatic and visceral), which are the central processes of unipolar neurones in the spinal root ganglia, but they may also contain a small number (3\%) of efferent fibres and autonomic vasodilator fibres.

Each ganglionic neurone has a single short stem that divides into a medial (central) branch that enters the spinal cord via a dorsal root, and a lateral (peripheral) branch that passes peripherally to a sensory end organ. The central branch is an axon while the peripheral one is an elongated dendrite (but when traversing a peripheral nerve is, in general structural terms, indistinguishable from an axon). The region of spinal cord associated with the emergence of a pair of nerves is a spinal segment but there is no actual surface indication of segmentation. Moreover, the deep neural sources or destinations of radicular fibres may lie far beyond the confines of the 'segment' so defined.

## MENINGES

## DURA MATER

In some areas within the skull, the dura mater can be distinguished from the endosteum, but at the base of the skull around the foramen magnum the two layers are fused and adherent to the bone. Distal to the foramen magnum, within the vertebral column, the dura is distinct from the tissues that line the vertebral canal, and separated from them by the epidural space (see below). The spinal dura mater forms a tube whose upper end is attached to the edge of the foramen magnum and to the posterior surfaces of the second and third cervical vertebral bodies, and also by fibrous bands to the posterior longitudinal ligament, especially towards the caudal end of the vertebral canal. The dural tube narrows at the lower border of the second sacral vertebra. It invests the thin spinal filum terminale, descends to the back of the coccyx, and blends with the periosteum.

## Epidural space

The epidural space lies between the spinal dura mater and the tissues that line the vertebral canal (see Fig. 45.2). It is closed above by fusion of the spinal dura with the edge of the foramen magnum, and below by the posterior sacrococcygeal ligament that closes the sacral hiatus. It contains loosely packed connective tissue, fat, a venous plexus, small arterial branches, lymphatics and fine fibrous bands that connect the theca with the lining tissue of the vertebral canal. These bands, the meningovertebral ligaments, are best developed anteriorly and laterally. Similar bands tether the nerve root sheaths or 'sleeves' within their canals. There is also a midline attachment from the posterior spinal dura to the ligamentum nuchae at atlanto-occipital and atlantoaxial levels (Dean and Mitchell 2002). The venous plexus consists of longitudinally arranged chains of vessels, connected by circumdural venous 'rings'. The anteriorly placed vessels receive the basivertebral veins.

The shape of the space within each spinal segment is not uniform, though the segmental pattern is metamerically repeated. It is difficult to define the true shape of the 'space' because it changes with the introduction of fluid or as a result of preservation techniques. In the lumbar region, the dura mater is apposed to the walls of the vertebral canal anteriorly and attached by connective tissue in a manner that permits displacement of the dural sac during movement and venous engorgement. Adipose tissue is present posteriorly in recesses between the ligamentum flavum and the dura. The connective tissue extends for a short distance through the intervertebral foramina along the sheaths of the spinal nerves. Like the main thecal sac, the root sheaths are partially tethered to the walls of the foramina by fine meningovertebral ligaments.

## Epidural injections

Contrast media and other fluids injected into the epidural space at the sacral level can spread up to the cranial base. Local anaesthetics injected near the spinal nerves, just outside the intervertebral foramina, may spread up or down the epidural space to affect the adjacent spinal nerves or may pass to the opposite side. The paravertebral spaces of

A variety of pathological processes can occur within the epidural space, compressing the dura and resulting in pain and potential neurological disturbance. Among the more common pathological entities seen are infection, haematoma and tumours (Figs 45.3-45.4).

Fig. 45.3 A T1 post-contrast sagittal lumbar spinal magnetic resonance (MR) image showing a spinal epidural abscess (arrow) adherent to the lumbar dura and spinal nerves in a 28 -year-old female with a history of intravenous drug abuse.

Fig. 45.4 A sagittal thoracic MR image showing a large ventral spinal epidural haematoma (arrow) resulting in severe neck and upper thoracic pain and ataxia.
each side communicate via the epidural space, particularly at lumbar levels.

For a review of the morphology of the epidural space and a discussion of the nature of the lining layer of the vertebral canal, see Newell (1999).

## Subdural space

The subdural space is a potential space in the normal spine because the arachnoid and dura are closely apposed (Haines et al 1993). It does not connect with the subarachnoid space but continues for a short distance along the cranial and spinal nerves. Accidental subdural catheterization may occur during epidural injections. Injection of fluid into the subdural space may damage the cord either by direct toxic effects or by compression of the vasculature.

## ARACHNOID MATER

The spinal arachnoid mater surrounds the spinal cord and is continuous with the cranial arachnoid mater (Fig. 45.5). It is closely applied to the deep aspect of the dura mater. At sites where vessels and nerves enter or leave the subarachnoid space, the arachnoid mater is reflected on to the surface of these structures and forms a thin coating of leptomeningeal cells over the surface of both vessels and nerves. Thus a subarachnoid angle is formed as nerves pass through the dura into the intervertebral foramina. At this point, the layers of leptomeninges (arachnoid and pia) fuse and become continuous with the perineurium. The epineurium is in continuity with the dura. Such an arrangement seals the subarachnoid space so that particulate matter does not pass directly from the subarachnoid space into nerves. The existence of a pathway of lymphatic drainage from the CSF is controversial.

## PIA MATER

The spinal pia mater (see Fig. 45.5) closely invests the surface of the spinal cord and passes into the ventral median fissure. The subpial collagenous layer in the spinal subpial 'space' is thicker than it is in the cerebral region and is continuous with the collagenous core of the ligamentum denticulatum (denticulate ligament).

The ligamentum denticulatum is a flat, fibrous sheet on either side of the spinal cord between the ventral and dorsal spinal roots. Its medial

Fig. 45.5 Part of the spinal cord exposed from the anterior aspect to show the meningeal coverings.
border is continuous with the subpial connective tissue of the cord and its lateral border forms a series of triangular processes, the apices of which are fixed at intervals to the dura mater. The first crosses behind the vertebral artery where it is attached to the dura mater, and is separated by the artery from the first cervical ventral root. Its site of attachment to the dura mater is above the rim of the foramen magnum, just behind the hypoglossal nerve; the accessory nerve ascends on its posterior aspect (see Fig. 29.11). The last of the dentate ligaments lies between the exiting twelfth thoracic and first lumbar spinal nerves and is a narrow, oblique band that descends laterally from the conus medullaris. Changes in the form and position of the dentate ligaments during spinal movements have been demonstrated by cine-radiography. Beyond the conus medullaris, the pia mater continues as a coating of the filum terminale.

## INTERMEDIATE LAYER

In addition to the well-defined coats of arachnoid and pia mater, the cord is also surrounded by an extensive intermediate layer of leptomeninges. This layer is concentrated in the dorsal and ventral regions, and forms a highly perforated, almost lace-like structure that is focally compacted to form the dorsal, dorsolateral and ventral ligaments of the spinal cord. Dorsally, the intermediate layer is adherent to the deep aspect of the arachnoid mater and forms a discontinuous series of dorsal ligaments that attach the spinal cord to the arachnoid. The dorsolateral ligaments are more delicate and fenestrated, and they extend from the dorsal roots to the parietal arachnoid. As the intermediate layer spreads laterally over the dorsal surface of the dorsal roots, it becomes increasingly perforated and eventually disappears. A similar arrangement is seen over the ventral aspect of the spinal cord but the intermediate layer is less substantial.

The intermediate layer is structurally similar to the trabeculae that cross the cranial subarachnoid space, i.e. it has a collagenous core coated by leptomeningeal cells. The intermediate layers of leptomeninges around the spinal cord may act as a baffle within the subarachnoid space to dampen waves of CSF movement in the vertebral canal. Inflammation within the spinal subarachnoid space may result in extensive fibrosis within the intermediate layer and the complications of chronic arachnoiditis (Fig. 45.6).

## COVERINGS AND RELATIONS OF THE SPINAL ROOTS AND NERVES IN THE RADICULAR CANAL

Tubular prolongations of spinal dura mater, closely lined by arachnoid, extend around the spinal roots and nerves as they pass through the lateral zone of the vertebral canal and through the intervertebral foramina (see Figs 45.5, 45.6A). These prolongations, the spinal nerve sheaths or root sheaths, gradually lengthen as the spinal roots become increasingly oblique. Each individual dorsal and ventral root runs in the subarachnoid space with its own covering of pia mater. Each root pierces the dura separately, taking a sleeve of arachnoid with it, before joining within the dural prolongation just distal to the spinal ganglion. The dural sheaths of the spinal nerves fuse with the epineurium, within or slightly beyond the intervertebral foramina. The arachnoid prolongations within the sheaths do not extend as far distally as their dural coverings, but the subarachnoid space and the CSF it contains extend sufficiently distally to form a radiologically demonstrable root sleeve for each nerve. Shortening or obstruction of this sleeve seen on magnetic resonance imaging (MRI) indicates compression of the spinal nerve. At the cervical level, where the nerves are short and the vertebral movement is greatest, the dural sheaths are tethered to the periosteum of the adjacent transverse processes. In the lumbosacral region, there is less tethering of the dura to the periosteum, though there may be an attachment posteriorly to the facet joint capsule.

## CEREBROSPINAL FLUID (CSF)

The cerebrospinal fluid is described in detail in Chapter 18. Although there is free communication between the spinal and cerebral subarachnoid spaces, the mode of circulation of the spinal CSF and the contribution that it makes to the overall circulation of CSF remain uncertain in humans: CSF may be absorbed from the spinal subarachnoid space; spinal arachnoid granulations and villi have been described (Kido et al 1976).

Fig. 45.6 A, A lumbar spinal nerve and its roots and meningeal coverings. B-D, Extradural anomalies of the lumbar nerve roots.

## SPINAL NERVES

In those body segments that largely retain a metameric (segmental) structure, e.g. the thoracic region, spinal nerves show a common plan (Fig. 45.7). The dorsal, epaxial, ramus passes back lateral to the articular processes of the vertebrae and divides into medial and lateral branches that penetrate the deeper muscles of the back; both branches innervate the adjacent muscles and supply a band of skin from the posterior median line to the lateral border of the scapula (Fig. 45.8) The ventral, hypaxial, ramus is connected to a corresponding sympathetic ganglion by white and grey rami communicantes. It innervates the prevertebral muscles and curves around in the body wall to supply the lateral muscles of the trunk. Near the mid-axillary line, it gives off a lateral branch that pierces the muscles and divides into anterior and posterior cutaneous branches. The main nerve advances in the body wall, where it supplies the ventral muscles and terminates in branches to the skin.

Spinal nerves are united ventral and dorsal spinal roots, attached in series to the sides of the spinal cord. The term spinal nerve strictly applies only to the short segment after union of the roots and before branching occurs. This segment, the spinal nerve proper, lies in the intervertebral foramen; it is sometimes mistakenly called the 'nerve root'. There are 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 1 coccygeal. The abbreviations C, T, L, S and Co, with appropriate numerals, are commonly applied to individual nerves

Fig. 45.7 The formation and branching pattern of a typical spinal nerve.

Fig. 45.8 The cutaneous distribution of the dorsal rami of the spinal nerves. The nerves are shown lying on the superficial muscles. The nerves are numbered on the right side; the spines of the seventh cervical, sixth and twelfth thoracic, and first and fifth lumbar vertebrae are labelled on the left side.
as individual 'root values'. The peripheral nerves emerge through the intervertebral foramina. At thoracic, lumbar, sacral and coccygeal levels, the numbered nerve exits the vertebral canal by passing below the pedicle of the corresponding vertebra, e.g. L4 nerve exits the intervertebral foramen between L4 and L5. However, in the cervical region, nerves

C1-7 pass above their corresponding vertebrae. C1 leaves the vertebral canal between the occipital bone and atlas, and hence is often termed the suboccipital nerve. The last pair of cervical nerves does not have a correspondingly numbered vertebra and C8 passes between the seventh cervical and first thoracic vertebrae. Each nerve is continuous with the spinal cord by ventral and dorsal roots; each dorsal root bears a spinal, sensory ganglion (dorsal root ganglion).

## SPINAL ROOTS AND GANGLIA

## Ventral (anterior) roots

Ventral roots contain axons of neurones in the ventral (anterior) and lateral spinal grey columns. Each emerges as a series of rootlets in two or three irregular rows in an area approximately 3 mm in horizontal width.

## Dorsal (posterior) roots

Dorsal roots contain centripetal processes of neurones sited in the spinal ganglia. Each consists of medial and lateral fascicles that both diverge into rootlets that enter the spinal cord along the posterolateral sulcus. The rootlets of adjacent dorsal roots are often connected by oblique filaments, especially in the lower cervical and lumbosacral regions.

Little is known of the detail of the regions of entry and emergence of afferent and efferent rootlets in humans, but these zones of transition between the central and peripheral nervous systems have been extensively described in rodents (Fraher 2000).

## Appearance and orientation of roots at each spinal level

The size and direction of spinal nerve roots vary. The upper four cervical roots are small, while the lower four are large. Cervical dorsal roots have a thickness ratio to the ventral roots of $3: 1$, which is greater than in other regions. The first dorsal root is an exception, being smaller than the ventral, and it is occasionally absent. The conventional view is that the first and second cervical spinal roots are short, running almost horizontally to their exits from the vertebral canal, and that from the third to the eighth cervical levels the roots slope obliquely down. Obliquity and length increase successively, although the distance between spinal attachment and vertebral exit never exceeds the height of one vertebra. An alternative view states that upper cervical roots descend, the fifth is horizontal, the sixth to eighth ascend, the first two thoracic roots are horizontal, the next three ascend, the sixth is horizontal and the rest descend (Kubik and Müntener 1969). This view is based on the observation that the cervicothoracic part of the spinal cord grows more in length than other parts.

Thoracic roots, except the first, are small, and the dorsal root only slightly exceeds the ventral in thickness. They increase successively in length. In the lower thoracic region, the roots descend in contact with the spinal cord for at least two vertebrae before emerging from the vertebral canal.

Lower lumbar and upper sacral roots are the largest, and their rootlets are the most numerous. Coccygeal roots are the smallest. Kubik and Müntener (1969) confirm that lumbar, sacral and coccygeal roots descend with increasing obliquity to their exits. The spinal cord ends near the lower border of the first lumbar vertebra, and so the lengths of successive roots rapidly increase; the consequent collection of roots is the cauda equina (see Fig. 45.1A). The largest roots, and hence the largest spinal nerves, are continuous with the spinal cervical and lumbar enlargements and innervate the upper and lower limbs.

## Spinal ganglia (dorsal root ganglia)

Spinal ganglia are large groups of neurones on the dorsal spinal roots. Each is oval and reddish; its size is related to that of its root. A ganglion is bifid medially where the two fascicles of the dorsal root emerge to enter the cord. Ganglia are usually sited in the intervertebral foramina, immediately lateral to the perforation of the dura mater by the roots (see Fig. 45.1B). However, the first cervical ganglion lies on the vertebral arch of the atlas, the second lies behind the lateral atlanto-axial joint, the sacral lie inside the vertebral canal, and the coccygeal ganglion usually lies within the dura mater. The first cervical ganglia may be absent. Small aberrant ganglia sometimes occur on the upper cervical dorsal roots between the spinal ganglia and the cord.

## SPINAL NERVES PROPER

Immediately distal to the spinal ganglia, ventral and dorsal roots unite to form spinal nerves. These very soon divide into dorsal and ventral rami, both of which receive fibres from both roots (see Fig. 45.6A). At all levels above the sacral, this division occurs within the intervertebral foramen. Division of the sacral spinal nerves occurs within the sacral vertebral canal, and the dorsal and ventral rami exit separately through posterior and anterior sacral foramina at each level. Spinal nerves trifurcate at some cervical and thoracic levels, in which case the third branch is called a ramus intermedius. At or distal to its origin, each ventral ramus gives off recurrent meningeal (sinuvertebral) branches and receives a grey ramus communicans from the corresponding sympathetic ganglion. The thoracic and first and second lumbar ventral rami each contribute a white ramus communicans to the corresponding sympathetic ganglia. The second, third and fourth sacral nerves also supply visceral branches, unconnected with sympathetic ganglia, which carry a parasympathetic outflow direct to the pelvic plexuses.

Cervical spinal nerves enlarge from the first to the sixth nerve. The seventh and eighth cervical and the first thoracic nerve are similar in size to the sixth cervical nerve. The remaining thoracic nerves are relatively small. Lumbar nerves are large, increasing in size from the first to the fifth. The first sacral is the largest spinal nerve; thereafter the sacral nerves decrease in size. The coccygeal nerves are the smallest spinal nerves. The size of the spinal nerve and its associated structures within the intervertebral foramen is not in direct relation to the size of the foramen. At lumbar levels, though L5 is the largest nerve, its foramen is smaller than those of $\mathrm{L} 1-4$, which renders this nerve particularly liable to compression.

In the radicular ('root') canal and intervertebral foramen, the spinal nerve is related to the spinal artery of that level and its radicular branch, and to a small plexus of veins. At the outer end of the foramen, the nerve may lie above or below transforaminal ligaments.

## Meningeal nerves

Recurrent meningeal (or sinuvertebral) nerves (Fig. 45.9) occur at all vertebral levels. They are mixed sensory and sympathetic nerves, represented by numerous fine filaments amongst which one, or two to four, larger trunks may be evident. At cervical levels, the autonomic roots arise from the grey rami that form the vertebral nerve. At thoracic and lumbar levels, each nerve is formed by a somatic root from the ventral ramus and by an autonomic root from the grey ramus communicans of that segment. Each nerve pursues a recurrent course through the

Fig. 45.9 The course and skeletal distribution of the lumbar sinuvertebral nerves. Each nerve supplies the intervertebral disc at its level of entry into the vertebral canal, the disc above, and the intervening posterior longitudinal ligament. In about one-third of cases, the nerve at a particular level may be represented by more than one filament.

intervertebral foramen, passing ventral to the spinal nerve, to enter the vertebral canal, where it divides into ascending, descending and transverse branches. These branches communicate with corresponding branches from the segments above and below, and from the opposite side, forming arcades along the floor of the vertebral canal. Meningeal branches of the arcades form a plexus on the ventral surface of the dural sac and nerve root sleeves that attenuates laterally; the posterior paramedian dura is devoid of nerve endings. Skeletal branches are distrib uted to the posterior longitudinal ligament, the periosteum of the vertebral bodies, and to the posterior and posterolateral aspects of the intervertebral discs (Garcia-Cosamalon et al 2010). Vascular branches accompany the veins and arteries of the vertebral canal and those of the vertebral bodies. The upper three cervical meningeal nerves ascend through the foramen magnum into the posterior cranial fossa, where they innervate the dura mater that covers the clivus. En route, they innervate the median atlanto-axial joint and its ligaments.

## Functional components of spinal nerves

A typical spinal nerve contains somatic efferent fibres and somatic and visceral afferent fibres. Some, but not all, spinal nerves also contain preganglionic autonomic fibres.

## Somatic components

Somatic efferent fibres innervate skeletal muscles and are axons of $\alpha, \beta$ and $\gamma$ neurones in the spinal ventral grey column. Somatic afferent fibres convey impulses into the central nervous system from receptors in the skin, subcutaneous tissue, muscles, tendons, fasciae and joints; they are peripheral processes of unipolar neurones in the spinal ganglia.

## Visceral components

Preganglionic visceral efferent sympathetic fibres are axons of neurones in the spinal intermediolateral grey column throughout the thoracic and upper two or three lumbar segments; they join the sympathetic trunk via corresponding white rami communicantes and synapse with postganglionic neurones that are distributed to smooth muscle, myocardium or exocrine glands. The preganglionic visceral efferent parasympathetic fibres are axons of neurones in the spinal lateral grey column of the second to fourth sacral segments; they leave the ventral rami of corresponding sacral nerves and synapse in pelvic ganglia. The postganglionic axons are distributed mainly to smooth muscle or glands in the walls of the pelvic viscera. Visceral afferent fibres have cell bodies in the spinal ganglia. Their peripheral processes pass through white rami communicantes and, without synapsing, through one or more sympathetic ganglia to end in the walls of the viscera. Some visceral afferent fibres may enter the spinal cord in the ventral roots.

Central processes of ganglionic unipolar neurones enter the spinal cord by dorsal roots and synapse on somatic or sympathetic efferent neurones, usually through interneurones, completing reflex paths. Alternatively, they may synapse with other neurones in the spinal or brainstem grey matter that give origin to a variety of ascending tracts.

## VARIATIONS OF SPINAL ROOTS AND NERVES

The courses of spinal roots and nerves in relation to the thecal sac and vertebral and radicular canals may be aberrant. An individual intervertebral foramen may contain a duplicated sheath, nerve and roots, which will then be absent at an adjacent level. Abnormal communications between roots may occur within the vertebral canal. These anomalies have been described and classified for the lumbosacral spine by Neidre and Macnab (1983) (see Fig. 45.6).

## RAMI OF THE SPINAL NERVES

Ventral (anterior) primary rami supply the limbs and the anterolateral aspects of the trunk, and in general are larger than the dorsal rami. Thoracic ventral rami run independently and retain a largely segmental distribution. Cervical, lumbar and sacral ventral rami connect near their origins to form plexuses. Dorsal rami do not join these plexuses. The ventral rami are described in the appropriate regional sections.

Dorsal (posterior) primary rami of spinal nerves are usually smaller than the ventral rami and are directed posteriorly. Retaining a segmental distribution, all, except for the first cervical, fourth and fifth sacral and the coccygeal, divide into medial and lateral branches that supply the muscles and skin of the posterior regions of the neck and trunk (see Fig. 45.8).

## Cervical dorsal spinal rami

Each cervical spinal dorsal ramus, except the first, divides into medial and lateral branches that all innervate muscles. In general, only medial branches of the second to fourth, and usually the fifth, supply the skin. Except for the first and second, each dorsal ramus passes posteriorly around an articular pillar as far as the root of the transverse process medial to a posterior intertransverse muscle, which it supplies.

## First cervical dorsal ramus (suboccipital nerve)

The first cervical dorsal ramus, the suboccipital nerve, is larger than the ventral (see Fig. 43.76). It emerges superior to the posterior arch of the atlas and inferior to the vertebral artery, and enters the suboccipital triangle to supply rectus capitis posterior major and minor, obliquus capitis superior and inferior, and semispinalis capitis. A filament from the branch to inferior oblique joins the second dorsal ramus. The suboccipital nerve occasionally has a cutaneous branch that accompanies the occipital artery to the scalp, and connects with the greater and lesser occipital nerves. It may also communicate with the accessory nerve.

## Second cervical dorsal ramus

The second cervical dorsal ramus is slightly larger than the ventral and all the other cervical dorsal rami (see Figs 43.76, 30.22). It runs between the lamina of the axis and inferior oblique, below which it divides into a large medial and smaller lateral branch. The dorsal ramus or its medial branch receives communicating branches from the first cervical dorsal ramus that pass both through and around inferior oblique. A descending communicating branch crosses the C2-3 facet joint to reach the third cervical dorsal ramus.

## Greater occipital nerve

The medial branch, termed the greater occipital nerve, passes transversely across inferior oblique deep to semispinalis capitis, which it innervates. Near the origin of inferior oblique, it turns rostrally along rectus capitis posterior major, where it receives a communicating branch from the third occipital nerve before turning dorsally to pierce semispinalis capitis. It emerges on to the scalp by passing above an aponeurotic sling between trapezius and sternocleidomastoid near their occipital attachments. It ascends with the occipital artery and divides into branches that connect with the third occipital and lesser occipital nerves, and which supply the back of the auricle and the skin of the scalp as far forwards as the coronal suture. The lateral branch of the second cervical dorsal ramus supplies longissimus capitis, semispinalis capitis and splenius capitis, and sends a communicating branch to the lateral branch of the third cervical dorsal ramus.

## Greater occipital neuralgia

Greater occipital neuralgia is a syndrome of pain and paraesthesiae felt in the distribution of the greater occipital nerve. This is usually caused by damage or irritation to the greater occipital nerve but more rarely can result from a similar process in the lesser occipital nerve or both greater and lesser occipital nerves. A similar syndrome may be caused by upper facet joint arthritis involving the second cervical root (Vanelderen et al 2010).

## Third cervical dorsal ramus

The third cervical dorsal ramus is intermediate in size between the second and fourth. It courses back round the articular pillar of the third cervical vertebra, medial to the posterior intertransverse muscle, and divides into medial and lateral branches. The lateral branch passes dorsally across the surface of semispinalis capitis to supply it and the overlying longissimus capitis and splenius capitis. It receives a communicating branch from the lateral branch of the second cervical dorsal ramus, and sends a similar branch to the lateral branch of the fourth cervical dorsal ramus. The deep medial branch curves dorsally and medially around the waist of the articular pillar before ending in multifidus. It sends an articular branch to the C3-4 facet joint, and may also send a branch into semispinalis capitis. The superficial medial branch, the third occipital nerve, curves around the lateral and dorsal surfaces of the C2-3 facet joint, which it supplies. It continues transversely, deep to semispinalis, which it supplies, and sends a communicating branch to the greater occipital nerve. Just above the second cervical spinal process, the third occipital nerve turns dorsally to pierce semispinalis capitis, splenius capitis and trapezius, and becomes cutaneous over a small area immediately below the superior nuchal line. Communicating branches join the cutaneous branches of the greater and lesser occipital nerves.

## Dorsal rami of the lower five cervical nerves

 The dorsal rami of the lower five cervical nerves curve back round the vertebral articular pillars and divide into lateral and medial branches. The lateral branches supply longissimus cervicis, splenius cervicis and iliocostalis cervicis. The medial branches curve around the lateral and dorsal surfaces of the articular pillar of their segment, deep to semispinalis capitis. They send articular branches to the facet joints above and below their course before entering and supplying multifidus. Terminal branches reach interspinalis at each segment. Cutaneous branches arise consistently from the fourth, and commonly from the fifth, sixth and eighth, but not usually from the seventh medial branches. These branches pass across multifidus or through semispinalis cervicis and turn dorsally around the medial border of semispinalis capitis, to pierce splenius cervicis and trapezius and reach the skin.
## Thoracic dorsal spinal rami

At each segmental level, the thoracic dorsal rami pass dorsally through an aperture bounded by the transverse processes superiorly and inferiorly, the facet joint medially, and the superior costotransverse ligament laterally. Thereafter, each dorsal ramus follows a prolonged course laterally, between the anterior lamella of the superior costotransverse ligament anteriorly, and the costolamellar ligament and the posterior lamella of the superior costotransverse ligament posteriorly. In this narrow space, the dorsal ramus divides into lateral and medial branches. The lateral branches continue laterally as far as the costotransverse joint, above which they turn dorsally and inferiorly to supply the levatores costarum, and enter the longissimus thoracis and iliocostalis muscles. Lateral branches from the upper six thoracic dorsal rami remain intramuscular. Those from the lower six levels emerge from iliocostalis lumborum to pierce serratus posterior inferior and latissimus dorsi in line with the costal angles. They descend across as many as four ribs before becoming superficial. The twelfth thoracic lateral branch sends a filament medially along the iliac crest and then passes down to the anterior gluteal skin. Some upper thoracic lateral branches may become cutaneous.

Each medial branch hooks dorsally around the lateral margin of the posterior lamella of the superior costotransverse ligament, lying a variable distance above the tip of the transverse process. At the first to fourth, and at the ninth and tenth thoracic levels, the medial branches cross the superior tip of the transverse process to turn inferiorly and medially across the posterior surface of the transverse process, lying between the attachment sites of multifidus medially and semispinalis laterally. Each nerve continues this oblique course to supply multifidus and semispinalis. At the fifth to eighth thoracic levels, the medial branches assume a course parallel to that of other levels, but do not reach the transverse process, instead passing superior and dorsal to the plane of the transverse processes. At the eleventh and twelfth levels, in keeping with the relatively short transverse processes at these levels, the medial branches run close to the superior articular processes. Each medial branch supplies articular branches to the facet joints above and below its course. Medial branches of the upper six thoracic dorsal rami furnish cutaneous branches that pierce trapezius and the rhomboids to reach the skin near the spinous processes. Cutaneous branches may occasionally arise from the medial branches of the lower six thoracic dorsal rami.

## Lumbar dorsal spinal rami

After leaving its spinal nerve, each of the first to fourth lumbar dorsal rami passes through an aperture in the dorsal leaf of the intertransverse ligament just above a transverse process (Fig. 45.10). Each dorsal ramus supplies the overlying medial intertransverse muscle before dividing into lateral and medial branches. The lateral branches supply the longissimus and iliocostalis components of the lumbar erector spinae. The upper three lumbar lateral branches emerge from the lateral border of iliocostalis lumborum and pierce the aponeurosis of latissimus dorsi to become cutaneous. They cross the iliac crest to reach the gluteal skin; some reach as far as the level of the greater trochanter. Medial branches cross the junction of the superior articular process and transverse process, and hook medially between the mammillary and accessory processes, deep to the mammillo-accessory ligament. Medial to the ligament, each medial branch sends articular branches to the facet joints above and below its course, before entering multifidus, which it supplies. Terminal branches reach interspinalis at each segment.

The fifth dorsal ramus has a longer course than other dorsal rami. It arches over the ala of the sacrum, lying against the root of the first sacral

Fig. 45.10 A left posterolateral view of the lumbar spine showing the branches of the lumbar dorsal rami.
superior articular process. Opposite the base of the lumbosacral joint, it sends a branch into the lowest fibres of longissimus thoracis, and a communicating branch to the first sacral dorsal ramus, before terminating as a medial branch that hooks around the lumbosacral joint to end in multifidus.

## Sacral dorsal spinal rami

Sacral dorsal rami are small, diminishing in size inferiorly; other than the fifth, all emerge through the dorsal sacral foramina. The upper three are covered at their exit by multifidus, and divide into medial and lateral branches. Medial branches are small and end in multifidus. Lateral branches join together and with branches of the last lumbar and fourth sacral dorsal rami to form loops dorsal to the sacrum. Branches from these loops run dorsal to the sacrotuberous ligament and form a second series of loops under gluteus maximus. From these, two or three gluteal branches pierce gluteus maximus (along a line from the posterior superior iliac spine to the coccygeal apex) to supply the posterior gluteal skin.

The dorsal rami of the fourth and fifth sacral nerves are small and lie caudal to multifidus. They unite with each other and with the coccygeal dorsal ramus to form loops dorsal to the sacrum; filaments from these supply the skin over the coccyx.

## Coccygeal dorsal spinal ramus

The coccygeal dorsal spinal ramus does not divide into medial and lateral branches. It communicates with the fourth and fifth sacral dorsal rami to supply the skin over the coccyx.

## VASCULAR SUPPLY OF SPINAL CORD, ROOTS AND NERVES

## ARTERIES

The spinal cord and its roots and nerves are supplied with blood by both longitudinal and segmental vessels (Fig. 45.11). Three major longitudinal vessels, a single anterior and two posterior spinal arteries (each of which is sometimes doubled to pass on either side of the dorsal rootlets) originate intracranially from the vertebral artery and terminate in a plexus around the conus medullaris. The anterior spinal artery forms from the fused anterior spinal branches of the vertebral artery, and descends in the ventral median fissure of the cord. Each posterior spinal artery originates either directly from the ipsilateral vertebral artery or from its posterior inferior cerebellar branch, and descends in a posterolateral sulcus of the cord. The segmental arteries are derived in craniocaudal sequence from spinal branches of the vertebral, deep cervical, intercostal and lumbar arteries. These vessels enter the vertebral canal through the intervertebral foramina and anastomose with branches of the longitudinal vessels to form a pial plexus on the surface of the cord. The segmental spinal arteries send anterior and posterior radicular branches to the spinal cord along the ventral and dorsal roots. Most anterior radicular arteries are small and end in the ventral nerve roots or in the pial plexus of the cord. The small posterior radicular arteries also supply the dorsal root ganglia; branches enter at both ganglionic poles to be distributed around ganglion cells and nerve fibres. (See also Crock (1996).)

## Segmental radiculomedullary feeder arteries

Some radicular arteries, mainly situated in the lower cervical, lower thoracic and upper lumbar regions, are large enough to reach the ventral median fissure, where they divide into slender ascending and large descending branches. These are the anterior radiculomedullary feeder arteries (Dommisse 1975). They anastomose with the anterior spinal arteries to form a single or partly double longitudinal vessel of uneven calibre along the ventral median fissure. The largest anterior medullary feeder, the great anterior radiculomedullary artery of Adamkiewicz, varies in level, arising from a spinal branch of either one of the lower posterior intercostal arteries (T9-11), or of the subcostal artery (T12), or less frequently of the upper lumbar arteries (L1 and L2). It most often arises on the left side (Carmichael and Gloviczki 1999). Reaching the spinal cord, it sends a branch to the anterior spinal artery below and another to anastomose with the ramus of the posterior spinal artery, which lies anterior to the dorsal roots. It may be the main supply to the lower two-thirds of the cord. Central branches of the anterior spinal artery enter the ventral median fissure, and then turn right or left to supply the ventral grey column, the base of the dorsal grey column, including the dorsal nucleus, and the adjacent white matter (Fig. 45.12).

Each posterior spinal artery contributes to a pair of longitudinal anastomotic channels, anterior and posterior to the dorsal spinal roots. These are reinforced by posterior medullary feeders from the posterior radicular arteries. The latter are variable in number and size, but smaller, more numerous and more evenly distributed than the anterior medullary feeders. The anterior channel is joined by a ramus from the descending branch of the great anterior segmental medullary artery of Adamkiewicz. In all longitudinal spinal arteries the width of the lumen is uneven and complete interruptions may occur. At the conus medullaris they communicate by anastomotic loops. Anastomoses other than those between the pial or peripheral spinal arterial branches may be important, e.g. a posterior spinal series of anastomoses between rami of the dorsal divisions of segmental arteries near the spinous processes.

## Intramedullary arteries

The central branches of the anterior spinal artery supply about twothirds of the cross-sectional area of the cord. The rest of the dorsal grey and white columns and peripheral parts of the lateral and ventral white columns are supplied by numerous small radial vessels that branch from posterior spinal arteries and the pial plexus. In a microangiographic study of the human cervical spinal cord, up to six anterior, and eight posterior, radicular spinal arteries were described, and up to eight central branches arose from each centimetre of the anterior spinal artery (Turnbull et al 1966).

## Spinal cord ischaemia

The spinal cord can rely for neither its transverse nor its longitudinal blood supply entirely on the longitudinal arteries. The anterior longitudinal artery and the intramedullary arteries are functional end-arteries, although overlap of territories of supply has been described (Backes and Nijenhuis 2008). Damage to the anterior longitudinal artery can result in loss of function of the anterior two-thirds of the cord (Fig. 45.13). The longitudinal arteries cannot supply the whole length of the cord, and the input of the segmental medullary feeder vessels is essential. This is especially true of the artery of Adamkiewicz, which may effectively carry the major supply for the lower cord; damage to this individual artery compromises perfusion of the distal cord and may be responsible for paraplegia following aortic bypass procedures. For many years, it was assumed that the anterior spinal artery system provided the dominant supply to the cord, but clinical evidence implies that the posterior spinal arteries may be as important as the anterior system in protecting the cord. The mid-thoracic cord, distant from the main anterior medullary feeders, is particularly liable to become ischaemic after periods of hypotension; T4-9 has been described as the critical vascular zone of the spinal cord, where interference with the circulation is most likely to result in paraplegia.

## VEINS

Intramedullary veins within the substance of the spinal cord drain into a circumferential plexus of surface veins, the coronal plexus (venous plexus of the pia mater). Six tortuous longitudinal channels are usually identified within this plexus: anterior and posterior spinal veins (anterior and posterior median veins) and four others that run on either side of the ventral and dorsal nerve roots (Fig. 45.14). Only the anterior spinal vein, which drains the central grey matter, is consistently complete. It receives sulcal veins and small pial veins from the coronal plexus and is largest in calibre in the lumbosacral region. The posterior spinal vein is frequently variable, appearing plexiform in some segments and as a single channel in others. These vessels connect freely and drain superiorly into the cerebellar veins and cranial sinuses, and segmentally into medullary veins mainly. The segmental veins drain into the intervertebral veins and thence into the external vertebral venous plexuses (see Fig. 43.21), the caval and azygos systems.

## Segmental veins

Anterior and posterior radiculomedullary veins run along some of the ventral and dorsal roots. Like the medullary feeder arteries, they are largest in the cervical and lumbar regions of the cord, but do not necessarily occur in the same segments as the medullary feeders. They drain the cord but not the roots themselves. Very small anterior and posterior radicular veins occur in most spinal segments, accompanying and draining the ventral and dorsal roots and some of the cord at the points of entry and exit of the rootlets; they usually drain into the intervertebral veins.

## THE EFFECTS OF INJURY

## SPINAL CORD INJURY AND VERTEBRAL COLUMN INJURY

Various clinical definitions have been described in the International Standards Booklet for Neurological and Functional Classification of Spinal Cord Injury, which was a landmark publication in standardizing the language of the neurological examination as it relates to spinal cord injury (Ditunno et al 1994). 'Tetraplegia' refers to impairment or loss of neural function secondary to a cervical injury. 'Paraplegia' refers to loss of function in the thoracic, lumbar or sacral segments of the cord. 'Dermatome' refers to the area of skin innervated by cutaneous axons in the distribution of a single spinal nerve. 'Myotome' refers to the muscle fibres innervated by the motor axons of a single spinal nerve. 'Neurological level' is the first level where motor and sensory function is normal on both sides of the body. 'Sensory level' refers to the most caudal level with normal sensation on both sides of the body. 'Motor level' refers to the most caudal segment with antigravity strength, providing that the next most rostral level is stronger. 'Complete injury' occurs when there is an absence of motor and sensory function below the motor and sensory levels and absence of function in the lowest sacral segment. 'Incomplete injury' refers to partial preservation of

Fig. 45.13 A, A sagittal thoracic MR image showing spinal cord ischaemic changes (arrow) secondary to thrombotic occlusion of the artery of Adamkiewicz in a patient with a hypercoagulable disorder. B, The changes were noted to be in the distribution of the anterior spinal artery, as seen on this axial image.

Fig. 45.11 Arteries of the spinal cord. (Reprinted from Netter Anatomy Illustration Collection, © Elsevier Inc. All Rights Reserved.)
sensory and/or motor function below the neurological levels, as well as evidence of 'sacral sparing' (evidence of preserved function of the lowest sacral segment) (Ditunno et al 2004). 'Spinal shock' refers to the absence of reflexes and motor/sensory function below the level of injury and occurs typically from the time at which spinal cord injury is
sustained to 24 hours after injury, followed by a phase of reflex return (Ditunno et al 2004).

In the assessment of a patient with spinal injury and neurological damage, it is important to remember that the level of cord and root injury will not coincide with that of the skeletal damage to the vertebral

Fig. 45.14 The venous drainage of the spinal cord. (With permission from Miyasaka K, Asano T, Ushikoshi S et al 2000 Vascular anatomy of the spinal cord and classification of spinal arteriovenous malformations. Interv Neuroradiol. 6 Suppl 1:195-8.)
column. In estimating the vertebral levels of cord segments in the adult, a useful approximation is that, in the cervical region, the tip of a vertebral spinous process corresponds to the succeeding cord segment (i.e. the sixth cervical spine is opposite the seventh spinal segment); at upper thoracic levels, the tip of a vertebral spine corresponds to the cord two segments lower (i.e. the fourth spine is level with the sixth segment), and in the lower thoracic region, there is a difference of three segments (i.e. the tenth thoracic spine is level with the first lumbar segment). The eleventh thoracic spine overlies the third lumbar segment and the twelfth is opposite the first sacral segment. In making this estimate by palpation of the vertebral spines, it is important to remember the relationship of the individual spines to their vertebral bodies. Clinical localization may be off by several levels because other factors may come into play, such as vascular insufficiency or venous obstruction, resulting in the lesion being localized as significantly lower than it actually is (Rousseff and Tzvetanov 2006, Sonstein et al 1996).

Complete division above the fourth cervical segment causes respiratory failure because of the loss of activity in the phrenic and intercostal nerves. Lesions between C5 and T1 paralyse all four limbs (quadriplegia), the effects in the upper limbs varying with the site of injury: at the fifth cervical segment, paralysis is complete; and at the sixth, each arm is positioned in abduction and lateral rotation, with the elbow flexed and the forearm supinated, due to unopposed activity in deltoid, supraspinatus, rhomboid and the brachial flexors (all supplied by the fifth cervical spinal nerves). Upper limb paralysis is less marked in lower cervical lesions. Lesions of the first thoracic segment paralyse small muscles in the hand and damage the sympathetic outflow to the head and neck, resulting in contraction of the pupil, recession of the eyeball, narrowing of the palpebral fissure and loss of sweating in the face and neck (Horner's syndrome). However, sensation is retained in areas innervated by segments above the lesion; thus cutaneous sensation is retained in the neck and chest down to the second intercostal space because this area is innervated by the supraclavicular nerves ( C 3 and $\mathrm{C} 4)$. At thoracic levels, division of the cord paralyses the trunk below the segmental level of the lesion, and both lower limbs (paraplegia). The first sacral neural segment is approximately level with the thoracolumbar vertebral junction; injury, which commonly occurs here, paralyses the urinary bladder, the rectum and muscles supplied by the sacral
segments, and cutaneous sensibility is lost in the perineum, buttocks, the back of the thighs and the legs, and soles of the feet. The roots of lumbar nerves descending to join the cauda equina may be damaged at this level, causing complete paralysis of both lower limbs. Lesions below the first lumbar vertebra may divide or damage the cauda equina, but severe nerve damage is uncommon and is usually confined to the spinal roots at the level of the trauma. Neurological symptoms may also occur as a result of interference with the spinal blood supply, particularly in the lower thoracic and upper lumbar segments.

## Spinal cord injury without radiological abnormality: 'SCIWORA'

The spinal cord may be damaged without radiological evidence of skeletal injury to the vertebral column. This most commonly occurs with motor vehicle accidents but also has been reported with sports injuries and falls. MRI may or may not show evidence of cord injury after SCIWORA occurs; the majority of patients sustaining these injuries have an abnormal MRI scan.

## Spinal cord syndromes

## Available with the Gray's Anatomy e-book

## LESIONS OF THE SPINAL ROOTS, NERVES AND GANGLIA

Spinal roots, nerves and ganglia may be damaged in the vertebral and root canals and at the intervertebral foramina. Neurofibromas and schwannomas may occur on the roots and nerves in the root canals. As they enlarge, these tumours become dumbbell-shaped, with both an intraspinal and an extraspinal component in continuity; the clinical picture may thus include paradoxical features as the asymmetrical space-occupying lesion grows. Root compression usually presents

Typical neural abnormalities include cord oedema, haemorrhage, contusion or transection. Typical extraneural abnormalities include intervertebral disc protrusion or herniation, ligamentum flavum bulging, cervical spondylitis, prevertebral soft tissue oedema, ligamentous abnormalities and/or ossification of the posterior longitudinal ligament. Originally, this was considered a paediatric diagnosis but it has now been shown to be equally common in adults. Spinal stenosis and pre-existing cord compression have been postulated as a risk factor for SCIWORA but clinical series have not supported this (Boese and Lechler 2013, Boese et al 2013).

For cervical spinal injury, several cord syndromes have been described, relating the clinical picture to the anatomy of the neurological lesion within the cord. The most common of these is central cord syndrome, which usually results from hyperextension injury to an osteoarthritic neck, when the major injury is to the central grey matter. This typically gives an incomplete cord injury pattern with greater motor loss in the upper extremities than in the lower limbs. There is also variable sensory loss and neurogenic bladder dysfunction (Pouw et al 2010). In anterior cord syndrome, which may occur in flexion-compression injuries of the neck, the damage occurs in the area of supply of the anterior spinal artery, sparing the posterior columns; the motor loss is usually proportionately greater in the lower than in the upper limbs, while sensory loss is less of a problem. A third syndrome that may be seen with penetrating trauma is Brown-Séquard syndrome. This is an injury directed to one side of the spinal cord, where there is ipsilateral loss of motor function and pinprick sensation and contralateral loss of pain and temperature sensation (Lee et al 1990). The anatomical basis for these symptoms is injury to the ipsilateral posterior columns and corticospinal tract, and injury to the lateral spinothalamic tract, which conveys contralateral pain and temperature sensation (see p. 306).
acutely with pain, which may be severe. The pain, paraesthesias and numbness occur in a dermatomal distribution; dermatomal overlap may make it difficult to demonstrate sensory loss on the trunk. Severe traction injuries of the upper limbs may cause avulsion of spinal roots from the cord in the cervical region.

## The anatomical basis for pain of spinal origin

In the diagnosis and description of pain of spinal origin, it is particularly important to distinguish between radicular pain and somatic referred pain.

Radicular pain is caused by disorders that affect a spinal nerve or its dorsal root ganglion. This type of pain characteristically radiates, along a narrow band, into the area of the limb (or trunk wall) that the spinal nerve supplies, and is typically (although not always) lancinating in quality, not unlike an electric shock.

Referred pain is pain felt in the distribution of a nerve that is not the nerve that innervates the source of pain, although typically these nerves are derived from the same spinal cord segment. Referred pain is felt deeply across a broad area, and is usually aching in quality; although it may radiate into a limb (or around the trunk wall), it is typically constant in location. Patients may find it hard to define the outer boundaries of this pain but they can clearly identify the centre of its distribution. Referred pain can be subdivided into somatic referred pain and visceral referred pain, according to its origin. As its name implies, visceral referred pain is caused by disorders in viscera; in some cases, the referral can be quite remote from the viscus, e.g. cardiac pain that radiates into the neck. Somatic referred pain is caused by disorders of muscular and skeletal structures. Examples include lumbar spinal pain referred to the gluteal region, thigh or leg; cervical spinal pain referred to the upper limb girdle; and cervical or thoracic spinal pain referred to the chest wall, where it may mimic cardiac pain. Often the source of somatic referred pain cannot be determined by clinical examination, and invasive tests are required to pinpoint its location.

## LESIONS OF THE CONUS AND CAUDA EQUINA

Lesions of the conus and cauda equina, e.g. tumours, cause bilateral deficit, often with pain in the back extending into the sacral segments and to the legs. Loss of bladder and erectile function can be early
features (Fig. 45.15). There are lower motor neurone signs in the legs with fasciculation and muscle atrophy. Sensory loss usually involves the perineal or 'saddle area', as well as other lumbar and sacral dermatomes. There may be congenital abnormalities, e.g. spina bifida (p. 759), lipomata or diastematomyelia, and the conus may extend below the lower border of L1, often with a tethered filum terminale (Fig. 45.16). Extramedullary lesions include prolapsed intervertebral discs. A midline (central) disc protrusion in the lumbar region may present with involvement of the sacral segments only.

Two distinct clinical syndromes, conus medullaris syndrome and cauda equina syndrome, have been described, the latter being much more common. Cauda equina syndrome typically presents in men who have a lumbar disc herniation in the setting of lumbar spinal stenosis, with symptoms of asymmetric saddle anaesthesia and asymmetric lower extremity weakness, and delayed presentation of atonic bladder and flaccid anal sphincter. Conus medullaris syndrome typically presents with symmetric saddle anaesthesia, symmetric motor deficit and earlier atonic bladder and sphincter dysfunction. The usual causes are intradural tumours or vascular lesions (Radcliff et al 2011).

Tethered cord syndrome may be associated with occult or non-occult spinal dysraphism. In its classic form, it refers to an unusually low conus medullaris (although in some 14-18\% of cases the position of the conus is anatomically normal). There is some debate as to what constitutes an abnormally low conus, whether below the L1-2 disc space or below the lower border of the body of the L2 vertebra. Most commonly, tethered cord syndrome is associated with a short filum terminale more than 2 mm wide, but it also may be related to an intradural lipoma. Traction on the caudal cord and loss of filum terminale elasticity are thought to predispose to decreased blood flow in the cord, leading to symptoms (Filippidis et al 2010). The clinical presentation varies according to age. In children, the most common presentation includes foot deformities, neurological deficits, spinal deformity and various cutaneous findings such as a lumbar capillary angioma. In adults, the syndrome more commonly presents with perianal pain and leg weakness (see Fig 45.16) (Pang and Wilberger 1982).

## ACCESS TO CEREBROSPINAL FLUID

The safest approach to the cerebrospinal fluid (CSF) is to enter the lumbar cistern of the subarachnoid space in the midline, well below the level at which the spinal cord normally terminates (see above). The fine needle employed is unlikely to damage the mobile nerve roots of the cauda equina. This procedure is called lumbar puncture. It is also possible to access the CSF by midline puncture of the cerebellomedullary cistern (cisterna magna) (Ch. 18): this is cisternal puncture.

## Lumbar puncture: adult

Lumbar puncture in the adult may be performed with the patient either sitting or lying on their side (lateral decubitus) on a firm, flat surface. In each position, the lumbar spine must be flexed as far as possible, in order to separate the vertebral spines maximally and expose the ligamentum flavum in the interlaminar window (Fig. 45.17). A line is then taken between the highest points of the iliac crests: this line almost always intersects the vertebral column at the L4 vertebral body or L4/ L5 intervertebral disc level (see Fig. 78.16). With the spines now identified, the skin is anaesthetized and a needle is inserted between the spines of L3 and L4 (or L4 and L5). Exact identification of the level by palpation is difficult (Broadbent et al 2000). The soft tissues that the needle will traverse should also be anaesthetized; care should be taken that the injection of an excessive amount of local anaesthetic does not compromise appreciation of the structures being traversed. These will be, in order: subcutaneous tissue, supraspinous ligament, interspinous ligament, ligamentum flavum, epidural space containing the internal vertebral venous plexus, dura, arachnoid, and finally, the subarachnoid space (Fig. 45.18). The lumbar puncture needle may then be inserted in the midline or just to one side, and angled in the horizontal and sagittal planes sufficiently to pierce the ligamentum flavum in or very near the midline. There is then a slight loss of resistance as the needle enters the epidural space; careful advancement will next pierce the dura and arachnoid to release CSF. For further details about the clinical anatomy of lumbar puncture, see Boon et al (2004).

## Lumbar puncture: neonate and infant

In premature and term neonates, the spinal cord usually terminates between the first and third lumbar vertebrae. In children between the ages of 1 and 7 years, the conus medullaris lies between the twelfth thoracic and third lumbar vertebrae (Barson and Sands 1977, Barson 1970, Vettivel 1991, Malas et al 2001, Kesler et al 2007, Suresh et al 2013). The supracristal plane intersects the vertebral column slightly higher (L3-4). These differences must be borne in mind when identifying the landmarks before undertaking lumbar puncture in the neonate and infant. A lumbar puncture is performed by placing the baby in a position, either lying or sitting, that gives maximum convex curvature to the lumbar spine. A needle with trocar is inserted into the back between the spines of the third and fourth lumbar vertebrae and into the subarachnoid space below the level of the conus medullaris. The space between L3 and L4 is approximately level with the iliac crests and it is usual to insert the needle and trocar into the intervertebral space immediately above or below the iliac crests. The distance from the skin to the subarachnoid space is approximately 1.4 cm in neonates; it increases progressively with age.

## Cisternal puncture

In cisternal puncture, the cisterna magna (see Fig. 18.15) is entered by midline puncture through the posterior atlanto-occipital membrane.

Further details of this difficult specialist technique are beyond the scope of this book.

## ACCESS TO THE EPIDURAL SPACE

The epidural space lies between the spinal dura and the wall of the vertebral canal. It contains epidural fat and a venous plexus. Access to this space, usually in the lumbar region, is required for the administration of anaesthetic and analgesic drugs, and for endoscopy. The caudal route is used mainly for analgesic injections.

## Thoracic and cervical epidurals

It is possible to access the epidural space at thoracic and cervical levels, but the specialist techniques required are beyond the scope of this book.

## Lumbar epidural

For access to the lumbar epidural space, the approach is as for lumbar puncture. The intention in epidural injection is to avoid dural puncture, so the epidural space should be entered in the midline posteriorly, where the depth of the space is greatest. The skin-epidural distance has been assessed in children at the L3-4 interspace; $1 \mathrm{~mm} / \mathrm{kg}$ of body
weight is considered to be a useful guideline for children between the ages of 6 months and 10 years (Bösenberg and Gouws 1995). Techniques for entering the epidural space rely on the appreciation of loss of resistance to injection of saline (air is used by some) as the space is entered. This loss of resistance results from the fact that when the needle tip is in the ligamentum flavum, saline cannot be injected into the dense ligament, but once the epidural space is entered, injection becomes easier into the loose tissues of the space. As there is very little distance between the ligamentum flavum and the underlying dura, care must be taken not to continue advancing the needle once loss of resistance has occurred.

## Caudal epidural

The route of access to the caudal epidural space is via the sacral hiatus. The space is therefore entered below the level of termination of the dural sac (the subarachnoid space and its contained CSF), which usually extends only to the level of the second sacral segment. Occasionally, the dural sac ends as high as the fifth lumbar vertebra, and very rarely it may extend to the third part of the sacrum, in which case it is occasionally possible to enter the subarachnoid space inadvertently during the course of a sacral nerve block.

With the patient in the lateral position or lying prone over a pelvic pillow, the sacral hiatus is identified by palpation of the sacral cornua (Fig. 45.19). These are felt at the upper end of the natal cleft approximately 5 cm above the tip of the coccyx. Alternatively, the sacral hiatus may be approximated by constructing an equilateral triangle based on a line joining the posterior superior iliac spines; the inferior apex of this triangle overlies the hiatus (see Fig. 78.16). After local anaesthetic infiltration, a needle is introduced at $45^{\circ}$ to the skin, in order to penetrate the posterior sacrococcygeal ligament and enter the sacral canal. The puncture of the ligament can usually be felt as the needle is advanced. Once the canal is entered, the hub of the needle is lowered so that the needle may be fed along the canal (see Fig. 45.2; Fig. 45.20). If the needle is angled too obliquely, it will strike bone; if it is placed too superficially, it will lie outside the canal and any fluid injected can be felt subcutaneously.

Fig. 45.19 Palpation of the sacral cornua for caudal epidural injection.

Fig. 45.20 Position of the needle in a caudal epidural injection.

# Minimally invasive surgical corridors to the lumbar spine 

Y Raja Rampersaud

As demonstrated in Ch. 43, the posterior spinal musculature consists of multiple layers of muscles with fibres running in varying directions and with varying segmental insertion points. Consequently, posterior exposure of the spine does not traditionally follow expansile planes that avoid neurovascular structures over multiple spinal levels. Dependent on the degree of exposure required for a given procedure, conventional posterior spinal approaches progressively release the posterior muscles from their bony attachments in a medial to lateral direction. This often requires a significant degree of muscle dissection and retraction (Fig. 5.1.1a), particularly for common procedures such as the placement of spinal pedicle screw fixations that require access lateral to the facet joints. This type of exposure has been shown to cause significant muscle

Fig. 5.1.1 A, An intraoperative photograph demonstrating a typical conventional midline spinal exposure for a one-level fusion (pedicle screw heads are visible at the lateral aspect of the exposure). Note the degree of muscle retraction from the midline (spinous process). B, An intraoperative photograph of a minimal access surgery (MAS) spinal tubular retractor ( 22 mm in diameter and 8 cm deep) placed in the paramedian intermuscular plane for a one-level fusion.
morbidity resulting from iatrogenic muscle denervation (particularly with exposure lateral to the facet joint), increased intramuscular pressures, ischaemia and revascularization injury (Rampersaud et al 2006). Denervation and ischaemia can result from two possible mechanisms that can occur independently or in combination: first, direct trauma to the segmental innervation (i.e. dorsal root branches) and vasculature; and second, increased intramuscular pressure (i.e. focal compartment syndrome) resulting from commonly used surgical retractors. These effects can lead to temporary or permanent paraspinal muscular atrophy, scarring, decreased extensor strength and endurance, as well as pain.

Minimal access surgery (MAS) approaches have been successfully applied to a variety of anatomical areas, wherein the relevant target(s) can be reliably accessed and manipulated within a defined anatomical space or cavity with minimal patient morbidity. Due to wide variation in the goals of spinal procedures and a variety of anatomical and surgical techniques and technological challenges, MAS approaches to the spine have been limited to very specific indications and have not been considered generalizable. However, in the last 10-15 years significant progress has been made in MAS for the treatment of spinal disorders. This is particularly so in relation to the lumbar spine, where the majority of MAS spinal procedures are performed. Minimal access techniques for spinal surgery have been enabled by the development of specialized retractors, dissecting instruments and spinal implants that allow less destructive and more reliable access to the spine by means of segmental transmuscular corridors. A detailed discussion of the anatomical and technical aspects of current procedures is beyond the scope of this brief commentary and only a general overview of the muscular corridors utilized for MAS spine procedures is provided.

Utilizing modifications of the sacrospinalis-splitting approach introduced by Wiltse several decades ago, transmuscular access to the spine is typically gained by splitting a specific paraspinal muscle (Fig. 5.1.2) in line with the fascicular bundles (i.e. intramuscular split) or by utilizing the natural cleavage plane between muscles (i.e. intermuscular split) (Wiltse et al 1968). MAS spinal procedures are highly dependent on the use of intraoperative imaging to allow accurate localization of the skin and fascial incision. The segmental operative corridor is typically created by the use of sequential muscle dilators over which a final retractor is docked on to the bony spinal anatomy. Alternatively, blunt dissection with a finger or a surgical instrument using a spreading technique can be utilized to create the operative corridor. Current retractors are typically tubular in shape (i.e. provide a 'keyhole' through the overlying muscle) and come in varying diameters (14-30 mm) with fixed or expandable aperture options (see Fig. 5.1.1b). For procedures such as posterior decompression of the spinal canal and/or discectomy, an intramuscular approach through the multifidus just paramedian to the spinous process is typically applied (see Fig. 5.1.2a). Due to the segmental nature and orientation of the multifidus fascicles, a corridor (via the same or multiple skin incisions) is recommended for each segment that requires intervention. For the placement of spinal instrumentation, a more lateral paramedian intermuscular corridor is utilized that takes advantage of the natural separation between multifidus and longissimus (see Fig. 5.1.2a). This plane provides direct access to the pars, transverse processes and facet joints with minimal soft tissue dissection and retraction. It also provides a less obstructed trajectory for pedicle screw fixation along the long axis of the pedicle. If required, release of multifidus from the facet joint also enables access to the dorsal spinal anatomy medial to the facet joint. The intermuscular corridor allows for an easily extensile exposure over 2-3 levels if required. For access to the lateral spinal structures cranial to the L5-S1 level, a transpsoas intramuscular plane is utilized (see Fig. 5.1.2b). Properly performed, this approach gives safe access to the anterior two-thirds of the vertebral body; however, it does carry the risk of injury to the major vessels anteriorly and to the lumbosacral plexus in the posterior aspect of the psoas (Goldstein et al 2014). At L5-S1 lateral MAS access is directly

Fig. 5.1.2 A, Axial magnetic resonance imaging (MRI) at the level of the L4-5 disc demonstrating the intramuscular corridor (paramedian 1) through the multifidus portion of sacrospinalis. The line labelled paramedian 2 demonstrates the intermuscular plane between multifidus and longissimus. Corresponding with the progressive narrowing of the bony spinal width from caudal to cranial, the intermuscular plane typically moves closer to the midline at more cranial levels. B, The intermuscular plane is more obvious in less densely muscled individuals. At the L2-3 level, the line labelled lateral demonstrates the transpsoas intramuscular corridor used for accessing the lateral aspect of the anterior spine above the L5-S1 level.
blocked by the ilium and also carries risk of injury to the common iliac vessels.

The current literature comparing conventional open spinal procedures to MAS spinal procedures supports the reduction of acute perioperative morbidity, with most reports demonstrating reduced blood loss, pain and length of hospital stay with MAS procedures (Goldstein et al 2014, Arnold et al 2012). In addition, there also appears to be a reduction in the incidence of deep surgical site infection, most likely due to the creation of minimal dead space with the MAS procedures. The overall long-term (more than 1-2 years post surgery) clinical and patient-reported outcomes, such as pain and function, appear not to be
inferior to traditional open spinal procedures; however, long-term superiority has yet to be proven. These MAS techniques can carry a significant technical learning curve and associated increased cost. At present, in the absence of compelling proof of superiority, MAS spinal procedures are to be considered an alternative technique for the surgical management of spinal disorders when appropriate indications are met. They are by no means to be considered a 'standard of care' and require a weighing up of patient and surgeon preferences, as well as surgeon experience, on a case-by-base basis. Anecdotally, MAS spinal procedures are welcomed by patients and provide significant patient and surgeon satisfaction when properly executed.

## Pectoral girdle and upper limb: overview and surface anatomy

The upper limb exhibits an exceptional range of movement, which permits such wide positioning of the hand that it acts as a powered, mobile, sensory organ. This range is enabled by a number of factors. The thoracoscapular and glenohumeral joints are remarkably little constrained and the muscles that both stabilize and move them are powerful. The skin is mobile, especially in the front of the neck, the axilla, across the joints, and on the dorsum of the hand. The deep fascial planes and the synovial tubes permit excursion of muscles and tendons against each other and adjacent structures, and the condensation of that fascia around the neurovascular bundles segregates them and enhances gliding. The excursion of the main nerves relative to the skeleton is increased by delicate vascular fascial adventitia and by gliding planes within the nerve trunks.

The innervation of the upper limb is complex and rich. There is a particular concentration of specialized sensory organelles in the wrist and hand, not only in the skin but also in the deep afferent system from muscles, tendons and joints. The postganglionic sympathetic vasomotor and sudomotor nerves are especially dense in the palmar skin. The basis of stereognosis, the ability to recognize the qualities of objects and textures, is a combination of stimuli from skin, tendon, muscle and joints. Movement is vital; blindfolded patients cannot identify the nature of an object if it is simply placed on the finger, but recognize it immediately if allowed to create spatial and temporal patterns by feeling the object or material between the moving finger and thumb.

## BONES AND JOINTS

The bones of the upper limb include the scapula, clavicle, humerus, radius and ulna (connected by the interosseous membrane along most of their length), the eight bones forming the carpus, five metacarpals and fourteen phalanges (Figs 46.1-46.2). There are two phalanges in the thumb and three in each finger.

The thoracoscapular joint is the platform for function of the upper limb; paralysis of either of the two great muscles, trapezius and serratus anterior, is crippling. The limb is directly attached to the axial skeleton by one bony articulation, the sternoclavicular joint. The glenohumeral joint is shallow and little constrained, whereas the acromioclavicular joint is a plane joint stabilized by strong ligaments. The range of movements provided by these joints and the muscles acting across them is enormous. Arthrodesis of the thoracoscapular joint is effective in scapulohumeral dystrophy; it restores full elevation of the limb but protraction and retraction is lost. A correctly performed glenohumeral arthrodesis retains powerful adduction, protraction and medial rotation, but lateral rotation and most of elevation are lost. The elbow includes a hinge between the humerus and ulna, and two pivot joints: one between the humerus and radius, the other between the proximal radius and ulna. This permits a range of about $150^{\circ}$ of extension and flexion, and $180^{\circ}$ of pronosupination in conjunction with the distal radio-ulnar joint. The wrist complex allows a range of flexion and extension of about $140^{\circ}$, supplemented by some $70^{\circ}$ of adduction and abduction. The condylar metacarpophalangeal joint enables $120^{\circ}$ of flexion and extension, about $40^{\circ}$ of abduction and adduction, and some rotation. Pronation and supination are unique to the primate upper limb. The range of movement of the thumb ray, which rests on the 'saddle' carpometacarpal joint, the qualities of the long muscles and the thenar muscles acting on the ray and the skin of the web space, are unique to humans.

## SKIN AND FASCIA

The skin over the front of neck and posterior triangle is mobile and is sustained by underlying platysma. Large flaps may be raised safely when

Fig. 46.1 The bones of the pectoral girdle and upper limb: anterior view.

Fig. 46.2 The bones of the pectoral girdle and upper limb: posterior view.
platysma is included with the skin. The postaxial skin of the posterior aspect of the neck, shoulder, arm and forearm is thicker and hairy, whereas the glabrous preaxial skin on the anterior surface of the arm and forearm is thinner and more mobile. The situation is reversed in the hand, where the thick palmar skin is firmly secured by a fibrous skeleton to the palmar aponeurosis, whereas the dorsal skin is thinner and more mobile, especially across the joints. The characteristic furrows or creases at the elbow, wrist and the interphalangeal joints represent places of anchorage of the deep fascia. The hairy skin of the axilla is especially mobile, permitting the extensive range of movement at the glenohumeral joint; it is rich in sweat glands and their sympathetic nerves. The dense sympathetic innervation in the axilla, the hand and
forearm is important in temperature homeostasis. The consequences of scarring from burn or other injury, or badly placed incisions, are severe, and nowhere more so than after a deep burn of the axilla.

The superficial fascia (see Chs 2 and 29) is generally thicker on the dorsal aspect of the neck, shoulder, arm and forearm. Measurement of its thickness in the arm provides a useful measure of obesity. This fascia is an important gliding plane between the skin and the underlying deep fascia. Nerves and vessels are at risk of entrapment or even rupture where they perforate the deep fascia to ramify into the superficial fascia and skin.

The deep fascia, intermuscular septa and the interosseous membrane between the radius and ulna define discrete compartments that enable gliding of segregated structures against one another. The medial and lateral intermuscular septa of the arm and the interosseous membrane also provide wide areas for the attachment of muscles. The various fascial compartments are relevant to the spread of infection and tumour, and are especially important in ischaemia.

The prevertebral fascia (see Fig. 29.4; p. 445) envelops the phrenic nerve, scalene muscles, cervical primary rami, cervical sympathetic chain, and subclavian and vertebral arteries. It projects below the clavicle as the axillary sheath, enveloping the divisions and cords of the brachial plexus with the axillary artery, and continues into the arm as the brachial sheath, surrounding the brachial artery with its venae comitantes, the median nerve and the proximal part of radial and ulnar nerves. The great muscles of the shoulder and axilla - deltoid, pectoralis major and latissimus dorsi - are covered by deep fascia that winds around their deep surfaces to blend with the deep fascia of the arm. This latter is drawn upwards by suspensory condensations of fascia to form the cone-shaped axillary space. This arrangement is obvious to the reader who traces the anterior surface of pectoralis major with a finger, then follows it round and deep, before thrusting the finger upwards as far at least as the lateral part of the second rib.

The deep fascia of the arm and forearm forms a sort of sleeve, attached to the medial and lateral intermuscular septa in the arm, to the periosteum of the medial and lateral epicondyles and olecranon at the elbow, and to the periosteum of the ulna and radius (Chs 48-49). There are important condensations, such as the bicipital aponeurosis at the elbow, and the flexor and extensor retinacula at the wrist, which are, in turn, subdivided by septa. Discrete compartments with the forearm separate the superficial muscles from the deep. The reader will note the relative mobility of the extensor muscles that traverse the elbow: brachioradialis and the radial extensor muscles of the wrist form the 'mobile wad', overlying the deeper compartment containing the posterior interosseous nerve and vessels, supinator, the digital extensors, extensor carpi ulnaris and the long muscles acting on the thumb ray. Three compartments are found in the anterior aspect of the forearm. The deep flexor compartment contains the anterior interosseous nerve and vessels, flexor pollicis longus, flexor digitorum profundus and pronator quadratus. The superficial compartment contains the radial artery, pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis. The ulnar nerve and vessels pass in a separate sheath close to the ulna. The anterior deep fascia of the forearm continues into the hand as the palmar aponeurosis, from which a complex arrangement of septa forms the fibrous skeleton of the hand (see Fig. 50.7A). The range of excursion of the main nerves of the upper limb across fixed points such as the first rib, the distal humerus and the distal radius is some $10-15 \mathrm{~mm}$ and is enabled by gliding between the adventitia and the epineurium. More movement occurs within the plane between the epineurium and perineurium, and also within the perineurium itself (Commentary 9.1).

## Cutaneous innervation

Bundles of nerves enter the skin deep in the dermis and course towards the skin surface, giving off axons, nearly all unmyelinated, that innervate the associated end organs. The few myelinated axons terminate at hair follicles, Meissner corpuscles and Merkel complexes (Ch. 7, Commentary 1.3). The density of innervation of the epidermis is greatest in the proximal segment of the limb and there is little change between the twentieth and eightieth years.

## MUSCLES

The sensorimotor cortex controls movements, not individual muscles. Reaching out to catch a flying object, such as a cricket ball, requires the coordination and integrated action of every muscle group in the upper limb, and indeed beyond. This system of complex and refined muscle
patterning depends on the integrity of the somatic afferent and efferent pathways in the central nervous system.

The muscles of the upper limb may be grouped according to their origin and the joints on which they act: (1) Muscles arising from the axial skeleton to act on the scapula include trapezius, levator scapulae, the rhomboids and serratus anterior. (2) Muscles arising from the axial skeleton to act on the glenohumeral joint include the sternal head of pectoralis major, pectoralis minor and latissimus dorsi. (3) Muscles passing between the scapula and the proximal humerus control the glenohumeral joint. They include supra- and infraspinatus, subscapularis, teres major and minor, and coracobrachialis. Deltoid and the clavicular head of pectoralis major also belong here, even though they arise in part from the clavicle. (4) The main muscles controlling the elbow include biceps and triceps; the long heads of both muscles traverse the glenohumeral joint to insert on the scapula. (5) The main muscles controlling supination and pronation are biceps brachii and supinator, pronator teres and pronator quadratus. (6) The radiocarpal joint is controlled by extensors carpi radialis longus and brevis, extensor carpi ulnaris, flexors carpi ulnaris and radialis, and palmaris longus. (7) The muscles acting on the thumb ray include the powerful flexor pollicis longus, the much weaker abductor pollicis longus, and extensors pollicis longus and brevis. These last three are essential for thumb function. The unopposed action of flexor pollicis longus leads to the virtually useless thumb in palm posture. (8) The extension and flexion of the metacarpophalangeal and interphalangeal joints of the fingers rest on coordinated activity in extensor digitorum, flexors digitorum superficialis and profundus, and the interosseous and lumbrical muscles. Extensor digitorum alone extends the metacarpophalangeal joints; the long flexors alone flex the interphalangeal joints. The imbalance caused by paralysis of the small muscles leads to 'clawing' deformity (see Fig. 46.27). (9) The small muscles of the hand may be considered as those controlling the thumb ray and web space; adductor pollicis lies deep to the first dorsal interosseous; abductor and flexor pollicis brevis and opponens pollicis are superficial and form the ball of the thumb. The interosseous muscles acting with the lumbricals flex, abduct and adduct the metacarpophalangeal joints and, in conjunction with the long flexor and extensor muscles, enable full extension of the proximal interphalangeal joints. Abductor and opponens digiti minimi and flexor digiti minimi brevis form the hypothenar eminence and act on the little finger.

Many muscles act on more than one joint; thus, the long heads of biceps and triceps flex and extend the glenohumeral joint, as well as the elbow. In addition, biceps brachii is a powerful supinator of the forearm. Extensor carpi radialis longus not only extends the wrist, but also is a powerful abductor of that joint and a flexor of the elbow. Flexor carpi ulnaris is the most powerful muscle in the forearm; it contributes to elbow flexion, flexes and adducts the wrist, and is active in all sustained movements of the wrist.

Certain muscles are functionally segregated, e.g. the anterior part of deltoid is a powerful flexor of the glenohumeral joint, whereas the posterior part is the most powerful extensor of that joint.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The detailed regional descriptions of these systems are found in Chapters 48, 49 and 50.

## ARTERIES

The axial vessel is the subclavian artery, which arises from the brachiocephalic trunk on the right and directly from the arch of the aorta on the left (Fig. 46.3). The artery is described in three parts that are successively anterior, deep and lateral to scalenus anterior. The second and third parts are in close relation to the primary ventral rami of $\mathrm{C} 7, \mathrm{C} 8$ and T1, and to the middle and lower trunks of the brachial plexus. The subclavian artery becomes the axillary artery at the posterior margin of the first rib. The axillary artery is closely related to the divisions of the brachial plexus deep to the clavicle, and to the cords below it. It continues deep to pectoralis minor and becomes the brachial artery at the inferior margin of teres major.

The brachial artery is closely related to the median nerve; both move from the medial side of the arm to the anterior aspect of the elbow, lying medial to the tendon of biceps brachii and deep to the bicipital aponeurosis. The artery divides into the radial and ulnar arteries just distal to the elbow. The ulnar artery is consistently the larger of the two. The common interosseous artery arises close to its origin and subsequently divides into the anterior and posterior interosseous arteries. The

Fig. 46.3 The arteries of the upper limb.
anterior interosseous artery, accompanied by the anterior interosseous nerve, lies on the interosseous membrane in the deepest part of the deep flexor compartment. The posterior interosseous artery is separated from the membrane by the deep extensor muscles. The radial and ulnar arteries remain in the flexor compartment of the forearm, the ulnar artery moving towards the ulnar nerve in the proximal quarter of the forearm; it is usually the dominant vessel for the hand. At the wrist, the radial artery passes dorsally and crosses the scaphoid and trapezium.

Important branches from the main axial vessels form extensive anastomoses that provide a collateral circulation. For example, the collateral circulation formed by branches of the thyrocervical trunk with the circumflex humeral and subscapular arteries permits survival of the limb
after occlusion of either the third part of the subclavian artery, or of the axillary artery deep to the clavicle and pectoralis minor. The profunda brachii is an important channel for the posterior muscles of the arm. It accompanies the radial nerve and contributes to the collateral circulation about the elbow with the ulnar collateral and recurrent vessels and the radial collateral and recurrent vessels. The anterior interosseous artery is effectively an end artery. A series of anastomoses between the radial and ulnar arteries, such as the transversely orientated palmar and dorsal arches and the superficial and deep palmar arches, maintain a rich blood supply to the wrist and hand. There are extensive interconnections between these arches and between the dorsal and palmar phalangeal arteries.

## Pulses

The pulsation of the subclavian artery is palpable at the lateral margin of sternocleidomastoid and is easily blocked by digital pressure against the first rib. This simple manœuvre has saved lives and limbs, and should be widely known and rehearsed because it is the best method for emergency control of bleeding from the deeply placed axillary artery. The method was used successfully for high amputation or disarticulation of the shoulder in the Napoleonic wars.

The brachial artery is palpable in the arm in the groove, or valley, between biceps brachii anteriorly and the medial head of triceps brachii posteriorly; it can be traced down to the anterior aspect of the elbow, where it moves towards the midline. The radial and ulnar pulses are palpable at the wrist, where the vessels emerge from under the cover of overlying muscles.

## VEINS

The upper limb is drained by superficial and deep groups of vessels.
The superficial group starts as an irregular dorsal arch on the back of the hand. The cephalic vein begins at the radial extremity of the arch, and ascends along the lateral aspect of the arm within the superficial fascia to enter the deltopectoral groove. It pierces the deep fascia above the superior margin of pectoralis minor and enters the axillary vein near the tip of the coracoid (Fig. 46.4). The basilic vein drains the ulnar end of the arch, passes along the medial aspect of the forearm, pierces the deep fascia at the elbow, and joins the venae comitantes of the brachial artery to form the axillary vein. The prominent median cubital vein links the cephalic and basilic veins on the flexor aspect of the elbow. It receives a number of tributaries from the flexor aspect of the forearm and gives off the deep median vein, which pierces the fascial roof of the antecubital fossa to join the venae comitantes of the brachial artery.

The deep group of veins drains the tissues beneath the deep fascia of the upper limb and is connected to the superficial system by perforating veins. The deep veins accompany the arteries, usually as venae comitantes, ultimately becoming the axillary, and subsequently the subclavian, vein.

The subclavian vein is the central continuation of the axillary vein. It starts at the inferior margin of the first rib, which it crosses. Initially deep to the clavicular head of pectoralis major and then to subclavius, which is a buffer between it and the overlying medial portion of the clavicle, the vein then runs deep to the insertion of sternocleidomastoid. Sometimes, only the superior margins of the vein rise above the medial end of the clavicle; sometimes, the entire vein does so. The phrenic nerve and the inferior part of scalenus anterior lie posteriorly. The subclavian vein joins the internal jugular vein to form the brachiocephalic vein at the medial border of scalenus anterior, behind the sternoclavicular joint (see Fig. 29.14). A pair of valves usually lies within 2 cm of this junction. The subclavian vein receives, as tributaries, the external jugular, dorsal scapular and, sometimes, the anterior jugular veins. The trifurcation of subclavian, external and internal jugular veins is demonstrable by a forced expiration (Valsalva) manœeuvre, when the distended veins rise up above the sternoclavicular joint, filling the fossa above the jugular notch of the sternum (Video 46.1). Main lymphatic vessels join the subclavian veins at, or very close to, this junction with the internal jugular vein. The left subclavian vein receives the thoracic duct; the right receives the right lymphatic duct (see Fig. 29.16). There is a risk of air embolism after wounding of the subclavian, external or internal jugular veins.

## Cutaneous blood supply

The blood supply of the skin of the upper limb is generally abundant (Fig. 46.5) and rather more robust than that in the lower limb.

Fig. 46.4 The veins of the upper limb.

Proximally based flaps of skin caused by 'degloving' injury are more likely to survive; even a distally based flap of palmar skin may do so. The skin of the lower leg is notoriously sensitive to the effects of fracture because of rupture of the vessels perforating the deep fascia; this problem is less severe in the upper limb. Three interconnected pathways may be recognized in the upper limb, namely: muscle perforators, deep fasciocutaneous vessels and the direct cutaneous supply.

## Muscle perforators

Available with the Gray's Anatomy e-book

## Fasciocutaneous system

Available with the Gray's Anatomy e-book

## Direct cutaneous supply

> Available with the Gray's Anatomy e-book

Vessels pass from deep axial vessels through muscle, perforate the deep fascia and supply the overlying skin. The latissimus dorsi myocutaneous flap based on the thoracodorsal vessels was an important development in plastic and reconstructive surgery, not only for the replacement of lost skin or reconstruction of the breast, but also in the evolution of the free-functioning muscle transfer.

The fasciocutaneous system rests on branches that arise from deep vessels and pass along intermuscular septa to perforate the deep fascia and ramify over its surface; extensive areas of skin are supplied in this way. The development of fasciocutaneous flaps, either as pedicle flaps or free grafts, has been a revolutionary advance in the treatment of severe wounds; not only is it possible to replace large areas of lost skin, but also the improvement of the tissue bed that overlies the main nerves enhances regeneration and relieves neuropathic pain.

The direct cutaneous supply is exemplified in the palmar skin, where branches from the underlying digital vessels pass directly into the overlying skin.

Fig. 46.5 The anatomical territories served by the cutaneous blood supply to the upper limb. (With permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd ed. Edinburgh: Churchill Livingstone.)

## LYMPHATIC DRAINAGE

## Superficial tissues

Superficial lymphatic vessels begin in cutaneous plexuses. In the hand, the palmar plexus is denser than the dorsal plexus. Digital plexuses drain along the digital borders to their webs, where they join the distal palmar vessels, which pass back to the dorsal aspect of the hand. The proximal palm drains towards the carpus, medially by vessels that run along its ulnar border, and laterally to join vessels draining the thumb. Several vessels from the central palmar plexus form a trunk that winds round the second metacarpal bone to join the dorsal vessels that drain the index finger and thumb.

In the forearm and arm, superficial vessels run with the superficial veins. Collecting vessels from the hand pass into the forearm on all carpal aspects. Dorsal vessels, after running proximally in parallel, curve successively round the borders of the limb to join the ventral vessels. Anterior carpal vessels run through the forearm parallel with the median vein of the forearm to the cubital region, then follow the medial border of biceps brachii before piercing the deep fascia at the anterior axillary fold to end in the lateral axillary lymph nodes.

Lymph vessels that lie laterally in the forearm receive vessels that curve round the lateral border from the dorsal aspect of the limb. They follow the cephalic vein to the level of the tendon of deltoid, where most incline medially to reach the lateral axillary nodes; a few continue with the vein and drain into the infraclavicular nodes. Vessels lying medially in the forearm are joined by vessels that curve round the medial border of the limb and follow the basilic vein. Proximal to the elbow, some end in supratrochlear lymph nodes whose efferents, together with the medial vessels that have bypassed them, pierce the
deep fascia with the basilic vein and end in the lateral axillary nodes or deep lymphatic vessels.

Collecting vessels from the deltoid region pass round the anterior and posterior axillary folds to end in the axillary nodes. The scapular skin drains either to subscapular axillary nodes or by channels that follow the transverse cervical vessels to the inferior deep cervical nodes.

## Deeper tissues

Deep lymph vessels follow the main neurovascular bundles (radial, ulnar, interosseous and brachial) to the lateral axillary nodes. They are less numerous than the superficial vessels and communicate with them at intervals. A few lymph nodes occur along the vessels. Scapular muscles drain mainly to the subscapular axillary nodes, and pectoral muscles drain mainly to the pectoral, central and apical nodes.

Efferent vessels from the deep cervical nodes form the jugular trunk. The right jugular trunk drains the right upper limb, the right half of the thorax and the right head and neck, and enters the right thoracic duct or directly enters the right subclavian vein close to its junction with the internal jugular. The left jugular trunk usually enters the thoracic duct, but it may directly enter either the subclavian or internal jugular vein (see Figs 29.16, 48.45).

## INNERVATION

The accessory nerve, dorsal scapular nerve, long thoracic nerve (nerve to serratus anterior), suprascapular nerve and nerve to subclavius all innervate muscles that act on the scapulothoracic 'joint' and therefore will be summarized here.

## Accessory nerve

The integrity of the accessory nerve is fundamental to thoracoscapular function and essential for scapulohumeral rhythm (Camp and Birch 2011). The intraspinal and intracranial course of the accessory nerve and of the segment of the nerve that lies in the anterior triangle are described on page 467 .

The accessory nerve passes either deep to or through sternocleidomastoid, to enter the posterior triangle in a consistent and important relation to the ascending nerves of the cervical plexus. The great auricular nerve is the key to exposure of the accessory nerve, which emerges, usually as one trunk, $5-10 \mathrm{~mm}$ cephalad to the point where the great auricular nerve winds around sternocleidomastoid, and moves from a plane posterior to the muscle to one that is anterior. The general relations of the posterior triangle vary with individual physique, but this relation between the two nerves is reliably consistent. The nerve now runs across the fatty areolar tissue at the apex of the posterior triangle, in close relation to the superior superficial cervical lymph nodes deep to platysma. It is separated from the underlying levator scapulae by this areolar tissue, and then, more deeply, by the prevertebral fascia. One slender branch passes to the upper fibres of trapezius either deep to sternocleidomastoid or just beyond it. The nerve pierces the fascia covering the deep surface of trapezius close to the anterior border of the muscle and then runs caudally about 2 cm from that border. The nerve passes down in a characteristic sinuous fashion, accompanied by slender vessels to the deep, inner face of trapezius. A branch from the cervical plexus $(\mathrm{C} 3,4)$ joins the nerve just above the clavicle. Intraoperative stimulation of this branch rarely evokes a muscular response; it probably conveys afferent fibres from the middle and lower parts of trapezius. The nerve now turns medially, continuing in parallel to the spine of the scapula about 4 cm above it. At the medial end of the spine, the nerve turns caudally again, passing down parallel to the medial border of the scapula. It divides into terminal muscular branches about 7 cm distal to the scapular spine. Although sternocleidomastoid, and the middle and the lower portions of trapezius, may be partially supplied by branches from the cervical plexus, the upper part of trapezius is innervated solely by the accessory nerve.

## Dorsal scapular nerve

The dorsal scapular nerve arises above the clavicle from the proximal segment of the ventral primary ramus of C5. It passes posteriorly, piercing scalenus medius, to run down in the plane between levator scapulae and serratus posterior superior and the posterior scalene muscles. It continues along the anterior border of the rhomboid muscles about 1.5 cm medial to the vertebral border of the scapula and is closely related to the dorsal scapular artery. The dorsal scapular nerve innervates the rhomboid muscles and, together with branches from C3 and C4, it supplies levator scapulae.

## Long thoracic nerve (nerve to serratus anterior)

The long thoracic nerve is formed by branches that arise above the clavicle from the proximal segments of the ventral primary rami of C5, C6 and C7. It innervates serratus anterior, a muscle that is essential for the function of the thoracoscapular joint. The muscular branches from the rami join deep to scalenus medius, and the trunk passes down posterolateral to the muscle, on the floor of the posterior triangle deep to the suprascapular nerve. The branches from C5 and C6 are the largest. The nerve follows a sinuous course deep to the investing fascia covering the anterior faces of the digitations of serratus anterior. It is accompanied here by a branch of the thoracodorsal artery, and trends posterolaterally towards the mid-axillary line.

## Suprascapular nerve

The suprascapular nerve $(\mathrm{C} 5,6)$ usually arises as the first branch of the upper trunk but it frequently springs directly from the ventral primary ramus of C5. It innervates supra- and infraspinatus.

## Nerve to subclavius

The slender nerve to subclavius $(\mathrm{C} 5,6)$ springs from the upper trunk and passes anteriorly. It descends anterior to the plexus and the subcla vian artery and passes above the subclavian vein to supply subclavius.

## Brachial plexus

The muscles, joints and skin of the upper limb are innervated by the ventral primary rami of C5, C6, C7 and C8, and nearly all of the ventral primary ramus from T1, collectively forming the brachial plexus (Figs 46.6-46.7). A branch from C4 to C5, which contributes to the innervation of the glenohumeral and elbow flexor muscles, is seen occasionally

,
Fig. 46.6 A schematic plan of the brachial plexus. (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
at operation. A muscular contribution from T2 is rare. The rami enter the posterior triangle of the neck between scalenus anterior and medius. Rami from C7 and C8 are the largest (C8 contains about 30,000 myelinated axons) and those from C5 and T1 are the smallest (between 15,000 and 20,000 myelinated axons). An adult brachial plexus contains between 120,000 and 150,000 myelinated axons, of which $25 \%$ innervate the shoulder girdle and glenohumeral joint. The proportion of motor fibres is greatest in C5 and C8; the sensory contribution is greatest in C7. A complex interchange of branches, before the main nerves of the upper limb are formed, produces the trunks, divisions and cords of the brachial plexus.

Blood supply The blood supply of the brachial plexus is derived from vessels arising from the subclavian and vertebral arteries. Important branches pass from the vertebral artery to the rami of C5 and C6 and the more proximal cervical nerves. Branches from the costocervical trunk provide a rich supply to T 1 and C 8 . Extensive contributions come from the suprascapular and superficial cervical arteries that arise from the thyrocervical trunk. In at least one-third of cases, the superficial cervical and dorsal scapular arteries arise from the thyrocervical trunk as the transverse cervical artery. In clinical terms, the arteries arising from the thyrocervical trunk have become the lifeline to the upper limb and must be preserved during operations in cases when the ruptured subclavian artery has not been repaired. The dorsal scapular artery may arise from the third part of the subclavian artery to pass between the upper and middle trunks of the brachial plexus.

## Trunks of the brachial plexus

The upper trunk is formed by C5 and C6, where these nerves emerge from deep to scalenus anterior. The middle trunk is the continuation of C7. The lower trunk is formed by C8 and T1, where these nerves cross anterior to the first rib. The ramus of T 1 takes an upward course across the deep face of the neck of the first rib behind the pleura and the vertebral and subclavian arteries towards the lower trunk. The formation of the trunks is fairly consistent; they lie in front of one another rather than side by side, with the subclavian artery passing anteromedially. The phrenic nerve crosses C 5 to pass anteromedially on the surface of scalenus anterior. The upper trunk, its divisions and the suprascapular nerve can all be palpated in the supraclavicular fossa in a subject of normal physique. The examining finger identifies first the subclavian pulse and then the nerves, whilst rolling the fingertip laterally (see Video 46.1).

## Divisions of the brachial plexus

The trunks divide into anterior and posterior divisions. The upper trunk divides $2-3 \mathrm{~cm}$ above the clavicle, and the divisions of the middle and lower trunk are formed deep to the clavicle. The posterior divisions of the upper and middle trunks are consistently larger than their anterior

Fig. 46.7 The brachial plexus. Note the sequence: ventral (anterior) primary rami; trunks; divisions; cords; nerves. The trunks are upper, middle and lower, and the cords are lateral, medial and posterior, according to their position in relation to the axillary artery, which is variable. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)
divisions. The posterior division of the lower trunk is consistently smaller than the anterior division and is absent in about $10 \%$ of cases.

## Cords of the brachial plexus

The cords are formed by the confluence of divisions: the lateral cord from the anterior divisions of the upper and middle trunks; the posterior cord by all three posterior divisions; and the medial cord by the anterior division of the lower trunk and, sometimes, by a branch from the anterior division of the middle trunks. The divisions of the trunks and the formation of the cords represent an important anatomical and functional differentiation. The posterior divisions and posterior cord innervate postaxial (extensor) musculature; the anterior divisions and the lateral and medial cords innervate preaxial (flexor) musculature.

The formation and relations of the three cords are variable and, indeed, their designations somewhat misleading. Immediately inferior to the clavicle, the posterior cord is lateral, the medial cord is posterior, and the lateral cord is anterior, in relation to the axillary artery; the cords assume their appropriate relations about the axillary artery deep to pectoralis minor. There is considerable variation in this arrangement; most commonly, the axillary artery lies anterior to the three cords and the median nerve.

The branches of the posterior cord, the largest of the three trunks, are consistent. In sequence, they are the upper subscapular, thoracodorsal, lower subscapular, axillary and radial nerves. The branches of the medial cord are usually predictable; the medial pectoral nerve and medial cutaneous nerve of the forearm are succeeded by the division into the medial root of the median nerve and the ulnar nerve. The ulnar

Fig. 46.8 Motor and sensory branches of the axillary nerve. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed, 2010, Edinburgh: Saunders, Elsevier.)
nerve may arise as two or three branches. The greatest variation in formation of trunk nerves is found within the lateral cord. Occasionally, the musculocutaneous nerve arises more distally than usual, springing either directly from the lateral cord as two or three branches or even from the median nerve itself. Sometimes, the highest of these branches enters coracobrachialis no more than 2 or 3 cm below the coracoid process. The lateral root of the median nerve may arise as two or three branches, and in some cases, it appears as a branch of the musculocutaneous nerve.

## Axillary (circumflex) nerve

The axillary nerve (C5, 6) (Fig. 46.8) runs freely in loose fatty tissue in the axilla before turning around subscapularis to pass almost horizontally through the quadrilateral tunnel, where it is accompanied by the posterior circumflex humeral vessels (see Fig. 48.33). It innervates teres minor and deltoid, and the skin overlying deltoid on the lateral aspect of the shoulder.

## Radial nerve

The radial nerve (C5, 6, 7, 8, T1) is the terminal branch of the posterior cord (Fig. 46.9). It is the largest nerve in the upper limb and the most commonly damaged. Between its origin at the level of the base of the coracoid and its entrance into the spiral groove, where it is accompanied by the profunda brachii artery, the radial nerve is supplied by fewer arteries than elsewhere along its course. The first $8-10 \mathrm{~cm}$ of the nerve may not have a nutrient artery and will, therefore, be relatively avascular if the nerve is transected at its origin. The nerve lies closest to the bone where it pierces the lateral intermuscular septum to pass through a short tunnel bounded by bone and unyielding fascia. The nerve is tethered here, a common level of rupture, entrapment or compression.

The nerve to the medial head of triceps arises in the axilla and accompanies the main nerve as it passes through the intermuscular septum. The nerve(s) to the lateral head of triceps arise(s) within the spiral groove; that to the lateral head just before the radial nerve re-enters the anterior compartment. Two cutaneous nerves, the lower lateral cutaneous nerve of the arm and the posterior cutaneous nerve of the forearm, pass away from the main nerve in the final part of the spiral groove and course along the anterior face of the lateral head of triceps to perforate the deep fascia about four fingers'-breadths above the lateral epicondyle. They innervate the skin of the lower lateral arm and the posterior aspect of the forearm.

The nerve to brachioradialis is formed about three fingers'-breadths proximal to the lateral epicondyle; the nerve to extensor carpi radialis longus about one finger's-breadth more distal; and that to extensor carpi radialis brevis about one finger's-breadth above the epicondyle. These branches spring from the main nerve as it runs in the valley between brachialis anteriorly and brachioradialis posteriorly, which is a site where the nerve may be palpated. At the level of the tip of the lateral epicondyle, the radial nerve divides into the posterior interos-

Fig. 46.9 Motor and sensory branches of the radial nerve. Variation exists in the cutaneous innervation of the dorsal aspects of the digits. Here, the radial nerve is shown to supply all five digits; the skin of the dorsum of the ring and little fingers is frequently innervated by the dorsal branch of the ulnar nerve. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed, 2010, Edinburgh: Saunders, Elsevier.)
seous and superficial radial nerves. Another branch to extensor carpi radialis brevis is usually given off here. The superficial radial nerve innervates the skin over the dorsum of the radial half of the ring, middle and index fingers, and that of the thumb as far as the distal interphalangeal joint. It often provides important sensation on the skin of the thumb web space and the skin on the adjacent sides of the thumb and index.

## Median nerve

The median nerve is formed by the union of the lateral root (C6, 7) from the lateral cord, and the medial root ( $\mathrm{C} 8, \mathrm{~T} 1$ ) from the medial cord, which meet anterior to the third part of the axillary artery (Fig. 46.10). Fibres in the lateral root innervate the palmar skin of the thumb, index and most of the middle fingers, and pronator teres, flexor carpi

Fig. 46.10 Motor and sensory branches of the median nerve. Flexor pollicis brevis may be supplied by both median and ulnar nerves. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed, 2010, Edinburgh: Saunders, Elsevier.)
radialis and some of flexor digitorum superficialis (Fig. 46.11). The lateral root conveys most of the sympathetic fibres to the median distribution in the hand. The medial root carries fibres to the skin of the medial side of the middle and the lateral side of the ring finger, and also fibres to palmaris longus, flexor digitorum superficialis and the lateral part of flexor digitorum profundus, flexor pollicis longus, pronator quadratus and the median innervated muscles within the hand. The first branch of the median nerve, to pronator teres, arises $2-3 \mathrm{~cm}$ above the medial epicondyle. A second branch, or leash of branches, arises at the level of the tip of the medial epicondyle and innervates palmaris longus, flexor carpi radialis and flexor digitorum superficialis. Just proximal to the tendinous arcade of flexor digitorum superficialis, the median nerve gives off the anterior interosseous nerve. Accompanied by the anterior interosseous vessels, this large branch dives deeply to pass down along the interosseous membrane and supplies flexor pollicis longus, the radial half of flexor digitorum profundus and pronator

Fig. 46.11 The normal course of the median nerve and the palmar cutaneous nerve at the wrist. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)
quadratus. There is no cutaneous distribution. The main nerve continues in the plane between the superficial and deep digital flexors, supplying two or three branches to the former. The palmar cutaneous nerve arises about 3 cm proximal to the proximal wrist crease, and passes lateral to the main nerve and superficial to the flexor retinaculum to innervate the skin of the proximal palm. The median nerve passes deep to the flexor retinaculum, into the carpal tunnel, to enter the palm. The nerve to the thenar muscles arises within, or just distal to, the tunnel, usually on the lateral side of the main nerve. The palmar digital nerves are formed within the palm of the hand.

The nerve is palpable along its course in the arm, where it is covered by deep fascia and skin, after emerging from deep to coracobrachialis. It is palpable on the flexor aspect of the elbow, deep to the bicipital aponeurosis, and is accompanied by the brachial artery in this segment of the limb. The median nerve is palpable at the wrist where it emerges from behind the superficial flexor tendons, just lateral to palmaris longus.

## Ulnar nerve

The ulnar nerve ( $\mathrm{C} 7, \mathrm{C} 8, \mathrm{~T} 1$ ) is the continuation of the medial cord (Fig. 46.12). It inclines posteromedially to perforate the medial intermuscular septum about 10 cm proximal to the medial epicondyle and passes through a fibrous canal, the arcade of Struthers, which is between 5 and 6 cm long. The walls of the canal include the medial intermuscular septum and the fascial sheath investing the medial head of triceps brachii. The nerve next passes behind the medial epicondyle, then between the capsule of the humero-ulnar joint and the overlying arcuate ligament, which joins the two origins of flexor carpi ulnaris, i.e. the nerve passes through the cubital tunnel. It is accompanied by the superior collateral ulnar vessels in the lower third of the arm as far as the entrance to the cubital tunnel, and then by the posteroinferior ulnar collateral vessels. The anastomosis between these vessels permits the use of most of the ulnar nerve as a free vascularized graft, in cases where the parent nerves, $\mathrm{C} 7, \mathrm{C} 8$ and T 1 , are irreparable. In the forearm, the nerve runs with the ulnar vessels in a well-defined sheath deep to the anterior margin of flexor carpi ulnaris. It divides into superficial (sensory) and deep (motor) components at the wrist, both passing through Guyon's canal.

The superficial division innervates the skin of the medial two digits and palmaris brevis. The deep branch passes, with the deep branch of the ulnar artery, between abductor and flexor digiti minimi, pierces opponens digiti minimi and then runs across the deep palmar space with the deep palmar arch. It innervates all the muscles of the hand, except for the first and second (index and middle) lumbricals, abductor pollicis brevis, opponens pollicis and part of flexor pollicis brevis.

Fig. 46.12 Motor and sensory branches of the ulnar nerve and the medial cutaneous nerves of the arm and the forearm. Flexor pollicis brevis may be supplied by both median and ulnar nerves. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed, 2010, Edinburgh: Saunders, Elsevier.)

A branch to the medial head of triceps is often given off in the distal third of the arm. There are usually two neurovascular pedicles to flexor carpi ulnaris, the first at the exit from the cubital tunnel, the second about one-quarter of the way down the forearm. Several branches pass to flexor digitorum profundus. The dorsal cutaneous nerve arises about 6 cm proximal to the ulnar styloid, winds around the ulna, at first deep to flexor carpi ulnaris, and then subcutaneously. It innervates the skin of the dorsum of the hand and little finger, and the medial side of the ring finger.

The ulnar nerve is palpable in the lower arm and behind the medial epicondyle, where it is subcutaneous. There is an important relation here: a posterior branch of the medial cutaneous nerve of the forearm sweeps across the cubital tunnel and gets in the way of medial surgical exposures. Inadvertent injury may cause severe pain. The ulnar nerve is palpable at the wrist where it emerges from under flexor carpi ulnaris.

Fig. 46.13 Motor and sensory branches of the musculocutaneous nerve. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed, 2010, Edinburgh: Saunders, Elsevier).

The dorsal cutaneous branch can be palpated in those of slender physique where it crosses the subcutaneous ulna.

## Musculocutaneous nerve

The musculocutaneous nerve $(\mathrm{C} 5,6,7)$ is one of the two terminal branches of the lateral cord, the other being the lateral root of the median nerve (Fig. 46.13). This division usually occurs at the level of the third part of axillary artery, where the lateral cord is lateral to the vessel, but it may occur more proximally, where the cord is anterior to the second part of the artery. The nerve may also arise as two or three branches from the cord, or even from the median nerve. It supplies coracobrachialis, both heads of biceps brachii and most of brachialis, and continues as the lateral cutaneous nerve of forearm, deep to biceps, before emerging lateral to it about 11 cm above the lateral epicondyle, and then running down the lateral aspect of the forearm. The nerve sometimes innervates the skin over the first metacarpal and the lateral part of the thenar eminence.

## Segmental innervation of the upper limb

There is a segmental pattern to the innervation of the upper limb. The most proximal muscles are supplied by branches of the uppermost rami, and the most distal muscles are supplied by branches derived from C8 and T1. The segmental pattern of innervation is shown more clearly in the cutaneous supply. The cervical supply has been, as it were, extruded from the supply to the trunk. Thus, in the transition of cutaneous innervation from the skin of the neck to that of the trunk, there is a change from the fourth cervical to the second thoracic segment anteriorly, and a change from the fifth cervical to the first thoracic segment posteriorly (Figs 46.14-46.15; see Fig. 16.10 for other variations). (For further reading, see Ladak et al (2014).) The truly autonomous area of cutaneous supply of each main component nerve is small and variable in extent and location.

C5 regularly controls extension, abduction and lateral rotation of the shoulder. C6 usually innervates biceps brachii, brachialis, lateral head of triceps, brachioradialis, extensor carpi radialis longus, and sometimes contributes to the innervation of pronator teres, supinator and flexor carpi radialis. C7 gives widespread innervation throughout the limb; in those unusual instances where it alone is damaged, the patient will note a rather diffuse loss of function throughout the upper limb, often without complete anaesthesia and sometimes without paralysis of any single significant muscle group. C7 consistently supplies latissimus dorsi. C8 innervates the extensors of the digits and of the thumb in at least one-third of cases. T1 innervates these muscles and also the medial head of triceps in at least $10 \%$. Muscles, movements and segmental innervation in the upper limb are set out in Tables 46.1-46.3. Table 46.4 helps to distinguish between upper and lower motor neurone lesions.

## Autonomic nerves

The preganglionic sympathetic inflow to the upper limb is derived from neurones in the intermediolateral horn of spinal cord segments T2-6/7. Myelinated preganglionic axons pass from the spinal nerves to the thoracic sympathetic chain via white rami communicates. They pass up the chain to the middle cervical and inferior cervical (stellate or cervicothoracic) ganglia, where they relay.

The unmyelinated postganglionic fibres are distributed by grey rami communicantes to the nerves of origin of the brachial plexus. C5 and C6 receive grey rami from the middle cervical ganglion; C7 and C8 receive grey rami from the inferior cervical ganglion; T1 not only receives a grey ramus from the inferior cervical ganglion but also contributes a white ramus to it (see Figs 16.13, Fig. 46.16). Interruption of this white ramus is one cause of Horner's (Bernard-Horner) syndrome: drooping eyelid, narrow palpebral fissure, a contracted pupil, and vasomotor with sudomotor paralysis in the ipsilateral face and neck. The sympathetic outflow to the upper limb passes with the peripheral nerves and is particularly rich in the palmar skin of the hand and in the skin of the axilla.

## SURFACE ANATOMY

## SKELETAL LANDMARKS

The clavicle is both visible and palpable from its prominent and relatively rounded medial (sternal) end, which forms the lateral boundary of the suprasternal notch, to its flattened lateral end, where it joins the acromion (Fig. 46.29A). The acromioclavicular joint line is palpable as an anteroposteriorly aligned ridge or groove. The anterior, superior and lateral surfaces of the acromion are subcutaneous and palpable (Fig. 46.29C). Posteriorly, the palpable acromial angle marks the junction of the acromion with the crest of the scapular spine. From this point, the spine of the scapula, which is subcutaneous and easily visible in thin subjects, is palpable to the medial (vertebral) border of the scapula, where it lies opposite the spine of the third thoracic vertebra.

The medial border of the scapula, superior to the level of the scapular spine, is covered by trapezius and, therefore, difficult to palpate. Below the spine, the medial border is palpable down to the inferior angle. Although covered by teres major and latissimus dorsi, the inferior angle is palpable when approached inferiorly, and can be seen and/or palpated as it moves around the thoracic wall during shoulder movements. The inferior angle is opposite the spine of the seventh thoracic vertebra and overlies the seventh rib; it is a convenient landmark from which the ribs can be counted along the lateral chest wall, e.g. when a thoracotomy is being performed.

Table 46.1 Movements, muscles and segmental innervation in the upper limb

| Joint | Movement | Muscle | Innervation | C3 | C4 | C5 | C6 | C7 | C8 | T1 |

|  | OPPOSITION | Opponens pollicis | Median n . and ulnar n . |  |  |  |  |  |  |  |

Muscles and movements that have diagnostic value are marked in red. Spinal roots have been given the same colour (light peach, dark peach, red) when they innervate a muscle to a similar extent. Red has been used to
indicate roots from which there is known to be a dominant contribution.
*These movements occur at the radio-ulnar joints.
Abbreviations: DIP, distal interphalangeal; IP, interphalangeal; MP, metacarpophalangeal; PIP, proximal interphalangeal.

The muscles listed in the 'Upper motor neurone' column are those that are preferentially affected in upper motor neurone lesions. The root level is the principal supply to a muscle.

In the acute injury, the object of the clinician must be to recognize the fact of injury as soon as possible after the event, and later, to go on to determine the nerve or nerves affected, the level(s) of injury, and the extent and depth of the lesion(s). The history is important: high injury transfer, open fracture and wounding (be it accidental, criminal, surgical, or all three) indicate a serious lesion and advice from witnesses or emergency paramedical staff is always valuable. Injuries that are potentially life- or limb-threatening complicate closed traction lesions of the supraclavicular brachial plexus in about $20 \%$ of cases. It is important to seek occult injuries to the head, spine, thorax, abdomen and pelvis before embarking on treatment of the nerve lesion(s).

The early symptoms of acute nerve injury include: abnormal spontaneous sensations; alteration or loss of sensibility; weakness and paralysis; impairment of function; an awareness of warming and dryness of all or part of an extremity (sometimes); and pain (sometimes). Neuropathic pain is never easy to recognize in an injured patient, who is probably confused, distressed and in pain. It can be distinguished from the pain of fracture or dislocation by loss of sensation; painful, spontaneous sensory symptoms, expressed throughout the territory of the nerve; and by lancinating or shooting pain, irradiating into the distribution of the nerve. Constant crushing, bursting or burning pain in an otherwise undamaged hand indicates serious and continuing injury to major trunk nerves more proximally. Progression of sensory loss, with a deep bursting or crushing pain within the muscles of the limb, signifies critical ischaemia.

The main nerves are stretched, ruptured or avulsed from muscle by violent hyperextension-abduction injuries of the arm. The axillary or brachial artery is ruptured in at least one-third of fractures of the proximal humerus or fracture dislocations of the shoulder. The axillary nerve and posterior circumflex vessels, which pass almost horizontally posterior to the neck of the humerus, are particularly at risk from anterior dislocation of the head of the humerus. The radial nerve and the profunda brachii artery are relatively fixed where they pass from the anterior to the posterior compartment by perforating the medial intermuscular septum in the axilla, and again when they re-emerge into the anterior compartment by perforating the lateral intermuscular septum. They may be stretched, ruptured or entrapped by displaced fractures of
the shaft of the humerus. The median, ulnar and radial nerves may be subjected to traction, or entrapment, by fracture or dislocation about the elbow. The median nerve is severely compressed by fractures or dislocations impinging into the carpal tunnel. All nerves may be transected by wounds from a knife, glass, a bullet or other missile anywhere along their course. The axillary artery and its main branches are commonly involved in nerve injuries. Wounds of the median nerve in the arm commonly extend to the brachial artery, and the ulnar artery is usually involved in wounds to the ulnar nerve in the forearm and at the wrist.

Nerves and related structures may be displaced by fracture, dislocation or haematoma. The ensuing fibrosis distorts normal anatomical relations; this increases the risk of intraoperative damage when nerves and accompanying vessels are not formally exposed. The incidence of such iatrogenic injuries is increasing, accounting for one-quarter of lesions of the radial nerve; the incidence is even higher for nerves around the elbow.

Injuries to nerves of cutaneous sensation are common after wounds, incisions or vessel puncture. It is remarkable that the elective removal of nerves such as the medial cutaneous nerve of the forearm for the purpose of grafting is followed by pain only very rarely, while lesions of the terminal branches are usually painful. The medial cutaneous nerve of the arm and the intercostobrachial nerve are at risk during operations in the axilla. The posterior cutaneous nerves of the arm and forearm are vulnerable during the lateral approach to the shaft of the humerus. The medial and lateral cutaneous nerves of the forearm are frequently damaged during operations around the elbow. The dorsal branch of the ulnar nerve is at risk during operations on the distal third of the ulna. The superficial radial and lateral cutaneous nerves are frequently injured by interventions on the lateral side of the wrist. Injuries to the palmar cutaneous branch of the median nerve and to the digital nerves are unwelcome complications of operations on the hand. These injuries cause pain, which may become severe. Mechanical allodynia, the perception of light touch as pain, is common; the spread of pain and allodynia beyond the territory of an injured nerve is frequent and indicates central sensitization of other neurones in the dorsal horn of the spinal cord.

## EXAMINATION

Examination complements the history and the interpretation of symptoms to provide an accurate diagnosis. All findings should be set down in an intelligible record. Unfortunately, the signs of acute nerve injury have to be sought at a time when the patient may be least able to cooperate in an examination: soon after wounding, when there is likely to be distress and when the general condition may be affected by loss of blood and other injuries and/or by drink and drugs. The examination often has to be undertaken in the frequently unfavourable surroundings of an accident department. When the lesion has been inflicted by a surgeon or anaesthetist, the patient's response is likely to be distorted by postoperative pain, by the effects of recent general anaesthesia or by sedative or analgesic drugs. These are inappropriate conditions for a quiet and comprehensive 'neurological examination', and yet this is the time when the fact of nerve injury must at least be recognized if the best result is to be obtained from treatment. The examiner should, at all times, bear in mind the fact that, if there is a wound over the line of a main nerve and if there is any suggestion of loss of sensibility or impairment of motor function in the distribution of that nerve, it must be regarded as having been cut until and unless it is proved otherwise.

## Local signs in closed injury

In closed injuries, swelling or ecchymosis and linear abrasions indicate severe soft tissue injury and also the line of application of force (see Fig. 6.1.1 in Commentary 6.1). Peripheral pulses and limb perfusion must be examined and re-examined.

## Wound characteristics

It is useful to distinguish between the tidy wound caused by a knife and the untidy, and usually contaminated, wound of open fracture, machinery or gunshot. A further distinction is made between wounds caused by a handgun, rifle and close-range shotgun, the latter being particularly destructive. The injuries of current conflicts are classed as: penetrating missile wound, (small) fragment wound, and blast wound, those from mines or improvised explosive devices (IEDs).

## Sensation

Sensory loss is determined by response to light touch and pinprick. If circumstances permit, the patient outlines the area of sensory loss, which is then marked by a black skin-marker pen. The surrounding zone of incomplete sensory loss can be similarly marked in red,
and the limb then photographed. For clinical examples, see Figures 46.17-46.27.

## Examination of muscles

Selected muscles are examined. The patient lying supine is usually able to demonstrate activity in serratus anterior by lifting the shoulders away from the couch, by means of 'forward shrugging'. It is usually possible to observe the presence of flexion and abduction at the shoulder, flexion

Fig. 46.24 A high median nerve injury; there is no active flexion of the index finger and thumb. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Fig. 46.25 Section of the median nerve and the palmar cutaneous nerve at the wrist. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)
and extension of the elbow and wrist, and flexion and extension of the fingers. The radial, median and ulnar nerves are tested by asking the patient to form an ' O ' between the thumb and little finger, to give the 'thumbs up' sign, and to open and close the fingers like a fan. The palmar skin is scrutinized for changes in colour and in sweating (Fig. 46.28). Although this may be more difficult in pigmented skin, such changes are detectable. The standard tendon reflexes are examined.

## Secondary examination

A more detailed examination is possible when the patient's condition is stable, and when pain has been controlled. Limb dominance, occupation, marital status, underlying disease and continuing medication are recorded, if this has not already been done. Neuropathic pain is now somewhat easier to recognize because it is less responsive to analgesics than is pain from skeletal injury.

## Recognition of the level of a lesion and the depth of injury

A sound grasp of the distribution of the spinal nerves and of the location of the formation and branching of the trunk nerves allows accurate diagnosis of the level of a lesion.

## Posterior cord and radial nerve

The extent of the sensory loss is variable. There is no cutaneous sensory loss in lesions confined to the posterior interosseous nerve. The examination of selected muscles is reliable in guiding the clinician to the level of injury. They include, in order: teres major (inferior scapular nerve), latissimus dorsi (thoracodorsal nerve) and deltoid (axillary nerve). Subscapularis (superior scapular nerve) is not an easy muscle to examine.

Paralysis of all three heads of triceps places the injury in the axilla. The nerves to the lateral head of triceps leaves the main nerve rather distally, so that radial palsy, with paralysis of the lateral head but active medial and long heads, points to a lesion in the spiral groove. The nerve to brachioradialis consistently passes away from the main trunk about three fingers'-breadths above the lateral epicondyle, and the nerve to extensor carpi radialis longus leaves the main trunk about 1 cm more distally. One nerve to extensor carpi radialis brevis leaves the main nerve about 1 cm proximal to the lateral epicondyle, and another leaves at the site of division into the superficial radial and posterior interosseous nerves.

## Lateral cord, musculocutaneous nerve and lateral root of the median nerve

It seems that most of the median nerve fibres that innervate the skin of the hand pass through the lateral cord. Paralysis involves biceps brachii, brachialis, flexor carpi radialis and pronator teres. That portion of brachialis innervated by the radial nerve may be intact. Division of the musculocutaneous nerve does not lead to loss of elbow flexion because brachioradialis acts as a powerful flexor of the joint (see Fig. 46.21).

## Medial cord, medial head of the median and ulnar nerves

The sensory loss does not extend into the arm. If it does, then the medial cutaneous nerve of the arm must be involved. Paralysis is extensive, and includes the long flexor muscles to the digits, the small muscles of the hand, and the smooth muscle associated with the vessels and sweat glands supplying the ulnar three fingers.

## Median nerve

Involvement of the palmar cutaneous nerve is useful in localizing a lesion at the wrist (see Figs 46.25, 46.26), but the extent of paralysis is a more precise guide to the level of a lesion. Injuries in the arm cause paralysis of all muscles innervated by the median nerve, including those arising from the medial epicondyle (flexor carpi radialis, pronator teres, palmaris longus, and part of flexor digitorum superficialis), as well as those innervated by the anterior interosseous nerve (flexor pollicis longus, flexor digitorum profundus to index finger) (see Fig. 46.24). Anterior interosseous palsy is distinguished from high median injury by the absence of any loss of skin sensation. Abductor pollicis brevis is the one small muscle of the hand that is consistently innervated by the median nerve.

## Ulnar nerve

The sensory loss is related to the involvement of the dorsal and palmar cutaneous branches (see Fig. 46.27). Ulnar palsy with paralysis of flexor carpi ulnaris places a lesion in the arm. Paralysis confined to the hand places a lesion in the distal half of the forearm. Preservation of the hypothenar muscles with paralysis of the other hand muscles innervated by the ulnar nerve places a lesion in the proximal part of the palm of the hand. There is no cutaneous sensory loss in a palsy of the deep branch of the ulnar nerve. The posture of the digits is characteristic in ulnar nerve lesions.

The examiner should bear in mind the possibility of anatomical variation and also the ability for other muscles to compensate for the actions of those paralysed by what are termed 'trick movements'. In fact, these muscles are acting appropriately and the movements are real enough (see Fig. 46.23B).

## Depth of a lesion

The distinction between conduction block and severance of an axon (axonotmesis or neurotmesis) is sometimes difficult. Serious injuries are likely to cause serious lesions of nerves. Severance of a nerve with a cutaneous sensory component will lead to well-defined loss of sensibility and to complete motor, sudomotor and vasomotor paralysis in the distribution of the nerve. Simple conduction block is likely to produce a patchy loss of sensibility and a patchy motor loss. Further, it is likely to bear more heavily on the large axons than on the small ones;
vibration sense and sensibility to light touch are likely to be impaired, whereas pain sensibility may be unaffected. There is a risk of underestimating the severity of a nerve lesion in cases of closed injury and after intraoperative events. Different populations of nerve fibres within a main nerve that has been violently stretched but not ruptured sustain lesions of all grades of severity. Some remain intact, whilst conduction is blocked in others. Some ruptured axons will recover spontaneously, whilst others will not, depending on their cellular microenvironment (see Commentary 1.6).

Testing of sensibility is often difficult soon after wounding, or when nerve injury is associated with fracture of a long bone. The actions of some muscles can be simulated by the actions of others, so that the fact of paralysis can be missed in the early stages after nerve injury. Thus, when the median nerve has been cut, opposition of the thumb can be mimicked by the action of extensor pollicis brevis (ulnar nerve) and abductor pollicis longus (radial nerve). Similarly, abductor pollicis longus can imitate the action of the abductor pollicis brevis. It is important to examine both hands, especially in the early days, when there is no wasting to guide the examiner. One almost infallible sign is always present in the first 48 hours after deep injury of a nerve with a cutaneous sensory component: because small, as well as large, fibres are affected, the skin in the distribution of the damaged nerve is warm and dry. In a small child, there may be an abnormal posture of the denervated digits; the 'immersion test' is also helpful. The injured hand or foot is placed, for a few minutes, in warm water; the skin of the denervated digits fails to wrinkle. In ischaemia, the large fibres conveying discriminative sensibility and vibration sense are first affected. It is not easy to test these modalities when ischaemia is developing because of the damage to a main vessel that is associated with a fracture of a long bone, but if action is not taken until superficial sensibility is lost, it will come too late.

## Tinel's sign

In closed injuries, percussion of the skin over a nerve in which axons have been ruptured evokes sensations usually described as a wave or surge of pins and needles into the cutaneous distribution of the nerve. This is Tinel's sign and it is a most useful aid to diagnosis. The sign is elicited on the day of injury in most conscious patients. It indicates not only where the nerve has been injured but also the fact that at least some axons have been ruptured. Tinel's sign can be detected from such 'motor' nerves as the posterior interosseous nerve; sensory symptoms radiate into muscular territory rather than into skin. It is more difficult to elicit the sign over deep-seated nerves such as the axillary, eighth cervical or first thoracic nerves.

## Eliciting Tinel's sign in closed lesions

The examiner's finger percusses along the course of the nerve from distal to proximal, starting below the presumed level of lesion. The patient is asked to say when the advancing finger elicits a wave or a surge of pins and needles or abnormal sensations, which may be painful, into the distribution of the nerve, which must be clearly indicated by the examiner. The level of the sign should be measured from a fixed bony point and the distance recorded. At times, the examination is painful and patients need to be warned of this. A Tinel's sign that remains static at the level of a lesion strongly suggests rupture of the nerve or persisting local conditions inimical to spontaneous regeneration.

Common examples of the classical compartment syndrome in the upper limb occur in the flexor and extensor compartments of the forearm. Although nerve conduction is lost before muscle contractility, ischaemia is more likely to produce infarction of muscle than necrosis of nerve. Decompression of a nerve embedded within muscle that has become fibrosed by ischaemia usually leads to relief of pain and considerable improvement in sensation and sympathetic function, even when delayed for some months.

Anoxia occurs either because of cessation of flow through a main axial artery or as a result of increasing pressure within an osseofascial compartment caused by bleeding, infusion of fluid or sepsis. It destroys the integrity of the cell membrane and capillary endothelium, which means that the homeostatic balance between the intravascular, extracellular and intracellular spaces is lost. Tissue death is imminent.

The increased permeability of the vascular endothelium leads to an increase in intracompartmental pressure by exudation, which collapses the low-pressure lymphatic and venous systems. The final event is the closure or obstruction of perfusing arterioles to muscles and the extrinsic supply to nerves, when tissue or extravascular pressure exceeds the cortical closing pressure of those vessels. The vicious circle is complete. The fluid entering the compartment cannot get out and continues to leak into the compartment until the pressure is so high that inflow is blocked. Increasing intracompartmental pressure occurs when the collateral circulation is inadequate after occlusion of the main artery or after restoration of flow through that vessel, unless the compartments have been decompressed adequately by fasciotomy. The vascular anastomoses about the joints of the upper limb provide a richer collateral circulation than those found in the lower limb. In a study of nearly 2,500 World War II battle casualties, at a time when ligation of damaged arteries was common, ligation of the popliteal artery led to amputation in 346 of 502 limbs. In contrast, the incidence of amputation after ligation was about one-quarter for the subclavian artery, one-third for the axillary artery and more than one-half when the brachial artery was ligated proximal to the profunda brachii artery. These figures are certainly lower in the less contaminated injuries of civilian life, but some degree of post-ischaemic fibrosis is almost inevitable after failure to repair these vessels. The principles of arterial repair include urgent restoration of flow by repair of the artery and restoration of tissue perfusion by decompression. Temporary intraluminal shunts are invaluable, as they buy time and permit adequate stabilization of the skeleton. Application of these principles in current conflicts ensures a remarkably high rate of limb survival and a remarkably low incidence of postischaemic fibrosis.

Flow through the brachial artery in adults and in children has been measured by high-resolution ultrasonography. Flow was calculated by the Laplace equation: BF (blood flow) $=[\pi \times(\mathrm{D} / 2)]^{2} \times \mathrm{FV}$ (flow velocity). The mean diameter of the brachial artery in children aged between 4 and 5 years is 2.7 mm , which provides a resting flow of about 200 ml per minute. The significance of the diameter of the vessel is emphasized by Poiseuille's law. This is the physical law describing the volume of flow ( $\Phi$ ) of an incompressible uniform viscous liquid, where R is the internal radius of the tube, P the pressure difference between the two ends, $\eta$ the dynamic fluid viscosity and $L$ the total length of the tube.

$$
\Phi=\frac{\pi \mathrm{R}^{4}}{8 \eta} \frac{[\Delta \mathrm{P}]}{\mathrm{L}}
$$

The diameter of the superior ulnar collateral artery at the elbow in a 5 -year-old child is, at most, 1 mm . This calibre provides flow of about 20 ml per minute, assuming that the pressure gradient is the same as that in the brachial artery itself. These facts must be borne in mind by any clinician inclined to the view that cessation of flow through the brachial artery is a matter of little consequence. The collateral channels take hours or days to develop and may be compromised by the original injury or during operation. The radial and ulnar nerves are often entrapped or compressed in fracture dislocations at the elbow, blocking flow through the ulnar and radial collateral systems that accompany these nerves.

The presence of peripheral pulses does not indicate adequate perfusion of the deep intracompartmental tissues; neither does the perfusion of skin or the nail bed when pulses are absent. The cardinal symptom of ischaemic anoxia is severe pain and the cardinal sign is loss of nerve conduction. This can be confirmed during exposure of limb nerves with an inflated tourniquet cuff in position proximally. For about 20 minutes, stimulation of the nerve evokes a brisk muscular response as a consequence of transmission through the neuromuscular junction. This response diminishes and disappears after
about 30 minutes, although conduction within the nerve itself can still be detected for up to another 20 minutes. However, direct stimulation of the muscle provokes a twitch that can be elicited for up to several hours. Indeed, it is the loss of this direct response that signifies impending death of the muscle, and with it, death of the limb. The earliest nerve fibres to suffer are the largest, i.e. those conveying vibration and proprioception sense.

## Ischaemia and acute compression within neurovascular fascial compartments

Sleeves of fascia surround main nerves and main vessels in some regions, an arrangement that predisposes nerves to injury from ischaemia or compression, or both. The ventral (anterior) primary rami of C7, C8 and T1 are enclosed in quite a rigid space after they enter the posterior triangle of the neck. This is bounded, posteriorly, by the dorsal part of the first rib, the transverse processes of the cervical vertebrae and by the fascia of levator scapulae. The nerves are embraced by scalenus anterior and scalenus medius, both of which are invested in an unyielding fascia. This is one envelope of the prevertebral fascia that also serves to bind the phrenic nerve down to the anterior face of scalenus anterior. The prevertebral fascia is particularly well developed in front of the vertebral column and also at the base of the posterior triangle, where it envelops C7, C8 and T1, the phrenic nerve, the cervical sympathetic chain, and the subclavian and vertebral arteries. Infusion of relatively large volumes of fluid, from 10 to 20 ml , deep to the prevertebral fascia for the purpose of inducing regional block may cause tamponade of the radicular vessels that enter the spinal canal and contribute to the anterior spinal artery. Wilbourn (2005) has described the medial brachial fascial compartment, which extends from the axilla to the elbow and is bounded by the tough medial intramuscular septum and the axillary sheath. Bleeding into this compartment is responsible for the majority of infraclavicular plexopathies that follow regional block, and for many of the neurological lesions that result from closed or even open injuries in this region. The anterior interosseous nerve and its accompanying artery may be damaged by compression because of swelling in the deepest part of the flexor compartment of the forearm. The ulnar nerve, accompanied by the ulnar artery, lies in a discrete fascial compartment in the distal two-thirds of the forearm.

Bleeding into the axillary fascia (the medial antebrachial compartment) causes a characteristic, progressive lesion. There is, almost always, pain accompanied by dysaesthesiae; loss of sensation soon follows and then, over the next 2-3 hours, paralysis ensues. Wilbourn's comment bears repeating:
Distal pulses are normal as they are with most compartment syndromes because the elevated pressure, although sufficient to collapse the vasae nervori, is far below mean arterial pressure. Ultrasound, MR and CT may reveal the vascular lesion, but, considering the very brief time available for surgical decompression before irreversible nerve damage occurs, obtaining these is rarely justified.
In one series of 16 patients (Stenning et al 2005), there was, in all cases, an injury to the axillary artery or one of its offsets, caused by dislocation of the shoulder or fracture of the proximal humerus. The diagnosis of continuing bleeding into the axillary sheath was made by the delayed onset of nerve palsy or the deepening of the lesion whilst under observation. A favourable outcome was seen in 87 nerve palsies, where urgent repair of the artery and decompression of the axillary sheath were performed. However, delay in diagnosis and treatment may lead to permanent loss of function (see Fig. 6.2.17).

Case report After a fracture/dislocation of the shoulder in a 59 -yearold man, the patient's complaints of pain and the signs of a deepening lesion were not appreciated for several days. Angiography showed bleeding from the subscapular artery. Two unsuccessful attempts were made to occlude this by embolization. The patient was reviewed at 6 weeks in right heart failure; haemoglobin was $4.9 \mathrm{~g} / \mathrm{litre}(49 \mathrm{~g} / \mathrm{dl})$. He was in great pain and there was a total and deep plexopathy. A magnetic resonance imaging (MRI) scan showed an enormous haematoma occupying the axilla and the arm, and suggested continuing bleeding. Treatment was simple: the axillary artery was exposed and controlled above pectoralis minor and the brachial artery exposed and controlled in the arm. More than 4 litres of altered blood were removed from the sac . The defect in the axillary artery was, at most, 2 mm in diameter and it was closed by direct suture. The pain was relieved and there was gradual recovery of the nerves, but the small muscles of the hand never recovered.

Fig. 46.16 The relations of the left cervicothoracic (stellate) ganglion. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

The infraclavicular fossa (deltopectoral triangle) is visible as a small depression located inferior to the clavicle between the clavicular origins of pectoralis major and deltoid, at the junction of the convex medial and concave lateral portions of the clavicle (see Fig. 46.29A). The apex of the coracoid process lies approximately 2.5 cm below the clavicle immediately lateral to this fossa, and is covered by the anterior fibres of deltoid. Deep palpation lateral to the coracoid process and through deltoid reveals the lesser tubercle of the humerus below the tip of the acromion. The greater tubercle of the humerus is the most lateral bony point in the shoulder region and is palpable inferolateral to the acromion. The greater and lesser tubercles can be felt moving under an examining finger during lateral and medial humeral rotation. The vertical groove or indentation of the intertubercular (bicipital) groove is palpable between the tubercles; regional tenderness occurs in bicipital tendinitis. When the arm is abducted, the head of the humerus can be palpated on deep pressure in the apex of the axilla.

The shaft of the humerus is covered by overlying muscles and is not easily palpable. Distally, the medial humeral epicondyle is both visible and palpable, particularly when the elbow is flexed, and can be traced proximally to the medial supracondylar ridge. The ulnar nerve passes posterior to the medial epicondyle and can be rolled from side to side just proximal to the epicondyle (Fig. 46.29B). The lateral epicondyle is less prominent, but its posterior surface is palpable and its lateral margin can be traced proximally on deep palpation to the lateral supracondylar ridge. Inspection of the posterior surface of an extended elbow reveals a depression lateral to the midline, bounded laterally by the fleshy elevation formed by the superficial forearm extensor muscles, and medially by the lateral side of the olecranon. The floor of this depression contains the posterior surface of the lateral epicondyle superiorly,
and the head of the radius covered by the anular ligament inferiorly. Rotations of the radial head are palpable during forearm pronation and supination. The humero-radial part of the elbow joint forms a palpable transverse depression between the lateral epicondyle and the radial head.

The posterior surface of the olecranon is subcutaneous and tapers as it passes inferiorly. When the elbow is extended, the apex of the olecranon lies on a line level with the medial and lateral humeral epicondyles (see Fig. 46.29B). When the elbow is flexed, the apex of the olecranon descends and the three bony points then form a triangle. This relationship is lost following elbow dislocation.

The elbow joint is situated 2 cm below a line joining the two humeral epicondyles. It slopes downwards and medially from its lateral extremity. When the elbow is fully extended with the forearm and hand in supination, the carrying angle is normally $165^{\circ}$ in females and $175^{\circ}$ in males. The angle is obscured in full forearm pronation and disappears on full elbow flexion, when the shafts of the ulna and humerus come to lie in the same plane. The elbow joint can be accessed with a needle from a posterior perspective via the anconeus triangle; the borders of the triangle join the olecranon, radial head and lateral epicondyle.

The posterior border of the ulna is subcutaneous and palpable from the olecranon superiorly to the styloid process inferiorly (see Fig. 46.29C). Its position corresponds to the longitudinal furrow that is visible on the posterior forearm when the elbow is fully flexed and marks the border between the anterior and posterior forearm compartments. In contrast, the radial shaft is covered by muscles and can only be felt indistinctly. The rounded head of the ulna forms a surface elevation on the medial part of the posterior aspect of the wrist (Fig. 46.30B),
especially when the hand is pronated. The ulnar styloid process projects distally from the posteromedial aspect of the ulnar head.

The expanded distal end of the radius forms a slight surface elevation on the lateral side of the wrist and can be traced downwards to the radial styloid process. The posterior aspect of the lower end of the radius is partly obscured by the extensor tendons but can be palpated without difficulty. The prominent dorsal radial (Lister's) tubercle is both visible and palpable, and aligns with the web space between digits 2 and 3 (Fig. 46.30B-C). The tendon of extensor pollicis longus in extensor compartment 3 sits medial to the tubercle, and the tendons of extensor carpi radialis longus and brevis sit lateral to the tubercle in compartment 2.

The wrist joint is identified between the distal ends of the radius and ulna and the proximal carpus on flexion and extension of the wrist. The line of the wrist joint corresponds to a line, convex superiorly, joining the radial and ulnar styloid processes. Its position is also marked by the proximal of the two transverse anterior wrist creases (Fig. 46.30A). The radial styloid process normally sits 1 cm distal to the ulnar styloid process. Alteration of this arrangement can indicate fracture.

Four of the carpal bones are palpable. The pisiform is both visible and palpable on the palmar aspect of the medial wrist at the base of the hypothenar eminence. It is often overlain by the distal wrist crease.

It can be moved over the articular surface of the triquetrum when the wrist is passively flexed. The hook of the hamate lies approximately 2.5 cm distal to the pisiform, in line with the ulnar border of the ring finger. It can be felt on deep palpation, and the superficial division of the ulnar nerve can be rolled from side to side over the tip of the hook. The tubercle of the scaphoid is situated at the base of the thenar eminence, in line with the tendon of flexor carpi radialis, and in many individuals forms a small visible elevation. Immediately distal to it, but covered by the muscles of the thenar eminence, the tubercle of the trapezium can be identified on deep palpation.

The dorsal aspects of the trapezium and of each of the metacarpal bones are partially palpable around the margins of the corresponding extensor tendons (see Fig. 46.30B). The heads of the metacarpal bones form the prominences of the knuckles, and are most obvious during digit flexion. On the dorsal hand, the metacarpophalangeal joint line forms a palpable depression lateral to the digital extensor tendon, and alternating digit flexion/extension aids identification. The joint can be aspirated/injected from this perspective. Palpation distal to the metacarpal head reveals the flared base of the corresponding proximal phalanx. The interphalangeal joints are palpable on the dorsal aspect of a flexed digit just distal to the prominences formed by the heads of the proximal and middle phalanges.

Key: 1, sternoclavicular joint; 2, clavicle; 3, infraclavicular fossa/deltopectoral triangle, and deltopectoral groove running inferolaterally; 4, acromion; 5, deltoid; 6, pectoralis major; 7, lateral head of triceps; 8, biceps brachii; 9, median nerve and brachial artery running anterior to triceps medial head; 10, epicondylar line and borders of cubital fossa (blue); 11, brachioradialis; 12, pronator teres; 13, biceps tendon (black) and aponeurosis (grey) passing inferomedially; 14, extensor muscle mass; 15, cephalic vein. B, The anterior aspect of the left elbow, forearm and hand. Key: 1, radial nerve; 2, brachial artery; 3, median nerve; 4, ulnar nerve (dashed part of line shows nerve passing posterior to medial epicondyle); 5 , zone of radial nerve bifurcation (white): $1.0 \pm 2.8 \mathrm{~cm}$ distal to the lateral epicondyle; 6 , cubital fossa borders (blue); 7, biceps tendon with brachial artery bifurcation medially; 8, ulnar artery; 9, radial artery; 10, pisiform with Guyon's canal (blue) laterally; 11, deep palmar arch; 12, superficial palmar arch; 13, plane of fully extended thumb.

Fig. 46.29, cont'd C, A posterior view of the left pectoral girdle, arm, elbow and forearm. Key: 1, trapezius; 2, supraspinatus; 3, spine of scapula; 4, acromion; 5 , infraspinatus; 6, zone of axillary nerve passing around proximal humerus (white): approximately 6.0 cm from proximal humeral margin; 7, deltoid; 8 , radial nerve and its zone of passage around spiral groove (white): enters the spiral groove approximately $46 \%$ and leaves it approximately $60 \%$ of the way down a line from greater tubercle to lateral epicondyle; 9 , triceps, long head; 10, triceps, lateral head; 11, radial nerve piercing intermuscular septum approximately $66 \%$ of the way down a line from greater tubercle to lateral epicondyle; 12, triceps tendon; 13, lateral epicondyle and borders of anconeus triangle shown as blue dashed line; 14, olecranon and olecronon bursa; 15, radial head; 16, zone of posterior interosseous nerve winding around radial neck (white): approximately 2.5 cm distal to radial head; 17, superficial radial nerve emerging from between the tendons of brachioradialis and extensor carpi radialis longus approximately 8.5 cm proximal to radial styloid process; 18, posterior border of ulna; 19, ulnar head; 20, dorsal radial tubercle.

The flexor retinaculum, and therefore the surface position of the carpal tunnel, can be mapped according to its palpable bony attachments (see Fig. 46.30A). The distal border is concave inferiorly and is marked by a curved line that joins the tubercle of the trapezium to the hook of the hamate. Its proximal border is marked by a curved line, concave superiorly, that joins the tubercle of the scaphoid to the pisiform. The dominant, most distal, wrist crease normally sits distal to the lunate and overlies pisiform and the proximal edge of the flexor retinaculum. The carpal tunnel passes distal to this crease for $2.5-3 \mathrm{~cm}$.

## MUSCULOTENDINOUS LANDMARKS

Deltoid can be identified when the arm is abducted against resistance. The deltoid tendon is palpable approximately halfway down the lateral aspect of the humerus. Its anterior border can be traced superomedially from the anterior aspect of the humerus, across the tendon of pectoralis major, to form the lateral boundary of the infraclavicular fossa (see Fig. 46.29A, Video 46.1). The posterior border runs superomedially from the posterior aspect of the deltoid tendon and reaches the crest of the scapular spine near its medial end. The normal rounded contour of the shoulder is produced by deltoid covering the lateral aspect of the greater tubercle of the humerus. Shoulder dislocation results in the loss of the normal rounded contour of the shoulder because the greater tubercle is displaced medially, and deltoid consequently descends vertically to its humeral attachment. Supraspinatus and infraspinatus are visible and palpable above and below the scapular spine, respectively (see Fig. 46.29C).

The lower border of pectoralis major forms the anterior axillary fold. It is visible and palpable when an abducted shoulder is adducted against resistance, e.g. by firmly pressing a hand on to the hip. The clavicular head of pectoralis major can be felt and seen to contract when flexing the shoulder to a right angle against resistance; the sternocostal head becomes visible when extending a flexed shoulder against resistance.

The posterior axillary fold, produced by latissimus dorsi and the underlying teres major, reaches a lower level on the humerus than the anterior axillary fold. When the abducted shoulder is adducted against resistance, the posterior axillary fold is accentuated and the lateral border of latissimus dorsi can be traced inferomedially to its attachment to the iliac crest. When the upper limb is raised above the head, the lower five or six serrations of serratus anterior are visible on the lateral aspect of the thorax; they pass downwards and forwards to interdigitate with the serrations of external oblique.

Biceps brachii produces a visible elevation on the anterior arm and shallow furrows mark its medial and lateral borders (see Fig. 46.29A). It diminishes superiorly where it is covered by pectoralis major, and inferiorly where it tapers to the biceps tendon just above the elbow joint. Flexion of the elbow against resistance aids identification of the muscle and of the bicipital tendon, which can be held between finger and thumb and traced down into the cubital fossa. With the elbow held in this position, the sharp upper margin of the bicipital aponeurosis can be traced passing inferomedially over the elevation produced by the superficial group of forearm flexor muscles. Coracobrachialis emerges from the lateral axillary wall and forms a rounded ridge on the upper part of the medial side of biceps.

On the posterior arm, the lateral head of triceps forms a laterally placed elevation, inferior to the posterior border of deltoid (see Fig. 46.29C). Triceps can be made visible by extending the elbow against resistance. On the medial side, the fleshy mass produced by the long head of triceps passes superiorly and disappears deep to deltoid.

Brachioradialis is the most superficial muscle on the lateral side of the forearm. When the elbow is flexed against resistance whilst in a mid pronation-supination position, brachioradialis stands out as a prominent ridge extending upwards beyond the level of the elbow joint to the lower lateral side of the arm. The medial (ulnar) border of brachioradialis marks the boundary between the anterior and posterior forearm compartments.

The three borders of the cubital fossa can be mapped out anterior to the elbow by a line joining the medial and lateral humeral epicondyles (superiorly), brachioradialis (laterally) and pronator teres (medially) (see Fig. 46.29A-B). Pronator teres passes inferolaterally from the medial epicondyle to a point approximately halfway down the radial shaft; its rounded belly is visible during resisted forearm pronation.

The fleshy mass of the superficial forearm flexors is visible and palpable in the upper medial forearm, and that of the extensor muscle mass is visible in the upper lateral forearm. The line of travel of the superficial forearm muscles can be mapped out according to their

Fig. 46.30 The surface anatomy of the wrist and hand. A, Key: 1, radial artery; 2, flexor carpi radialis tendon; 3, median nerve; 4, ulnar nerve; 5, palmaris longus tendon; 6, flexor carpi ulnaris tendon; 7, proximal transverse wrist crease: marks the line of the wrist joint; 8, distal transverse wrist crease: marks the proximal boundary of the carpal tunnel; 9, scaphoid tubercle; 10, pisiform (black oval): aligns with distal wrist crease; 11, trapezium tubercle; 12 , hook of hamate and superficial branch of ulnar nerve passing anteriorly; 13, thenar eminence; 14, hypothenar eminence; 15, plane of deep palmar arterial arch; 16, plane of superficial palmar arterial arch; 17, positions of palmar digital neurovascular bundles; shaded rectangle indicates position of flexor retinaculum. B, Key: 1-6, first to sixth extensor compartments of the wrist; 7, wrist joint needle insertion point; 8, hypothenar eminence; 9, dorsal venous network of the hand; 10, extensor pollicis longus tendon; 11, extensor tendon and metacarpophalangeal joint line; A, head of the ulna; B, dorsal radial (Lister's) tubercle. C, Key: 1, dorsal radial (Lister's) tubercle; 2, wrist joint needle insertion point; 3, extensor digitorum tendon; 4, extensor compartment 2, containing the tendons of extensors carpi radialis longus and brevis; 5 , extensor pollicis longus tendon; 6 , cephalic vein; 7 , superficial branch of radial nerve; 8, first dorsal interosseous muscle; 9, extensor compartment 1, containing abductor pollicis longus and extensor pollicis brevis; 10, radial styloid process; 11, radial artery; 12, flexor carpi radialis tendon.
attachment points. Inflammation of the common flexor or extensor tendons can be indicated by tenderness to palpation over the respective muscle mass or humeral epicondyle.

Palpating lateral to flexor carpi radialis, $3-4 \mathrm{~cm}$ proximal to the wrist crease, reveals the muscle belly of flexor pollicis longus (flexing and extending the thumb will confirm that the examining finger is correctly placed). The area on the ulnar side of flexor carpi radialis tendon is packed with functionally important structures. The median nerve is either covered by, or situated just lateral (radial) to, the tendon of palmaris longus. The latter can be identified by gently pinching the tips of the digits together and partially flexing the wrist (see Fig. 46.30A). Near to the wrist, the median nerve lies very close to the skin and can, therefore, be injured by relatively superficial lacerations. When palmaris longus is absent, only a thin covering of subcutaneous fat and deep fascia separate skin and nerve. The four tendons of flexor digitorum superficialis lie deep to the median nerve; the tendons to the middle and ring fingers lie anterior to those for the index and little fingers as they pass deep to the flexor retinaculum, and can be felt and, usually, seen to move during finger flexion/extension. Deeper still are the tendons of flexor digitorum profundus. The broad tendon of flexor carpi ulnaris is easily palpated passing to the pisiform on the ulnar side of the anterior wrist; the ulnar nerve, artery and venae comitantes lie along its lateral (radial) edge. Any sharp injury that cuts through the tendon usually has enough energy to sever the ulnar neurovascular bundle.

When the thumb is fully extended, the depression of the anatomical snuff-box is seen on the lateral aspect of the wrist immediately distal to the radial styloid process (see Fig. 46.30C). The snuff-box is bounded on its anterolateral (radial) side by the tendons of abductor pollicis longus (laterally) and extensor pollicis brevis (immediately medial), and on its posteromedial/ulnar side by the tendon of extensor pollicis longus. Running a finger along extensor pollicis brevis enables palpa-
tion of the superficial radial nerve, which can be rolled from side to side on the tendon. The cephalic vein passes over the roof of the snuffbox, where it is visible and palpable, and the pulsation of the radial artery can be palpated deeply on its floor.

The tendons located within the six extensor compartments of the wrist are subcutaneous and palpable (see Fig. 46.30B). Compartment 1 (containing abductor pollicis longus and extensor pollicis brevis) sits over the lateral radius. Regional tenderness to palpation occurs in de Quervain's tenosynovitis. Compartment 2 (containing extensors carpi radialis longus and brevis) and 3 (containing extensor pollicis longus) flank the lateral and medial sides of the dorsal radial (Lister's) tubercle, respectively. Compartments 5 (containing extensor digiti minimi) and 6 (containing extensor carpi ulnaris) flank the posterior and medial sides of the ulnar head, respectively. Compartment 4 (containing extensors digitorum and indicis) sits between the ulnar head and compartment 3. The tendons of extensors carpi radialis longus and brevis can be identified on the dorsal carpus when the fist is clenched and relaxed. The tendons of extensor digitorum are visible and palpable on the dorsal hand with the fingers fully extended. The tendon of extensor carpi ulnaris is palpable distal to the ulnar styloid as it crosses the wrist, with the wrist in extension and adduction. The first dorsal interosseous forms a visible fleshy mass on the lateral part of the dorsal hand between the index finger and thumb, especially whilst abducting the index finger against resistance.

The first metacarpal is both visible and palpable on the dorsolateral hand. Its dorsal aspect forms the lateral border of the hand. The fleshy elevation of the thenar eminence, produced by abductor and flexor pollicis brevis overlying opponens pollicis, is located on the lateral palm (see Fig. 46.30A). The less prominent hypothenar eminence is located on the medial palm and is formed by the comparable muscles of the little finger. The medial aspect of the hypothenar eminence forms the medial border of the hand.

## VESSELS, PULSES AND NERVES

## Arteries

The brachial artery travels along the medial arm in the depression posterior to coracobrachialis and along the furrow to the medial side of biceps, to a point just medial to the biceps tendon and level with the radial head/neck (see Fig. 46.29A-B). Its pulsations are palpable along this line of travel and proximal to the bicipital aponeurosis, via compression against the humerus. Brachial artery catheterization just proximal to the aponeurosis is used for coronary angiography or cardiac catheterization. The ability to compress the brachial artery against the humerus makes the arm the favoured site for non-invasive blood pressure measurement. The median nerve is intimately related to the brachial artery throughout its course in the arm. Proximally, it sits lateral to the artery; then, around the midpoint of the arm, it passes anterior to the artery and descends on its medial side to the cubital fossa.

The radial and ulnar arteries originate in the anterior forearm at a point situated medial to the biceps tendon and level with the lower head/neck of the radius (see Fig. 46.29B). From here, the ulnar artery passes inferomedially to a point one-third of the way down flexor carpi ulnaris (which passes along a line joining the medial humeral epicondyle to the pisiform). The ulnar artery and nerve then pass inferiorly to a point just lateral to the pisiform along the line of flexor carpi ulnaris, with the ulnar artery lying on the lateral (radial) side of the nerve. The radial artery passes inferolaterally through the forearm, from its point of origin to a point just lateral to the tendon of flexor carpi radialis, anterior to the distal radius. The upper part of its course can be represented by a line that passes deep to the medial part of the elevation produced by brachioradialis on the anterior aspect of the forearm. It then passes posteriorly, deep to the tendons of abductor pollicis longus and extensor pollicis brevis, and enters the anatomical snuffbox, where its pulsations are palpable.

The radial pulse is palpable on the anterior (volar) aspect of the wrist between the tendon of flexor carpi radialis medially and the radial styloid process laterally. This is the simplest pulse to palpate during routine patient examination. The pulse of the ulnar artery is usually palpable on deep pressure lateral to the tendon of flexor carpi ulnaris at the wrist.

The position of the superficial palmar arterial arch is indicated by a horizontal line, approximately 4 cm long, drawn at the level of the fully extended and partially abducted thumb (see Fig. 46.30A). A horizontal line, approximately 4 cm long, running from a point just distal to the hook of the hamate, indicates the position of the deep palmar arterial arch. The deep arch is located approximately 1 cm proximal to the superficial arch. The digital neurovascular bundles pass along the medial and lateral sides of the dorsal and volar surfaces of the digits, and can be anaesthetized in these positions via the web space.

## Sites for arterial cannulation

At the wrist, the radial artery is commonly used for arterial cannulation for arterial blood sampling and blood pressure monitoring. Thrombosis or vasospasm of the radial artery at this site should not normally jeopardize the circulation to the hand since the interconnecting palmar arterial arches provide a collateral circulation to the hand. Allen's test should be performed prior to any such procedure.

## Allen's test

Allen's test examines the patency of the interconnection between the superficial and deep palmar arches, and determines whether either artery is capable of maintaining the arterial supply to the hand in isolation. To perform the test, the radial and ulnar arteries of one hand are compressed by the examiner's thumbs. The forearm is then elevated and the hand exsanguinated by clenching the fist. The hand is then opened while arterial compression is continued. The palm of the hand appears pale, unless there is an anomalous arterial supply, e.g. from a persistent median artery. The rapid return of a normal pink colour to the palmar skin following removal of digital pressure from one of the arteries suggests that that artery is capable of perfusing the hand adequately in isolation. If the palmar skin remains pale, it must be assumed either that there is a distal obstruction to the artery or that the artery cannot adequately perfuse the hand in isolation. The test is then repeated with release of digital pressure on the other artery.

## Veins

The superficial veins of the upper limb are usually visible and palpable, especially when a tourniquet occludes venous return proximally. At the
wrist, the cephalic vein consistently passes over the roof of the anatomical snuff-box (see Fig. 46.30C) and the dorsolateral aspect of the distal radius. Here, it sits next to the superficial branch of the radial nerve. The cephalic vein ascends the anterolateral forearm and the lateral arm in the groove lateral to biceps brachii. Superiorly, it ascends the deltopectoral groove to the infraclavicular fossa, where it pierces the clavipectoral fascia to enter the axillary vein.

The median cubital and basilic veins may be identified over the cubital fossa. In the proximal forearm, the cephalic vein runs alongside the lateral cutaneous nerve of the forearm. The veins are frequently covered by fat, especially in the female, which makes them difficult to see. The median cubital vein usually arises from the cephalic vein approximately 2.5 cm distal to the lateral epicondyle of the humerus, and runs upwards and medially over the bicipital aponeurosis to join the basilic vein approximately 2.5 cm above the transverse crease of the elbow. The median vein of the forearm drains the venous plexuses on the palmar surface of the hand. It ascends on the front of the forearm and usually ends in either the basilic vein or the median cubital vein; sometimes, it divides, just distal to the elbow, into two branches, one of which joins the basilic vein and the other the cephalic vein.

## Venepuncture at the elbow

Commonly accessed superficial veins include the cephalic or median cubital vein at the cubital fossa, and the dorsal venous network of the hand. The cephalic vein may also be accessed over the distal radius and anatomical snuff-box. The latter site has many advantages for placing an indwelling cannula when a lengthy period is contemplated, although the vein lies close to the superficial branch of the radial nerve.

A high bifurcation of the brachial artery is seen occasionally and may produce an anomalous superficial ulnar artery that descends superficial to the common origin of the forearm flexor muscles. When this occurs, the ulnar artery, although deep to the deep fascia, may lie subcutaneously and pass superficial to the bicipital aponeurosis. Such an artery is therefore at risk of puncture during median cubital vein access.

## Lymph nodes

Supratrochlear lymph nodes (in reality, supra-epicondylar nodes) lie next to the basilic vein. If enlarged, they may be palpated along the line of the vein, a few centimetres above the elbow joint.

## Nerves

The trunks of the brachial plexus lie in the posterior triangle of the neck posterior to the subclavian artery (whose pulsations are palpable), in the angle between the clavicle and the lower posterior border of the clavicular head of sternocleidomastoid. The upper trunk can be palpated by passing the fingers inferiorly along the vertical groove between scalenus anterior and scalenus medius.

The axillary nerve and circumflex humeral vessels pass around the posterior and lateral aspects of the proximal humerus, close to the surgical neck, approximately 5 cm from the posterior edge, and 6 cm from the anterior edge, of the acromion (Cetik et al 2006). Bono et al (2000) found the axillary nerve to lie approximately 6 cm from the proximal humerus, passing within approximately 2 cm of the surgical neck of the humerus (see Fig. 46.29C).

The radial nerve passes inferolaterally along the spiral groove on the posterior arm (see Fig. 46.29C). The distance from the acromion to a line passing through the humeral epicondyles can be used as a baseline measurement; the radial nerve reaches the spiral groove approximately $46 \%$, leaves it approximately $60 \%$, and pierces the intermuscular septum approximately $66 \%$ of the way down this line (Cox et al 2010, Cho et al 2013). The radial nerve then passes inferiorly, approximately 1 cm lateral to the tendon of biceps, and bifurcates into the posterior interosseous and superficial radial nerves just distal to the lateral epicondyle (Cox et al 2010) (see Fig. 46.29B). The posterior interosseous nerve winds around the radial neck approximately 2.5 cm distal to the radial head (Cox et al 2010); this is an important surgical consideration when making an incision to expose the radial head. The nerve then passes inferiorly through the posterior forearm to a point midway between the ulnar head and the dorsal radial tubercle. The superficial radial nerve passes inferiorly, deep to brachioradialis, and becomes superficial passing between brachioradialis and extensor carpi radialis longus, approximately 8.5 cm proximal to the radial styloid process (Auerbach et al 1994, Park et al 2010). Its terminal branches are palpable as they pass over the tendon of extensor pollicis longus where it borders the anatomical snuff-box.

Fig. 46.31 The dermatomes of the left upper limb. Overlap across the axial lines is minimal, whereas overlap is considerable across the interrupted lines. A, Viewed from the anterior aspect. B, Viewed from the posterior aspect. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

The median nerve is intimately related to the brachial artery throughout its course in the arm. In the forearm, it passes along a line joining a point just medial to the pulsating brachial artery in the cubital fossa to the tendon of palmaris longus, or to a point just lateral to the tendon at the wrist (see Fig. 46.29B).

The ulnar nerve passes posterior to the medial epicondyle and can be rolled from side to side just proximal to the epicondyle (see Fig. 46.29B). In the forearm and proximal hand, its course corresponds to a line drawn from the base of the posterior aspect of the medial epicondyle of the humerus to the lateral side of the pisiform, where it passes through Guyon's canal and across the hook of the hamate. Deep pressure at these bony landmarks can produce paraesthesia in the distribution of the nerve. Proximally, the nerve sits deep to flexor carpi ulnaris; distally, it sits lateral to the tendon of flexor carpi ulnaris and medial to the ulnar artery and its venae comitantes.

## Dermatomes

Knowledge of the extent of individual dermatomes is largely based on clinical evidence. The dermatomes of the upper limb arise from spinal nerves C5-8 and T1; C7 supplies the central part of the hand (Figs 46.31-46.32). Considerable overlap exists between adjacent dermatomes innervated by nerves derived from consecutive spinal cord segments.

## Myotomes

The predominant segmental origin of the nerve supply for each of the muscles of the upper limb and for the movements that take place at the joints of the upper limb are summarized in Tables 46.1-46.4.

## Reflexes

Biceps jerk (C5, 6) The elbow is flexed to a right angle and slightly pronated. A finger is placed on the biceps tendon and struck with a percussion hammer; this should elicit flexion and slight supination of the forearm.

Fig. 46.32 The distribution of skin territories supplied by the cutaneous nerves of the left upper limb. A, Viewed from the anterior aspect. B, Viewed from the posterior aspect.

Triceps jerk (C6-8) The arm is supported at the wrist and flexed to a right angle. Triceps tendon is struck with a percussion hammer just proximal to the olecranon; this should elicit extension of the elbow.

Radial jerk $(C 7,8)$ The radial jerk is a periosteal, not a tendon, reflex. The elbow is flexed to a right angle and the forearm placed in the mid pronation/supination position. The radial styloid is struck with the percussion hammer. This elicits contraction of brachioradialis, which causes flexion of the elbow.

## Nerve blocks

Brachial plexus There are three common approaches to achieve anaesthetic blockade of the brachial plexus: the interscalene, supraclavicular and axillary routes.

The interscalene route requires identification of the interscalene groove. The patient is asked to sniff, an action that involves the scalene muscles as accessory muscles of respiration. A needle is inserted perpendicular to the skin and enters the interscalene groove. Paraesthesia may be elicited, and local anaesthetic solution is injected. There is a risk that some local anaesthetic may move in a retrograde direction and reach the cervical epidural space. The proximal nature of the block means that there is almost always some involvement of the phrenic nerve, and sympathetic block (as evidenced by a Horner's syndrome) is universal.

The supraclavicular route places local anaesthetic solution in the plane occupied by the trunks of the brachial plexus as they emerge between scalenus anterior and medius on the first rib, immediately posterior to the third part of the subclavian artery. The site of injection is 2 cm above the midpoint of the clavicle. The needle is directed backwards, inwards and downwards to make contact with the upper surface of the first rib. During this procedure, the patient will usually complain of paraesthesia down the arm, which indicates that the needle is correctly placed; preliminary aspiration ensures that a major vessel has not been punctured. If the first rib is missed, there is the risk of producing
a pneumothorax. There is often a transient Horner's syndrome, caused by diffusion of the local anaesthetic towards the stellate ganglion.

The axillary approach blocks the nerves as they group around the axillary artery.

Wrist Useful anaesthesia of the palm of the hand (except for the lateral surface of the thumb base) can be achieved by blockade of the ulnar and median nerves at the wrist (see Video 50.2). The ulnar nerve may be blocked via a needle inserted lateral to the tendon of flexor carpi ulnaris at the wrist. The median nerve may be blocked via a needle inserted at the midline between the tendons of palmaris longus and flexor carpi radialis at the level of the proximal wrist crease.

The radial nerve, which supplies the dorsal skin of the hand, may be blocked by injecting local anaesthetic around the subcutaneous
dorsoradial border of the wrist, where branches of the nerve can be rolled over the tendon of extensor pollicis longus (see Fig. 46.30C).

## Digital nerves

The digital nerves lie on either side of the flexor sheath in a plane immediately anterior to the phalanx (see Fig. 46.30A). Therefore, the needle should be inserted on either side of the base of the digit, just anterior to the anterolateral margin of the phalanx. A common alternative approach to blocking the digital nerves is via a dorsal skin approach; the needle is inserted through the dorsal skin on either side of the base of the proximal phalanx and advanced towards the volar location of the digital nerves while the local anaesthetic agent is continually infused. This is thought to be less painful than the volar approach because the dorsal skin is less sensitive than the volar skin.

## PECTORAL GIRDLE DEVELOPMENT

The pectoral girdle develops at an interface between the tissues forming the head and neck, the back and the upper limb. Each of these regions appears to have different cell lineages and genes contributing to the development of similar tissues. Studies on the development of the avian scapula, also confirmed in the mouse, show that lateral scapular structures derive from the somatopleuric mesenchyme, whereas the medial border of the scapula and the attachment sites for the rhomboid muscles originate from dermomyotomes of somites: specifically, the hypaxial domain (Wang et al 2005, Valasek et al 2010, Valasek et al 2011). The connective tissues of those muscles and their attachment sites on the pectoral girdle innervated by the accessory nerve are derived from neural crest (Matsuoka et al 2005).

Early limb development is patterned by somatopleuric mesenchyme, within a permissive interaction with the limb ectoderm. Upper limb myoblasts migrate laterally from the ventrolateral border of cervical dermomyotomes and form dorsal and ventral masses prior to migration into the limb bud. After a brief period within the limb bud, a subset of the myoblasts migrate medially out of the limb bud and into the axial mesenchyme to form the pectoral muscles ventrally and latissimus dorsi dorsally. This origin of superficial pectoral girdle muscles has been described as an 'in-out' mechanism (Valasek et al 2011), and refers to the initial migration into the limb bud and the subsequent migration back towards axial structures. Only myoblasts undergo this second, medial, migration out of the limb bud; the somatopleuric mesenchyme remains within the proximal limb anlagen and produces the glenohumeral joint and coracoid process.

Some myoblasts, originating from the ventrolateral edges of cervical dermomyotomes and extending as the hypaxial domain of the somite, switch off their myogenic fate and follow a cartilage lineage to form the medial part of the scapula. The remaining hypaxial domain myoblasts form serratus anterior, and the rhomboid muscles, deep pectoral girdle muscles, attach to this medial part (Valasek et al 2011).

Trapezius and sternocleidomastoid, innervated by the accessory nerve, are derived from the upper occipital somites (see Fig. 36.7); they migrate into neural crest mesenchyme, which forms their connective tissue. The proximal and distal attachments of trapezius, to the nuchal line of the occipital bone and the upper part of the spine of the scapula, respectively, are derived from post-otic neural crest cells (Matsuoka et al 2005). The attachment of sternocleidomastoid to the clavicle also demonstrates its dual origin from neural crest cells and somatopleuric mesenchyme. The sternum is derived from somatopleuric mesenchyme, although there is evidence of neural crest within the manubrium.

The 'muscle scaffold model' proposed by Matsuoka et al (2005), where muscle connective tissue and muscle attachment sites illustrate the origin of the mesenchymal cells patterning their development, may explain a range of anomalies based on defects of post-otic neural crest and which affect the pharynx and larynx as well as the shoulder region, e.g. Klippel-Feil disease, Sprengel's deformity and cleidocranial dysplasia.

## UPPER LIMB DEVELOPMENT

The upper limb bud is first visible as a thickening along the lateral longitudinal axis of the body wall opposite somites $8-10$, at the level of the entrance to the cranial intestinal portal during stage 12 . It enlarges, protruding laterally from its elliptical base at the body wall as a symmetrical bud, with a curved border and an apical ectodermal ridge forming its distal tip. Initially, it has equal and relatively flat dorsal and ventral ectodermal surfaces and a somatopleuric mesenchymal core. By stage 13, the upper limb bud is curved ventrally. By stage 14, it has
elongated and is opposite the developing ventricles of the heart; it is directed caudally because of preferential elongation of the preaxial part of the bud. At stage 15, the upper limb can be subdivided into definite regions. The proximal portion, still showing the dorsal bulge and ventral curve, is the shoulder and upper arm region; the next distal portion can now be identified as the forearm; the most distal portion is now expanded into a flattened hand plate.

At stage 16, there are the first indications of digit rays in the hand plate. The limb may be close to the body wall or may be abducted. By stage 17, the upper limb has an elbow region and well-defined digit rays; the hand plate may show a crenated rim, indicating the start of tissue removal between the digits (see Fig. 15.1). Crenation of the hand plate between the digit rays continues in stage 18 embryos ( 44 days). Changes during stages 19-23 are concerned with growth of the limb and separation of the digits. The hands now curve over the cardiac region. The distal phalangeal portions of the fingers enlarge at stage 21, forming the nail beds. For more details, see O'Rahilly and Gardner (1975), Gupta et al (2000).

Most of the bones in the appendicular skeleton are derived from somatopleuric mesenchyme. Within the upper limb, although the clavicle and coracoid portion of the scapula arise from somatopleuric mesenchyme, studies in both avian and mouse embryos have shown that the distal third of the blade of the scapula is derived from the somites (Shearman et al 2011, Valasek et al 2010). Prechondroblasts are present in the upper limb at stage 13, and condensations of cartilage can be detected at stage 16, when the humeral anlage can be recognized. Cavitation of the shoulder and elbow joints occurs at 7-8 weeks. By stage 17, when the radius and ulna chondrify, the branched tips of the radial, median and ulnar nerves have migrated to the distal hand plate. The carpals chondrify at stage 18 , when the hand plate shows notching of the digital rays.

## VESSELS

## Arteries

In the upper limb, usually only one arterial trunk, the subclavian, persists; it probably represents the lateral branch of the seventh intersegmental artery. Its main continuation, the axial artery of the upper limb, becomes the axillary and brachial arteries, passes into the forearm deep to the flexor muscle mass and terminates as a deep plexus in the developing hand (Fig. 47.1). The original axial vessel ultimately persists as the anterior interosseous artery and the deep palmar arch. A branch from the main trunk passes dorsally between the early radius and ulna as the posterior interosseous artery; a second branch accompanies the median nerve into the hand, where it ends in a superficial capillary plexus. The radial and ulnar arteries are the latest arteries to appear in the forearm. Initially, the radial artery arises more proximally than the ulnar artery, crosses anterior to the median nerve, and supplies biceps brachii. Later, the radial artery establishes a new connection with the main trunk at or near the level of origin of the ulnar artery, and the upper portion of its original stem usually disappears. On reaching the hand, the ulnar artery links up with the superficial palmar plexus, from which the superficial palmar arch is derived. The median artery commonly loses its distal connections and is reduced to a small vessel. The radial artery passes to the dorsal surface of the hand, gives off dorsal digital branches, traverses the first intermetacarpal space and joins the deep palmar arch.

Anomalies of the arterial tree in the forelimb are fairly common: there are several potential causes. The arteries have multiple and plexiform sources; the principal arteries, anastomoses and periarticular networks emerge according to a temporal sequence; and some paths that are initially functionally dominant subsequently regress. In general,

Fig. 47.1 Stages in the development of the arteries of the arm. The path of the axial artery is indicated by an interrupted line.
anomalous patterns may present as differences in the mode and proximodistal level of branching; the presence of unusual compound arterial segments; aberrant vessels that connect with other principal vessels, arcades or plexuses; vessels that occupy exceptional tissue planes (e.g. superficial fascia instead of the usual subfascial route), or vessels that have unexpected neural, myological or osteoligamentous relationships.

## Veins

In the upper limb, the preaxial vein becomes the cephalic vein and drains into the axillary vein at the shoulder. The postaxial vein becomes the basilic vein, which passes deep in the arm to continue as the axillary vein.

## ULTRASOUND ANTENATAL IMAGING

In the routine 18-20-week ultrasound fetal assessment, shortening of long bones below 2 standard deviations should lead to a full assessment of all bones (McHugo 2007). Whereas the majority of lethal short limb dysplasias show marked shortening by this time, non-lethal short limb dysplasias seen at birth are not apparent at 20 weeks' gestation. Normally, the humerus should be slightly longer than the radius and ulna. The term rhizomelia is used where limb shortening affects the proximal bones more than the distal bones.

## NEONATAL UPPER LIMB

In general, the upper limbs in the neonate are proportionately shorter than they are in the adult. They are long compared with the neonatal trunk and lower limbs, and extend to the upper thigh as they do in the adult, but the trunk is much shorter in the neonate (see Fig. 14.8). At birth, the upper limbs are about the same length as the lower limbs,
but much more developed. When the proportions of parts of the upper limb are examined, the forearm is longer than the arm in the newborn, and more so in boys than girls. Only primary centres of ossification are present in the upper limb, apart from a centre in the head of the humerus. The elbow of the newborn can flex to $145^{\circ}$ but lacks some $10-15 \%$ of full extension. The neonate has a relatively strong grasp within the first few days. The fingernails usually extend to the fingertips or just beyond. They are soft at birth but soon dry and become quite firm and sharp.

## Peripheral arterial puncture in the neonate

It is common practice to insert a small-bore cannula into a peripheral artery in neonates receiving intensive care when either the umbilical artery is not accessible or there are clinical reasons to avoid cannulation of the umbilical vessels. Trans-illumination can be used to provide an outline of the artery to be cannulated. The peripheral arteries that are most commonly used are the radial artery, just above the anterior surface of the wrist, and the posterior tibial artery, posterior to the medial malleolus. The proximity of the ulnar nerve to the ulnar artery increases the risk of nerve damage associated with arterial cannulation of the ulnar artery, and the relatively poor collateral circulation associated with the dorsalis pedis artery means that this artery is used only as a last resort. The brachial artery at the antecubital fossa also has a poor collateral circulation and the median nerve is in close proximity; it is generally considered, therefore, that cannulation of this artery is not justified.

Confirmation that an adequate collateral circulation is present when cannulating the radial artery can be obtained by performing Allen's test, in which both the radial and ulnar arteries are compressed at the wrist after exsanguination of the hand; release of pressure on the ulnar artery while maintaining occlusion of the radial artery should result in reperfusion of the hand if an adequate collateral ulnar arterial supply is present. Alternatively, intact arterial flow can usually be confirmed, particularly in the preterm infant, by direct visualization of the arteries
using trans-illumination. A cold light source is placed on the posterior aspect of the lower forearm and the shadow of the pulsating arteries can be seen on the anterior surface of the forearm.

## DEVELOPMENTAL ANOMALIES OF THE UPPER LIMB

Approximately 1 in 600 neonates will have a congenital anomaly of the hand or forearm, $30 \%$ of which will be bilateral. They occur with an approximately equal frequency in males and females. A defect is twice as likely to occur in the upper limb as in the lower limb. The most critical period for the development of anomalies is during stages 12-16.

One classification of congenital limb malformation uses seven subgroups (Swanson 1976). These describe a clinical picture and do not always relate accurately to the developmental process occurring in the limb. The first subgroup is failure of formation of parts of a limb. The second subgroup, failure of differentiation, includes unsuccessful separation of parts, and so includes the range of syndactylies. Groups three to five include limb duplication, overgrowth and undergrowth. Group six includes limb amputations, mainly by adherent amniotic bands, and the last group includes all other generalized skeletal anomalies. A more recent classification of upper limb anomalies, based on developmental molecular biology and pathogenetics, clearly defines all terms used to describe anomalous structure and provides a comprehensive and consistent terminology for the range of anomalies (Oberg et al 2010, Tonkin et al 2013, Goldfarb 2015).

## LIMB REDUCTION DEFECTS

Limb reduction defects are categorized as failures of development. The basis of limb reductions seen in infants whose mothers took thalidomide during their pregnancy seems likely to be due to death of mesenchyme cells in the early limb bud, causing phocomelia. Proximal segments of the limb were lost, although, in some cases, normal distal
segments still formed. There is evidence from experiments in chick embryos that thalidomide interferes with vascularization of the limbs (Vargesson 2009), and this could lead to mesenchymal cell death. Recent work has identified a protein to which thalidomide binds and could eventually lead to uncovering molecular mechanisms of thalidomide teratogenicity (Ito et al 2010).

Inheritance of autosomal dominant genes may cause anomalies of the hand. This could, for example, result in absence of the central digit ray of the distal hand plate and subsequent absence of the middle or ring finger and its metacarpals. Extra preaxial digits can result from ectopic polarizing activity due to mutations in regulatory regions that control expression of the Shh gene, specifically in the developing limb bud (Anderson et al 2012). Other changes in digit number may be the result of alterations in limb bud width and the length of the apical ectodermal ridge.

## ANOMALIES OF THE DIGITS

Webbing of the fingers is the most common congenital anomaly of the hand. It occurs because of failure to remove cells between the digit rays during stages 19-23. Clinodactyly is a congenital condition in which the little finger is curved towards the ring finger. It can occur in isolation, or in association with chromosomal abnormalities like Down's syndrome. Camptodactyly is a congenital condition in which the little finger, and sometimes the ring finger, are held in a fixed, flexed position. Symphalangism is a rare congenital disorder in which there is fusion of the interphalangeal joints. The affected finger is stiff, skin creases are absent over the affected joint, there is minimal joint space, and sometimes the digit is shorter than normal. Several different types of brachydactyly, shortening of the digits, can be recognized according to which digits and which parts of these digits are affected. The genetic basis of different types of brachydactyly has now been determined, which is particularly gratifying because brachydactyly was the first condition in humans to be recognized as a dominant Mendelian condition (Gao and He 2004).

## Shoulder girdle and arm

The upper limb is differentiated to achieve complex patterns of stereotactic, non-stereotactic and gestural movements (each with a distinct neurological basis) that enable hand function. The combined motion of the shoulder and elbow brings objects in the hand into the visual field, while the great range of the shoulder and pectoral girdle enable reaching into a wide external environment. Oculospinal afferents appear to be the most important modulators of shoulder joint stability necessary for reaching. An object is first reached and then grasped (increasing both superficial and deep peripheral afferent inputs that enhance proximal shoulder girdle stability (Alizadehkhaiyat et al 2011)), before being retrieved into the visual field. The requirements of attention to the visual field define the need for stability in the shoulder girdle: the closer the attention to an object in the centre of the field of vision ('macular vision'), the finer is the control of the motion and stability of the shoulder girdle.

The joints of the upper limb become more complex proximodistally. The greatest potential for stability is gained through 'close-packing' (the state of a joint where the greatest stability is achieved for the least energy) in the carpus of the hand, while the range of available motion in each joint becomes more restricted. Close-packing occurs through a lesser, more specific, range of motion in the elbow; the flexed elbow with a supinated forearm is the position for carrying the greatest load with the least energy expenditure or the greatest resistance to fatigue. Close-packing occurs in the glenohumeral joint, so providing for stability, but it is almost entirely gained through muscular activity; at the extremes of range, through capsular fibre spiralling, it is costly in terms of muscular energy expenditure, especially on a background of age- and gene-dependent musculotendinous degeneration. The least intrinsically stable joint in the body, the scapulothoracic, is entirely dependent on muscular activity for stable position and motion around the fulcrum of the acromioclavicular joint.

For the purposes of this chapter, the junction between the 'arm' and the 'elbow joint' will be taken to be the level at which the radial nerve perforates the lateral intermuscular septum to enter the anterior compartment of the arm, and the ulnar nerve perforates the medial intermuscular septum to gain the posterior compartment of the arm at the elbow.

## SKIN AND SOFT TISSUES

## SKIN

## Cutaneous vascular supply

The skin over the lateral end of the clavicle is supplied by the supraclavicular artery, which pierces the deep fascia superior to the clavicle and anterior to trapezius. In the majority of cases, this artery arises from the superficial cervical/transverse cervical artery, but it occasionally arises from the suprascapular artery. The area over deltoid is supplied by the anterior and posterior circumflex humeral arteries. The deltoid branch of the thoraco-acromial axis contributes to the blood supply of the anterior aspect of the shoulder via musculocutaneous perforators through deltoid.

The blood supply to the skin of the upper arm may be divided into three regions with separate supplies. The deltoid region is supplied by musculocutaneous perforators, and the medial and lateral regions are supplied by fasciocutaneous perforators (Cormack and Lamberty 1994; Salmon, in Taylor and Razaboni 1994).

The deltoid region is supplied by the posterior circumflex humeral artery via musculocutaneous perforators. After exiting from the quadrangular space, it gives off a descending branch that runs down to the insertion of deltoid and the overlying skin, and an ascending branch
that passes superiorly towards the acromion and pierces the edge of deltoid and the deep fascia to fan out and supply the overlying skin.

The medial side of the upper arm is supplied by five or six fasciocutaneous perforators that arise from the brachial artery, the superior ulnar collateral artery and, if present, the single artery to biceps brachii. These perforators pass along the medial intermuscular septum to spread out in the deep fascia and anastomose with perforating vessels superiorly and inferiorly, and from the lateral side. There are virtually no musculocutaneous perforators through biceps or triceps.

The lateral side of the upper arm below deltoid is supplied by perforating vessels from the middle collateral and radial collateral arteries (the terminating bifurcation of the profunda brachii). The middle collateral artery sends perforators to the skin via the lateral intermuscular septum between brachioradialis and triceps, while the radial collateral artery gives off cutaneous perforators via the intermuscular septum between brachialis and brachioradialis. These cutaneous vessels anastomose with those from the medial side.

## Cutaneous innervation

The skin over the anterior shoulder region is mobile and accommodates the great mobility of the shoulder girdle. The skin over the posterior aspect of the shoulder girdle is thicker and less mobile, being held to the underlying scapula by coarse connective tissue fibres. The cutaneous innervation reflects this difference in skin quality; the supraclavicular nerves (see Fig. 29.1) are long, mobile nerves passing deep to platysma before piercing the muscle and the investing cervical fascia over or immediately caudal to the clavicle. The medial clavicular skin, including the skin over the sternoclavicular joint, is innervated by the small, often multifilamentous, medial supraclavicular nerve. The skin over the clavicle and over a variable extent of the anterior chest skin, including a variable extent of the anterior axillary fold, is innervated by the large,

middle supraclavicular nerve. This nerve is frequently injured by injudicious incisions for the surgical treatment of fractures of the clavicle; a painful neuroma is a common outcome. The skin over the lateral clavicle, acromion and deltoid region is innervated by the lateral supraclavicular nerve or nerves. The floor of the axilla, together with part of the upper medial aspect of the arm, is supplied by the intercostobrachial nerve (lateral branch of the second intercostal nerve). Occasionally, the lateral branch of the third intercostal nerve contributes to the supply of the skin in the floor of the axilla. The lower aspect of the medial side of the upper arm is supplied by the medial cutaneous nerve of the arm. The lateral aspect of the upper arm is supplied by the upper lateral cutaneous nerve (a branch of the axillary nerve) and the lower lateral cutaneous nerve (a branch of the radial nerve). The posterior aspect is supplied by the posterior cutaneous nerve of the arm (a branch of

the muscles were attached only to the scapular fossae. The blood supply to the muscles of the upper limb is defined by their fascial compartmentation.

Compartment syndrome of the arm The muscular compartments of the arm (and thigh) are not so well defined as those of the forearm (and leg). Compartment syndrome is not so common in trauma of the arm but remains a concern, particularly after extensive reconstruction procedures and high-energy or crushing injuries of the limb.

## Fascia over deltoid

The deep fascia over deltoid is thickest anteriorly and posteriorly, and is adherent in a linear fashion to the external aspect of the superficial fibrous septa of the central (lateral) part of that muscle. It blends with the pectoral fascia in front, and with the thick and strong fascia overlying infraspinatus behind. Above, it blends with the periosteum of the lateral part of the clavicle, the thin periosteum of the acromion, the crest of the scapular spine and the cranial part of the medial border of the scapula, caudal to the spine of the scapula, where it blends with the infraspinatus fascia. Below, it is continuous with the deep brachial fascia, blending with the lateral intermuscular septum (Leijnse et al 2008).

## Pectoral and axillary fascia

The pectoral fascia is thin over pectoralis major. It is attached medially to the sternum and is continuous with the fascia of the rectus sheath caudally. Cranially, it blends with the periosteum of the clavicle and the anterior aspect of the capsule of the sternoclavicular joint. Laterally, it is continuous with the fascia over deltoid; it forms the roof of the infraclavicular fossa between the muscular attachments of pectoralis major and deltoid to the clavicle. The fascia is loosely adherent to the septum between the sternal and clavicular parts of pectoralis major. Inferolaterally, between pectoralis major and latissimus dorsi, the fascia thickens to form the floor of the axilla as the axillary fascia. At the caudal edge of pectoralis major, a deep lamina of fascia ascends to envelop the caudal border of pectoralis minor; it becomes the clavipectoral fascia at the upper edge of pectoralis minor. The hollow of the armpit is produced mainly by the action of this fascia in tethering the axillary skin to the floor of the axilla; it is sometimes referred to as the suspensory ligament of the axilla. The axillary fascia is pierced by the tail of the breast (see Fig. 53.22). The pectoral fascia envelops the lateral margin of latissimus dorsi, and the deep and superficial layers then ensheathe that muscle and are attached behind to the spines of the thoracic and lumbar vertebrae, blending with the thoracolumbar fascia medially and caudally.

## Clavipectoral fascia

The clavipectoral fascia is the cranial continuation of the deep lamina of the pectoral fascia and the medial continuation of the parietal layer of the subscapular bursal fascia. Laterally, it is continuous with the coraco-acromial ligament above and lateral to the coracoid. It envelops the coracoid, short head of biceps brachii and coracobrachialis. It covers the interval between those two muscles and pectoralis minor, which it envelops, and then traverses the interval between pectoralis minor and subclavius. It splits around subclavius and is attached to the clavicle anterior and posterior to the groove for subclavius. The posterior layer is contiguous with the deep cervical fascia, a condensation of which forms a tether around the central tendinous part of omohyoid, so indirectly connecting it to the clavicle. The deep aspect of the posterior lamina of the clavipectoral fascia blends with the sheath of the axillary vessels. Medially, it blends with the fascia over the first two intercostal spaces and is attached to the first rib, medial to subclavius. Occasionally, the fascia thickens to form a band between the first rib and coracoid process, the costocoracoid ligament, under which the lateral cord of the brachial plexus is closely applied (Atasoy 2004). The cephalic vein, thoraco-acromial artery and associated veins and lymphatic vessels, and the lateral pectoral nerve all pass through the fascia, immediately cranial to the upper border of pectoralis minor.

## Subscapular fascia

The subscapular fascia is thin and attached to the entire circumference of the subscapular fossa. Subscapularis is partly attached to its deep surface medially, an example of the extension of the attachment zone of a muscle for more effective action. The fascia extends laterally and blends with the deep layer of the subscapular bursa in front of the tendon of subscapularis and with the external layer of the capsule of the rotator interval of the glenohumeral joint. Inferiorly, it continues as the fascia enveloping teres major.

## Infraspinous fascia

The infraspinous fascia covers infraspinatus and is attached to the margins of the infraspinous fossa, except cranially and medially, where there is a loose attachment to the lower aspect of the spine of the scapula. Cranially and laterally, the infraspinatus fascia is continuous with the supraspinatus fascia, creating a single muscular compartment for the two muscles. The deep fibres of deltoid are attached to the infraspinatus fascia over a strip of about 1 cm for the entire length of the spine of the scapula; the examining finger cannot palpate the spine of the scapula from within the space between deltoid and infraspinatus. The fascia is contiguous with the strong lower border of the deltoid fascia along the overlapping posterior border of deltoid.

## Supraspinous fascia

The supraspinous fascia completes the osseofibrous compartment containing supraspinatus; it is attached to the scapula around the boundaries of the attachment of supraspinatus. It is thick medially, where supraspinatus attaches to its own fascia, but thinner laterally under the coraco-acromial ligament.

## Brachial fascia

The deep fascia of the upper arm, the brachial fascia, is continuous with the fasciae covering deltoid and pectoralis major; it forms a thin, loose covering for the anterior muscles of the arm and a more robust covering for the posterior muscles. Medially, just below the middle of the upper arm, it is perforated by the basilic vein, lymphatic vessels and, at various levels, by branches of the brachial cutaneous nerves.

The fascia is thickest distally, where it contains the brachial muscles in distinct compartments, anteriorly and posteriorly, and defined medially and laterally by tough septa. The lateral intermuscular septum is continuous with the fascia overlying the lateral part of deltoid proximally, and has an upward, thinner extension to the lateral crest of the intertubercular sulcus (groove) contiguous with the fascia over the anterior border of deltoid. It is attached to the supracondylar ridge of the lateral epicondyle of the humerus, and is perforated at the level of the junction of the upper three-fifths and lower two-fifths of the humerus by the radial nerve and the radial collateral branch of the profunda brachii artery passing into the anterior compartment from behind. It provides extension for the zone of attachment of lateral head of triceps posteriorly, and of brachialis, brachioradialis and extensor carpi radialis longus anteriorly. The medial intermuscular septum extends from the medial lip of the intertubercular sulcus, where it is contiguous with the fascia of teres major, then blends with the aponeurosis of attachment of coracobrachialis to the medial aspect of the humerus, and passes as a thick septum along the medial aspect of the humerus to the medial supracondylar ridge of the medial epicondyle. It gives attachment to the medial head of triceps posteriorly, and brachialis anteriorly. It is perforated by the ulnar nerve at about the same level as the radial nerve laterally, together with the superior ulnar collateral artery and the posterior branch of the inferior ulnar collateral artery. At the elbow, the brachial fascia is attached to the epicondyles of the humerus, so completing the muscular compartments, and the olecranon of the ulna, and is continuous with the antebrachial fascia.

## Axillary neurovascular sheath

The axillary neurovascular sheath is closely contiguous with the posterior aspect of the clavipectoral fascia. The second part of the axillary artery lies behind pectoralis minor; most intimal ruptures of the vessel caused by distraction trauma occur in this part of the vessel.

## Spread of infection

Available with the Gray's Anatomy e-book

## BONES

## CLAVICLE

The clavicle lies almost horizontally at the root of the neck (see Figs $46.7,29.13$ ). It is a crank-shaped cantilever that carries the scapula, so enabling the limb to swing clear of the trunk. It transmits part of the weight of the limb to the axial skeleton. The lateral or acromial end of the bone is flattened and articulates with the medial side of the acromion, whereas the medial or sternal end is enlarged and articulates with the clavicular notch of the manubrium sterni and first costal cartilage. The shaft is gently curved and resembles the italic letter $f$ in shape, being convex forwards (the antecurve) in its medial two-thirds and

During forceful flexion/adduction/protraction of the upper limb across the trunk (e.g. when the scapula is wrenched from the lateral end of the clavicle in thoracoscapular dissociation), the axillary sheath containing the axial vessels and cords of the brachial plexus is forced into pectoralis minor, which acts as a fulcrum or guillotine, around which the vessels angle sharply, so rupturing the arteria intima. Acute neural injuries occur as a result of direct injury (traction, compression, or both) to the nerve trunks, causing acute sensorimotor deficits, arterial adventitial haematoma or acute aneurysm expanding within the axillary sheath to cause the syndrome of causalgia (rapidly progressive, severe pain in the distribution of the affected nerve trunks with neural deficits). Arterial thrombosis following intimal rupture is associated with late nerve deficits as a result of inadequate neural perfusion, local scarring with distortion of the axillary sheath and its contents, and poor posture of the affected limb.

The neurovascular bundle, enclosed within the sheath, is separated from the subscapular fascia by a virtual space traversed by the subscapular nerves; this permits full excursion of subscapularis without distortion of the neurovascular bundle during normal arm movements. The tip of the coracoid can be likened to the tip of the shaft of a steering oar attached to a vessel (the scapula) tethered within the thick clavipectoral fascia: the effect of pectoralis minor as an antagonist of trapezius in scapular position and motion control (see below) is optimized by the wide attachment of the clavipectoral fascia and coraco-acromial ligament to the clavicle and scapula (see Fig. 48.18).

When axillary suppuration occurs, the local fascial arrangement affects the spread of pus. Suppuration may be superficial or deep to the clavipectoral fascia. In the former, an abscess would appear at the edge of the anterior axillary fold or in the groove between deltoid and pectoralis major; in the latter, pus would tend to track upwards in the axillary neurovascular sheath and appear at the root of the neck, taking the direction of least resistance. Lymphangitis in the medial aspect of the arm suggests infection deep to the clavipectoral fascia with lymphatic obstruction. When an axillary abscess is incised, the knife should enter the axillary 'base', midway between the anterior and posterior margins and near the thoracic side, to avoid the lateral thoracic, subscapular and axillary vessels on the anterior, posterior and lateral walls, respectively.

Fig. 48.6 The left clavicle, showing sites of muscular and ligamentous attachment and articular surfaces. A, Superior view. Key: 1, sternocleidomastoid (clavicular head); 2, sternal end; 3, pectoralis major; 4, trapezius; 5, acromial end; 6, deltoid. B, Inferior view. Key: 1, pectoralis major; 2, for costoclavicular ligament; 3, for first costal cartilage; 4, for sternum; 5, sternohyoid; 6, subclavius; 7 , deltoid; 8 , for acromion; 9 , trapezoid line; 10, trapezius; 11, conoid tubercle.
concave forwards (the retrocurve) in its lateral third (Fig. 48.6). The inferior aspect of the intermediate two-fifths is grooved in its long axis for the attachment of subclavius. Laterally, the internal architecture of the clavicle is trabecular; there is a medullary cavity in its medial twothirds. The cortical bone is thickest at the transition zone between the antecurve and retrocurve. The female clavicle is typically shorter, thinner, less curved and smoother. Mid-shaft circumference is the most reliable single indicator of sex; a combination of this measurement with weight and length yields more reliable and consistent results. The clavicle is subcutaneous throughout its whole length and accordingly can be palpated for its entire length; the medial (sternal) end forms an expanded, blunt-faced margin of the jugular notch. The anterior border of the lateral (acromial) end is not readily distinguished from the acromion; the attachment of deltoid obscures the anterior aspect of the acromioclavicular joint. By contrast, the posterior border of the lateral end forms the anterior margin of a roughly parabolic hollow under the lateral fibres of trapezius, the posterior border being formed by the anterior border of the spine of the scapula. The hollow will admit at least one palpating finger. If the pulp of the finger is placed on the spine of the scapula as far laterally as the hollow will permit, the nail will inevitably point to the posterior capsule of the acromioclavicular joint; this landmark is always palpable, even in well-muscled individuals, when other shoulder landmarks can be obscured.

## Lateral two-fifths

The lateral two-fifths of the clavicle are flattened and have a superior and an inferior surface, limited by an anterior and a posterior border. The anterior border is concave, thin and roughened, and may be marked by a small deltoid tubercle. The posterior border, also roughened by muscular attachments, is convex backwards. The superior surface is roughened near its margins but is smooth centrally, where it can be felt through the skin. The inferior surface presents two obvious markings. Close to the posterior border, at the junction of the lateral fourth with the rest of the bone, a prominent conoid tubercle gives attachment to the conoid part of the coracoclavicular ligament. A narrow, roughened strip, the trapezoid line, runs forwards and laterally from the lateral side of this tubercle, almost as far as the acromial end (see Fig. 48.6B). The trapezoid part of the coracoclavicular ligament is attached to it. A small, oval articular facet, for articulation with the medial aspect of the acromion, faces laterally and slightly downwards at the lateral end of the shaft.

Subclavius is attached to the groove on the inferior surface (see Fig. 48.6B). The clavipectoral fascia is attached to the edges of the groove. The posterior edge of the groove runs to the conoid tubercle, where fascia and conoid ligament merge. There is a laterally inclined nutrient foramen lateral to the groove. Deltoid (anterior) and trapezius (posterior) are attached to the lateral two-fifths of the shaft; both muscles are directly inserted into the clavicle but are also indirectly inserted into the clavicular periosteum. The coracoclavicular ligaments, attached to
the conoid tubercle and trapezoid line (see Fig. 48.6B), transmit the weight of the upper limb to the clavicle, and are counteracted by the cervical part of trapezius, which supports its lateral part (see Fig. 48.18).

## Medial three-fifths

The medial three-fifths of the shaft of the clavicle are cylindrical or prismoid in form and have four surfaces, although the inferior surface is often reduced to a mere ridge. The anterior surface is roughened over most of its extent but is smooth and rounded laterally, where it forms the upper boundary of the infraclavicular fossa. The upper surface is roughened medially and smooth laterally. The posterior surface is smooth and featureless medially; its lateral half bears a groove in the long axis of the bone. The inferior surface is marked near its sternal end by a roughened oval impression, which is often depressed below the surface. Its margins give attachment to the costoclavicular ligament, which connects the clavicle to the upper surface of the first rib and its cartilage. Rarely, this area is smooth or raised to constitute an eminence that may form a synovial pseudarthrosis with the upper surface of the first rib; in older subjects, an extra-articular synostosis may form.

The medial three-fifths provide attachment, anteriorly, for the clavicular head of pectoralis major. The clavicular head of sternocleidomastoid is attached to the medial half of the superior surface, but the marking on the bone is not conspicuous. The smooth, posterior surface is devoid of muscular attachments, except at its lower part immediately adjoining the sternal end, where the lateral fibres of sternohyoid are attached. Medially, this surface is related to the lower end of the internal jugular vein (from which it is separated by sternohyoid), the termination of the subclavian vein, and the start of the brachiocephalic vein. More laterally, the clavicle arches in front of the trunks and divisions of the brachial plexus and the third part of the subclavian artery. The thyrocervical trunk and its branches, the suprascapular and transverse cervical vessels, are immediately behind and above the upper aspect of this surface. Subclavius is inserted in the subclavian groove on the inferior surface; the clavipectoral fascia is attached to the edges of the groove. The posterior lip of the groove is continuous with the conoid tubercle laterally and brings the clavipectoral fascia into continuity with the conoid ligament. A nutrient foramen is found in the lateral end of the groove, running in a lateral direction; the nutrient artery is derived from the suprascapular artery.

## Sternal end

The sternal end of the clavicle is directed medially, downwards and forwards, and articulates with the clavicular notch of the manubrium sterni. The sternal surface, usually irregular and pitted, is quadrangular (sometimes triangular). Its uppermost part is slightly roughened for attachment of the interclavicular ligament, sternoclavicular capsule and articular disc. Elsewhere, the surface is smooth and articular, and it extends on to the inferior surface for a short distance, where it articulates with the first costal cartilage. The sternal end of the clavicle projects
upwards beyond the manubrium sterni; it can be felt and seen easily, forming the lateral wall of the jugular notch, behind which are the cricoid cartilage, cricothyroid membrane, the lower part of the thyroid cartilage of the larynx and the brachiocephalic vein. The sternal ends of each clavicle thus form a guide to the jugular notch: if the sternal end of the clavicle is displaced backwards (by traumatic dislocation), the landmarks of the notch are lost, the trachea is displaced and there will be difficulty breathing. If the trachea is displaced to one side (for instance, by pneumothorax), the features of the larynx cannot be palpated readily.

## Ossification

The clavicle begins to ossify before any other bone in the body. The shaft of the bone is ossified in condensed mesenchyme from two primary centres, medial and lateral, that appear between the fifth and sixth weeks of intrauterine life, and fuse about the fourth-fifth day. Cartilage then develops at both ends of the clavicle. The medial cartilaginous mass contributes more to growth in length than does the lateral mass; the two centres of ossification meet between the medial three-fifths and lateral two-fifths of the clavicle. A secondary centre for the sternal end appears in the late teens, or even early twenties, usually 2 years earlier in females (Fig. 48.7). Fusion is probably rapid but reliable data are lacking. An acromial secondary centre sometimes develops

Fig. 48.7 The three constant centres of ossification of the clavicle.
at around 18-20years, but this epiphysis is always small and rudimentary, and rapidly joins the shaft. Growth is usually complete by 23 years in both sexes.

## SCAPULA

The scapula is a large, triangular bone that lies over the posterolateral chest wall, covering parts of the second to seventh ribs (see Fig. 46.7), with a vertical long (craniocaudal) axis. It has costal and dorsal surfaces; superior, lateral and medial borders; inferior, superior and lateral angles; and three processes: the spine, its continuation - the acromion, and the coracoid process (Figs 48.8, 48.9).

The superior and lateral borders and the supraspinous and infraspinous fossae converge laterally at the lateral angle of the scapula. This region comprises the glenoid fossa, the coracoid process and the neck of the scapula. Thus, three robust columns of bone converge at the neck region: the lateral border of the spine of the scapula, the coracoid, and the lateral border of the scapula. Load applied through the glenoid fossa or through the coracoid is transmitted into the scapula through these columns, which also provide a robust framework for the scapular body. The main processes, and thicker parts of the scapula, contain trabecular bone for load-bearing; the rest consists of a thin layer of compact bone for muscular attachments.

## Costal surface

The costal surface, which is directed medially and forwards when the arm is by the side, is gently concave, especially in its upper part, matching the contour of the chest wall (see Fig. 48.8B).

Near the lateral border, there is a longitudinal rounded ridge, prominent near the neck but less so below, which is separated from the lateral border by a narrow, grooved area. Subscapularis arises from the subscapular fossa that comprises nearly the whole of the costal surface,

Fig. 48.8 The left scapula, showing sites of muscular and ligamentous attachment and articular surfaces. A, Posterior aspect. Key: 1, clavicular facet; 2, biceps brachii (short head); 3, acromion; 4, deltoid; 5, glenoid fossa; 6, triceps brachii (long head); 7 and 9, teres minor; 8, groove for circumflex scapular artery; 10, teres major; 11, conoid tubercle; 12, coracoid process; 13 , omohyoid (inferior belly); 14, superior angle; 15, supraspinatus; 16, levator scapulae; 17, spine; 18, trapezius; 19, rhomboid minor; 20, infraspinatus; 21, rhomboid major; 22, latissimus dorsi; 23, inferior angle. B, Anterior aspect. Key: 1, attachment of trapezoid ligament; 2, attachment of conoid ligament; 3, acromion process; 4, suprascapular notch; 5, omohyoid (inferior belly); 6, serratus anterior; 7, subscapularis; 8, ridge for intermuscular tendon of subscapularis; 9, deltoid; 10, biceps brachii (short head) and coracobrachialis; 11, pectoralis minor; 12, glenoid fossa; 13, triceps brachii (long head).

The shaft of the clavicle is usually fractured as a result of a violent impact to the side of the shoulder. The fracture typically occurs at the junction of the lateral two-fifths and medial three-fifths, where the transition from antecurve to retrocurve occurs. The weight of the arm causes displacement of the lateral fragment downwards, inwards and into forward (ventral) rotation. If the fracture heals in this position, the dimensions and shape of the retroclavicular space are altered, particularly during elevation of the arm above shoulder level, and the brachial plexus (and its perfusion) and the subclavian vessels can be distorted (one of the many causes of the syndrome associated with thoracic outlet obstruction).

The clavicle does not ossify exclusively by intramembranous ossification. In 14 mm embryos, the clavicle is a band of condensed mesenchyme between the acromion and apex of the first rib, and is continuous with the sternal rudiment. Medial and lateral zones of early cartilage transformation ('precartilage') occur within this band; intramembranous centres of ossification appear, and soon fuse, in the mesenchyme between them. Sternal and acromial zones become true cartilage into which ossification extends from the shaft. Length increases by interstitial growth of these terminal cartilages; the latter develop zones of hypertrophy, calcification and advancing endochondral ossification like other growth cartilages. Diameter increases by subperichondral deposition in the extremities and subperiosteal deposition in the shaft. Epiphyses are endochondral and probably fuse in the same way as they do in long bones. Clavicle growth and development defects include those of ossification, of morphology (shape) and of length. Defects of ossification in the clavicle and those cranial bones that ossify by intramembranous ossification occasionally coincide, e.g. in cleidocranial dysostosis.

Defects of morphology and length occur in the immature clavicle in birth lesions of the brachial plexus; the lateral two-fifths are affected. In a typical case, the acromial end of the clavicle is hypercurved, ventrally rotated by up to $90^{\circ}$ and short. The coracoclavicular ligaments are normal. The coracoid is long and more vertical than usual; the scapula is often small, and the scapular neck region short with variable glenoid dysplasia. These characteristic defects are predominantly associated with the upper trunk lesion (C5 and C6) that results in a muscular imbalance across the acromioclavicular and glenohumeral joints; the flexor and medial (internal) rotator muscles are relatively short. The short, tight pectoralis minor and coracobrachialis produce a distorting force on the coracoid, which elongates and rotates dorsally. With retropulsion of the humeral head posteriorly, the scapula rotates ventrally, particularly if there is posterior glenoid dysplasia. Deltoid shortening creates a downward distraction on the developing acromion, which lengthens and curves distally. The spine of scapula is parallel to the body of the scapula rather than dorsally directed; these deformities cause the acromioclavicular joint to be orientated more horizontally. As a result, the lateral clavicle hypercurves ventrally. The concept here is that dysmorphology is driven by asymmetrical muscle paralysis and partial recovery, and that form follows the neural lesion. While poor movement (causing a lack of 'motivation' for growth in length) might explain the clavicular shortening, an equally valid explanation might involve a vascular insufficiency of the lateral ossification centre of the clavicle (with a similar insufficiency of the lateral ossification centres of the scapula for the glenoid): both have a contribution from the suprascapular artery, which is 'at risk' during injuries that lead to brachial plexus palsy. Length is a function of perfusion and shortening follows vascular insufficiency (Kambhampati et al 2006).

Fig. 48.9 The left scapula, showing sites of muscular and ligamentous attachment and articular surfaces. A, Superior aspect. Key: 1, facet for clavicle; 2, acromial process; 3, spine; 4, superior border; 5, head; 6, glenoid fossa; 7, neck; 8, conoid tubercle (for conoid ligament); 9, coracoid process; 10, attachment of trapezoid ligament. B, Lateral aspect. Key: 1, coracoid process; 2, supraglenoid tubercle; 3, glenoid fossa; 4, infraglenoid tubercle for long head of triceps brachii; 5, ventral surface; 6, acromion; 7, acromial angle; 8, lateral border; 9, inferior angle.
including the grooved area immediately adjoining the lateral border, but excluding the area next to the neck of the bone. Small, fibrous intramuscular septa are attached to four or five roughened ridges that subdivide this surface incompletely into a number of smooth areas. The anterior aspect of the neck is separated from subscapularis by a bursal protrusion of the synovial membrane of the shoulder joint (subscapular 'bursa'). The lower five or six digitations of serratus anterior are attached to an oval area near the inferior angle. The remainder of the muscle is inserted into a narrow strip along the ventral aspect of the medial border, which is wider above, where it receives the large first digitation. The longitudinal thickening of the bone near the lateral border provides a column of the necessary strength to withstand the pull of serratus anterior on the inferior angle during lateral scapular rotation, when the glenoid cavity is turned to face more directly upwards as the arm is raised from the side and carried above the head against gravity.

## Dorsal surface

The dorsal surface is divided by the transverse, shelf-like spine of the scapula into two unequal parts: a smaller supraspinous fossa above and an infraspinous fossa below. The fossae are confluent at the spinoglenoid notch between the lateral border of the spine and the dorsal aspect of the neck; their central parts may be very thin (see Fig. 48.8A). The supraspinous fossa is bounded superiorly and anteriorly by the superior border, from the suprascapular notch and dorsal aspect of the root of the coracoid laterally, to the superior angle medially; and medially, by the upper part of the medial border. The infraspinous fossa is bounded by the medial and lateral borders and the inferior angle.

Supraspinatus is attached to the medial two-thirds of the supraspinous fossa on the dorsal surface; the fascia that covers the muscle is attached to the margins of the fossa. A fat pad lies between the supraspinatus fascia and the under-surface of trapezius. Teres minor is attached to the upper two-thirds of a flattened strip that adjoins the lateral border. The strip is grooved near its upper end by the circumflex scapular vessels passing between teres minor and the bone as they enter
the infraspinous fossa. The lower limit of the attachment of teres minor is indicated by an oblique ridge, which runs from the lateral border to the neighbourhood of the inferior angle and cuts off a somewhat oval area where teres major is attached. The dorsal aspect of the inferior angle may give origin to a small slip that joins the deep surface of latissimus dorsi. The infraspinous fossa is hollowed out laterally but is convex medially. Infraspinatus is attached to the infraspinous fossa, with the exception of an area near the neck of the bone. The strong infraspinatus fascia passes on to teres minor and teres major, and sends fascial partitions between them that reach the bone along the ridges marking the limits of their attachments.

## Superior border

The superior border, thin and sharp, is the shortest. At its anterolateral end, it is separated from the root of the coracoid process by the suprascapular notch (see Fig. 48.8B), which can vary in shape and size. Medial to the suprascapular notch, the superior border gives origin to the inferior belly of omohyoid. The notch is bridged by the superior transverse ligament (or suprascapular ligament), which is attached laterally to the root of the coracoid process and medially to the limit of the notch. The ligament is sometimes ossified. The foramen, thus completed, transmits the suprascapular nerve to the supraspinous fossa, whereas the suprascapular vessels pass backwards above the ligament.

## Lateral border

The lateral border has a triangular or rhomboidal cross-section. It forms a clearly defined, sharp, roughened ridge that runs sinuously from the inferior angle to the glenoid cavity. At its upper end, it widens into a rough, somewhat triangular, area: the infraglenoid tubercle (see Fig. 48.9B). The lateral border separates the attachments of subscapularis and teres minor and major. These muscles project beyond the bone and, with latissimus dorsi below, cover it so completely that it cannot be felt through the skin. The long head of triceps is attached to the infraglenoid tubercle.

The grooved part of the costal surface, the narrow, flat lateral strip of the dorsal surface and the adjacent thickened ridge (see Fig. 48.9B) are often included in the 'lateral column' in surgical practice. By definition, the remainder of the scapular body (costal and dorsal surfaces) and the medial border are called the 'medial column'.

## Medial border

The medial border extends from the inferior to the superior angle. It is slightly thickened and flat, and is further thickened at the medial end of the spine. In its lower two-thirds, this border can easily be felt through the skin, but its upper third is more deeply placed and more difficult to palpate. It is thin and often angled opposite the root of the spine. Levator scapulae is attached to a narrow strip, extending from the superior angle to the root of the spine, and rhomboid minor is attached below this, opposite the root of the spine. Rhomboid major is attached to the remainder of the border.

## Scapular angles

The inferior angle lies over the seventh rib, or over the seventh intercostal space. It can be felt through the skin and the muscles that cover it, and, when the arm is raised above the head, it can be seen to rotate forwards (protract) around the chest wall; when the arm is lowered, the scapula should restitute (retract) to its original position without a disturbance of rhythm. It is covered on its dorsal aspect by the upper border of latissimus dorsi, a small slip from which is frequently attached to the inferior angle. The superior angle, at the junction of the superior and medial borders, is obscured by the upper part of trapezius. It lies over the dorsal surface of the second rib and can be palpated deeply above and behind the clavicle.

The lateral angle, truncated and broad, comprises the glenoid fossa (cavity) and scapular neck, with the coracoid projecting forwards. When the arm is by the side, the fossa is directed forwards, laterally and slightly upwards. When the arm is raised above the head, it is directed almost straight upwards, i.e. the plane of the fossa is horizontal. The supraglenoid tubercle is a small, rough, sloping area at the cranial margin of the fossa; it often encroaches on the root of the coracoid process, and is the site of attachment for the tendon of the long head of biceps brachii. The infraglenoid tubercle is a larger, rough area at the caudal margin of the glenoid fossa, at the upper end of the lateral margin, and is the site of attachment for the tendon of the long head of the triceps brachii. The anatomical neck is the region of the scapula extending between the infraglenoid and supraglenoid tubercles anteriorly and posteriorly, lateral to the root of the coracoid process; anteriorly, there is no landmark to distinguish the anatomical neck from the costal surface of the body of the scapula. Posteriorly, the anatomical neck is limited by the spinoglenoid notch at the root of the spine of the scapula. The bone here has an asymmetric, triangular cross-sectional shape; the plane of the anterior surface of the neck makes an acute angle of about $60^{\circ}$ with the plane of the glenoid fossa, but the dimension and shape of the posterior surface are more variable.

## Spine of the scapula

The spine of the scapula forms a shelf-like projection on the upper part of the dorsal surface of the bone, and is triangular in shape (see Fig. 48.8A). Its lateral border is free, thick and rounded, and bounds the spinoglenoid notch, which lies between it and the dorsal surface of the neck of the bone. Its anterior aspect joins the dorsal surface of the scapula along a line that runs laterally and slightly upwards from the junction of the upper and middle thirds of the medial border. The plate-like body of the bone is bent along this line, which accounts for the concavity of the upper part of the costal surface. The dorsal border is the crest of the spine and is subcutaneous throughout nearly its whole extent. The crest expands into a smooth, triangular area at its medial end. Elsewhere, the upper and lower edges and the surface of the crest are roughened for muscular attachments. The upper surface of the spine widens as it is traced laterally and is slightly hollowed out. Together with the upper area of the dorsal surface of the bone, the upper surface of the spine forms the supraspinous fossa. The lower surface is overhung by the crest at its medial, narrow end, but is gently convex in its wider, lateral portion. Together with the lower area of the dorsal surface of the bone, the lower surface of the spine forms the infraspinous fossa, which communicates with the supraspinous fossa through the spinoglenoid notch.

Supraspinatus is attached to the upper surface of the spine of the scapula; the infraspinatus, by contrast, is not attached to the lower surface of the spine. The flattened triangular area at its root lies opposite the spine of the third thoracic vertebra and is covered by the tendon of trapezius; a bursa intervenes to enable the tendon to play over this part of the bone. The posterior fibres of deltoid are attached to the lower
border of the crest and, to a variable extent, to the medial border by attachment to the infraspinatus fascia. The middle fibres of trapezius are attached to the upper border of the crest. The lowest fibres of trapezius terminate in a flat, triangular tendon that glides over the smooth area at the base of the spine and inserts into a rough prominence, erroneously called the deltoid tubercle, on the dorsal or subcutaneous aspect of the spine near its medial end.

## Acromion

The acromion projects forwards, almost at right angles, from the lateral end of the spine, with which it is continuous. The lower border of the crest of the spine becomes continuous with the lateral border of the acromion at the acromial angle, which forms a reliable, subcutaneous, bony landmark. The medial border of the acromion is short and is marked anteriorly by a small, oval facet, directed upwards and medially, for articulation with the lateral end of the clavicle. The lateral border, tip and upper surface of the acromion can all be felt through the skin without difficulty. There may be an accessory articular facet on the inferior surface of the acromion.

The acromion is subcutaneous over its dorsal surface, being covered only by the skin and superficial fascia. The lateral border, which is thick and irregular, and the tip of the process, as far round as the clavicular facet, give origin to the middle fibres of deltoid. The medial aspect of the tip gives attachment, below deltoid, to the lateral end of the coracoacromial ligament. The articular capsule of the acromioclavicular joint is attached around the margins of the clavicular facet. Behind the facet, the medial border of the acromion gives insertion to the horizontal (middle) fibres of trapezius. The inferior aspect of the acromion is relatively smooth and forms a protective arch over the shoulder joint, together with the coraco-acromial ligament and the coracoid process. The tendon of supraspinatus passes below the overhanging acromion and is separated from it and from deltoid by the subacromial bursa.

## Coracoid process

The coracoid process arises from the upper border of the neck of the scapula and its body is bent sharply so as to project forwards and slightly laterally (see Figs $48.8,48.9$ ). When the arm is by the side, the coracoid process points almost straight forwards. Its tip can be felt through the skin and is covered by the anterior fibres of deltoid, about 2.5 cm below the clavicle at the junction of the lateral fifth with the rest of the bone, at the lateral border of the infraclavicular fossa. It forms a short, curved cantilever fixed to the scapula at its base and is displaced by the actions of the muscles attached to its body and tip. Pectoralis minor pulls the coracoid (and, therefore, the scapula) forwards and medially around the chest wall, balanced by trapezius, its antagonist; this action forms the foundation on which coracobrachialis can help support the long lever arm of the humerus during humeral motion, together with its antagonist, the deltoid.

The infraclavicular brachial plexus and the axillary vessels lie below and medial to the coracoid. The acromial branch of the thoracoacromial artery passes above it, and the sensory branch of the lateral pectoral nerve to the rotator interval capsule, together with accompanying vessels, lies immediately below.

On the dorsal aspect of the coracoid process, at the point where it changes direction, a rough impression forms part of the region of attachment of the conoid portion of the coracoclavicular ligament. The trapezoid portion of the coracoclavicular ligament is attached to the upper aspect of the horizontal part of the process, anterior to the conoid part. Pectoralis minor is attached to the superior and medial aspects of the coracoid process. The wider, medial, end of the coraco-acromial ligament is attached to the lateral border and is continuous inferiorly with the lateral aponeurotic part of the tendon of the short head of biceps brachii. The coracohumeral ligament is attached to the root of the coracoid at its lateral border. The interval between the anterior aspect of the scapular neck immediately medial to the glenoid fossa and the deep surface of the coracoid is often bridged by the glenocoracoid ligament. The inferior aspect of the coracoid process is otherwise smooth and saddle-shaped. When the arm is elevated, the upper border of subscapularis is apposed to, and runs under, this surface, which forms a pulley for the muscle, increasing the power generated during forceful medial (internal) rotation of the shoulder in elevation, such as during a serve in tennis. Coracobrachialis is attached to the deep aspect of the lower part of the medial side and the deep surface of the tip of the process, and the short head of biceps is attached to the lateral side and superficial aspect of the tip.

## Scapular movements

Scapular movement is a product of interconnected suspension, motion and articulation mechanisms. The suspension mechanism consists of
the scapular articulation with the clavicle and the suspension muscles of the scapula and clavicle, notably trapezius, attached to the lateral clavicle, the acromion and the spine of scapula. The articulation with the clavicle comprises two linked systems: 'clavicle - acromioclavicular joint - acromion - spine of scapula - lateral scapular angle' and 'clavicle - coracoclavicular ligament - coracoid - lateral scapular angle - spine of scapula'. This mechanism therefore subserves the function of scapular rotation or tilt limited by the ellipsoid range of motion of the lateral clavicle. The motion mechanism consists of the agonist-antagonist force couple of serratus anterior passing to the chest wall anterolaterally, and levator scapulae, rhomboid major, rhomboid minor and serratus posterior (when present), which all pass to the vertebral column medially. This mechanism therefore subserves the function of scapular protraction and retraction around the elliptic paraboloid of the chest wall. The articulation mechanism consists of the scapular neck region and the glenoid fossa, which articulates with the humeral head. The muscles that subserve the function of holding the humeral head on the glenoid through the wide range of motion of the glenohumeral joint are the rotator cuff muscles, which take their attachment from the body of the scapula. This mechanism therefore concerns the relationship between the position and orientation of the glenoid fossa and the scapular body.

## Ossification

The cartilaginous scapula is ossified from eight or more centres: one in the body, two each in the coracoid process and the acromion, and one each in the medial border, inferior angle and lower part of the rim of the glenoid cavity (Fig. 48.10). The centre for the body appears in the eighth intrauterine week. Ossification begins in the middle of the coracoid process in the first year or, in a small proportion of individuals, before birth; the process joins the rest of the bone about the fifteenth year. At or soon after puberty, centres of ossification occur in the rest of the coracoid process (subcoracoid centre), in the rim of the lower part of the glenoid cavity, frequently at the tip of the coracoid process, in the acromion, in the inferior angle and contiguous part of the medial border and in the medial border. A variable area of the upper part of the glenoid cavity, usually the upper third, is ossified from the subcoracoid centre; it unites with the rest of the bone in the fourteenth year in the female and the seventeenth year in the male. A horseshoe-shaped epiphysis appears for the rim of the lower part of the glenoid cavity; thicker at its peripheral than at its central margin, it converts the flat glenoid cavity of the child into the gently concave fossa of the adult. The base of the acromion is formed by an extension from the spine; the rest of the acromion is ossified from two centres that unite and then join the extension from the spine. The various epiphyses of the scapula have all joined the bone by about the twentieth year.

The normal fetal scapula differentiates in somitic ectoderm at about 5 weeks in utero juxtaposed to the fourth, fifth and sixth cervical vertebral anlagen. As the neural axis and cardiac primordia develop between the ninth and twelfth weeks, the primordial scapula migrates caudally to its usual position at a level between the second and seventh ribs. With further development, the scapula alters shape.

## Ligaments

The intrinsic scapular ligaments are strengthening ligaments (coracoacromial ligament) and bounding ligaments (superior transverse scapular or suprascapular ligament, inferior transverse scapular or spinoglenoid ligament, and the variable glenocoracoid ligament).

Coraco-acromial ligament The coraco-acromial ligament is a strong triangular band between the coracoid process and acromion. It is attached apically to the acromion anterior to its clavicular articular surface, and by its base along the whole lateral border of the coracoid. Together with the coracoid process and acromion, it completes an arch above the humeral head. It may be composed of two strong marginal bands with a thinner centre; when pectoralis minor is inserted into the humeral capsule instead of the coracoid process, which happens occasionally, its tendon passes between the bands. The subacromial bursa facilitates movement between the coraco-acromial arch and the subjacent supraspinatus and shoulder joint, functioning as a secondary synovial articulation. When the coraco-acromial ligament is cut, it is impossible to appose the two cut surfaces afterwards: this suggests there is resting tension in the ligament, which forms a 'tension band' between the acromial and coracoid processes of the scapula, so 'pre-tensioning' both processes against the distracting forces of deltoid and trapezius, and pectoralis minor and the conjoined short head of biceps brachii and coracobrachialis, respectively.

Superior transverse scapular (suprascapular) ligament The superior transverse scapular (suprascapular) ligament converts the scapular

A

B

Fig. 48.10 Ossification of the scapula. A, Dorsal aspect. B, Lateral aspect. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)
notch into a foramen; it is sometimes ossified. A flat fasciculus, it narrows towards its attachments to the base of the coracoid process, blending with the lower fibres of the conoid ligament, and to the medial side of the scapular notch. The suprascapular nerve traverses the foramen, and the suprascapular vessels cross above the ligament.

Inferior transverse scapular (spinoglenoid) ligament When present, the inferior transverse scapular ligament is a membranous ligament that may stretch from the lateral border of the spine of the scapula to the glenoid margin (see Fig. 48.33). It forms an arch over the branches of the suprascapular nerve and vessels entering the infraspinous fossa to supply infraspinatus.

## HUMERUS

The humerus, the longest and largest bone in the upper limb, has expanded ends and a shaft (Figs 48.11-48.12). The spheroidal humeral head forms an enarthrodial articulation with the glenoid fossa of the scapula. The lesser tubercle projects from the front of the shaft, close

Initially, the horizontal diameter exceeds the vertical but the ratio gradually decreases until mature dimensions are reached, an adaptation thought to provide upright hominids with increased range, and therefore freedom of use, of the upper limb. Avian gene-deletion studies have shed light on the development of the scapula. Scapular body development appears to be controlled by the Emx2 gene, also expressed in the developing mesonephros. The development of the acromion and the spine of the scapula are controlled by the Pax1 gene, and glenoid and coracoid development is controlled by the Hoxc6 gene (Huang et al 2000), one of the homeobox genes responsible for somite differentiation and development; development of the glenoid and coracoid appears likely to be more intimately related to the development of the upper limb bud as a whole. The development of the scapular body appears to be independent of that of the processes and glenoid region. Adult scapulae may show a line of fusion across the body and spine of the scapula, suggesting that the primordia of the processes (including the glenoid) and the primordium of the body migrate towards each other; since the trapezius is derived from branchial arch mesoderm it would appear that the development of the spine of the scapula and acromion and trapezius are intimately related, but separate from the body. This hypothesis is supported by the observation that; in the condition of so-called Sprengel shoulder (more correctly termed congenital undescended scapular syndrome), the development of the scapular body is altered, and there is intramuscular ossification of variable parts of the medial scapulospinal muscles, but the development of the processes (including the glenoid) is unaffected (Dhir and Lambert 2014).

The suprascapular nerve may be entrapped by the ligament if this is thickened or ossified and this may cause the syndrome of neurostenalgia, a typical pain of unremitting burning or aching nature, due to stenosis or distortion of the nerve trunk by extrinsic compression. Weakness of supraspinatus and infraspinatus may subsequently occur. Surgical release of the ligament is often helpful; this may be undertaken by open or arthroscopic surgical exposure and division of the ligament.

A ganglion (an outpouching of the synovial membrane of the glenohumeral joint) may occur immediately behind and above the posterosuperior corner of the glenoid fossa; this can compress the branch of the suprascapular nerve that supplies infraspinatus as it courses around the lateral aspect of the spine of the scapula under the inferior scapular ligament. Since the nerve cannot move aside (it is 'held' under the ligament), it can be readily distorted; there is characteristic severe pain, followed by specific atrophy of infraspinatus. Decompression of the ganglion and division of the ligament are curative in the early stage of this syndrome. An intraneural ganglion may arise from the articular branch of the suprascapular nerve; muscular pain and atrophy would be expected to be more rapid than in the case of the synovial ganglion (Spinner et al 2006).

Fig. 48.12 The proximal end of the left humerus. A, Anterior aspect. Key: 1, head; 2, anatomical neck; 3, surgical neck; 4, greater tubercle; 5 , lesser tubercle; 6, intertubercular sulcus; 7, shaft. B, Posterior aspect. Key: 1, greater tubercle; 2, surgical neck; 3 , shaft; 4, radial groove; 5 , head; 6 , anatomical neck.
to the head, and is limited on its lateral side by the well-marked groove, the intertubercular sulcus, by which it is separated from the greater tubercle. The distal end is adapted to the forearm bones at the elbow joint and carries the medial and lateral epicondyles with the articular surfaces for the radius and ulna between them. The axis between the epicondyles is the inter-epicondylar axis.

The shaft of the human (and primate) humerus is relatively medially rotated with respect to the humeral head, compared with quadripedal ancestors; this gives the characteristically greater range of external rotation at the glenohumeral joint than that obtaining in other species. This is reflected in the spiroidal architecture of the adult humeral medullary cavity, the arrangement and relationship of the posterior compartment of brachial muscles and the radial nerve, and the disposition to long spiroidal fractures caused by external twisting forces.

With the arm by the side in the anatomical position, and with the medial and lateral epicondyles in the same (frontal) plane (i.e. the inter-epicondylar axis is in the frontal plane), the humeral head is rotated posteriorly at an angle averaging $15-20^{\circ}$ in European cadaveric specimens (Boileau and Walch 1997). Since the glenoid fossa of the scapula faces anterolaterally, the humerus is not rotated posteriorly relative to the scapula in the anatomical position. It is important to remember this position of the bone when movements of the arm and forearm are considered; movements are recorded relative to the trunk (starting in the anatomical position) or relative to the scapula, and it is important to define which method is in use.

## Proximal end

The proximal end of the humerus consists of the head, anatomical neck, and the greater and lesser tubercles. It joins the shaft at an ill-defined 'surgical neck', which is closely related on its medial side to the axillary nerve and posterior humeral circumflex artery (see Figs 48.22, 48.31, 48.33). The proximal end of the humerus makes up the upper fifth of the length of the bone.

## Head

The head of the humerus forms rather less than half a spheroid; in sectional profile, it is spheroidal (strictly, ovoidal) (see Fig. 48.12). Its smooth articular surface is covered with hyaline cartilage that is thicker centrally. When the arm is at rest by the side, it is directed medially, backwards and upwards to articulate with the glenoid cavity of the scapula. The humeral articular surface is much more extensive than the glenoid cavity, which means that only a portion of it is in contact with the cavity in any one position of the arm.

## Anatomical neck

The anatomical neck of the humerus immediately adjoins the margin of the head, forming a slight constriction that is least obvious next to the greater tubercle. A slight roughness indicates the line of capsular attachment of the shoulder joint, other than at the intertubercular sulcus, where the long tendon of biceps brachii emerges. Medially, the capsular attachment diverges from the anatomical neck and descends 1 cm or more on to the shaft.

## Lesser tubercle

The lesser tubercle is anterior to and just distal to the anatomical neck. It is palpable through the thickness of deltoid about 3 cm below the anterior edge of the acromion. It can be distinguished from the coracoid by rotation of the humerus under the palpating finger; the lesser tubercle slips away from the examining finger, the tip of the coracoid does not. The lateral edge of the lesser tubercle is sharp and forms the medial border of the intertubercular sulcus. Subscapularis is attached to the lesser tubercle (see Fig. 48.11A). The transverse ligament of the shoulder (transverse humeral ligament) is attached to the upper aspect of the lateral margin of the tubercle.

## Greater tubercle

The greater tubercle is the most lateral part of the proximal end of the humerus and projects beyond the lateral border of the acromion. Its posterosuperior aspect, near the anatomical neck, bears three smooth, flattened impressions for the attachment of supraspinatus (uppermost), infraspinatus (middle) and teres minor (lowest and placed on the posterior surface of the tubercle) (see Fig. 48.11). The attachments of subscapularis and teres minor are not confined to their respective tubercles, but extend for varying distances on to the adjacent metaphysis. The projecting lateral surface of the tubercle presents numerous vascular foraminae and is covered by deltoid, producing the normal rounded contour of the shoulder. A part of the subacromial bursa may cover the
upper part of this area and separate it from deltoid. The intertubercular sulcus (bicipital groove) lies between the tubercles. It contains the long tendon of biceps, its synovial sheath, and an ascending branch from the anterior circumflex humeral artery. The rough lateral lip of the groove is marked by the bilaminar tendon of pectoralis major, and its medial lip by the tendon and muscular insertion of teres major. The floor of the groove provides attachment for a frequent upward extension of the tendon of pectoralis major, and for the tendon of latissimus dorsi more caudally (Dancker 2013).

## Shaft

The shaft of the humerus is almost cylindrical in its proximal half. Distal to the deltoid tuberosity, it is equilaterally triangular in crosssection, flaring out into a broad isosceles triangular cross-section just above the elbow joint. It can be readily palpated laterally and medially, but the muscles of the anterior and posterior compartments obscure the bone to palpation anteriorly and posteriorly. It has three surfaces and three borders, which are only distinct towards the elbow joint. The shaft comprises the middle three-fifths of the humerus.

## Surfaces

The posterior surface, between the medial and lateral borders, is broad, flat and convex distally. The medial head of triceps is attached to the posterior surface over an elongated triangular area, the apex of which is placed on the medial part of the bone above the level of the lower limit of insertion of teres major. The area widens below and covers the whole surface almost down to the lower end of the bone. The lateral head of triceps is attached to a ridge, sometimes rough, that descends obliquely and laterally above the attachment for the medial head. Above triceps, the axillary nerve and the posterior circumflex humeral vessels wind around the bone on the deep surface of deltoid. Below the attachment of the lateral head of triceps, but above the attachment of the medial head, a shallow groove runs from the upper medial aspect of the surface downwards and laterally towards the lateral border; it contains the radial nerve and its branches, and the profunda brachii vessels.

The anterolateral surface is bounded by the anterior and lateral borders, and is smooth and featureless in its upper part, which is covered by deltoid. About, or a little above, the middle of this surface, deltoid is attached to the deltoid tubercle. Further distally, the surface gives origin to the lateral fibres of brachialis, which extend upwards into the floor of the lower end of the groove for the radial nerve (see Fig. 48.11). The nerve perforates the lateral intermuscular septum close to the bone at the level of the junction of the upper three-fifths and lower two-fifths of the humerus, and enters the anterior compartment of the arm close to the anterolateral surface, between brachialis medially and brachioradialis laterally.

The anteromedial surface is bounded by the anterior and medial borders. Below the intertubercular sulcus, the rest of the upper half of the surface is smooth and devoid of muscular attachment; its lower half is occupied by the medial part of brachialis (see Fig. 48.11A). Coracobrachialis is attached to a long rough strip in the middle third of the medial border, posterior to the brachial neurovascular sheath, which lies in close relation to the humerus in the middle third of this surface. The humeral head of pronator teres is attached to a narrow area close to the lowest part of the medial supracondylar ridge; the ridge itself gives attachment to the medial intermuscular septum of the arm.

A little below its midpoint, the nutrient foramen, which is directed downwards, opens close to the medial border. A hook-shaped process of bone, the supracondylar process, ranging from 2 to 20 mm in length, occasionally projects from the anteromedial surface of the shaft, approximately 5 cm proximal to the medial epicondyle. It is curved downwards and forwards, and its pointed apex is connected to the medial border, just above the epicondyle, by a fibrous band, to which part of pronator teres is attached. The foramen completed by this fibrous band usually transmits the median nerve and brachial artery, but sometimes encloses only the nerve, or the nerve plus the ulnar artery (in cases of high division of the brachial artery). A groove that lodges the artery and nerve usually exists behind the process.

## Anterior border

The anterior border starts on the front of the greater tubercle and runs downwards almost to the lower end of the bone. Its proximal third forms the lateral lip of the intertubercular sulcus and is roughened for muscular attachments. The succeeding portion is also roughened and forms the anterior limit of the deltoid tubercle; the lower half of the border is smooth and rounded.

## Lateral border

The lateral border is most conspicuous at the lower end of the bone， where it is thickened to form the lateral supracondylar ridge，and its sharp edge is roughened along its anterior aspect．In its middle and upper thirds，the border is barely discernible，but in a well－marked bone it can be traced upwards to the posterior surface of the greater tubercle． A little above its middle，it is marked by a V－shaped，roughened area： the deltoid tubercle．The limbs of the V are broad；the groove for the radial nerve runs downwards and laterally behind the posterior limb and fades away on the lower part of the anterolateral surface．The lateral intermuscular septum is attached to the lateral border，and is a condensation of the fascia over the lower part of deltoid and the neigh－ bouring brachialis，forming a septum between the anterior and poste－ rior muscular compartments．The septum is most obvious in the lower three－fifths of the arm，and is perforated by the radial nerve and accom－ panying vessels．

## Medial border

The medial border，although rounded，can be identified without diffi－ culty in the lower half of the shaft，where it becomes the medial supra－ condylar ridge．In its proximal third，the medial border is indistinct until it broadens out to form a triangular area．The lateral border of this area forms the medial lip of the intertubercular sulcus，and the medial border runs upwards as the calcar humerale to the anatomical neck，where it is roughened，with vascular apertures，and forms the area of attachment of the inferior part of the shoulder capsule．In its middle third，the medial border is interrupted by a wide，shallow groove，the radial（spiral）groove that crosses the bone obliquely，passing down－ wards and forwards from its posterior to its anterior surface．

## Fractures of the humeral shaft

Humeral shaft fractures are common；the pattern of the fracture and the displacement of the fragments depend on the force of injury and on the level at which the bone is broken．If there is wide displacement at the time of fracture，closely associated nerves and vessels are at risk of direct injury．Nerves that are＇fixed＇in relation to the bone and attached septa are at further risk of indirect injury by stretching or，later， by the callus of bone healing．（For a discussion of radial nerve injury and fractures of the humeral shaft，see Lambert（2005）．）

## Distal end

The distal end of the humerus is described in on page 838.

## Ossification

The proximal humerus and shaft are ossified from four centres：one each in the shaft，head，greater and lesser tubercles（Fig．48．13）．The centre for the shaft appears near its middle in the eighth week of intrau－ terine life，and gradually extends towards the ends．Most growth occurs at the distal end of the bone．Ossification begins in the head before birth $(20 \%)$ or in the first 6 months afterwards；the greater tubercle starts to ossify during the first year in females and second year in males； the lesser tubercle begins to ossify at about the fifth year．

By the sixth year，the centres for the head and tubercles have joined to form a single large epiphysis，hollowed out on its inferior surface to adapt to the conical upper end of the metaphysis．This macroscopic topography provides for mechanical stability in the physis during

Fig. 48.14 The sternoclavicular joints, anterior aspect. The joint on the left side is intact and the joint on the right side is shown in coronal section.
growth, although rotational stability is still relatively poor; adolescent proximal humeral physial fracture-separations are commonly unstable in rotation. The proximal humeral epiphysis fuses with the shaft of the humerus at about the thirteenth or fourteenth year in females, beginning on the medial aspect of the physial line, and between the fourteenth to sixteenth year in males.

## JOINTS

## STERNOCLAVICULAR JOINT

The sternoclavicular joint is a synovial sellar (saddle, or hyperbolic paraboloid) joint with an intra-articular fibrocartilaginous disc. It is the only skeletal articulation between the upper limb and the axial skeleton (Sewell et al 2013).

Articulating surfaces The articulating surfaces are the sternal end of the clavicle and the clavicular notch of the sternum, together with the adjacent superior surface of the first costal cartilage (Fig. 48.14). The larger clavicular articular surface is covered by fibrocartilage, which is thicker than the fibrocartilaginous lamina on the sternum. The joint is convex vertically but slightly concave anteroposteriorly, and is therefore sellar; the clavicular notch of the sternum is reciprocally curved but the two surfaces are not fully congruent. An articular disc completely divides the joint.

Fibrous capsule The capsule is thickened anteriorly and posteriorly, but superiorly and especially inferiorly, it is little more than loose areolar tissue.

Ligaments There are two sets of associated ligaments. The intrinsic ligaments are the anterior and posterior sternoclavicular ligaments; the extrinsic ligaments are the midline interclavicular ligament and the costoclavicular ligaments on each side.

Anterior sternoclavicular ligament The anterior sternoclavicular ligament is broad and attached above to the anterosuperior aspect of the sternal end of the clavicle. It passes inferomedially to the upper anterior aspect of the manubrium, spreading on to the first costal cartilage.

Posterior sternoclavicular ligament The posterior sternoclavicular ligament is a weaker band posterior to the joint. It descends inferomedially from the posterior aspect of the sternal end of the clavicle to the posterior aspect of the upper manubrium.

Interclavicular ligament The interclavicular ligament is continuous above with the deep cervical fascia. It unites the superior aspect of the
sternal ends of both clavicles; some fibres are attached to the superior manubrial margin.

Costoclavicular ligament The costoclavicular ligament is like an inverted cone, but short and flattened. It has anterior and posterior laminae that are attached to the upper surface of the first rib and costal cartilage, and ascends to the margins of an impression on the inferior clavicular surface at its medial end. Fibres of the anterior lamina ascend laterally and those of the posterior lamina (which are shorter) ascend medially (see Fig. 48.14). They fuse laterally and are closely related to the attachments of subclavius, particularly the tendon of origin; it can be hard to distinguish the lateral border of the ligament from the tendon. The ligament merges medially with the capsule. It can be ossified in older adults, particularly females. A few deep fibres of pectoralis major attach to the external surface of the ligament, adjacent first rib, first costal cartilage and manubrium sterni.

Articular disc The fibrocartilaginous articular disc divides the cavity of the joint into two compartments between the sternal and clavicular surfaces. It is attached above to the posterosuperior border of the articular surface of the clavicle, below to the first costal cartilage near its sternal junction, and by the rest of its circumference to the capsule, and therefore adapts to the contour of the clavicular surface. It is thicker peripherally, especially superoposteriorly and inferomedially; the central part of the disc may be perforated in later life.

Vascular supply The sternoclavicular joint is supplied by branches from the internal thoracic and suprascapular arteries.

Innervation The sternoclavicular joint is innervated superficially by branches from the medial supraclavicular nerve and deeply by the nerve to subclavius.

Factors maintaining stability There is almost no bony articular congruence at the sternoclavicular joint. However, the strength of its associated ligaments and the articular disc produce durable stability. These factors make sternoclavicular joint dislocation rare; fracture of the clavicular shaft is far more common for the same force directed along the clavicle. (See Sewell et al (2013)) for a review of the mechanisms and treatment of sternoclavicular instability.)

Movements The capsule around the clavicular attachment is more lax. Movements between the clavicle and the disc are more extensive than those between the disc and sternum. The sellar shape of the articular surfaces permits translation or gliding in approximately anteroposterior and vertical planes, with rotation about the long axis of the clavicle. Close-packing coincides with maximum posterior rotation associated with full scapular rotation, i.e. in high elevation of the arm above shoulder height.

In this position, the tension developed in the anterior sternoclavicular ligament and anterior component of the costoclavicular ligament causes the clavicle to undergo an obligatory posterior translation. It also acts as a check-rein on further rotation and displacement, so protecting the relatively weaker posterior sternoclavicular ligament from overload. Although the function of subclavius is unknown, a consideration of the simple biomechanics of forceful elevation of the arm above shoulder height suggests that this muscle has an important role in decelerating the elevating arm, so protecting the medial 'clavicular-costal-sternal' ligamentous structures from recurrent stretching that is likely to accelerate degeneration and injury. The common innervation of the sternoclavicular joint (the deep afferent-mechanoceptor system) and subclavius suggests an intimate functional relationship between these structures. In daily activities, in which the upper limb is used largely in front of the trunk, the sternal end of the clavicle glides on the sternal facet about the fulcrum provided by the costoclavicular ligament. All joints in which polyaxial gliding occurs, producing shear forces (rotation with translation), possess either intra-articular synovial bursae or intraarticular fibrocartilaginous discs; the latter degenerate over time, producing characteristic exophytic degenerative arthritis. In this context, it is interesting that degeneration of the sternoclavicular joint and ossification of the costoclavicular ligaments (claviculocostal synostosis) are almost exclusively found in females above the age of 50 years.

## ACROMIOCLAVICULAR JOINT

The acromioclavicular joint is a synovial plane joint and has an intraarticular fibrocartilaginous disc.

Articulating surfaces The articulating surfaces are between the acromial end of the clavicle and the medial acromial margin (Fig. 48.15). The joint is approximately plane but either surface may be slightly convex, the other being reciprocally concave; both surfaces are covered by fibrocartilage. The clavicular surface is a narrow, oval area that faces laterally or inferolaterally and overlaps a corresponding facet on the medial acromial border. The long axis is anteroposterior (Colegate-Stone et al 2010).

Fibrous capsule The capsule completely surrounds the articular margins. It is lined by synovial membrane and is strengthened superi-
orly by the acromioclavicular ligament and the fibres of the attachment of trapezius, posteriorly by the fibres of attachment of trapezius, and anteriorly by the fibres of attachment of deltoid. The inferior capsule is often incomplete in later life.

Ligaments There are two sets of associated ligaments. The intrinsic ligaments are the acromioclavicular ligaments; the extrinsic ligaments are the coracoclavicular ligaments.

Acromioclavicular ligaments The superior acromioclavicular ligament is quadrilateral. It extends between the upper aspects of the lateral end of the clavicle and the adjoining acromion. Its parallel fibres interlace with the aponeuroses of trapezius and deltoid. The inferior acromioclavicular ligament is thin, and often perforated in later life; it extends between the inferior surface of the lateral end of the clavicle and the adjoining acromion. It provides attachment for the intra-articular disc when this is present and complete.

Coracoclavicular ligament The coracoclavicular ligament connects the clavicle and the coracoid process of the scapula (Fig. 48.16). Though separate from the acromioclavicular joint, it is an efficient and important accessory ligament because it helps to maintain the apposition of the acromion to the clavicle, and so contributes to the suspension mechanism of the scapula (see above). The trapezoid and conoid parts of the ligament, usually separated by fat or, frequently, by a bursa, connect the posterior (more horizontal) part of the coracoid process and the lateral end of the subclavian groove of the clavicle: these adjacent areas may even be covered by cartilage to form a coracoclavicular joint.

The trapezoid part is anterolateral and is broad, thin and quadrilateral, ascending slightly from the upper coracoid surface to the trapezoid line on the inferior clavicular surface. Its anterior border is free, and its posterior border is joined to the conoid part, forming an angle that projects backwards and upwards. Quadrilateral ligaments twist when the adjoined bones rotate with respect to each other, and as they twist, the apposed surfaces must approach each other; such ligaments, therefore, act to oppose excessive rotation of the adjoining bones.

The conoid part is posteromedial and is a dense, almost vertical, triangular or conical band. Its broader base is attached superiorly to the conoid tubercle of the clavicle; its inferior apex is attached posteromedially to the dorsal surface and root of the coracoid process immediately

Fig. 48.16 A, The ligaments associated with the left shoulder, anterior aspect. B, A deeper view, showing the subscapularis bursa.
lateral to the scapular notch, and is contiguous with the superior transverse scapular ligament. Conical ligaments are constructed to oppose distraction; the conoid ligament, therefore, helps to keep the coracoid and the clavicle closely apposed. If the trapezoid ligament is disrupted, the conoid ligament forms a vertical fulcrum around which the coracoid can rotate under the clavicle, particularly if the acromioclavicular ligaments are also disrupted. This is the anatomical basis for the spectrum of acromioclavicular joint dislocation.

Articular disc The articular disc is a complete fibrocartilaginous partition in juvenile and adolescent joints, creating medial and lateral compartments; over time, the centre of the disc perforates, and in adults (more than 20 years old), it is often incomplete inferiorly.

Vascular supply The acromioclavicular joint receives its arterial supply from branches of the suprascapular and thoraco-acromial arteries.

Innervation The acromioclavicular joint is innervated by branches from the suprascapular and lateral pectoral nerves. It has been suggested that the density of nociceptors is greatest in the inferior acromioclavicular ligament and capsule.

Factors maintaining stability The acromioclavicular ligaments provide the greatest resistance to anteroposterior displacement of the acromioclavicular joint, while the coracoclavicular ligaments resist rotation and vertical translation of the joint.

Movements Movements at the joint complement those of the sternoclavicular joint (Figs 48.17-48.20). The sternal end of the clavicle is robustly supported by strong ligaments, and a similar, but less robust, arrangement of ligaments suspends the scapula from the lateral end of the bone. The motion of the acromioclavicular joint is limited by its small surface area and the articular capsule.

## MOVEMENTS AT THE SCAPULOTHORACIC ‘JOINT’

are known collectively as the scapulothoracic articulation. Scapular movements on the thoracic wall are facilitated by loose areolar tissue between subscapularis and serratus anterior, and between serratus anterior and the chest wall; the latter gliding plane is the scapulothoracic joint. It is a virtual space. There may be a bursa between the superior angle of the scapula and the dorsal aspect of the second rib.

The following account should be read together with the description of movements of the glenohumeral joint. It is important to keep in mind the fact that the purpose of scapular motion is the appropriate positioning of the glenohumeral joint in space, and the purpose of scapular stability is to provide a foundation for glenohumeral motion.

## Elevation and depression

Scapular elevation, as in 'shrugging the shoulders', is generated by trapezius acting on the lateral clavicle, acromion and spine of the scapula. If levator scapulae is less active, the scapula rotates laterally (i.e. the inferior angle protracts around the chest wall), with dorsal rotation at the acromioclavicular joint; this is resisted by the rhomboid muscles and controlled by pectoralis minor. If levator scapulae is more active, then the scapula ascends with less rotation. The sternal end of the clavicle, rotating about an anteroposterior axis through the bone above the medial attachment of the costoclavicular ligament, slides down over the articular disc. This is resisted by subclavius and by tension in the costoclavicular ligament and sternoclavicular joint capsule. In scapular depression, ventral rotation occurs at the acromioclavicular joint, and the clavicle slides up on the disc at the sternoclavicular joint. The movements are checked by the cervical fibres of trapezius, the interclavicular and superior sternoclavicular ligaments and the articular disc. Usually, gravity alone is sufficient; when necessary, the lowest part of serratus anterior and pectoralis minor are active depressors.

## Protraction and retraction

Protraction (forward movement) round the thoracic wall occurs in pushing, thrusting and reaching movements, usually with some lateral rotation. The acromion advances over the clavicular facet to the limit, and the shoulder is simultaneously advanced by forward movement of the lateral end of the clavicle and posterior translation of its sternal end

The three long nerves innervating the scapulothoracic 'joint', i.e. accessory, long thoracic and dorsal scapular, innervate the three major muscle groups of scapulothoracic motion, namely: trapezius, serratus anterior and the medial scapular stabilizing muscles (levator scapulae and the rhomboids).

Fig．48．17 Clavicular motion about the medial fulcrum of the sternoclavicular joint．The lateral（acromial）end of the clavicle describes an asymmetric conical path during motion of the upper extremity．The maximal range of rotation of the clavicle（subtended by the sternoclavicular joint）is $30^{\circ}$ ；the maximal range of rotation of the scapula（sternoclavicular and acromioclavicular joints combined）is about $60^{\circ}$ with respect to the sternum．The scapula is suspended from the distal clavicle at the acromioclavicular joint，which can be considered as the true joint（the cavity bounded by the acromioclavicular capsule and ligaments）；it is also part of an extended articulation that comprises the true joint and the coracoclavicular suspensory ligaments．Arguably，the ligaments might be better defined as the claviculocoracoid ligaments，to acknowledge their role as the spiroid fulcrum around which the body of the scapula，and therefore the glenoid fossa，rotate during protraction and retraction of the scapula．The action of subclavius is to resist upward displacement of the distal clavicle，or to decelerate the clavicle moving into elevation．Linear measurements are given in centimetres．

Fig．48．18 The distal clavicle is moved by trapezius，which has an extensive attachment along the spine of the scapula and the medial aspect of the distal third of the clavicle．The antagonist of trapezial power is pectoralis minor， which，rarely，has an extension or slip of tendon that joins the coraco－acromial ligament．The latter acts as a tension band between the＇outriggers＇of the acromion and coracoid．If surgically divided， the cut surfaces of the coraco－acromial ligament cannot be readily reapposed，suggesting a mechanical role in pre－tensioning the acromion and coracoid against the pull of trapezius． Shortening or tightness of pectoralis minor will create fixed protraction of the scapula，which then rotates ventrally around the chest wall．As a consequence，the acromion tilts and the space between it and the cranial surface of the rotator cuff below（the subacromial space）diminishes， creating the conditions in which forceful coaptation of the apposed surface of the rotator cuff and the coraco－acromial ligament may occur．This is the painful condition of＇impingement＇．
over the sternal facet，carrying the disc with it．Pectoralis major，together with the anterior sternoclavicular ligament and posterior lamina of the costoclavicular ligament，check backward slide of the sternal end．Ser－ ratus anterior and pectoralis minor are prime movers and maintain continuous apposition of the scapula，especially its medial border，in smooth gliding on the thoracic wall，with the rhomboid muscles con－ trolling the rate and range of motion．The upper part of latissimus dorsi
also acts like a strap across the inferior scapular angle in protraction and lateral rotation．

In scapular retraction，i．e．bracing back the shoulders，these move－ ments are reversed and checked at the sternoclavicular joint by the posterior sternoclavicular ligament and anterior lamina of the costo－ clavicular ligament．Trapezius（horizontal and lower fibres）and the rhomboids are prime movers．

Fig. 48.20 The closely related humeral attachments of pectoralis major and deltoid (between one-third and one-half of the way down the shaft of the bone) enable the pectoralis major-deltoid muscular envelope to move the elbow, forearm and hand in space, using the shoulder as a fulcrum for effective delivery of power through a wide range of motion from in front of the trunk to behind. The relative coarseness of these muscles underlies their ability to produce great torque in upper-extremity motion; motion generated by these muscles is 'fine-tuned' by the rotator cuff working concordantly with the outer envelope (each segment or part of the rotator cuff can be said to have an equivalent segment or part in the outer envelope of muscles; this pattern is considered as a force-couple generating stable motion of the humerus on the scapula at the glenoid).

## Lateral and medial rotation

Lateral (upward) rotation of the scapula increases the range of humeral elevation by turning the glenoid cavity to face almost directly up, e.g. when raising the arm above the head. This movement is always associated with humeral elevation and rotation at the glenohumeral joint, and with protraction of the scapula. Scapular rotation requires movement at both sternoclavicular and acromioclavicular joints; the sternoclavicular joint permits elevation of the lateral end of the clavicle, a movement that is almost complete when the arm is abducted to $90^{\circ}$. The acromioclavicular joint moves in the first $30^{\circ}$ of abduction, when the conoid ligament becomes taut, and is subsequently accompanied by clavicular rotation at the sternoclavicular joint around the longitudinal axis of the bone. The medial end is depressed further as the lateral end continues to rise. Some acromioclavicular movement also occurs in the final stages of humeral abduction. Trapezius (cervical fibres) and serratus anterior (the lower part) are prime movers, with the rhomboids providing resistance to motion.

Medial (downward) rotation is usually effected by gravity; gradual active lengthening of trapezius and serratus anterior is sufficient to control it. When more force is needed, levator scapulae, the rhomboids and, in the initial stages, pectoralis minor are prime movers in returning the scapula to a position of rest.

## GLENOHUMERAL (SHOULDER) JOINT

The glenohumeral joint is a synovial multiaxial spheroidal joint between the roughly hemispherical head of the humerus and the shallow glenoid fossa of the scapula (Fig. 48.21). It is the most mobile joint in the body and the most frequently dislocated. Its anatomy is a compromise between the requirements for motion and stability; both depend on the surrounding muscular and soft tissue envelope more than on the shape and surface area of the articulating surfaces.

The humeral head is held to the concave glenoid fossa by the compressive action of the rotator cuff muscles; the stabilizing mechanism of the glenohumeral joint is one of concavity compression. The rotator cuff muscles are attached to the proximal humerus through a musculotendinous envelope (see below), the deep surface of which fuses with the lateral part of the articular fibrous capsule. The humeral head is then contained in a spherical space bounded medially by the glenoid fossa and elsewhere by the deep surface of the fibrous capsule, a form of osseofibrous acetabulum. The walls of this 'acetabulum' (i.e. the rotator cuff muscles and tendons) are contained within a roughly spherical space bounded by the coracoid anteriorly; the coraco-acromial ligament anterosuperiorly; the acromion and spine of the scapula posteriorly, posterosuperiorly and posterolaterally; and the deep surface of deltoid anterolaterally and laterally. This arrangement creates two gliding planes, one internal (the glenohumeral articular gliding plane) and one external (the subcoracoid-subacromial-subdeltoid plane); the latter is continuous with the plane under the scapula (the scapulothoracic gliding plane). Gliding is facilitated by the synovial lined cavities of the glenohumeral joint and the subcoracoid, subacromial and subdeltoid bursae, which are nearly always contiguous. Infection, inflammation and injury commonly cause adhesions and fibrosis (with subsequent contracture) in these planes; restriction of motion follows, specific to the site and extent of adhesion. The surfaces of both gliding planes are extensive and fibrosis is consequently very restricting.

Articulating surfaces The articular surfaces are reciprocally curved and are correctly termed ovoids. The surface area of the humeral convexity is approximately four times that of the glenoid concavity, which means that only a small portion of the head opposes the glenoid in any position (Fig. 48.22). The radius of curvature of the glenoid fossa in the coronal plane is greater than that of the humeral head, and is deepened by a fibrocartilaginous rim, the glenoid labrum (see Fig. 48.15; Fig. 48.23). Both articular surfaces are covered by hyaline cartilage, thickest centrally and thinner peripherally over the humerus, and vice versa over the glenoid cavity. In most positions, their curvatures are not fully congruent and the joint is loose-packed; close-packing (full congruence) is probably only reached with the humerus abducted and laterally rotated.

Glenoid labrum The glenoid labrum is a fibrocartilaginous rim around the glenoid fossa. Anteriorly, it is triangular in section; posteriorly, it is more ovoid; while inferiorly, it may be flattened and almost deficient. It varies in size and thickness. The attachment to the edge of the glenoid fossa is secure superiorly where it blends with the anterior and posterior fasciculi of the long tendon of biceps (Vangsness et al 1994), less secure posteriorly, but relatively more secure anteroinferiorly (Bankart 1923). There may be an aperture between the free deep edge of the labrum and the anterior glenoid rim above the midpoint of the fossa. In slightly less than one-fifth of normal shoulders, there may be no anterior labrum, in which case its place taken by a cord-like middle glenohumeral ligament. The labrum may be hypoplastic or absent in patients with collagen deficiency but with normal shoulder function (hypermobility syndrome); these shoulders are not necessarily unstable. The labrum deepens the glenoid cavity and so may assist in stabilizing the humeral head on the fossa, although the mechanism of this function remains uncertain. It may protect the bone and probably assists lubrication.

Fibrous capsule A fibrous capsule envelops the joint (see Figs 48.16, 48.22). It is attached medially to the glenoid neck at a variable distance from the glenoid labrum, so forming recesses anterior and posterior to the scapular neck; it includes the supraglenoid tubercle, to which the long head of biceps attaches, and which is therefore intracapsular. Laterally, it is attached to the anatomical neck of the humerus, i.e. near the articular margin, except inferomedially, where it descends more than 1 cm on the calcar humerale. The fibres of the capsule are orientated in a spiral fashion, so that, in elevation of the arm, the capsule tightens, so bringing the articular surfaces into closer apposition and contributing to the concavity compression. In some individuals, a deeper band of fibres orientated in a reverse obliquity to the main capsular fibres passes from the region of the lesser tubercle to the lower part of the anterior rim of the glenoid fossa. This is the anterior oblique band; its contribution to stability is uncertain.

The lateral part of the external surface of the fibrous capsule is blended with the tendons of supraspinatus (superiorly), infraspinatus and teres minor (posteriorly), subscapularis (anteriorly) and by the tendon of the long head of triceps at the infraglenoid tubercle (inferiorly). The rotator interval is a medially based, triangular area of uncovered capsule between the superior edge of subscapularis and the anterior edge of supraspinatus, with the base of the coracoid as the medial boundary of the interval. It is reinforced by the coracohumeral ligament, the superior glenohumeral ligament, and fibres from the supraspinatus tendon laterally. The axillary nerve and posterior circumflex

humeral vessels are separated from the inferior capsule by the inferior border of subscapularis. The capsule is least supported inferiorly, and subjected to the greatest strain in full abduction, when it is stretched tightly across the humeral head. It is supported in this position by the proximal part of the long head of triceps and the broad bulk of teres major.

There are two openings in the capsule: below the coracoid process, connecting the joint cavity to a bursa that may envelop the upper border of the tendon of subscapularis (anteriorly); and between the humeral tubercles, allowing passage of the long tendon of biceps and its synovial sheath.

Ligaments The ligaments associated with the glenohumeral joint are the glenohumeral (superior, middle and inferior), coracohumeral and transverse humeral. A ligament only restricts a specific motion of a joint when discrete parts of the ligament become tight; this only occurs at the limits of a specific motion of the joint when the ligament acts as a 'check-rein'. For movements that lie within the limit of motion, ligaments have no mechanical role. Mechanoreceptors and nociceptors are clustered at each end of the ligaments, more on the glenoid side than the humeral side (Halata and Baumann 2008). The capsule, ligaments

Fig. 48.24 A sagittal magnetic resonance arthrogram image following distension of the glenohumeral joint by intra-articular contrast injection in a 28 -year-old male. Note the clearly outlined glenohumeral ligaments.
and labrum contain the deep afferent innervation of the glenohumeral joint and therefore contribute to stability of the joint through facilitation of the rotator cuff activity within the normal range of human shoulder motion.

Glenohumeral ligaments Three glenohumeral ligaments, only visible from within the joint, reinforce the capsule anteriorly and inferiorly (Fig. 48.24). The superior glenohumeral ligament passes from the supraglenoid tubercle, just anterior to the origin of the long head of biceps, to the humerus at the fovea capitis, near the proximal tip of the lesser tubercle on the medial ridge of the intertubercular sulcus. It forms an anterior cover around the long head of biceps and is part of the rotator interval. Together with the coracohumeral ligament, it is an important stabilizer in the inferior direction, helping to keep the humeral head suspended (the coracohumeral ligament is more robust than the superior glenohumeral ligament).

The middle glenohumeral ligament arises from a wide attachment below the superior glenohumeral ligament, along the anterior glenoid margin as far as the inferior third of the rim, and passes obliquely inferolaterally, enlarging as it does so, to attach to the lesser tubercle deep to the tendon of subscapularis, with which it blends. The width and thickness of this ligament may be as much as 2 cm and 4 mm , respectively. It provides anterior stability between $45^{\circ}$ and $60^{\circ}$ of abduction in the scapular plane. However, $30 \%$ of individuals may not have a middle glenohumeral ligament; these individuals are not more likely to have unstable shoulders. It may be thickened and cord-like in the Buford complex (a congenital glenoidal labrum variant), again with no apparent disadvantage for stability.

The thicker and longer inferior glenohumeral ligament complex is a hammock-like structure with anchor points on the anterior and posterior sides of the glenoid. It arises from the anterior, middle and posterior margins of the glenoid labrum, below the epiphysial line, and passes anteroinferiorly to the inferior and medial aspects of the neck of the humerus. The anterior, superior edge of the inferior ligament is thickened as the anterior band; there is an equivalent, but not so robust, thickening of the posterior capsule: the posterior band. Between the two bands is a region of thin capsule known as the axillary pouch. (For further details, consult Burkart and Debski (2002); Di Giacomo et al (2008).)

Coracohumeral ligament The coracohumeral ligament is attached to the dorsolateral base of the coracoid process and extends as two bands,
which blend with the capsule, to the greater and lesser tubercles (see Fig. 48.16). Portions of the coracohumeral ligament form a tunnel for the biceps tendon on the anterior side of the joint. The rotator interval is reinforced by the coracohumeral ligament. It also blends inferiorly with the superior glenohumeral ligament. The ligament tightens in external rotation of the glenohumeral joint.

Transverse humeral ligament The transverse humeral ligament is a broad band that passes between the humeral tubercles, and is attached superior to the epiphysial line (see Fig. 48.16). It converts the intertubercular sulcus into a canal, and acts as a retinaculum for the long tendon of biceps.

Synovial membrane The synovial membrane lines the capsule and covers parts of the anatomical neck. The long tendon of biceps brachii traverses the joint in a synovial sheath that continues into the intertubercular sulcus as far as the surgical neck of the humerus (see Figs 48.16, 48.22A). The intra-articular bicipital sheath may be connected to the articular surface of the superior capsule above by a mesotenon, which may be incomplete, presenting as one or several strands. This arrangement can only be the case if the biceps tendon was originally an extra-articular structure and invaginated, with its synovial sheath, into the glenohumeral joint as the upper limb rotated into external rotation relative to the trunk during development.

Bursae Many bursae adjoin the shoulder joint (see Fig. 48.16). They are usually found between the tendon of subscapularis and the capsule, communicating with the joint between the superior and middle glenohumeral ligaments; on the superior acromial aspect; between the coracoid process and capsule; between teres major and the long head of triceps; and anterior and posterior to the tendon of latissimus dorsi. The subacromial bursa, between deltoid and the capsule, does not communicate with the joint cavity but is prolonged under the acromion and coraco-acromial ligament, and between them and supraspinatus: it appears to be attached, together with the subdeltoid fascia, to the acromion. Bursae sometimes occur behind coracobrachialis and between the tendon of infraspinatus and the capsule, occasionally opening into the joint.

Vascular supply The glenohumeral joint is supplied by branches from the anterior and posterior circumflex humeral, suprascapular and circumflex scapular vessels.

Innervation The glenohumeral joint is innervated mainly from the posterior cord of the brachial plexus through the subscapular nerves. The capsule is supplied by the suprascapular nerve (posterior and superior parts), axillary nerve (anteroinferior) and the lateral pectoral nerve (anterosuperior, including the rotator interval capsule).

Factors maintaining stability The articulation between the relatively large humeral head and the shallow glenoid fossa allows a wide range of movement but is a challenge for the stability of the joint.

## MOVEMENTS AT THE GLENOHUMERAL JOINT

The shoulder is capable of any combination of swing and spin over a range far wider than that of any other joint in the body. Flexionextension, abduction-adduction, and medial (internal) and lateral (external) rotation all occur at the shoulder. A combination of all of these results in the motion of circumduction, which is not a useful movement to record in clinical practice. Although the majority of the movement of the shoulder occurs at the glenohumeral joint, the scapulothoracic articulation contributes to overall shoulder motion in all directions, including lateral rotation.

Muscles producing movements The muscles that produce movements at the glenohumeral joint are principally the scapulohumeral and thoracobrachial muscles: deltoid, pectoralis major and latissimus dorsi, assisted by coracobrachialis. The translating effect of these muscles on the shoulder joint is counteracted by the rotator cuff, a group of short muscles (subscapularis, supraspinatus, infraspinatus and teres minor), including teres major, that are attached closer to the joint, and that centre the head of the humerus in the glenoid fossa through the entire range of motion.

Flexion Flexion is carried out by pectoralis major (clavicular part), deltoid (anterior fibres) and coracobrachialis, assisted by biceps. The

In anatomical analysis of shoulder movements，it is usual to relate humeral movement to the scapula，rather than to conventional ana－ tomical planes．However，in clinical practice，movements are related to the conventional anatomical planes．When the arm hangs at rest，the glenoid fossa faces almost equally forwards and laterally，and the humeral capitular and scapular（topographical）axes correspond， although the humerus，relative to the anatomical position，is medially rotated．With the humerus in the anatomical position，i．e．with the inter－epicondylar axis in the frontal plane，the humeral head axis is posteriorly directed，in line with the axis of the scapula．

Using the anatomical description，flexion carries the arm antero－ medially on an axis through the humeral head orthogonal to the glenoid fossa at its centre．Abduction and adduction occur in a vertical plane orthogonal to that of flexion－extension and the axis is horizontal， through the humeral head and parallel with the glenoid plane．Pure abduction raises the arm anterolaterally in the plane of the scapula． However，when referred to the trunk，flexion and extension occur in the paramedian plane，and abduction and adduction occur in the coronal plane．In this sense，raising the arm vertically from flexion or raising it from abduction are both accompanied by humeral rotation in opposite directions．Whether＇scapular＇or any other plane of abduction is described，these are selections from an infinite series．In scapular abduc－ tion，points on the humeral surface pursue vertical cords，but in rota－ tion，they are horizontal．In＇pure＇flexion－extension，in a plane orthogonal to the scapula，the axis of movement and the notional ＇mechanical axis＇are regarded as projected from the centre of the glenoid cavity．

Glenohumeral abduction is about $120^{\circ}$ or more（see p．831；see Fig．48．21）．Abduction may reach $180^{\circ}$ after thoracoscapular arthrod－ esis for facioscapulohumeral dystrophy（Copeland and Howard 1978）． Abduction is restricted to about $45^{\circ}$ after glenohumeral arthrodesis． Some $60^{\circ}$ of further abduction occurs at the sterno－and acromiocla－ vicular articulations，and contralateral vertebral flexion also aids in bringing the arm to the vertical．During active elevation，movements at the glenohumeral and acromioclavicular joints are simultaneous， except in the initial few degrees，when most，often all，movement is glenohumeral．For every $15^{\circ}$ of elevation，glenohumeral movement is
said to be $10^{\circ}$ and scapular movement $5^{\circ}$ ，but this ratio is not linear throughout the range of motion．During the initial stages of abduction， the entire rotator cuff counteracts the strong upward component of the pull of deltoid，which would otherwise cause the humeral head to slide up the glenoid surface；the additive turning moments exerted by the combined deltoid and supraspinatus force－couple may then abduct the arm．Deltoid also acts with the other elements of the rotator cuff， according to the position of the arm in space，to maintain rotation， flexion and extension of the arm．It is important to consider the syner－ gistic relation between the rotator cuff and deltoid as a continuum in which the rotator cuff muscles act to provide a stable base on which deltoid can work effectively，whatever the position of the arm．

In flexion，the humerus swings at right angles to the scapular plane， and scapular rotation cannot increase the elevation $\left(120^{\circ}\right)$ that is obtainable in full flexion．If the fully flexed humerus is also abducted， elevation increases pro rata until，when the humerus reaches the scapu－ lar plane，i．e．when true abduction is reached， $180^{\circ}$ of elevation becomes possible．In medial or lateral rotation，the humerus revolves about one－ quarter of a circle around a vertical axis；the range is greatest when the arm is pendant，and least when it is vertical．When the rotational range at the glenohumeral joint is assessed，the forearm should be flexed to a right angle at the elbow in order to prevent the effects of superadded pronation or supination in the pendant limb．In circumduction，which is a succession of the foregoing movements，the distal end of the humerus describes the base of a cone with its apex at the humeral head． This glenohumeral movement may be greatly increased by scapular movements，e．g．in acts of slinging objects with force．

The peculiar relation of the long head of biceps brachii to the shoul－ der joint may serve several purposes．By its connection with both the shoulder and elbow，the muscle harmonizes their actions as an elastic connection during all upper limb movements．It helps to prevent the humeral head impinging on the acromion when deltoid contracts and also to steady it in movements of the arm．In paralysis or absence（i．e． in rotator cuff tendon tears）of supraspinatus，the long head of biceps may also help initiate abduction of the arm，particularly when the humerus is laterally rotated．
sternocostal part of pectoralis major is a major force in flexion forwards to the coronal plane from full extension.

Extension Extension is carried out by deltoid (posterior fibres) and teres major, from the dependant position. When the fully flexed arm is extended against resistance, latissimus dorsi and the sternocostal part of pectoralis major act powerfully until the arm reaches the coronal plane.

Abduction Abduction is carried out by supraspinatus and deltoid. The effect of deltoid is mainly upward and, unless opposed, this would displace the humerus upwards. Subscapularis, supraspinatus, infraspinatus and teres minor exert a centralizing force and so apply a balancing force; together with deltoid, they constitute a 'couple' to produce abduction in the scapular plane.

Medial rotation Medial rotation is carried out by pectoralis major, deltoid (anterior fibres), latissimus dorsi, teres major and, with the arm pendant, subscapularis.

Lateral rotation Lateral rotation is carried out by infraspinatus, deltoid (posterior fibres) and teres minor. Lateral rotation is important for clearance of the greater tubercle and its associated tissues as it passes under the coraco-acromial arch during elevation of the arm.

Glenohumeral joint dislocation The glenohumeral joint is the most frequently dislocated joint in the body. The vast majority of dislocations are anterior, and occur when the forearm is forced backwards into greater lateral (external) rotation when it is in abduction, lateral rotation and extension. A dislocated shoulder loses its normal contour because the humeral head is displaced anterior to the glenoid rim and, sometimes, under the coracoid, which means that the acromion process, rather than the greater tubercle, becomes the most lateral bony structure, affording the shoulder a 'squared-off' appearance.

## MUSCLES

The shoulder girdle and shoulder joint musculature are arranged in layered, functional groups (Table 48.1). The muscles of the shoulder girdle may suspend or move the scapula; these functions are interdependent. The muscles of the shoulder joint may stabilize the joint, move the arm on the stable shoulder joint, or coordinate shoulder and elbow movement; these functions are also interdependent. The closer a muscle is to the centre of motion of the joint on which it acts, the greater its effect on the stability of that joint at rest and during motion. The farther away from the centre of motion, the greater the effect of the resultant muscular vector on translation of the joint surfaces. As an

Table 48.1 The relationship between functional muscle grouping and actions of the pectoral girdle*

| Functional group | Specific muscles | Action |
| :---: | :---: | :---: |
| Occipitospinoscapular | Trapezius | Scapular suspension |
| Thoracoscapular | Pectoralis minor | Position and motion of the |
| Spinoclavicular | Trapezius | acromioclavicular joint in relation to the thorax and (neur)axis |
| Thoracoclavicular | Subclavius | Deceleration of the lateral clavicle during motion |
| Thoracoscapular (medial border) | Levator scapulae | Scapular motion |
|  | Rhomboid minor | Position and motion of the glenohumeral joint in relation to the thorax and (neur)axis |
|  | Rhomboid major |  |
|  | Serratus anterior |  |
|  | Serratus posterior superior |  |
|  | Serratus posterior inferior |  |
| Thoracohumeral | Pectoralis major | Thoracobrachial motion Position of the arm |
|  | Latissimus dorsi |  |
| Scapulohumeral | Deltoid |  |
|  | Coracobrachialis |  |
|  | Biceps brachii (short head) |  |
|  | Teres minor | Concavity compression of the glenohumeral joint |
|  | Infraspinatus |  |
|  | Supraspinatus |  |
|  | Subscapularis |  |
|  | Teres major |  |
|  | Triceps brachii (long head) | Coordination of shoulder and elbow |
|  | Biceps brachii (long head) | motion |

*As a principle, a muscle will act on a motion segment to alter the position of the distal extent of that segment in space. As an example, deltoid acts on the shoulder joint but its effect is to move the distal extent of the humerus, i.e. the elbow.
example, both subscapularis and pectoralis major generate medial rotation of the glenohumeral joint; subscapularis contributes to concavity compression at the glenohumeral joint (i.e. stability), while pectoralis major causes anterior displacement into flexion and adduction in the absence of subscapularis; when these muscles are working synergistically, the arm is both stabilized at the glenohumeral joint, and flexed and adducted.

The clinical examination of the shoulder girdle muscles is demonstrated in Video 46.1.

## MUSCLES OF SCAPULAR SUSPENSION

Trapezius acts on the spine of the scapula, acromion and lateral clavicle to rotate the acromioclavicular joint upwards and dorsally; movement is guided and limited by the length and shape of the clavicle. Pectoralis minor acts to control the position of the coracoid as trapezius acts on the scapula, while subclavius acts to control clavicular elevation and rotation. These muscles act on the processes of the scapula, while the coraco-acromial ligament acts as a tension band between the processes. Disruption of the continuity of this arrangement (fracture of the clavicle or coracoid, or dislocation of the acromioclavicular joint) will have a profound effect on scapular suspension.

## Trapezius

Trapezius is derived from head paraxial mesenchyme with neural crest connective tissue, rather than from the dermomyotomes of lower somites, and is therefore unique among shoulder girdle muscles. It is attached to the spine of the scapula and acromion, segments of the scapula for which development is encoded by a single gene (804.e1).

Attachments Trapezius is a flat, triangular muscle that extends over the back of the neck and upper thorax (see Fig. 53.16). The paired trapezius muscles form a diamond shape, from which the name is derived. On either side, the muscle is attached to the medial third of the superior nuchal line, external occipital protuberance, ligamentum nuchae, and apices of the spinous processes and their supraspinous ligaments from C7 to T12. The occipital attachment is by a fibrous lamina, which is also adherent to the skin. The spinal attachment is by a broad triangular aponeurosis from the sixth cervical to the third thoracic vertebrae, and by short tendinous fibres below this.

Superior fibres descend, inferior fibres ascend, and the fibres between them are directed horizontally; all converge laterally on the scapula. The superior fibres are attached to the posterior border of the lateral third of the clavicle; the middle fibres to the medial acromial margin and superior lip of the crest of the scapular spine; and the inferior fibres pass into an aponeurosis that glides over a smooth triangular surface at the medial end of the scapular spine and is attached to a tubercle at its lateral apex.

Variants The clavicular attachment of trapezius varies in extent, sometimes reaching mid-clavicle, and occasionally blending with sternocleidomastoid. The vertebral attachment sometimes stops at the eighth thoracic spine. The occipital attachment may be absent. Cervical and dorsal parts are occasionally separate. The inferior part may be hypoplastic or absent.

Vascular supply The upper third of trapezius is supplied by a transverse muscular branch that arises from the occipital artery at the level of the mastoid process. It enters the muscle on its deep surface and gives off several musculocutaneous perforators to the overlying skin. The middle portion of trapezius, together with an area of overlying skin, is supplied by the superficial cervical artery or by a superficial branch of the transverse cervical artery, via musculocutaneous perforators. The lower third of trapezius is supplied by a muscular branch from the dorsal scapular artery, passing medial to the medial border of the scapula. It reaches the deep surface of the muscle either by piercing the rhomboids or by passing between rhomboids major and minor at the level of the base of the spine of the scapula. It anastomoses with the medial and lateral perforating branches of the posterior intercostal arteries.

Innervation Trapezius is innervated by the accessory nerve (see Chs 29 and 46 for more details). Sensory (proprioceptive) branches are derived from the ventral rami of C3 and C4.

Actions Trapezius cooperates with other muscles in steadying the scapula, controlling it during movements of the arm and maintaining the level and poise of the shoulder. Electromyographic activity is

The axillary nerve and vessels may be injured during dislocation or, more commonly, during inexpert attempts at relocation, particularly in older patients. This can lead to an inability to maintain abduction of the shoulder as a result of paralysis of deltoid. If, after relocation of the joint, the patient cannot initiate elevation (abduction) from the pendant position, then there may be an associated rotator cuff rupture and/or suprascapular nerve lesion. If the patient can initiate, but cannot maintain, abduction beyond $15^{\circ}$, then deltoid palsy should be suspected. Patients, particularly the elderly, can have a rotator cuff rupture and an axillary nerve palsy causing deltoid paralysis; it can be difficult to distinguish between the two. There may also be an area of hypoaesthesia or anaesthesia over the distal part of the muscle (sometimes referred to as the 'regimental badge patch' of skin; see Fig. 48.2), reflecting loss of function in the upper lateral cutaneous nerve of the arm (a branch of the axillary nerve), as well as venous occlusive changes (swelling) in the limb. After more violent dislocation, younger patients may have deltoid paralysis and an intact, but stretched, rotator cuff or partial tearing of the tendons, with a suprascapular nerve injury; these patients may have unexpected pain in the supraspinous fossa with weakness of infraspinatus (lateral rotation), as well as the anticipated anterior shoulder pain. Posterior dislocation is rare and typically occurs when violent movements produce marked medial rotation and adduction, e.g. in epileptic seizures or electric shock. The upper limb is held in fixed medial rotation, and external rotation is impossible to perform.
minimal in the unloaded arm, and heavy loads can be suspended with only a small contribution from the upper part; it is the lower part of the muscle that resists lateral rotation of the scapula under load. Acting with levator scapulae, the upper fibres elevate the scapula and, with it, the point of the shoulder; acting with serratus anterior, the lower fibres of trapezius protract and rotate the scapula medially (upwards) so that the arm can be raised above the head; acting with the rhomboids, it retracts the scapula, bracing the shoulder. With the shoulder fixed, trapezius may bend the head and neck backwards and laterally. Trapezius, pectoralis minor, levator scapulae, rhomboids and serratus anterior combine to produce a variety of scapular rotations see below.

If the muscle is denervated, the functions of trapezius cannot be substituted readily by muscle transfer; its unique suite of complex actions suggest that it should rarely, if ever, be used as a muscle for transfer elsewhere.

Testing The upper fibres of trapezius are palpated while the shoulder is shrugged against resistance (see Video 46.1). The lower fibres are palpated during scapular retraction. A better discriminative test is as follows: the hand is brought by medial rotation to the small of the back and the patient is asked to maintain it firmly in this position while the examiner tries to pull the hand off the back. The lower fibres of the trapezius are activated to hold the scapular spine horizontal. Failure to do so implies paresis or paralysis of trapezius, but this must be distinguished from congenital hypoplasia of the lower fibres of the muscle.

Trapezius palsy results in a characteristic posture: the shoulder is tilted laterally and forwards, the acromioclavicular joint is lowered, the superior pole of the scapula is rotated upwards and the inferior pole is displaced medially and, usually, away from the chest wall. This distinguishes trapezius palsy from that of serratus anterior, in which the entire medial border of the scapula tends to elevate away from the chest wall (so-called 'winging'). The scapula is displaced upwards and towards the spine (see p. 838). The altered posture and disordered motion of the scapula create distortion (narrowing and elongation) of the cervicoaxillary sheath and its contents; symptoms of reduced venous return, lymphatic obstruction and disturbed neural perfusion (pain, paraesthesiae, dysaesthesiae) are almost universal.

## Pectoralis minor

Attachments Pectoralis minor is a thin, triangular muscle lying posterior (deep) to pectoralis major (Fig. 48.25). It arises from the upper
margins and outer surfaces of the third to fifth ribs (frequently, second to fourth), near their cartilages, and from the fascia over the adjoining external intercostal muscles. Its fibres ascend laterally under cover of pectoralis major, converging in a flat tendon that is attached to the medial border and upper surface of the coracoid process of the scapula. Part or all of the tendon may appear to cross the coracoid process into the coraco-acromial ligament.

Variants Slips of the muscle are sometimes separated and vary in number and level. In rare cases, one passes from the first rib to the coracoid (pectoralis minimus). The costal attachments can be second to fifth ribs; third to fifth; second to fourth; or third to fourth. The muscle may be present or absent when pectoralis major is absent (in Poland's syndrome).

Relations Pectoralis major, the lateral pectoral nerve and pectoral branches of the thoraco-acromial artery are anterior. The ribs, external intercostals, serratus anterior, the axilla, axillary vessels, lymphatics and brachial plexus are all posterior. The upper border of pectoralis minor is separated from the clavicle by a triangular gap filled by the clavipectoral fascia, behind which are the axillary vessels, lymphatics and nerves. The lateral thoracic artery follows the lower border of the muscle. The medial pectoral nerves pierce and partly supply the muscle.

Vascular supply Pectoralis minor is supplied by pectoral and deltoid branches of the thoraco-acromial and superior and lateral thoracic arteries.

Innervation Pectoralis minor is innervated by branches of the medial and lateral pectoral nerves: C5, 6, 7, 8 and T1.

Actions Pectoralis minor assists serratus anterior in drawing the scapula forwards around the chest wall. With levator scapulae and the rhomboids, it rotates the scapula, depressing the point of the shoulder. It resists scapular rotation caused by trapezius. Both pectoral muscles are electromyographically quiescent in normal inspiration, but are active in forced inspiration.

## Subclavius

Attachments Subclavius is a long, asymmetric triangular muscle between the clavicle and the first rib (see Fig. 48.25). It arises from

Fig. 48.25 Deep muscles of the chest and left shoulder girdle, anterior aspect. Roman numerals refer to costal cartilages. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
the junction of the first rib and its costal cartilage by a thick tendon, prolonged at its inferior margin and anterior to the costoclavicular ligament. It passes upwards and laterally to attach by direct muscular fibres into a groove on the undersurface of the middle third of the clavicle; the lower and most lateral fibres are the longest. Subclavius may be attached to the coracoid process or the upper border of the scapula as well as, or instead of, the clavicle.

Relations Posteriorly, subclavius is separated from the first rib by the subclavian vessels and brachial plexus; anteriorly, it is separated from pectoralis major by the anterior lamina of the clavipectoral fascia. The suprascapular artery, which has a variable pattern, descends behind the muscle, passing between it and omohyoid anteriorly and the subclavian vessels posteriorly; the artery, therefore, has a close relationship to the posterior surface of the clavicle, a feature that makes it susceptible to injury during clavicular fracture and surgical fixation.

Vascular supply Subclavius is supplied by the clavicular branch of the thoraco-acromial artery and the suprascapular artery.

Innervation Subclavius is supplied by the subclavian branch of the brachial plexus (the nerve to subclavius), C5 and 6. A muscle, however apparently insubstantial, that has a unique, solitary nerve supply must have an important function; subclavius is no exception (see above and below).

Actions Subclavius resists accelerated elevation and rotation of the clavicle during elevation of the shoulder girdle, and may help to closepack the medial end of the clavicle against the articular disc of the sternoclavicular joint for greater stability under load. It is inaccessible to palpation and difficult to investigate by electromyography. Incidentally, it 'protects' the subclavian vessels and brachial plexus that lie behind it.

## MUSCLES OF SCAPULAR MOTION

## Levator scapulae

Attachments Levator scapulae is a slender muscle attached by tendinous slips to the transverse processes of the atlas and axis, and to the posterior tubercles of the transverse processes of the third and fourth cervical vertebrae (see Fig. 29.6; Fig. 48.26). It descends diagonally to attach to the medial scapular border between its superior angle and the triangular smooth surface at the medial end of the scapular spine.

Variants Levator scapulae varies considerably in its vertebral attachments and the extent to which it separates into slips. There may be accessory attachments to the mastoid process, occipital bone, first or second rib, the scaleni, trapezius and the serratus muscles.

Vascular supply Levator scapulae receives its arterial supply mainly from the transverse cervical and ascending cervical arteries. The vertebral extremity of the muscle is supplied by branches from the vertebral artery.

Innervation Levator scapulae is innervated directly by branches of the third and fourth cervical spinal nerves, and from the fifth cervical nerve via the dorsal scapular nerve.

Actions Levator scapulae elevates the superior angle of the scapula. If unopposed, this causes a lateral rotation of the scapula. With the cervical vertebral column fixed, levator scapulae acts with trapezius to elevate the scapula or to sustain a weight carried on the shoulder; with the shoulder fixed, the muscle inclines the neck to the same side.

## Rhomboid minor

Attachments Rhomboid minor is a small, cylindrical muscle. It runs from the lower ligamentum nuchae and the spines of the seventh cervical and first thoracic vertebrae to the base of a smooth triangular surface at the medial end of the spine of the scapula, where dorsal and ventral layers enclose the inferior border of levator scapulae (see Fig. 48.26). The dorsal layer of rhomboid minor is attached to the rim of the triangular surface, dorsolateral to and below levator scapulae. The ventral layer is strong and wide, extending $2-3 \mathrm{~cm}$ medial to and below levator scapulae; here, the fasciae of rhomboid minor and serratus anterior are fused. Rhomboid minor is usually separate from rhomboid major, but the muscles overlap and are occasionally united.

Fig. 48.26 Muscles of the back and shoulder girdles. Superficial muscles are shown on the left. Deeper muscles, revealed after excision of deltoid, latissimus dorsi and trapezius, are shown on the right.

Variants There is some variability in the vertebral and scapular attachments of rhomboids major and minor. A slip of muscle may extend from the upper border of rhomboid minor to reach the occipital bone (rhomboid occipitalis).

## Rhomboid major

Attachments Rhomboid major is a quadrilateral sheet of muscle that arises by tendinous fibres from the spines and supraspinous ligaments of the second to fifth thoracic vertebrae, and descends laterally to the medial border of the scapula between the root of the spine and the inferior angle (see Fig. 48.26). Most of its fibres usually end in a tendinous band between these two points, joined to the medial border by a thin membrane. Occasionally, this is incomplete, in which case some muscular fibres are attached directly into the scapula. The attachments of rhomboid major (and also those of rhomboid minor, levator scapulae and serratus anterior) may be more extensive, with 'folds' or extensions passing to both dorsal and costal aspects of the scapula adjacent to its medial margin.

Vascular supply of the rhomboids Rhomboids major and minor are supplied by the dorsal scapular artery or the deep branch of the transverse cervical artery and by dorsal perforating branches from the upper five or six posterior intercostal arteries.

Innervation of the rhomboids Rhomboids major and minor are innervated by a branch of the dorsal scapular nerve, C4, 5 .

Actions of the rhomboids Both rhomboid major and rhomboid minor retract the medial border of the scapula superiorly and medially, and are used in retraction of the shoulders.

Testing of the rhomboids Rhomboids major and minor can be palpated deep to trapezius on bracing the shoulder back against resistance with the arm in elevation at shoulder level.

## Serratus anterior

Attachments Serratus anterior is a large muscular sheet that curves around the thorax. It arises from an extensive costal attachment and inserts on the scapula (see Fig. 48.25). Fleshy digitations arise anteriorly
from the outer surfaces and superior borders of the upper eight to ten ribs, and from fasciae that cover the intervening intercostal muscles. The line of origin of the muscle is long and slightly curved, and passes inferolaterally around the thorax. There are three parts: the upper fibres arise from the first and second ribs and intercostal fascia, the middle fibres arise from the third to sixth ribs, and the lower fibres interdigitate with the upper five slips of external oblique. The muscle follows the contour of the chest wall closely, reaching the medial border of the scapula anterior to subscapularis. The first (uppermost) digitation encloses, and is attached to, a triangular area of both the costal and the dorsal surfaces of the superior scapular angle. The next two or three digitations form a triangular sheet that is attached to the costal surface along almost its entire medial border. The lower four or five digitations converge to be attached by musculotendinous fibres to a triangular impression on the costal surface of the inferior angle; they enclose the inferior angle and are also attached to a smaller triangular part of its dorsal surface near its tip.

Variants Digitations may be absent, particularly the first and eighth, and sometimes also the intermediate part. Serratus anterior may be partly fused with levator scapulae, adjacent external intercostals or external oblique.

Vascular supply Serratus anterior is supplied by superior and lateral thoracic arteries, and by branches from the thoracodorsal artery before (occasionally, after) it divides in latissimus dorsi.

Innervation Serratus anterior is innervated by the long thoracic nerve, C5, 6 and 7, which descends on the external surface of the muscle.

Actions With pectoralis minor, serratus anterior protracts (draws forwards) the scapula, as a prime mover in all reaching and pushing movements. The upper part, with levator scapulae and the upper fibres of trapezius, suspends the scapula; only slight activity is sufficient to support the unloaded arm. The more extensive lower insertion pulls the inferior scapular angle forwards around the thorax, assisting trapezius in upward rotation of the bone, an action that is essential to raising the arm above the head. In the initial stages of abduction, serratus anterior helps other muscles to fix the scapula, so that deltoid acts effectively on the humerus and not the scapula. While deltoid is raising the arm to a right angle with the scapula, serratus anterior and trapezius are simultaneously rotating the scapula; the combination allows the arm to be raised to the vertical. To effect this upward rotation of the scapula, forward pull on the inferior angle by the lower digitations of serratus anterior is coupled with an upward and medial pull on the lateral end of the clavicle and acromion by the upper fibres of trapezius, and a downward pull on the base of the scapular spine by the lower fibres of trapezius. Conversely, slow downward scapular rotation, assisted by gravity, is achieved by controlled lengthening of these muscles. More powerful downward rotation requires balanced contraction of the upper fibres of serratus anterior, levator scapulae, rhomboids, pectoralis minor and the middle part of trapezius. When weights are carried in front of the body, serratus anterior prevents backward rotation of the scapula. Electromyography shows that serratus anterior is not active in normal human respiration. This may not apply to laboured respiration, e.g.
when asthmatics and athletes may be observed to fix the scapula by grasping a rail or other support.

Testing The muscular digitations of serratus anterior can be seen and felt when the outstretched hand pushes against resistance.

When serratus anterior is paralysed, the medial border of the scapula, and especially its lower angle, stand out prominently. The arm cannot be raised fully. Pushing is ineffective; indeed, attempts to do so produce further projection, known as 'winging' of the scapula (Streit et al 2012; see p. 831).

## Serratus posterior inferior

Serratus posterior inferior is described on page 942 (see Fig. 48.26).

## Serratus posterior superior

Serratus posterior superior is described on page 941.

## MUSCLES OF THORACOBRACHIAL MOTION

The large muscles from the trunk to the arm, and from the scapula to the arm, act on the shoulder joint. Pectoralis major and latissimus dorsi are attached to the metaphysis of the humerus below the centre of rotation of the joint, while deltoid and coracobrachialis are attached to the midpoint of the diaphysis or shaft, some way from the centre of rotation of the shoulder joint. These four muscles move the arm in relation to the shoulder joint, so that, although they act through the shoulder joint, their role is to position the elbow joint (and, thus, the hand) in space. The continuous sheet of muscle that is pectoralis major and deltoid positions the elbow through a wide, asymmetrical, conical range of motion from adduction across the trunk with medial rotation, through flexion, abduction and external rotation, into extension at the shoulder. The cervical spinal segmental levels at which this range of movement is represented, C5 and C6, give rise to the anterior division innervation to pectoralis major (thus, pre-axial or predominantly flexor muscles) and the posterior division innervation (thus, post-axial or predominantly extensor muscles) to deltoid. Similarly, coracobrachialis (a flexor and adductor of the abducted arm) is innervated through the anterior division of C5, 6 and (predominantly) 7 segmental levels, while latissimus dorsi is innervated through the posterior division of C6, 7 and 8 (predominantly C7). These are examples of the movements of a joint, rather than individual muscles, being subserved in a biologically efficient manner by the minimum number of spinal segmental levels required to achieve the aim of positioning the elbow in space, while maintaining subtlety in effect.

## Pectoralis major

Attachments Pectoralis major (Fig. 48.27) is a thick, fan-shaped muscle. It arises from the anterior surface of the sternal half of the clavicle (clavicular head); half the breadth of the anterior surface of the sternum down to the level of the sixth or seventh costal cartilage (sternal head); the first to the seventh costal cartilages (first and seventh often omitted); the sternal end of the sixth rib; and the aponeurosis of external oblique (rectus head). The clavicular fibres are usually separated from the sternal fibres by a slight cleft. The muscle converges to a flat tendon, approximately 5 cm wide, that is attached to the lateral

Fig. 48.27 The left deltopectoral groove, dissected to show the clavipectoral fascia and thoraco-acromial axis. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
lip of the intertubercular sulcus of the humerus. The tendon is bilaminar. The thicker anterior lamina is formed by fibres from the manubrium, joined superficially by clavicular fibres and deeply by fibres from the sternal margin and the second to fifth costal cartilages. Clavicular fibres may be prolonged into the tendon of deltoid. The posterior lamina receives fibres from the sixth (and, often, seventh) costal cartilages, sixth rib, sternum, and aponeurosis of external oblique. Costal fibres join the lamina without twisting. Fibres from the sternum and aponeurosis curve around the lower border, turning successively behind those above them, which means that this part of the muscle is twisted so that the fibres that are lowest at their medial origin are highest at their attachment on the humerus. The posterior lamina reaches higher on the humerus than the anterior, and gives off an expansion that covers the intertubercular sulcus and blends with the capsular ligament of the shoulder joint. An expansion from the deepest part of the lamina lines the intertubercular sulcus at its linear insertion; another expansion descends from its lower border into the deep fascia of the upper arm.

The rounded lower border of pectoralis major forms the anterior axillary fold and becomes conspicuous in abduction against resistance.

Variants The abdominal slip from the aponeurosis of external oblique is sometimes absent. The number of costal attachments and the extent to which the clavicular and costal parts are separated vary. Right and left muscles may decussate across the sternum. A superficial vertical slip, or slips, may ascend from the lower costal cartilages and rectus sheath to blend with sternocleidomastoid or to attach to the upper sternum or costal cartilages. This is sternalis (rectus sternalis).

Relations Skin, superficial fascia, platysma, medial and intermediate supraclavicular nerves, breast tissue and deep fascia are all anterior. The sternum, ribs and costal cartilages, clavipectoral fascia, subclavius, pectoralis minor, serratus anterior, external intercostal muscles and membranes are all posterior. Pectoralis major forms the superficial layer of the anterior axillary wall, and hence lies anterior to the axillary vessels and nerves and the upper parts of biceps brachii and coracobrachialis. Its upper border is separated from deltoid by the infraclavicular fossa, which contains the cephalic vein and deltoid branch of the thoracoacromial artery. Pectoralis major is separated from latissimus dorsi on the medial axillary wall but the two muscles converge as they approach the lateral axillary wall; the floor of the intertubercular sulcus lies between their attachments.

Vascular supply Pectoralis major is supplied by one dominant vascular pedicle from the pectoral branch of the thoraco-acromial axis, supplemented by several smaller secondary segmental vessels from the deltoid and clavicular branches of the thoraco-acromial axis, and perforating branches of the internal thoracic arteries and superior and lateral thoracic arteries.

Innervation Pectoralis major is supplied through the medial and lateral pectoral nerves. Fibres for the clavicular part are from C5 and 6; those for the sternocostal part are from C7, 8 and T1.

Actions The two parts of pectoralis major can act separately or together. The whole muscle assists adduction and medial rotation of the humerus against resistance. It swings the extended arm forwards and medially, its clavicular part acting with the anterior fibres of deltoid and coracobrachialis; the sternocostal part is relaxed. The opposite movement is usually aided by gravity. When it is resisted, the sternocostal part acts together with latissimus dorsi, teres major and the posterior fibres of deltoid; the clavicular part is relaxed. With the raised arms fixed, e.g. gripping a branch, the same combination of muscles draws the trunk up and forwards. Pectoralis major is active in deep inspiration.

Testing To test the clavicular head, the abducted arm is flexed against resistance. To test the sternocostal head, the arm is adducted against resistance.

## Poland's syndrome

Available with the Gray's Anatomy e-book
Chondro-epitrochlearis Chondro-epitrochlearis is a rare extra 'head' of pectoralis major, arising deep to the sternal and rectus
components of that muscle from the anterior aspect of the fifth, sixth and seventh ribs and their costal cartilages, and in the same plane as pectoralis minor.

## Deltoid

Attachments Deltoid is a thick, curved triangle of muscle. It arises from the anterior border and superior surface of the lateral third of the clavicle, the lateral margin and superior surface of the acromion, and the lower edge of the crest of the scapular spine (other than its smooth, medial, triangular surface) (see Figs 48.26, 48.27). The fibres converge inferiorly to a short, substantial tendon that is attached to the deltoid tubercle on the lateral aspect of the midshaft of the humerus. Anterior and posterior fibres converge directly to this tendon. The intermediate part is multipennate; four intramuscular septa descend from the acromion to interdigitate with three septa ascending from the deltoid tubercle. The septa are connected by short muscle fibres that provide powerful traction (Leijnse et al 2008). The fasciculi are large, producing a coarse longitudinal striation. The muscle surrounds the glenohumeral articulation on all sides, except inferomedially, giving the shoulder its rounded profile. In contraction, its borders are easily seen and felt. The tendon gives off an expansion into the brachial deep fascia that may reach the forearm.

Variants Deltoid may fuse with pectoralis major or may receive additional slips from trapezius, the infraspinous fascia or the lateral scapular border. Teres minor shares a common innervation and could be considered as a fourth, posteroinferior, part of deltoid.

Relations The skin, superficial and deep fasciae, platysma, lateral supraclavicular and upper lateral brachial cutaneous nerves are all superficial. The coracoid process, coraco-acromial ligament, subacromial bursa, tendons of pectoralis minor, coracobrachialis, both heads of biceps brachii, pectoralis major, subscapularis, supraspinatus, infraspinatus, teres minor, long and lateral heads of triceps, circumflex humeral vessels, axillary nerve, and the surgical neck and upper shaft of the humerus, including both tubercles, are all deep. The anterior border of deltoid is separated from pectoralis major proximally by the infraclavicular fossa, which contains the cephalic vein and deltoid branches of the thoraco-acromial artery; distally, these muscles are in contact. The posterior border of deltoid overlies infraspinatus and triceps.

Vascular supply Deltoid is supplied by acromial and deltoid branches of the thoraco-acromial artery; the anterior and posterior circumflex humeral arteries; subscapular artery; and the deltoid branch of profunda brachii.

Innervation Deltoid is innervated by the axillary nerve, C5 and 6.
Actions Different parts of the muscle can act independently, as well as together. Anterior fibres assist pectoralis major in drawing the arm forwards and rotating it medially. Posterior fibres act as external rotators, and act with latissimus dorsi and teres major in drawing the arm backwards (into extension). The posterior fibres of deltoid provide up to $80 \%$ of the external rotation power of the arm when elevated into the plane of the scapula. The multipennate, acromial, part of deltoid is a strong abductor; aided by supraspinatus, it abducts the arm until the inferior joint capsule is tight. Movement takes place in the plane of the body of the scapula, which is the only way that scapular rotation can be fully effective in raising the arm above the head. In true abduction, acromial fibres contract strongly, while clavicular and posterior fibres prevent departure from the plane of motion. In the early stages of abduction, traction by deltoid is upward, but the humeral head is prevented from translating upward by the synergistic centralizing effect of the rotator cuff muscles (supraspinatus, subscapularis, infraspinatus and teres minor). Electromyography suggests that deltoid contributes little to medial (internal) or lateral (external) rotation but confirms that it takes part in most other shoulder movements.

Testing Deltoid can be seen and felt to contract when the arm is abducted against resistance in the scapular plane. Since this motion can also be achieved by supraspinatus, a more specific test for the activity of deltoid is to assess extension against resistance with the arm in $30^{\circ}$ abduction in the scapular plane: this reduces the confounding effect of latissimus dorsi and triceps as extensors of the adducted arm. Subtle weakness can be determined using the deltoid lag sign (Hertel et al 1998).

Poland's syndrome is a rare congenital anomaly, in which there is hypoplasia of the thoracic chest wall muscles and ipsilateral hypoplasia of the arm and hand. It occurs in approximately 1:50,000 live births. The major clinical feature is absence of the sternocostal head of pectoralis major and all of pectoralis minor. In addition, there may be hypoplasia of latissimus dorsi, serratus anterior, external oblique, supraspinatus, infraspinatus, deltoid and the intercostal muscles, and hypoplasia of the hemithorax and ribs. Hypoplasia affecting the arm ranges from syndactyly to symbrachydactyly and ectrodactyly. The second, third and fourth fingers are the most affected; the wrist, forearm, upper arm and scapula are variably involved. There may be ipsilateral breast hypoplasia and absent nipple-areolar complex.

The aetiology is unclear. It has been suggested that the condition is caused by disruption of lateral plate mesenchyme 2-4 weeks after fertilization, or by disruption of the arterial blood supply to the subclavian vessels during the sixth and seventh weeks of embryonic life.

The muscle has an extensive attachment to the lateral crest of the intertubercular sulcus, the medial intermuscular septum and the medial epicondylar ridge. It is innervated by branches of the lateral pectoral nerve that perforate pectoralis minor or pass to the muscle in the plane between pectoralis minor and major. It is noted as a pterygium deep to the anterior axillary wall with a sharply defined inferior border in the axilla, made more noticeable by flexion and medial rotation against resistance with the arm elevated into the scapular plane. With the arm in the elevated position, contraction of the muscle causes a retropulsion of the glenohumeral joint, a rare cause of posterior glenohumeral instability.

## Coracobrachialis

Coracobrachialis is the most medial of the three anterior compartment muscles of the arm. It has a common origin with the short head of biceps brachii. In turn, the short head of biceps shares a common distal attachment with the long head of biceps. The three anterior compartment muscles, therefore, form a single functional group that brings the supinated hand into flexion and medial rotation, towards the face.

Attachments Coracobrachialis arises from the deep surface of the apex of the coracoid process, deep to the tendon of the short head of biceps brachii, and by muscular fibres from the proximal $5-10 \mathrm{~cm}$ of this tendon. It ends on an impression, $3-5 \mathrm{~cm}$ in length, midway along the medial border of the humeral shaft between the attachments of
the medial head of triceps and brachialis (Fig. 48.28). Accessory slips may be attached to the lesser tubercle, medial epicondyle or medial intermuscular septum.

Relations Coracobrachialis forms an inconspicuous rounded ridge on the upper medial side of the arm; pulsation of the brachial artery can be felt and often seen in the depression behind it. The muscle is perforated and supplied by the musculocutaneous nerve. Anteriorly, it is related to pectoralis major above and, at its humeral insertion, to the brachial vessels and median nerve, which cross it. The tendons of subscapularis, latissimus dorsi, teres major, the medial head of triceps, the humerus and the circumflex humeral vessels are all posterior. The third part of the axillary artery and proximal parts of the median and

A

Fig. 48.28 Deep muscles of the left shoulder girdle. A, The anterior aspect after removal of the superficial muscles. B, Posterior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
musculocutaneous nerves are first medial and become posterior further distally; they may be partially obscured by the muscle if it is bulky. Biceps brachii and brachialis are lateral.

Vascular supply One or more branches from the axillary artery pass deep to the lateral root of the median nerve and the musculocutaneous nerve to reach the deep surface of coracobrachialis. Branches from the anterior circumflex humeral artery supply the deep surface of the muscle. The artery accompanying the musculocutaneous nerve sends a recurrent branch to the coracoid attachment and gives off a series of branches to coracobrachialis during its intramuscular course. Accessory branches from the thoraco-acromial artery supply the superficial part of coracobrachialis.

Innervation Coracobrachialis is innervated by the musculocutaneous nerve, C5, 6 and 7.

Actions Deltoid and coracobrachialis insert into the humerus approximately opposite each other. Coracobrachialis acts as an antagonist to the action of deltoid, particularly when the arm is in abduction and extension; it flexes the arm forwards and medially. In abduction, it acts with the anterior fibres of deltoid to resist departure from the plane of motion.

Testing Coracobrachialis can be tested by palpating its fibres during adduction and medial rotation of the flexed shoulder against resistance. Alternatively, the muscle can be palpated during forceful depression of the elbow against resistance or with the arm by the side.

## Latissimus dorsi

Attachments Latissimus dorsi is a large, flat, triangular muscle that sweeps over the lumbar region and lower thorax, and converges to a narrow tendon (see Fig 48.26). It arises by tendinous fibres from the spines of the lower six thoracic vertebrae anterior to trapezius; from the posterior layer of thoracolumbar fascia, by which it is attached to the spines and supraspinous ligaments of the lumbar and sacral vertebrae; and from the posterior part of the iliac crest. It also springs by muscular fibres from the posterior part (outer lip) of the iliac crest lateral to erector spinae, and by fleshy slips from the three or four lower ribs, interdigitating with external oblique (see Fig. 61.6). From this extensive attachment, fibres pass laterally with different degrees of obliquity (the upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical), to form a sheet 12 or 13 mm thick that overlaps the inferior scapular angle, and may attach to it. The muscle curves around the inferolateral border of teres major to gain its anterior surface and ends as a flattened tendon, up to 7 cm long, anterior to the tendon of teres major. It is attached to the floor of the intertubercular sulcus of the humerus with an expansion to the deep fascia (Dancker 2013). The attachment extends higher on the humerus than that of teres major. As the muscle curves round teres major, the fasciculi rotate around each other, so that fibres that originate lowest at the midline insert highest on the humerus, and fibres that originate highest at the midline insert lowest on the humerus. A bursa sometimes occurs between the muscle and the inferior scapular angle. The tendons of latissimus dorsi and teres major are united at their lower borders but separated by a bursa near their humeral attachments.

Latissimus dorsi and teres major together form the posterior axillary fold. When the arm is adducted against resistance, this fold is accentuated, and the whole inferolateral border of latissimus dorsi can be traced to its attachment to the iliac crest. The radial nerve and the branch or branches it supplies to the medial head of triceps are close anterior relations of the tendon of the latissimus dorsi, $3-5 \mathrm{~cm}$ medial to the shaft of the humerus, before the radial nerve traverses the lower triangular space and passes into the posterior compartment of the arm (see quadrangular and triangular spaces below).

The lower, lateral margin of latissimus dorsi is usually separated from the posterior border of external oblique by the lumbar triangle. The base of this small triangle is the iliac crest and its floor the internal oblique; it should not be confused with the triangle of auscultation, medial to the scapula, which is bounded above by trapezius, below by latissimus dorsi and laterally by the medial border of the scapula. Part of rhomboid major is exposed in the triangle. If the scapulae are drawn forwards, by folding the arms across the chest, and the trunk is bent forwards, parts of the sixth and seventh ribs and the interspace between them (overlying the apex of the lower pulmonary lobe) become subcutaneous.

Variants Latissimus dorsi commonly receives some additional fibres from the scapula as it crosses the inferior scapular angle. A muscular
axillary arch, $7-10 \mathrm{~cm}$ in length and $5-15 \mathrm{~mm}$ in breadth, may sometimes be present; it crosses from the edge of latissimus dorsi, midway in the posterior fold, and passes anterior to the axillary vessels and nerves to join the tendons of pectoralis major, coracobrachialis or the fascia over biceps brachii. The vertebral and costal attachments of latissimus dorsi may be reduced or, in rare cases, increased. A fibrous slip usually passes from the tendon, near its humeral insertion, to the long head of triceps.

Vascular supply Latissimus dorsi is supplied by a single dominant vascular pedicle, the thoracodorsal artery, itself a continuation of the subscapular artery. The thoracodorsal artery and its accompanying venae comitantes enter the muscle at a single neurovascular hilum on its costal surface, $6-12 \mathrm{~cm}$ from the subscapular artery and $1-4 \mathrm{~cm}$ medial to the lateral border of the muscle. The artery gives off up to three large branches to serratus anterior before dividing at, or even before, the neurovascular hilum for latissimus dorsi. The basic pattern of branching is a bifurcation into lateral and medial branches. The larger lateral branch follows a course parallel to, and 1-4 cm from, the upper border of the muscle; the smaller branch diverges at an angle of $45^{\circ}$ and travels medially. In a small number of cases, the artery trifurcates. This usually yields a small recurrent branch that returns to supply the proximal part of the muscle but, in some cases, it provides a third major branch that supplies the distal part of the muscle. Occasionally, the lateral branch gives off a further collateral to serratus anterior. The major branches give off 5-9 longitudinal branches that travel distally, parallel with the muscle fibres. Musculocutaneous perforators arising from these vessels supply the overlying skin.

In addition to the dominant vascular pedicle, latissimus dorsi is supplied inferiorly by several smaller, secondary, segmental vascular pedicles. These are dorsal perforating arteries derived from the ninth, tenth and eleventh posterior intercostal arteries and the first, second and third lumbar arteries. They all enter the muscle on its deep surface and anastomose within the muscle with branches of the thoracodorsal artery.

Innervation Latissimus dorsi is supplied by the thoracodorsal nerve, from the posterior cord of the brachial plexus, C6, 7 and 8 (predominantly C7). This nerve runs in the neurovascular pedicle and divides approximately 1.5 cm proximal to the point of bifurcation or trifurcation of the thoracodorsal artery. The neural and vascular branches travel together and so the pattern of branching of the nerve follows that of the artery closely.

Actions Latissimus dorsi is active in adduction, extension and, especially, in medial rotation of the humerus. Humeral adduction and extension are most powerful when the initial position of the arm is one of partial abduction or flexion, or a combination of the two. With the sternocostal part of pectoralis major and teres major, it adducts the raised arm against resistance. When the arms are raised above the head, as in climbing, it pulls the trunk upwards and forwards. It takes part in all violent expiratory efforts, such as coughing or sneezing; this is readily confirmed by palpation. Electromyography suggests that latissimus dorsi aids deep inspiration, but it is also active towards the end of forcible expiration, e.g. when blowing a sustained note on a musical instrument. When the arm is elevated, the stretched fibres of latissimus dorsi press on the inferior scapular angle (to which it may also be attached), keeping it in contact with the chest wall. Despite this range of actions, surgical transposition of the muscle does not appear to produce any serious restriction of normal activity.
Testing Latissimus dorsi is palpated when the abducted arm is adducted against resistance and can be felt to contract during coughing.

## MUSCLES OF CONCAVITY COMPRESSION

The function of the rotator cuff muscles is to generate a concavity compressive force in all positions of the arm at the shoulder. The term 'rotator cuff' is conventionally taken to mean the tendinous parts of the four rotator cuff muscles: subscapularis, supraspinatus, infraspinatus and teres minor. Since teres minor, parts of infraspinatus and most of subscapularis do not have tendons, this use of the term excludes important parts of the rotator cuff apparatus. In this description, the term 'rotator cuff' will be used to define the entire musculotendinous apparatus that centralizes the humeral head on the glenoid. The tendons of the rotator cuff will be referred to specifically.

It is also maintained that the inferior capsule of the glenohumeral joint is exposed as a weak part of the capsule, and so predisposed to
injury（dislocation）．However，in elevation of the arm above $90^{\circ}$ ，the bulk of teres major forms a muscular buttress to the lower part of the joint and，in this position，clearly draws the humeral head into the glenoid，i．e．it has a centralizing effect．Teres major is a part of the cen－ tralizing function of the rotator cuff，and should be considered along with the conventional definition of the rotator cuff．

The mechanism of the rotator cuff has been likened to that of the fibrous＇endoskeleton＇of the heart，in which the muscular chambers are constructed around the fibrous architecture of the valvular system，and muscle contraction is centralized on this fibrous support．The muscles of the rotator cuff are attached to their tendons in a similar manner： the fibrous architecture of the tendons provides a framework for the action of the rotator cuff so that it always generates a centralizing force on the glenoid（Gagey et al 1993）．

The muscles of the rotator cuff combine in three groups（subscapu－ laris and teres major，supraspinatus and infraspinatus，and teres minor） by virtue of their innervation．Subscapularis and teres major are innervated through the subscapular nerves（C5， 6 and 7，posterior divi－ sion，posterior cord）；supraspinatus and infraspinatus by the supras－ capular nerve（C5，6，upper trunk）；and teres minor by the axillary nerve（C5，6，posterior division，posterior cord）．The common origin of their innervation suggests a common final action，namely：the gen－ eration of the centralizing compression force．In functional terms， supraspinatus and infraspinatus can be considered as one muscle on the grounds that they have the same innervation and the same vascular supply；their attachment to the scapula is a continuum broken only by the spine of scapula for the attachment of trapezius；and their actions are complementary．

## Supraspinatus

Attachments Supraspinatus arises from the medial two－thirds of the supraspinous fossa and from the supraspinous fascia（Fig．48．28）．The fibres converge，under the acromion，into a thick tendon that passes obliquely through the muscle，crosses above the humeral head，and is attached to the highest facet of the greater tubercle of the humerus．The tendon has a posterior，flatter，component closer to the facet of attach－ ment．The anterior，obliquely directed，fibres of supraspinatus are inserted into the anterior aspect of the thick tendon，while the more parallel posterior fibres are inserted into both the thick tendon and the flatter component．The thick tendon is contiguous with the transverse humeral and coracohumeral ligaments；it forms an anterior pillar to the posterosuperior part of the rotator cuff．The deep surface of the tendon blends into the articular capsule over its distal 1 cm or so． Fibrocartilage has been described at the tendinous insertion，as in other tendons attached to epiphysial bone．

Vascular supply Supraspinatus is supplied by the suprascapular and dorsal scapular arteries．

Innervation Supraspinatus is innervated by the suprascapular nerve， C5 and 6.

Actions The conventional view is that supraspinatus initiates abduc－ tion of the shoulder and assists deltoid in abduction thereafter． However，there is evidence that both supraspinatus and deltoid are involved throughout the range of abduction，including initiation of the movement．In complete axillary nerve lesions（complete，irrevers－ ible deltoid palsy），supraspinatus，acting with other cuff muscles，can initiate，regulate，achieve and maintain full abduction of the arm （although endurance is limited）．If supraspinatus is detached，torn or paralysed，and deltoid is also paralysed，investigation and surgical exploration and repair of damaged rotator cuff tendon，muscle or nerve supply is mandatory．With a functioning rotator cuff but poor deltoid，the arm is functionally adept and useful，whereas with a poorly functioning rotator cuff and normal deltoid，arm function is potentially poor because stability of the joint is adversely compro－ mised and deltoid cannot function to overcome this disability．As part of the rotator cuff，supraspinatus helps to stabilize the head of the humerus in the glenoid fossa during movements of the glenohumeral joint．With the arm dependent，even when moderately loaded，suprasp－ inatus assists deltoid in prevention of downward displacement of the humerus．

Testing It is extremely difficult to palpate supraspinatus unless trape－ zius is thin．The tendon of supraspinatus is separated from the coraco－ acromial ligament，acromion and deltoid by the large subacromial bursa；when this is inflamed，abduction of the shoulder joint is painful． The tendon is the most frequently torn element of the musculotendi－ nous cuff around the shoulder joint．

## Infraspinatus

Attachments Infraspinatus is a thick，triangular muscle that occu－ pies most of the infraspinous fossa（see Fig．48．28）．It arises by mus－ cular fibres from the medial two－thirds of the fossa，by tendinous fibres from ridges on its surface and from the deep surface of the infraspinous fascia，which separates it from teres major and minor．Its fibres converge to a tendon that glides under the lateral border of the spine of the scapula，and then passes across the posterior aspect of the capsule of the shoulder joint to be attached to the middle facet on the greater tubercle of the humerus．The tendon fuses with that of supraspinatus immediately lateral to the thick lateral margin of the spine of the scapula；the tendon fibres decussate so that fibres of infra－ spinatus can be traced to the facet for supraspinatus，and vice versa （Mochizuki et al 2008）．The tendon is sometimes separated from the capsule by a bursa，which may communicate with the joint cavity．The tendon is flattened，but is thickened in several places，reinforcing its posterior aspect as it attaches to the middle facet．From this region， fibres passing orthogonally within the deeper substance of the tendon of infraspinatus pass forwards into supraspinatus，then pass across the rotator interval to subscapularis．This band of fibres is termed the ＇cable＇（Burkhart et al 1993）；it provides the mechanical link between the posterosuperior and anterior parts of the rotator cuff，thus ensur－ ing that there is intrinsic coordination of the rotator cuff mechanism． The muscular part of infraspinatus is attached directly to the middle facet on the greater tubercle and is sometimes fused with teres minor laterally，although their tendons are usually separable closer to the joint capsule．

Vascular supply Infraspinatus is supplied by the suprascapular and circumflex scapular arteries．

Innervation Infraspinatus is innervated by the suprascapular nerve， C5 and 6.

Actions Infraspinatus is a lateral rotator of the humerus．Together with supraspinatus，subscapularis and teres minor，it helps to stabilize the head of the humerus in the glenoid fossa during shoulder movements．

## Teres minor

Attachments Teres minor is a narrow，elongated muscle that arises from the upper two－thirds of a flattened strip on the dorsal surface of the scapula adjoining its lateral border，and from two aponeurotic laminae that separate it from infraspinatus and teres major（see Fig． 48．28）．It runs upwards and laterally．The upper fibres end in a short tendon（which may be absent），attached to the lowest facet on the greater tubercle of the humerus．The lower fibres are attached directly into the humerus distal to this facet and above the origin of the lateral head of triceps．The tendon passes across，and blends with，the lower posterior surface of the capsule of the shoulder joint．Teres minor may be fused with infraspinatus．

Vascular supply Teres minor is supplied by the circumflex scapular artery，which pierces the origin of the muscle as it turns upwards in the infraspinous fossa，and by the posterior circumflex humeral artery．

Innervation Teres minor is innervated by a branch of the axillary nerve that is given off the main trunk as it enters the quadrangular space，C5 and 6.

Actions Teres minor acts as a lateral rotator and weak adductor of the humerus with the arm pendant．Together with supraspinatus，infra－ spinatus，subscapularis and teres major，it helps to stabilize the head of the humerus in the glenoid fossa during shoulder movements．

## Subscapularis

Attachments Subscapularis is a bulky，triangular muscle that fills the subscapular fossa（see Figs 48．25，48．28A）．In its medial two－thirds，the fibres are attached to the periosteum of the costal surface of the scapula． Other fibres arise from tendinous intramuscular septa，attached to ridges on the bone，and from the aponeurosis that covers the muscle and separates it from teres major and the long head of triceps．The fibres converge laterally into a broad tendon above，which has a thickened， rounded upper margin，and is attached to the lesser tubercle of the humerus and the anterior part of the articular capsule，with a wide direct muscular attachment to the lower part of the lesser tubercle．The tendon is separated from the neck of the scapula by the large subscapular bursa， which may communicate with the shoulder joint．

Variation is unusual. A separate inferior slip (subscapularis accessorius) may pass from the lateral border of the scapula to the glenohumeral capsule or to the periosteum medial to the intertubercular sulcus of the humerus. This should be distinguished from the true infraglenoid muscle (Staniek and Brenner 2012).

Relations Subscapularis forms much of the posterior axillary wall. Its anterior surface is apposed inferomedially to serratus anterior, the axillary vessels, brachial plexus and subscapular vessels and nerves, and superolaterally to coracobrachialis and biceps. Its posterior surface is attached to the scapula and glenohumeral capsule. Its lower border contacts teres major and latissimus dorsi. Its upper border is contiguous with the capsule of the rotator interval; at the most lateral extent of the interval, the long tendon of biceps passes lateral to the attachment of subscapularis, covered by the transverse humeral ligament.

Vascular supply Subscapularis is supplied by small branches from the suprascapular, axillary and subscapular arteries.

Innervation Subscapularis is innervated by the upper and lower subscapular nerves, C5, 6 (posterior cord).

Actions Subscapularis is a medial rotator of the humerus. Together with supraspinatus, infraspinatus, teres minor and teres major, it helps to stabilize the head of the humerus in the glenoid fossa during shoulder movements.

The attachment of teres major lies in direct continuity with the attachment of subscapularis on the lesser tubercle. The muscles lie in virtually the same plane as they approach the humerus, share a similar innervation from the posterior cord of the brachial plexus, and perform the same actions. Like the spinati, subscapularis and teres major might be considered as a functional unit.

## Teres major

Attachments Teres major is a large, thick, ovoid muscle that arises from the oval area on the dorsal surface of the inferior scapular angle, and from the fibrous septa interposed between the muscle and teres minor and infraspinatus (see Fig. 48.28). Its fibres ascend laterally and end in a short, flat tendon, $2-5 \mathrm{~cm}$ long, attached to the medial lip of the intertubercular sulcus of the humerus. The tendon lies behind that of latissimus dorsi, from which it is separated by a bursa; the tendons are united along their lower borders for a short distance but are readily separated.

Variants Teres major may be fused with the scapular part of latissimus dorsi, and may send a slip to join the long head of triceps or the brachial fascia.

Vascular supply Teres major is supplied by the thoracodorsal branch of the subscapular artery on its way to latissimus dorsi and by the posterior circumflex humeral artery (Dancker 2013).

Innervation Teres major is innervated by the lower subscapular nerve, C5, 6 and 7 .

Actions Despite its name, teres major has a nerve supply and action that is distinct from teres minor. Teres major draws the humerus backwards and rotates it medially. Electromyographic studies are equivocal about its major role in movement, but its involvement as a contributor to static posture and arm-swinging is not contested.

Testing Teres major can be palpated posterior to the posterior axillary fold during adduction of the humerus against resistance.

## Rotator cuff disease

The subacromial space is defined inferiorly by the superior surface of the rotator cuff (supraspinatus and the anterior part of infraspinatus); superiorly by the anterior edge and inferior surface of the anterior third of the acromion, coraco-acromial ligament and acromioclavicular joint, forming the coraco-acromial arch; and posteriorly by the posterior wall of the subacromial bursa. It is occupied by the subacromial bursa, lined by synovial membrane, that extends anterolaterally under deltoid as the subdeltoid bursa, and which facilitates movement of the rotator cuff under the coraco-acromial arch. The upper surface of the rotator cuff normally impinges, without symptoms, under the coraco-acromial arch when the humerus is abducted, flexed and medially rotated. If the upper surface of the rotator cuff is damaged, the bursa is thickened or inflamed, or the undersurface of the coraco-acromial arch is rough, then the impingement can become abrasive: this is the painful condition called 'impingement syndrome'.

## MUSCLES THAT COORDINATE SHOULDER AND ELBOW MOTION

The muscles of the upper arm are coracobrachialis, which acts only on the shoulder joint; biceps and triceps, which cross both shoulder and elbow joints; and brachialis, which acts only at the elbow joint. Coracobrachialis is described on page 821.

## Anterior compartment of the arm

## Biceps brachii

Attachments Biceps brachii derives its name from its two proximally attached parts or 'heads' (see Figs 48.15, 48.16, 48.25, 48.28A). The short head arises by a thick, flattened tendon from the coracoid apex, together with coracobrachialis. The long head starts within the capsule of the shoulder joint as a long narrow tendon, running from the supraglenoid tubercle of the scapula at the apex of the glenoidal cavity, where it is continuous with the glenoidal labrum. The tendon of the long head, enclosed in a double tubular synovial sheath, arches over the humeral head, emerges from the joint under the transverse humeral ligament, and descends in the intertubercular sulcus, where it is retained by the transverse humeral ligament and a fibrous expansion from the tendon of pectoralis major. The two tendons lead into elongated bellies that, although closely applied, can be separated to within 7 cm or so of the elbow joint. At this joint, they end in a flattened tendon, which is attached to the rough posterior area of the radial tuberosity; a bursa separates the tendon from the smooth anterior area of the tuberosity. As it approaches the radius, the tendon spirals, its anterior surface becoming lateral before being applied to the tuberosity. The tendon has a broad medial expansion, the bicipital aponeurosis, which descends medially across the brachial artery to fuse with deep fascia over the origins of the flexor muscles of the forearm (Fig. 48.29). The tendon can be split without difficulty as far as the tuberosity; it can, thus, be confirmed that its anterior and posterior layers receive fibres from the short and long heads, respectively.

Occasionally, a third head arises from the superomedial part of brachialis and is attached to the bicipital aponeurosis and medial side of the tendon of insertion. It usually lies behind the brachial artery but it may consist of two slips, which descend in front of and behind the artery. Less often, other slips may spring from the lateral aspect of the humerus or intertubercular sulcus.

Relations Biceps is overlapped proximally by pectoralis major and deltoid; distally, it is covered only by fasciae and skin, and it forms a conspicuous elevation on the front of the arm. Its long head passes through the shoulder joint; its short head is anterior to the joint. Distally, it lies anterior to brachialis, the musculocutaneous nerve and supinator. Its medial border touches coracobrachialis and overlaps the brachial vessels and median nerve; its lateral border is related to deltoid and brachioradialis.

Vascular supply Biceps brachii is typically supplied by up to eight vessels originating from the brachial artery in the middle third of the arm. These vessels pass laterally, posterior to the median nerve, and divide into ascending and descending branches just before reaching the deep surface of the muscle. Smaller branches arise from the anterior circumflex humeral artery and the deltoid branch of the acromial division of the thoraco-acromial axis.

There is great variation in the arterial supply to the muscle. The main arterial supply may originate from the superior or inferior ulnar collateral arteries, subscapular artery, axillary artery, ulnar or radial arteries in cases of proximal bifurcation of the brachial artery, or the profunda brachii artery. There is often a single large pedicle, attending the nerve to biceps; injury to the muscle and musculocutaneous nerve at this level in the arm commonly results in a fibrotic, atonic muscle with distal sensory dysfunction.

Innervation Biceps brachii is innervated by the musculocutaneous nerve, C5 and 6, with separate branches passing to each belly.

Actions Biceps brachii is a powerful supinator, especially in rapid or resisted movements. It flexes the elbow - most effectively, with the forearm supinated - and acts, to a slight extent, as a flexor of the shoulder joint. The long head helps to check upward translation of the humeral head during contraction of deltoid, in synergy with the action of the rotator cuff. It is attached, via the bicipital aponeurosis, to the posterior border of the ulna, the distal end of which is drawn medially in supination. When the elbow is flexed against

Pain is generated during abduction of the arm in the scapular plane; typically, an arc of pain is experienced (between $60^{\circ}$ and $120^{\circ}$ of elevation, the impingement arc). Rotator cuff disease is a painful condition with a multifactorial aetiology, in which severe or chronic impingement of the rotator cuff tendons on the undersurface of the coraco-acromial arch is often a significant factor. The supraspinatus tendon is anatomically affected most by the impingement, which coincides with an area of reduced vascularity in this tendon. When associated with a tendinopathy from age-related degenerative changes within the tendon, impingement may be associated with partial or complete tears of the cuff. Clinically, this condition causes tenderness over the anterior portion of the acromion, and pain that typically occurs on abducting the shoulder between $60^{\circ}$ and $120^{\circ}$ (the painful arc).

Lowering the hand under the influence of gravity by extension at the elbow calls for controlled lengthening of biceps brachii. This is an example of a habitual movement in which muscle tension increases despite increasing length. (This is 'eccentric' loading of a muscle; during such loading, the muscle-tendon junction is at greater risk of rupture. 'Concentric' loading occurs when the muscle shortens as tension increases, see p. 114.) As the hand descends and the elbow extends, the vertical through the centre of gravity of the forearm is carried further from the fulcrum of movement; therefore, the turning moment exerted by the load increases and must be matched by an increase in the moment exerted by the muscle.

Fig. 48.29 Muscles, vessels and nerves of the left upper arm, anterior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
resistance, the tendon of insertion and bicipital aponeurosis become conspicuous.

Testing With the forearm supinated, biceps brachii can be tested by palpating its fibres during elbow flexion against resistance.

## Brachialis

Attachments Brachialis arises from the lower half of the anterior surface of the shaft of the humerus, starting on either side of the insertion of deltoid, and extending distally to within 2.5 cm of the cubital articular surface (Fig. 48.30). It also arises from the intermuscular septa, more from the medial than the lateral, since it is separated distally from the lateral intermuscular septum by brachioradialis and extensor carpi radialis longus. Its fibres converge to a thick, broad tendon that is attached to the ulnar tuberosity and to a rough impression on the anterior aspect of the coronoid process (see Fig. 49.5).

Brachialis may be divided into two or more parts. It may be fused with brachioradialis, pronator teres or biceps. In some cases, it sends a tendinous slip to the radius or to the bicipital aponeurosis.

Relations Biceps, the brachial vessels and the musculocutaneous and median nerves are anterior. The humerus and the capsule of the elbow joint are posterior. Pronator teres and the medial intermuscular septum, which separates it from triceps and the ulnar nerve, are medial. The radial nerve, radial recurrent and radial collateral arteries, brachioradialis and extensor carpi radialis longus are all lateral.

Vascular supply The blood supply to brachialis typically consists of two main arteries (superior and inferior), supplemented by a system of accessory arteries. The superior main artery originates from the brachial

Fig. 48.30 A, A transverse section through the left arm, a little below the middle of the shaft of the humerus. B, A magnetic resonance imaging (MRI) scan at a similar level.
artery distal to the site of origin of the superior ulnar collateral artery and travels laterally to enter the anterior surface of the upper third of the muscle. The inferior main artery originates either from the superior ulnar collateral artery or directly from the brachial artery, and enters the mid-portion of the muscle. The accessory arteries are small and variable in number, origin and course. They can arise from the brachial artery, the superior and inferior ulnar collateral arteries, or the profunda brachii artery. The fact that brachialis has a greater vascular supply than biceps brachii suggests that its metabolic demands are greater; brachialis is the prime flexor of the forearm at the elbow, while biceps has more subtle actions on the shoulder and elbow, coordinating the two joints while positioning the hand in space.

Innervation Brachialis is innervated by at least two branches. The musculocutaneous nerve (C5 and 6) supplies a large medial part of the muscle, and the radial nerve (C7) supplies a small lateral part. This arrangement is consistent (Oberlin et al 1994).

Action Brachialis is a flexor of the elbow joint with the forearm either prone or supine, whether or not the movement is resisted.

Testing Brachialis can be tested by palpating its fibres during elbow flexion against resistance.

## Posterior compartment of the arm

## Triceps

Attachments Triceps fills most of the extensor compartment of the upper arm (see Figs 48.28-48.30). It has three heads (long, lateral and medial), from which it takes its name.

The long head arises by a flattened tendon from the infraglenoid tubercle of the scapula, blending above with the glenohumeral capsule. Its muscular fibres descend medial to the lateral head and superficial to the medial head, and join them to form a common tendon. The lateral head arises by a flattened tendon from a narrow, linear, oblique ridge on the posterior surface of the humeral shaft, and from the lateral intermuscular septum. The origin on the humerus ascends with varying obliquity from its lateral border above the radial groove and behind the deltoid tuberosity to the surgical neck medial to the insertion of teres minor. These fibres also converge to the common tendon. The medial head, which is overlapped posteriorly by the lateral and long heads, has a particularly extensive origin. It is attached to the entire posterior surface of the humeral shaft, below the radial groove from the insertion of teres major to within 2.5 cm of the trochlea; the medial border of the humerus; the medial intermuscular septum; and the lower part of the lateral intermuscular septum. Some muscular fibres reach the olecranon directly; the rest converge to the common tendon (Keener et al 2010). Some fibres from the medial head attach to the posterior capsule of the elbow joint, like those of articularis genus in the knee; these fibres are the articularis cubiti.

The tendon of triceps begins near the middle of the muscle. It has two laminae organized in a similar arrangement to the tendon of the gastrocnemii and soleus in the posterior compartment of the leg. The superficial lamina in the lower half of the superficial parts of the muscle forms an aponeurotic layer to which the deep fascia of the arm is adherent; the other lamina is more vertical. After receiving the muscle fibres, the two layers unite above the elbow and are attached, for the most part, to the upper surface of the olecranon. On the lateral side, a band of fibres continues down over anconeus to blend with antebrachial fascia.

Relations The long head of triceps descends between teres minor and major, dividing the wedge-shaped interval between them and the humerus into triangular and quadrangular spaces (Fig. 48.28). The lateral head of triceps forms an elevation, parallel and medial to the posterior border of deltoid, which stands out prominently when the elbow is actively extended. The mass that lies medial to it, and that disappears under deltoid, is the long head.

Vascular supply The blood supply to triceps is mainly from the profunda brachii artery and the superior ulnar collateral artery, with an accessory supply from the posterior circumflex humeral artery. The medial head of triceps is supplied on its anterior surface by two or three branches from the superior ulnar collateral artery. The posterior surface is supplied by a large proximal branch from the profunda brachii that passes medially anterior to the radial nerve. The long head of triceps is supplied on its anterior surface by two arteries, one arising from the axillary artery anterior to the tendon of latissimus dorsi and the other arising from either the brachial artery or the superior ulnar collateral artery. The posterior surface receives a recurrent branch from the posterior circumflex humeral artery immediately after it has traversed the quadrangular space. The lateral surface receives a number of small branches from the profunda brachii artery in its distal portion. The lateral head of triceps is primarily supplied by branches of the profunda brachii, with an additional supply from a branch of the posterior circumflex humeral artery.

Innervation Triceps is innervated by branches from the radial nerve, C6 (lateral head), 7 (long head) and 8 (medial head); there are separate branches for each head.

Actions Triceps is the major extensor of the forearm at the elbow joint. The medial head is active in all forms of extension, whereas the lateral and long heads are minimally active, except in extension against resistance, as in thrusting or pushing or supporting body weight on the hands with the elbows semi-flexed. When the flexed arm is extended at the shoulder joint, the long head may assist in drawing back and adducting the humerus to the thorax. The long head supports the lower part of the capsule of the shoulder joint, especially when the arm is raised.

Articularis cubiti probably draws up the posterior part of the capsule of the elbow joint during extension of the forearm. In forceful supination of the semi-flexed forearm, involving contraction of both supinator and biceps brachii, triceps contracts synergistically to maintain the semiflexed position.

Testing Triceps can be tested by palpating its fibres during elbow extension against resistance.

## Quadrangular and triangular spaces

The quadrangular space (quadrilateral space; foramen of Velpeau) is more a horizontal cleft or tunnel than a vertical space; it has defined boundaries. Anteriorly, the space is bounded by subscapularis, the capsule of the shoulder joint and teres minor superiorly, teres major inferiorly, the long head of triceps medially and the surgical neck of the humerus laterally. Posteriorly, the quadrangular space is bounded above by teres minor. The axillary nerve and the posterior circumflex humeral artery and vein pass obliquely through the space (see Figs 48.33, 48.47).

There are two triangular spaces (see Figs 48.28, 48.47). The upper triangular space is bounded above by subscapularis anteriorly, teres minor posteriorly, teres major inferiorly and the long head of triceps laterally. The circumflex scapular vessels pass through this space. The lower triangular space (the triangular interval) is bounded above by subscapularis anteriorly, teres major posteriorly, the long head of triceps medially and the humerus laterally. The radial nerve and the profunda brachii vessels pass through this space.

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES

## Dorsal scapular artery

In the majority of cases, the dorsal scapular artery arises from the third, or less often the second, part of the subclavian artery. It passes laterally through the trunks of the brachial plexus in front of scalenus medius and then deep to levator scapulae to reach the superior scapular angle. Here, it descends with the dorsal scapular nerve under the rhomboids along the medial border of the scapula to the inferior angle. It supplies the rhomboids, latissimus dorsi and the inferior portion of trapezius and the skin over the inferomedial aspect of trapezius via musculocutaneous perforators. It anastomoses with the suprascapular and subscapular arteries and with posterior branches of some posterior intercostal arteries. It sends a small branch to scalenus anterior; sometimes, this arises directly from the subclavian artery.

Variants About one-third of the superficial cervical and dorsal scapular arteries arise as a common vessel - the transverse cervical artery from the thyrocervical trunk, which then divides into a superficial and a deep branch (superficial cervical and dorsal scapular arteries, respectively) (see Figs 26.1A, 48.31). In this case, the dorsal scapular artery arises near the superior border of the scapula; it passes laterally, anterior to the brachial plexus and then posterior to levator scapulae.

## Suprascapular artery

The suprascapular artery usually arises from the thyrocervical trunk of the subclavian artery, although it may arise from the third part of the subclavian artery (see Fig. 29.7A). It first descends laterally across scalenus anterior and the phrenic nerve, posterior to the internal jugular vein and sternocleidomastoid, then crosses anterior to the subclavian artery and brachial plexus, posterior and parallel with the clavicle, subclavius and the inferior belly of omohyoid, to reach the superior border of the scapula. Here, it passes above (sometimes, under) the superior transverse ligament, separating it from the suprascapular nerve, and enters the supraspinous fossa (Fig. 48.31, see Fig. 48.33), where it lies on the bone, and supplies supraspinatus. It descends behind the scapular neck, and passes through the spinoglenoid notch deep to the inferior transverse ligament to gain the deep surface of infraspinatus, where it anastomoses with the circumflex scapular and deep branch of the transverse cervical artery. Its muscular branches supply sternocleidomastoid, subclavius and infraspinatus. It also gives off a suprasternal branch that crosses the sternal end of the clavicle to supply the skin of the upper thorax, and an acromial branch that pierces trapezius to supply the skin over the shoulder. This last branch anastomoses with the thoracoacromial and posterior circumflex humeral arteries.

As the suprascapular artery passes over the superior transverse ligament, it gives off a branch that enters the subscapular fossa beneath

Fig. 48.32 Axillary angiograms. A, View with the arm by the side. B, View with the arm elevated.
subscapularis and anastomoses with the subscapular artery and the deep branch of the transverse cervical artery. It also supplies the acromioclavicular and glenohumeral joints, the clavicle and the scapula.

## Angiomyosomes

Available with the Gray's Anatomy e-book

## Supraclavicular artery

This small vessel arises from either the transverse cervical or superficial cervical artery. It pierces the deep fascia just superior to the clavicle and anterior to trapezius, and supplies an area of skin over the lateral end of the clavicle.

## Axillary artery

The axillary artery, a continuation of the subclavian artery, begins at the outer border of the first rib and ends nominally at the inferior border of teres major, where it becomes the brachial artery (see Fig. 48.31). Its direction varies with the position of the limb; it is almost straight when the arm is raised at right angles, concave upwards when the arm is
elevated above this, and convex upwards and laterally when the arm is by the side (Fig. 48.32). At first deep, it subsequently becomes superficial, when it is covered only by the skin and fasciae. Pectoralis minor crosses it and so divides it into three parts, which are proximal, posterior and distal to the muscle.

## Relations of the first part

The skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular fibres of pectoralis major and the clavipectoral fascia, lateral pectoral nerve and the loop of communication between the lateral and medial pectoral nerves, and the thoraco-acromial and cephalic veins are all anterior. The first intercostal space and external intercostal, first and second digitations of serratus anterior, long thoracic and medial pectoral nerves, and the medial cord of the brachial plexus are all posterior. The posterior cord of the brachial plexus is lateral and the axillary vein is anteromedial. The first part is enclosed with the axillary vein and brachial plexus in a fibrous axillary sheath, which is continuous with the prevertebral layer of the deep cervical fascia.

## Relations of the second part

The skin, superficial and deep fascia, and pectoralis major and minor are all anterior. The posterior cord of the brachial plexus and the areolar tissue between it and subscapularis are posterior. The axillary vein is

Two branches of the subclavian artery perfuse the dorsal scapular suspension and medial motion muscles (the dorsal scapular artery), the posterosuperior rotator cuff muscles (the suprascapular artery) and the clavicle. These vessels correspond to the equivalent innervation for the same muscles. In this sense, innervation and angiomyotomes correspond. Pain afferents from the muscles, mostly small, unmyelinated axons, travel in the nerves; ischaemic ('fatigue-related') pain from these three groups of dorsal muscles is felt as a diffuse, burning sensation in the same region as the vascular supply, without radiation or referral, and without respite during rest for a characteristic period, somewhat equivalent to the period over which the symptoms of a chronic ischaemic muscular compartment syndrome may resolve. The suprascapular artery supplies a muscular compartment that is contained in a welldefined and relatively restricting fascia; it is, therefore, not a surprise that the ischaemic ('fatigue-related') pain generated in this compartment may present earlier and be more persistent than elsewhere in muscles less well contained by fascial sheaths.
medial, separated from the artery by the medial cord of the brachial plexus and the medial pectoral nerve. The lateral cord of the brachial plexus is lateral, separating the artery from coracobrachialis. The cords of the brachial plexus thus surround the second part on three sides, with the dispositions implied by their names, and separate it from the vein and adjacent muscles.

## Relations of the third part

Pectoralis major and, distal to the muscle, skin and fasciae are anterior. The lower part of subscapularis and the tendons of latissimus dorsi and teres major are posterior. Coracobrachialis is lateral and the axillary vein is medial. Branches of the brachial plexus are arranged as follows: laterally, the lateral root and then trunk of the median nerve and, for a short distance, the musculocutaneous nerve; medially, the medial cutaneous nerve of the forearm between the axillary artery and vein anteriorly, and the ulnar nerve between these vessels posteriorly; anteriorly, the medial root of the median nerve; and posteriorly, the radial and axillary nerves, the latter only to the distal border of subscapularis. The dispositions of the branches of the brachial plexus around the axillary artery have, therefore, altered: there has been a rotation such that the nerves derived from the lateral cord are now more anterior, those from the medial cord more posterior, and those of the posterior cord come to lie more laterally.

## Branches

The branches of the axillary artery are one from the first part (superior thoracic), two from the second part (thoraco-acromial, lateral thoracic) and three from the third part (subscapular, anterior and posterior circumflex humeral) (see Fig. 48.47).

## Superior thoracic artery

The superior thoracic artery is a small vessel that arises from the first part of the axillary artery near the lower border of subclavius; it sometimes arises from the thoraco-acromial artery (see Fig. 48.47). It runs anteromedially above the medial border of pectoralis minor, then passes between it and pectoralis major to gain the thoracic wall. It supplies these muscles and the thoracic wall, and anastomoses with the internal thoracic and upper intercostal arteries.

## Thoraco-acromial (acromiothoracic) artery

The thoraco-acromial artery is a short branch that arises from the second part of the axillary artery (see Figs 48.27, 48.47). It is, at first, overlapped by pectoralis minor, skirting its medial border; it next pierces the clavipectoral fascia and divides into pectoral, acromial, clavicular and deltoid branches, which supply pectoralis major and minor, an area of skin over the clavipectoral fascia, and the anterior portion of deltoid.

Pectoral branch The pectoral branch is the largest branch. It descends between the pectoral muscles, gives a branch to pectoralis minor, and then continues on the deep surface of pectoralis major. It enters the muscle and anastomoses with the intercostal branches of the internal thoracic and lateral thoracic arteries. It gives off perforating branches to the breast, and musculocutaneous perforators to the skin over pectoralis major.

Acromial branch The acromial branch crosses the coracoid process under deltoid, which it supplies, then pierces the muscle and ends on the acromion. It anastomoses with branches of the suprascapular artery, the deltoid branch of the thoraco-acromial artery and the posterior circumflex humeral arteries.

Clavicular branch The clavicular branch ascends medially between the clavicular part of pectoralis major and the clavipectoral fascia. It supplies the sternoclavicular joint and subclavius.

Deltoid branch The deltoid branch often arises with the acromial branch. It crosses pectoralis minor to accompany the cephalic vein between pectoralis major and deltoid, and supplies both muscles.

## Lateral thoracic artery

The lateral thoracic artery arises from the second part of the axillary artery. Following the lateral border of pectoralis minor, it passes to the deep surface of pectoralis major as far distally as the fifth intercostal space (see Fig. 48.45). It supplies serratus anterior and the pectoral muscles, the axillary lymph nodes and subscapularis. It anastomoses with the internal thoracic, subscapular and intercostal arteries, and with the pectoral branch of the thoraco-acromial artery. In females, it is large and has lateral mammary branches, which curve round the lateral
border of pectoralis major to the breast. In both males and females, it gives off cutaneous branches that pass around the lateral border of pectoralis major to supply the skin in this region.

## Subscapular artery

The subscapular artery is the largest branch of the axillary artery (see Figs 48.31, 48.47). It usually arises from the third part of the axillary artery at the distal (inferior) border of subscapularis, which it follows to the inferior scapular angle, where it anastomoses with the lateral thoracic and intercostal arteries and the deep branch of the transverse cervical artery. It supplies adjacent muscles and the thoracic wall. It is accompanied distally by the nerve to latissimus dorsi. Approximately 4 cm from its origin, the subscapular artery divides into the circumflex scapular and thoracodorsal arteries.

Circumflex scapular artery The circumflex scapular artery, the larger of the two terminal branches of the subscapular artery, curves backwards around the lateral border of the scapula, traversing a triangular space between subscapularis above, teres major below and the long head of the triceps laterally (see Fig. 48.33). It enters the infraspinous fossa under teres minor and then divides. One branch (infrascapular) enters the subscapular fossa deep to subscapularis, and anastomoses with the suprascapular and dorsal scapular arteries (or deep branch of the transverse cervical artery). The other branch continues along the lateral border of the scapula between teres major and minor, then, dorsal to the inferior angle, anastomoses with the dorsal scapular artery. Small branches supply the posterior part of deltoid and the long head of triceps, and anastomose with an ascending branch of the profunda brachii artery.

Thoracodorsal artery The other terminal branch of the subscapular artery, the thoracodorsal artery, follows the lateral margin of the scapula, posterior to the lateral thoracic artery, between latissimus dorsi and serratus anterior. Before entering the deep surface of latissimus dorsi, it supplies teres major and the intercostals, and sends one or two branches to serratus anterior. It enters latissimus dorsi muscle with the thoracodorsal nerve; this constitutes the principal neurovascular pedicle to the muscle. It provides numerous musculocutaneous perforators that supply the skin over the superior part of latissimus dorsi. The intramuscular portion of the artery anastomoses with intercostal arteries and lumbar perforating arteries.

## Anterior circumflex humeral artery

The anterior circumflex humeral artery arises from the lateral side of the axillary artery at the distal border of subscapularis (see Fig. 48.31). It runs horizontally behind coracobrachialis and the short head of biceps, anterior to the surgical neck of the humerus. Reaching the intertubercular sulcus, it sends an ascending branch to supply the humeral head and shoulder joint (Brooks et al 1993). It continues laterally under the long head of biceps and deltoid, and anastomoses with the posterior circumflex humeral artery.

## Posterior circumflex humeral artery

The posterior circumflex humeral artery is larger than the anterior (see Fig. 48.31). It branches from the third part of the axillary artery at the distal border of subscapularis and runs backwards with the axillary nerve through a quadrangular space (see Fig. 48.22B), which is bounded by subscapularis, the capsule of the shoulder joint and teres minor above, teres major below, the long head of triceps medially, and the surgical neck of the humerus laterally. It curves round the humeral neck and supplies the shoulder joint, deltoid, teres major and minor, and long and lateral heads of triceps (Gerber et al 1990). It gives off a descending branch that anastomoses with the deltoid branch of the profunda brachii artery and with the anterior circumflex humeral and acromial branches of the suprascapular and thoraco-acromial arteries.

## Variants

The branches of the axillary artery exhibit considerable variation. An alar thoracic artery, often from the second part, may supply fat and lymph nodes in the axilla. The lateral thoracic artery may be absent, in which case it is replaced by lateral perforating branches of the intercostal arteries; alternatively, it may become, or give off, a direct cutaneous vessel (named the superficial thoracic artery by some sources) that supplies the skin over the lateral border of pectoralis major. In up to onethird of cases, the subscapular artery can arise from a common trunk with the posterior circumflex humeral artery. Occasionally, the subscapular, circumflex humeral and profunda brachii arteries arise in common; in this case, branches of the brachial plexus surround this common vessel instead of the axillary artery. The posterior circumflex

Two significant cutaneous branches arise from the circumflex scapular artery as it emerges through the upper triangular space. The superior, or horizontal, branch is a direct cutaneous artery that passes medially at the level of the deep fascia parallel with the spine of the scapula; it supplies a band of skin overlying the spine of the scapula. The lower branch (parascapular branch) is also a direct cutaneous vessel that passes in an inferomedial direction, again at the level of the deep fascia, and supplies an area of skin overlying the lateral border of the scapula. Both of these cutaneous vessels provide the anatomical basis of skin flaps that can be surgically raised in this region (scapular flap based on the horizontal branch and parascapular flap based on the lower, parascapular branch) to reconstruct areas of missing tissue elsewhere in the body.
humeral artery may arise from the profunda brachii artery and pass back below teres major, instead of passing through the quadrangular space. Sometimes, the axillary artery divides into radial and ulnar arteries (anomalous 'high division'), and is, occasionally, the source of the anterior interosseous artery.

## Potential vascular anastomoses around the shoulder girdle: clinical relevance

Available with the Gray's Anatomy e-book

## Angiomyosomes

Available with the Gray's Anatomy e-book

## Brachial artery

The brachial artery, a continuation of the axillary, begins at the distal (inferior) border of the tendon of teres major and ends about a centimetre distal to the elbow joint (at the level of the neck of the radius) by dividing into the radial and ulnar arteries (see Figs 48.33, 48.44, $49.21,49.22$ ). At first, it is medial to the humerus, but gradually spirals anterior to it until it lies midway between the humeral epicondyles. Its pulsation can be felt throughout the arm.

Relations The brachial artery is wholly superficial, covered anteriorly only by skin and superficial and deep fasciae. The bicipital aponeurosis crosses it anteriorly at the elbow, separating it from the median cubital vein; the median nerve crosses it lateromedially near the distal attachment of coracobrachialis. Posterior to the artery are the long head of triceps, separated by the radial nerve and profunda brachii artery, and then successively by the medial head of triceps, the attachment
of coracobrachialis and brachialis. Proximally, the median nerve and coracobrachialis lie laterally and the medial cutaneous nerve of the forearm and ulnar nerve lie medially. Distally, biceps brachii overlaps the artery laterally and the median nerve and basilic vein lie medially. The artery is accompanied by two venae comitantes, connected by transverse and oblique branches. At the elbow, the brachial artery sinks deeply into the triangular intermuscular cubital fossa and its further course is described on page 856 .

Variants The brachial artery, with the median nerve, may diverge from the medial border of biceps brachii and descend towards the medial humeral epicondyle, usually behind a supracondylar process from which a fibrous arch crosses the artery, and which then runs behind or through pronator teres to the elbow. Occasionally, the artery divides proximally into two trunks that reunite. Frequently, it divides more proximally than usual into radial, ulnar and common interosseous arteries. Most often, the radial branches arise proximally, leaving a common trunk for the ulnar and common interosseous arteries. Sometimes, the ulnar artery arises proximally and the radial and common interosseous arteries form the other division, or the common interosseous may also arise proximally. Slender vasa aberrantia may connect the brachial artery to the axillary artery or to one of the forearm arteries, usually the radial. The brachial artery may be crossed by muscular or tendinous slips from coracobrachialis, biceps brachii, brachialis or pronator teres. Rarely, the median nerve crosses posterior, rather than anterior, to the brachial artery near the insertion of coracobrachialis.

Branches The branches of the brachial artery are the profunda brachii, nutrient, superior, middle and inferior ulnar collateral, deltoid, muscular, radial and ulnar arteries.

Profunda brachii artery The profunda brachii (Fig. 48.33; see Figs $48.29,48.31$ ) is a large branch from the posteromedial aspect of the

Fig. 48.33 Muscles, vessels and nerves of the left upper arm, posterior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The potential vascular anastomoses around the shoulder girdle are numerous, so that collateral perfusion of the upper limb is possible in axillary artery or vein occlusion. In acute occlusion of the axillary artery, these potential anastomoses are not reliable; clinicians should not rely on anastomotic perfusion of the acutely ischaemic limb. The axillary artery is most 'at risk' of occlusion due to intimal separation and dissection in its second part, behind the pectoralis minor. This injury is associated with infraclavicular brachial plexus traction lesions (Birch 2011). Although magnetic resonance imaging (MRI) with angiography is recommended for the diagnosis of the poorly perfused limb after distraction trauma, the site of intimal rupture is so consistent as to make urgent surgical exploration without imaging a reasonable clinical decision.

The axillary artery supplies the muscles of the ventral compartments of the shoulder, including the pectoral-deltoid muscle sheet, the scapulohumeral muscles (other than the posterosuperior rotator cuff) and the shoulder joint, including the scapula (with the serratus muscles) and proximal humerus. Its terminal branch, the brachial artery, supplies the muscles of the anterior compartment of the arm (for the branches of the brachial artery at the elbow and in the forearm, see pages 856-858); the profunda brachii artery, the major proximal branch of the brachial artery, supplies the muscles of the posterior compartment of the arm and the shaft of the humerus.
brachial artery, distal to teres major. It follows the radial nerve closely, at first posteriorly between the long and medial heads of triceps, then in the spiral groove covered by the lateral head of triceps. It supplies muscular branches, and the nutrient artery of the humerus, and finally divides into terminal radial and middle collateral branches (see Fig. 48.33). The radial collateral branch pierces the lateral intermuscular septum to reach the anterior aspect of the epicondyle of the humerus in the groove between brachioradialis and brachialis, and takes part in the anastomosis around the elbow. The middle collateral branch runs posterior to the septum and epicondyle.

The profunda brachii may originate from a common origin with the posterior circumflex humeral artery, from the axillary artery proximal to the tendon of latissimus dorsi, or from the distal portion of the axillary artery.

Middle collateral (posterior descending) branch The middle collateral artery is the larger terminal branch of the profunda brachii artery. It arises posterior to the humerus and descends along the posterior surface of the lateral intermuscular septum to the elbow. Proximally, the artery lies between brachialis (anteriorly) and the lateral head of triceps (posteriorly). Distally, it lies between brachioradialis (anteriorly) and the lateral head of triceps (posteriorly). It may pierce the deep fascia and become cutaneous, or remain deep to the fascia until it anastomoses with the interosseous recurrent artery behind the lateral epicondyle; it gives off about five small fasciocutaneous perforators and often has a small branch that accompanies the nerve to anconeus.

Radial collateral (anterior descending) branch The radial collateral artery accompanies the radial nerve through the lateral intermuscular septum, descending between brachialis and brachioradialis anterior to the lateral epicondyle and anastomosing with the radial recurrent artery (see Figs 49.29, 49.31). It supplies brachialis, brachioradialis, the radial nerve and a few fasciocutaneous perforators.

Nutrient artery of humerus The nutrient artery of the humerus arises near the mid-level of the upper arm and enters the nutrient canal near the attachment of coracobrachialis, posterior to the deltoid tuberosity; it is directed distally.

Superior ulnar collateral artery The superior ulnar collateral artery arises a little distal to the mid-level of the upper arm, usually from the brachial artery, but often as a branch from the profunda brachii (see Fig. 48.44). It accompanies the ulnar nerve, piercing the medial intermuscular septum to descend in the posterior compartment and supply the medial head of triceps. It passes between the medial epicondyle and olecranon, ending deep to flexor carpi ulnaris by anastomosing with the posterior ulnar recurrent and inferior collateral arteries. A branch sometimes passes anterior to the medial epicondyle and anastomoses with the anterior ulnar recurrent artery.

Middle ulnar collateral artery If present, the middle ulnar collateral artery arises from the brachial artery between the superior and inferior ulnar collateral arteries. It passes anterior to the medial epicondyle and anastomoses with the anterior ulnar recurrent artery. It supplies triceps and sends small fasciocutaneous perforators to the skin.

Inferior ulnar collateral (supratrochlear) artery The inferior ulnar collateral artery begins approximately 5 cm proximal to the elbow, passes medially between the median nerve and brachialis, and, piercing the medial intermuscular septum, curls round the humerus between triceps and bone (see Fig. 48.33). By its junction with the middle collateral branch of the profunda brachii artery, it forms an arch proximal to the olecranon fossa. As it lies on brachialis, it gives off branches that descend anterior to the medial epicondyle to anastomose with the anterior ulnar recurrent artery. Behind the epicondyle, a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

Muscular branches Muscular branches are distributed to coracobrachialis, biceps and brachialis.

Deltoid (ascending) branch The deltoid branch ascends between the lateral and long heads of triceps, and anastomoses with a descending branch of the posterior humeral circumflex artery.

Radial and ulnar arteries The radial and ulnar arteries are described in detail on page 856 and 857 , respectively. For an account of the anastomosis about the elbow, see page 858.

## VEINS

The deep veins have numerous anastomoses with each other and with the superficial veins.

## Axillary vein

The axillary vein is the continuation of the basilic vein (see Fig. 46.4). It begins at the lower border of teres major and ascends to the outer border of the first rib, where it becomes the subclavian vein. It is joined by the brachial vein near subscapularis, and by the cephalic vein near its costal end; other tributaries follow the axillary arterial branches. It lies medial to the axillary artery, which it partly overlaps. The medial pectoral nerve, medial cord of the brachial plexus, ulnar nerve and medial cutaneous nerve of the forearm lie between the artery and the vein. The medial cutaneous nerve of the arm is medial to the vein; the lateral group of axillary lymph nodes is posteromedial. There are a pair of valves near its distal end, and valves also occur near the ends of the cephalic and subscapular veins.

## Subclavian vein

The subclavian vein is a continuation of the axillary vein (see Fig. 46.4). It extends from the outer border of the first rib to the medial border of scalenus anterior, where it joins the internal jugular to form the brachiocephalic vein. The clavicle and subclavius are anterior; the subclavian artery is posterosuperior, separated by scalenus anterior and the phrenic nerve; and the first rib and pleura are inferior. The vein usually has a pair of valves about 2 cm from its end. Its tributaries are the external jugular, dorsal scapular and (sometimes) anterior jugular veins, and, occasionally, a small branch from the cephalic vein that ascends anterior to the clavicle. At its junction with the internal jugular vein, the left subclavian receives the thoracic duct, and the right subclavian vein receives the right lymphatic duct (see Fig. 29.16).

## Brachial veins

The brachial veins flank the brachial artery, as venae comitantes with tributaries similar to the arterial branches; they join the axillary vein near the lower margin of subscapularis. The medial branch often joins the basilic vein before it becomes the axillary vein.

## Superficial veins

The cephalic vein ascends anterior to the elbow, superficial to a groove between brachioradialis and biceps brachii, crosses superficial to the lateral cutaneous nerve of the forearm, and ascends lateral to biceps and between pectoralis major and deltoid, where it adjoins the deltoid branch of the thoraco-acromial artery (Fig. 48.34). Entering the infraclavicular fossa to pass posterior to the clavicular head of pectoralis major, it pierces the clavipectoral fascia, crosses the axillary artery and joins the axillary vein just below clavicular level. It may connect with the external jugular vein by a branch anterior to the clavicle. Sometimes, the median cubital vein is large, transferring most blood from the cephalic to the basilic vein, in which case the proximal cephalic vein is either absent or much diminished.

## LYMPHATIC DRAINAGE

Lymphatics follow the usual pattern, in that superficial lymphatics follow the veins, and deep lymphatics follow the arteries. For details of the infraclavicular nodes, see Fig. 48.45 and page 834.

## INNERVATION

## BRACHIAL PLEXUS

For an overview of the brachial plexus, see pages 781-786 and Figure 46.7.

In the axilla, the lateral and posterior cords of the brachial plexus are anterior and lateral to the first part of the axillary artery, respectively, and the medial cord is behind the artery. The cords assume their appropriate relations around the second part of the artery, deep to pectoralis major. In the lower axilla, the cords divide into nerves that supply the upper limb (Fig. 48.35). Other than the medial root of the median

Fig. 48.34 Superficial veins and nerves, left arm, anterior (flexor) aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
nerve, these nerves are related to the third part of the artery in the same way as their cords are related to the second part, i.e. branches of the lateral cord are lateral to the artery, branches of the medial cord are medial, and branches of the posterior cord are posterior.

## Suprascapular nerve

The suprascapular nerve is a large branch of the upper trunk (C5, 6) (see Figs 29.17, 48.35). It runs laterally, deep to trapezius and omohyoid, and enters the supraspinous fossa through the suprascapular notch inferior to the superior transverse scapular ligament. It runs deep to supraspinatus, supplies it, and curves round the lateral border of the spine of the scapula with the suprascapular artery to reach the infraspinous fossa, where it gives two branches to infraspinatus and articular rami to the shoulder and acromioclavicular joints. The suprascapular nerve rarely has a cutaneous branch. When present, it pierces deltoid close to the tip of the acromion and supplies the skin of the proximal third of the arm within the territory of the axillary nerve.

## Lateral pectoral nerve

The lateral pectoral nerve (C5, 6) is larger than the medial, and may arise either from the anterior divisions of the upper and middle trunks, or by a single branch from the lateral cord, just above or deep to the clavicle. It crosses anterior to the axillary artery and vein, pierces the clavipectoral fascia and supplies the deep surface of pectoralis major. It sends a branch to the medial pectoral nerve, forming a loop in front of the first part of the axillary artery to supply some fibres to pectoralis minor.

## Medial pectoral nerve

The medial pectoral nerve ( $\mathrm{C} 8, \mathrm{~T} 1$ ) branches from the medial cord while the latter lies posterior to the axillary artery and curves forwards between the axillary artery and vein. Anterior to the artery, it joins a ramus of the lateral pectoral nerve and enters the deep surface of pectoralis minor, which it supplies. Two or three branches pierce pectoralis minor and others may pass round its inferior border to end in pectoralis major.

## Upper (superior) subscapular nerve

The superior subscapular nerve is smaller than the inferior. It arises from the posterior cord (C5, 6), enters subscapularis at a high level, and is frequently double.

## Lower (inferior) subscapular nerve

The inferior subscapular nerve arises from the posterior cord (C5, 6). It supplies the lower part of subscapularis and ends in teres major, which is sometimes supplied by a separate branch.

## Thoracodorsal nerve

The thoracodorsal nerve arises from the posterior cord (C6-8) between the subscapular nerves. It accompanies the subscapular artery along the posterior axillary wall and supplies latissimus dorsi, reaching its distal border (see Fig. 48.29).

## Axillary nerve

The axillary nerve arises from the posterior cord (C5, 6) (see Figs 48.33, $48.35,46.8$ ). It is, at first, lateral to the radial nerve, posterior to the axillary artery and anterior to subscapularis. At the lower border of subscapularis, it curves back inferior to the humeroscapular articular capsule and, with the posterior circumflex humeral vessels, traverses a quadrangular space bounded above by subscapularis (anteriorly) and teres minor (posteriorly), below by teres major, medially by the long head of triceps, and laterally by the surgical neck of the humerus. It divides in the space into anterior and posterior branches. The anterior branch curves round the neck of the humerus with the posterior circumflex humeral vessels, deep to deltoid, to reach the anterior part of the muscle. At the level of the anterior border of the acromion, the nerve often consists of two or more thin filaments that supply the anterior deltoid; it gives off a few small cutaneous branches that pierce deltoid and ramify in the skin over its lower part. The posterior branch courses medially and posteriorly along the attachment of the lateral head of triceps, inferior to the glenoid rim. It usually lies medial to the anterior branch in the quadrangular space. It gives off the nerve to teres minor and the upper lateral cutaneous nerve of the arm at the lateral edge of the attachment of the long head of triceps. The nerve to teres minor enters the muscle on its inferior surface. The posterior branch frequently supplies the posterior aspect of deltoid, usually via a separate branch from the main stem, but occasionally from the superior lateral cutaneous nerve of the arm. However, the posterior part of deltoid has a more consistent supply from the anterior branch of the axillary nerve, which should be remembered when performing a posterior deltoid-splitting approach to the shoulder. The upper lateral cutaneous nerve of the arm pierces the deep fascia at the medial border of the posterior aspect of deltoid, and supplies the skin over the lower part of deltoid and the upper part of the long head of triceps. The posterior branch is intimately related to the inferior aspects of the glenoid and shoulder joint capsule. There is often an enlargement or pseudoganglion on the branch to teres minor. The axillary trunk supplies a branch to the shoulder joint below subscapularis.

## Injuries to the shoulder girdle involving the accessory, long thoracic, axillary and suprascapular nerves

Available with the Gray's Anatomy e-book

## Musculocutaneous nerve

The musculocutaneous nerve arises from the lateral cord (C5-7), opposite the lower border of pectoralis minor (Fig. 48.44; see Figs 46.13,

Diagnosis of injuries to the accessory, long thoracic, axillary and suprascapular nerves is by no means straightforward; serious mistakes are most common in the diagnosis of severe injuries about the shoulder girdle. The delay before diagnosis is inexplicable despite the reliability of precise but elementary clinical examination. Matters are not helped by the persistence with which incorrect and discredited ideas about what muscles do continue to be taught. Many nerve injuries in this region are painful and, too often, a patient is passed to a pain clinic without a diagnosis.

## Inferior scapulohumeral angle (ISHA)

Assessing the inferior scapulohumeral angle (ISHA) informs the clinician about function at the thoracoscapular and shoulder joints (Fig. 48.36). The ISHA is subtended by the long axis of the humerus and the lateral border of the scapula; the apex of the angle is centred over the glenohumeral joint. Stiffness of the joints is detected by measuring passive range, which is normally between $170^{\circ}$ and $180^{\circ}$. The excursion between the humerus and the scapula in a healthy adult is between $130^{\circ}$ and $140^{\circ}$ : that is, the difference between the ISHA at rest and in full elevation. It is important to remember that full elevation is possible
after successful thoracoscapular arthrodesis in scapulohumeral dystrophy (Copeland and Howard 1978). This range of movement occurs at the shoulder joints, mainly the glenohumeral joint, with some involvement of the acromioclavicular and sternoclavicular joints. Successful glenohumeral arthrodesis enables a range of elevation of $30-40^{\circ}$; this is provided by the thoracoscapular joint.

## Accessory nerve

The integrity of the accessory nerve is fundamental to thoracoscapular function and essential for scapulohumeral rhythm. The nerve is usually divided at the apex of the posterior triangle, usually by surgeons, and is a crippling injury. Typically, there is immediate pain, then dropping of the shoulder and a remarkable loss of function. The average ISHA is about $50^{\circ}$. The pain is characteristic: often severe, deep-seated, dull, constant and boring in nature, and felt around the scapula and the posterior aspect of the neck and shoulder. The posture of the scapula is also characteristic: because of the loss of the great suspensory muscle, trapezius, the scapula drops down and away from the spinal column (Fig. 48.37). There is often winging of the scapula, which is easily distinguished from that caused by paralysis of serratus anterior by the

Fig. 48.36 The active inferior scapulohumeral angle (ISHA) in a normal shoulder is about $170^{\circ}$. A, At rest. B, Arm abducted. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Fig. 48.37 A right accessory palsy. A, At rest. B, Attempted abduction. The scapula drops down and away from the spine. The active ISHA is $30^{\circ}$. Fig. 48.38 A left accessory palsy. Scapular winging, without prominence of the lower fibres of trapezius, in a case where there is some early recovery into the upper fibres after repair of the accessory nerve. A, At rest, the scapula is displaced downwards and away from the spine. B, Arm abducted. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)
posture of the scapula (Fig. 48.38). It is fortunate that repair of the nerve is usually successful, even when repair is performed as late as 4 years after injury, with early relief of pain long before there is reinnervation of muscle (Camp and Birch 2011). The nerve appears to be relatively immune to the harmful effects of delayed repair.

## Long thoracic nerve (nerve to serratus anterior)

The long thoracic nerve is frequently injured during operations around the first rib, in the posterior triangle and in the axilla, and by misplaced intercostal drains. It is particularly susceptible to involvement in neuralgic amyotrophy. Serratus palsy is usual in preganglionic injury to C5, 6 and 7. Pain and loss of function are usual and are only slightly less than those seen after accessory nerve palsy. The signs are characteristic. The active ISHA is, on average, $130^{\circ}$; this is the only nerve lesion in which the active ISHA actually exceeds the total range of active abduction. The scapula is pulled upwards and towards the spine by the unopposed action of trapezius (Fig. 48.39). This action is increased by the weight of the limb, which contributes to the winging and is most notable in protraction.

## Dislocation of the shoulder: the suprascapular and axillary nerves

Although most nerve lesions in uncomplicated anterior dislocations are benign, it is well to remember the risk to adjacent vessels, more so in high-energy transfer injuries, in older patients and in those with peripheral vascular disease. The consequences of delay in treatment are severe. It is very hard to examine muscles in a patient with a fracture dislocation of the shoulder. Sensory loss is inconsistent. Consider, for example, a patient after successful reduction of a dislocated shoulder, whose arm is supported in a sling. There are three simple tests: initiation of abduction shows that the suprascapular nerve is intact and that the rotator cuff is not ruptured; abnormal sensibility in the skin over deltoid indicates a lesion of the axillary nerve; and gentle extension of the shoulder on the part of the patient, supported as it is in a sling, means that the examiner can palpate activity in the posterior fibres of deltoid (Figs 48.40-48.41).

The diagnosis of nerve injury is by no means straightforward. All too often, rupture of the axillary nerve is not recognized until deltoid is atrophied, long past the ideal time for repair. The widely held view that deltoid is the abductor of the shoulder is erroneous. Deltoid provides power and stamina, and abduction is initiated and maintained by the suprascapular nerve, acting through supra- and infraspinatus, their tendons and attachments. Disruption of any component of this abductor mechanism interferes with or precludes abduction. Wynn Parry (1981) treated 145 patients in whom paralysis was confined to deltoid. The range of abduction was full or nearly so, and a system of training enabled most patients to return to full military duties. He wrote:

It must be stressed that these movements providing full abduction and elevation are not trick movements, in the sense usually associated with this word; all the muscles involved normally help to abduct the shoulder. The scapulohumeral rhythm is quite normal and in the later stages of re-education the patient does not even need to rotate the humerus externally to initiate movement.
Seddon (1975) was a little more cautious, finding abduction to about $155^{\circ}$ was more usual. The ISHA is diminished by about $20^{\circ}$ in uncomplicated ruptures of the axillary nerve when there is no stiffness of the shoulder.

## Suprascapular nerve

The suprascapular nerve is essential for abduction and lateral rotation at the glenohumeral joint. When the nerve or the rotator cuff is torn, or both are injured, the ISHA is so reduced that the patient is unable to move the arm away from the body. At rest, the head of the humerus drops inferiorly and migrates proximally in attempted abduction (see Fig. 48.41). In isolated cuff tears, the ISHA opens to about $30^{\circ}$ or even more. In isolated axillary palsy, the ISHA is sometimes normal, or, more often, reduced by about $20^{\circ}$ (Figs $48.42,48.43$ ).

## Axillary nerve

The axillary nerve innervates deltoid. Although a good range of elevation is usually maintained by an intact abductor mechanism, strength and stamina are greatly reduced. Early diagnosis of rupture of the axillary nerve can prove difficult; the nerve is deeply seated, which means that Tinel's sign is rarely detectable. Active movement is restricted by pain and by the restraint of any sling. The loss of sensation varies and there may not be complete anaesthesia. Patients with an intact suprascapular nerve and an intact rotator cuff are able to initiate abduction and many can fully elevate the arm, or nearly so. The power of forward flexion and of abduction is reduced to, at most, $30-40 \%$ of normal, whereas extension, with the shoulder at $90^{\circ}$ of abduction, is $10 \%$ or less. One useful test is to palpate the posterior third of deltoid with the fingers and ask the patient to move the elbow gently backwards. It should be possible to detect activity in the muscle when the arm is supported in a sling or by the examiner's arm.

Fig. 48.39 Scapular winging in long thoracic palsy. This is easily distinguishable from the winging provoked by accessory palsy by the position of the scapula, which is drawn upwards and towards the spine by the unopposed action of trapezius, levator scapulae and the rhomboids.

Note the activity in the clavicular head of pectoralis major in C. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Fig. 48.35 The brachial plexus and its major branches. The axillary artery, shown in red outline, runs anterior to the radial nerve. The vertebral levels are labelled C4-T2; the spinal nerves are labelled C5-T1 (white circles).
48.45). It pierces coracobrachialis a variable distance below the tip of the coracoid process and then descends laterally between biceps brachii and brachialis to the lateral side of the arm. The first branch, to coracobrachialis, may pass into the muscle no more than 2 cm distal to the tip of the coracoid; fibres from C7 may branch directly from the lateral cord. Branches to biceps brachii and brachialis leave after the musculocutaneous nerve has pierced coracobrachialis. There are usually two branches to brachialis; the lower branch also supplies the anterior aspect of the elbow joint. The nerve to biceps brachii is consistently accompanied by a vascular pedicle. The nerve now inclines lateral and deep, into the plane between brachialis posteriorly and biceps anteriorly, where it supplies a small branch to the humerus that enters the shaft with the nutrient artery. Below the branches to brachialis, the musculocutaneous nerve continues as the lateral cutaneous nerve of the forearm.

The musculocutaneous nerve has frequent variations. It may run behind coracobrachialis or adhere for some distance to the median nerve and pass behind biceps brachii. Some fibres of the median nerve may run in the musculocutaneous nerve, leaving it to join their proper trunk; less frequently, the reverse occurs, and the median nerve sends a branch to the musculocutaneous nerve. Occasionally, it supplies pronator teres and may replace radial branches to the dorsal surface of the thumb.

## Medial cutaneous nerve of the arm

The medial cutaneous nerve of the arm ( $\mathrm{C} 8, \mathrm{~T} 1$ ) is the smallest and most medial branch of the brachial plexus, arising from the medial cord (see Fig. 48.35). It crosses the axilla, either anterior or posterior to the axillary vein, then passes medial to the axillary vein, communicates with the intercostobrachial nerve, and descends medial to the brachial artery and basilic vein. It pierces the deep fascia at the midpoint of the upper arm to supply the skin over the medial aspect of the distal third of the upper arm (see Fig. 48.34). Sometimes, the medial cutaneous nerve of the arm and the intercostobrachial nerve are connected in a plexiform manner in the axilla. The intercostobrachial nerve may be large and reinforced by part of the lateral cutaneous branch of the third intercostal nerve. It then replaces the medial cutaneous nerve of the arm and receives a connection representing the latter from the brachial plexus (occasionally, this connection is absent). It connects with the posterior branch of the medial cutaneous nerve of the forearm.

## Medial cutaneous nerve of the forearm

The medial cutaneous nerve of the forearm comes from the medial cord (T1) (see Fig. 48.34). It lies initially between the axillary artery and vein, and gives off a ramus that pierces the deep fascia to supply the skin over the biceps, almost to the elbow. The nerve descends medial to the brachial artery, pierces the deep fascia with the basilic vein midway in the arm, and divides into anterior and posterior branches. Its further course is described on page 860 .

## Median nerve

The median nerve has two roots from the lateral $(C 5,6,7)$ and medial (C8, T1) cords, which embrace the third part of the axillary artery and unite anterior or lateral to it (see Figs 48.29, 48.44, 46.7, 46.10). Some fibres from C7 often leave the lateral root in the lower part of the axilla; they pass distomedially posterior to the medial root, and usually anterior to the axillary artery, to join the ulnar nerve. Clinically, they are believed to be mainly motor and to supply flexor carpi ulnaris. If the lateral root is small, the musculocutaneous nerve ( $\mathrm{C} 5,6,7$ ) connects with the median nerve in the arm. It gives off vascular branches to the brachial artery. The further course of the median nerve is described on pages 858 and 891 .

## Ulnar nerve

The ulnar nerve arises from the medial cord (C8, T1) but often receives fibres from the ventral ramus of C7. It usually has no branches in the arm, but occasionally may give a branch to the medial head of triceps (see Figs 48.29, 48.44, 46.12). The nerve runs distally through the axilla, medial to the axillary artery and between it and the vein, and continues distally medial to the brachial artery as far as the midarm. Here, it pierces the medial intermuscular septum, inclining medially as it descends anterior to the medial head of triceps to the interval between the medial epicondyle and the olecranon. The further course of the ulnar nerve is described on pages 859 and 893.

## Radial nerve

The radial nerve is the largest branch of the brachial plexus. It arises from the posterior cord (C5, 6, 7, 8, occasionally T1) (see Figs 48.33,

Fig. 48.44 The left upper arm dissected to show the musculocutaneous nerve. Note also the changing relationship of the brachial artery and median nerve. Anterior aspect. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
$48.45,46.9$ ) and descends behind the third part of the axillary artery and the upper part of the brachial artery, anterior to subscapularis above and the tendons of latissimus dorsi and teres major below, giving branches to the medial head of triceps at this level (see Fig. 48.33). With the profunda brachii artery, it inclines dorsally, passing through the lower triangular space below the lower border of teres major, between the long head of triceps and the humerus. Here, it supplies the long head of triceps and gives rise to the posterior cutaneous nerve of the arm, which supplies the skin along the posterior surface of the upper arm. It then spirals obliquely across the back of the humerus, lying posterior to the uppermost fibres of the medial head of triceps, which separate the nerve from the bone in the first part of the spiral groove. It gives off a muscular branch to the lateral head of triceps and a branch that passes through the medial head of triceps to innervate anconeus. On reaching the lateral side of the humerus, the radial nerve pierces the lateral intermuscular septum to enter the anterior compartment of the arm. The further course of the radial nerve is described on pages 860 and 894.

The branches of the radial nerve in the upper arm are: muscular, cutaneous, articular and superficial terminal and posterior interosseous.

## Muscular branches

Muscular branches supply triceps, anconeus, brachioradialis, extensor carpi radialis longus and brachialis in medial, posterior and lateral groups. Medial muscular branches arise from the radial nerve on the medial side of the arm. They supply the medial and long heads of triceps. The branch to the medial head is a long, slender filament that lies close to the ulnar nerve as far as the distal third of the arm, and is often termed the ulnar collateral nerve. A large posterior muscular branch arises from the nerve as it lies in the humeral groove. It divides to supply the medial and lateral heads of triceps and anconeus. The branch to anconeus is a long nerve that descends in the medial head of triceps and partially supplies it; the nerve is accompanied by the middle collateral branch of the profunda brachii artery and passes behind the elbow joint to end in anconeus. Lateral muscular branches arise in front of the lateral intermuscular septum and supply the lateral part of brachialis, brachioradialis and extensor carpi radialis longus.

## Cutaneous branches

Cutaneous branches are the posterior and lower lateral cutaneous nerves of the arm and the posterior cutaneous nerve of the forearm.

Posterior cutaneous nerve of the arm The small posterior cutaneous nerve of the arm arises in the axilla and passes medially to supply the skin on the dorsal surface of the arm nearly as far as the olecranon. It crosses posterior to, and communicates with, the intercostobrachial nerve.

Lower lateral cutaneous nerve of the arm The lower lateral cutaneous nerve of the arm perforates the lateral head of triceps distal to the deltoid tuberosity, passes to the front of the elbow close to the cephalic vein, and supplies the skin of the lateral part of the lower half of the arm.

Posterior cutaneous nerve of the forearm The posterior cutaneous nerve of the forearm arises with the lower lateral cutaneous nerve of the arm. Perforating the lateral head of triceps, it descends first lateral in the arm, then along the dorsum of the forearm to the wrist, supplying the skin in its course and joining, near its end, with dorsal branches of the lateral cutaneous nerve of the forearm.

## AXILLA

## BOUNDARIES

The axilla is a pyramidal region between the upper thoracic wall and the arm (Figs 48.45-48.46; see Fig. 48.35). Its blunt apex continues into the root of the neck (cervico-axillary canal) between the external border of the first rib, superior border of the scapula, posterior surface of the clavicle, and the medial aspect of the coracoid process. Its triangular base, which is virtual, can be imagined as facing downwards; it is broad at the chest and narrow at the arm, and corresponds to the skin and a thick layer of axillary fascia between the inferior borders of pectoralis major anteriorly and latissimus dorsi posteriorly. It is convex upwards, conforming to the concavity of the armpit.

The anterior wall is formed by pectorales major and minor, the former covering the whole wall, and the latter its intermediate cranial part, with a clear fascial plane between the two muscles. The interval between the upper border of pectoralis minor and clavicle is occupied by the clavipectoral fascia. The posterior wall is formed by subscapularis superiorly and teres major and latissimus dorsi inferiorly (Fig. 48.47). The medial 'wall' is convex laterally and is composed of the first four ribs and their associated intercostal muscles, together with the upper part of serratus anterior. The anterior and posterior walls converge laterally; the 'wall' is narrow and consists of the humeral intertubercular sulcus. The lateral angle lodges coracobrachialis and biceps.

## CONTENTS

The axilla contains the axillary vessels, the infraclavicular part of the brachial plexus and its branches, lateral branches of some intercostal nerves, many lymph nodes and vessels, loose adipose areolar tissue and, in many instances, the 'axillary tail' of the breast. The axillary vessels and brachial plexus run from the apex to the base along the lateral wall, nearer to the anterior wall; the axillary vein is anteromedial to the artery.

Lateral thoracic artery and vein
Fig. 48.45 The left axillary fossa and the deep aspect of the thoracic inlet, anterior aspect. The clavicle has been partially removed and the pectoral muscles have been reflected. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The obliquity of the upper ribs means that the neurovascular bundle, after it emerges from behind the clavicle, crosses the first intercostal space; its relations are, therefore, different at upper and lower levels. Thoracic branches of the axillary artery are in contact with the pectoral muscles; the lateral thoracic artery reaches the thoracic wall along the lateral margin of pectoralis minor. Subscapular vessels descend on the posterior wall at the lower margin of subscapularis. The subscapular and thoracodorsal nerves cross the anterior surface of latissimus dorsi at different inclinations. Circumflex scapular vessels wind round the lateral border of the scapula; posterior circumflex humeral vessels and the axillary nerve curve back and laterally around the surgical neck of the humerus (see Figs 48.47, 48.31).

No large vessel lies on the medial 'wall', which is crossed proximally only by small branches of the superior thoracic artery. The long thoracic nerve descends on serratus anterior and the intercostobrachial nerve perforates the upper anterior part of this wall, crossing the axilla to its lateral 'wall'.

## AXILLARY LYMPH NODES

There are between 20 and 30 axillary nodes, which may be divided into five not wholly distinct groups, namely: lateral, anterior (pectoral), posterior (subscapular), central and apical (see Fig. 53.24). Four of the groups are intermediary; only the apical group is terminal. Collectively, they drain the entire upper limb, breast and trunk above the umbilicus.

The lateral group of four to six nodes is posteromedial to the axillary vein; its afferents drain the whole limb, except the vessels that accompany the cephalic vein (Fig. 48.48, see Fig. 53.24). Efferent vessels pass
partly to the central and apical axillary groups, and partly to the inferior deep cervical nodes. The anterior group of four or five nodes spreads along the inferior border of pectoralis minor near the lateral thoracic vessels. Their afferents drain the skin and muscles of the supra-umbilical anterolateral body wall and breast, and efferents pass partly to the central and partly to the apical axillary nodes. The posterior group of six or seven nodes lie on the inferior margin of the posterior axillary wall, along the subscapular vessels. Their afferents drain the skin and superficial muscles of the inferior posterior region of the neck and the dorsal aspect of the trunk down to the iliac crest; efferents pass to the apical and central axillary nodes. A central group of three or four large nodes embedded in axillary fat receives afferents from all preceding groups, and their efferents drain to the apical nodes. An apical group of six to twelve nodes is partly posterior to the superior part of pectoralis minor and partly above its superior border, extending to the apex of the axilla medial to the axillary vein. The only direct territorial afferents are those that accompany the cephalic vein and/or some that drain the upper peripheral region of the breast; the group drains all the other axillary nodes. Their efferents unite as the subclavian trunk and drain directly to either the jugulosubclavian venous junction, the subclavian vein, the jugular lymphatic trunk or (occasionally) to a right lymphatic duct; the left trunk usually ends in the thoracic duct (see Fig. 29.16). A few efferents from apical nodes usually reach the inferior deep cervical nodes.

One or two infraclavicular nodes appear beside the cephalic vein in the groove between pectoralis major and deltoid, just inferior to the clavicle. Their efferents pass through the clavipectoral fascia to the apical axillary nodes. Occasionally, some pass anterior to the clavicle to the inferior deep cervical (supraclavicular) nodes.

A book that contains the translated work of Dr Michel Salmon: it describes the blood supply to muscle, as well as the anastomotic pathways in the limbs.

Vangsness CT Jr, Jorgenson SS, Watson T et al 1994 The origin of the long head of the biceps from the scapula and glenoid labrum. An anatomical study of 100 shoulders. J Bone Joint Surg Br 76:951-4.
A detailed description of the variation in the cadaveric anatomy of the origin of biceps brachii, permitting more accurate interpretation of the clinical variance of this structure.

## SKIN AND SOFT TISSUES

## SKIN

## Cutaneous vascular supply

The skin of the elbow and forearm receives its blood supply from muscle perforators, fasciocutaneous networks and direct cutaneous vessels. The skin of the anterolateral cubital fossa is supplied by muscle perforators arising from the radial collateral and radial recurrent arteries. The skin of the medial cubital fossa receives branches from an anastomosis between the inferior ulnar collateral and the ulnar recurrent arteries. Small direct cutaneous vessels spring from the brachial artery. The skin of the posterolateral aspect of the elbow is supplied by branches of the posterior interosseous recurrent artery and a rich plexus of collateral and anastomosing arteries. The skin of the posteromedial aspect is supplied by branches of the superior and inferior ulnar collateral arteries and the posterior ulnar recurrent artery feeding into the plexus.

The skin of the anterior forearm is supplied by fasciocutaneous perforators; the largest is the inferior cubital artery, which arises from the radial artery at the distal apex of the cubital fossa and extends to midway down the forearm. Fasciocutaneous perforators from the radial artery supply the lateral two-thirds of the anterior surface of the forearm (see Fig. 46.5). The vessels pass in the intermuscular septa between brachioradialis and flexor carpi radialis, and between flexor carpi radialis and flexor digitorum superficialis. Fasciocutaneous perforators from the ulnar artery supply skin over the ulnar side of the anterior forearm and the medial quarter of the posterior forearm from the cubital fossa to the wrist. A small contribution comes from musculocutaneous perforators that pass through brachioradialis and flexor carpi ulnaris.

The skin of the distal third of the lateral forearm is supplied by the terminal perforating branches of the anterior interosseous artery. The central half of the posterior surface of the forearm, from the lateral edge of extensor digitorum, just below the lateral epicondyle of the humerus, to the wrist, is supplied by fasciocutaneous perforators from the posterior interosseous artery that pass along the intermuscular fascia between extensor carpi ulnaris and extensor digiti minimi.

## Cutaneous innervation

A small area of skin anterolateral to the elbow is supplied by the lateral cutaneous nerve of the arm. The skin overlying the posterior aspect of the elbow is innervated by the posterior cutaneous nerve of the arm and proximal branches of the posterior cutaneous nerve of the forearm. The lateral cutaneous nerve of the forearm innervates the skin of the anterior half and radial posterior quarter of the forearm. The medial cutaneous nerve of the forearm supplies the skin overlying most of the elbow, the ulnar half of the anterior forearm and the ulnar quarter of the posterior forearm (Fig. 49.1 and p. 860).

## SOFT TISSUES

## Cubital fossa

The cubital fossa is a triangular depression in the anterior aspect of the upper forearm (see Fig. 46.29). It is bounded proximally by the epicondylar line, medially by the lateral margin of pronator teres, and laterally by the medial face of brachioradialis; it is bisected by the tendon of biceps brachii. The deep fascia of the forearm forms its roof. It is continuous with the deep fascia of the anterior arm, attached to

Fig. 49.1 Sensory loss or disturbance after complete section of the medial and lateral cutaneous nerves of the forearm.
the medial and lateral humeral epicondyles and augmented by the bicipital aponeurosis, which sweeps across the medial and inferior part of the fossa to the fascia over the superficial flexor muscles. Supinator and brachialis lie in the floor of the fossa. From medial to lateral, the basilic, median cubital and cephalic veins lie in the superficial fascia. Branches of the medial cutaneous nerve of the forearm are closely related to the basilic vein. The lateral cutaneous nerve of the forearm runs down alongside the lateral edge of the tendon of biceps brachii. Deep to the deep fascia, and passing from medial to lateral, are the median nerve and the brachial artery, the latter inclining from the medial side of the arm to pass down the fossa close to the midline. The radial and ulnar arteries, with their accompanying veins, originate in the lower part of the fossa. The radial nerve enters the fossa laterally in the groove between brachioradialis and brachialis, and divides into the superficial radial and posterior interosseous nerves above the humero-radial joint. The superficial radial nerve continues down the forearm under cover of brachioradialis.

## Compartments of the forearm

The deep fascia, the interosseous membrane and the fibrous intermuscular septa, some of which pass between the deep fascia and bone, divide the forearm into compartments. These include the superficial and deep flexor (anterior) compartments, the extensor (posterior) compartment, and a proximolateral compartment that includes brachioradialis and extensors carpi radialis longus and brevis (the mobile wad) (Fig. 49.2). The dense sheath of the antebrachial fascia (the deep fascia of the forearm) is continuous above with the brachial fascia. It is attached to the olecranon, the posterior border of the ulna, and the lateral and medial epicondyles. The fascia is thicker posteriorly and in the lower forearm. It is strengthened above by tendinous fibres from biceps and triceps. Near the wrist, two localized thickenings, the flexor and extensor retinacula, retain the digital tendons in position (Ch. 50). From its deep surface, septa pass between muscles, providing areas of additional attachment. Muscles arise from its inner aspect in the upper forearm. Vessels and nerves pass through apertures in the fascia; a large aperture anterior to the elbow transmits a venous communication between superficial and deep veins.

## BONES

## HUMERUS

## Distal end of humerus

The distal end of the humerus is a modified condyle; it is wider transversely and has articular and non-articular parts (Figs 49.3-49.4). The articular part is curved forwards, so that its anterior and posterior surfaces lie in front of the corresponding surfaces of the shaft. It articulates with the radius and the ulna at the elbow joint, and is divided by a faint groove into a lateral capitulum and a medial trochlea

The capitulum is a rounded, convex projection, considerably less than half a sphere, which covers the anterior and inferior surfaces of the lateral part of the condyle of the humerus but does not extend on to its posterior surface. It articulates with the discoid head of the radius, which lies in contact with its inferior surface in full extension of the elbow but slides on to its anterior surface during flexion. The groove of the trochlea winds backwards and laterally from the anterior to the posterior surface of the bone, and is wider, deeper and more symmetrical posteriorly. Anteriorly, the medial flange of the pulley is longer than the lateral, and the surface adjoining its projecting medial margin is convex to accommodate itself to the medial part of the upper surface of the coronoid process of the ulna. These asymmetries entail varying angulation between the humeral and ulnar axes, together with some conjunct rotation. The non-articular part of the condyle includes the medial and lateral epicondyles, and the olecranon, coronoid and radial fossae.

Fig. 49.2 Compartments of the forearm. A cross-section through the upper third of the left forearm.

## Trochlea

The trochlea is a pulley-shaped surface that covers the anterior, inferior and posterior surfaces of the condyle of the humerus medially and articulates with the trochlear notch of the ulna. On its lateral side, it is separated from the capitulum by a faint groove; its medial margin projects distally beyond the rest of the bone. When the elbow is extended, the inferior and posterior aspects of the trochlea are in contact with the ulna but, as the joint is flexed, the trochlear notch slides on to the anterior aspect so that its posterior aspect is then left uncovered. The downward projection of the medial edge of the trochlea is the principal factor in determining the degree of angulation between the long axis of the humerus and the long axis of the supinated forearm when the elbow is extended.

## Medial epicondyle

The medial border of the humerus ends by turning slightly backwards as the medial epicondyle, which forms a conspicuous, blunt projection on the medial side of the condyle. It is subcutaneous and usually visible, especially in passive flexion of the elbow. Its posterior surface is smooth and is crossed by the ulnar nerve, which lies in a shallow sulcus as it enters the forearm. The nerve can be felt and rolled against the bone here; if jarred against the epicondyle, a characteristic tingling sensation results. The lower part of the anterior surface of the medial epicondyle is marked by the attachment of the superficial group of forearm flexors. They arise from the epiphysis for the epicondyle but are entirely extracapsular.

## Lateral epicondyle

The lateral border of the humerus ends at the lateral epicondyle; its lower portion constitutes the lateral supracondylar ridge. The lateral epicondyle occupies the lateral part of the non-articular portion of the condyle but does not project beyond the lateral supracondylar ridge. It

turns slightly forwards, unlike the medial epicondyle, which turns slightly backwards. Its lateral and anterior surfaces show a well-marked impression for the superficial group of the extensor muscles of the forearm (see Fig. 48.11A), which arise from the lateral side of the lower humeral epiphysis; like the flexors, they are extracapsular. The posterior surface, which is very slightly convex, is easily felt in a depression visible behind the extended elbow. A small area on the posterior surface gives origin to anconeus.

## Olecranon, coronoid and radial fossae

The olecranon fossa is a deep hollow on the posterior surface of the condyle, immediately above the trochlea, that lodges the tip of the olecranon of the ulna when the elbow is extended. The floor of the fossa is always thin and may be partially deficient. A similar but smaller hollow, the coronoid fossa, lies immediately above the trochlea on the anterior surface of the condyle and accommodates the anterior margin of the coronoid process of the ulna during flexion of the elbow. A very slight depression, the radial fossa, lies above the capitulum on the lateral side of the coronoid fossa and is related to the margin of the head of the radius in full flexion of the elbow.

## Ossification

The distal humerus ossifies as follows. During the first year, ossification begins in the capitulum and extends medially to form the main part of the articular surface. The centre for the medial part of the trochlea appears in the ninth year in females and tenth year in males. Ossification begins in the medial epicondyle in the fourth year in females and the sixth in males, and in the lateral epicondyle in about the twelfth year. The centre for the medial epicondyle forms a separate epiphysis, which is entirely extracapsular, on the posteromedial aspect of the epicondyle. It is separated from the rest of the lower epiphysis by a downgrowth from the shaft, with which it unites at about the twentieth year. The centres for the lateral epicondyle, capitulum and trochlea fuse around puberty, and the composite epiphysis unites with the shaft in the fourteenth year in females and sixteenth in males.

## RADIUS

The radius is the lateral bone of the forearm (Figs 49.5-49.7). It has expanded proximal and distal ends; the distal is much the broader. The shaft widens rapidly towards its distal end, and is convex laterally and concave anteriorly in its distal part. The radius articulates with the humeral capitulum, the ulna and the carpus.

## Proximal radius

The proximal radius includes a head, neck and tuberosity. The head is discoid, its proximal surface a shallow cup for articulation with the humeral capitulum. Its smooth articular periphery is vertically deepest medially, where it contacts the ulnar radial notch. The posterior surface of the radial head is palpable on the posterolateral aspect of the extended elbow. The head overhangs the neck, which is the circumferential constriction immediately below it, particularly laterally. The tuberosity is distal to the medial part of the neck; posteriorly, it is rough, whereas anteriorly, it is usually smooth.

## Radial shaft

The radial shaft has a lateral convexity and is triangular in cross-section. The interosseous border is sharp, except proximally, near the tuberosity, and distally, where the interosseous border is the posterior margin of a small, elongated, triangular area, proximal to the ulnar notch. These two areas form the medial surface of the radial shaft. The interosseous membrane is attached to the distal three-quarters of the radial shaft, and connects the radius to the ulna. The anterior surface, between anterior and interosseous borders, is concave transversely and shows a distal anterior curvature. There is a proximally directed nutrient foramen and canal near the midpoint of the shaft. The posterior surface of the shaft, between the interosseous and posterior borders, is largely flat but may be slightly hollow proximally. The lateral surface is gently convex. A finely irregular oval area occurs near the midshaft; further distally, the surface is smooth.

## Distal radius

The distal end of the radius (Fig. 49.8) is the widest part and is foursided in section. The lateral surface is slightly rough, projecting distally as the radial styloid process. The smooth carpal articular surface is divided by a ridge into medial and lateral areas. The medial distal radial articular surface is quadrangular, whereas the lateral part of the articular surface is triangular and curves on to the styloid process. The anterior surface of the distal radius is a thick, palpable, prominent ridge 2 cm

proximal to the thenar eminence. The medial surface is the ulnar notch, which is smooth and anteroposteriorly concave for articulation with the head of the ulna. The posterior surface has a palpable dorsal tubercle (Lister's tubercle), limited medially by an oblique groove and in line with the cleft between the index and middle fingers. Lateral to the tubercle is a wide, shallow groove, divided by a vertical ridge.

## Muscular, ligamentous and articular attachments

The proximal articular surface of the radial head and its circumference are covered by hyaline cartilage. The upper rim fits the groove between the capitulum and trochlea and enters the radial fossa in flexion. The articular circumference articulates with the ulnar radial notch and anular ligament, within which it rotates in pronation and supination. The radial neck is enclosed by the narrower distal part of the ligament, from which it is separated by a synovial protrusion from the superior radio-ulnar joint. The posterior area of the tuberosity is marked by the tendon of biceps brachii, which is separated from a smooth anterior area by a bursa. The oblique cord is attached just distal to the bursa.

Flexor digitorum superficialis is attached to the proximal anterior surface of the radius by a thin, wide head. Flexor pollicis longus has an extensive attachment to the proximal two-thirds of the anterior surface of the radial shaft, overlying the nutrient foramen. Pronator quadratus is attached to the distal quarter of the anterior radial shaft; a small, triangular area proximal to the ulnar notch gives attachment to the deepest part of the muscle. Pronator teres is attached to a rough area near the midpoint of the lateral surface of the radial shaft, at its maximal curvature. Proximally, supinator is attached to a long, V-shaped area on the lateral surface of the shaft. Distal to pronator teres, the lateral

Fig. 49.8 The distal end of the left radius and ulna. Key: 1, styloid process of radius; 2, dorsal tubercle; 3, groove for tendon of extensor carpi ulnaris; 4, styloid process of ulna; 5 , facet for scaphoid; 6, facet for Iunate; 7, inferior radio-ulnar articulation; 8, area of contact with articular disc; 9, area for attachment of articular disc. Compare with Fig. 50.18A.
surface is covered by tendons of brachioradialis, extensor carpi radialis longus and brevis. On the posterior surface, abductor pollicis longus is attached proximally, and extensor pollicis brevis more distally. The remaining surface is devoid of attachments and covered by the long and short extensors of the thumb. The lateral surface, proximal to the styloid process, receives the attachment of brachioradialis and is crossed obliquely, downwards and forwards, by the tendons of abductor pollicis longus and extensor pollicis brevis. The radial styloid process projects beyond that of the ulna, its apex covered by the tendons of abductor pollicis longus and extensor pollicis brevis. The lateral radiocarpal ligament is attached to its tip, and the palmar radiocarpal ligament is attached to the terminal ridge on the anterior surface of the lower end. The base of the triangular articular disc of the inferior radio-ulnar joint is attached to a smooth ridge distal to the ulnar notch. A narrow protrusion of synovial membrane extends proximally from the ulnar notch, anterior to the lower end of the interosseous membrane. The lateral part of the carpal articular surface articulates with the scaphoid, and the medial part with the lateral part of the lunate. In full adduction, the proximal surface of the lunate is wholly in contact with the radius.

The radial dorsal tubercle receives a slip from the extensor retinaculum and is grooved medially by the tendon of extensor pollicis longus. The wide groove lateral to the tubercle contains the tendons of extensor carpi radialis longus laterally and extensor carpi radialis brevis medially, together with their synovial sheaths. Medially, the dorsal surface is grooved by the tendons of extensor digitorum, separated from the bone by the tendons of extensor indicis and the posterior interosseous nerve. The dorsal radiocarpal ligament is attached to the distal margin of this surface.

## Vascular supply

The radius is supplied by branches of the radial, ulnar, and anterior and posterior interosseous arteries through multiple metaphysial nutrient foramina. Usually, there is one nutrient diaphysial foramen located on the anterior surface of the bone, which is directed proximally towards the elbow. A network of small fascioperiosteal and musculoperiosteal vessels arise from the compartmental vessels and reach the bone via its septal and muscular attachments.

The dorsal metaphysis of the distal radius is richly supplied (Fig. 49.9A). Branches connect the anterior interosseous artery proximally to the dorsal carpal arch distally. These pass through the fourth and fifth extensor compartments of the wrist and provide metaphysial nutrient arteries. Intercompartmental vessels send nutrient arteries to the radius through the retinaculum between the first and second dorsal compartments, and the second and third dorsal compartments. These vessels originate from the radial artery and anterior interosseous arteries, respectively, and anastomose with the dorsal carpal arch.

## Ossification

The radius ossifies from three centres. One appears centrally in the shaft in the eighth week of fetal life, and the others appear in each end (see Figs 48.13, 49.12). Ossification begins in the distal epiphysis towards the end of the first postnatal year and in the proximal epiphysis during the fourth year in females and the fifth year in males. The proximal

c

Fig. 49.9 A-B, The extraosseous arterial supply to the distal radius and ulna and the carpus. A, Dorsal aspect; B, Palmar aspect; C Lateral aspect viewed from the radial side.
epiphysis fuses in the fourteenth year in females and seventeenth in males, and the distal in the seventeenth and nineteenth years, respectively. A fourth centre sometimes appears in the tuberosity at about the fourteenth or fifteenth year.

## ULNA

The ulna is medial to the radius in the supinated forearm. Its proximal end is a massive hook, concave forwards, that articulates with the distal humerus (Figs 49.10-49.11). The lateral border of the shaft is a sharp interosseous crest. The bone diminishes progressively from its proximal mass throughout almost its whole length, but, at its distal end, expands into a small, rounded head and styloid process. The shaft is triangular in cross-section proximally, and almost cylindrical distally. Along its whole length, the ulna is slightly convex posteriorly. Mediolaterally, its profile is sinuous; the proximal half has a slight curvature that is concave laterally and the distal half a curvature that is concave medially.

## Proximal ulna

The proximal end of the ulna has large olecranon and coronoid processes, and trochlear and radial notches that articulate with the humerus and radius, respectively. The olecranon is more proximal and is bent forwards at its summit like a beak that enters the olecranon fossa of the humerus in extension. Its posterior surface is smooth, triangular and subcutaneous, and its proximal border underlies the 'point' of the elbow. In extension, it can be felt near a line joining the humeral epicondyles, but in flexion, it descends, so that the three osseous points form an isosceles triangle. Its anterior, articular surface forms the
proximal area of the trochlear notch. Its base is slightly constricted where it joins the shaft and is the narrowest part of the proximal ulna. The coronoid process projects anteriorly distal to the olecranon. Its proximal aspect forms the distal part of the trochlear notch. On the lateral surface, distal to the trochlear notch, a shallow, smooth, oval radial notch articulates with the radial head. Distal to the radial notch, the surface is hollow to accommodate the radial tuberosity during pronation and supination. The anterior surface of the coronoid is triangular. Its distal part is the tuberosity of the ulna and its medial border is sharp and bears a small tubercle proximally.

The trochlear notch articulates with the trochlea of the humerus. It is constricted at the junction of the olecranon and coronoid processes, where their articular surfaces may be separated by a narrow, rough, non-articular strip. A smooth ridge, adapted to the groove on the humeral trochlea, divides the notch into medial and lateral parts. The medial fits into the trochlear flange. The radial notch, an oval or oblong proximal depression on the lateral aspect of the coronoid process, articulates with the periphery of the radial head and is separated from the trochlear notch by a smooth ridge.

## Ulnar shaft

The ulnar shaft is triangular in cross-section in its proximal threequarters, but distally is almost cylindrical (see Figs 49.31-49.32). It has anterior, posterior and medial surfaces and interosseous, posterior and anterior borders. The interosseous border is a conspicuous lateral crest in its middle half. Proximally, it becomes the supinator crest, which is continuous with the posterior border of a depression distal to the radial notch. Distally, it disappears. The rounded anterior border starts medial to the ulnar tuberosity, descends backwards, and is usually traceable to the base of the styloid process. The posterior border, also rounded,

Fig. 49.10 The interosseous membrane and oblique cord of the forearm: anterior aspect. Membrane and cord are syndesmoses.

descends from the apex of the posterior aspect of the olecranon, and curves laterally to reach the styloid process. It is palpable throughout its length in a longitudinal furrow, most obvious when the elbow is fully flexed.

The anterior surface, between the interosseous and anterior borders, is longitudinally grooved, sometimes deeply (see Fig. 49.10). Proximal to its midpoint, a proximally directed nutrient foramen admits a branch of the anterior interosseous artery. Distally, it is crossed obliquely by a rough, variable prominence, descending from the interosseous to the anterior border. The medial surface, between the anterior and posterior borders, is transversely convex and smooth. The posterior surface, between the posterior and interosseous borders, is divided into three areas. The most proximal is limited by a sometimes faint, oblique line that ascends laterally from the junction of the middle and upper thirds of the posterior border to the posterior end of the radial notch. The region distal to this line is divided into a larger medial and narrower lateral strip by a vertical ridge, which is usually distinct only in its proximal three-quarters.

## Distal ulna

The distal end of the ulna is slightly expanded and has a head and styloid process. The head is palpable and visible in pronation on the posteromedial aspect of the wrist. Its lateral convex articular surface fits the radial ulnar notch. Its smooth distal surface is separated from the carpus by an articular disc, the apex of which is attached to a rough area between the articular surface and styloid process. The ulnar styloid process is a short, round, posterolateral projection of the distal end of the ulna, palpable in supination about 1 cm proximal to the plane of the radial styloid. A posterior vertical groove is present between the head and styloid process.

## Muscular, ligamentous and articular attachments

The capsule of the elbow joint is attached to the proximal, anterior surface of the olecranon, and the tendon of triceps is attached to its rough posterior two-thirds; the capsule and tendon may be separated by a bursa. The medial surface of the olecranon is marked proximally by the attachment of the posterior and oblique bands of the ulnar collateral ligament and by the ulnar part of flexor carpi ulnaris. The smooth area distal to this is the most proximal attachment of flexor digitorum profundus. Anconeus is attached to the lateral surface of the olecranon and the adjoining posterior surface of the ulnar shaft as far as its oblique line. The posterior surface of the ulna is separated from the skin by a subcutaneous bursa.

Brachialis is attached to the anterior surface of the coronoid process, including the ulnar tuberosity. The oblique and anterior bands of the ulnar collateral ligament and the distal part of the humero-ulnar slip of flexor digitorum superficialis are attached to a small tubercle at the proximal end of the medial border. Further distally, the margin of the coronoid process provides attachment for the ulnar head of pronator teres. An ulnar head of flexor pollicis longus may be attached to the lateral or, more rarely, the medial, border of the coronoid process. Fibres of flexor digitorum profundus are attached to its medial surface. The anular ligament is attached to the anterior rim of the radial notch and, posteriorly, to a ridge at, or just behind, the posterior margin of the notch. The depressed area distal to the notch is limited behind by the supinator crest, and both provide attachment for supinator.

The olecranon area of the trochlear notch is usually divided into three areas. The most medial faces anteromedially, and is grooved to fit the medial flange of the humeral trochlea, with which it makes increasing contact during flexion. A flat intermediate area fits the lateral flange. The most lateral area is a narrow strip that abuts the trochlea in extension. The articular surface is narrower than the base of the olecranon; non-articular areas are related to the synovial processes. The coronoid area of the trochlear notch is also divided; its medial and lateral areas correspond to the medial and intermediate areas of the olecranon. The medial is the deeper, and conforms to the convex medial trochlear flange. The medial and anterior parts of the capsular ligament are attached to its medial and anterior borders.

The deep fascia of the forearm is attached to the subcutaneous posterior border, which also provides an attachment for the aponeurosis of flexor digitorum profundus in its proximal three-quarters, for flexor carpi ulnaris in its proximal half, and for extensor carpi ulnaris in its middle third. These three muscles are attached to the posterior border through a common blended aponeurosis. The interosseous membrane is attached along the interosseous border, except for a short length proximally.

Flexor digitorum profundus is attached to the proximal threequarters of the anterior border and medial surface, arising medial to the
coronoid process and olecranon. The rough strip across the distal fourth of the anterior surface provides part of the bony attachment for pronator quadratus. Anconeus is attached to the posterior surface proximal to the oblique line and lateral to the olecranon. The narrow strip between the interosseous border and vertical ridge gives rise to the attachment of three deep muscles: abductor pollicis longus arises from the proximal quarter, extensor pollicis longus from the succeeding quarter (sometimes a ridge is interposed between them), and extensor indicis from the third quarter. Extensor carpi ulnaris covers the broad strip medial to the vertical ridge and its tendon grooves the posterior aspect of the distal end of the ulna.

## Vascular supply

The ulna receives its vascular supply from branches of the radial, ulnar, anterior and posterior interosseous arteries via multiple metaphysial nutrient foramina. Usually one, but occasionally two, major nutrient diaphysial foramina are located on the anterior surface of the bone, directed proximally towards the elbow. A network of small fascioperiosteal and musculoperiosteal branches given off from the compartmental vessels reaches the bone via septal and muscular attachments.

## Ossification

The ulna ossifies from four main centres: one each in the shaft and distal end, and two in the olecranon (see Fig. 48.13; Fig. 49.12). Ossification begins in the midshaft about the eighth fetal week and extends rapidly. A centre appears in the distal end in the fifth year in females

Fig. 49.12 Radiographs of the forearm of a girl aged 11 years. A, Anteroposterior view. Key: 1, cartilaginous growth plates; 2, conjoined epiphyses of capitulum and lateral epicondyle; 3, proximal radial epiphysis; 4, distal radial epiphysis; 5 , epiphysis of medial epicondyle; 6 , diaphysial bone; 7, trochlear epiphysis; 8, distal ulnar epiphysis. B, Lateral view, semi-flexed at the elbow. Note the epiphyses and adjacent radiotranslucent growth cartilages. Key: 1, olecranon; 2, distal ulnar epiphysis; 3, proximal radial epiphysis; 4, distal radial epiphysis.
and sixth year in males, and extends into the styloid process. The distal olecranon is ossified as an extension from the shaft, the remainder from two centres, one for the proximal trochlear surface and the other for a thin, scale-like proximal epiphysis on its summit. The proximal epiphysis appears in the ninth year in females and eleventh year in males, and the whole proximal epiphysis has usually joined the shaft by the fourteenth year in females and sixteenth year in males. The distal epiphysis usually unites with the shaft in the seventeenth year in females and eighteenth in males. Along with the distal humerus, the proximal ulna ossifies in a sequential manner; skeletal maturity may be assessed by observations of elbow radiographs.

## JOINTS

The elbow joint acts as a platform for the forearm and hand. The humero-ulnar and humero-radial joints form a complex hinge that enables flexion and extension of the forearm. The humero-radial joint, in conjunction with the proximal and distal radio-ulnar joints, allows full pronation and supination of the forearm. The configuration of the humero-ulnar joint, between the trochlea and the trochlear notch of the ulna and the distal prolongation of the medial edge of the trochlear pulley, tilts the ulna, forming a 'carrying angle' (approximately $14^{\circ}$ in women and $11^{\circ}$ in men) between the longitudinal axes of the humerus and ulna when the elbow is fully extended and supinated. These axes become aligned in full flexion.

## HUMERO-ULNAR JOINT

The humero-ulnar joint is a complex hinge joint and is continuous with two pivot joints between the distal humerus and proximal radius, and between the proximal radius and ulna (Figs 49.13, 49.15-17). There is a high degree of congruity between the deep trochlea of the humerus and the large trochlear notch of the ulna. This stable arrangement is enhanced by strong medial and lateral collateral ligaments and, in full extension, by the anterior capsule. An arc of $150^{\circ}$ of flexion and extension is possible. A range of $180^{\circ}$ of pronation and supination is achieved by synchronous movements at the proximal and distal radioulnar joints, aided by minor contributions from the radiocarpal and carpal joints.

Articulating surfaces The distal humerus possesses two distinct articulating surfaces: the humeral trochlea and the capitulum (see Fig. 49.3). The shape of the humeral trochlea is asymmetric, with a longer medial flange. It is widest posteriorly in the adult. The joint line lies 2 cm distal to the interepicondylar line and is tilted inferomedially. The flexion-extension arc of elbow movement is not a simple hinge. Different parts of the distal humerus are in contact with the corresponding articular surface of the proximal ulna throughout the range of movement; in full extension of the elbow, a medial segment of the distal humerus is not in contact with the ulna, whereas in full flexion, a lateral segment is not in contact.

The surface of the trochlear notch has an asymmetrical sellar surface that allows some rotation during swing in the flexion-extension plane. It is predominantly concave in the transverse plane, but convex in the anteroposterior plane. There is a 'bare area' devoid of hyaline cartilage between the olecranon and coronoid areas of the trochlear notch that is covered by fibrofatty tissue and synovium. The humeral capitulum is reciprocally convex with the concavity of the articulating surface of the radial head. The more prominent medial rim of the radial head sits in the groove between the capitulum and trochlea. Contact between the capitulum and radial head is maximal with the elbow in mid-flexion and the forearm in mid-pronation.

Fibrous capsule The fibrous capsule is broad and thin anteriorly. It is attached proximally to the front of the medial epicondyle and humerus above the coronoid and radial fossa, and distally to the edge of the ulnar coronoid process and anular ligament. It may be augmented by fibres from brachialis and blends into the ulnar collateral ligament medially and the radial collateral ligament laterally. Posteriorly, the capsule is even thinner and is related to the tendon of triceps and anconeus. It is attached proximally to the superoposterior aspect of the humeral capitulum, the posterior aspect of the medial epicondyle and the olecranon fossa. Only the lowest part of the olecranon fossa is devoid of a capsular attachment. Inferomedially, it reaches the superior and lateral margins of the olecranon and is laterally continuous with the superior radio-ulnar capsule deep to the anular ligament. The olecranon bursa lies between the capsule of the elbow and the

Fig. 49.13 A-D, The left elbow joint. A, The synovial cavity partially distended: anterior aspect. The fibrous capsule of the elbow joint has been removed but the thick part of the anular ligament has been left in situ. Note that the synovial membrane (blue) descends below the lower border of the anular ligament. B, The synovial cavity partially distended: posterior aspect of the specimen represented in A. C, Medial aspect. D, Lateral aspect.
triceps insertion. Inflammation caused by pressure, friction or infection of the bursa can result in marked swelling and limitation in elbow function.

Ligaments The humero-ulnar and humero-radial articulations have ulnar and radial collateral ligaments (see Fig. 49.13).

Ulnar collateral ligament This triangular ligament consists of thick anterior, posterior and inferior bands connected by thinner tissue. The strongest and stiffest anterior band is attached by its apex to the anterior aspect of the medial epicondyle and by its broader base to a proximal tubercle on the medial margin of the coronoid. The anterior band is taut throughout most of the range of flexion and contributes to the stability of the joint. The posterior band of the ulnar collateral ligament is also triangular in shape; its apex attaches to the back of the medial epicondyle and its distal attachment is the medial margin of the olecranon. The posterior band becomes taut between $90^{\circ}$ and full flexion of the elbow. Connecting these two thick bands is a less sturdy inferior oblique band that runs between the olecranon and coronoid processes, converting a depression on the medial margin of the trochlear notch into a foramen, through which the intracapsular fat pad is continuous with the extracapsular fat medial to the joint. The ulnar collateral ligament of the elbow lies beneath triceps, flexor carpi ulnaris, the ulnar nerve and the attachment of flexor digitorum superficialis as it extends from the medial epicondyle to the medial coronoid border

Radial collateral ligament The radial collateral ligament is attached low on the lateral epicondyle and to the anular ligament. Some of the posterior fibres cross the ligament to the proximal end of the supinator crest of the ulna. The ligament blends with the bony attachments of supinator and extensor carpi radialis brevis. It is taut throughout most of the range of flexion of the elbow and contributes to the stability of the joint.

Synovial membrane The synovial membrane extends from the articular margins of the humerus and lines the coronoid, radial and olecranon fossae, the flat medial surface of the trochlea, the deep surface of the elbow capsule and the distal part of the anular ligament. A crescentic synovial fold projecting between the proximal radius and ulna contains extrasynovial fat and forms the division between the humeroulnar and humero-radial joints.

There are three other fat pads between the capsule and synovium; the largest is in the olecranon fossa, where it is pushed into the fossa by triceps during flexion of the elbow. The two other fat pads are in the coronoid and radial fossae, and are pushed into these fossae by brachialis on extension of the elbow. Smaller fat pads covered by synovium project into the joint at the trochlear notch and also cover non-articular areas of bone.

Vascular supply The articular arteries of the elbow are derived from numerous small periarticular anastomoses around the joint (see Fig. 49.29).

Innervation The elbow joint is innervated by filaments arising from all of the main nerves of the upper limb, except for the axillary nerve. The ulnar posterior part is supplied by the ulnar nerve and the medial cutaneous nerve of forearm; the ulnar anterior part is supplied by the median and musculocutaneous nerves. The radial nerve is the sole supplier of the radial posterior part, and the radial anterior part is innervated by both radial and musculocutaneous nerves (de Kesel et al 2012).

## PROXIMAL RADIO-ULNAR JOINT

The proximal radio-ulnar joint is a uniaxial pivot joint (Fig. 49.14).
Articulating surfaces Articulating surfaces include the articulation between the circumference of the radial head and the fibro-osseous ring of the ulnar radial notch and anular ligament.

Fibrous capsule The fibrous capsule of the proximal radio-ulnar joint is continuous with that of the elbow and is attached to the anular ligament.

Ligaments The proximal radio-ulnar joint has anular and quadrate ligaments.

Anular ligament The anular ligament is the principal stabilizer of the joint. It is a strong composite band that winds around four-fifths of the
radial head and holds it against the radial notch of the ulna. It is attached to the anterior margin of the notch. The ligament is wider posteriorly, where it may be composed of several bands. It is attached to a rough ridge at or behind the posterior margin of the notch. Some bands may diverge and attach superiorly to the lateral margin of the trochlear notch, or inferiorly to the supinator crest. Proximally, the anular ligament blends into the joint capsule, except posteriorly where the capsule is deep to the ligament. Distally, the anular ligament gives off a few fibres, which pass over the synovial membrane to attach to the radial neck. The superficial surface of the anular ligament blends into the radial collateral ligament and provides an attachment for a part of supinator. The deep surface of the anular ligament is lined with a thin layer of cartilage where it is in contact with the radial head. Distally, there is a synovial membrane that is reflected up on to the radial neck. The anconeus and the interosseous recurrent artery lie behind the ligament.

Quadrate ligament The quadrate ligament is a much thinner and more fibrous structure than the anular ligament. It runs between the radial neck and the upper part of the supinator fossa of the ulna, and is taut throughout pronation and supination. It lies over the synovial membrane on the distal surface of the joint.

Synovial membrane The synovial membrane of the proximal radioulnar joint is continuous with that of the elbow joint, forming one continuous synovial cavity. It attaches to the joint margins, lining

Fig. 49.14 The proximal left radio-ulnar joint. A, A transverse section. B, An axial magnetic resonance imaging (MRI) scan.

the capsule and anular ligament. The quadrate ligament prevents herniation of the synovial membrane between the free edges of the anular ligament.

Vascular supply The vascular supply of the proximal radio-ulnar joint is derived from a rich periarticular anastomotic plexus (Fig. 49.18; see Fig. 49.19).

Innervation The proximal radio-ulnar joint is innervated by small branches arising from the musculocutaneous, median, radial and ulnar nerves.

## RADIO-ULNAR SYNDESMOSES

The radial and ulnar shafts are connected by two syndesmoses, an oblique cord and an interosseous membrane.

## Oblique cord

The oblique cord is a small, inconstant, flat fascial band on the deep head of supinator (see Fig. 49.10). It extends from the lateral side of the ulnar tuberosity to the radius a little distal to its tuberosity. Its fibres are at right angles to those in the interosseous membrane. Its functional significance is unclear.

## Interosseous membrane

The interosseous membrane is a broad, thin, collagenous structure (see Fig. 49.10). Its fibres slant distomedially between the interosseous borders of the radius and ulna, and its distal part is attached to the posterior division of the radial shaft. Two or three posterior bands occasionally descend distolaterally across the other fibres. The membrane is deficient proximally, starting 2 or 3 cm distal to the radial tuberosity, and broadest at midlevel. An oval aperture near its distal margin conducts the anterior interosseous vessels to the back of the forearm. The posterior interosseous vessels pass through a gap between its proximal border and the oblique cord.

The membrane provides attachments for the deep forearm muscles. Anteriorly, in its proximal three-quarters, it is related laterally to flexor pollicis longus and medially to flexor digitorum profundus; between them, it is related to the anterior interosseous vessels and nerve. In its distal quarter, it is related to pronator quadratus. Its posterior relations are supinator, abductor pollicis longus, extensors pollicis brevis, longus and indicis, and, near the carpus, the anterior interosseous artery and posterior interosseous nerve.

The interosseous membrane consists of several parts, the most important of which is the central band originally described by Hotchkiss et al (1989). This probably acts in conjunction with the radial head to restrain the radius from proximal migration and stabilize the forearm. Previously described as being at its most taut in almost every position of rotation of the forearm, it now appears to maintain the same tension throughout pronation and supination. Noda et al (2009) have described four other subsidiary portions.

## DISTAL RADIO-ULNAR JOINT

The distal radio-ulnar joint is a uniaxial pivot joint.
Articulating surfaces The articulating surfaces are between the convex distal head of the ulna and the concave ulnar notch of the radius; they are connected by an articular disc.

Fibrous capsule The fibrous capsule is thicker anteriorly and posteriorly, and more lax proximally.

Triangular fibrocartilage complex and distal radio-ulnar ligaments The triangular fibrocartilage complex (TFCC) is a ligamentous and cartilaginous structure that suspends the distal radius and ulnar carpus from the distal ulna. It stabilizes the ulnocarpal and radioulnar joints, transmits and distributes load from the carpus to the ulna, and facilitates complex movements at the wrist. By definition, it is made up of the triangular fibrocartilage proper (the articular disc), meniscus homologue (the ulnocarpal meniscus), ulnar collateral ligament, dorsal and palmar radio-ulnar ligaments, floor of extensor carpi ulnaris subsheath, and the ulnolunate and ulnotriquetral ligaments. The triangular fibrocartilage proper is a biconcave body composed of chondroid
fibrocartilage that extends across the dome of the ulnar head, ranging in thickness between 2 and 5 mm . The meniscal homologue is a broad expansion of loose connective tissue that runs from the articular disc to the ulnar styloid and the surrounding joint capsule; it is not a major contributor to the structural integrity of the triangular fibrocartilage complex.

The triangular fibrocartilage complex is attached to the ulnar aspect of the lunate fossa of the radius. Medially, it is inserted into the head of the ulna and the base of the ulnar styloid. Here, it is joined by fibres from the ulnar part of the ulnar styloid (the ulnar collateral ligament); thus thickened, it attaches to the lunotriquetral interosseous ligament, triquetrum, hamate and base of the fifth metacarpal. A constant perforation just distal to the level of the ulnar styloid leads to the prestyloid recess. The dorsal and palmar (volar) aspects of the triangular fibrocartilage complex are thickened to form the dorsal and palmar radioulnar ligaments, which are attached to the dorsal and volar ulnar corners of the distal radius and to the fovea of the ulnar head at the base of the ulnar styloid (Palmer and Werner 1981, Pacek and Buterbaugh 2015).

The triangular fibrocartilage complex receives its blood supply from the ulnar artery via its palmar and dorsal radiocarpal branches, the dorsal branch of the anterior interosseous artery and the palmar branch of the anterior interosseous artery. Only the outer 15-20\% of the disc is vascularized; the rest is avascular (Thiru-Pathi et al 1986, Bednar et al 1991) (Fig. 49.19).

The triangular fibrocartilage complex acts as a cushion for the ulnar carpus, preventing ulnocarpal abutment and overloading of the ulna in ulnar deviation. It is a major stabilizer of the distal radio-ulnar joint. Degenerative perforation of the triangular fibrocartilage complex becomes more common with age and is a constant finding after the age of 50 years (Mikić 1978).

Synovial membrane The synovial membrane lines the capsule and forms a sacciform recess in front of the distal part of the interosseous membrane (see Fig. 50.41).

Vascular supply The arterial supply of the distal radio-ulnar joint is derived from the palmar and dorsal branches of the anterior interosseous artery, reinforced by the posterior interosseous and ulnar arteries.

Innervation The distal radio-ulnar joint is innervated by branches of the anterior and posterior interosseous nerves.

## MOVEMENTS AT THE HUMERO-ULNAR, HUMERO-RADIAL AND PROXIMAL AND DISTAL RADIO-ULNAR JOINTS

The main movements that occur at the humero-ulnar, humero-radial and proximal and distal radio-ulnar joints are flexion, extension, supination and pronation.

## Flexion and extension

The elbow joint has relatively stable semi-congruent articular surfaces that are assisted by strong static and dynamic stabilizers, and which allow a flexion-extension arc of approximately $150^{\circ}$. When the elbow is extended and supinated, the forearm forms a 'carrying angle' with the humerus of approximately $17^{\circ}$; the absolute angle varies from individual to individual. It exists because the medial edge of the trochlear projects distally by 6 mm and because the superior articular surface of the coronoid is oblique. The carrying angle is not present in flexion when the humerus and ulna are in the same plane. With the arm adducted and the elbow flexed, the little finger meets the clavicle. If the humerus is rotated laterally, the little finger reaches the anterior shoulder. Pronation of the extended forearm masks the carrying angle by lining up the arm, forearm and hand.

## Accessory movements

Available with the Gray's Anatomy e-book

## Pronation and supination

Movements at the humero-radial, proximal and distal radio-ulnar joints pronate and supinate the hand. In pronation, the radius turns

The surface topography of the humero-ulnar joint permits some rotation of the ulna against the humerus. The radius acts as a mobile strut within the forearm, such that rotation of the distal radius around the ulna carries the radiocarpal joint, wrist and hand into pronation or supination. The medial side of the head of radius is longer than the lateral side; this eccentric morphology causes a cam effect during rotation of the proximal radio-ulnar joint. The radius gives longitudinal stability to the forearm by protecting the ulna from side-to-side forces.

The interosseous membrane contributes to longitudinal stability by virtue of its oblique course from the radius proximally to the ulna distally. It appears to maintain the same tension throughout pronation and supination (Ekenstam et al 1984). If the membrane is disrupted, as in an Essex-Lopresti injury (fracture of the head of the radius, disruption of the interosseous membrane and dislocation of the distal radioulnar joint), the radius will migrate proximally; persistent radio-ulnar dissociation causes a complex instability of the forearm (Hotchkiss et al 1989). Correction of the fixed deformity of the forearm commonly seen in untreated cases of spastic cerebral palsy or birth lesions of the brachial plexus usually requires release of the membrane because it has become relatively shortened. Pronator quadratus and supinator protect the interosseous membrane, to some extent, during forced, rapid rotation of the forearm by 'paying out' eccentrically, thereby reducing the load applied across the membrane.

The elbow is stabilized by the intrinsic shape of the joint and by its ligaments and muscles. The trochlear pulley is deeply seated within the trochlear notch, while the olecranon provides anteroposterior stability. Anterior stability in the sagittal plane is enhanced by the joint capsule, biceps, brachialis and the bicipital aponeurosis; posterior stability is enhanced by the triceps tendon and aponeurosis.

The radial and ulnar collateral ligaments are key to stability in the coronal plane. Resistance to varus strain comes from the radial ligament complex, of which the posterior band is the most important. Resistance to valgus strain is provided by the ulnar collateral ligament complex, of which the anterior band is the most important. If the head of the radius is lost, an intact ulnar collateral ligament maintains stability of the elbow. If the ligament is disrupted, the ulna drifts into valgus, there is rotational instability and the trochlea is damaged. Stability of the radius is enhanced by anconeus and by the muscles arising from the lateral aspect of the distal humerus. Muscles that arise from the medial epicondyle contribute to stability of the ulna. Muscles that act across the elbow have a shunting effect, creating articular joint reaction compression forces that contribute to close-packing (the position of a joint in which the greatest stability is achieved for the least expended effort). The humero-ulnar joint is most closely packed and, therefore, most resistant to fatigue in flexion and supination.

The flexion-extension arc of the elbow is accompanied by some rotation; the ulna is slightly pronated in extension and supinated in flexion. In full extension, the radial head can be palpated posteriorly because the radial facet is larger than the capitulum. The excursion of the radial head in extension is limited by tension in the posterior capsule, by the muscles anterior to the joint and by the tip of the olecranon entering the olecranon fossa. In flexion, the rim of the radial head enters the radial fossa and the tip of the coronoid process enters the coronoid fossa. Flexion is principally limited by the apposition of soft tissues.
Accessory movements include anterior and posterior translation of the radial head on the ulnar radial notch, and of the ulnar head on the radial ulnar notch.

Accessory movements of the human elbow are minimal and facilitate the movements described above. The ulna rotates slightly at the elbow and allows a few degrees of abduction and adduction. The radial head exhibits a little anteroposterior translation on the capitulum when it moves on the ulnar radial notch and the anular ligament moves back and forth; this occurs maximally with the elbow in $90^{\circ}$ of flexion.

Fig．49．15 Radiographs of the left elbow joint of an adult． A，Anteroposterior view．Key：1，olecranon fossa；2，medial humeral epicondyle；3，shadow of olecranon superimposed on trochlea；4， humero－ulnar joint；5，radial head articulating with radial notch of ulna；6， lateral humeral epicondyle；7，capitulum；8，humero－radial joint；9，head of radius；10，radial tuberosity．B，Lateral view．Key：1，head of radius；2， profile of capitulum；3，profile of trochlea；4，olecranon．
anteromedially and obliquely across the ulna．Its proximal end remains lateral to the ulna while its distal end lies medially and the interosseous membrane becomes spiralled．In supination，the radius returns to its former position lateral and parallel to the ulna and the interosseous membrane becomes unspiralled．The hand can be turned through 140－ $150^{\circ}$ with the elbow extended；this can be increased to nearly $360^{\circ}$ by humeral rotation and movements of the scapula．Power is greater in supination，a fact that has affected the design of nuts，bolts and screws， which are tightened by supination in the right－handed．

## Stability of the distal radio－ulnar joint

With the wrist in neutral extension and deviation，the main axis for transmission of force from the hand to the forearm passes through the head of the capitate，then through the scapholunate ligament and finally into the distal radius．Loading is transferred to the triangular fibrocartilage complex and distal ulna in ulnar deviation．The joint is stabilized by extrinsic and intrinsic structures．

Fig．49．16 A sagittal section through the left elbow joint：medial aspect． The synovial membrane is shown in blue．（With permission from Waschke J，Paulsen F（eds），Sobotta Atlas of Human Anatomy，15th ed，Elsevier， Urban \＆Fischer．Copyright 2013．）

Extrinsic stabilizers Extrinsic stabilizers include the tendon of extensor carpi ulnaris，pronator quadratus，the interosseous membrane and the sheath of the sixth dorsal compartment，which overlies extensor carpi ulnaris（Spinner and Kaplan 1970）．

Intrinsic stabilizers Intrinsic stabilizers are stronger than extrinsic sta－ bilizers．They include the radio－ulnar capsule and the dorsal and palmar radio－ulnar ligaments．The dorsal and palmar radio－ulnar ligaments contain superficial and deep components．The superficial layers insert on to the ulnar styloid．The stronger deep layers insert more laterally into the fovea adjacent to the articular surface of the pole of the distal ulna（Kleinmann 2010）．

## Muscles producing movement

Flexion Movement is produced by brachialis，biceps brachii and brachioradialis．In slow flexion or its maintenance against gravity， brachialis and biceps are principally involved，even for light loads．With

Rotation of the forearm occurs between the head of the radius and the radial notch of the ulna proximally and the articulation of the head of the ulna and sigmoid notch. These proximal and distal radio-ulnar joints are pivot-type synovial joints; they act as a unit, permitting stable rotary motion (pronation $61-66^{\circ}$, supination $70-77^{\circ}$ ). During rotation, the distal radius moves around the head of the ulnar. The axis for pronation and supination is often represented as a line through the centre of the radial head proximally and the ulnar attachment of the articular disc distally. This represents the axis of movement of the radius relative to the ulna but this does not remain stationary. The radial head rotates in the fibro-osseous ring; its distal lower end and articular disc swing round the head of the ulna. Rotation of the radial head occurs on the humeral capitulum. As the forearm moves from full pronation into supination, the ulna translocates medially by $9-10 \mathrm{~mm}$, so that the axis of rotation shifts but still passes through the head of the ulna. In addition, the sigmoid notch changes its position of contact with the ulnar head, lying dorsal proximally in pronation and volar distally in supination. The distal end of the ulna is not stationary during these movements; it moves along a curved course, posterolaterally in pronation and anteromedially in supination. The axis of movement, as defined above, is therefore displaced laterally in pronation and medially in supination. Hence, the axis for pronation and supination of the forearm and hand passes between the bones at both the proximal and distal radio-ulnar joints when ulnar movement is marked, but through the centres of the radial head and ulnar styloid when it is minimal. The axis may be extended along any digit, depending on whether the distal end of the ulna is medially or laterally displaced. The hand will rotate further than the forearm because of the sliding-rotatory movement that occurs between the carpal bones and the bases of the metacarpals, and, to a very minor degree, at the radiocarpal joint.

Fig. 49.18 The prime intrinsic stabilizer of the distal radio-ulnar joint is the triangular fibrocartilage. The triangular fibrocartilage complex consists of superficial and deep radio-ulnar fibres, the two disc carpal ligaments (disc-lunate (D-L) and disc-triquetral ( $\mathrm{D}-\mathrm{T}$ ), and the central articular disc. The articular disc is responsible for transferring load from the medial carpus to the pole of the distal ulna. The vascularized, peripheral radio-ulnar ligaments are nourished by dorsal and palmar branches of the posterior interosseous artery and are responsible for guiding the radiocarpal unit around the seat of the ulna. (Redrawn with permission from Kleinmann WB 2010 Stability of the distal radioulnar joint: biomechanics, pathophysiology, physical diagnosis and restoration of function. In: Slutsky DJ (ed) Principle and Practice of Wrist Surgery. Chapter 5, pp. 41-45.)

Fig. 49.19 The arterial anatomy of the triangular fibrocartilage complex. (Redrawn with permission from Thiru-Pathi RG, Ferlic DC, Clayton MI, McClure DC 1986 Arterial anatomy of the triangular fibrocartilage of the wrist and its surgical significance. Journal of Hand Surgery 11A, 258-263.)
increasing speed and activity, brachioradialis is increasingly prominent; its attachments determine that it acts most effectively in mid-pronation. Against resistance, pronator teres, longus and brevis, flexors carpi radialis and ulnaris, and extensor carpi radialis may contribute.

Extension Movement is produced by triceps, anconeus and gravity.
Pronation Pronator quadratus is aided in rapid movement and against resistance by pronator teres. Gravity also assists.

Supination Movement is produced by supinator, in slow unresisted movement and extension, assisted by biceps in fast movements in flexion, especially when resisted.

## MUSCLES OF THE FOREARM

There is some anatomical segregation by function of muscles that cross the elbow. Most of those that arise medially pass to the flexor aspect of the wrist, or stabilize or move the ulnar column of the carpus and the ulnar side of the hand. Those that arise laterally pass to the lateral column of the forearm and carpus, and to the extensor aspect of the wrist. The muscles that act on the thumb have a wide origin; the extensor and abductor muscles arise from the entire width of the interosseous membrane. Rotator muscles, such as supinator, pronator teres and pronator quadratus, pass between the radius and ulna, crossing the longitudinal axis of the forearm.

## ANTERIOR COMPARTMENT

The anterior compartment contains the flexor muscles of the forearm. These are arranged in superficial and deep groups.

## Superficial flexor (volar) compartment

Muscles of the superficial flexor compartment are pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum superficialis and flexor carpi ulnaris.

## Pronator teres

Attachments Pronator teres arises from two heads. The humeral origin of pronator teres is the larger and more superficial. It arises at the medial supracondylar ridge just proximal to the medial epicondyle from the common tendon of origin of the flexor muscles, from the intermuscular septum between it and flexor carpi radialis, and from the antebrachial fascia (see Fig. 49.6, Figs 49.20-49.22). The smaller ulnar head arises from the medial side of the coronoid process of the ulna, distal to the attachment of flexor digitorum superficialis, and joins the humeral head at an acute angle. This ulnar coronoid attachment may be absent in some individuals. The muscle passes obliquely across the forearm to end in a flat tendon that is attached to a rough area midway along the lateral surface of the radial shaft at the apex of its lateral curve (see Fig. 49.25). Accessory slips may arise from a supracondylar process of the humerus, if present, or from biceps, brachialis or the medial intermuscular septum.

Relations The median nerve usually enters the forearm between the two heads of pronator teres, separated from the ulnar artery by the ulnar head. The lateral border of pronator teres is the medial margin of the cubital fossa (see Fig. 46.29). Proximally, the medial border of pronator teres is related to the lateral aspect of flexor carpi radialis. Pronator teres is anterior to flexor digitorum superficialis.

Vascular supply The humeral head of pronator teres is supplied by the inferior ulnar collateral and anterior ulnar recurrent arteries. The ulnar head is supplied by the common interosseous artery, the mid portion of the muscle belly by direct branches from the ulnar artery, and the radial insertion by the radial artery.

Innervation Pronator teres is innervated by the median nerve, C6 and 7.

Actions Pronator teres pronates the forearm by rotating the radius medially on the ulna. It is a weak flexor of the elbow joint.

Testing Pronator teres is tested by palpating its contracting fibres during pronation against resistance.

## Flexor carpi radialis

Attachments Flexor carpi radialis arises from the medial epicondyle via the common composite flexor tendon, from the antebrachial fascia and from adjacent intermuscular septa (see Fig. 48.11A). Its fusiform muscular belly converges in the mid-forearm into a long tendon that passes within a synovial sheath through a lateral canal, formed by the flexor retinaculum above and a groove on the trapezium beneath. It inserts on the palmar surface of the base of the second metacarpal and sends a slip to the third metacarpal. These distal attachments lie beneath the oblique head of adductor pollicis. Rarely, the muscle may be absent.

Fig. 49.20 The superficial flexor muscles of the left forearm. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

There may be accessory slips from the biceps tendon, bicipital aponeurosis, coronoid process or radius. Distally, it may also be attached to the flexor retinaculum, trapezium or fourth metacarpal.

Relations At its origin, flexor carpi radialis lies medial to pronator teres. In the lower part of the forearm, the radial artery lies between the tendon of flexor carpi radialis and the tendon of brachioradialis; the radial pulse may be palpated proximal to the wrist between these two tendons.

Vascular supply Flexor carpi radialis is supplied by a single dominant proximal pedicle and several distal minor pedicles. The dominant pedicle is formed by a branch that arises from either the anterior or the posterior ulnar recurrent artery. The posterior ulnar recurrent artery passes deep to pronator teres to enter the deep surface of flexor carpi radialis; from here, it divides into a small ascending branch and a larger descending branch. The distal minor pedicles supplying flexor carpi radialis are six to eight branches from the radial artery that enter the muscle on the anterolateral side.

Innervation Flexor carpi radialis is innervated by the median nerve, C6 and 7.

Fig. 49.21 The deep flexor muscles of the left forearm. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Actions Flexor carpi radialis is a wrist flexor. It acts with flexor carpi ulnaris to effect balanced wrist flexion, and in concert with the radial extensors of the wrist to achieve balanced abduction of the hand.

Testing Flexor carpi radialis is tested by palpating its contracting fibres during flexion of the wrist against resistance.

## Flexor digitorum superficialis

Attachments Flexor digitorum superficialis is the largest of the superficial flexors, and arises by two heads (see Figs 48.11A, 49.20-49.21). The humero-ulnar head arises from the medial epicondyle of the humerus via the common flexor origin, the anterior band of the ulnar collateral ligament, adjacent intermuscular septa, and from the medial side of the coronoid process proximal to the ulnar origin of pronator teres. The radial head, a thin sheet of muscle, arises from the anterior radial border between the radial tuberosity and the insertion of pronator teres. The median nerve and ulnar artery descend between the heads. The muscle usually separates into two strata, directed to digits two to five. The superficial stratum, joined laterally by the radial head, divides into two tendons for the middle and ring fingers. The deep stratum gives off a muscular slip to join the superficial fibres directed to the ring finger, and ends in two tendons for the index and little fingers. As the tendons pass behind the flexor retinaculum, they are arranged in pairs; the superficial pair passes to the middle and ring fingers, the deep pair to the index and little fingers (see Fig. 50.41). The four tendons diverge

Fig. 49.22 The deep flexor aspect of the left forearm. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
distal to the carpal tunnel. Each passes towards a finger superficial to the corresponding tendon of flexor digitorum profundus. The two tendons for each finger enter the digital flexor sheath at the metacarpophalangeal joint. The superficialis tendon splits into two bundles that pass around the profundus to lie posteriorly, and then reunite to insert into the anterior surface of the middle phalanx. Some fibres interchange from one bundle to another.

An intermediate tendon is always found in the central branching area of the muscle belly and is an important landmark in deep dissection; it may be confused with the median nerve. The radial head of flexor digitorum superficialis may be absent and the muscular slip from the deep stratum may provide most or all of the fibres acting on the index finger. The fibres associated with the little finger may be absent, in which case they are replaced by a separate slip from the ulna, flexor retinaculum or palmar fascia. Variations occur in the arrangement of the tendons.

Relations Flexor digitorum superficialis runs deep to pronator teres and flexor carpi radialis. The median nerve and ulnar artery descend between the heads of flexor digitorum superficialis, and the nerve continues distally deep to the muscle.

Vascular supply The humeral head of flexor digitorum superficialis is supplied by the anterior ulnar recurrent artery. The main body of the muscle is supplied on its anterior surface by three or four branches from
both the ulnar and the radial arteries. The posterior surface is supplied by the ulnar artery and median artery, and the lateral surface by additional branches from the radial artery.

Innervation Flexor digitorum superficialis is innervated by the median nerve, C8 and T1.

Actions Flexor digitorum superficialis is a flexor of all the joints over which it passes, i.e. the wrist, metacarpophalangeal and proximal interphalangeal joints; its precise action depends on which other muscles are acting. It has independent muscle slips to all four fingers, and is therefore able to flex the proximal interphalangeal joints individually, unlike flexor digitorum profundus, which has a muscle group common to the middle, ring and little fingers.

Testing The independent action of flexor digitorum superficialis for a particular finger is tested by flexing that digit while holding the three other fingers in full extension. This eliminates any simultaneous contraction of the flexor digitorum profundus that might flex the digit.

## Palmaris longus

Attachments Palmaris longus arises from the medial epicondyle of the humerus via the common flexor origin and from adjacent intermuscular septa and deep fascia. It is a slender, fusiform muscle that runs medial to flexor carpi radialis (see Figs 48.11A, 49.20, 49.32). It becomes tendinous in the mid-forearm, and the long tendon passes anterior (superficial) to the flexor retinaculum. A few fibres leave the tendon and interweave with the transverse fibres of the retinaculum but most of the tendon passes distally. As the tendon crosses the retinaculum, it broadens out to become a flat sheet that becomes incorporated into the palmar aponeurosis. Palmaris longus is occasionally absent on one or both sides.

Relations Palmaris longus runs distally, flanked by flexor carpi radialis and flexor carpi ulnaris, and superficial to flexor digitorum superficialis. The median nerve at the wrist lies partly under the cover of the tendon of palmaris longus and partly between the tendons of palmaris longus and flexor carpi radialis.

Vascular supply The muscle belly of palmaris longus is supplied by a small branch from the anterior ulnar recurrent artery. A contribution is sometimes made by the median artery, if this is well developed.

Innervation Palmaris longus is innervated by the median nerve, C7 and 8 .

Actions Palmaris longus is a weak wrist flexor. Through its insertion in the palmar aponeurosis, it also acts as an anchor for the skin and fascia of the hand against horizontal shearing forces.

Testing If the wrist is flexed against resistance, the taut tendon of palmaris longus will be seen in the midline of the flexor wrist crease as the tendon passes superficial to the flexor retinaculum. When testing palmaris longus, it helps to oppose the thumb to the middle fingertip at the same time as the wrist is flexed, in order to make palmaris stand out.

## Flexor carpi ulnaris

Attachments Flexor carpi ulnaris is the most medial of the superficial forearm flexors (see Figs 49.20, 49.31, 49.32). It arises by two heads, humeral and ulnar, connected by a tendinous arch. The smaller humeral head arises from the medial epicondyle via the common composite tendon (see Fig. 48.11A). The ulnar head has an extensive origin from the medial margin of the olecranon and proximal two-thirds of the posterior border of the ulna (from an aponeurosis shared with extensor carpi ulnaris and flexor digitorum profundus) and from the intermuscular septum between it and flexor digitorum superficialis (see Fig. 49.6). Occasionally, there is a slip from the coronoid process. A thick tendon forms along its anterolateral border in its distal half. The tendon is attached to the pisiform, and from here it is prolonged to the hamate and fifth metacarpal by pisohamate and pisometacarpal ligaments. The attachment to the flexor retinaculum and the fourth or fifth metacarpal bones is sometimes substantial.

Relations Flexor carpi ulnaris is the most medial of the forearm flexors and forms the bulk of the soft tissue cover of the medial aspect of the ulna. The ulnar nerve and posterior ulnar recurrent artery pass under the tendinous arch between its humeral and ulnar heads. Ulnar vessels and nerve lie lateral to its tendon in the distal forearm.

Vascular supply The main arterial supply of flexor carpi ulnaris is derived from three pedicles. The proximal pedicle arises from a branch of the posterior ulnar recurrent artery as it passes between the humeral and ulnar heads. The middle pedicle arises from the ulnar artery and enters the muscle at the junction of the upper and middle thirds. The distal pedicles arise from the ulnar artery and enter the muscle at the musculotendinous junction. Flexor carpi ulnaris also receives a small supply near its origin from the inferior ulnar collateral artery.

Innervation Flexor carpi ulnaris is innervated by the ulnar nerve, C7, 8 and T1.

Actions Flexor carpi ulnaris is a powerful flexor and also adductor (ulnar deviation) of the wrist. When it acts with flexor carpi radialis, balanced wrist flexion is achieved. When it acts with extensor carpi ulnaris, balanced adduction occurs.

Testing Flexor carpi ulnaris is tested by palpating its tendon while the wrist is flexed against resistance, or by palpating the tendon while the patient abducts the little finger against resistance. The muscle synergistically stabilizes the pisiform, giving abductor digiti minimi a stable origin.

## Deep flexor (volar) compartment

The muscles of the deep flexor compartment are flexor digitorum profundus, flexor pollicis longus and pronator quadratus (see Fig. 49.22).

## Flexor digitorum profundus

Attachments Flexor digitorum profundus arises deep to the superficial flexors from the proximal three-quarters of the anterior and medial surfaces of the ulna (see Figs 49.5, 49.6, 49.22). It embraces the attachment of brachialis above and extends distally almost to pronator quadratus. It also arises from a depression on the medial side of the coronoid process, from the proximal three-quarters of the posterior ulnar border by an aponeurosis that it shares with flexor and extensor carpi ulnaris, and from the anterior surface of the ulnar half of the interosseous membrane. The muscle ends in four tendons that run deep to the tendons of flexor digitorum superficialis and the flexor retinaculum (see Fig. 50.41). The part of the muscle that acts on the index finger is usually distinct throughout, while the tendons for the other fingers are interconnected by areolar tissue and tendinous slips as far as the palm. Anterior to their proximal phalanges, the tendons pass through the tendons of flexor digitorum superficialis to insert on the palmar surfaces of the bases of the distal phalanges. The tendons of the profundus undergo fascicular rearrangement as they pass through those of superficialis. Flexor digitorum profundus may be joined by accessory slips from the radius (which act on the index finger), flexor superficialis, flexor pollicis longus, the medial epicondyle or the coronoid process.

Relations Flexor digitorum profundus forms most of the surface elevation medial to the palpable posterior ulnar border. In the forearm, the median nerve runs on the anterior surface of its lateral aspect. In the palm, the lumbricals are attached to its tendons.

Vascular supply The origin of flexor digitorum profundus is supplied by the inferior ulnar collateral and ulnar recurrent arteries. The proximal part is supplied by one or two branches from either the ulnar or the common interosseous artery. The distal part is supplied by a series of branches from the ulnar artery, the anterior interosseous artery and the median artery.

Innervation The medial part of flexor digitorum profundus, i.e. the muscle bellies to the little and ring fingers, is innervated by the ulnar nerve. The lateral part, i.e. the muscle bellies to the middle and index fingers, is innervated by the anterior interosseous branch of the median nerve, C8 and T1.

Actions Flexor digitorum profundus flexes the distal interphalangeal joints of the fingers. It is also capable of flexing any or all of the joints over which it passes and therefore has a role in coordinated finger flexion. The index finger tendon is usually capable of independent function, whereas the other three work together.

Testing Flexor digitorum profundus is tested by flexing the distal interphalangeal joint while holding the proximal interphalangeal joint in extension.

## Flexor pollicis longus

Attachments Flexor pollicis longus arises from the grooved anterior surface of the radius, and extends from below its tuberosity to the upper attachment of pronator quadratus (see Figs 49.5, 49.21-49.22). It also arises from the adjacent interosseous membrane and, frequently, by a variable slip from the lateral, or more rarely medial, border of the coronoid process, or from the medial epicondyle of the humerus. The muscle ends in a flattened tendon that passes behind the flexor retinaculum, between opponens pollicis and the oblique head of adductor pollicis, to enter a synovial sheath. It inserts on the palmar surface of the base of the distal phalanx of the thumb.

Flexor pollicis longus can sometimes be connected to flexor digitorum superficialis or profundus, or pronator teres. The interosseous attachment, and, indeed, the whole muscle, may be absent. Anomalous tendon slips from the flexor pollicis longus to flexor digitorum profundus are common.

Relations Flexor pollicis longus runs lateral to flexor digitorum profundus. The anterior interosseous nerve and vessels descend on the interosseous membrane between these muscles.

Vascular supply The medial half of flexor pollicis longus is supplied by the anterior interosseous artery. The lateral half is supplied by branches of the radial artery. The median artery may contribute if it is well developed.

Innervation Flexor pollicis longus is innervated by the anterior interosseous branch of the median nerve, C7 and 8 .

Actions Flexor pollicis longus principally flexes the phalanges of the thumb. It also flexes the carpometacarpal joint of the thumb, especially if the more distal joints are stiff or fused.

Testing Flexor pollicis longus is tested by flexing the interphalangeal joint of the thumb against resistance.

## Pronator quadratus

Attachments Pronator quadratus is a flat, quadrilateral muscle that extends across the front of the distal parts of the radius and ulna (see Figs 49.5, 49.27). It arises from the oblique ridge on the anterior surface of the shaft of the ulna, the medial part of this surface and a strong aponeurosis that covers the medial third of the muscle. The fibres pass laterally and distally to the distal quarter of the anterior border and surface of the shaft of the radius (see Fig. 50.30). Deeper fibres insert into the triangular area above the ulnar notch of the radius.

Vascular supply Pronator quadratus receives its main arterial supply from the anterior interosseous artery as it passes through the interosseous membrane.

Innervation Pronator quadratus is innervated by the median nerve, C7 and 8.

Actions Pronator quadratus is a pronator of the forearm. The deeper fibres oppose separation of the distal ends of the radius and ulna when axial load is transmitted through the carpus.

Testing Pronator quadratus is tested by pronation of the forearm against resistance while the wrist finger flexors are relaxed. The simultaneous contraction of pronator teres makes it difficult to test the independent action of pronator quadratus.

## POSTERIOR COMPARTMENT

The posterior compartment contains the extensor muscles of the forearm, brachioradialis and supinator. The superficial posterior muscles include anconeus, brachioradialis, extensor carpi radialis longus, extensor carpi radialis brevis, extensor digitorum, extensor digiti minimi and extensor carpi ulnaris. The deep posterior group of muscles includes supinator, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus and extensor indicis.

## Superficial extensor compartment

## Brachioradialis

Attachments Brachioradialis is the most superficial muscle along the radial side of the forearm and forms the lateral border of the cubital
fossa (see Figs 49.22, 49.25). It arises from the proximal two-thirds of the lateral supracondylar ridge of the humerus and the anterior surface of the lateral intermuscular septum (see Figs 48.11A, 49.5). The muscle fibres end above mid-forearm level in a flat tendon that is inserted on the lateral side of the distal end of the radius, just proximal to the styloid process. This attachment may be more proximal; the muscle may fuse proximally with brachialis and the tendon may, occasionally, divide into two or three separately attached slips. In rare instances, it is double or absent.

Relations The radial nerve and the anastomosis between the profunda brachii artery and the radial recurrent artery lie in the groove between brachioradialis and brachialis, anterior to the lateral intermuscular septum. The tendon is crossed near its distal end by the tendons of abductor pollicis longus and extensor pollicis brevis. The radial artery is on its ulnar (medial) side. The superficial radial nerve emerges from between brachioradialis and extensor carpi radialis brevis to run superficially over the tendon of extensor carpi radialis brevis and extensor pollicis brevis, and then superficial to the extensor retinaculum.

Vascular supply Brachioradialis is supplied by branches of the radial recurrent artery that pierce the posteromedial surface of the muscle. It also receives branches from the radial collateral branch of the profunda brachii and directly from the radial artery in the distal part of the muscle.

Innervation Brachioradialis is innervated by the radial nerve, C5 and 6 .

Actions Brachioradialis is a powerful flexor of the elbow, acting most strongly with the forearm in mid-pronation. It is minimally active in slow flexion or with the forearm supine, but generates a powerful burst of activity in both flexion and extension when movement is rapid. Under these conditions, it develops a pronounced transarticular component of its force that helps to stabilize the elbow joint by balancing the centrifugal force of rapid swings in either direction.

Testing Brachioradialis can be seen and felt when the semi-pronated forearm is flexed against resistance.

## Extensor carpi radialis longus

Attachments Extensor carpi radialis longus arises from the distal third of the lateral supracondylar ridge of the humerus and the front of the lateral intermuscular septum (see Fig. 48.11A). Some fibres join from the common tendon of origin of the forearm extensors. The muscle belly ends at the junction of the proximal and middle thirds of the forearm in a flat tendon that runs along the lateral surface of the radius, deep to abductor pollicis longus and extensor pollicis brevis. The tendon passes deep to the dorsal carpal ligament in a radial groove behind the styloid process alongside extensor carpi radialis brevis. Just before it is inserted on the radial side of the dorsal surface of the base of the second metacarpal, the tendon is crossed obliquely by the tendon of extensor pollicis longus. It may send slips to the first or third metacarpal bones and contributes to the intermetacarpal ligaments.

Relations Extensor carpi radialis longus runs alongside brachioradialis and is partly overlapped by it.

Vascular supply Extensor carpi radialis longus receives its principal arterial supply from a single branch of the radial recurrent artery. Additional blood supply comes from branches of the radial collateral branch of the profunda brachii and directly from the radial artery in the distal part of the muscle.

Innervation Extensor carpi radialis longus is innervated by the radial nerve, C6 and 7.

Actions Extensor carpi radialis longus acts as an extensor and abductor of the wrist and midcarpal joints.

Testing The muscle belly and tendon of extensor carpi radialis longus can be palpated when the wrist is extended and abducted against resistance with the forearm pronated.

## Extensor carpi radialis brevis

Attachments Extensor carpi radialis brevis arises from the lateral epicondyle of the humerus by a common tendon shared with extensor digitorum, extensor digiti minimi and extensor carpi ulnaris, the radial collateral ligament of the elbow joint, a strong aponeurosis that covers
its surface, and adjacent intermuscular septa. The muscle belly ends at mid-forearm in a flat tendon that closely accompanies that of extensor carpi radialis longus to the wrist. The tendon passes under the extensor retinaculum, is crossed by the tendon of extensor pollicis longus, and is attached to the dorsal surface of the base of the third metacarpal on its radial side, distal to its styloid process, and on adjoining parts of the base of the second metacarpal. The tendons of both extensor carpi radialis longus and brevis share a common synovial sheath (see Fig. 50.41); they may split into slips that are variably attached to the second and third metacarpal bones. The muscles themselves may be united or may exchange muscular slips.

Relations Extensor carpi radialis brevis is shorter than extensor carpi radialis longus and is covered by it. The tendon passes deep to abductor pollicis longus and extensor pollicis brevis in the distal third of the forearm, then under the extensor retinaculum, where it lies in a shallow groove on the back of the radius, medial to the tendon of extensor carpi radialis longus, and separated from it by a low ridge.

Vascular supply Extensor carpi radialis brevis receives its arterial supply principally from two pedicles: a single branch from the radial recurrent artery, and a branch of the radial artery that arises about onethird of the way down the forearm. There is an additional blood supply proximally from branches from the radial collateral branch of the profunda brachii.

Innervation Extensor carpi radialis brevis is innervated by a branch from the radial nerve or from the posterior interosseous nerve, C7 and 8. The branch to extensor carpi radialis brevis arises before the nerve enters the arcade of Frohse.

Actions Extensor carpi radialis brevis is the prime dorsiflexor of the wrist. It acts with extensor carpi radialis longus as an extensor and abductor of the wrist and mid-carpal joints. It acts in synergism with the finger flexors when making a fist.

Testing The muscle belly and tendon of extensor carpi radialis brevis can be palpated when the wrist is extended and abducted against resistance with the forearm pronated.

## 'Mobile wad' of Henry

Available with the Gray's Anatomy e-book

## Extensor digitorum

Attachments Extensor digitorum arises from the lateral epicondyle of the humerus via the common extensor tendon, the adjacent intermuscular septa and the antebrachial fascia (see Fig. 48.11A). The muscle belly divides in the distal third of the forearm into four tendons, which pass in a common synovial sheath with the tendon of extensor indicis through a tunnel under the extensor retinaculum (see Fig. 50.41). The tendons diverge on the dorsum of the hand, one to each finger. The tendon to the index finger is accompanied by extensor indicis, which lies ulnar (medial) to it. On the dorsum of the hand, adjacent tendons are linked by three variable intertendinous connections (juncturae tendinae), which are inclined distally and radially (see Figs 49.23, 50.6). The digital attachments enter a fibrous expansion on the dorsum of the proximal phalanges, to which lumbrical, interosseous and digital extensor tendons all contribute.

The tendons of extensor digitorum may be variably deficient. More commonly, they are doubled, or even tripled, in one or more digits: most often, the index finger or the middle finger. Occasionally, a slip of tendon passes to the thumb. The arrangement of the intertendinous connections on the dorsum of the hand is highly variable. The medial connection is strong and pulls the tendon of the little finger towards that of the ring finger, whereas the connection between the middle two tendons is weak and may be absent.

Relations The extensor tendon to the index finger lies radial (lateral) to the tendon of extensor indicis. The extensor tendon to the little finger lies radial (lateral) to the tendon of extensor digiti minimi.

Vascular supply The proximal third of extensor digitorum is supplied by branches from the radial recurrent artery, and the distal twothirds are supplied by branches from the posterior interosseous artery. The very distal portion is supplied by a perforating branch from the anterior interosseous artery that passes through the interosseous membrane.

Henry (1957) described a 'mobile wad' of three muscles, brachioradialis and the extensors carpi radialis longus and brevis, which are visible and palpable below the lateral epicondyle of the humerus, lying on the lateral aspect of the radius. The wad is tethered by a fan-shaped leash of vessels derived from the radial artery (the radial recurrent artery) that has to be released before the muscles can be fully mobilized. Its anterior and posterior margins are used to define the surgical approaches to the radius and to discover planes of cleavage. The anterior margin is used to define the anterior approach (of Henry) to the radius and can be extended down to the wrist at the level of the insertion of brachioradialis. This requires detachment of supinator from the radius, taking care not to damage the posterior interosseous nerve. More distally, pronator teres is released. This approach is particularly useful for plating fractures of the radius. The posterior margin is used to expose the back of the forearm (posterior approach of Thompson) and, if need be, the posterior interosseous nerve, which, in any event, should be protected; unlike the anterior approach, this approach cannot be extended.

Innervation Extensor digitorum is innervated by the posterior interosseous nerve, C7 and 8 .

Actions Extensor digitorum can extend any or all of the joints over which it passes: wrist, metacarpophalangeal, and proximal and distal interphalangeal joints (the latter two via the extensor expansion of the digits). When acting on the metacarpophalangeal joints, extensor digitorum tends to spread the digits apart because of the different axes of the individual joints imposed by the transverse arch of the hand. The intertendinous bands stabilize the individual tendons as they cross the dorsum of the hand and permit some extension when a tendon has been divided in the metacarpal segment. The extent to which this occurs depends on the presence and orientation of the juncturae tendinae.

Testing The tendons of extensor digitorum can be readily felt, and usually seen, when the fingers are extended against resistance and the forearm is pronated.

## Extensor digiti minimi

Attachments Extensor digiti minimi is medial to, and usually covered by, extensor digitorum; proximally, the bellies of these two muscles may be connected and indistinct from each other, whereas, in the midforearm, extensor digiti minimi is clearly discernible as a slender muscle (Fig. 49.23). It arises from the common extensor tendon by a thin, tendinous slip and adjacent intermuscular septa, and frequently has an additional origin from the antebrachial fascia. It forms a long tendon that constitutes the fifth dorsal compartment as it proceeds beneath the extensor retinaculum. Distal to the retinaculum (see Fig. 50.41), the tendon typically splits into two, and the lateral slip is joined by a tendon from extensor digitorum. All three tendons are attached to the dorsal digital expansion of the fifth digit; there may be a slip to the fourth digit. Extensor digiti minimi is rarely absent but, sometimes, it is fused with extensor digitorum.

Relations The tendon of extensor digiti minimi lies ulnar (medial) to the common extensor tendon to the little finger. The dorsal branch of the ulnar artery and the dorsal branch of the ulnar nerve pass superficial to the extensor retinaculum and cross the tendon of extensor digiti minimi as it lies beneath the retinaculum.

Vascular supply Extensor digiti minimi is supplied by branches from the radial recurrent and posterior interosseous arteries, and by terminal branches from the anterior interosseous artery after it has pierced the interosseous membrane.

Innervation Extensor digiti minimi is innervated by the posterior interosseous nerve, C7 and 8.

Actions Extensor digiti minimi can extend any of the joints of the little finger, or contribute to wrist extension. It permits extension of the little finger independently of the other digits, even in extremes of ulnar or radial wrist deviation.

Testing Extensor digiti minimi is tested by extending the little finger while holding the remaining fingers flexed at the metacarpophalangeal joints; this eliminates any simultaneous contraction of extensor digitorum.

## Extensor carpi ulnaris

Attachments Extensor carpi ulnaris arises from the lateral epicondyle (where it forms the most medial part of the common extensor origin), the posterior border of the ulna (by an aponeurosis shared with flexor carpi ulnaris and flexor digitorum profundus) and overlying fascia (see Fig. 49.6). It runs between extensor digiti minimi and anconeus proximally, and extensor digiti minimi and flexor carpi ulnaris in the midforearm (see Figs 49.31, 49.32). It forms a tendon in the distal third of the forearm that slides in a groove between the head and the styloid process of the ulna. It forms the content of the sixth dorsal compartment as it runs under the extensor retinaculum (see Fig. 50.41) and is attached to a tubercle on the medial side of the base of the fifth metacarpal.

Vascular supply Proximally, extensor carpi ulnaris receives branches from the radial recurrent artery. Distally, it is supplied by several branches from the posterior interosseous artery.

Innervation Extensor carpi ulnaris is innervated by the posterior interosseous nerve, C7 and 8 .

Fig. 49.23 The superficial extensor muscles of the left forearm.
Actions Extensor carpi ulnaris works synergistically with extensors carpi radialis longus and brevis and the digital flexors to effect balanced wrist extension, enabling a power grip with a clenched fist. It also acts with flexor carpi ulnaris to adduct the hand.

Testing The tendon can be felt lateral to the groove that overlies the posterior subcutaneous border of the ulna when the wrist is adducted against resistance.

## Anconeus

Attachments Anconeus is a short, triangular muscle posterior to the elbow joint, partially and variably blended with triceps or extensor carpi ulnaris (Fig. 49.24). It arises by a separate tendon from the posterior surface of the lateral epicondyle of the humerus, proximal to the common extensor tendon. The tendon lies beneath the muscle belly of extensor carpi radialis longus. The muscle fibres run obliquely and medially towards the ulna, covering the posterior aspect of the anular ligament, and are attached to the lateral aspect of the olecranon and proximal quarter of the posterior surface of the shaft of the ulna.

Vascular supply Anconeus is supplied by branches of the posterior interosseous recurrent artery. A small number of musculocutaneous perforators reach the skin overlying the muscle.

Fig. 49.24 The deep layer of the dorsal muscles of the forearm. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

Innervation Anconeus is innervated by the radial nerve, C6, 7 and 8 .
Actions Anconeus is an extensor of the elbow. Its principal function is not fully understood but it may control ulnar abduction in pronation, which is necessary if the forearm is to turn over the hand without translating it medially. In this way, a tool can be revolved 'on the spot' or it can be swept through an arc.

## Deep extensor compartment

The five deep forearm extensor muscles are abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis (all of which act on the thumb), extensor indicis and supinator. Apart from supinator, the other four deep forearm extensors all arise from the bones of the forearm and do not, therefore, act on the elbow.

## Abductor pollicis longus

Attachments Abductor pollicis longus arises in part from the posterior surface of the shaft of the ulna, just distal to the insertion of anconeus, and from the adjoining interosseous membrane (see Fig. 49.6). The muscle runs obliquely in a lateral and distal direction from an apex formed by anconeus and supinator, and is joined by fibres that arise from the middle third of the posterior surface of the radius distal to the attachment of supinator (see Fig. 49.24). As it proceeds distally, abductor pollicis longus becomes more superficial in the forearm, where it is visible as an oblique elevation. The muscle fibres form a tendon just proximal to the wrist. The tendon runs in a groove on the lateral side of the distal end of the radius, accompanied by the tendon
of extensor pollicis brevis. It runs under the extensor retinaculum in the first dorsal compartment (see Fig. 50.41). It usually splits into two slips; one is attached to the radial side of the first metacarpal base, and the other is attached to the trapezium. Slips from the tendon may continue into opponens pollicis or abductor pollicis brevis. Occasionally, the muscle itself may be wholly or partially divided.

Relations Abductor pollicis longus runs on the radial aspect of extensor pollicis longus. The posterior interosseous nerve runs over the belly of abductor pollicis longus with the accompanying posterior interosseous artery; the nerve runs to the border of abductor pollicis longus and then dives between the muscles bellies of abductor pollicis longus and extensor pollicis longus at the apex of their divergence.

Vascular supply Abductor pollicis longus is supplied proximally by a lateral branch from the posterior interosseous artery. Distally, it is supplied on the medial side by a perforating branch from the anterior interosseous artery.

Innervation Abductor pollicis longus is innervated by the posterior interosseous nerve, C7 and 8 .

Actions Abductor pollicis longus abducts the metacarpal of the thumb. It is the prime radial abductor of the thumb. It also acts to abduct the wrist. With abductor pollicis brevis, it effects palmar abduction.

Testing The tendon of abductor pollicis longus can be seen and felt at the radial aspect of the anatomical snuff-box when the thumb and wrist are abducted against resistance at the carpometacarpal joint.

## Extensor pollicis longus

Attachments Extensor pollicis longus arises from the lateral part of the middle third of the posterior surface of the shaft of the ulna below abductor pollicis longus and from the adjacent interosseous membrane. It partly overlies the proximal attachment of the smaller extensor pollicis brevis (see Fig. 49.24). The tendon is formed just proximal to the wrist and passes through the third compartment of the extensor retinaculum in a narrow, oblique groove on the back of the distal end of the radius (see Fig. 50.41). It turns around a bony fulcrum, Lister's tubercle, which changes its line of pull from that of the forearm to that of the thumb, and is attached to the base of the distal phalanx of the thumb. The sides of the tendon are joined on the dorsum of the proximal phalanx by expansions from the tendon of abductor pollicis brevis laterally and from the first palmar interosseous and adductor pollicis medially.

Relations Extensor pollicis longus runs between abductor pollicis longus and extensor indicis in the forearm. The posterior interosseous artery runs over its muscle belly. After passing around Lister's tubercle, the tendon of extensor pollicis longus crosses the tendons of extensor carpi radialis brevis and longus obliquely.

Vascular supply Extensor pollicis longus is supplied on its superficial surface by branches from the posterior interosseous artery, and on its deep surface by perforating branches from the anterior interosseous artery.

Innervation Extensor pollicis longus is innervated by the posterior interosseous nerve, C7 and 8.

Actions Extensor pollicis longus extends the distal phalanx of the thumb. Acting in association with extensor pollicis brevis and abductor pollicis longus, it extends the proximal phalanx and the metacarpal. In continued action, as a consequence of the obliquity of its tendon, extensor pollicis longus adducts the extended thumb and rotates it laterally. It is a weak extensor of the wrist.

Testing The tendon of extensor pollicis longus can be palpated at the ulnar border of the anatomical snuff-box when the thumb is extended at the interphalangeal joint against resistance. When the thumb is opposed and adducted, abductor pollicis brevis can extend the interphalangeal joint of the thumb, mimicking the action of extensor pollicis longus.

## Extensor pollicis brevis

Attachments Extensor pollicis brevis arises from the posterior surface of the radius distal to abductor pollicis longus and from the adjacent interosseous membrane (see Fig. 49.6). It runs between abductor
pollicis longus and extensor pollicis longus. The tendon is attached to the base of the proximal phalanx of the thumb and, commonly, has an additional attachment to the base of the distal phalanx, usually through a fasciculus that joins the tendon of extensor pollicis longus. Extensor pollicis brevis may be absent or fused completely with abductor pollicis longus.

Relations Extensor pollicis brevis is ulnar (medial) to, and closely connected with, abductor pollicis longus. In the distal forearm, the two muscles emerge between extensor carpi radialis brevis and extensor digitorum, and pass obliquely across the tendons of extensors carpi radialis brevis and longus (see Fig. 49.24). They cover the distal part of brachioradialis, and pass through the most lateral compartment of the extensor retinaculum in a single synovial sheath, sharing a groove in the distal radius. Ultimately, they cross, superficial to the radial styloid process and radial artery, to reach the dorsolateral base of the proximal phalanx of the thumb.

Vascular supply Extensor pollicis brevis is supplied from branches from the posterior interosseous artery, together with perforating branches from the anterior interosseous artery.

Innervation Extensor pollicis brevis is innervated by the posterior interosseous nerve, C7 and 8.

Actions Extensor pollicis brevis extends the proximal phalanx and metacarpal of the thumb.

Testing The tendon of extensor pollicis brevis can be felt at the radial border of the anatomical snuff-box, lying medial to the tendon of abductor pollicis longus, when the metacarpophalangeal joint of the thumb is extended against resistance.

## Extensor indicis

Attachments Extensor indicis is a narrow muscle that lies medial and parallel to extensor pollicis longus (see Fig. 49.24). It arises from the posterior surface of the ulna distal to extensor pollicis longus and the adjacent interosseous membrane. The tendon is formed just proximal to the wrist and passes under the extensor retinaculum in a common compartment with the tendons of extensor digitorum (see Fig. 50.41). Opposite the head of the second metacarpal, it joins the ulnar side of the tendon of extensor digitorum that serves the index finger. Extensor indicis occasionally sends accessory slips to the extensor tendons of other digits. Its tendon may be interrupted on the dorsum of the hand by an additional muscle belly (extensor indicis brevis manus).

Relations The posterior interosseous artery passes over the muscle belly of extensor indicis. On the dorsum of the hand, the tendon of extensor indicis lies on the ulnar aspect of the tendon of extensor digitorum to the index finger.

Vascular supply Extensor indicis is supplied on its superficial surface by branches from the posterior interosseous artery, and on its deep surface by perforating branches from the anterior interosseous artery.

Innervation Extensor indicis is innervated by the posterior interosseous nerve, C 7 and 8 .

Actions Extensor indicis extends the index finger independently of the other digits. It is a weak extensor of the wrist.

Testing Extensor indicis is tested by extending the index finger while holding the remaining fingers flexed at the metacarpophalangeal joints in order to eliminate the effects of any simultaneous contraction of extensor digitorum.

## Supinator

Attachments Supinator is a wide muscle that surrounds the proximal third of the radius. It has superficial and deep layers The two parts arise together - the superficial by tendinous fibres, and the deep by muscular fibres - from the lateral epicondyle of the humerus, the radial collateral ligament of the elbow joint, the anular ligament of the superior radioulnar joint, the supinator crest of the ulna and the posterior part of the triangular depression in front of it, and an aponeurosis that covers the muscle (see Figs 49.5, 49.6; Figs 49.25-49.26). Supinator is attached distally to the lateral surface of the proximal third of the radius, down to the insertion of pronator teres. The radial attachment extends on to the anterior and posterior surfaces between the anterior oblique line and the fainter posterior oblique 'ridge'. Supinator is subject to frequent

Fig. 49.25 The forearm, antebrachium, in supination position. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
variation; small parts have acquired individual names, e.g. lateral and medial tensors of the anular ligament.

Relations Supinator emerges under the lower border of anconeus and is related to abductor pollicis longus at its inferior medial border. Extensor carpi radialis brevis and longus pass over its radial aspect. The posterior interosseous nerve enters the forearm by passing between its superficial and deep heads.

Vascular supply The superficial part of supinator is supplied by branches from the radial recurrent artery. The deep part of supinator is supplied by branches from the posterior interosseous artery and the posterior interosseous recurrent artery.

Innervation Supinator is innervated by the posterior interosseous nerve, C6 and 7 .

Actions Supinator rotates the radius to bring the palm to face anteriorly. It acts alone in slow, unopposed supination, and together with biceps brachii in fast or forceful supination. An object, which potentially may be heavy, is often picked up with the forearm initially pronated. The more powerful supinator lifts the object against gravity; rotation is often combined with increasing elbow flexion in order to bring the object towards the eyes.

Testing Supinator lies too deep to be palpated. It may be assessed by supinating the forearm against resistance with the elbow extended, on

Fig. 49.26 The forearm, antebrachium, in pronation position. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)
the grounds that biceps brachii is inactive on supination when the elbow is fully extended.

COMPARTMENT SYNDROME OF THE FOREARM

Available with the Gray's Anatomy e-book

## VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

## ARTERIES

## Brachial artery

The brachial artery is medial in the arm but moves towards the midline, medial to the tendon of biceps brachii and deep to the bicipital aponeurosis. The latter separates the artery from the anterior structures, namely: the skin, superficial fascia and the median cubital vein. Posteriorly, brachialis separates it from the elbow joint. The median nerve passes close to the medial side of the artery. The artery divides into its terminal branches, the radial and ulnar arteries, at the level of the radial neck (Fig. 49.27A).

## Radial artery

The radial artery is smaller than the ulnar artery, yet appears a more direct continuation of the brachial artery (see Figs 49.21-49.22). It

A

Fig. 49.27 A, The arterial anastomoses around the left elbow joint, viewed from the anterior aspect. B, Arteriogram demonstrating anterior arterial anastomoses around the elbow.
passes deep to brachioradialis and gives off the radial recurrent artery before continuing into the forearm. It descends along the lateral side of the forearm, accompanied by paired venae comitantes, from the medial side of the neck of the radius to the wrist. The artery is medial to the radial shaft proximally, and anterior to it distally. Proximally, it is overlapped anteriorly by the belly of brachioradialis, but elsewhere in its course it is covered only by the skin and superficial and deep fasciae. Its posterior relations in the forearm are, successively, the tendon of biceps, supinator, the distal attachment of pronator teres, the radial head of flexor digitorum superficialis, flexor pollicis longus, pronator quadratus and the lower end of the radius (where its pulsation is

A compartment syndrome exists where increased pressure in an osseofascial compartment leads to decreased perfusion of the contents of the compartment. In the forearm, this commonly occurs as a result of trauma, external pressure, burns, arterial injury or post-ischaemic swelling. The resultant increase in interstitial pressure causes vascular occlusion and myoneural ischaemia. The patient presents with pain that is disproportionate to the severity of the injury and which is provoked or markedly increased by passive extension of the fingers. There may also be reduced sensation or paraesthesiae in the affected hand. If a compartment syndrome is suspected, compartment pressure measurements may be indicated, but, in unequivocal cases, the definitive treatment is emergency fasciotomies of the forearm. The absolute intracompartmental pressure threshold for decompression is the subject of debate: an absolute value of 30 mmHg is generally accepted, although some authorities prefer a figure that comes within 30 mmHg of diastolic pressure. The pressure in each compartment should be measured separately.

Incisions to decompress the flexor compartment (Ronel et al 2004) run from the medial epicondyle and curve down the anterior aspect of the forearm, ending on the radial side of flexor carpi ulnaris; from here, they may be extended distally to decompress the carpal tunnel, if necessary. The bicipital aponeurosis (lacertus fibrosus) is routinely released to decompress the median nerve. After retraction of the superficial flexors, the fascia over the deep muscles of the forearm may be incised over its full length. Both median and ulnar nerves should be inspected to ensure that their decompression is complete. The mobile wad and dorsal compartment are decompressed through a straight longitudinal incision that starts just distal to the lateral epicondyle; this is deepened through the plane between extensor digitorum and extensor carpi radialis brevis, and ends over the midline of the wrist. In both cases, the wounds are left open and dressed, and only closed when circumstances permit.

Failure to decompress a compartment syndrome promptly may lead to Volkmann's ischaemic contracture with severe loss of function in the affected forearm and hand. Subsequent amputation is not unknown.
most accessible). Brachioradialis is lateral to the artery throughout its length. Pronator teres is medial to the proximal part of the artery, and the tendon of flexor carpi radialis is medial to the distal portion. The superficial radial nerve lies lateral to the middle third of the radial artery; multiple branches from the artery supply the nerve throughout its length.

The radial artery may occasionally arise from a continuation of a superficial brachial artery, or as a high proximal division of an otherwise normal brachial artery. It can give rise to the common interosseous artery.

## Branches in the forearm

Radial recurrent artery The radial recurrent artery is given off by the radial artery just distal to the elbow joint (see Figs 49.21-49.22, 49.27). It passes between the superficial radial nerve and the posterior interosseous nerve before ascending beneath brachioradialis, anterior to supinator and brachialis. It supplies these muscles and then anastomoses with the radial collateral branch of the profunda brachii artery. The radial recurrent artery also gives branches to extensor carpi radialis longus, extensor digitorum, extensor digiti minimi and extensor carpi ulnaris. Its cutaneous branches are described on page 837.

Muscular branches Muscular branches are distributed to the muscles on the radial side of the forearm. Direct branches from the radial artery supply the radial insertion of pronator teres, the anterolateral aspect of flexor carpi radialis, the lateral surface of flexor digitorum superficialis, the lateral half of flexor pollicis longus, and the distal sections of extensor carpi radialis longus and extensor carpi radialis brevis.

## Ulnar artery

The ulnar artery arises from the brachial artery just distal to the flexion crease of the elbow the level of the radial neck, and reaches the medial side of the forearm in its upper third (see Figs 49.21-49.22). It is larger than the radial artery and is accompanied throughout its length by venae comitantes. In the forearm, the ulnar artery initially lies on brachialis before passing deep to pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis. It then lies on flexor digitorum profundus, between flexor carpi ulnaris and flexor digitorum superficialis, and is covered by the skin and superficial and deep fasciae. The artery crosses the flexor retinaculum, lateral to the ulnar nerve and pisiform bone, to enter the hand. The median nerve is a medial relation for approximately 2.5 cm distal to the elbow, and then crosses the artery, from which it is separated by the ulnar head of pronator teres. The ulnar nerve lies medial to the distal two-thirds of the artery, which supplies the nerve throughout its length; the palmar cutaneous branch of the ulnar nerve descends along the ulnar artery to reach the hand.

The ulnar artery may arise above the elbow, when it can lie superficial to the forearm flexors under the deep fascia; only rarely is it subcutaneous. When this occurs, the brachial artery supplies the common interosseous and the ulnar recurrent arteries.

## Branches in the forearm

Anterior ulnar recurrent artery The anterior ulnar recurrent artery arises from the ulnar artery distal to the elbow and close to the origin of the ulnar artery itself. It ascends between brachialis and pronator teres, which is supplies, then anastomoses with the inferior ulnar collateral artery anterior to the medial epicondyle (see Fig. 49.27A).

Posterior ulnar recurrent artery The posterior ulnar recurrent artery arises from the ulnar artery distal to the anterior ulnar recurrent artery, passes dorsomedially between flexor digitorum profundus and flexor digitorum superficialis, and ascends between the posterior aspect of the medial epicondyle and the olecranon. It is deep to flexor carpi ulnaris, ascending between its heads with the ulnar nerve. It supplies flexor digitorum profundus, flexor digitorum superficialis, flexor carpi ulnaris, the ulnar nerve, underlying bone and the elbow joint, and anastomoses with the ulnar collateral artery and interosseous recurrent artery. The posterior ulnar recurrent artery and ulnar nerve are both vulnerable to injury behind the medial epicondyle (Figs 49.28-49.29).

Common interosseous artery The common interosseous artery is a short branch of the ulnar artery (see Figs 49.10, 49.22). It arises just distal to the radial tuberosity and passes back to the proximal border of the interosseous membrane, where it divides into the anterior and posterior interosseous arteries. Occasionally, the common interosseous artery is a branch of the radial artery.

Fig. 49.29 The posterior aspect of the left elbow region: deep structures.

Anterior interosseous artery The anterior interosseous artery arises from the common interosseous artery and descends on the anterior aspect of the interosseous membrane with the anterior interosseous branch of the median nerve (see Figs 49.10, 49.22, 49.27, 49.32). It is overlapped by contiguous sides of flexor digitorum profundus and flexor pollicis longus. Shortly after its origin, it usually gives off a slender median artery. This accompanies and supplies the median nerve as far as the palm, where it may join the superficial palmar arch or end as one or two palmar digital arteries. The median artery can also arise from the ulnar or the common interosseous artery. Muscular and nutrient branches from the anterior interosseous artery pierce the interosseous membrane to supply deep extensor muscles and the radius and ulna, respectively. A branch descends deep to pronator quadratus before piercing the interosseous membrane to join the anterior 'carpal' arch.

The anterior interosseous artery leaves the anterior compartment by piercing the interosseous membrane proximal to pronator quadratus. It anastomoses with the posterior interosseous artery in the posterior compartment of the forearm, and travels through a tunnel under the extensor retinaculum with the tendons of the digital extensors before joining the dorsal carpal arch. Three small cutaneous perforating branches supply the skin over the lower lateral border of the forearm.

Posterior interosseous artery The posterior interosseous artery arises from the common interosseous artery and is usually smaller than the anterior interosseous artery (see Figs 49.10, 49.27A). It passes dorsally between the oblique cord and proximal border of the interosseous membrane, and then between supinator and abductor pollicis longus. It descends deep in the groove between extensor carpi ulnaris and the extensor digiti minimi component of extensor digitorum. While in the groove, it gives rise to multiple muscular branches that supply these muscles and fasciocutaneous perforators that travel in the intermuscular septum between extensor carpi ulnaris and extensor digiti minimi. The posterior interosseous artery accompanies the deep branch of the radial nerve (posterior interosseous nerve) on abductor pollicis longus. Distally, it anastomoses with the terminal part of the anterior interosseous artery and the dorsal carpal arch.

Sometimes, the posterior interosseous artery disappears halfway down the forearm, in which case the anterior interosseous artery pierces the interosseous membrane more proximally to anastomose with it. Occasionally, the two vessels do not anastomose.

Fig. 49.28 The posterior aspect of the left elbow: superficial structures.

Posterior interosseous recurrent artery The posterior interosseous recurrent artery leaves the posterior interosseous artery near its origin and ascends between the lateral epicondyle and olecranon, either on or through supinator, and deep to anconeus. It anastomoses with the middle collateral branch of the profunda brachii artery, posterior ulnar recurrent artery and ulnar collateral artery. Occasionally, the artery is absent. Its cutaneous branches are described on page 837.

## Collateral circulation at the elbow

## Available with the Gray's Anatomy e-book

## VEINS

## Deep veins

Venae comitantes run with the radial and ulnar arteries to drain the deep and superficial palmar venous arches, respectively. They unite near the elbow as paired brachial veins. The radial veins are smaller and receive the deep dorsal veins of the hand. The ulnar veins are larger and drain the deep palmar venous arch. They connect with superficial veins near the wrist and receive the venae comitantes of the anterior and posterior interosseous arteries near the elbow. A large branch connects them to the median cubital vein.

## Superficial veins

## Cephalic vein

The cephalic vein usually forms over the anatomical snuff-box on the radial side of the wrist from the radial end of the dorsal venous plexus (see Figs 46.4, 50.39). It curves proximally around the radial side of the forearm, receiving tributaries from both radial and ulnar aspects of the forearm. Distal to the elbow, a branch, the median cubital vein, diverges proximomedially to reach the basilic vein. The median cubital vein is joined by a branch from the deep veins (Fig. 49.30). The further course of the cephalic vein is described on page 830 .

Accessory cephalic vein The accessory cephalic vein may arise either from a dorsal forearm plexus or from the ulnar side of the dorsal venous network in the hand. It joins the cephalic vein distal to the elbow. A large oblique vein often connects the basilic and cephalic veins dorsally in the forearm.

## Basilic vein

The basilic vein arises medially in the dorsal venous network of the hand (see Figs 46.4, 50.39). It ascends posteromedially in the forearm, inclining forwards to the anterior surface distal to the elbow, where it is joined by the median cubital vein. It then ascends superficially between biceps and pronator teres, and is crossed by filaments of the medial cutaneous nerve of the forearm that pass both superficial and deep to the vein. The basilic vein continues as the axillary vein from the lower border of teres major (p. 830).

## Median vein

The median vein of the forearm drains the superficial palmar venous plexus and ascends through the anterior part of the forearm to join either the basilic or the median cubital vein (see Figs 48.34, 49.30). It may divide distal to the elbow to join both veins.

## LYMPHATIC DRAINAGE

One or two supratrochlear nodes are superficial to the deep fascia proximal to the medial epicondyle and medial to the basilic vein; their efferents accompany the vein to join the deep lymph vessels. Small, isolated nodes sometimes occur along the radial, ulnar and interosseous vessels, in the cubital fossa near the bifurcation of the brachial artery, or in the arm medial to the brachial vessels.

## INNERVATION

## Median nerve

In the cubital fossa, the median nerve lies medial to the brachial artery, deep to the bicipital aponeurosis and anterior to brachialis. It usually enters the forearm between the heads of pronator teres, although, occasionally, it may pass posterior to both heads of the muscle, or it may pass through its humeral head (Fig. 49.31; see Figs 49.21-49.22). The nerve crosses to the lateral side of the ulnar artery, from which it is separated by the deep head of pronator teres, passes behind a tendinous bridge between the humero-ulnar and radial heads of flexor digitorum superficialis, and descends through the forearm posterior and adherent to flexor digitorum superficialis and anterior to flexor digitorum profundus. It is accompanied by the median branch of the anterior interosseous artery. The first branch of the median nerve to pronator teres arises $2-3 \mathrm{~cm}$ above the medial epicondyle. A second branch, or leash of branches, arises at the level of the tip of the medial epicondyle and innervates palmaris longus, flexor carpi radialis and flexor digitorum superficialis. About 5 cm proximal to the flexor retinaculum, the median nerve emerges from behind the lateral edge of flexor digitorum superficialis, and becomes superficial just proximal to the wrist. Here, it lies between the tendons of flexor digitorum superficialis and flexor carpi radialis, projecting laterally from beneath the tendon of palmaris longus. It then passes deep to the flexor retinaculum into the palm (see Fig. 50.41).

## Branches in the forearm

## Anterior interosseous nerve

The anterior interosseous nerve arises from the posterior aspect of the median nerve between the two heads of pronator teres, just distal to the branches to the superficial forearm flexors and proximal tendinous arch of flexor digitorum superficialis (see Figs 49.10, 49.22). It descends with the anterior interosseous artery anterior to the interosseous membrane, between and deep to flexor pollicis longus and flexor digitorum profundus (Fig. 49.32), supplying flexor pollicis longus and the lateral part of flexor digitorum profundus (to the index and middle fingers). Terminally, the anterior interosseous nerve lies posterior to pronator quadratus, which it supplies via its deep surface. It also supplies articular branches to the distal radio-ulnar, radiocarpal and carpal joints.

## Palmar cutaneous branch

The palmar cutaneous branch starts about 3 cm proximal to the flexor retinaculum. It runs in a small tunnel in the sheath of flexor carpi radialis before piercing the deep fascia, where it divides into lateral branches that supply the thenar skin and connect with the lateral cutaneous nerve of the forearm. Medial branches supply the central palmar skin and connect with the palmar cutaneous branch of the ulnar nerve (see Figs 46.11, 49.21, 50.35, 50.40A-50.41).

A

C

Fig. 49.30 A-C, Variations in the superficial veins of the left cubital fossa. (With permission from Waschke J, Paulsen F (eds), Sobotta Atlas of Human Anatomy, 15th ed, Elsevier, Urban \& Fischer. Copyright 2013.)

The collateral circulation at the elbow is more robust than that at the knee. Alternative pathways include the profunda brachii artery, which accompanies the radial nerve through the lateral intermuscular septum to become the radial collateral artery. The superior ulnar collateral artery accompanies the ulnar nerve. In the adult, it may be as wide as 1.5 mm at its origin; hence its regular use as the artery to a free vascularized ulnar nerve graft. The inferior ulnar collateral artery is regularly seen during medial approaches to the elbow as a vessel that pierces the intermuscular septum to curl around the humerus between triceps and bone. On occasion, there is a substantial artery running with the median nerve. These vessels anastomose with recurrent branches from the ulnar and radial arteries to form a network that may maintain perfusion of the hand and the extensor muscles in cases where the brachial artery has been divided in the lower third of the arm (when there is no associated fracture or dislocation). Collateral circulation will diminish or cease altogether if the ulnar or radial nerve is entrapped within the fracture or compressed by haematoma (Birch 2011, Blakey et al 2009).

Fig．49．31 A transverse section through the left forearm at the level of the radial tuberosity： proximal aspect．

Fig．49．32 A transverse section through the middle of the left forearm．

## Muscular branches

Muscular branches are given off near the elbow to all the superficial flexor muscles except flexor carpi ulnaris．The branch to the part of flexor digitorum superficialis that serves the index finger is given off near the mid－forearm and may be derived from the anterior interos－ seous nerve．The median nerve is palpable in the anterior aspect of the elbow，deep to the bicipital aponeurosis．It is closely related to the brachial artery in the anterior aspect of the elbow，where it courses anterior to brachialis and medial to the artery．

## Median nerve compression

The median nerve may be compressed at four sites in the elbow and forearm．The most proximal is the ligament of Struthers，where，if the median nerve is accompanied by the brachial artery，vascular symptoms
and signs may also be present．More distally，it may become entrapped by a thickened bicipital aponeurosis．The other sites of compression are between the superficial and deep heads of pronator teres，and the proxi－ mal fibrous arch of flexor digitorum superficialis．

## Martin－Gruber nerve connection

Available with the Gray＇s Anatomy e－book

## Ulnar nerve

The ulnar nerve passes behind the medial epicondyle in a groove where it is easily palpable（see Figs $49.29,46.12$ ）．It runs through the cubital

Patients essentially present with one of two syndromes. The anterior interosseous nerve syndrome presents as a failure of pinch grip due to weakness of flexor pollicis longus and the radial portion of flexor or digitorum profundus. This reduces the flexion power of the interphalangeal joint of the thumb and the distal interphalangeal joint of the index finger. The pronator syndrome presents with symptoms and signs that mimic carpal tunnel syndrome. Patients present with pain and altered sensation in the radial three and a half fingers of the hand that are aggravated by activity. However, a Tinel's sign will be positive over the proximal forearm, and sensation over the thenar eminence may be diminished, because the palmar cutaneous branch of the nerve arises above the carpal tunnel. The clinical presentation may vary in the presence of a Martin-Gruber anastomosis (Rodriguez-Niedenführ et al 2002).

Most patients will respond to non-operative treatment but those who fail to do so usually respond well to surgical decompression. Exploration and decompression should address all the potential areas of compression.

A motor communicating branch between the median and ulnar nerves in the forearm occurs in approximately one-quarter of patients. The most common variant has a branch passing from the anterior interosseous to the ulnar nerve. A number of patterns have been described where branches pass between flexors digitorum superficialis and profundus, deep to the ulnar artery, to join the ulnar nerve; such branches may explain the variations in innervation of the intrinsic muscles.
tunnel, between the capsule of the humero-ulnar joint and the overlying arcuate ligament joining the two heads of flexor carpi ulnaris. It gives off articular branches to the elbow as it lies between the medial epicondyle and the olecranon. The ulnar nerve enters the forearm between the two heads of flexor carpi ulnaris, which it supplies by two neurovascular pedicles: one arising just distal to the cubital tunnel and one in the forearm. It is superficial to the posterior and oblique parts of the ulnar collateral ligament.

The ulnar nerve descends on the medial side of the forearm on flexor digitorum profundus (see Fig. 49.32). Proximally, it is covered by flexor carpi ulnaris; its distal half lies lateral to the muscle and is covered only by skin and fasciae. In the upper third of the forearm, the nerve is distant from the ulnar artery but, more distally, it comes to lie close to the medial side of the artery. About 5 cm proximal to the wrist, it gives off the dorsal cutaneous branch. At the wrist, the ulnar nerve passes under the superficial part of the flexor retinaculum (in Guyon's canal) and divides into superficial and deep branches (see Fig. 50.40A).

## Branches in the forearm Muscular branches

There are two main muscular branches of the ulnar nerve in the forearm. They arise near the elbow and supply flexor carpi ulnaris and the medial half of flexor digitorum profundus.

## Dorsal branch

The dorsal branch of the ulnar nerve continues distally and dorsally, deep to flexor carpi ulnaris. It perforates the deep fascia and descends along the medial side of the back of the wrist and hand. Its further course is described on page 893.

## Palmar cutaneous branch

The palmar cutaneous branch of the ulnar nerve arises in mid-forearm, descends on the ulnar artery, which it supplies, and then perforates the deep fascia. It communicates with the palmar branch of the median nerve and ends in the palmar skin. It sometimes supplies palmaris brevis. Its further course is described on page 894.

## Ulnar nerve compression

The ulnar nerve may be compressed by the arcade of Struthers at the level of the medial intermuscular septum or at the level of the flexor/ pronator aponeurosis as it enters the forearm between the heads of flexor carpi ulnaris. It is most often compressed at the level of the cubital tunnel; this is the most common nerve compression syndrome after that of the median nerve in the carpal tunnel.

## Radial nerve

The radial nerve at the elbow lies in the deep groove between brachialis medially and brachioradialis and extensor carpi radialis longus laterally (see Fig. 49.21). The nerve to brachioradialis arises about three fingers'breadths proximal to the lateral epicondyle; the nerve to extensor carpi radialis longus about one finger's-breadth more distal; and the nerve to extensor carpi radialis brevis about one finger's-breadth above the epicondyle. These branches arise from the main radial nerve as it runs between brachialis and brachioradialis. The nerve may be palpable at this level. The radial nerve divides into the posterior interosseous and superficial radial nerves anterior to the elbow at the level of the tip of the lateral epicondyle. Another branch to extensor carpi radialis brevis is usually given off here. There is some variation in the level at which branches of the radial nerve arise from the main trunk in different individuals. Branches to extensor carpi radialis brevis and supinator may arise from the main trunk of the radial nerve or from the proximal part of the posterior interosseous nerve, but almost invariably above the arcade of Frohse.

## Branches in the forearm

## Superficial radial nerve

The superficial radial nerve descends from the lateral epicondyle anterolaterally in the proximal two-thirds of the forearm, initially lying on supinator, lateral to the radial artery and behind brachioradialis. In the middle third of the forearm, it lies behind brachioradialis, close to the lateral side of the artery. It runs anterior to pronator teres, the radial head of flexor digitorum superficialis and flexor pollicis longus, and usually leaves the artery 7 cm proximal to the wrist and passes deep to the tendon of brachioradialis. It curves round the lateral side of the radius as it descends, pierces the deep fascia and divides into five, sometimes four, dorsal digital nerves. On the dorsum of the hand, it
usually communicates with the posterior and lateral cutaneous nerves of the forearm.

## Posterior interosseous nerve

The posterior interosseous nerve is the deep terminal branch of the radial nerve (see Figs 46.9, 49.21, 49.29). It reaches the back of the forearm by passing round the lateral aspect of the radius between the two heads of supinator (see Figs 49.25, 49.26). It supplies supinator both before entering the muscle and as it passes through it. As it emerges from supinator posteriorly, the nerve gives off three short branches to extensor digitorum, extensor digiti minimi and extensor carpi ulnaris, and two longer branches: a medial branch to extensor pollicis longus and extensor indicis, and a lateral branch that supplies abductor pollicis longus and extensor pollicis brevis. The nerve at first lies between the superficial and deep extensor muscles, but at the distal border of extensor pollicis brevis, it passes deep to extensor pollicis longus and, diminished to a fine thread, descends on the interosseous membrane to the dorsum of the carpus. Filaments arising from its flattened termination supply the carpal ligaments and articulations. Articular branches from the posterior interosseous nerve supply carpal, distal radio-ulnar and some intercarpal and intermetacarpal joints. Digital branches supply the metacarpophalangeal and proximal interphalangeal joints.

The distal portion of the nerve lies in a separate fascial sheath in the radial, deep, aspect of the fourth dorsal compartment of the extensor retinaculum of the wrist, where it is located deep to extensor digitorum and extensor indicis.

## Radial nerve compression

Radial nerve compression may occur at several sites in the elbow and forearm. The most proximal of these is within the radial tunnel at the level of the radial head, where fibrous bands may be present. More distally, it has been suggested that branches of the radial recurrent artery may compress the posterior interosseous nerve. Other sites of compression are the tendinous edge of the deep surface of extensor carpi radialis brevis and the point at which the nerve passes under the arcade of Frohse and between the two heads of supinator. Rarely, the nerve may be compressed at the level of the distal border of supinator.

## Lateral cutaneous nerve of the forearm

The lateral cutaneous nerve of the forearm is the cutaneous division of the musculocutaneous nerve (p. 831). It lies between biceps brachii and brachialis, inclining from the medial to the lateral side; passes through the cubital fossa lateral to the tendon of biceps brachii (see Figs 48.33, $48.34,49.31-49.32$ ) and deep to the cephalic vein; and descends along the radial border of the forearm to the wrist. It supplies the skin of the anterolateral surface of the forearm (see Fig. 49.1) and connects with the posterior cutaneous nerve of the forearm and the terminal branch of the radial nerve by branches that pass around its radial border. Its trunk gives rise to a slender recurrent branch that extends along the cephalic vein as far as the middle third of the upper arm, distributing filaments to the skin over the distal third of the anterolateral surface of the upper arm close to the vein. At the wrist joint, the lateral cutaneous nerve of the forearm is anterior to the radial artery. It gives off filaments that pierce the deep fascia and accompany the artery to the dorsum of the carpus. The nerve then passes to the base of the thenar eminence, where it ends in cutaneous rami, some of which connect with the terminal branch of the radial nerve and the palmar cutaneous branch of the median nerve.

## Medial cutaneous nerve of the forearm

The medial cutaneous nerve of the forearm has already divided into anterior and posterior branches before it enters the forearm (see Figs 48.34, 49.12, 49.31-49.32). The larger anterior branch usually passes in front of, or occasionally behind, the median cubital vein, and descends anteromedially in the forearm to supply the skin as far as the wrist. It curves round to the back of the forearm, descending on its medial border to the wrist, supplying the skin (see Fig. 49.1). It connects with the medial cutaneous nerve of the arm, the posterior cutaneous nerve of the forearm, and the dorsal branch of the ulnar nerve.

## Posterior cutaneous nerve of the forearm

The posterior cutaneous nerve of the forearm passes along the dorsum of the forearm to the wrist (see Figs 48.34, 49.31, 49.32). It supplies the central forearm skin along its course and, near its end, joins the dorsal branches of the lateral cutaneous nerve of the forearm.

The cross-sectional area of the cubital tunnel has been shown to narrow by almost $55 \%$ in full flexion. Ultrasound studies have suggested that the ratio of the cross-sectional area of radial nerve:cubital tunnel is most strongly linked to reduced conduction velocity (Yoon et al 2007). Combining elbow flexion with direct pressure over the cubital tunnel for 60 seconds will elicit symptoms in most affected patients (Novak et al 1994). Other contributory factors are previous trauma, especially supracondylar and medial epicondyle fractures in childhood, valgus instability of the elbow in athletes involved in throwing sports, and degenerative disease.

The most reliable treatment for patients who fail to respond to nonsurgical remedies is a simple release of cubital tunnel. The release should be complete; care should be taken to avoid damage to branches of the medial cutaneous nerve of the forearm that usually cross the line of incision approximately 2 cm above the medial epicondyle and a mean 3.1 cm distal to the medial epicondyle in all patients (Lowe et al 2004). The nerve should not be circumferentially denuded of its retinaculum because this contains its intrinsic blood supply. Transposition of the nerve should be reserved for cases of persistent snapping or of failure of a simple release to achieve symptomatic relief. This is relatively unusual and is said to occur in only $7 \%$ of cases.

The ulnar nerve is a mixed nerve and so patients may present with sensory or motor symptoms or a combination of the two, sometimes with additional physical signs of autonomic disturbance. There may be tenderness and a positive Tinel's sign over the nerve at the point of compression. Numbness and paraesthesiae occur early, followed, in more severe cases, by weakness of power grip and, ultimately, atrophy of the lumbricals and interossei with clawing of ring and little fingers.

Patients present with one of two syndromes: the radial tunnel syndrome, in which the presentation is that of pain along the lateral border of the elbow and upper forearm (Roles and Maudsley 1972), or the posterior interosseous nerve syndrome, which presents with motor weakness in the distribution of the nerve particularly affecting the extensors digitorum and extensor carpi ulnaris muscles. Primary treatment is non-operative and involves the avoidance of activities that cause pain, aided by appropriate splintage. In resistant cases, surgical decompression may be necessary. A complete release of all potential areas of compression is essential.

ANATOMICAL CONSIDERATIONS IN COMMON FOREARM AND ELBOW INJURIES

Fig. 49.28 The posterior aspect of the left elbow: superficial structures.

Fig. 49.33 A type 1 Monteggia fracture with anterior dislocation of the radial head.

Fig. 49.34 A Galeazzi fracture-dislocation.
Fig. 49.35 Elbow dislocation.

The elbow is a notorious site for nerve injuries, especially in children. The close proximity of all the major nerve trunks to bone makes them vulnerable. The ulnar nerve is particularly at risk in elbow dislocation, especially when the medial epicondyle is displaced into the joint. All three nerves are at risk of displacement into a dislocated joint. The posterior interosseous and radial nerves are particularly at risk from a Monteggia fracture-dislocation. Any nerve may become entrapped within a fracture, e.g. the median nerve is often accompanied by the brachial artery in cases of supracondylar fracture. Pain that persists, or worsens, after reduction of a fracture suggests impending critical ischaemia, continuing irritation of the nerve, or both. The nerves are at risk during operations or other medical interventions, particularly so when normal anatomical planes are distorted by haematoma, fibrosis or bone fragments.

Fractures of the shaft of the radius and ulna are commonly displaced, reflecting not only the violence required to cause such injury but also the pull of the forearm muscles that may accentuate displacement of the fracture fragments. Open fractures or penetrating injuries to the forearm may be associated with nerve and vessel injury. Compartment syndrome can occur. Monitoring of compartment pressures and careful neurological examination are required.

## Fracture-dislocations of the forearm

Monteggia, Galeazzi and Essex-Lopresti injuries are common combinations of high-energy forearm fractures associated with accompanying soft tissue injury.

## Monteggia fracture-dislocation

A Monteggia fracture-dislocation injury is a fracture of the proximal ulna with dislocation of the radial head; the interosseous membrane and the triangular fibrocartilage complex remain largely intact, which means that anatomical reduction of the ulnar fracture will usually restore congruity of the radiocapitellar and proximal radio-ulnar joints. The most common type of Monteggia fracture, type 1 (anterior dislocation), occurs when falling on to an outstretched arm hyperextends the elbow (Fig. 49.33). The forearm is in neutral to mid-pronation, biceps brachii resists the hyperextension, the anular and quadrate ligaments rupture under the bending force, and the radial head dislocates. Compressive load then transfers to the ulnar diaphysis, which fails in tension in an oblique fracture. Type II (posterior dislocation) involves longitudinal force directed up the forearm with the elbow in a flexed position. The ulnar cortex fails first before rupture of the ulnar collateral ligament complex and posterior dislocation of the radial head. Four subtypes of this injury pattern have been identified, based on the location and force direction through the ulnar fracture (Jupiter et al 1991). Type III Monteggia injuries result in lateral or anterolateral dislocation of the radial head, associated with a metaphysial fracture of the proximal ulna. Type IV Monteggia injuries result in an anterior dislocation of the radial head and a fracture through the proximal third of both the radius and the ulna. The mechanism of injury is similar to that seen in type I injuries but the anteriorly directed force of the distal ulnar fragment, combined with the biceps resistance force, causes a fracture through the proximal radius (Waters 2010).

## Galeazzi fracture-dislocation

A Galeazzi injury is a fracture at the junction of the middle and distal thirds of the radius, associated with disruption of the distal radio-ulnar joint (Fig. 49.34). The injury occurs when the forearm is axially loaded and fully pronated. The radius fractures first, force transmission continues along the interosseous membrane to the distal ulna, the triangular fibrocartilage complex is disrupted and the ulnar head dislocates. The ulnar styloid can also be fractured in this injury (Galeazzi 1934).

## Essex-Lopresti injury

Essex-Lopresti injury is a radio-ulnar dissociation injury, usually caused by a fall on to an outstretched hand that involves a fracture of the radial head, force transmission between the radius and ulna, and disruption of the interosseous membrane and the distal radio-ulnar joint. The radius migrates proximally relative to the ulna (Chow and Leung 2010).

Fig. 49.33 A type 1 Monteggia fracture with anterior dislocation of the radial head (arrow).

Fig. 49.34 A Galeazzi fracture-dislocation.

## Traumatic elbow instability

Posterolateral rotatory pattern instability and dislocation of the elbow, with or without associated fracture of the radial head and coronoid, are the three general patterns of traumatic elbow instability (Ring 2010). Posterolateral rotatory pattern instability is an injury of the capsule and ligaments that progresses from lateral to medial with a posterolateral rotatory mechanism (O'Driscoll et al 1992). It usually occurs as the result of a fall on to an outstretched hand that creates a valgus, axial posterolateral rotatory force. The ulna and forearm supinate away from the distal humerus and a posterior dislocation of the elbow occurs (Fig. 49.35). As the elbow dislocates posteriorly, the radial head and coronoid impact on the distal humerus, where either can fracture; the anterior band of the ulnar collateral ligament is the last structure to be disrupted. Varus posteromedial rotational pattern instability and anteromedial coronoid facet fractures occur when a fall on to an outstretched hand produces a varus, axial posteromedial force through the elbow. The anteromedial facet of the coronoid is fractured and the lateral ligament complex may be injured or the olecranon may be fractured. Anterior olecranon fracture-dislocations occur as a result of direct violence to the flexed elbow. The mechanism of posterior olecranon fracture dislocation is less certain; it occurs more commonly in osteopaenic bone.

## SKIN AND SOFT TISSUES

## SKIN

## Dorsal skin versus palmar skin

The dorsal skin is thin, mobile and frequently hirsute over the proximal phalanges and the ulnar aspect of the dorsum of the hand. The skin of the palm and the palmar surface of the digits is thick and hairless, and has a well-defined stratum lucidum and a higher density of nerve endings and eccrine sweat glands, but no sebaceous glands.

## Skin creases and fingerprints

Flexure lines crease the skin of the flexor surfaces of the wrist and hand (Fig. 50.1) where they are anchored to the deep fascia. Less regular, mainly transverse, creases cross the dorsal aspect of the radiocarpal, carpal, metacarpophalangeal and interphalangeal joints. The dorsal creases are more prominent in extension; the loose skin becomes stretched in flexion. (For a general review of 'skin lines', see p. 156.)

Three anterior transverse lines cross the wrist. The proximal line marks the proximal limit of the flexor synovial sheaths, the intermediate line overlies the radiocarpal joint, and a distal line marks the proximal border of the flexor retinaculum.

Fig. 50.1 The relation of the skin flexure lines and palmar arterial arches to the bones of the left hand. (Adapted from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed, Elsevier, Churchill Livingstone. Copyright 2010.)

In the palm, a curved radial longitudinal line bounds the thenar eminence, ending close to the distal wrist crease. Proximal and distal transverse lines ascend medially across the palm. The proximal line begins at the distal end of the thenar crease and runs obliquely to the middle of the hypothenar eminence across the shafts of the metacarpals. The distal line begins at or near the cleft between the index and middle finger, and curves across the palm over the second to fourth metacarpal heads, near the proximal ends of the fibrous flexor sheaths.

The second to fifth digits show proximal, middle and distal sets of transverse lines. The proximal, often double, lies approximately 2 cm distal to the metacarpophalangeal joints. The middle creases are usually double, the proximal line lying directly over the proximal interphalangeal joint. The distal lines are usually single, and lie proximal to the distal interphalangeal joints. The metacarpophalangeal joint of the thumb is crossed by a crease that starts on the radial side and ends in the web space level with the base of the proximal phalanx. There is a second, shorter, crease, usually 1 cm distal to this line. Two creases cross the interphalangeal joint of the thumb (see Fig. 50.1).

## Cutaneous vascular supply

The skin of the palmar aspect of the wrist is supplied by branches from the superficial palmar branch of the radial artery, the ulnar artery and, occasionally, the median artery (see Fig. 46.3). The skin over the thenar eminence is supplied by small perforating branches from the superficial palmar branch of the radial artery and the princeps pollicis. The skin over the hypothenar eminence is supplied by perforating branches from the ulnar artery, some of which pass through palmaris brevis. The remainder of the palm is supplied by branches from the common palmar digital arteries that pierce the palmar aponeurosis, and branches from the radialis indicis artery. The palmar digital skin is supplied by branches from each digital artery. In the distal phalanx, the two digital arteries typically form an H-shaped anastomosis, from which cutaneous perforators fan out within the pulp. Deep digital veins accompanying the digital arteries are usually very small and frequently absent. Superficial palmar veins tend to pass dorsally and drain into the larger superficial dorsal venous system.

The dorsal skin of the wrist is supplied by branches from an arterial plexus that lies over the extensor retinaculum, formed by branches of the radial artery, including its dorsal carpal branch, the dorsal carpal branch of the ulnar artery, and anterior and posterior interosseous arteries. The blood supply to the dorsum of the hand arises from longitudinal rows of four or five branches from each of the dorsal metacarpal arteries, which usually arise either directly from the radial artery or from the dorsal carpal arch. At the level of the neck of the metacarpals, where the second, third and fourth dorsal metacarpal arteries communicate with branches from the corresponding common palmar digital arteries, a large cutaneous perforating branch passes proximally to supply an area of skin as far as the dorsal aspect of the wrist.

The blood supply to the dorsum of the fingers arises proximally from the terminal branches of the dorsal metacarpal arteries, (supplying a region as far distally as the proximal interphalangeal joint) as well as from dorsal branches of the palmar digital arteries that are given off at each phalangeal level. At the level of the distal phalanx, the cutaneous supply comes from three dorsal arcades: a superficial arcade over the base of the distal phalanx, and two distal subungual arcades. The skin of the dorsum of the thumb is supplied by longitudinal axial branches of the princeps pollicis and dorsal branches from the palmar digital arteries.

## Degloving injuries of the hand and wrist

A degloving injury is one in which the skin is avulsed from its underlying structures, and usually occurs as the result of a low-velocity injury such as a ring avulsion or when the hand is caught in industrial machinery, typically between rollers or in a conveyor belt. The plane of cleavage is through the subcutaneous tissues, leaving the underlying structures essentially intact. The degloving may be complete or partial; complete avulsion is rare, whereas avulsion of the skin of all or part of the finger is relatively common.

Urbaniak et al (1981) grouped ring avulsion injuries into three classes: those in which the blood supply is intact (class I); those in which the blood supply is compromised (class II); and those in which digits are either completely degloved or amputated (class III). While these represent an increasing injury, the avulsion force required to achieve them does not occur in a linear manner (Kupfer et al 1999). The longitudinal force applied to a finger causes a traction injury to the blood vessels, which may extend over a considerable distance. The crushing element of a degloving injury may cause skin necrosis and thrombosis of the underlying vessels (Brooks et al 2007).

Treatment of these injuries depends on their extent (Krishnamoorthy and Karthikeyan 2011). In the acute phase, replantation is the best option in cases where the skin has been completely separated from the body. Where the skin remains attached but is devascularized, revascularization by microvascular anastomoses is preferred. If neither of these procedures is feasible, the avulsed skin may be defatted and reapplied to the affected part, where it is effectively acting as a split skin graft. If none of these techniques is practicable, primary amputation may be considered. Subsequently, reconstruction may be by split skin graft, skin/fasciocutaneous flap or free flap.
